CHAPTER 50A

Cancer of the bile ducts: intrahepatic cholangiocarcinoma

Jonathan Koea

OVERVIEW

Intrahepatic cholangiocarcinoma is a primary adenocarcinoma of the liver. Like other primary adenocarcinomas of the upper gastrointestinal (GI) tract, these tumors often present with symptoms resulting from advanced local or metastatic disease. They are biologically aggressive, and when possible, surgery is the only known potentially curative therapy, although a few active systemic therapies are available.

Intrahepatic cholangiocarcinoma is also known as *peripheral cholangiocarcinoma*, *cholangiolar cancer,* or *cholangiocellular carcinoma,* terms that have previously been used interchangeably. Cholangiocellular carcinoma was first used by Steiner and Higginson (1959) to describe a subtype of cholangiocarcinoma in which the glands are small and regular and resemble proliferating cholangioles with inconspicuous lumens. Current nomenclature uses the term *intrahepatic cholangiocarcinoma* (IHCC) to define tumors arising from biliary epithelium in intrahepatic bile ducts above the level of the left main and right main ducts (Liver Cancer Study Group of Japan, 1990). These tumors constitute 10% of primary hepatic malignancies, and although much is known about extrahepatic cholangiocarcinoma, IHCC is less well understood.

Hepatic resection for IHCC was infrequently described until recently. Foster and Berman (1977) describe only 13 cases in their summary of hepatic surgery in the United States, although they present 112 resections for hepatocellular carcinoma (HCC) and 47 cases of hepatoblastoma. This low number of resections may represent the frequency with which advanced disease was diagnosed at presentation and also reflects that recognition of IHCCs as a discrete primary liver tumor was slow to occur and that many were historically diagnosed as metastatic adenocarcinoma from unknown primary sites.

EPIDEMIOLOGY AND DEMOGRAPHICS

The incidence of cholangiocarcinoma is rising worldwide and is now the second most common primary cancer of the liver behind HCC (Olnes & Erlich, 2004). Approximately 5000 new cases are diagnosed annually in the United States (Vauthey & Blumgart, 1994), and more than 1000 cases are diagnosed annually in the United Kingdom (Khan et al, 2008). However, overall, cholangiocarcinoma is rare and makes up only 3% of all GI tract cancers (Lazaridis & Gores, 2005). This means that it is infrequently seen by general surgeons or gastroenterologists, and its rarity has frustrated attempts to design therapeutic trials to treat it.

More detailed analysis of epidemiologic data shows that the incidence and mortality rates of IHCC are increasing and those of extrahepatic cholangiocarcinoma are decreasing (see Chapter 50B; Endo et al, 2008; Khan et al, 2002; Patel, 2001, 2002), suggesting that the tumors may have different etiologic factors but similar microscopic morphology. These findings must be interpreted with caution. IHCC may occur as solitary or multiple liver lesions and, in the past, many were probably diagnosed as metastatic tumors and not further investigated. In addition, analysis of the Surveillance, Epidemiology, and End Results (SEER) database has shown that more than 90% of hilar tumors were wrongly classified as IHCCs, and extrahepatic lesions were often classified as gallbladder cancers (Shaib & El-Serag, 2004). Indeed, even when these classification issues are addressed, the mortality rate of IHCC is still increasing worldwide (Fig. 50A.1; Shaib et al, 2005).

IHCC currently has an incidence of 0.85 per 100,000 population in the United States (Shaib et al, 2004; Shaib & El-Serag, 2004); the highest incidence in the world is recorded in northeast Thailand (96 per 100,000) (Khan et al, 2008). Patients most commonly are seen in the seventh decade, and IHCCs are more common in men (Khan et al, 2002; Shaib et al, 2005).

ETIOLOGY AND RISK FACTORS

The majority of patients presenting with IHCC have no known risk factors. However, a number of specific risk factors are recognized, many of which result in chronic inflammation of the biliary epithelia. Most of these risk factors are recognized to contribute to the development of both intrahepatic and extrahepatic cholangiocarcinoma.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) (see Chapter 41) is the most common risk factor for cholangiocarcinoma in the West (Farrant et al, 1991). The cumulative annual risk of cholangiocarcinoma in patients with PSC is 1.5% per year (Farrant et al, 1991), and the prevalence of cholangiocarcinoma in these patients is between 8% and 40% (Pitt et al, 1995; Rosen et al, 1991). The risk of developing cholangiocarcinoma is increased in those with associated inflammatory bowel disease, in whom the 10- and 20-year rates for cholangiocarcinoma are 14% and 31% versus 2% and 2% in patients without inflammatory bowel disease, respectively (Claessen et al, 2009).

Cholangiocarcinoma often develops 2 to 3 decades earlier in patients with PSC than in those with sporadic tumors (30 to 50 years vs. 60 to 70 years of age, respectively) (Bergquist & Broome, 2001; Farrant et al, 1991). In addition, PSC-associated tumors often present later with advanced-stage disease because of difficulties in detecting malignant change in inflammatory

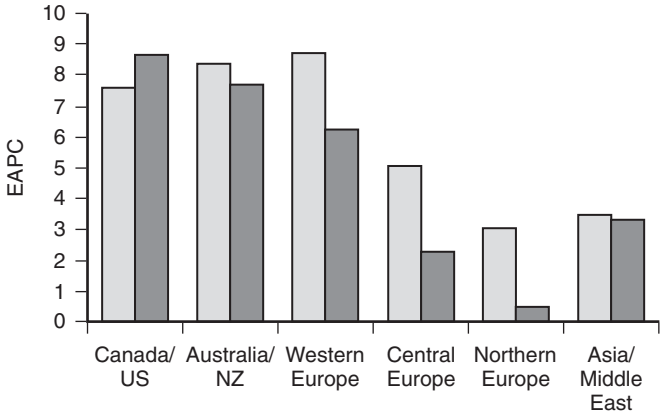

FIGURE 50A.1. Estimated annual percent change (EAPC) in age-adjusted mortality rate for intrahepatic cholangiocarcinoma by geographical region for males and females. *(Modified from Patel T, 2002: Worldwide trends in mortality from biliary tract malignancies. BMC Cancer 2:1-5.)*

strictures. Surgical treatment can be difficult in the presence of chronic liver disease, and such patients are often ineligible for orthotropic liver transplantation. Consequently. they have a poor prognosis (Kaya et al, 2001). Factors suggestive of cholangiocarcinoma in patients with PSC are the sudden development of jaundice, weight loss, marked biliary dilation proximal to a dominant stricture, a sudden rise in carbohydrate antigen 19-9 (CA19-9), the presence of a hypovascular mass with late contrast enhancement on radiologic imaging, and cytologic evidence of dysplasia or malignancy obtained on brushings of the bile ducts (Harewood, 2008).

Parasitic Infections (See Chapter 45)

Chronic infection with liver flukes (*Opisthorchis viverrini* and *Clinorchis sinensis*) is closely related to increased risk of developing cholangiocarcinoma, especially in Southeast Asia (Hasweel-Elkins et al, 2008; Jang et al, 2008; Sripa & Pairojkul, 2008; Watanapa, 1996; Watanapa & Watanapa, 2002). The mechanism of carcinogenesis is unclear; however, mechanical irritation, excreted metabolic products, and the actions of pro-inflammatory cytokines, particularly those that stimulate the release of nitric oxide from activated white cells, may all play a role (Sripa et al, 2007).

A further parasitic hepatic infection is caused by the trematodes *Fasciola hepatica* and *F. gigantica*. These parasites are widely spread throughout Asia, Africa, the Americas, and Oceania. They migrate into the liver from the duodenum and cause hepatic fibrosis, but no evidence is available to support the theory that fascioliasis increases the risk of cholangiocarcinoma. In addition, the fibrotic pathologic changes accompanying an infection can be difficult to distinguish from carcinoma (Kim et al, 2005; Marcos et al, 2008).

Hepatolithiasis (See Chapters 39 and 44)

Recurrent pyogenic cholangiohepatitis (RPC) is characterized by recurrent episodes of ascending cholangitis, hepatolithiasis, biliary stricturing, and dilation. The syndrome is present in one fifth of the population of Southeast Asia, and up to 10% of these patients develop IHCC (Chen et al, 1993; Kubo et al, 1995; Lesurtel et al, 2002; Su et al, 1997). Patients are seen with recurrent episodes of cholangitis and, on investigation, have significant hepatolithiasis and associated inflammatory biliary strictures (Chu et al, 1997). Infection with liver flukes may also be present, but RPC appears to be a separate condition and can develop in the absence of parasitic infection (Kim et al, 2003).

Congenital Biliary Cystic Disease (See Chapter 46)

Untreated choledochal cysts carry an increased risk of developing malignant change. The incidence of cholangiocarcinoma is estimated at between 10% and 20% if the cyst is not resected by the age of 20 years (Lipsett et al, 1994; Ohtsuka et al, 2001). Correspondingly, patients who have had their cysts resected have a very low incidence of cholangiocarcinoma (Hewitt et al, 1995), although the subsequent development of cholangiocarcinoma has been recorded after cyst excision (Goto et al, 2001). The mechanism of malignant transformation is not well understood, but many patients with choledochal disease have an abnormally high union of the pancreatic and bile ducts, suggesting that biliary stasis and chronic reflux of pancreatic secretions may contribute to the development of chronic inflammation of biliary epithelium (Chapman, 1999).

Hepatic Cirrhosis and Viral Infections (See Chapter 64)

The risk of developing cholangiocarcinoma is increased in patients with cirrhosis (10.7% vs. 0.7% in the general population) (Shaib & El-Serag, 2004; Sorensen et al, 1998). In addition, the incidence of cholangiocarcinoma is increased in patients with hepatitis C viral infection (0.8% vs. 0.2% in the general population) (Donato et al, 2001; Shaib et al, 2005) and in patients with chronic hepatitis B viral infection (11.5% vs. 5.5% in the general population) (Donato et al, 2001). It has been suggested the increasing incidence of cholangiocarcinoma in Western populations is related to the increasing prevalence of chronic liver disease and chronic viral infection (Shaib et al, 2005; Shaib & El-Serag, 2004).

Human immunodeficiency virus (HIV) does not cause cirrhosis, but cholangiocarcinomas have been found in up to 0.5% of patients infected with the virus compared with 0.1% in control subjects, suggesting that HIV is also associated with an increased risk of biliary carcinogenesis (Shaib et al, 2005).

Benign Biliary Tumors (See Chapter 79B)

The development of biliary cystadenocarcinomas from biliary cystadenomas is rare; in general, it occurs if a cystadenoma is untreated for many years. Patients are first seen with cystadenocarcinomas in the sixth or seventh decades of life, although cystadenomas present at an earlier age (Buetow et al, 1995). Intrahepatic cholangiocarcinoma has also been reported to develop in patients with biliary papilliomas (Cox et al, 2005; Galluoglu et al, 2007).

Chemical Agents

Thorotrast (thorium dioxide) was used as a radiologic contrast agent between 1928 and 1950. It is an α-emitter with a biologic half-life of 400 years. It accumulates in the reticuloendothelial cells in the liver and spleen and increases the risk of developing

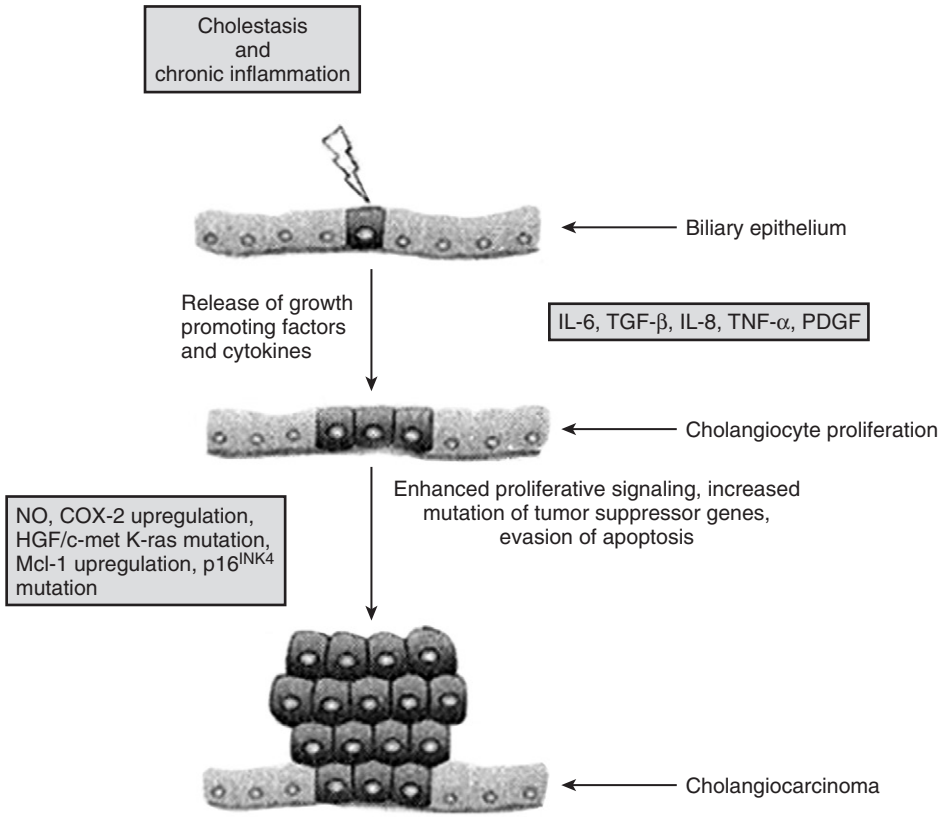

FIGURE 50A.2. Summary of possible mechanisms involved in biliary carcinogenesis. HGF, human growth factor; IL, interleukin; NO, nitric oxide; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-β; TNF-α, tumor necrosis factor-α. *(Modified from Wise C, et al, 2008: Mechanisms of biliary carcinogenesis and growth. World J Gastroenterol 14:2986-2989.)*

cholangiocarcinoma by 300 times compared with the general population (Lipshutz et al, 2002; Rubel & Ishak, 1982). It is now no longer in use, although the latency period of 16 to 45 years means that patients who received this agent during childhood radiologic examinations will still occasionally come to medical attention (Massachusetts General Hospital, 1981).

A number of other agents have been implicated in the development of cholangiocarcinoma. Associations have been shown for asbestos (Szendroi et al, 1983), vinyl chloride (Wong et al, 1991), nitrosamines (Mitacek et al, 1999), the antituberculosis agent isoniazid (Lowenfels & Norman, 1978), and first-generation oral contraceptives (Yen et al, 1987).

General Risk Factors

Diabetes and obesity are associated with an increased risk of cholangiocarcinoma (Malhi & Gores, 2006; Oh et al, 2005). Similarly, surgical biliary-enteric bypass and surgical sphincteroplasty may also increase the risk (Hakamada et al, 1997). Smoking tobacco is a significant risk factor for the development of cholangiocarcinoma in patients with PSC (Bergquist et al, 1998), although the relationship is less marked in the general population (Shaib et al, 2005).

PATHOGENESIS

Cholangiocarcinoma develops from the malignant transformation of cholangiocytes. These cells line the intrahepatic bile ducts and canaliculi. Their physiologic functions center around the modification of bile at the canalicular surface and the detoxification of xenobiotics (Alpini et al, 2001). Normal growth and renewal of cholangiocytes is important in the maintenance of biliary mass, as well as hepatic secretory and detoxification functions, and is achieved by careful regulation of proliferation and apoptosis; however, when this process becomes uncontrolled, cholangiocarcinogenesis can occur (Wise et al, 2008).

Chronic inflammation is the most common and important feature of many of the risk factors associated with malignant transformation of cholangiocytes (see Chapter 6). Chronic inflammation can result in biliary obstruction, injury to the biliary epithelium, and increased cholangiocyte turnover (Jaiswal et al, 2000). Chronic inflammation also causes DNA damage, activates local tissue repair, stimulates cellular proliferation, and results in a local environment that promotes neoplastic transformation (Fig. 50A.2) (Schottenfeld & Beebe-Dimmer, 2004). Cholangiocytes exert significant paracrine and autocrine effects and stimulate secretion of cytokines, such as interleukin-6 (IL-6), IL-8, transforming growth factor-β (TGF-β), tumor necrosis factor-α (TNF-α), and platelet-derived growth factor (PDGF) (see Chapter 10; Berthiaume & Wands, 2004).

These cytokines activate nitric oxide synthase in cholangiocytes and result in the generation of nitric oxide, which reacts with other active oxygen species such as superoxide, all of which can damage DNA and downregulate DNA repair mechanisms (Jaiswal et al, 2000). This damage can lead to expression of oncogenes and reduced expression of tumor suppressor genes. Overexpression of the epidermal growth-factor receptor (EGFR), erb-2, K-ras, BRAF, and hepatocyte growth factor

c-Met have been reported in cholangiocarcinoma (Endo et al, 2002; Lai et al, 2005). The protooncogene *Erbb2* is activated in cholangiocarcinoma, and tumor suppressor genes *CDKN2A, P53, APC,* and *SMAD4* are underexpressed (Rashid, 2002; Taniai et al, 2002). Cytokines may also assist cholangiocytes in evading apoptosis. IL-6 is secreted by cholangiocytes and activates the prosurvival p38 mitogen-activated protein kinase (see Chapter 8B; Ishimura et al, 2004; Park et al, 1999).

PATHOLOGIC SUBTYPES AND MODE OF SPREAD

Macroscopically, IHCCs are firm, white, sclerotic tumors often with associated satellite lesions nearby. However, the variability in gross morphologic appearance has led to a number of pathologic subclassifications. Nakanuma and colleagues (1985) initially classified IHCCs into two types: mass forming and periductal. *Mass-forming tumors* were described as tumors with clear borders between malignant and nonmalignant tissues; *periductal tumors* were described as more infiltrative and extended along peri–bile duct tissues without forming a discrete nodular mass. This classification was widely adopted in Japan (Fujita, 1990) and was further modified by Ohashi and colleagues (1994), who added a specula-forming lesion present when a nodular tumor has poorly defined and irregular borders. Yamamoto and colleagues (1998) emphasized that all three morphologic types appear to have different proliferative activity and different biologic behavior. According to their research, the distinctive feature of the mass-forming type is its tendency to develop intrahepatic metastases as a result of localized vascular invasion, and the infiltrative type is distinguished by infiltrative spread via the Glisson capsule and hilar lymph node metastases. On the basis of these observations, these researchers recommended hepatectomy as the procedure of choice for the mass-forming subtype; hepatectomy with extrahepatic ductal resection and hilar lymphadenectomy is the procedure of choice for the infiltrating subtype. They also added a fourth subtype, the *intraductal variant,* characterized by papillary or granular growth within the lumen. They also were able to show that the frequency of lymph node metastases was higher in the mass-forming and periductal types compared with the intraductal subtype. A single report of a Western hepatobiliary unit used this classification and was unable to show any difference in overall survival or the frequency of lymph node metastases (Weber et al, 2001), although the intraductal subtype may carry a more favorable prognosis, as it does in the extrahepatic bile duct (Jarnagin et al, 2005). Although the subclassification of IHCC is intriguing and may have implications for surgical therapy, one significant weakness of this approach is that many tumors exhibit features of a number of the described subtypes (Shirabe et al, 2002).

Other less common histologic variants of IHCC have been reported, including mucin-hypersecreting lesions, which are similar to intraductal papillary mucinous neoplasms of the pancreas and are characterized by large mucin-filled cystic spaces (see Chapter 57; Chow et al, 1997; Kim et al, 2000; Suh et al, 2000) and intraductal oncocytic papillary carcinoma. These lesions have a distinctive appearance defined by the presence of oncocytes but appear to behave in a favorable manner, similar to the papillary type (Sudo et al, 2001; Wolf et al, 1992).

Intraabdominal lymph nodes are the most common site of metastatic spread for IHCCs and are present in up to 75% of cases at presentation (Shirabe et al, 2002). In addition, up to two thirds of patients may have evidence of remote organ metastases, most commonly lung and bone, at presentation (Endo et al, 2008; Shirabe et al, 2002). The common sites of lymphatic metastases are at the hepatic hilus, around the pancreas, in the retroperitoneum, around the aorta, and in the mediastinum (Nakajima et al, 1988). Nozaki and colleagues (1998) showed significant differences in lymphatic spread between left lobar and right lobar tumors. Patients with right lobar tumors always had lymph node metastases in the hepatoduodenal ligament, whereas in patients with left lobar tumors, 50% of nodal metastases were found distant from the hepatoduodenal ligament in the cardia and around the lesser curvature of the stomach. Furthermore, no lymph node metastases were present in the hepatoduodenal ligament in these patients.

CLINICAL PRESENTATION

In contrast to extrahepatic cholangiocarcinoma, which usually presents with jaundice and symptoms of biliary obstruction, IHCC often presents as asymptomatic hepatic masses detected during physical examination or on cross-sectional imaging. In patients with symptoms, abdominal pain is most common (Martin & Jarnagin, 2003). A significant proportion of patients may present with nonspecific constitutional symptoms, such as weight loss and decreased energy and appetite (Weber et al, 2001). Jaundice can be present in centrally placed lesions that compress or invade the biliary confluence, although extensive replacement of hepatic parenchyma by tumor, along with portal vein compromise, intrabiliary tumor invasion, or mucobilia, can also cause symptoms of biliary obstruction. An increase in liver enzymes, most commonly alkaline phosphatase or γ-glutamyl transferase, may be the only presenting feature to prompt further investigations, including physical examination and cross-sectional imaging. Roayaie and colleagues (1998) have shown that jaundice as a presenting symptom is predictive of unresectable disease because of significant involvement of inflow structures bilaterally or because of massive parenchymal replacement.

DIAGNOSIS AND EVALUATION

Resection is currently the only potentially curative therapy for IHCC. Evaluation of patients with IHCC should be focused on establishing the correct diagnosis and distinguishing it from metastatic adenocarcinoma or another primary tumor because this has significant implications on potentially available systemic therapies and in the assessment of the suitability of the patient and the tumor for operation. Thorough evaluation should include a detailed history, physical examination, assessment of comorbid conditions, assessment of hepatic function, measurement of tumor markers, and radiologic imaging to assess the extent of disease.

History and examination may reveal presenting symptoms, a liver mass, signs of jaundice, and sometimes metastatic disease. Liver function should be assessed with measurement of platelet count, serum levels of bilirubin, γ-glutamyl transferase, aspartate transaminase, alkaline phosphatase, albumin, total protein, and prothrombin time (PT) or international normalized ratio (INR). Any abnormality in hepatic function, particularly signs of underlying chronic liver disease, should be investigated in more detail.

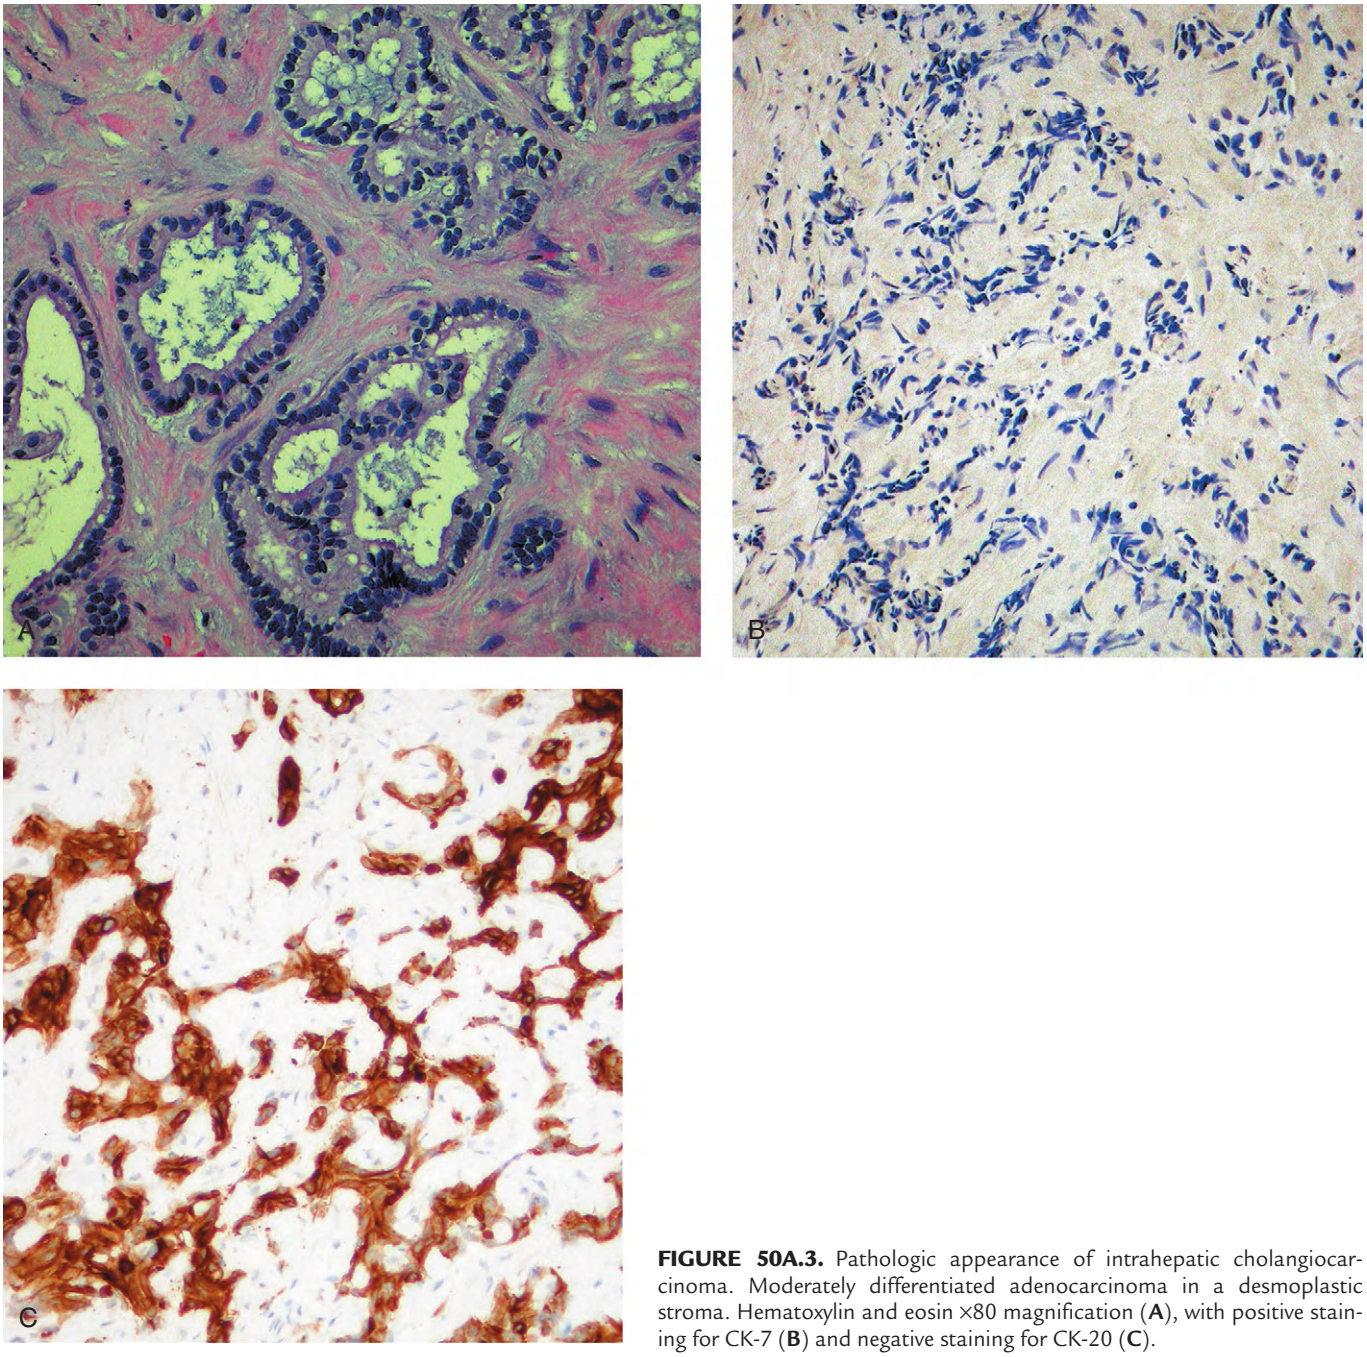

FIGURE 50A.3. Pathologic appearance of intrahepatic cholangiocarcinoma. Moderately differentiated adenocarcinoma in a desmoplastic stroma. Hematoxylin and eosin ×80 magnification (**A**), with positive staining for CK-7 (**B**) and negative staining for CK-20 (**C**).

In clinical practice, the diagnosis of IHCC is established with the typical finding of a hypovascular mass present on cross-sectional imaging (see Chapters 16 and 17). GI metastases are excluded by performing upper and lower GI endoscopies without the finding of a primary tumor and in the absence of other primary malignancies (pancreas, kidney, lung) on a staging computed tomography (CT) scan of the chest, abdomen, and pelvis. Women should have had a recent mammogram and gynecologic examination. Routine tumor biopsy is often unnecessary, particularly in patients who will undergo resection, and it is not recommended because of the small risk of tumor dissemination (Metcalfe et al, 2004; Ohlsson et al, 1994). In general, biopsy is indicated only to establish the presence of irresectable disease. Final pathologic confirmation of cholangiocarcinoma is defined by a specimen showing an adenocarcinoma that stains positively for CK-7 and CK8/18 but is negative for CK-20 (Fig. 50A.3). Staging laparoscopy is also useful in the evaluation of IHCC to exclude peritoneal disease, nodal disease, or abdominal wall invasion, which may preclude an attempt at resection (D'Angelica et al, 2003).

Serum Markers for Cholangiocarcinoma

Serum tumor markers are an attractive method for diagnosing and monitoring treatment response in cholangiocarcinoma because of the ease of obtaining samples and their relatively low cost. To be effective a marker must be accurate in detecting the presence of malignancy (sensitivity) and in defining the presence of benign disease (specificity). Most of the research on tumor markers in cholangiocarcinoma has been directed at diagnosis of extrahepatic tumors, particularly in the context of PSC; however, much of this is applicable to peripheral cholangiocarcinoma. The data on tumor markers that have been applied to cholangiocarcinoma are summarized in Table 50A.1.

Carcinoembryonic antigen (CEA) is widely used because of its availability but is elevated in only one third of patients with cholangiocarcinoma (Blechacz & Gores, 2008a, 2008b; Patel & Singh, 2007; Yachimski & Pratt, 2008). CA19-9 is also widely used in the diagnosis of cancers of the upper GI tract and is elevated in gastric cancer, pancreatic cancer, biliary, and gallbladder cancers as well as in smokers, during cholangitis, and in conditions causing cholestasis. In addition, it is not present in 7% of the population who are Lewis^a-antigen negative (Alvaro, 2009). In a retrospective investigation of patients with suspected biliary malignancies, of whom 10% were later found to have benign disease, CA19-9 was elevated in all patients and was decreased after biliary decompression. Elevated bilirubin was identified as the most important predictor of raised CA19-9 (Ong et al, 2008).

Other biomarkers investigated have included IL-6 either alone or in conjunction with CA19-9. Serum levels of IL-6 correlate with tumor burden in cholangiocarcinoma, but this marker is also elevated in hepatocellular carcinoma, metastatic disease, and benign biliary lesions (Cheon et al, 2007). Smith and colleagues (2008) recently proposed that an elevated preoperative platelet/lymphocyte ratio (PLR) may be a prognostic marker for resected ampullary cancer, but this ratio is also elevated in conditions associated with systemic inflammation. Serum trypsinogen-2 has also been evaluated in patients with cholangiocarcinoma and was found to be accurate in differentiating between patients with PSC and benign stricture and those who had cholangiocarcinoma develop (Lempinen et al, 2007). In addition, no correlation between serum trypsinogen-2 and bilirubin levels was found, indicating that this marker is unaffected by the presence of biliary obstruction or cholangitis (Lempinen et al, 2007). Abnormal expression of mucin 5AC (*MUC5AC*) is observed in mucin-producing adenocarcinomas, such as cholangiocarcinoma, and is detectable in 70% of patients with cholangiocarcinoma. Its presence is associated with poorer prognosis (Bamrungphon et al, 2007).

Bile Markers for Cholangiocarcinoma

Bile markers of cholangiocarcinoma have been investigated for their use in the diagnosis of biliary obstruction, and they may play a significant role in the evaluation of extrahepatic biliary obstruction because they can be easily obtained during ERCP. It is much less common for IHCC to be seen initially with biliary obstruction, however, and the use of bile markers in this tumor is limited. However, in the future they may play a role in the diagnosis of central lesions related to the hilus or intrahepatic lesions developing in patients with PSC. Bile markers

that have been suggested for use in the diagnosis and management of cholangiocarcinoma are summarized in Table 50A.1.

Imaging

IHCCs often present with vague and nonspecific symptoms. Accurate cross-sectional imaging is required to diagnose and stage the tumors as well as to plan resection or other possible treatments. Most patients will be imaged with a number of modalities.

Transabdominal Ultrasound (See Chapter 13)

Ultrasound is often used as a screening examination by primary health care practitioners investigating patients with right upper quadrant pain, a palpable mass, or unexplained jaundice. IHCC has a nonspecific appearance as a hypoechoic hepatic mass (Bloom et al, 1999; Slattery & Sahani, 2006). Satellite lesions and capsular retraction may be seen, and the tumors are hypovascular and usually have minimal Doppler evidence of internal blood flow. Ultrasound is useful for defining associated biliary dilatation, portal venous invasion, hepatic venous invasion and, rarely, portal lymphadenopathy (Bach et al, 1996; Hann et al, 1997).

Computed Tomography

Triple-phase CT scan (see Chapter 16) is widely available and is the single most effective investigation in diagnosing and staging IHCC, which is seen as hypodense lesions with irregular, infiltrative margins and a variable degree of delayed enhancement in the portal venous phase (Fig. 50A.4) (Bach et al, 1996). CT scan will also demonstrate the presence of biliary dilatation, portal or hepatic venous involvement (Asayama et al, 2006), lobar atrophy as a result of long-standing biliary obstruction, or portal venous involvement (Kim et al, 2002). CT scan is also useful in detecting metastatic disease affecting regional lymph nodes, peritoneum, or lung fields. Digital Imaging and Communications in Medicine data from newer, multiphase, fast-acquisition scanners can also be used to construct three-dimensional representations of hepatic and tumor anatomy for use in the planning of resections and in obtaining accurate measurement of hepatic volumetry, particularly in relation to remnant volume and risk of postoperative liver failure (see Chapter 93A). This is an emerging area of hepatic imaging but is particularly relevant in the management of large central tumors (Wigmore et al, 2001).

Magnetic Resonance Imaging

IHCC appears as hypointense on T1-weighted images and hyperintense on T2-weighted images with pooling of contrast within the lesions on delayed images (6 to 8 minutes after contrast injection) (Manfredi et al, 2004). Magnetic resonance imaging (MRI) is also useful in defining venous and arterial involvement by tumor, and cholangiopancreatography is a noninvasive method of obtaining cholangiograms.

Positron Emission Tomography

Positron emission tomography (PET) scanning is now a commonly used modality for staging GI malignancy, and the integration of PET and CT now provides the opportunity to obtain anatomic and functional information in a single scan (Iglehart, 2006; Slattery & Sahani, 2006). IHCCs are present as glucose-avid lesions within the liver. PET CT is also useful in detecting intraabdominal lymph node metastases (sensitivity, 42%; specificity, 80%) and distant metastases (sensitivity, 56%; specificity, 88%) (Iglehart, 2006). However, PET is limited by false-positive results in patients with biliary inflammation (Petrowsky et al, 2006), and patients with mucinous tumors can have false-negative scan findings (Fritscher-Ravens et al, 2001).

STAGING

IHCCs are classified as primary cancers of the liver by the American Joint Committee on Cancer (AJCC). Western hepatobiliary centers commonly use the AJCC systems to stage tumors. The sixth edition of the AJCC staging manual proposes a single staging system for primary cancers of the liver and applies this to both HCCs and IHCCs (Greene et al, 2002). The seventh edition of the staging manual (Edge et al, 2009), which entered clinical use in January 2010, includes a number of changes (Table 50A.2) and incorporates the staging system of Nathan and colleagues (2009), who used data from the SEER database to develop a new staging system for IHCC. They found that the sixth edition of the AJCC staging system failed to stratify T2 and T3 cohorts into distinct groups. Survival in the T3 group exceeded that of the T2 group (43% vs. 31%). In addition, these investigators found that the presence of multiple tumors at presentation and vascular invasion had an adverse effect on outcome, but tumor size at presentation was not predictive of outcome. Lymph node metastases and extrahepatic extension were also associated with poorer outcome.

Two other staging systems have been proposed from Japan, one by Okabayashi and colleagues (2001) and one by Yamasaki (2003), with that of Yamasaki being adopted by the Liver Cancer Study Group of Japan as its preferred staging system for IHCC (Table 50A.3).

TREATMENT

Because of its rarity, treatment protocols for IHCC are in their infancy compared with other intrahepatic tumors such as HCC. Nevertheless, there is a clear role for hepatic resection when feasible and in patients with disease confined to the liver. Orthotopic liver transplantation has been studied in some detail but is currently not used routinely for IHCC (see Chapter 97E). The roles of neoadjuvant and adjuvant chemotherapy, both systemic and regional; conformal radiation therapy; and ablative therapies have yet to be fully clarified.

Surgical

Hepatic Resection

Surgical therapy for intrahepatic cholangiocarcinoma is based on the principles applied to resections for HCC and metastatic tumors. Criteria for irresectability of IHCC are 1) locally advanced solitary tumors involving either inflow or outflow bilaterally, 2) multiple intrahepatic tumors, and 3) metastatic disease to distant sites. Regional lymph node metastases are an indicator of poor outcome but are not necessarily an absolute contraindication to surgery (Endo et al, 2008). An R0 resection must be performed for a potential survival benefit to be achieved. Hepatic resection is undertaken with the aim of obtaining a clear margin of 1 cm or greater, leaving a well-vascularized remnant with adequate venous and biliary drainage. Resection of up to 80% of hepatic volume can be

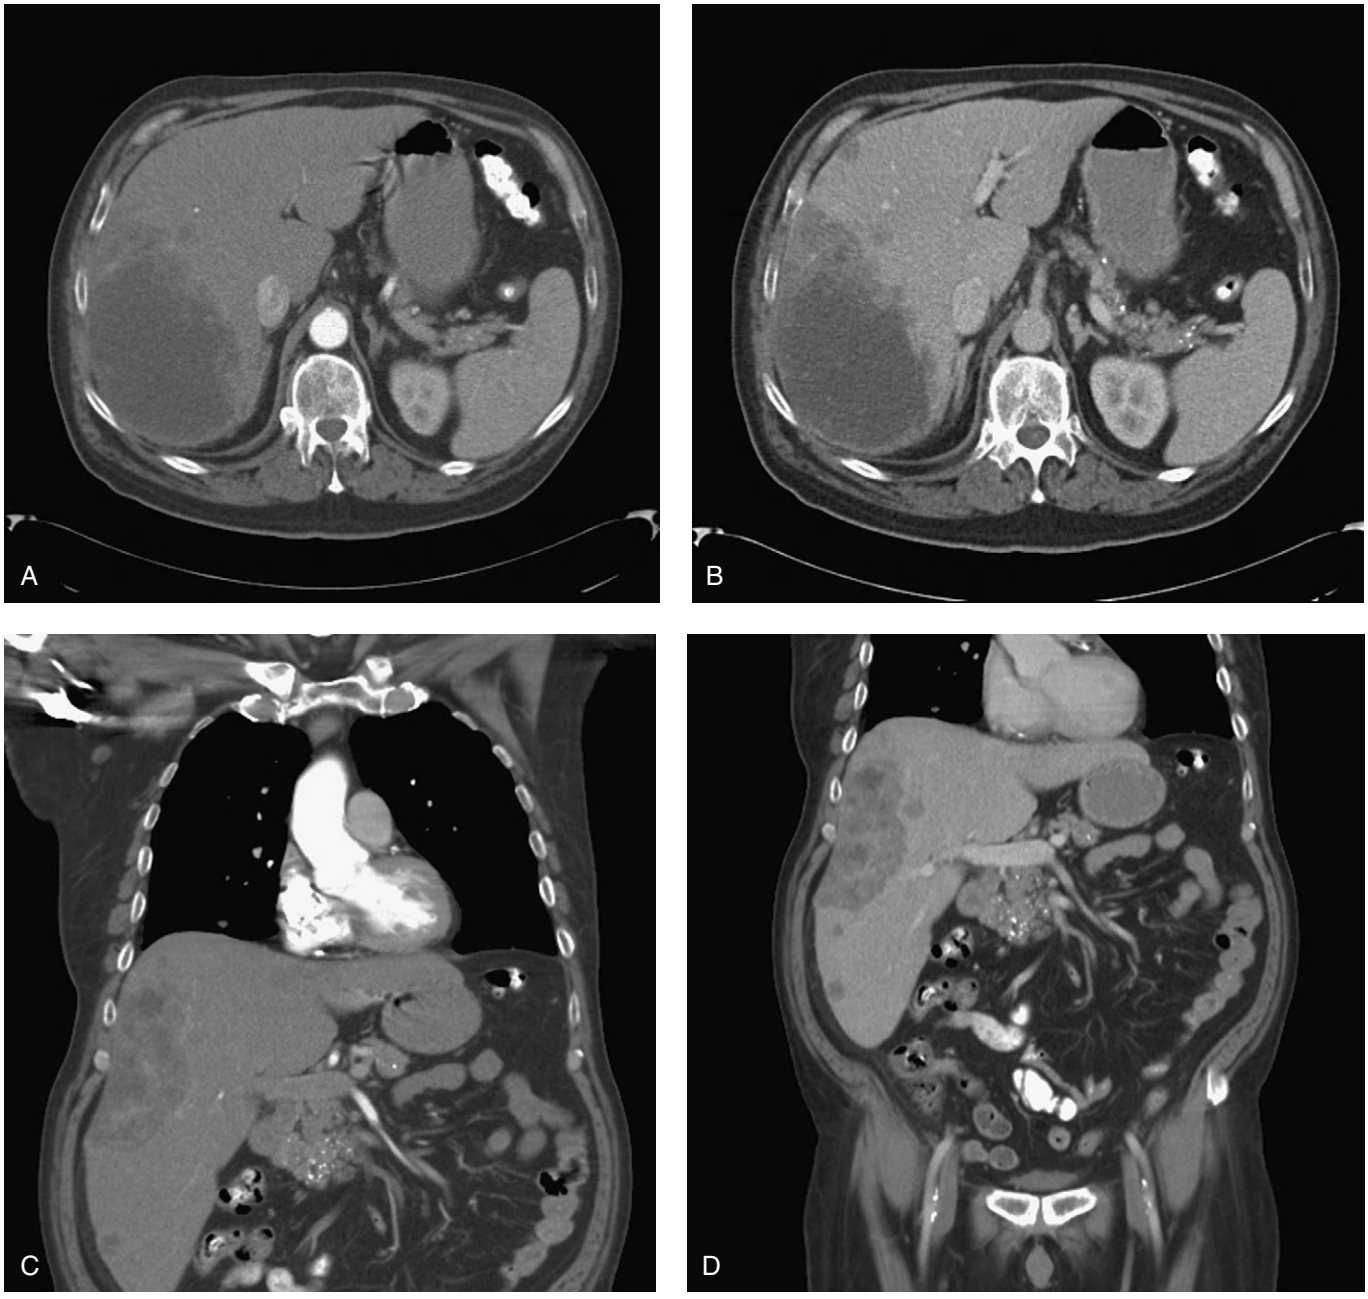

FIGURE 50A.4. Arterial (**A** and **C**) and portal venous (**B** and **D**) axial and coronal CT scans demonstrating the typical appearance of an intrahepatic cholangiocarcinoma with a large hypovascular mass involving segments VI and VII with associated satellite lesions. *(From Valle J, et al, 2010: N Engl J Med 362[14]:1273-1281.)*

contemplated, but resections of this magnitude often need to be preceded by portal vein embolization.

Untreated patients with IHCC have a median survival of less than 12 months (Chu & Fan, 1999; Kim et al, 1999). Resection with positive margins or residual macroscopic disease is associated with median survivals of 1.8 months to 3 months (Chu & Fan, 1999; Kim et al, 1999), indicating that a cytoreductive approach is ineffective at prolonging survival.

In contrast, 5-year survival rates after complete resection range between 13% and 42%. The principal reason for the variability in survival appears to be the presence of lymph node metastases. Lieser and colleagues (1998) reported a 5-year survival of 42%, but only 13% of patients presented with lymph node metastases. In the series of Chu and Fan (1999), 50% of patients presented with nodal metastases, and none survived 5 years. Recently presented data from a number of centers in the United States, Asia, and Europe show reasonable survival after curative resection (Table 50A.4). Cherqui and colleagues (1995) report 100% survival 2 years after resection, Nakeeb and collegues (1996) report a 5-year survival of 44%, Lieser and colleagues (1998) report a 60% survival at 3 years, and Shirabe and colleagues (2002) report a 5-year survival of 32%. All these clinical series emphasize the importance of obtaining an R0 resection in achieving long-term survival.

This point was further emphasized by Lang and colleagues (2005), who reported a single-center experience with extended hepatectomy for IHCC. Twenty-seven patients underwent extended hepatectomies (19 extended right, 8 extended left), and 16 patients had en bloc resections of other structures. The median survival in this series was 46 months with a 3-year survival rate of 82%. Cherqui and others (1995) have achieved similar results with an aggressive surgical policy.

Although the importance of achieving an R0 resection is clear, the role of routine lymph node dissection is debated. The presence and extent of nodal metastatic disease is an important prognostic factor. Chu and Fan (1999) dissected portal lymph nodes in their series, and all patients with portal lymph node metastases died within 10 months of resection. A further study from Japan (Shirabe et al, 2002) confirmed that no survival benefit was evident for patients undergoing hepatectomy with portal lymphadenectomy versus hepatectomy alone. However, Nozaki and colleagues (1998) have recommended routine dissection of cardia and lesser curvature nodes for left-sided tumors and dissection of the hepatoduodenal ligament for right-sided tumors, although using this approach did not improve survival, and extended surgery was associated with a higher mortality rate (Yamamoto et al, 1999).

No clear therapeutic benefit is currently attributable to routine nodal dissection accompanying hepatectomy for IHCC. Thorough assessment of all intraabdominal nodal basins should be undertaken before hepatic resection, and sampling of suspicious nodes is indicated to stage disease accurately and assist in planning postoperative treatment. In the West, the finding of involved intraabdominal lymph nodes is a contraindication to hepatic resection.

Most surgical series confirm that the presence of lymph node metastases is the most important prognostic factor. Endo and colleagues (2008) documented a recurrence rate of 93% in node-positive patients undergoing R0 resection versus 47% in node-negative patients. These investigators also showed that a tumor greater than 5 cm in diameter and the presence of

Table 50A.4

Summary of Contemporary Results for Surgical Resection of Intrahepatic Cholangiocarcinoma

First Author	Year	Country	No. Patients	Median Survival (mo)	SURVIVAL (%)		
					1-Year	3-Year	5-Year

Ercolani	2010	Italy	72	–	91 overall, 65 disease-free survival	62 overall, 30 disease-free survival	48 overall, 25 disease-free survival

multiple intrahepatic tumors were significant adverse prognostic factors. Other investigators have also defined lymphatic permeation, vascular invasion, and intrahepatic satellite lesions as predictors of poor survival, and two Japanese groups (Isaji et al, 1999; Shirabe et al, 2002) have also shown that the survival is higher in patients with the mass-forming tumor type than in those with the periductal infiltrating type.

After resection, the most common site of recurrence is in the liver, followed by intraabdominal sites (lymph nodes, peritoneum), lungs, and bone (Jan et al, 2005). Salvage surgery for intrahepatic recurrence or metastasectomy is usually not indicated.

Transplantation

The first significant report regarding liver transplantation for IHCC is that of Pichlmayr and colleagues (1995), who reported a median survival of 5 months in 18 patients treated with liver transplantation, with a 1-year survival rate of 13.9%. Several studies confirmed these findings (Ismail et al, 1990; O'Grady et al, 1988), although Cherqui and colleagues (1995) reported two long-term survivors and concluded that an intrahepatic tumor with no extrahepatic spread that cannot be resected for anatomic reasons may be a candidate for liver transplantation.

More recent experience has resulted in improved survival with disease-free survivals at 5 and 10 years of 27% and 23%, respectively, reported in 23 patients with IHCC treated with orthotopic liver transplantation (Robles et al, 2004). Most of these patients were deemed irresectable but showed no evidence of extrahepatic spread, and the authors concluded that transplantation could be considered in this group because the results achieved are better than palliative treatment. However, the role of transplantation in peripheral cholangiocarcinoma will continue to be limited by the lack of an effective adjuvant systemic treatment regimen. This is in contrast to the emerging protocol of neoadjuvant chemoradiation before transplantation for hilar cholangiocarcinoma (Schwartz et al, 2009).

Tumor Ablation

The role of ablative therapies in peripheral cholangiocarcinoma is currently limited but subject to significant investigation. Cryotherapy and radiofrequency ablation (RFA) are widely used in the treatment of metastatic colorectal cancer, either in addition to hepatectomy or as a primary therapy. Unfortunately, in IHCC neither of these approaches can be used; the primary tumors are hard, and percutaneous or operative ablation can be difficult to achieve. Because many of the lesions are large at presentation, their size often precludes effective ablation, and smaller lesions can be resected. Likewise, the use of ablation to treat intrahepatic metastases is ill advised because these are indicative of vascular invasion. However, Rai and colleagues (2005) reported a case of recurrent tumor after transplantation that was treated with RFA and controlled for 12 months, and others have used this technique to manage small cholangiocarcinomas that are unsuitable for resection (Zgodzinzki & Espat, 2005).

Both cryotherapy (Cuschieri et al, 1995; Sheen et al, 2002) and selective internal radiation therapy (Dubel & Soares, 2008) have been used in heterogeneous series of hepatic tumors treated with ablative therapies. Both treatments are reported to be safe, although no long-term follow-up data are available.

A number of publications have reported on the use of transarterial chemoembolization (TACE) of unresectable IHCC (Gusani et al, 2008; Herber et al, 2007; Kim et al, 2008) with gemcitabine in combination with cisplatin, oxaliplatin, or mitomycin C. Repeated treatments are usually undertaken at 8-week intervals, with median survivals reported between 12 (Kim et al, 2008) and 21 months (Herber et al, 2007). Overall combination therapy appears to be more effective than single-agent therapy (Gusani et al, 2008), with large tumor size, tumor hypovascularity, and Child-Pugh class B being adverse prognostic factors (Kim et al, 2008).

Chemotherapy

Systemic

Unfortunately, no effective adjuvant chemotherapy protocols are currently available for IHCC. This reflects the aggressive nature of the tumor as well as its rarity. Much of the information on the effectiveness of chemotherapy in this tumor has been derived from Phase II trials rather than Phase III trials. In addition, most of these trials have been carried out in groups of patients with tumors of biliary epithelia and include patients with intrahepatic and extrahepatic cholangiocarcinoma, gallbladder cancer, and pancreatic cancer. Many postoperative therapy regimens have been based on 5-fluorouracil (5-FU) and have included irinotecan, mitomycin C, and gemcitabine. None has been effective, and routine use of adjuvant chemotherapy after an R0 resection is not current practice. A recent randomized trial established the superiority of combined gemcitabine and cisplatin compared with gemcitabine alone in patients with locally advanced or metastatic biliary cancer (Valle et al, 2010); however, this study included the full range of biliary tract adenocarcinoma, including ampullary cancers, and it remains to be seen whether this therapy has any impact in the adjuvant setting. Ercolani and colleagues (2010) retrospectively analyzed long-term results of resection in 72 patients with IHCC and demonstrated improved survival in those who received adjuvant gemcitabine-based chemotherapy (5-year survival 65% after chemotherapy vs. 40% with resection alone), although this observation has not been confirmed prospectively (Ercolani et al, 2010).

Systemic chemotherapy for unresectable disease is associated with partial responses in between 10% and 20% of patients and uses either 5-FU or contemporary combination therapy with gemcitabine and cisplatin or oxaliplatin. The responses are modest, but the use of newer, targeted therapies continues to stimulate investigative trials in this area (Hezel & Zhu, 2008). More recent Phase I and II investigations have used the biologic agents sunitinib (Sweeney et al, 2010), cetuximab (Chang et al, 2010), or bevacizumab and erlotinib (Lubner et al, 2010) in the treatment of patients with advanced-stage disease. Endo and colleagues (2008) described five patients with initially unresectable tumors treated with either regional fluorodeoxyuridine in combination with systemic camptothecin-11 or systemic gemcitabine-based therapy whose tumors were downstaged sufficiently to undergo resection, indicating that effective neoadjuvant therapy is a realistic future goal for this tumor.

Regional

Regionally administered chemotherapy has not been extensively investigated in peripheral cholangiocarcinoma, although sporadic reports of its effectiveness have surfaced. Shirabe and colleagues (2002) report a single case treated with intraarterial cisplatin and 5-FU achieving a complete response for

12 months. Regional chemotherapy is an attractive means to attempt to downstage large hepatic tumors for subsequent resection, although adequate pretherapy staging would need to be undertaken to exclude extrahepatic disease, and patients with underlying cirrhosis could not be treated because of the risk of treatment-related complications (Jarnagin et al, 2009).

Radiation Therapy

Cholangiocarcinoma is a radiosensitive tumor, although the doses required (60 Gy) are toxic to normal liver and adjacent structures, including the stomach, duodenum, and kidney. However, when accurately administered, radiation therapy does have an emerging role in the management of IHCC. Postoperative radiation therapy is ineffective in improving survival after R0 resections, but several studies have shown a potential benefit in postoperative radiation therapy in patients with microscopically positive margins after resection (Stein et al, 2005), suggesting that radiation in this setting may be an effective salvage therapy. Lawrence and colleagues (Ben-Josef et al, 2005; Robertson et al, 1993, 1997) have reported on the use of conformal radiation combined with intraarterial infusional chemotherapy in patients with unresectable IHCC. This treatment resulted in a median survival of 13.3 months, which was significantly better than historical controls (Ben-Josef et al, 2005), although 30% of patients developed grade 3 or 4 toxicity, and there was one treatment-related death.

Palliation

Up to 90% of patients presenting with IHCC may not be candidates for surgical resection because of patient comorbidity or extent of disease, and these will be managed palliatively (Endo et al, 2008). Unlike extrahepatic cholangiocarcinoma, jaundice is unusual except in patients with centrally placed tumors compressing the hilus; these can be treated by placement of biliary endostents radiologically or endoscopically. Other priorities for these patients are management of capsular pain and ascites and maintenance of adequate nutritional intake.

SUMMARY

IHCCs are rare primary tumors of the liver arising in intrahepatic biliary epithelium. They constitute 10% of primary hepatic tumors, and although many are sporadic, conditions leading to chronic inflammation of biliary epithelium constitute significant risk factors for their development. Cross-sectional imaging with CT scan or MRI usually demonstrates a hypovascular mass. A specific staging system has been developed, and for patients with liver disease only, R0 resection offers the chance of cure in 20% to 40%. No active adjuvant systemic therapy is currently available, and chemotherapy (both systemic and regional), radiation therapy, and ablative therapies are reserved for patients with unresectable tumors.

SECTION I
Inflammatory, Infective, and Congenital

A. Congenital Disorders

CHAPTER 51

Congenital disorders of the pancreas: surgical considerations

Ewen M. Harrison and Rowan W. Parks

OVERVIEW

The pancreas is a glandular organ that lies on the posterior abdominal wall in the retroperitoneum. It is an exocrine gland that secretes enzymes of digestion into the duodenum; it also performs endocrine functions, producing insulin, glucagon, somatostatin, pancreatic polypeptide, and ghrelin. Congenital abnormalities of the pancreas may be so severe that they are diagnosed in utero or in the neonatal period, such as pancreatic agenesis. However, many congenital conditions go undetected until adulthood, when the patient comes to medical attention with nonspecific symptoms or an abnormality is discovered incidentally. This chapter describes the diagnosis, investigation, and treatment of the various congenital pancreatic abnormalities.

EMBRYOLOGIC DEVELOPMENT OF THE PANCREAS

The basis for the understanding of congenital abnormalities of the pancreas is the embryologic development of the organ (see Chapter 1A). The pancreas develops from two buds originating from the endodermal lining of the duodenum. The dorsal bud forms posteriorly within the mesentery, whereas the ventral bud is associated with the hepaticopancreatic duct (Fig. 51.1). During the second month of development, the stomach rotates and the duodenum becomes C-shaped. As part of this process, the ventral pancreatic bud migrates dorsally, coming to lie posteroinferiorly to the dorsal bud, forming what will become the inferior head/uncinate process of the pancreas. In the majority of individuals, the main pancreatic duct (of Wirsung) is formed by the entire ventral duct, and the distal dorsal duct and enters the duodenum at the major papilla. The persistence of the proximal part of the dorsal duct occurs in approximately 25% and results in an accessory duct (of Santorini), which enters the duodenum by the minor papilla (see Fig. 51.1) (Rösch et al, 1976). There is no known pathologic consequence of this normal variation. A failure of fusion of the ductal system occurs in roughly 10% of the normal population (Dawson & Langman, 1961; Millbourn, 1959), resulting in the entire dorsal pancreas—superior head, body, and tail—draining through the minor papilla and ventral pancreas, the inferior head and uncinate process, and finally through the major papilla (Fig. 51.2). This abnormality is termed *pancreas divisum* and is described in more detail below.

Annular pancreas is a rare congenital abnormality, the embryologic basis of which is poorly understood. A complete or incomplete ring of pancreatic tissue is found around the second part of the duodenum, and it may cause symptoms (also discussed below).

A number of studies published recently have identified mechanisms by which the pancreas is specified from the early endoderm (Kumar & Melton, 2003). Retinoic acid and bone morphogenic peptide both appear to have important roles in defining early endodermal compartments in the embryo (Stafford & Prince, 2002; Tiso et al, 2002). The origins of the signaling mechanisms involved in the specification of the dorsal and ventral pancreas are different. In the dorsal pancreas, signals arising from the notochord (Kim et al, 1997) and dorsal aorta (Lammert et al, 2001) are required; in the ventral pancreas, the lateral plate mesoderm is important (Kumar et al, 2003). The specific identity of these signals has not yet been established, although the Hedgehog family of signaling molecules appears to be significant (Kim & MacDonald, 2002).

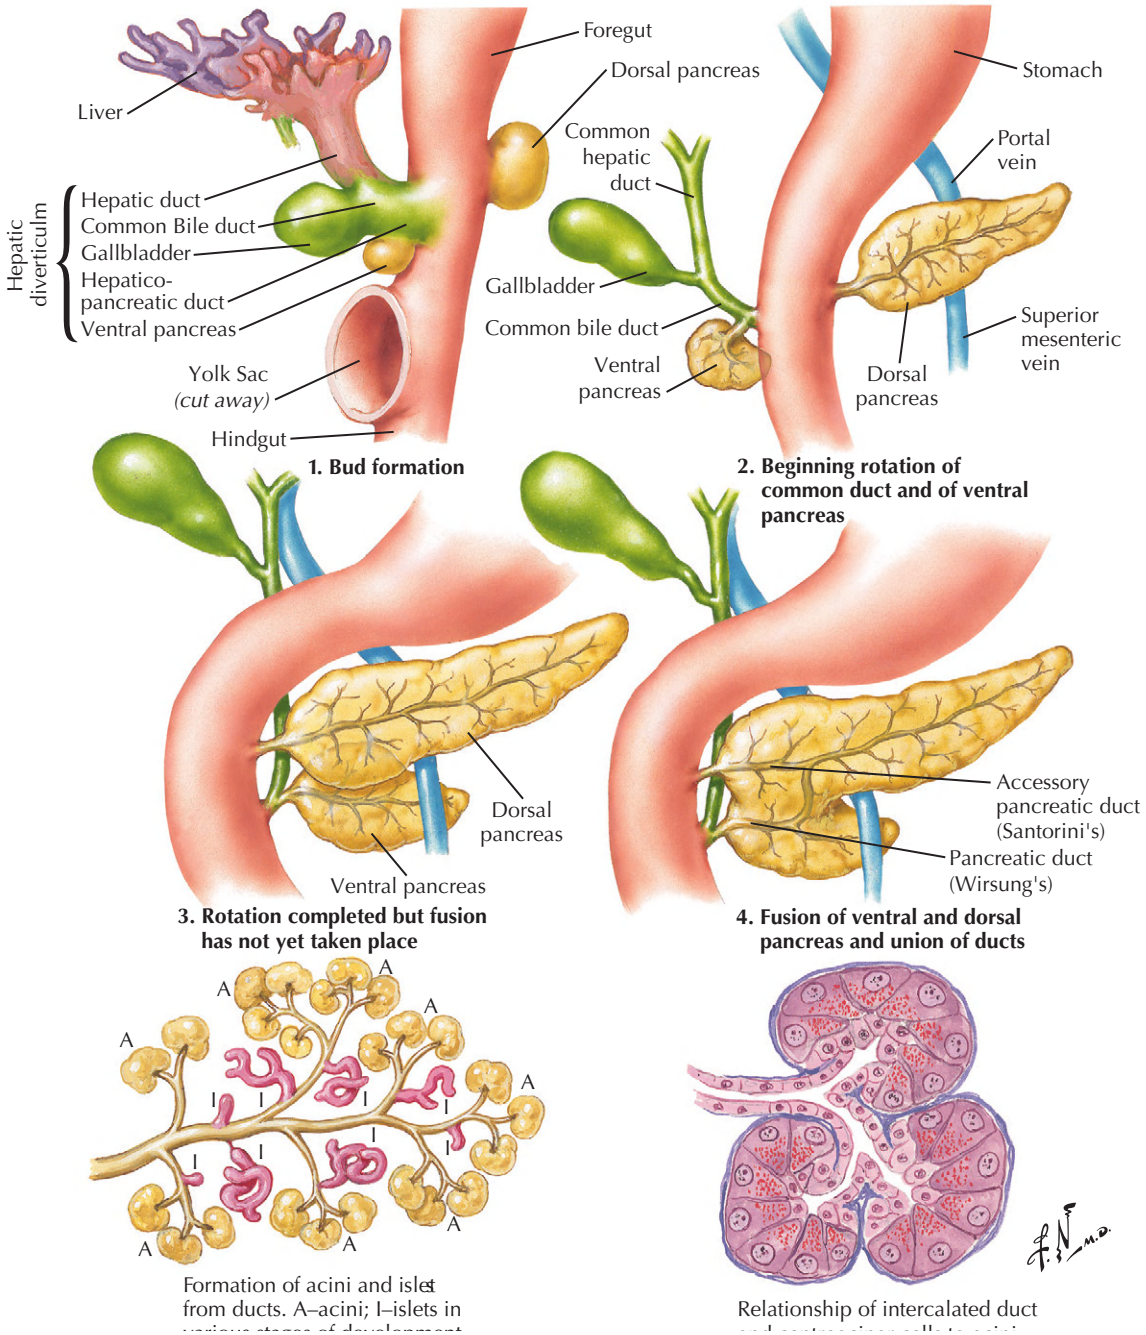

FIGURE 51.1. Embryologic development of the pancreas. *(Netter illustration from http://www.netterimages.com. Copyright Elsevier, Inc. All rights reserved.)*

PANCREAS DIVISUM

Pancreas divisum (PD) results from incomplete fusion of the dorsal and ventral pancreatic ducts toward the end of the second month of embryogenesis. The distal dorsal pancreatic duct typically fuses with the ventral pancreatic duct to drain the entire pancreas into the duodenum via the major papilla (see Chapter 1B). The proximal dorsal duct can persist as an accessory pancreatic duct and may drain via the minor papilla. Complete PD exists when there is no communication between the dorsal and ventral systems and the majority of the pancreas drains via the dorsal duct through the minor papilla (see Fig. 51.2). Variations exist where a small branch may connect the two ducts, termed *incomplete pancreas divisum*.

Recent investigations have suggested that PD may be explained by distinct patterns of incomplete fusion of branches of the dorsal and ventral pancreatic ducts (Kamisawa et al, 2007a), confirming theories first proposed in early anatomic studies (Dawson & Langman, 1961). The first description of PD is from 1865, attributed to Josef Hyrtl (1810-1894), professor of anatomy at the Universities of Prague and Vienna. However, as discussed by Stern (1986), a number of anatomists were aware of it much earlier than this, including Regnier de Graaf, who described the finding in 1664.

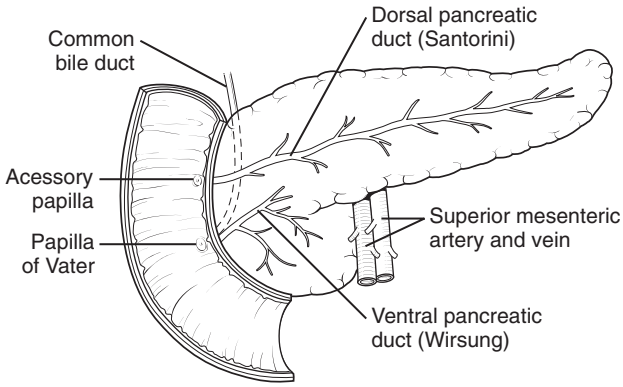

FIGURE 51.2. Pancreas divisum describes the incomplete fusion of the dorsal and ventral pancreatic ducts.

In postmortem studies performed throughout the twentieth century, the prevalence of PD is reported to be approximately 8% (range, 4% to 14.5%) (Baldwin, 1911; Berman et al, 1960; Birnstingl, 1959; Cameron, 1924; Charpy, 1898; Dawson & Langman, 1961; Fogel et al, 2007; Clairmont & Hadjipetros, 1920; Hand, 1963; Helly, 1898; Hjorth, 1947; Keyl, 1925: Kleitsch, 1955; Mehnen, 1938; Millbourn, 1959; Naatanen, 1941; Opie, 1903; Rienhoff, 1945; Schirmer, 1893; Schmieden & Sebening, 1927; Schwarz, 1926; Sigfusson et al, 1983; Smanio, 1969; Stimec et al, 1996). With the development of endoscopic retrograde pancreatography (ERCP) in the late 1960s, however, the considerable congenital variation in the ductal system of the pancreas became more widely appreciated (Cotton, 1972; McCune et al, 1968). The prevalence of PD is lower in published ERCP series than in anatomic series for reasons that are not clear, although it may be due to referral bias, difficulty in the interpretation of pancreatograms, or inability to cannulate the minor papilla. The reported prevalence is particularly low in Japanese series (0.3% to 0.6%) compared with Western populations (approximately 5%; Cotton, 1980).

PD is clinically relevant from three main points of view (Fogel et al, 2007). First, the small ventral duct seen in PD must be differentiated from a similar appearance seen in some cases of pancreatic cancer. Second, on cannulating the major papilla at ERCP, only the ventral portion of the pancreas may be visualized in PD, which risks missing important pathology if a pancreatogram is not performed via the minor papilla (see Chapter 18). Third, PD may be associated with disease, such as pancreatitis (see Chapter 53). With regard to the first point, it is important for those performing ERCP to be aware of the anomaly to become proficient in interpreting pancreatograms (Fig. 51.3). Other forms of imaging, such as computed tomography (CT), must be used if there is uncertainty whether a mass lesion is present and causing a ductal abnormality. In relation to the second point, it is important to become proficient at cannulation of the minor papilla, which is considerably more challenging than cannulating the major papilla (see Chapter 18). It commonly sits in a superior, more ventral position. Cannulation may be facilitated by having the duodenoscope in the "long position" and by administration of intravenous secretin (O'Connor & Lehman, 1985). The third point is discussed in detail below.

Possible Association Between Pancreas Divisum and Pancreatitis

The question of whether PD causes recurrent acute pancreatitis, chronic pancreatitis, or pancreas-related pain has been debated for many years (Table 51.1). Those proposing the theory suggest that obstruction occurs at the level of the minor papilla, the caliber of which is too narrow to drain the majority of the pancreas. This is supported by an early study reporting an elevated pressure in the dorsal duct (23.7 ± 1.3 mm Hg) compared with the ventral duct (10.8 ± 1.9 mm Hg) in six patients with PD, whereas pressures were similar when two ducts existed in patients without PD (Staritz & Meyer zum Buschenfelde, 1988). This was contradicted in a subsequent study in which no difference in duct pressures was observed between the major and minor papillae in four patients with recurrent acute pancreatitis and PD (Satterfield et al, 1988). Another early report demonstrated chronic pancreatitis confined to the dorsal pancreas in two pancreatoduodenectomy specimens from patients with PD who had resections for symptom control (Blair et al, 1984).

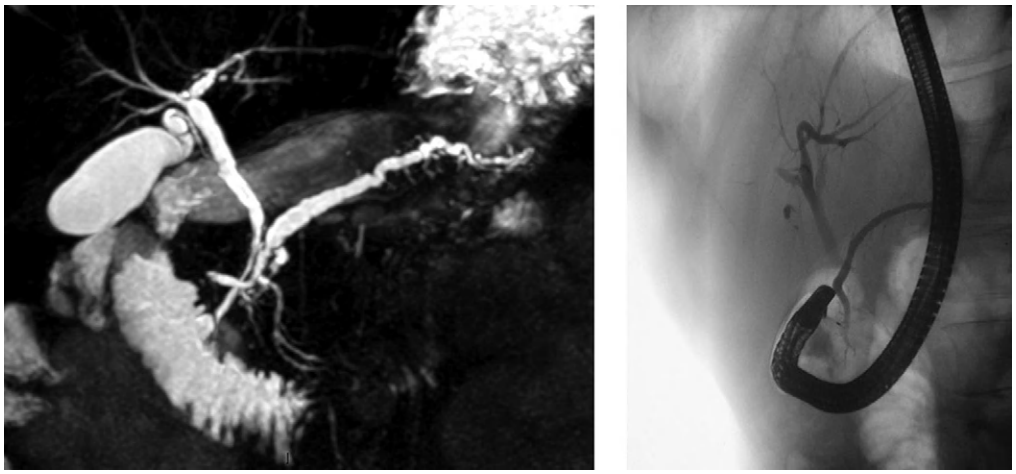

FIGURE 51.3. Imaging in pancreas divisum (PD). A magnetic resonance cholangiopancreatography image shows PD with the dorsal pancreatic duct draining through the minor papilla (*left*). Endoscopic retrograde cholangiopancreatography in PD performed through the minor papilla (*right*). Contrast can still be seen in the common bile duct after cannulation of the major papilla. *(Courtesy Dr. K. Palmer, Edinburgh.)*

Early Series Reporting Pancreas Divisum

Study	Pancreatitis Relationship Supported	Study Type	N (%)	Intervention
Phillip J et al, 1974	—	ERCP series	18/911 (2.0)	—
Rösch et al, 1976	—	ERCP series	63/1850 (3.4)	—
Gregg, 1977	—	ERCP series	33/1100 (3.0)	—
Heiss & Shea, 1978	Yes	ERCP series	4	—
Mitchell et al, 1979	No	ERCP series	21/449 (4.7)	—
Cotton, 1980	Yes	ERCP series	47/810 (5.8)	—
Tulassay & Papp, 1980	Yes	ERCP series	33/2410 (1.4)	Unspecified surgery in 11; no outcomes described
Richter et al, 1981	Yes	ERCP series	519	Open sphincteroplasty to minor ampulla in 9; decreased pain: 5/6 with acute pancreatitis, 0/3 with chronic
Thompson et al, 1981	Yes	ERCP series	11/850 (1.3)	—
Cooperman et al, 1982		Case series	21/314 (6.7)	Open sphincteroplasty to minor ampulla in 5; 4 of 6 "have done well" at 28 months
Sahel et al, 1982	Yes	ERCP series	41/812 (5.0)	—
Blair et al, 1984	Yes	Case series	14	15 operative resections in 14 patients with RAP; 7/14 had no pain after surgery
Delhaye et al, 1985	No	ERCP series	304 total; 6.9% AP/CP, 5.7% no pancreatitis	—
Sugawa et al, 1987	No	ERCP series	55/1529 (3.6)	Open sphincteroplasty to minor ampulla in 3; no improvement in symptoms
Bernard et al, 1990	Yes	ERCP series	137/1825 (7.5)	—

ERCP, endoscopic retrograde cholangiopancreatography; RAP, recurrent acute pancreatitis; AP, acute pancreatitis; CP, chronic pancreatitis

Difficulty exists in demonstrating an epidemiologic relationship between PD and pancreatitis because early anatomic studies were small and confounded by different definitions, and ERCP series are skewed by selection bias (Blair et al, 1984). In the largest early series of 1850 successful major ampulla cannulations, Rösch and colleagues (1976) identified PD in 63 cases (3.4%). The indications for pancreatography were not given, but pathologic findings were seen in 13 of 63 patients with PD; changes were consistent with pancreatitis in 12 and tumor in one. In the next large series by Gregg (1977), 33 patients with PD were identified among 1100 patients referred primarily for investigation of pancreatic-type pain or pancreatitis. Documented pancreatitis was present in 15 patients, and another 11 had recurrent episodes of pain typical of pancreatitis.

These and similar studies have been used as evidence of a link between PD and pancreatitis, but the absence of a suitable control group makes the assertion weak. Mitchell and colleagues (1979) identified this problem and performed a retrospective analysis of patients who had undergone ERCP and observed that 21 (4.7%) of 449 patients had PD, whereas 4 (3.3%) of 120 patients with pancreatitis defined by clinical and/or ERCP criteria had PD. Thus in this series the prevalence of PD in patients with pancreatitis was the same as the prevalence of PD in the series as a whole. This has been supported by the largest published ERCP series of 304 patients, in which the dorsal duct was visualized in 97 patients (Delhaye et al, 1985). The frequency of PD was similar in patients with acute or chronic pancreatitis (6.9%) as in all patients in the series undergoing ERCP (5.7%).

Contrary to these findings, Cotton reported that in patients with primary biliary disease who had an incidental pancreatogram at the time of endoscopic cholangiogram, the prevalence of PD was 3.6% (Cotton, 1980). This was compared with a prevalence of 16.4% in those with chronic or recurrent acute pancreatitis. In 83 patients with idiopathic pancreatitis, recurrent pancreatitis with no clear etiology such as gallstones, alcohol, or trauma—the prevalence of PD was 25.6%.

This controversy is a good example of the difficulty in determining a causal relationship between two factors that appear to be associated. The traditional criteria used in evaluating such a relationship can be applied: 1) strength of association, 2) consistency across studies, 3) dose-response relationship, and 4) biologic plausibility. The relationship is not a strong one, and many of those in the general population who have PD (approximately 10%) never have any related symptoms, and many with pancreatitis do not have PD; fewer than 5% of individuals with PD are estimated to ever develop pancreatic symptoms. Furthermore, those with a more pronounced form of the anomaly (i.e., complete PD) do not seem to be more likely to develop pancreatitis than those with incomplete PD. The question of biologic plausibility is more interesting and is discussed further below.

Imaging in Pancreas Divisum

One of the difficulties in relating PD to pancreatitis is the inconsistency in making the diagnosis. ERCP studies of patients without pancreatitis consistently report a lower prevalence of PD when compared with MRCP or postmortem studies (Table 51.2). The use of secretin during MRCP (S-MRCP) improves the detection rate of PD (Manfredi et al, 2000), yet it is still reported to be missed on S-MRCP, possibly because of

Table 51.2

Prevalence of PD in Patients Without Pancreatitis by Method of Investigation or Imaging Modality

Investigation Type	N	% Prevalence of PD (95% CI)
Postmortem	2895	7.8 (6.8-8.8)
MRCP	505	9.3 (6.8-11.8)
S-MRCP	156	17.9 (11.9-24.0)
ERCP	16,078	4.1 (3.8-4.4)

suboptimal magnetic resonance techniques or inexperience in those reporting the MRCP (see Chapter 17; Carnes et al, 2008). Endoscopic ultrasound (EUS) as an alternative imaging modality has gained in popularity and is reported to be useful in the investigation of patients with acute recurrent pancreatitis of unknown etiology (see Chapter 14; Petrone et al, 2008). A recent study reported the use of portal venous phase 64 multirow detector CT. Five of 93 patients had PD diagnosed on MRCP or ERCP. Of these, one observer detected three cases and a second observer found four cases by reviewing the MDCT images (Anderson & Soto, 2009). ERCP features of the minor papilla that suggest the presence of PD include an enlarged papilla or open orifice and are believed to moderately predict the presence of PD; however, a significant number of patients with PD do not have these features (Alazmi et al, 2007; Lawrence et al, 2009).

Therapy to the Minor Papilla in Those with Pancreas Divisum and Pancreatitis

If PD is associated with obstruction at the minor papilla, which in turn contributes to the occurrence of pancreatitis and pancreatic pain, then it follows that surgical intervention to relieve this obstruction would be beneficial. As has been discussed, significant controversy exists as to whether this assumption is correct or not. A number of studies have been performed examining whether therapy to the minor papilla is beneficial in patients with acute recurrent pancreatitis, chronic pancreatitis, or pancreas-related pain; however, little in the way of randomized controlled data has been generated (Table 51.3; see Chapters 53 and 55). Interventions examined include endoscopic dilation, papillotomy, and sphincterotomy of the minor papilla, with or without stent placement, and surgical sphincteroplasty.

The first minor papilla endoscopic sphincterotomy was described by Cotton in 1978, and the majority of publications since have been small case series with short follow-up times. Lehman and colleagues (1993) described the effects of minor papilla sphincterotomy in 52 PD patients with chronic pancreatic pain (n = 24), recurrent acute pancreatitis (n = 17), or chronic pancreatitis (n = 11) with longstanding symptoms refractory to conservative management. Minor papilla sphincterotomy was performed with a needle knife over a previously placed dorsal pancreatic duct stent, with a mean follow-up of 1.7 years. When compared with the chronic pain and chronic pancreatitis groups, patients with recurrent acute pancreatitis had a significant reduction in mean symptom score (recurrent acute pancreatitis, 76.5%; chronic pancreatitis, 27.3%; chronic pain, 26.1%) and inpatient hospital stay. This reflects other published results that consistently show less benefit after minor papilla therapy in those with chronic pancreatitis or chronic

pain compared with those with recurrent acute pancreatitis. Complications were seen in 15%, and one patient died of a pancreatic abscess after a failed cannulation. Of concern, 50% of patients evaluated at the time of stent removal had stent-induced dorsal duct changes.

In a prospective, randomized, controlled trial published by Lans and colleagues (1992), 19 patients with PD and recurrent acute pancreatitis—two or more episodes of abdominal pain associated with a rise in amylase greater than twice the upper limit of normal—and no other identified etiology were recruited. Ten patients were randomized to stent placement, and nine were randomized to no treatment, with follow-up for 1 year. In the stent group, no patients subsequently came to the hospital with pain, but five patients in the control group were admitted, and two more came in with pain. Furthermore, nine patients in the stent group rated their pain improved by 50% or more, but only one patient in the control group reported a similar improvement.

It has been pointed out that a significant period of time can exist between attacks of pancreatitis in this patient group, and this study has since been criticized on the basis of the short duration of follow-up. Sherman and colleagues (1994) have also published randomized data in abstract form in which patients with chronic abdominal pain thought to be pancreatic in origin and PD were randomized to minor papilla sphincterotomy (n = 16) or no intervention (n = 17). Mean follow-up time in the treated and untreated groups was 2.1 and 1.2 years, respectively. Although an improvement in pain was seen in 43.8% of treated patients compared with 23.5% in the control group, this trend did not reach statistical significance.

Borak and colleagues (2009) published the long-term outcomes after endoscopic minor papilla therapy in 145 patients with PD over a 6-year period. Follow-up data were available for 113 patients (78%), and the median follow-up time was 43 months. The majority of patients had a needle-knife sphincterotomy (82%) and temporary stent placement (90%). Primary success, defined as the patient being better or cured after a single ERCP session, was seen in 53.2% of patients with recurrent acute pancreatitis, 18.2% of those with chronic pancreatitis, and 41.4% of those with chronic/recurrent epigastric pain. Two or more ERCP sessions were required in 41.6%, with success in 71% of patients with recurrent acute pancreatitis, 46% of those with chronic pancreatitis, and 55% of those with chronic, recurrent epigastric pain. In a multivariate analysis that corrected for age, sex, symptom frequency/duration, and length of follow-up, chronic pancreatitis and younger age both independently predicted failure of improvement after treatment. Complications occurred in 13% after ERCP, including mild and moderate pancreatitis, mild bleeding, and anesthetic complications.

Surgical sphincteroplasty to the minor papilla, usually combined with cholecystectomy and major papilla sphincteroplasty, has been used in the treatment of recurrent acute pancreatitis, chronic pancreatitis, and chronic pancreatic-type pain associated with PD (Table 51.4). In the largest published series by Warshaw and colleagues (1990), 88 patients with recurrent acute pancreatitis (49%) or "pancreatic pain" (51%) had minor papilla sphincteroplasty with a mean follow-up of 53 months; 70% of patients were reported to show improvement, 85% if the minor papilla was stenotic at surgery, compared with 27% if it was not ($P < .01$). Of those with recurrent acute pancreatitis, 82% were reported to have improved compared with 56% in the chronic pain group ($P < .01$). Preoperative ultrasonography (US) with secretin stimulation was compared with examination of the minor papilla and had a sensitivity of 78% and a specificity of 97%. Thus preoperative US with secretin stimulation was judged to be a good predictor of surgical success (92% success if positive, 40% success if negative). Seven patients were documented to have developed a restenosis at the minor papilla, six of whom had further surgery. The study concluded that a demonstrable stenosis at the minor papilla was a necessary cofactor in the development of recurrent acute pancreatitis or pancreatic pain in patients with PD.

Surgical sphincteroplasty is not without risk, however. In a recent large series of 446 patients, complications were reported in 34.8% of patients; pancreatitis (8.8%), asymptomatic hyperamylasemia (6.0%), and wound/abdominal infection (7.1%) were the most common morbidities. One death occurred after a duodenal leak (Madura et al, 2005).

The Case Against an Association Between Pancreas Divisum and Pancreatitis

Those making the case against an association between PD and pancreatitis begin by highlighting problems with the epidemiologic studies. It is argued that in ERCP series, the true incidence of PD is underdiagnosed. This is supported by autopsy studies that demonstrate the prevalence of PD to be approximately 10%, whereas ERCP series show it to be half this. It is argued that were ERCP to accurately diagnose PD, its prevalence in control and pancreatitis groups would be the same. Patients in groups used as controls often only have cholangiography and do not undergo intentional pancreatography. Pancreatitis patients, on the other hand, have the pancreatic ducts imaged intentionally; therefore PD may be diagnosed more accurately. Furthermore, the ERCP prevalence of PD in pancreatitis patients is the same as the prevalence of PD in the general population in autopsy studies (7.6% vs. 7.8%). The argument therefore follows that if ERCP accurately diagnosed PD in the general population, no difference would exist.

An argument is also made against the theory of minor papilla obstruction. It is argued that patients with pancreatitis secondary to PD should have a dilated ductal system, but this has not been shown to be the case in the majority of studies that have assessed for it (Fogel et al, 2007). Similarly, if pancreatitis were associated with PD, only the dorsal pancreas should be affected, yet ventral duct pancreatitis is present in up to 11.8% of patients with PD and is the only duct involved in 4.2% of patients.

Cystic Fibrosis and Recurrent Pancreatitis

Cohn and colleagues (1998) and Sharer and colleagues (1998) first described the link between cystic fibrosis gene mutations and idiopathic pancreatitis. More recently, Choudari and colleagues (2004) demonstrated that mutations of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene were present in 8 (22%) of 37 patients with PD and pancreatitis compared with 0 of 20 patients with PD and no history of pancreatitis (odds ratio [OR], 11.8; confidence interval [CI], 8.9 to 14.7; $P = .02$). The authors concluded that in patients with PD, *CFTR* mutations increased the risk for pancreatitis. Furthermore, Gelrud and colleagues directly measured *CFTR* gene function in nasal epithelium in response to isoproterenol

From Fogel EL, et al, 2007: Does endoscopic therapy favorably affect the outcome of patients who have recurrent acute pancreatitis and pancreas divisum? Pancreas 34:21-45.

and demonstrated that those with PD and recurrent acute pancreatitis had results somewhere between those observed for healthy controls and those for classic cystic fibrosis patients. Thus CFTR dysfunction may explain why some PD patients have recurrent acute pancreatitis but others with PD do not. Moreover, of 12 patients with PD and recurrent acute pancreatitis, 10 had undergone therapy to the minor papilla, and only 2 had resolution of their symptoms.

Summary

Despite the association of pancreatitis and PD being described in the 1970s, significant controversy still exists regarding whether a causal relationship exists. Although many case series report the benefit of therapy to the minor papilla in patients with PD and pancreatitis, a lack of randomized, controlled data means interpretation of these studies must be guarded. At best, careful case selection is paramount before embarking on any such therapy: patients most likely to benefit are older, have documented recurrent acute pancreatitis, and have been exhaustively investigated for a recognized cause of pancreatitis. Those with chronic pancreatitis or pancreas-type pain are much less likely to benefit. Recurrence of symptoms is common, and repeat therapy involving the minor ampulla may be required. The *CFTR* data are interesting and may begin to explain why few patients with PD experience pancreatitis.

ANNULAR PANCREAS

Annular pancreas is a rare congenital abnormality in which the head of the pancreas completely encircles the second part of the duodenum (Fig. 51.4). It was first described in 1862 by Ecker, who reported a "ring derived from the head of the pancreas which surrounded the descending portion of the duodenum and was formed by uninterrupted glandular tissue" (Ravitch & Woods, 1950). The prevalence in autopsy studies is approximately 3 in 20,000 (Ravitch & Woods, 1950) but is higher in patients undergoing ERCP, at approximately 3 in 1000 (Fogel et al, 2006). Given the difficulty in making the diagnosis during autopsy and the highly selected patient population undergoing ERCP, the true prevalence likely lies somewhere in between.

Pathogenesis

In early development, the ventral pancreas is formed by two buds (see Chapter 1A). In mammals, the left ventral pancreatic bud is thought to regress (Lammert et al, 2001; Odgers, 1930), and the larger right ventral pancreatic bud migrates to take up the position seen in the adult. A number of hypotheses have been proposed to explain the occurrence of annular pancreas. The most persistent is that of Lecco (1910), who suggested that adherence of the right ventral pancreatic bud to the duodenum before gut rotation resulted in a partial or complete ring

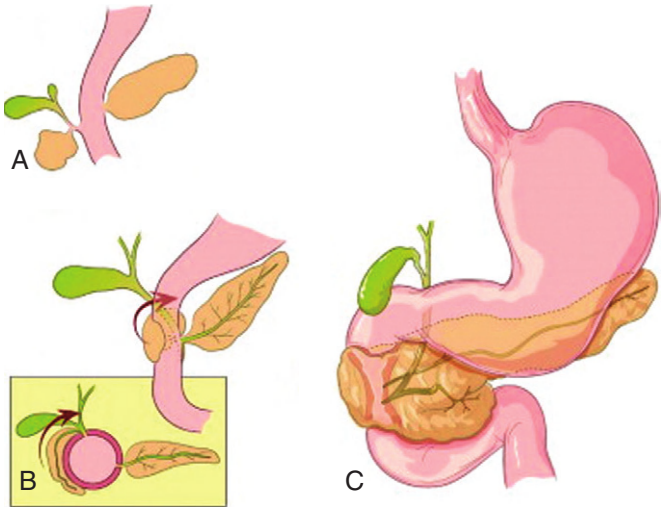

FIGURE 51.4. Development of annular pancreas. *(Modified from Zyromski, et al, 2008: Annular pancreas: dramatic differences between children and adults. J Am Coll Surg 206:1019-1025.)*

of pancreatic tissue around the duodenum. A competing hypothesis offered by Baldwin (1910) postulates that the left ventral bud persists to form the annulus. Although in most annular pancreas specimens, only one ventral lobe is apparent, reports of a bilobar ventral pancreas have surfaced that support Baldwin's theory (Nobukawa et al, 2000). Neither of these theories explains the variation in the position of the annular duct seen in various specimens, and Kamisawa and colleagues (2001) proposed a new theory that the tip of the left ventral bud adheres to the duodenum and stretches to form a ring. The exact location of this attachment in relation to the bile duct determines the final arrangement of the annular duct.

Reports of familial annular pancreas support a genetic basis for the disease. Annular pancreas has been described in siblings (Claviez et al, 1995; Lainakis et al, 2005; Montgomery et al, 1971), a mother and three of her children (Jackson & Apostolides, 1978), a mother and son (MacFadyen & Young, 1987), a mother and daughter (Hendricks & Sybert, 1991; Rogers et al, 1993), and a father and son (Mitchell et al, 1993), and a recent report describes the anomaly in monozygotic twins (Hulvat et al, 2006).

Clues as to the genetic basis of the disease are beginning to emerge. Only recently has it been shown that the cells that form the annulus are derived entirely from the ventral pancreas (Jarikji et al, 2009). In the same report, it was demonstrated that in *Xenopus* embryos, inactivation of transmembrane 4 superfamily member 3 (*TM4SF3*), a member of the tetraspanin family, inhibited fusion of the dorsal and ventral pancreatic buds. Overexpression of the same gene promoted development of annular pancreas. This would suggest that the product of this gene directly regulates the migration of ventral pancreatic bud cells, although whether it plays a role in the formation of annular pancreas in humans remains to be seen.

Another recent study has demonstrated a link between the Hedgehog signaling pathway and the development of annular pancreas. Members of the Hedgehog family of genes promote growth and differentiation of organs, and defects are associated with congenital malformations of the foregut (Litingtung et al, 1998). In 42% of mice embryos with a targeted inactivation of the Indian Hedgehog (*IHH*) gene, a member of the mammalian Hedgehog family, changes in the morphology of the ventral pancreatic bud similar to annular pancreas were seen (Hebrok et al, 2000). In most, the annulus was complete, although pancreas cells were not seen within the muscularis of the duodenum, as has been described in humans. Annular pancreas is also frequently seen after inactivation of Sonic Hedgehog (*SHH*), although the incidence of the anomaly is closely related to the background strain of the transgenic mouse, suggesting interaction with other genetic modifiers (Ramalho-Santos et al, 2000). *SHH* is not expressed in pancreatic tissue; therefore it has been suggested that a defect in duodenal Hedgehog signaling may lead to the anomaly because both *SHH* and *IHH* are expressed in the developing gut (Bitgood & McMahon, 1995; Hebrok et al, 2000). *SHH* knockout mice embryos also demonstrate a number of other abnormalities, including gut malrotation (100%), intestinal transformation of the stomach (100%), duodenal stenosis (67%), and imperforate anus (100%), strikingly similar to congenital malformations seen in humans with annular pancreas (see below).

Clinical Presentation and Diagnosis in Adults

An estimated one half to two thirds of cases of annular pancreas in adults remain asymptomatic (Sandrasegaran et al, 2009). Annular pancreas presents with equal frequency in adults and children; in a recent series of 103 patients with annular pancreas, 55 (53.4%) were seen as adults (median age, 47 years), and 48 (46.6%) were seen as children (median age, 1 day) (Zyromski et al, 2008). Of those seen as adults, 41 (75%) were seen with pain, and 12 (22%) were diagnosed with pancreatitis; only 13 (24%) had gastrointestinal symptoms that included vomiting, and 6 (11%) had obstructive jaundice and/or abnormal liver function test results. In addition, 16 patients (29%) were also found to have PD, a higher prevalence than is seen in the general population (see previous section), which may suggest that similar genetic abnormalities link the two conditions. The diagnosis of annular pancreas was made by ERCP in 26 patients (47%), by abdominal CT in 10 patients (18%), by MRCP in 9 patients (16%), and at operation in 7 patients (13%; Fig. 51.5) (Zyromski et al, 2008).

In a recent ERCP series, 26 (93%) of 28 patients with annular pancreas without previous bypass were noted to have duodenal narrowing but no retained gastric contents (Fogel et al, 2006). Pancreatography was attempted in 32 patients and was successful in 30 (94%). Improvements in imaging have led to the identification of incomplete annular pancreas, in which the annulus does not fully encircle the duodenum (Sandrasegaran et al, 2009). The presence of pancreatic tissue on cross-sectional imaging posterolateral to the second part of the duodenum has a high sensitivity (92%) and specificity (100%) for this. Three (33%) of nine patients found to have incomplete annular pancreas on imaging had gastric outlet obstruction (Sandrasegaran et al, 2009).

A number of case reports describe annular pancreatitis in association with neoplasm, most commonly periampullary or pancreatic malignancy, raising the question as to whether annular pancreas predisposes to neoplasia (Ben-David et al, 2004; Benger & Thompson, 1997; Foo et al, 2007; Kamisawa et al, 1995; Shan et al, 2002; Yasui et al, 1995). The adult population in whom annular pancreas is diagnosed is a highly select group with a variety of symptoms. The incidence of annular pancreas is too small to be certain, but it is likely that the association is a result of bias rather than pathogenesis. What should be remembered is that the symptoms of a patient diagnosed

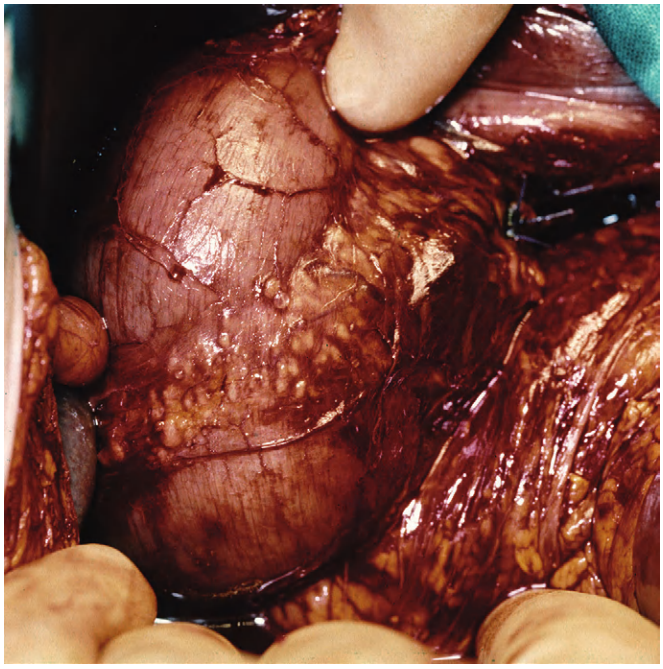

FIGURE 51.5. Annular pancreas.

with annular pancreas are not necessarily secondary to the annular pancreas; a second condition may be present. For instance, annular pancreas rarely presents with obstructive jaundice; therefore, when a patient with obstructive jaundice is found to have annular pancreas, a high index of suspicion for an underlying malignancy must be maintained.

Clinical Presentation and Diagnosis in Children

A significant difference between the adult and pediatric populations with annular pancreas is the prevalence of associated congenital abnormalities in children. The majority of children with annular pancreas show evidence of the condition in the first days after birth: in a recent series of 16 patients, 12 (75%) came to medical attention during the first week of life, one during the first month, and the remainder within the first year (Table 51.5) (Jimenez et al, 2004). If complete duodenal obstruction is present, polyhydramnios will usually be a feature; primary biliary obstruction and jaundice are not typical (Merrill & Raffensperger, 1976).

Preampullary obstruction resulting in nonbilious vomiting has been reported to be more common in annular pancreas than in other causes of duodenal obstruction (94% vs. 10%; Hays et al, 1961; Jimenez et al, 2004). In the series by Zyromski and colleagues (2008), 27 (56%) of 48 children with annular pancreas were suspected to have the condition based on prenatal US, and the remainder were seen with gastrointestinal obstruction, 37 (77%) of whom were diagnosed within the first 2 days of life; 34 (71%) of children with annular pancreas were reported to have at least one other congenital abnormality, the most common being trisomy 21 (Down syndrome), seen in 10 (21%). Gastrointestinal abnormalities included intestinal malrotation in 10 of the 48 children (21%), tracheoesophageal fistula in 4 (8.3%), and 1 each of mobile right colon, omphalocele, nonrotation, duodenal atresia, and situs inversus. In addition, 10 children (21%) had significant cardiac anomalies, and genitourinary abnormalities were seen in 5 children (10%).

Diagnosis was made in a similar way in both the Jimenez and Zyromski series; plain abdominal radiographs showed the "double-bubble" sign, or air in the stomach and first part of the duodenum, in 14 (88%) of 16 and 30 (63%) of 48 patients, respectively. Upper gastrointestinal contrast was used in 9 (56%) of 16 and 9 (19%) of 48 patients, respectively, and neonatal ultrasonography was used in 3 infants (6%) of 48 in the Zyromski series only.

Therapy for Annular Pancreas

A review of the existing literature published in 1980 concluded that "while there is no single operative procedure of choice, experience militates against any direct attack on the offending annulus" (Kiernan et al, 1980). This conclusion stands, and any attempt to divide the annulus itself risks the formation of a pancreatic fistula. Early pediatric series established duodenal bypass as the treatment of choice, although mortality rates remained high, likely related to the presence of other congenital malformations and the lack of supportive care (Hays et al, 1961; Kiesewetter & Koop, 1954; Merrill & Raffensperger, 1976). Duodenoduodenostomy has replaced duodenojejunostomy as the treatment of choice because it has a lower incidence of postoperative complications, particularly obstruction and blind-loop

syndromes (Jimenez et al, 2004). Before the procedure, care should be given to ensure adequate fluid replacement and correction of electrolyte abnormalities. A right upper quadrant incision gives excellent access, and a full examination should be performed to exclude other congenital abnormalities. An end-to-end or side-to-side duodenoduodenostomy should be performed, ensuring adequate mobilization of proximal and distal ends. Where the first part of the duodenum is distended, a tapering duodenoplasty or plication can be performed, although this may not always be required. Consideration should be given to the placement of a gastrostomy tube; however, this should be reserved for those patients who are likely to have long-term problems, such as those with complex gastrointestinal malformations or chromosomal abnormalities. An enteral feeding tube is often useful and allows early feeding to be commenced.

Outcome after surgery has improved markedly, with early mortality rates decreasing from 83% in the 1950s (Kiesewetter & Koop, 1954) to less than 10% in most recent series (Jimenez et al, 2004; Zyromski et al, 2008), largely as a result of improvements in surgical decision making and technique and advances in neonatal intensive care and anesthesia. Deaths in contemporary series are usually attributed to severe associated congenital anomalies.

In the series from Zyromski, 35 (63%) of 55 adults were reported to have had surgical therapy for symptoms related to annular pancreas. Duodenal bypass was performed in 13 adult patients (24%) compared with 100% of the children. Adults also underwent a number of other surgical procedures, including cholecystectomy, pancreatoduodenectomy, pancreatic sphincteroplasty, lateral pancreatojejunostomy, hepaticojejunostomy, and biliary sphincteroplasty. Therapeutic ERCP with sphincterotomy/stenting was performed in 37 (67%) of 55 adults.

Summary

Annular pancreas is a rare condition that is being increasingly diagnosed as a consequence of improvements in modern imaging. Children are seen at birth with gastrointestinal obstruction and often have other congenital abnormalities. Adults come to medical attention with pain or vague upper abdominal symptoms, and diagnosis can be confirmed using CT, MRCP, or ERCP. In children, duodenoduodenostomy is the treatment of choice; in adults an array of interventions may be required, often in the treatment of a coexisting pathology.

PANCREATOBILIARY MALJUNCTION

Pancreatobiliary maljunction was first described by Babbitt in 1969, and it has since been defined as "a congenital anomaly in which a junction of the pancreatic duct and biliary ducts is detected radiologically and/or anatomically outside the duodenal wall" (see Chapter 1B; Todani et al, 1994). It is often associated with congenital bile duct dilation (choledochal cyst; see Chapter 46), which is significant because it results in regurgitation of pancreatic juice into the biliary tree (pancreatobiliary reflux) and of bile into the pancreatic duct (biliopancreatic reflux). It has been associated with a number of pathologic conditions, most notably carcinoma of the biliary tree (see Chapter 50).

Pathogenesis

The anatomic relationship between the junction of the duodenum and the pancreatobiliary ducts is subject to significant variation (Suda et al, 1980, 1983). The pancreatic and bile duct may open into the duodenum in one of three configurations: 1) separately, 2) through a single opening with no common channel, or 3) through a single opening with a common channel (Fig. 51.6). Within the wall of the duodenum, the pancreatic and bile ducts are under the control of the sphincter of Oddi; proximal to this extend the sphincter choledochus (of Boyden) and the sphincter pancreaticus. A single opening with a short common channel is usual, but when the common channel extends beyond the duodenal wall, the pancreatobiliary ductal junction is not controlled by these sphincter mechanisms, allowing regurgitation to occur between the two ducts. This is termed *pancreatobiliary maljunction,* which was reported to have a prevalence of 3.1% in a recent ERCP series (Kamisawa et al, 2007b). A further 3.7% of patients were shown to have a high confluence of the pancreatobiliary ducts, and although sphincter function existed at the junction, the group was still susceptible to the same pathologic consequences as those with maljunction. The incidence of maljunction is higher in Asian compared with Western populations, although the reasons for this remain unclear.

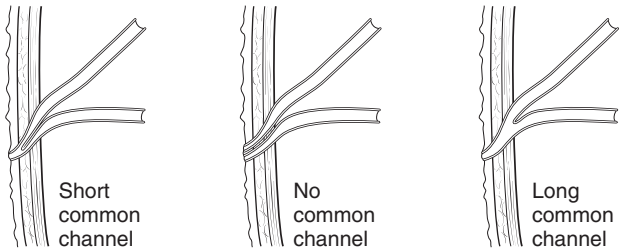

FIGURE 51.6. Normal variations in the configuration of the pancreatic and bile ducts. *(Adapted from Rizzo RJ, Szucs RA, Turner MA, 1995: Congenital abnormalities of the pancreas and biliary tree in adults. Radiographics 15:49.)*

The embryologic origins of pancreatobiliary maljunction have not been fully elucidated. Small pancreatic radicals arising from the long common channel have led to the suggestion that it originates from the ventral pancreatic duct (Matsumoto et al, 2001; Suda et al, 1991a, 1991b). In one such hypothesis, it is suggested that the persistence of the left ventral duct, usually seen to regress in normal development, associated with regression of the distal bile duct results in a long common channel (Oi, 1996). An alternative hypothesis suggests that maljunction results from a disturbance in embryologic connections of the terminal bile duct and the ductal system of the ventral pancreas (Matsumoto et al, 2001). A case report of pancreatobiliary maljunction in monozygotic twins provides strong support for a genetic basis for the disease (Yamao et al, 2004).

Diagnosis and Investigation

Maljunction is closely associated with choledochal cyst and in one series was described in all patients with type I choledochal cysts (see Chapter 46; Miyano et al, 1997). Clinical presentation in this context can be at any age and may feature a right upper quadrant mass, hepatomegaly, jaundice, abdominal pain, cholangitis, or pancreatitis. In maljunction without bile duct dilatation, patients may be asymptomatic (30%), or they may be seen with abdominal pain (24%), recurrent acute pancreatitis (18%), obstructive jaundice (18%), or acute cholangitis 9% (Matsumoto et al, 2002). When pancreatic maljunction is

suspected, the lack of effect of the sphincter muscle on the pancreatobiliary ductal junction can be confirmed radiologically, and regurgitation can be demonstrated by MRCP, ERCP, operative cholangiography, or percutaneous transhepatic cholangiography. Biliary amylase levels have also been shown to be high in this group (Ohta et al, 1990). On hepatobiliary scintigraphy, the passage time from the bile duct to the second part of the duodenum was significantly longer in maljunction patients than in controls (49 ± 13 vs. 3 ± 14 minutes) (Fujii et al, 1991).

Carcinogenesis in Pancreatobiliary Maljunction

The association of bile duct cancer and choledochal cyst is well established (Irwin & Morrison, 1944), and resection of the extrahepatic bile duct and gallbladder with biliary reconstruction is now standard treatment (Edil et al, 2009). A number of published series have described a high incidence of gallbladder cancer in patients with pancreatobiliary maljunction in the absence of a dilated bile duct (see Chapter 49; Chao et al, 1995; Chijiiwa et al, 1995; Elnemr et al, 2001; Kamisawa et al, 2006, 2007b; Kimura et al, 1985; Kinoshita et al, 1984; Mori et al, 1993; Sandoh et al, 1997; Yamauchi et al, 1987). The hydrostatic pressure in the pancreatic duct is greater than that of the bile duct (Carr-Locke & Gregg, 1981; Csendes et al, 1979), so it follows that when free communication exists between the two ducts, pancreatic juice flows from the pancreatic to the bile duct. The pathogenesis of malignant change is not fully characterized but is likely due to the effect of activated pancreatic enzymes on the biliary epithelium, together with biliary stasis. *KRAS* and *P53* mutations have been reported in noncancerous biliary epithelium of patients with maljunction, which may be important given the apparent higher incidence of carcinoma in this group (Hanada et al, 1996, 1999; Kasuya et al, 2009; Matsubara et al, 1996, 2002).

Therapy for Pancreatobiliary Maljunction Without Bile Duct Dilatation

Given the risk of malignant transformation in patients with pancreatobiliary maljunction without biliary dilation, resectional surgery is generally advocated. However, significant controversy exists as to whether a complete excision of the extrahepatic biliary tree is required or just a simple cholecystectomy. Those arguing the former cite case reports of choledochal cyst patients developing cancer in the hepatic duct above the reconstruction after bile duct resection (Thistlethwaite & Horwitz, 1967; Yamamoto et al, 1996). This, together with the *P53*/*KRAS* mutation, suggests the biliary epithelium is in a "premalignant state" (Funabiki et al, 1997; Hara et al, 2001; Ng & Lui, 1999; Toufeeq Khan & Manas, 1999; Tuech et al, 2000). Other investigators argue that cholecystectomy alone is sufficient and base this on reasonable follow-up data, albeit in small cohorts, showing no patients developed bile duct malignancy in this group (Aoki et al, 2001; Kusano et al, 2005; Ohuchida et al, 2006; Sugiyama & Atomi, 1998). It is currently impossible to confirm which strategy is correct, and any decision must be made on an individual basis.

CONGENITAL CYSTS OF THE PANCREAS

Of the cystic diseases of the pancreas (see Chapter 57), true congenital cysts are uncommon and comprise less than 1% of the total (Howard, 1989). Cysts may be solitary, but this is rare—fewer than 30 have been described in the world literature. They are usually multiple, and some are associated with a systemic disorder, such as von Hippel–Lindau syndrome or polycystic kidney disease (Boulanger et al, 2003). Enteric duplication cysts of the gastrointestinal tract are also rare (2 in 9000 fetal/neonatal autopsies) (Potter, 1962) and can lie in the pancreatic head in isolation or in communication with the pancreatic duct (Black et al, 1986). They are lined with gastrointestinal mucosa and take a layer of smooth muscle from their associated viscus. Several hypotheses on their embryologic origins exist, but no consensus has been reached (Bentley & Smith, 1960; Bishop & Koop, 1964; Bremer, 1944; Lewis & Thyng, 1908).

Congenital pancreatic cysts are most commonly seen in neonates or infants as an asymptomatic epigastric mass. It is very rare for them to present in adulthood, although case reports do exist (Casadei et al, 1996). In the case of duplication cysts, presentation with acute pancreatitis is not uncommon. This is likely to be due to the secretions of the gastrointestinal mucosa within the cyst activating pancreatic enzymes. Other modes of presentation relate to compression of other structures by the cyst and include abdominal pain, obstructive jaundice, and splenic vein thrombosis (Boulanger et al, 2003).

Diagnosis can be difficult, and most of the published cases describe extensive investigation of patients with recurrent abdominal pain or pancreatitis before the diagnosis being made. In patients with solitary congenital pancreatic cysts, US, CT, and ERCP have all been used in making the diagnosis (Casadei et al, 1996). Enteric duplication cysts involving the head of the pancreas can be differentiated from pseudocysts on US by the identification of hyperechoic muscoa and hypoechoic smooth muscle (Barr et al, 1990). Peristalsis has also been seen in these lesions (Spottswood, 1994). CT helps further characterize the lesion, and MRCP and ERCP can determine ductal relationships (Siddiqui et al, 1998).

Complete resection of solitary pancreatic cysts has been advocated, given that cystic neoplasms represent a possible differential diagnosis (Boulanger et al, 2003). Drainage procedures have been performed successfully, but multiple biopsies of the cyst wall should be taken to exclude malignancy. Drainage procedures have been performed for enteric duplication cysts but are not usually definitive because patients often return with further pain or pancreatitis. When possible, local or mucosal resection is preferable to major resection, such as pancreatoduodenectomy, which should be reserved for when malignancy cannot be excluded. The spleen should be preserved whenever possible, particularly in the pediatric population.

HETEROTOPIC PANCREAS

Heterotopic pancreas is defined as pancreatic tissue outside the boundaries of the pancreas that lacks anatomic or vascular continuity with the organ (Fig. 51.7). The first description is credited to Jean Schultz in 1729, and sporadic cases have been described since (Barbosa et al, 1946). Heterotopic pancreas is a congenital anomaly that is usually asymptomatic but can become clinically apparent when the inflamed or enlarged pancreas compresses adjacent viscera. The prevalence in the general population is difficult to determine; estimates range from 0.6% to 13.7% (Barbosa et al, 1946; Feldman & Weinberg, 1952).

The pathogenesis of heterotopic pancreas is unclear. It has been hypothesised that during embryologic development,

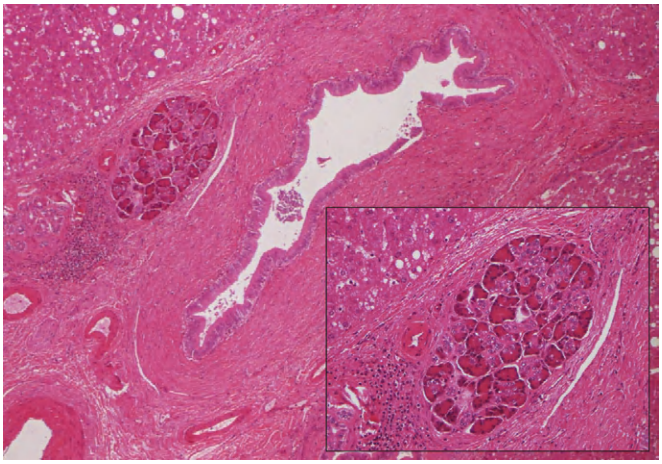

FIGURE 51.7. Heterotopic pancreas in a large portal tract in the liver found incidentally. The liver resection was for metastatic colorectal cancer. *(Courtesy Dr. Barbara Langdale-Brown, Edinburgh.)*

pancreatic tissue may become attached to the duodenum and be carried proximally or distally as the bowel elongates (Horgan, 1921). This, however, does not explain the rare instances of heterotopic pancreas at sites distant from the gastrointestinal tract, for instance, in the uterine tube (Mason & Quagliarello, 1976). As has been described, the pancreas is endodermal in origin, and contemporary studies are beginning to uncover the mechanisms by which cells destined to become pancreas are specified from surrounding tissues (Kumar & Melton, 2003). The observation that heterotopic pancreas tissue usually drains into the gastrointestinal tract via a primitive duct (Pang, 1988) suggests in situ differentiation rather than migration from elsewhere (Slack, 1995). Thus it is possible that heterotopic pancreas is the result of a process in which cells destined for other endodermal structures are anomalously diverted to a pancreatic fate.

Clinical presentation depends entirely on anatomic site. An early series of 34 patients by Armstrong and colleagues is representative: heterotopic tissue was found in stomach (24%), duodenum (32%), jejunum (29%), Meckel diverticulum (15%; Fig. 51.8), and gallbladder (3%). Occurrences have also been documented in the esophagus, bile duct, spleen, mesentery, and fallopian tubes. In the same series, heterotopic pancreas was thought to be clinically significant in 13 patients (38%) and possibly significant in four patients (12%). All gastric lesions, and four of 11 duodenal lesions, presented with epigastric pain. Two of the duodenal lesions presented with ulcer bleeding and one with chronic anemia.

Investigation and diagnosis again depend on the mode of presentation. In a contemporary series, diagnosis was made at gastroduodenoscopy in 36% and at surgery in 64% (Eisenberger et al, 2004). It was noted that definitive diagnosis was only obtained with histologic assessment. Heterotopic pancreas was the indication for surgery in 36% of cases, and in 45%, it was diagnosed incidentally during surgery. In 18% it was diagnosed on gastroduodenoscopy, and definitive surgical management was not required.

In the majority of cases found at open surgery, the lesion is resected even when thought to be asymptomatic. This is advised because the diagnosis cannot be made clinically, and the main differential is malignancy. A frozen histologic section is an alternative approach but is rarely worthwhile unless an extensive resection is required. When identified at endoscopy, initial

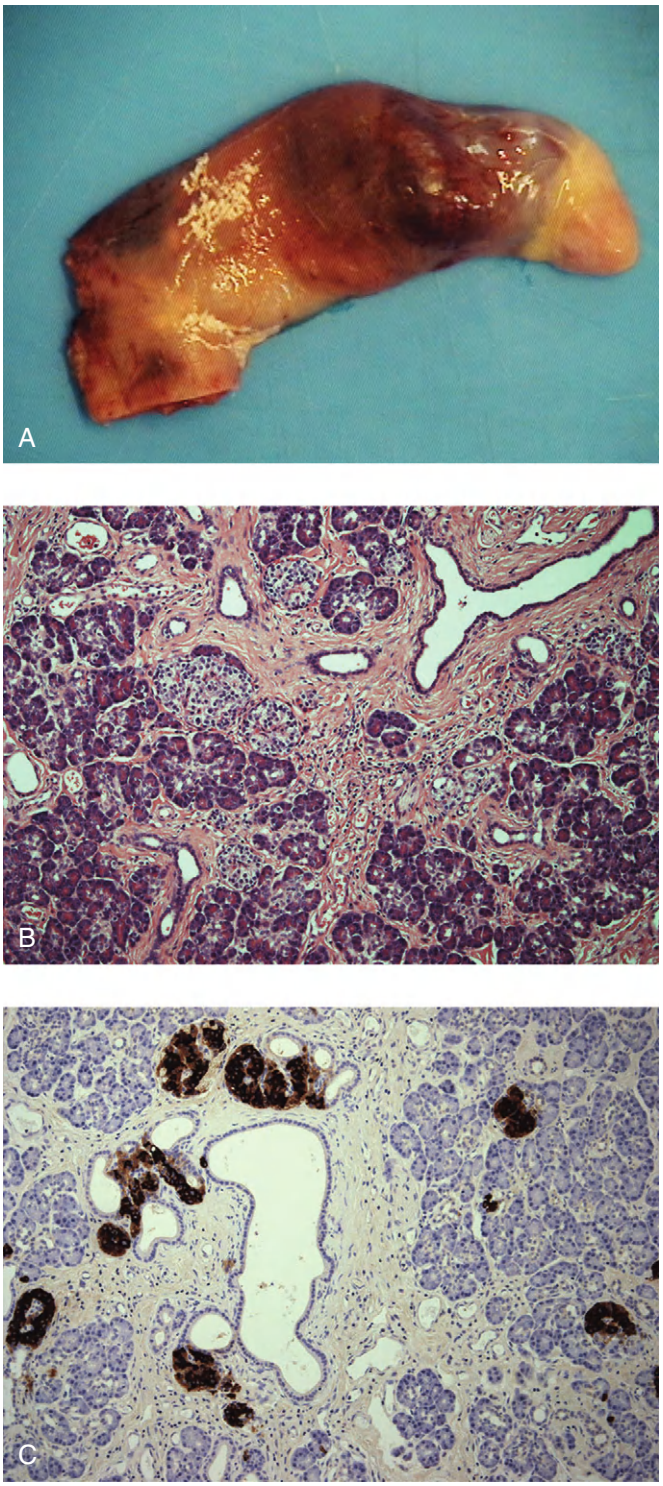

FIGURE 51.8. A, Heterotopic pancreas found in Meckel diverticulum. **B,** Hematoxylin and eosin section. **C,** Immunohistochemistry with primary antibody specific for human insulin. *(Courtesy Dr. Kathryn McKenzie, Edinburgh.)*

biopsies are often negative because the overlying mucosa may be normal. Recently, endoscopic US-guided core biopsies have been ideal. If the lesion is thought to be symptomatic, a resection can be planned, but many can be treated conservatively with no negative long-term consequences.

CHAPTER 52

Definition and classification of pancreatitis

Claudio Bassi, Giovanni Butturini, and Giovanni Marchegiani

OVERVIEW

Despite four international consensus meetings over 40 years, the issue of definition and classification of pancreatitis (see Chapters 53 to 55) is still under critical revision. The main reason is the difficulty, in contrast to other common inflammatory gastroenterologic diseases, to obtain pancreatic tissue specimens to define the diagnosis better during the inflammatory process. Any classification of pancreatitis must be based on clinical, morphologic, and laboratory features.

The history of the definition and classification of pancreatitis is characterized mainly by the distinction between acute and chronic pancreatitis as stated by Lagerlof in 1942. These two clinical conditions seemed to be two different and separate pathologic processes. In recent years, with the widening of clinical observation and improved accuracy of imaging studies, particularly magnetic resonance imaging (MRI) of the bile ducts and duct of Wirsung, the classic distinction between acute and chronic pancreatitis is under critical revision.

The process leading to fibrotic changes in the glandular tissue usually begins with typical acute abdominal pain with increases of serum amylase and lipase and subsequent resolution. Acute pancreatitis leads to chronic pancreatitis because of episodes of obstruction secondary to edema or inflammatory response of the sphincter of Oddi. As in other inflammatory disease, timing seems to play the main role in determining whether glandular inflammation leads to a chronic condition or self-limits with no sequelae.

The most typical natural history regarding the correlation between acute and chronic pancreatitis is so-called *recurrent pancreatitis.* It is not possible to define this condition as acute or chronic per se, and it represents the best example of the new comprehension of the pathologic process. Nevertheless, today we must keep in mind a classification of acute and chronic pancreatitis to help in developing diagnostic and therapeutic algorithms.

HISTORY OF THE DEFINITION AND CLASSIFICATION OF PANCREATITIS

Pancreatitis is an inflammation of glandular parenchyma lead to injury or destruction of acinar components. The pathologic process could result in a self-limited disease with no sequelae or in catastrophic autodigestion activity with systemic cytotoxic effects and life-threatening complications in the acute form. In the case of chronic inflammation, fibrosis and calcification are the main features of the disease.

The history of the definition and classification of pancreatitis shows the progressive awareness of experts that acute and chronic inflammation should be defined by different pathologic, clinical, and etiogenetic perspectives (Table 52.1). The different points of view correlate with each other and together provide the best comprehension of the inflammatory process. Consequently, the clinical management of an individual patient can be improved only by considering all the features of pancreatitis.

The first effort to classify and define pancreatitis by a worldwide group of experts led to the Marseille Consensus Meeting in 1963 (Sarles, 1965). The panel of pancreatologists agreed that acute and chronic pancreatitis were different diseases mainly because of different morphologic patterns. Relapsing pancreatitis was characterized by the presence of multiple episodes in a morphologic pattern of acute or chronic processes. The distinctive features of the two diseases were the pathologic benign course of acute inflammation, with biologic restitution in the acute condition, and the progressively worsening parenchymal lesions in the chronic condition (Table 52.2). The present histology-based classification does not provide clinically useful definitions, making it impossible to compare different experiences. From the clinical point of view, acute and chronic pancreatitis show a similar pattern, at least in the earlier phases.

Progress in the comprehension of pancreatitis and its classification resulted from the Cambridge meeting (Sarner & Cotton, 1984). The distinction between *acute* and *chronic*

Table 52.1

A Synopsis of Pancreatitis Classification from 1946 to 2011

Classification	Definition
Marseille, 1965	Description of morphologic characteristics and etiologic factors of the disease; no categorization according to disease severity, no imaging findings
Cambridge, 1984	Classification of disease severity based on pancreatic imaging criteria (US, CT, ERCP); discussion of etiologic factors and pancreatic function
Revised Marseille, 1985	Description and further subclassification of morphologic changes; definition of "obstructive chronic pancreatitis" as a distinct form; no discussion of the correlation between anatomic and functional changes, no inclusion of pancreatic imaging findings
Marseille-Rome, 1988	Further description of "chronic calcifying" and "chronic inflammatory" pancreatitis as distinct forms; description of etiologic factors; no further elaboration of clinical, functional, or imaging criteria
Atlanta, 1992	Description of clinical and morphologic features of pancreatitis; dynamic classification system able to characterize the individual patient and predict severity
Zurich, 1997	Description of clinical presentation and classification of the disease in "definite" and "probable" chronic pancreatitis according to imaging findings, functional testing, and histologic examination
Japan Pancreas Society, 1997	Description of clinical presentation and classification of the disease in "definite" and "probable" chronic pancreatitis according to imaging findings, functional testing, and histologic examination; definition of radiologic and laboratory features in patients lacking etiologic and pathogenetic features
TIGAR-O, 2001	Detailed categorization of etiologic risk factors and correlation between acute and chronic pancreatitis
ABC, 2002	Disease grading according to clinical criteria; limited separation of different disease severities; not all clinical presentations categorized
Manchester, 2006	Disease grading according to clinical criteria; limited separation of different disease severities
M-ANNHEIM, 2007	Categorization of patients according to etiology, clinical stage, and severity of disease; severity of pancreatic inflammation assessed using a specific scoring system

US, ultrasound; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography

pancreatitis was confirmed, and the term *relapsing pancreatitis* was avoided in the chosen terminology. The importance of the clinical impact of different severity systemic responses was emphasized (Table 52.3), and the importance of definition of a morphologic characterization of the inflammatory process was recognized, particularly for the acute pancreatitis group. The Cambridge group pointed out the relevant problem of etiology, and the role of imaging in chronic pancreatitis was addressed.

Endoscopic retrograde cholangiopancreatography (ERCP) classification (Table 52.4) is still in use in some centers. Several studies in the literature showed that ERCP findings are not pathognomonic of chronic pancreatitis but could coexist with many clinical conditions. In particular, cholelithiasis and its complications lead to demonstrable alterations in the morphology of the duct of Wirsung, as stated in the Cambridge classification (Buchler et al, 1987; Misra et al, 1990), and these morphologic changes could persist for many months. In biliary cirrhosis, Sjögren syndrome, and sclerosing cholangitis, pancreatic duct changes are commonly observed at ERCP (Bastid et al, 1990; Epstein et al, 1982; Lindstrom et al, 1991). For all these reasons, the ERCP morphology of the duct of Wirsung is not mandatory to diagnose chronic disease. In addition, increasing use of MRI of the bile ducts and duct of Wirsung provides excellent morphologic imaging of the main and side branch ducts.

The increasing attention to duct morphology and consequently to the cause-and-effect relationship of obstruction resulted in new terminology at the second Marseille meeting held in 1984 (Singer et al, 1985). In addition to the classic distinction between acute and chronic disease, a new entity was identified: *obstructive chronic pancreatitis* (Table 52.5). The role of duct obstruction in the chronic inflammatory process was recognized as a distinctive pathway to developing pancreatitis. This new concept has gained importance over the years in

Table 52.2

Marseille Classification of Pancreatitis

Feature	Acute Pancreatitis/Acute Relapsing Pancreatitis	Chronic Relapsing Pancreatitis/Chronic Pancreatitis
Clinical characteristics	Single/multiple episodes	Multiple episodes/no acute exacerbations is common
Morphologic characteristics	Not defined	Irregular sclerosis with destruction and focal segmental or diffuse loss of parenchyma with varying dilation of ductal system; strictures, intracanalicular stones (calcifications), cysts, pseudocysts; islets of Langerhans are involved much later in the course of the disease; morphologic picture is similar, independent of cause
Course	Clinical and biologic restitution if the cause is removed	Functional and morphologic lesions persist or progress after the cause is removed

Modified from Sarles H, 1965: Proposal adopted unanimously by the participants of the symposium of acute pancreatitis in Marseille, 1963. Bibl Gastroenterol 7:7-8.

Table 52.3

Cambridge Classification of Pancreatitis

Feature	Acute Pancreatitis	Chronic Pancreatitis
Clinical characteristics	Clinically defined as an acute illness owing to inflammatory pancreatic disease that typically presents with abdominal pain and usually is associated with an increase in pancreatic enzymes in blood or urine Mild pancreatitis: if no multisystem failure occurs and no complications in recovery are seen Severe pancreatitis: if multisystem failure occurs or early or late local or systemic complications occur	Defined as a continuing inflammatory disease of the pancreas; typically presents with abdominal pain or features of pancreatic insufficiency; also can remain painless Only sign of an inflammatory process may be fibrosis, indicating earlier pancreatic inflammation
Morphologic characteristics	Early: subcellular changes Later: fat necrosis or pancreatic tissue necrosis, which may be associated with hemorrhage Complications Phlegmon: an inflamatory mass in or around the pancreas Pseudocyst: a localized collection of fluid containing high concentrations of pancreatic enzymes within, adjacent to, or remote from the pancreas Abscess: pus in or around the pancreas	Not clearly defined; characterized by "irreversible morphologic changes"; classification is based on results of imaging studies
Course	Acute pancreatitis may recur	Many patients may have acute exacerbations of pain

Modified from Sarner M, Cotton PB, 1984: Classification of pancreatitis. Gut 25:756-759.

distinguishing chronic calcifying pancreatitis in alcoholics from obstructive chronic pancreatitis initially presenting as relapsing acute attacks owing to strictures resulting from different conditions, such as solid tumors, mucinous plugs typical of intraductal papillary mucinous tumors, severe pancreatitis with duct disruption, and scar and inflammation of the sphincter of Oddi of biliary origin. Regarding acute pancreatitis, another hallmark was recognized by the second Marseille meeting: The rule in mild pancreatitis is the absence of necrosis. The recognition of a dramatic and central role of necrosis in severe pancreatitis opened the doors to wide-ranging and fundamental studies on severity assessment and complication prevention; increasing use of CT scan in staging of the disease also contributed (Beger et al, 1985).

A panel of experts met in Rome in 1988 to integrate the second Marseille classification into use (Table 52.6). The main feature of the new classification (Sarles et al, 1989) was the statement about the reversibility of the lesions observed in the course of acute pancreatitis; even the severe forms responded to clinical observation in almost half of severe pancreatitis patients. In contrast, in chronic pancreatitis, some pathologic features were defined as permanent, and the condition was described as *chronic inflammatory pancreatitis*, morphologically characterized by loss of exocrine parenchyma and fibrosis with mononuclear cell infiltration. For the first time, etiology specifically was addressed, with pancreas divisum and alcohol as possible causes of acute pancreatitis.

The need for further effort to better define acute pancreatitis resulted from the observation that the terminology of the Rome meeting was conflicting and not widely applied all over the world (Lumsden & Bradley, 1990). In 1992, 40 pancreatologists met in Atlanta and developed a new, reliable classification system of acute pancreatitis (Table 52.7; Bradley, 1993). The clinical and morphologic features of pancreatitis were considered, resulting in a dynamic ongoing classification system better able to characterize the individual patient and predict disease severity.

The Zurich classification for alcoholic chronic pancreatitis (Table 52.8; Amman, 1997) specifically addresses the most common cause of the disease and gives less importance to other causes, which are sometimes difficult to diagnose, resulting in a quite complex classification system not widely adopted. In 1997, a new definition of chronic pancreatitis was published, dividing *definite* from *probable* chronic pancreatitis (Table 52.9; Homma et al, 1997). This definition provided a list of radiologic or laboratory features in chronic pancreatitis patients lacking etiologic and pathogenetic features. The TIGAR-O risk factor classification system (***t***oxic-metabolic, ***i***diopathic, ***g***enetic, ***a***utoimmune, ***r***ecurrent severe, ***o***bstructive) (Table 52.10), provides a complete overview of the risk factors for chronic pancreatitis development with special attention to the relationship between acute and chronic disease (Etemad & Whitcomb, 2001). In recent years, two main three-stage categorization systems have been mainly proposed: the ABC system (Ramesh, 2002) and the Manchester classification

Table 52.4

Grading of Chronic Pancreatitis by Endoscopic Retrograde Cholangiopancreatography

Normal	Visualization of the gland without abnormal signs
Equivocal	<3 abnormal branches
Mild	>3 abnormal branches
Moderate	Above + abnormal main duct
Marked	Above + ≥1 of: Cavity >10 mm Intraductal filling defects Calculi/pancreatic calcification Duct obstruction (stricture) Severe duct dilation or irregularity Contiguous organ invasion on ultrasound or CT

CT, Computed tomography

Table 52.5

Revised Marseille Classification of Pancreatitis

Feature	Acute Pancreatitis	Chronic Pancreatitis	Special Form: Obstructive Chronic Pancreatitis
Clinical characteristics	Acute-onset abdominal pain and increase in pancreatic enzymes	Relapsing or persistent abdominal pain; occasionally painless; evidence of pancreatic insufficiency; steatorrhea or diabetes may be present	
Morphologic characteristics	Mild form: interstitial edema, pancreatic necrosis absent; possible peripancreatic fat necrosis	Irregular sclerosis with focal, segmental, or diffuse destruction and permanent loss of exocrine parenchyma; varying degrees of dilation of segments of the ductal system; protein plugs, intraductal calculi, edema, focal necrosis, inflammatory cells, cysts, and pseudocysts; islets of Langerhans are relatively well preserved The following descriptive terms can be used: *chronic pancreatitis with focal necrosis, chronic pancreatitis with segmental or diffuse fibrosis, chronic pancreatitis with or without calculi*	Dilation of the ductal system proximal to occlusion of one of the main ducts (e.g., by tumor or scar)
	Severe form: extensive peripancreatic and extrapancreatic fat necrosis, parenchymal necrosis, and hemorrhage; lesions may be either localized or diffuse		
Course	Usually benign, but severe forms may be fatal; seen as a single episode or recurrent disease; exocrine and endocrine functions impaired to a variable degree for a variable duration Restitution to normal occurs if primary cause and complications are removed; rarely, acute pancreatitis may lead to chronic pancreatitis	Progressive and permanent loss of pancreatic exocrine and endocrine function Further investigation needed about the possibility to regress after removal of primary cause	Structural and functional changes tend to improve when the obstruction is removed

From Singer MV, et al, 1985: Revised classification of pancreatitis: report of the Second International Symposium on the classification of pancreatitis in Marseille, France, March 28-30, 1984. Gastroenterology 89:683-690.

Table 52.6

Marseille-Rome Classification of Pancreatitis

Feature	Acute Pancreatitis	Chronic Pancreatitis	Chronic Inflammatory Pancreatitis
Clinical characteristics	Not defined	First stages: attacks of acute pancreatitis responsible for recurrent pain, which may be the only clinical symptom Generally, after some years, exocrine and endocrine insufficiency develop; acute attacks decrease and disappear	
Morphologic characteristics	Edema, necrosis, hemorrhagic necrosis, fatty necrosis	*Chronic calcifying pancreatitis:* irregular fibrosis, lobular spotty distribution of lesions of different density in between neighboring lobules; intraductal protein precipitates or plugs are always found and, at least in late stages, calcified precipitates (calculi) Atrophy and stenosis of duct frequent, more often than in the obstructive form; structural and functional changes may progress, even if primary cause is removed *Chronic obstructive pancreatitis:* as defined by the revised Marseille meeting (1984).	Loss of exocrine parenchyma, replaced by a dense fibrosis infiltrated by mononuclear cells —
Etiology	Extrapancreatic: gallstones, trauma, drugs, surgery, ERCP, hyperlipoproteinemia	Chronic alcohol consumption, high-protein diet, abnormally low or high-lipid diets frequently associated with disease and probably represent etiologic factors, as does hypercalcemia	—
	Intrapancreatic: tumors, chronic pancreatitis, pancreas divisum (?), alcohol (?)	Other clinical forms: *nonalcoholic, tropical, hereditary*	—
Course	Generally considered reversible; necrosis may be infected; fluid collection filled with pancreatic juice, blood, and necrotic fragments may follow; pseudocysts may form If necrosis involves a segment of the main pancreatic duct, stenosis may result, leading to obstructive chronic pancreatitis distal to necrosis	Generally progresses from painful to painless disease; may progress despite removal of cause Intrapancreatic retention cysts form when these cysts expand into peripancreatic tissues; necrotic pseudocysts form after an acute exacerbation; infected cysts or pseudocysts, called *abscesses,* form	—

ERCP, endoscopic retrograde cholangiopancreatography

Table 52.7

Atlanta Classification

Terminology	Definition	Clinical Manifestation	Pathology
Acute pancreatitis	Acute inflammatory process with involvement of other organs	Mild with minimal organ involvement; severe disease characterized by organ failure	Interstitial edema, intrapancreatic or extrapancreatic necrosis
Acute fluid collections	Occur early, lack a wall	30% to 50% in severe pancreatitis	Absence of well-defined wall
Pancreatic necrosis	Devitalized pancreatic parenchyma	Multiorgan failure	Extensive vessel, acinar cell, islet cell, and pancreatic duct damage
Postacute pseudocysts	Nonepithelialized collection of pancreatic juice	Main symptom pain; rarely palpable	Well-defined wall with clear, often sterile contents
Pancreatic abscess	Circumscribed intraabdominal collection of pus	If present, infection	Pus confined within a wall of granulation tissue

Modified from Bradley EL 3rd, 1993: A clinically based classification system for acute pancreatitis. Arch Surg 128:586-590.

Table 52.8

Zurich Classification for Alcoholic Chronic Pancreatitis

Definite Alcoholic Chronic Pancreatitis	Probable Alcoholic Chronic Pancreatitis
In addition to a typical history or a history of excessive alcohol intake (≥80 g/day), ≥1 of the following criteria establish the diagnosis: • Calcification in the pancreas • Moderate to marked ductal lesions (Cambridge criteria) • Marked exocrine insufficiency defined as steatorrhea (>7 g fat/24 h) normalized or markedly reduced by enzyme supplementation • Typical histology of an adequate surgical specimen	In addition to a typical history or a history of excessive alcohol intake (≥80 g/day), the diagnosis of probable chronic pancreatitis is likely if any of the following criteria are present: • Mild ductal alterations (Cambridge criteria) • Recurrent or persistent pseudocysts • Pathologic secretin test • Endocrine insufficiency

Etiologic Factors*

Alcoholic chronic pancreatitis
Nonalcoholic chronic pancreatitis
Tropical (nutritional) chronic pancreatitis
Hereditary chronic pancreatitis
Metabolic (hypercalcemic, hypertriglyceridemic) chronic pancreatitis
Idiopathic (early and late onset) chronic pancreatitis
Autoimmune chronic pancreatitis
Chronic pancreatitis resulting from miscellaneous causes (e.g., radiation injury, phenacetin abuse)
Chronic pancreatitis associated with anatomic abnormalities (anatomic chronic pancreatitis—periampullary duodenal wall cysts, pancreas divisum, obstructive pancreatitis, posttraumatic pancreatic duct scars)

Clinical Staging

Early stage: recurrent attacks of clinical alcoholic acute pancreatitis (with or without local complications) without evidence of chronic pancreatitis abnormalities
Late stage: any evidence of probable or definite chronic pancreatitis

*These diagnostic definitions also may be used for nonalcoholic chronic pancreatitis.

From Amman RW, 1997: A clinically based classification system for alcoholic chronic pancreatitis: summary of an international workshop on chronic pancreatitis. Pancreas 14:215-221.

Table 52.9

Diagnostic Criteria for Chronic Pancreatitis from the Japan Pancreas Society

Definite Chronic Pancreatitis	Probable Chronic Pancreatitis
Ultrasound: pancreatic stones evidenced by intrapancreatic hyperreflective echoes with acoustic shadows behind	Ultrasound: intrapancreatic coarse hyperreflective echoes, irregular dilation of pancreatic ducts, or pancreatic deformity with irregular contour
CT: pancreatic stones evidenced by intrapancreatic calcifications	CT: pancreatic deformity with irregular contour
ERCP: irregular dilation of pancreatic duct branches of variable intensity with scattered distribution throughout the entire pancreas or irregular dilation of the main pancreatic duct and branches proximal to complete or incomplete obstruction of the main pancreatic duct (with pancreatic stones or protein plugs)	ERCP: irregular dilation of the main pancreatic duct alone; intraductal filling defects suggest noncalcified pancreatic stones or protein plugs
Secretin test: abnormally low bicarbonate concentration combined with either decreased enzyme outputs or decreased secretory volume	Secretin test: abnormally low bicarbonate concentration alone or decreased enzyme output plus decreased secretory volume; tubeless tests: simultaneous abnormalities in benzoyl-tyrosyl-p-amino benzoic acid and fecal chymotrypsin tests observed at two points several months apart
Histologic examination: irregular fibrosis with destruction and loss of exocrine parenchyma in tissue specimens obtained by biopsy, surgery, or autopsy; fibrosis with an irregular and patchy distribution in the interlobular spaces; intralobular fibrosis alone not specific for chronic pancreatitis	Histologic examination: intralobular fibrosis with one of the following findings: loss of exocrine parenchyma, isolated islets of Langerhans, or pseudocysts
Protein plugs, pancreatic stones, dilation of the pancreatic ducts, hyperplasia and metaplasia of the ductal epithelium, and cyst formation	

CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography

Table 52.10

TIGAR-O Classification System for Chronic Pancreatitis

Toxic-Metabolic	Idiopathic	Genetic	Autoimmune	Recurrent and Severe Acute	Obstructive
Alcoholic Tobacco smoking Hypercalcemia Hyperlipidemia Chronic renal failure Medications (phenacetin abuse) Toxins (organotin compounds)	Early onset Late onset Tropical (tropical calcific and fibrocalculous pancreatic diabetes) Other	Autosomal dominant: cationic trypsinogen gene (codon 29 and 122 mutations) Autosomal recessive/modifier genes: *CFTR* mutations, *SPINK1* mutations, cationic trypsinogen (codon 16, 22, and 23 mutations), α_1-antitrypsin deficiency possible	Isolated autoimmune chronic pancreatitis Syndromic autoimmune chronic pancreatitis (Sjögren syndrome–associated, inflammatory disease–associated, primary biliary cirrhosis–associated)	Postnecrotic (severe acute pancreatitis) Recurrent acute pancreatitis Vascular disease/ischemic Radiation injury	Pancreas divisum Sphincter of Oddi disorders (controversial) Duct obstruction (e.g., tumor) Periampullary duodenal wall cysts Posttraumatic pancreatic duct scars

CFTR, cystic fibrosis transmembrane conductance regulator; *SPINK1*, serine protease inhibitor, Kazal type 1

Modified from Etemad B, Whitcomb DC, 2001: Chronic pancreatitis: diagnosis, classification, and new genetic developments. Gastroenterology 120:682-707.

(Table 52.11; Bagul & Siriwardena, 2006). The aim of these systems is to provide an accurate description of chronic pancreatitis, underlining different therapeutic approaches and prognoses depending on disease stage. The ABC system divides patients into grades depending on the presence or absence of abdominal pain, complications, and deficiency in pancreatic function. The Manchester classification uses the terms *mild*, *moderate*, and *end stage* to represent disease progression, allowing comparison between patient groups.

Table 52.11

Manchester Classification System for Chronic Pancreatitis

Mild: Five Essential Criteria

1. ERP/MRP/CT evidence of chronic pancreatitis
2. Abdominal pain
3. No regular analgesia
4. Preserved endocrine and exocrine function
5. No peripancreatic complications

Moderate: Five Essential Criteria

1. ERP/MRP/CT evidence of chronic pancreatitis
2. Abdominal pain
3. Regular (weekly) opiates
4. Evidence of impaired endocrine/exocrine function
5. No peripancreatic complications

End Stage

1. ERP/MRP/CT evidence of chronic pancreatitis
2. One or more of the following "extrapancreatic features"
   - i. Biliary stricture
   - ii. Segmental portal hypertension
   - iii. Duodenal stenosis
3. Plus one or more of the following
   - i. Diabetes
   - ii. Steatorrhea

Note that abdominal pain may or may not be present.
ERP, endoscopic retrograde pancreatography; MRP, magnetic resonance pancreatography; CT, computed tomography

Modified from Bagul A, Siriwardena AK, 2006: Evaluation of the Manchester Classification System for Chronic Pancreatitis. J Pancreas (Online) 7(4):390-396.

The most recent classification attempt is represented by the M-ANNHEIM multiple risk factor system (Table 52.12), aimed to provide a standardized method for the clinical diagnosis of chronic pancreatitis according to etiology, clinical stage, and severity of disease and to direct clinical practice (Schneider et al, 2007).

It is therefore evident how all these more recent advances in the "definition dilemma" abandoned the mere clinical purpose of a classification to better investigate different specific features of this complex disease. The classification systems will likely come full circle with the recognition of the deep but still controversial correlation between acute and chronic inflammation.

FUTURE PERSPECTIVES

The history of every patient must be carefully considered to identify risk factors that may include alcohol abuse, obstruction, genetics, and autoimmune disease. The clinical evidence of pancreas-related abdominal pain associated with alterations of serum amylase and lipase led to the term *pancreatitis*. The ongoing clinical observations obtained with imaging studies that include ultrasound, CT, and especially MRI of the bile ducts and duct of Wirsung should address the required treatment patient by patient. The early stage is the most difficult to diagnose, but it is also important to give the right medical or surgical option. Only the dynamic observation of patients with controlled follow-up enables us to classify pancreatitis and to define the disease better, assigning the definitive labels supported by the biochemical and radiologic sources well characterized by the different classification systems available. The clinician should recognize pancreatitis at an early stage but avoid assigning a definitive classification immediately, instead investigating all the factors available to determine whether a first acute attack could lead to chronic changes with fibrosis, permanent disruptions, and exocrine endocrine insufficiency.

References are available at expertconsult.com.

Table 52.12

The M-ANNHEIM Multiple Risk Factor Classification System

Multiple Risk Factor Classification	Clinical Staging of Chronic Pancreatitis
Alcohol consumption	*Asymptomatic chronic pancreatitis*
Nicotine consumption	0. Stage of subclinical chronic pancreatitis
Nutritional factors	*Symptomatic chronic pancreatitis*
Hereditary factors	I. Stage without pancreatic insufficiency
Efferent duct factors	II. Stage of partial pancreatic insufficiency
Immunologic factors	III. Stage of painful complete pancreatic insufficiency
Miscellaneous and rare metabolic factors	IV. Stage of secondary painless disease (burnout)

Diagnostic Criteria of Chronic Pancreatitis

The diagnosis requires a typical clinical history of chronic pancreatitis, such as recurrent pancreatitis or abdominal pain, except for primary painless pancreatitis. Based on these features, the three forms of chronic pancreatitis are 1) definite chronic pancreatitis, 2) probable chronic pancreatitis, and 3) borderline chronic pancreatitis.

Scoring System for the Grading of Clinical Features of Chronic Pancreatitis	Points
Patient report of pain	0-4
Pain control	0-2
Surgical intervention	0 or 4
Exocrine insufficiency	0-2
Endocrine insufficiency	0 or 4
Morphologic status on pancreatic imaging	0-4
Severe organ complications	0, 2, or 4

Severity Index of Chronic Pancreatitis

Severity Level	*Point Range*
M-Annheim A Minor	0-5 Points
M-Annheim B Increased	6-10 points
M-Annheim C Advanced	11-15 points
M-Annheim D Marked	16-20 points
M-Annheim E Exacerbated	>20 points

CHAPTER 53

Etiology, pathogenesis, and diagnostic assessment of acute pancreatitis

Julia V. Mayerle, Colin J. McKay, Clem W. Imrie, and Markus M. Lerch

OVERVIEW

The incidence of acute pancreatitis ranges from 10 to 46 cases a year per 100,000. For 2004, per 100,000 population, 94 cases of pancreatitis were listed as the hospital discharge diagnosis, suggesting an increasing incidence in the United States. Pancreatitis was the eleventh most common cause of death from digestive diseases and the fifth most common nonmalignant cause for mortality, just after peptic ulcer disease (Everhart & Ruhl, 2009). The mortality rate of acute edematous interstitial (mild) pancreatitis is less than 1%, whereas in patients with hemorrhagic necrotizing (severe) pancreatitis, it is reported to be between 10% and 24% (see Chapter 52). Clinically acute pancreatitis thus affects a heterogeneous group of patients in whom determining the etiology, severity assessment at admission, and triage to either symptomatic or intensive care treatment remains a significant challenge.

ETIOLOGY AND PATHOGENESIS OF ACUTE PANCREATITIS

Pancreatitis is an inflammatory disorder of the exocrine pancreas caused, in most cases, by immoderate alcohol consumption or the passage of gallstones (see Chapters 30 and 35). Recent studies involving animal and isolated cell models have elucidated many of the pathophysiologic, cellular, and molecular processes involved in the disease onset. More than 100 years ago, it was proposed that pancreatitis was essentially a disease in which the pancreas falls prey to its own, prematurely activated digestive enzymes regardless of the underlying etiology (Chiari, 1896).

Etiology and Pathogenesis of Acute Biliary Pancreatitis

In roughly 30% of acute pancreatitis cases, gallstone disease is the underlying cause. The prevalence of gallstones is 18.8% (Volzke et al, 2005), which puts nearly one fifth of the population at risk of developing an acute episode of biliary pancreatitis at some point in their lifetime. Although a male/female ratio of 1:3 exists for gallstone disease, acute biliary pancreatitis is observed with a ratio of 1:1.4 to 1:1.7, suggesting that men with gallstones are at a greater risk of developing biliary pancreatitis than women with gallstones. Further studies have shown that the gender ratio changes with age. Imrie and colleagues reported a male/female ratio of 1:2.7 in younger patients with gallstone pancreatitis, whereas the ratio changed to 1:1.1 in patients older than 50 years. In the group between 60 and 70 years of age, the gender predominance was reversed; more men than women had biliary pancreatitis (Imrie & Blumgart, 1975; Imrie & Whyte, 1975).

Lankisch studied the epidemiology of acute pancreatitis and reported a worldwide predominance of alcohol-induced pancreatitis (36%) over biliary pancreatitis (28.1%). In the United Kingdom, biliary pancreatitis is more common than alcoholic pancreatitis, whereas the United States reports a steady increase in alcoholic pancreatitis, and in Sweden a shift from biliary pancreatitis to alcoholic pancreatitis over the last 50 years has also been observed. The socioeconomic impact of gallstone disease remains one of the highest in gastroenterology, in spite of the fact that the risk of developing pancreatitis remains well below 1% for gallstone carriers.

Ever since 1856, when Claude Bernard reported that bile injection into the pancreatic duct of laboratory animals leads to acute pancreatitis, the pathophysiology of gallstone pancreatitis has been a matter of dispute (Bernard, 1856; Lerch & Aghdassi, 2009). The first investigator to systematically address the issue of biliary pancreatitis was Eugene Lindsay Opie, who in 1901 published two autopsy reports, from which he concluded that two mutually exclusive triggering mechanisms exist for gallstone-induced pancreatitis (Opie, 1901a, 1901b). He tried to support his hypotheses with a series of animal studies. The first autopsy report showed that an impacted gallstone had occluded the orifice of the pancreatic duct, and the patient had died from acute pancreatitis (Opie, 1901a). When Opie simulated this finding by pancreatic duct ligation in cats, he noted the development of pancreatic tissue and fat necrosis and proposed pancreatic outflow obstruction as the triggering event for acute pancreatitis. Unfortunately, his first "impaired outflow hypothesis" was rapidly forgotten after he published his second hypothesis.

In another patient who underwent a postmortem examination, Opie found a distinctly different anatomic situation, which he regarded to be of pathophysiologic relevance. The impacted stone at the papilla of Vater had created a communication between the common bile duct and the main pancreatic duct that would have permitted the patient's bile to enter the pancreatic duct. Opie proposed the presence of infected bile in the pancreatic duct as the triggering mechanism of pancreatitis, the so-called *common channel hypothesis*. We and others have tested Opie's common channel hypothesis in the past, using the opossum model of acute necrotizing pancreatitis. This model appears ideally suited to test whether bile reflux into the pancreatic duct or blockage of pancreatic secretion triggers pancreatitis because the opossum not only possesses a gallbladder, a common bile duct, and a single pancreatic duct but also has a

long communication between the two ductal systems. If this common channel is ligated at the papilla of Vater, it creates a communication between the pancreatic and bile ducts, through which bile could potentially flow (Lerch et al, 1992).

Our experiments consistently showed that neither a common channel nor reflux of bile into the pancreas is required for the onset of acute necrotizing pancreatitis (Lerch et al, 1993), but pancreatic duct ligation is sufficient for triggering the disease. For obvious reasons, no controlled experiments in humans that would replicate the opossum data are possible; however, support comes from case observations in which unique anatomic situations allow for pathophysiologic interpretations (Lerch et al, 1994a, 1994b; Pohle et al, 2003). One of these cases is that of a young woman in whom an impacted gallstone at the papilla had caused acute pancreatitis, and a surgically inserted common bile duct T-tube had prevented any potential bile reflux into the pancreas (Lerch et al, 1994a, 1994b; Pohle et al, 2003). This case demonstrates further that therapeutic measures aimed at preventing bile reflux through a common channel will not afford protection against pancreatitis, but those aimed at preventing pancreatic duct obstruction will (Lerch et al, 1994a).

Patients in whom congenital biliopancreatic fistulas have caused a life-long flow of bile through the pancreatic duct without ever causing pancreatitis provide more arguments against Opie's common channel theory (Lerch et al, 1994b; Pohle et al, 2003). Although these studies and observations firmly put the blame for gallstone pancreatitis on the mechanisms that involve impairment of pancreatic outflow, rather than bile reflux into the pancreatic duct, there may still be a role for cholestasis in regulating its severity. Senninger and colleagues (1996) found in the opossum model that bile duct obstruction in addition to pancreatic duct ligation can aggravate pancreatitis, and two groups found independently that increased bile acid concentrations, such as those in cholestasis, can increase the susceptibility of pancreatic cells to injury (Kim et al, 2002; Perides et al, 2009; Voronina et al, 2002, 2004, 2005).

Experimental studies and reports from human case series have tried to elucidate the mechanisms through which migrating gallstones cause pancreatitis. In spite of its former popularity, Opie's common channel hypothesis of bile reflux into the pancreatic duct appears no longer valid; the *duodenal content reflux hypothesis* has also been firmly refuted in human studies (Hernandez & Lerch, 1993). The most accurate description of the pathophysiology of gallstone pancreatitis is based in Opie's original report, in which he proposes pancreatic outflow obstruction as the most critical event for the disease onset. To what extent cholestasis and circulating bile acids contribute to acinar cell injury in humans and what factors determine the ultimate disease severity must be elucidated by future investigations.

Etiology and Pathogenesis of Acute Alcoholic Pancreatitis

Alcohol abuse is a major cause of acute pancreatitis and the leading cause of chronic pancreatitis. Although the incidence of pancreatic disease increases as a function of the extent of alcohol abuse in a population, only a minority of subjects who greatly abuse alcohol develop pancreatitis. According to studies from Marseille (Levy et al, 1995), the logarithm of the relative risk of pancreatitis increases linearly as a function of the quantity of alcohol and protein consumed. Unlike the liver, no alcohol toxicity threshold has been established beyond which the pancreas is damaged. Furthermore, the type of alcoholic beverages consumed appears to be less relevant. Patients with pancreatitis and alcohol-induced liver cirrhosis do not generally differ with regard to their daily intake of alcohol. However, the duration of alcohol consumption is shorter in pancreatitis. In most studies the time between the onset of alcohol abuse and first pancreatitis symptoms ranges from 7 to 29 years. The prevalence of pancreatitis clearly correlates with the alcohol consumption in a given population (Ammann & Muellhaupt, 1994).

The mechanisms involved in alcohol-induced pancreatitis have been extensively studied in ethanol-fed laboratory animals. Although a number of biologic cell changes have been reported from these studies, their relevance to the human disease is questionable, because neither rats nor mice develop pancreatitis when fed a high-alcohol diet over an extended time. Animal studies have led to the working hypothesis that alcohol abuse sensitizes individuals to pancreatitis but does not directly cause the disease. Experimentally, ethanol can mediate its damaging effect on pancreatic acinar cells through several mechanisms. First, ethanol affects the inflammatory signaling cascade in pancreatic acini, namely the NF-κB pathway (Tando et al, 1999). Furthermore, ethanol feeding results in a decrease of in the expression and/or activity of both "initiator" and "executioner" caspases, leading to cell death (Fortunato et al, 2006).

Recent studies observing the effect of ethanol on the intracellular activation of digestive protease zymogen were rather successful in elucidating potentially disease-relevant mechanisms. Ethanol feeding enhanced the expression and activity of cathepsin B, which catalyzes 80% of the intracellular trypsinogen activation and results in active trypsin and, ultimately, cell necrosis (Fortunato et al, 2006; Halangk et al, 2000).

A number of studies found that ethanol can sensitize acinar cells to cholecystokinin (CCK)-induced procarboxypeptidase A1 processing in vitro, and it can also sensitize the pancreas to various forms of pancreatitis in vivo (Katz et al, 1996; Pandol et al, 1999; Saluja et al, 1997). Thus ethanol is believed to enhance the pathophysiologic stimuli that induce pancreatitis, and this process may explain the effects of ethanol toxicity on the pancreas.

A recent study addressed several issues relevant to zymogen activation and the effects of ethanol in isolated pancreatic acini (Gorelick, 2003). Trypsinogen and chymotrypsinogen were observed to exhibit distinct patterns of activation in response to supraphysiologic concentrations of the CCK-analogue cerulein, supraphysiologic concentrations of which are known to cause calcium-dependent intracellular protease activation and cell death; this model is regarded as *in vitro pancreatitis.* Moreover, ethanol and other alcohols were shown to sensitize acinar cells to cerulein-induced trypsin and chymotrypsin activation, and other short-chain n-aliphatic alcohols—methanol, propanol, and butanol—enhanced the effects of cerulein on the acinar cell. Ethanol alone, on the other hand, was not found to induce pancreatitis or zymogen activation in experimental models of pancreatitis (Lu et al, 2002; Ramo, 1987).

The aforementioned descriptions of the effects of alcohol on the pancreas do not take into consideration the unique metabolism of ethanol in the pancreas. The pancreas differs from the liver in that it transiently converts ethanol to fatty acid ethyl esters (FAEEs) (Gukovskaya et al, 2002; Werner et al, 1997). Recent data suggest that FAEEs cause sustained increases in the cytosolic calcium concentrations, which are closely connected

to the premature activation of zymogens, as well as mitochondrial injury, subsequently leading to necrotic cell death (Ponnappa et al, 1997).

In summary, ethanol and its metabolites have multiple effects on the pancreas that are involved in sensitizing the pancreas to pathologic stimuli. These include effects on inflammatory and cell death signaling pathway that can promote inflammation and necrosis. Mainly identified in animal models, the findings are consistent with a recent report that indicates alcohol abuse in humans is a risk factor for pancreatic necrosis during pancreatitis (Papachristou et al, 2006).

Etiology and Pathogenesis of Nonalcoholic and Nonbiliary Pancreatitis

Several other disease-causing factors have previously been elucidated. The following paragraph briefly outlines metabolic changes—such as hyperlipidemia or hypercalcemia—infectious agents, and drugs involved in the onset of acute pancreatitis. Furthermore, genetic alterations that are either closely linked or associated with an increased susceptibility to pancreatitis are discussed.

Hyperlipidemia

As with other forms of acute pancreatitis, acute hyperlipidemic pancreatitis presents clinically with varying degrees of severity. Complications typical of acute pancreatitis, such as infected necrosis and pseudocyst formation, also occur in pancreatitis triggered by hypertriglyceridemia (Toskes, 1990). According to Fortson and colleagues (1995), patients coming to medical attention with hyperlipidemic pancreatitis fit one of the following clinical scenarios: they are either patients whose diabetes mellitus is out of control; alcoholics with a lactescent serum; nondiabetic, nonalcoholic, nonobese patients with hypertriglyceridemia caused by nutrition or medication; or patients with familial hypertriglyceridemia.

The diagnosis of acute hyperlipidemic pancreatitis is made as for other etiologies of this disease. However, a few important peculiarities must be considered, such as a lipemic serum that signals hyperlipemic pancreatitis. It is also striking that in more than 50% of patients, serum and urinary amylase levels remain within the normal range (Lesser & Warshaw, 1975). The reason for this phenomenon has long been suspected to be an interference of the test assay with the plasma lipids or an unknown amylase inhibitor in plasma and urine that impairs the assay. This inhibitor has not been identified so far (Fallat et al, 1973; Warshaw et al, 1975). Although during the course of hyperlipemic pancreatitis, serum amylase levels may remain normal, renal amylase clearance increases. In the past, a higher ratio in amylase/creatinine clearance in the urine has been shown to be a diagnostic parameter of hyperlipemic pancreatitis (Fallat et al, 1973; Warshaw et al, 1975); however, this method has not entered clinical routine. Triglycerides are usually above 1000 mg/dL, and when enteral nutrition regimens cannot lower triglyceride levels below that level within 2 days, sometimes even extracorporeal lipid-lowering therapies should be considered (Iskandar & Olive, 2004).

Drug-Induced Pancreatitis

A database of the World Health Organization (WHO) lists 525 drugs that can, as an adverse reaction, induce acute pancreatitis (Table 53.1). Compared with other causes, drugs represent a relatively rare cause of pancreatitis. They should be regarded as a triggering event in patients with no other identifiable cause of the disease who take medications that have been shown to induce pancreatitis. The prevalence of drug-induced pancreatitis is still unclear because most incidences have been documented only as isolated case reports. The overall incidence probably ranges somewhere between 0.1% and 2% of pancreatitis cases.

For only very few substances, evidence from controlled trials has been obtained. Epidemiologic data suggest that the risk of pancreatitis is highest for mesalazine (hazard ratio [HR], 3.5), azathioprine (HR, 2.5), and simvastatine (HR, 1.8). Even when a definite association has been demonstrated, it is often impossible to determine whether the drug or the underlying condition for which the drug was taken has conferred the risk of pancreatitis (e.g., azathioprine and Crohn disease or pentamidine and HIV). Knowledge about the underlying pathophysiologic mechanisms and evidence for a direct causality often remains sparse. A definite causality has been established for only 31 drugs, although a cause-effect relationship is generally accepted when symptoms recur upon rechallenge. Available data from case control studies suggest that even drugs with solid evidence for an association with pancreatitis only rarely cause the disease. Even when pancreatitis is induced as an adverse drug event, the disease course is usually mild or even subclinical (Nitsche et al, 2010).

Infectious Causes

A number of viral, bacterial, parasitic, and fungal infections have been linked to acute pancreatitis (Parenti et al, 1996). As early as 1817, infection with mumps has been suspected as a cause of pancreatitis; in 1905, Lemoine described a patient whose symptoms were those typical of mumps who also had acute pancreatitis. Today, acute pancreatitis as part of an infectious disease has to be distinguished from an infectious complication of acute pancreatitis that occurs regardless of the underlying etiology. The incidence of acute pancreatitis in connection with infectious diseases is difficult to determine, as there are hardly any prospective studies, but an incidence of less than 2% is generally assumed. In many cases, somewhat increased amylase and lipase levels are described in the course of an infectious disease, and the patient is often prematurely diagnosed with pancreatitis; however, often no other evidence for pancreatitis is present, either clinically or on imaging studies (Parenti et al, 1996).

The most frequent association of a viral infection with acute pancreatitis is mumps. The incidence of pancreatitis associated with mumps (parvovirus B19) is 0.3% to 14% according to the relevant literature (Kaplan et al, 1988; Witte & Schanzer, 1968). Acute pancreatitis mainly occurs after the swelling of the parotid gland has subsided, usually 8 to 14 days after the initial onset of the disease. Every now and then, acute pancreatitis occurs up to 1 week prior to parotitis. In rare individual cases, acute pancreatitis has been reported as the only manifestation of a mumps infection (Kaplan et al, 1988; Witte & Schanzer, 1968). Acute pancreatitis associated with mumps is usually mild, with symptoms that normally persist only 3 to 7 days. For a laboratory-based diagnosis of acute pancreatitis, lipase activity should be measured. Amylase measurements may result in an incorrect diagnosis because increased activity may be due to amylase from affected salivary glands and may not necessarily reflect acute pancreatitis. There is no specific therapy for either mumps infection or for acute pancreatitis associated with mumps (Kaplan et al, 1988; Witte & Schanzer, 1968).

	Mesalazine			3	0				
	Rifampin	25	0					1	0
	Sulindac			1	0				

The second most common viral infection associated with pancreatitis is coxsackievirus B. During a coxsackievirus type B5 aseptic meningitis epidemic in Japan, 31% of patients showed an increase in amylase activity in serum or urine (Nakao et al, 1964). During an epidemic of coxsackievirus type B4 infection in Australia, acute pancreatitis could be confirmed in 3% of the patients (Murphy & Simmul, 1964). In prospective and retrospective serologic studies, coxsackie virus infections were found in 0% to 11% of patients with positive titers for acute pancreatitis (Parenti et al, 1996). In mouse experiments, acute pancreatitis has successfully been induced with coxsackie viruses; a direct infection of acinar and islet cells with the virus led to an inflammatory reaction and necrosis.

An acute infection with hepatitis virus A, B, or C may result in a secondary infection of the pancreas (Achord, 1968). When a mild form of acute hepatitis occurs, an increase in amylase activity can be detected in up to 30% of patients. When the course of acute hepatitis was severe and ultimately lethal, acute pancreatitis was confirmed on autopsy in up to 44% of patients.

Autopsy studies have detected pathologic changes of the pancreas in up to 50% of patients who died from AIDS. Similarly, 50% of HIV patients showed elevated amylase levels and clinical signs of acute pancreatitis (Cappell & Hassan, 1993; Pezzilli et al, 1992). However, a number of factors could have caused hyperamylasemia and acute pancreatitis in patients with HIV. Apart from damage caused by the virus itself, a nonspecific amylase elevation as a result of renal insufficiency or amylase elevations may be caused by extrapancreatic factors, such as damage to the salivary glands; an infection of the pancreas through opportunistic infections; a medication-induced etiology, especially didanosine (ddI); or a pancreatic neoplasm (Cappell & Hassan, 1993).

Individual case reports have been published on acute pancreatitis in association with infections with Epstein-Barr virus, rubella, adenovirus, rubeola, herpes simplex virus, rotavirus, and after mumps vaccinations (Parenti et al, 1996).

Several bacterial infections have been found in association with acute pancreatitis, such as *Yersinia enterocolitica* and *Y. pseudotuberculosis, Salmonella enteritis* and *S. typhimurium, Campylobacter jejuni,* and *Mycoplasma pneumoniae*. Of those with yersiniosis, 2% to 14% were diagnosed with secondary acute pancreatitis. In these patients, serotypes 3 and 9 (*Y. enterocolitica*) and IA (*Y. pseudotuberculosis*) were isolated. The majority of these patients also had gastroenteritis, and the course of pancreatitis was mild in all cases (Leino et al, 1987; Saebo & Lassen, 1991). Elevated serum amylase and lipase levels in serum were diagnosed in 43% of the patients with confirmed *S. typhimurium* and in 71% of the patients with *S. enteritidis* infection. In approximately half of these patients, signs of acute pancreatitis were detected by ultrasound examination (Hermans et al, 1991). Acute pancreatitis induced by a *Campylobacter* infection is a rare event, with reports on approximately 20 cases in the literature. Amylase and lipase levels elevated three to six times above normal were reported, but the course of the acute pancreatitis was again mild in all cases (Hermans et al, 1991).

Parasites are known to be a relevant cause of acute pancreatitis, mainly on the Indian, African, and Asian continents (see Chapter 45). The incidence of ascariasis differs from region to region worldwide but is the most common type of helminthic infection in humans. An endemic manifestation is found mainly in tropical and subtropical countries. In India, for example, ascariasis is the second most common cause of acute pancreatitis, next to gallstone pathogenesis (Parenti et al, 1996). The worms can travel from the intestines to either the biliary or pancreatic ducts, where they lead to obstruction. The obstruction of the flow from the pancreatic duct then triggers pancreatitis as proposed by Opie's first hypothesis. In addition to examining the stool for worm eggs, the disease can be diagnosed by sonography or endoscopic retrograde cholangiopancreatography (ERCP). The appropriate treatment is a combination of standard therapy for acute pancreatitis and antihelminthic therapy (Lim & Ko, 1990).

The Chinese liver fluke *Clonorchis sinensis* can lodge in the biliary tract and often does not cause symptoms for years (see Chapter 45). The endemic form of the disease is found mainly in Asia (Lim & Ko, 1990; Parenti et al, 1996). An obstruction of the biliary or pancreatic ducts is rarely caused by the presence of the worm alone. Via adenomatous proliferation and squamous metaplasia, infection by *C. sinensis* causes periductal fibrosis, which then leads to further obstruction that can result in acute pancreatitis.

Post-ERCP Pancreatitis

ERCP is an important technique in gastroenterology, used for the diagnosis and treatment of pathologic conditions in the biliary tract and the pancreatic ducts (see Chapters 27 and 28). The most common complication of this intervention is procedure-related acute pancreatitis, which occurs in 2% to 9% of ERCPs in unselected prospective studies (Freeman, 2004). The severity of post-ERCP pancreatitis can range from mild disease with full recovery to critical illness with pancreatic necrosis, multiorgan failure, prolonged hospitalization, and even death (see Chapter 52). Of all cases of post-ERCP pancreatitis, approximately 10% are severe, and up to 1% take a fatal course (Freeman, 2001). Increasing pressure in the pancreatic duct, as well as chemical injury from the injection of contrast media, may play a role in the initiation of the protease activation cascade and inflammatory response that ultimately results in procedure-related pancreatitis. Very recently a low pH of 6.9 in contrast media used for ERCP was identified as contributing to the development of post-ERCP pancreatitis via activation of the α-cation channel expressed on C and Aδ fibers of primary sensory neurons called *transient receptor potential vanilloid 1* (TRPV1) neurons (Noble et al, 2008).

GENETIC CHANGES ASSOCIATED WITH RECURRENT ATTACKS OF ACUTE PANCREATITIS

Patients without identifiable risk factors for pancreatitis are classified as having idiopathic pancreatitis. This group has been diminishing since Comfort and Steinberg reported in 1946 on an inherited form of chronic pancreatitis that follows an autosomal dominant inheritance pattern (Comfort et al, 1946). Hereditary pancreatitis represents a genetic disorder closely associated with mutations in the cationic trypsinogen gene and presents with a disease penetrance of approximately 80% (Whitcomb et al, 1996). Patients with hereditary pancreatitis develop recurrent bouts of acute pancreatitis that usually begin in early childhood and progress to chronic pancreatitis (see Chapter 55). In rare cases the disease onset can be as late as the

sixth decade of life. The severity of the acute attacks in hereditary pancreatitis ranges from mild abdominal discomfort to severe disease complicated by pancreatic necrosis, organ failure, and eventually death, although the latter course is exceedingly rare. Compared with the general population, the risk of developing pancreatic carcinoma is 50 to 60 times greater in patients with hereditary pancreatitis (Schneider et al, 2003; see Chapter 55).

Because hereditary pancreatitis represents an autosomal dominant disorder, it was suspected that the disease results from a single genetic defect that disrupts a critical component that protects pancreatic function in unaffected individuals. In 1996, Whitcomb and colleagues identified a single point mutation in the third exon of the cationic trypsinogen gene on chromosome 7 (7q35) that associates with the phenotype of hereditary pancreatitis. This guanine (G) to arginine (A) transition results in an A-R-CGC to histidine (H)-CAC substitution, referred to as *R122H*. It was predicted to eliminate a failsafe trypsin hydrolysis site that is necessary to initiate the self-destruction of activated trypsin. Since 1996, more than 20 mutations in the trypsinogen gene have been reported, but the *R122H* mutation is still the most common (Whitcomb et al, 1996).

As far as the role of premature zymogen activation is concerned, the available data from hereditary pancreatitis are inconclusive. Because trypsin activation is an event known to occur in pancreatitis, and because trypsin can activate many other digestive proteases of the pancreas in vitro, previous attempts to interpret the functional consequences of trypsinogen mutations have focused on features that would either allow for premature intracellular activation of trypsinogen or permit an extended intracellular activity of trypsin. Other studies have suggested that trypsin activity may be a critical factor for the degradation of other, much more destructive digestive proteases.

The idea of digestive protease activation dates back a century, when the pathologist Hans Chiari suggested that the pancreas of a patient who had died during an episode of acute necrotizing pancreatitis "had succumbed to its own digestive properties," and he postulated pancreatic "autodigestion" as the underlying pathophysiologic mechanism of the disease (Chiari, 1896). Although the importance of digestive proteases in the onset of pancreatitis is now undisputed, the roles of individual serine proteases in that cascade-like event, and those of the different isoforms of trypsin in particular, are still a matter of intense research and debate. Other serine proteases, such as chymotrypsin C, have been found to be associated with chronic pancreatitis but do not follow an autosomal dominant inheritance pattern (Rosendahl et al, 2008).

Shortly after the identification of mutations in the trypsinogen gene associated with chronic pancreatitis, another important observation was made by Witt and colleagues (2000), who described mutations in the *SPINK1* gene, encoding the pancreatic secretory trypsin inhibitor (PSTI) associated with idiopathic chronic pancreatitis in children. *SPINK1* mutations can often be detected in patients who do not present with a family history of pancreatitis and are devoid of any classic risk factors for chronic pancreatitis (Weiss et al, 2003). *SPINK1* is believed to form a first line of defense in inhibiting trypsin in the pancreas. The discovery of *SPINK1* mutations therefore provides additional evidence for the role of protease activation in the development of pancreatitis (Bhatia et al, 2002).

ASSESSMENT OF ACUTE PANCREATITIS

Diagnostic Assessment of Acute Pancreatitis (See Chapters 52 and 54)

The diagnosis of acute pancreatitis can be made when a patient presents with threefold elevated serum levels of amylase or lipase, abdominal pain, and vomiting. If the patient presents within 24 hours after the onset of pain, the elevated serum pancreatic enzymes predict pancreatitis with a sensitivity of 98%. Sensitivity will then steadily decline over the next 5 to 7 days; serum levels will eventually be normal or below reference levels, even in the presence of acute necrotizing pancreatitis. The specificity of amylase and lipase measurements is in the range of 90%, but upper gastrointestinal perforation, mesenteric infarction, and retroperitoneal hemorrhage can present with similar clinical symptoms and elevated pancreatic serum enzymes (Farinon et al, 1987).

Clinical Assessment of Acute Pancreatitis

A prediction of the course and outcome of the disease is needed most when a patient comes in to the emergency room, but it is often rather difficult to make such a prediction. For example, although enzymatic activity of serum amylase and lipase are used to diagnose pancreatitis, they are not helpful in determining disease severity.

Although in 75% to 80% of cases, acute pancreatitis is a mild disease without associated mortality, it is important to identify the 20% to 25% of patients who are likely to develop severe disease associated with major complications and who would benefit from early intensive care monitoring and treatment. In addition to an initial clinical assessment by an experienced gastroenterologist or surgeon, several prognostic markers and scoring systems are available that help to distinguish severe from mild disease. Severity scoring systems have been used since the 1970s, the first being the widely used Ranson criteria, closely followed by the Imrie or Glasgow severity scoring system (Imrie, 2003; Imrie & Blumgart, 1975; Ranson et al, 1974).

Mortality from acute pancreatitis has a biphasic distribution. Early death is related to the development of severe and irreversible multiorgan dysfunction, whereas late death occurs in the second phase of illness, where organ failure is associated with peripancreatic sepsis and its sequelae. Several organ dysfunction scores have been developed for use in critically ill patients. Those most commonly used in the setting of acute pancreatitis are the Multiple Organ Dysfunction Score (MODS) and the Sequential Organ Failure Assessment (SOFA; Marshall et al, 1995; Vincent et al, 1996, 2000). The main difference between MODS and SOFA lies in the evaluation of cardiovascular function. In addition to the severity of organ dysfunction and the number of organ systems involved, the dynamic nature of organ impairment has been increasingly recognized as an important variable in predicting and determining mortality from acute pancreatitis. Several authors have described the prognostic significance of distinguishing transient and persistent organ failure for predicting mortality from severe acute pancreatitis. Persistent or deteriorating multiorgan dysfunction in the first 7 days after admission is the most significant predictor of death (Buter et al, 2002; Johnson & Abu-Hilal, 2004; Mayer et al, 2000; Mofidi et al, 2006, 2009a). In addition, multiorgan dysfunction during the first week of admission is closely related to the

development of local complications of severe acute pancreatitis, such as infected necrosis, which also contributes to the biphasic distribution in mortality.

From a practical point of view, if a patient has three or more laboratory signs of organ failure, such as a fall in Po_2 or a rise in creatinine levels; if an overt extrapancreatic complication develops, such as respiratory or renal insufficiency; or if pancreatic necrosis is diagnosed by contrast-enhanced CT, the course of the disease is more likely to be severe (Balthazar et al, 1994; Mofidi et al, 2009b; Mortele et al, 2004).

Laboratory Assessment of Acute Pancreatitis

C-Reactive Protein

As a stand-alone prognostic marker, an elevated C-reactive protein (CRP) concentration of greater than 130 mg/L predicts a complicated course with a sensitivity of 85% in the first 72 hours after the onset of symptoms. Although detection of elevated CRP levels is sensitive for the severity of acute pancreatitis, it is not specific for the disease; other causes of inflammation, such as cholangitis and pneumonia, need to be ruled out before severity assessment by measurement of CRP is undertaken (Buchler et al, 1986).

Trypsinogen and Trypsinogen Activation Peptide

In an attempt to use the extent of pancreatic zymogen activation to determine the severity of disease, trypsinogen activation peptide (TAP) levels have been evaluated (Neoptolemos et al, 2000). Urinary TAP concentrations have been shown to correlate well with the severity of acute pancreatitis at admission, but its measurement by a manual enzyme immunoassay combined with the limited stability of the TAP assay restricts its use as an emergency room test. By using a similar principle, a Finnish group developed a dipstick test for urinary trypsinogen-2 (Lempinen et al, 2001). They were able to show a higher positive likelihood ratio for the urinary trypsinogen-2 test strip than for CRP at 24 hours after admission, which was confirmed in a multicenter trial led by Glasgow (Johnson et al, 2004). Unfortunately, the TAP test kit is not commercially available, and therefore the TAP measurement is not a routine clinical measurement.

Hematocrit

The use of hematocrit as a prognostic marker for the severity of acute pancreatitis is an exciting development that emphasizes the pathophysiologic role of fluid loss on the severity of pancreatitis and the role of vigorous fluid replacement on the course of the disease. A hematocrit of more than 44% on admission or the absence of a fall in hematocrit during the first 24 hours after admission indicate pancreatic necrosis with a positive predictive value (PPV) of 96% and multiorgan failure with a PPV of 97% (Brown et al, 2000). A retrospective data analysis from Germany could not entirely reproduce these data, but it confirmed that a normal hematocrit predicted the absence of pancreatic necrosis with a high negative predictive value (Lankisch et al, 2001). Interestingly, Banks and colleagues provided evidence that the early hemoconcentration was associated with increased mortality only in a group of transferred cases (odds ratio [OR], 7.4; 95% confidence interval [CI], 1.6 to 35.4), pointing to the fact that hemoconcentration and its adverse effects are reversible if adequately treated on initial admission (Wu et al, 2009).

Procalcitonin

Another marker that has been evaluated as a prognostic indicator for pancreatitis is procalcitonin (PCT), which is encoded by the *CALCA* gene. Proinflammatory cytokines and bacterial lipopolysaccharides strongly induce the synthesis and release of PCT in inflammation. Although numerous attempts have been made to unravel the biologic function of PCT, its physiologic role in inflammation and sepsis is far from being understood. Nevertheless, a remarkable number of clinical studies have demonstrated the pivotal role of this parameter in the host response to microbial and fungal infections, and these have shown a strong correlation to disease severity. In addition, high serum levels of PCT implicate the synthesis of the calcitonin gene–related peptide by alternative splicing of the CALCA RNA, which directly induces peripheral vasodilation and extravasation of fluid. As a consequence, hypovolemia can occur, and this is causally related to multiorgan failure.

For the diagnosis of acute pancreatitis, it remains controversial whether high PCT levels should be regarded as a valuable marker for the prediction of either infected necrosis in pancreatitis or a severe disease course. A meta-analysis that included 24 of 59 available studies published last year reports a sensitivity and specificity of PCT for development of severe acute pancreatitis of 72% and 86%, respectively (area under the curve [AUC], 0.87; 95% CI, 5.6 to 39.8), albeit with a significant degree of heterogeneity ($Q = 28.56$; $P < .01$). The sensitivity and specificity of PCT for prediction of infected pancreatic necrosis were 80% and 91%, respectively (AUC, 0.91; OR, 28.3; 95% CI, 13.8 to 58.3) with no significant heterogeneity ($Q = 7.83$; $P = .18$). Serum measurements of PCT may therefore be valuable in predicting the severity of acute pancreatitis and the risk of developing infected pancreatic necrosis (Mofidi et al, 2009b; Rau et al, 2007).

Imaging Assessment of Acute Pancreatitis

CT and MRI (See Chapters 16 and 17)

Dynamic contrast-enhanced CT scan (DCT) is the imaging modality of choice for staging acute pancreatitis and for detecting complications. Most importantly, DCT has been shown to detect pancreatic parenchymal necrosis with a diagnostic sensitivity of 87% and an overall detection rate of 90% (Arvanitakis et al, 2004; Balthazar, 2002; Balthazar et al, 1990, 1994; Mortele et al, 2004). DCT therefore has two major roles in the evaluation of patients with known or suspected acute pancreatitis. First, DCT is used for the initial staging of the severity of the inflammatory process. Second, DCT is used for the early detection of intrapancreatic and extrapancreatic complications. Although the application of contrast media has been found to aggravate acute pancreatitis in certain animal models, an extensive analysis by Uhl and colleagues (2002) showed that no negative effect of contrast-enhanced CT is to be expected in humans, and the benefits of a CT diagnosis far outweighs the risks in pancreatitis patients. On the other hand, a CT scan of the pancreas without intravenous contrast enhancement is of little use in the context of pancreatitis.

The morphologic severity of acute pancreatitis can be determined using a CT severity index (CTSI) that was developed by Balthazar and colleagues and then simplified and extended to monitor organ failure by Silverman and colleagues in 2004 (Balthazar, 2002; Balthazar et al, 1994, 1990; Mortele et al, 2004). Comparison of the original CTSI with mortality showed

Table 53.2

Modified CT Grading System of Silverman and Colleagues

Evaluation of Pancreatic Morphology Without Considering the Extent of Pancreatic Necrosis	
0 Points, grade A	Normal pancreas consistent with mild pancreatitis
2 Points, grade B/C	Focal or diffuse enlargement of the gland, including contour irregularities and inhomogeneous attenuation with or without peripancreatic inflammation
4 Points, grade D/E	Pancreatic or peripancreatic fluid collection or peripancreatic fat necrosis
Additional 2 points	Extrapancreatic complications (one or more of the following: pleural effusion, ascites, vascular complications, parenchymal complications, or gastrointestinal tract involvement)
Scoring Pancreatic Necrosis	
0 Points	No pancreatic necrosis
2 Points	≤30% pancreatic necrosis
4 Points	>30% pancreatic necrosis

CT, computed tomography

From Balthazar EJ, Freeny PC, vanSonnenberg E, 1994: Imaging and intervention in acute pancreatitis. Radiology 193:297-306; Balthazar EJ, et al, 1990: Acute pancreatitis: value of CT in establishing prognosis. Radiology 174:331-336; and Mortele KJ, et al, 2004: A modified CT severity index for evaluating acute pancreatitis: improved correlation with patient outcome. Am J Roentgenol 183:1261-1265.

a good correlation between higher CTSI values and mortality and morbidity rates (Table 53.2), which holds true for the modified CTSI. Furthermore, the modified CTSI correlates well with the length of hospital stay and the development of organ failure (Balthazar, 2002; Balthazar et al, 1994, 1990; Mortele et al, 2004).

Although contrast-enhanced, multislice CT remains the gold standard in imaging acute pancreatitis, MRI has been investigated in several studies for utility in imaging acute pancreatitis. MRI not only avoids the administration of radiation and nephrotoxic contrast media, it is also highly suited to the detection of vascular complications, such as pseudoaneurysms and venous thromboses. A recent study reported that, compared with the Ranson score as a gold standard, MRI detected severe acute pancreatitis with 83% sensitivity (95% CI, 58% to 96%) and 91% specificity (95% CI, 68% to 98%), whereas the sensitivity for CT was 78% (95% CI, 52% to 93%), and its specificity was 86% (95% CI, 63% to 96%). Unfortunately, MRI is not universally available, it is unsuitable for patients with ferromagnetic implants, and it is rather expensive. For this reason, current guidelines recommend DCT as the imaging procedure of choice and regard it as mandatory for patients with persistent organ failure, for those who develop systemic inflammatory response syndrome or sepsis, for those who do not improve within 6 to 10 days into the disease course, and for those with probable infected pancreatic necrosis (evidence-based medicine recommendation grade B) (Working Party of the British Society of Gastroenterology et al, 2005).

Diagnostic Assessment of Biliary Pancreatitis (See Chapter 30)

An accurate diagnosis of the cause of pancreatitis modifies the therapeutic strategy: during the acute phase in a patient with prognostically severe pancreatitis, early endoscopic intervention might be beneficial (Neoptolemos et al, 1988); during the convalescence phase, cholecystectomy and/or endoscopic sphincterotomy (ES) are indicated (Sharma & Howden, 1999; Vazquez-Iglesias et al, 2004); and patients with microlithiasis or cholesterolosis might benefit from ES or cholecystectomy (Venneman et al, 2005b, 2005c). To conclude that gallstone pancreatitis is the cause of belt-like abdominal pain, vomiting, tachycardia, and mild pyrexia, a patient must meet two criteria in addition to the threefold elevated plasma pancreatic enzymes: 1) detection of gallbladder or bile duct stones and 2) exclusion of other etiologic factors such as alcohol abuse, hyperlipidemia, and hypercalcemia.

Overweight women are obviously more at risk of biliary, rather than alcohol-induced, pancreatitis. However, a previous history of biliary colic is rarely reported by patients suspected to have biliary pancreatitis. In addition to clinical risk factors, several combinations of laboratory markers have been prospectively evaluated regarding their accuracy in predicting a biliary cause of pancreatitis (Tables 53.3 and 53.4). The latest study reported an accuracy of 85% if the patient was female, older

Table 53.3

Predicting Morbidity and Mortality with the CT Severity Index Combining Scores for Pancreatic Morphology and Extent of Pancreatic Necrosis

Index	Morbidity	Mortality
0-3	8%	3%

Comparison of Transcutaneous US, ERCP, and EUS in the Detection of Choledocholithiasis in Patients with Acute Pancreatitis

			SENSITIVITY (%)			SPECIFITY (%)			OVERALL ACCURACY		
Study	N	Time of ERCP	US	ERCP	EUS	US	ERCP	EUS	US	ERCP	EUS
Chak et al, 1999	36	Within 72 h of admission	50	92	91	100	97	100	83	89	97
Liu et al, 2005b	100	Within 24 h of admission	26	97	97	100	95	98	75	96	98

According to two recently published studies by Chak et al (1999) and Liu et al (2005b); the presence of gallbladder stones was confirmed by direct inspection of the gallbladder contents whenever cholecystectomy was performed, and the presence of choledocholithiasis was assessed by comparing ERC and EUS.
US, ultrasound; ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound

than 58 years, and had serum alanine aminotransferase (ALT) levels above 150 IU/L. In this study the authors used endoscopic ultrasound (EUS) as the gold standard (Liu et al, 2005a).

Previous studies suggested a correct prediction of 74% for ALT/AST (aspartate aminotransferase) greater than 60 IU/L (Mayer & McMahon, 1985) and 76% for alkaline phosphatase (AP) greater than 225 IU/L combined with ALT/AST greater than 60 IU/L plus bilirubin above 49 µmol/L (Goodman, 1985; Goodman et al, 1985). The accuracy was 71% for three or more of the following parameters: female, amylase greater than 4000 IU/L, ALT/AST greater than 100 IU/L, and AP greater than 300 IU/L (Blamey et al, 1983). No single serum marker can diagnose biliary pancreatitis with certainty, but a serum bilirubin twice above the normal range and an elevated ALT within the first 24 hours after onset of pain show a sensitivity of 73%, a specificity of 86%, and a PPV of 92% and are therefore somewhat predictive of a biliary cause (Grau et al, 1999).

In addition to laboratory markers of cholestasis, abdominal ultrasound (US) is used to confirm the diagnosis of biliary pancreatitis. Although transabdominal US has an accuracy greater than 95% for detecting gallbladder stones, this number is reduced to 70% to 80% in patients with acute pancreatitis (Ammori et al, 2003; Neoptolemos et al, 1984a; Wang et al, 1988). This is partly due to meteorism in acute pancreatitis, which prevents visualization of the gallbladder in 20% of patients; it is also partly due to the association of pancreatitis with smaller gallstones (Neoptolemos et al, 1984b; Sugiyama & Atomi, 2004) that escape US detection. The use of CT scans alone to detect gallbladder stones is obsolete (sensitivity 30% to 53%) (Wang et al, 1988; London et al, 1989). In patients with gallbladder stones, pancreatitis is most likely of biliary origin, and a risk assessment for biliary pancreatitis can be performed by US during recovery from the acute episode. If the diameter of the smallest stones is 5 mm or less, if the cystic duct diameter is 5 mm or more, and 20 or more gallbladder stones are present, pancreatitis will most likely recur (Venneman et al, 2005a, 2005c; Sugiyama & Atomi, 2004).

If biliary pancreatitis is suspected, ERCP is indicated in some patients, often combined with endoscopic sphincterotomy; this will confirm the diagnosis of biliary pancreatitis with a sensitivity of 90%, provided the stones are larger than 4 mm in diameter (Ney et al, 2005; see Chapter 18). Stones smaller than 4 mm in diameter can be detected with a sensitivity of up to 97% by EUS. If bile duct stones or stones impacted at the papilla are suspected, EUS should be used before ERCP, because EUS has fewer complications and shows a higher sensitivity for the detection of small common bile duct stones than ERCP (EBM grade Ib, recommendation grade A) (Buscarini et al, 2003; Fusaroli & Caletti, 2005a, 2005b; Liu et al, 2005a; Prat et al, 2001; Sugiyama & Atomi, 1997a, 1997b; see Chapter 14).

As biliary microlithiasis is increasingly recognized as a major cause of recurrent idiopathic pancreatitis, EUS is gaining in importance as a diagnostic tool. In 52.4% of patients with repeatedly negative transabdominal US examinations, gallstones were ultimately diagnosed by EUS, and patients subsequently underwent endoscopic papillotomy or cholecystectomy (Saraswat et al, 2004;Thorboll et al, 2004). It is noteworthy that biliary microlithiasis is present in 75% of patients with recurrent idiopathic pancreatitis (Saraswat et al, 2004). The sensitivity of MRCP for common bile duct stones varies; it can be as high as 88.9%, but it decreases to 72.7% if the bile duct is dilated to a diameter greater than 10 mm (Moon et al, 2005). This only applies for an elective setting, clarifying the etiology of an episode of acute pancreatitis. Emergency ERCP for severe acute biliary pancreatitis follows a different algorithm and is still much debated (Table 53.5).

SUMMARY

The incidence of acute pancreatitis varies considerably among geographical regions and is estimated at 5 to 80 per 100,000 worldwide. The mortality rate of acute edematous interstitial pancreatitis is less than 1%, whereas 10% to 24% of patients with severe acute pancreatitis die of the disease. The etiology of 80% of acute pancreatitis episodes is either gallstone disease or excessive alcohol consumption. Early prognostic factors for evaluating the clinical course and severity of acute pancreatitis are three or more signs of organ failure, according to the Ranson or Imrie score, as well as nonpancreatic complications or the detection of pancreatic necrosis by imaging techniques. Elevated CRP levels above 130 mg/L can also predict a severe course of acute pancreatitis with high sensitivity. An accurate diagnosis of the cause of pancreatitis modifies the therapeutic strategy, and appropriate diagnostic measures to establish biliary pancreatitis need to be undertaken.

CHAPTER 54

Management of acute pancreatitis and complications

Maxim S. Petrov, Benjamin Loveday, and John A. Windsor

OVERVIEW

The severity of acute pancreatitis (AP) varies from mild uncomplicated disease to critical disease associated with both local and systemic complications (see Chapters 52 and 53). It is important to determine the severity of acute pancreatitis in the individual patient for triage, treatment, and prognosis. Since 1992, when the International Symposium on Acute Pancreatitis in Atlanta published its consensus, it has become customary to define the severity of acute pancreatitis as either mild or severe (Bradley, 1993). Acute pancreatitis is severe when it is associated with local or systemic complications. Although the Atlanta classification was a significant advance, it is now accepted that the dichotomous approach fails to capture clinically relevant categories of patients (Petrov & Windsor, 2010). For instance, it does not allow for discrimination among patients with transient and persistent organ failure, those with sterile and infectious local complications, and those with either local or systemic complications.

A large body of evidence now demonstrates that the two key determinants of severity in acute pancreatitis are *organ failure*—absent, transient, or persistent—and *pancreatic complications*—absent, noninfectious, or infectious. Determinants-based classification of the severity of acute pancreatitis composed of four categories (Table 54.1) appears to be more useful for the clinical assessment of severity in individual patients and for comparing groups of patients (Petrov & Windsor, 2010). The distinct advantages of this new classification is that it uses widely accepted and unambiguous terms, it can be applied in both early and late phases of acute pancreatitis, it can facilitate communication between treating physicians, and it promotes standardization for management of acute pancreatitis (Petrov et al, 2010).

Although many aspects of the management of acute pancreatitis remain controversial, significant overall progress has been made during the last few decades, evidenced by a reduction in morbidity and mortality rates (Lowenfels et al, 2009; Banks & Freeman, 2006). The improved outcomes have not been due to any treatments based on specific, critical pathophysiology. A wide range of drugs has been evaluated in randomized controlled trials (RCTs) and have proved ineffective in the treatment of acute pancreatitis. These include aprotinin, atropine, calcitonin, fresh frozen plasma, glucagon, gabexate, glucocorticoids, lexipafant, nonsteroidal antiinflammataory drugs (NSAIDs), and octreotide. The overall improvement in outcome for patients with acute pancreatitis has been due to a combination of factors that include improvements in intensive care medicine, imaging techniques, severity prediction, and selection of patients for endoscopic retrograde cholangiopancreatography (ERCP) and surgery.

This chapter describes the current management of acute pancreatitis, and considerable opportunities remain for improvement. The discussion of the evidence base for current practice will highlight these points.

GENERAL MANAGEMENT

Pain Management

Pain is the cardinal symptom of acute pancreatitis, and its relief is a clinical priority. The strategy in patients with acute pancreatitis, as for all acute pain, is the staged use of analgesics. Although some debate still surrounds step-up and step-down approaches, it is best practice to use NSAIDs for the management of mild pain (Pezzilli et al, 2007). The potential risk of bleeding as a result of the antiplatelet effect of NSAIDS has not been an issue in practice. For patients with moderate and severe pain, and for those for whom NSAIDs are inadequate, the second step is to use a weak opioid; the third step is to use a strong opioid.

Although experimental findings show that morphine can induce spasm of the sphincter of Oddi and exacerbate the severity of acute pancreatitis, it is worth noting that the avoidance of morphine as an analgesic has not been supported by clinical studies (Economou & Ward-McQuaid, 1971). A comprehensive review of the literature shows that all opiates increase the pressure in the sphincter of Oddi but that physiologic effect is of marginal clinical relevance (Thompson, 2001).

In practice, patients with severe acute pancreatitis require intravenous analgesia, and patient-controlled analgesia should be considered. Epidural analgesia can be considered for patients with severe and critical acute pancreatitis who require high doses of opioids for an extended period. Oral analgesics can be introduced but are less helpful in the acute setting because of the longer onset of action and concerns about variable absorption. Because the pain in acute pancreatitis is continuous, oral analgesics should be prescribed at regular intervals that are at least equal to the half-life of the drug. Although it has been reported that analgesics can also be given transdermally or rectally, no RCTs have compared the different routes of administration of the same analgesic in patients with acute pancreatitis.

Different analgesics have been compared in patients with acute pancreatitis, and the six published RCTs are summarized in Table 54.2 (Blamey et al, 1984; Ebbehoj et al, 1985; Jakobs et al, 2000; Kahl et al, 2004; Peiro et al, 2008; Stevens et al, 2002). These trials had a different study design, evaluated different analgesics, and had small sample sizes; only three of the trials were double-blinded. From these studies it can be said that no credible clinical evidence supports avoiding the use of

Table 54.1

Determinants-Based Classification of Acute Pancreatitis

Severity Category*	Local Determinant		Systemic Determinant
Mild	No local complications	*and*	No organ failure
Moderate	Sterile pancreatic and peripancreatic complications	*or*	Transient organ failure
Severe*	Infectious pancreatic and peripancreatic complications	*or*	Persistent organ failure
Critical	Infectious pancreatic and peripancreatic complications	*and*	Persistent organ failure

*Severity is graded on the basis of more severe local or systemic complication (e.g., sterile pancreatic necrosis without organ failure has to be graded as moderate; sterile pancreatic necrosis with persistent organ failure has to be graded as severe).

Petrov MS, Windsor JA, 2010: Classification of the severity of acute pancreatitis: how many categories make sense? Am J Gastroenterol 105(1):74-76.

morphine in treating the pain associated with acute pancreatitis; however, the NSAID of choice is metamizole (2 g/8 h IV), and the opioid of choice is buprenorphine (0.3 g/4 h IV). There is no evidence to support the use of parenterally administered local anesthetics such as procaine in the management of pain associated with acute pancreatitis. However, the lack of high-quality evidence means that the choice of analgesic and the strategy for administration remain uncertain. No recent guidelines relating to the management of acute pancreatitis provide a specific recommendation regarding pain management (Loveday et al, 2010).

Fluid Resuscitation

Acute pancreatitis can be associated with substantial third-space fluid losses, and the resultant hypovolemia that impairs the microcirculation of the pancreas is a major determinant of pancreatic necrosis. The reflex splanchnic vasoconstriction in response to hypovolemia may compound pancreatic hypoperfusion and further predispose to ischemia. Fluid resuscitation is one of the most important aspects of the early management of acute pancreatitis (Gardner et al, 2008; Talukdar & Vege, 2009) and is the intervention most likely to improve outcome. No high-level evidence describes the optimal resuscitation fluid, required fluid rate, or best marker to guide resuscitation and indicate its adequacy (Banks & Freeman, 2006; Pandol et al, 2007). It is not even known whether colloids or crystalloids are more effective in improving pancreatic microcirculation and outcome. The initial goal of fluid resuscitation is to restore circulating blood volume (euvolemia), with the aim of normalizing heart rate, blood pressure, central venous pressure, and urine output, even though these do not reflect the adequacy of pancreatic and splanchnic perfusion (Flint & Windsor, 2003). In

Table 54.2

Randomized Controlled Trials of Analgesics in Patients with Acute Pancreatitis

First Author	Year	Setting	Intervention Group	Control Group	NO. PATIENTS		Allocation Concealment	Reduction of Pain Score	Other Important Findings
					Intervention Group	Control Group			
Blamey	1984	U.K.	IM buprenorphine	IM pethidine	17	15	Single blind	No difference	No difference in terms of adverse effects
Ebbehoj	1985	Denmark	Indomethacin (rectal)	Placebo (rectal)	14	16	Double blind	Significantly greater in the intervention group over the first 168 h	The number of opiate injections was significantly less in the intervention group
Jakobs	2000	Germany	IV buprenorphine	IV procaine	20	20	Open label	Significantly greater in the intervention group over the first 48 h	The number of additional analgesics was significantly less in the intervention group
Stevens	2002	U.S.	Fentanyl (transdermal)	Placebo (transdermal)	16	16	Double blind	Significantly greater in the intervention group between 36 and 60 h	A significantly reduced LOS was reported in the intervention group
Kahl	2004	Germany	IV pentazocine	IV procaine	50	51	Open label	Significantly greater in the intervention group over the first 72 h	The number of additional analgesics was significantly less in the intervention group
Peiro	2008	Spain	IV metamizole	SC morphine	8	8	Open label	Insignificantly greater in the intervention group over the first 24 h	No difference reported in terms of adverse effects

Randomized Controlled Trials of Intravenous Antibiotic Prophylaxis vs. No Antibiotics in Patients with Acute Pancreatitis

First Author	Year	Setting	Intervention Group	Control Group	NO. PATIENTS		Allocation Concealment	Main Findings
					Intervention Group	Control Group		
Howes	1975	U.S.	Ampicillin	None	48	47	Open label	No significant difference in any outcome
Craig	1975	U.S.	Ampicillin	None	23	23	Open label	No significant difference in any outcome
Finch	1976	U.S.	Ampicillin	Placebo	31	27	Double blind	No significant difference in any outcome
Pederzoli	1993	Italy	Imipenem	None	41	33	Open label	Significantly lower rate of pancreatic infection in the intervention group
Sainio	1995	Finland	Cefuroxime	None	30	30	Open label	Significantly lower mortality rate, but not pancreatic infection, in the intervention group
Delcenserie	1996	France	Ceftazidime + amikacin + metronidazole	None	11	12	Open label	No significant difference in any outcome
Schwarz	1997	Germany	Ofloxacin + metronidazole	None	13	13	Open label	No significant difference in any outcome
Spicak	2003	Czech Republic	Meropenem	None	20	21	Open label	No significant difference in any outcome
Isenmann	2004	Germany	Ciprofloxacin + metronidazole	Placebo	58	56	Double blind	No significant difference in an outcome
Dellinger	2007	North America and Europe	Meropenem	Placebo	50	50	Double blind	No significant difference in any outcome
Rokke	2007	Norway	Imipenem	None	36	37	Open label	Significantly lower rate of pancreatic and extrapancreatic infection in the intervention group
Xue	2009	China	Imipenem	None	29	27	Open label	No significant difference in any outcome
Garcia-Barrasa	2009	Spain	Ciprofloxacin	Placebo	22	19	Double blind	No significant difference in any outcome

general, urine output should be restored at greater than 0.5 mL/h/kg body weight, and the central venous pressure should be restored to between 8 and 12 cm H_2O. Swan-Ganz monitoring can be helpful in hemodynamically unstable patients, and some evidence shows that as an independent risk factor of pancreatitis severity and a marker of hydrations status, hematocrit might be useful with fluid resuscitation (Pitchumoni et al, 2005; Wu et al, 2009). Adequate fluid resuscitation is likely when the hematocrit is restored to between 30% and 35%. A number of other approaches to guide resuscitation offer promise but have not become established in clinical practice. An example is the use of intramucosal pH (pHi) derived by nasogastric tonometry (Juvonen et al, 2000a; van Haren et al, 2007), which is predictive of severity and reflects the adequacy of perfusion in the splanchnic circulation.

Antibiotics

Although the use of broad-spectrum antibiotics to treat the established infection in acute pancreatitis is a well-established practice, the use of prophylactic antibiotics has been controversial for decades. Three RCTs in the 1970s failed to demonstrate a beneficial effect of antibiotic prophylaxis, probably because of a small sample size, inappropriate selection of antibiotics—such as ampicillin, which does not sufficiently penetrate the pancreas—and inclusion of patients with mild pancreatitis (Table 54.3; Craig et al, 1975; Finch et al, 1976; Howes et al, 1975). Between 1993 and 2009, several randomized, controlled, open-label trials were published evaluating the efficacy of prophylactic antibiotic treatment in patients with severe acute pancreatitis (Delcenserie et al, 1996; Pederzoli et al, 1993; Rokke et al, 2007; Sainio et al, 1995; Schwarz et al, 1997; Spicak et al, 2003; Xue et al, 2009). The results of these trials were conflicting. Although some RCTs demonstrated a significant reduction of infectious complications and mortality with the use of prophylactic antibiotics, others failed to do so (see Table 54.3). Only three double-blind, placebo-controlled RCTs were published between 2004 and 2009, and all of them were unable to show a beneficial effect of antibiotic prophylaxis regarding infectious pancreatic complications, the need for surgery, and mortality (Dellinger et al, 2007; Garcia-Barrasa et al, 2009; Isenmann et al, 2004). This is in line with the

findings of a meta-analysis that showed an inverse relationship between methodologic quality of the studies and impact of antibiotic prophylaxis on mortality (de Vries et al, 2007).

On the other hand, it is worth noting that the three double-blind RCTs mentioned were not without flaws. These include a large crossover to open-label antibiotics in the control group (i.e., a high percentage of patients in the placebo group were treated with intravenous antibiotics) and the inclusion of patients on the basis of predicted severity of acute pancreatitis rather than proven necrotizing pancreatitis. All the studies were underpowered because the power calculation was based on an infection rate of 40%, whereas the actual infection rates in the placebo groups of the trials were only 12% to 17%.

Several attempts have been made to statistically aggregate data on the use of prophylactic antibiotics in acute pancreatitis. Although only two new RCTs were published from 2006 through 2007, it is notable that seven of the 10 meta-analyses were published within this period (Petrov, 2008). Thirteen RCTs were included in these seven meta-analyses. Because of different inclusion criteria and various meta-analysis techniques used, concordance is lacking, and they provide contradictory recommendations regarding the role of prophylactic antibiotics in reducing the risk of pancreatic infectious complications. Overall, it appears that the most recent studies do not support the use of prophylactic antibiotics to reduce the frequency of pancreatic infectious complications, surgical intervention, and death in patients with acute pancreatitis. Therefore routine broad-spectrum prophylactic antibiotics in patients with severe acute pancreatitis cannot be recommended on the basis of current evidence.

Nutritional Management

Severe acute pancreatitis is associated with a cytokine-mediated systematic inflammatory response and a hypercatabolic state (Windsor & Hammodat, 2000; see Chapter 10). The adverse consequences of this include protein-calorie malnutrition, expansion of the extracellular fluid compartment, and immune suppression. A meta-analysis of RCTs showed that nutritional support, both enteral and parenteral, significantly reduced risk of mortality in patients with acute pancreatitis compared with no nutritional support (Petrov et al, 2008c). Nutritional support is thus an essential part of the management of patients with severe acute pancreatitis (Banks & Freeman, 2006; Pandol et al, 2007).

Type of Feeding

The feasibility of providing nutritional support in patients with acute pancreatitis has been known for more than 3 decades. Parenteral nutrition (PN), rather than enteral nutrition (EN), became the standard of care because of the concept of "resting" the pancreas. The rationale for this was to prevent stimulating increased secretion of pancreatic proteolytic enzymes and exacerbating pancreatitis severity. But the use of PN has decreased in the face of well-recognized problems, such as catheter-related sepsis, the high cost of treatment, electrolyte and metabolic disturbances, villous atrophy and gut barrier failure with promotion of bacterial translocation, systemic sepsis, and multiple organ failure.

A number of RCTs compared total PN and total EN in the management of predicted severe AP (Table 54.4; Casas et al, 2007; Doley et al, 2009; Eckerwall et al, 2006; Gupta et al, 2003; Kalfarentzos et al, 1997; Louie et al, 2005; Petrov et al, 2006; Wu et al, 2010). A meta-analysis of high-quality RCTs has shown a significant twofold reduction in the risk of total and pancreatic infectious complications and a 2.5-fold reduction in the risk of death in patients receiving total EN (Petrov et al, 2008f). The basis for the clinical benefits of EN over PN remain unclear, although EN may prevent or attenuate mucosal barrier failure and bacterial translocation (Windsor & Hammodat, 2000). Intestinal permeability studies are a surrogate marker for clinically relevant events and provide conflicting results. Three clinical studies showed increased intestinal permeability to both micromolecules and macromolecules in patients with severe acute pancreatitis when compared with mild acute pancreatitis

Table 54.4

Randomized Controlled Trials of Total Enteral vs. Total Parenteral Nutrition in Patients with Predicted Severe Acute Pancreatitis

			NO. OF PATIENTS		
First Author	Year	Setting*	Intervention Group†	Control Group	RI and Mortality Rate
Kalfarentzos	1997	Greece	18	20	Significantly lower RI in the intervention group
Gupta	2003	UK	8	9	Insignificantly lower RI in the intervention group
Louie	2005	Canada	10	18	Insignificantly lower RI in the intervention group
Eckerwall	2006	Sweden	23	25	No significant difference in outcomes
Petrov	2006	Russia	35	34	Significantly lower RI and mortality rate in the intervention group
Casas	2007	Spain	11	11	Insignificantly lower RI in the intervention group
Doley	2009	India	25	25	No significant difference in outcomes
Wu	2010	China	53	54	Significantly lower RI and mortality rate in the intervention group

*Allocation concealment was open-label in all studies.
†The intervention group received enteral nutrition, whereas the control group received parenteral nutrition.
RI, rate of pancreatic infection

and healthy volunteers (Ammori et al, 1999; Juvonen et al, 2000b; Nagpal et al, 2006). But an early RCT from the United Kingdom (Powell et al, 2000) in which patients with predicted severe AP were randomized to receive either EN or no artificial nutritional support showed significantly increased intestinal permeability by day 4 in patients allocated to the EN group. Similarly, a recent RCT from Sweden comparing nasogastric EN and PN in patients with predicted severe acute pancreatitis demonstrated impaired gut permeability on day 3 in the EN group (Eckerwall et al, 2006). This difference might be explained by the inclusion of a considerable number of patients with mild AP in whom intestinal permeability is unlikely to change (Petrov et al, 2008f).

Route of Enteral Feeding

Nasogastric (NG) tube insertion may be more practical than nasojejunal (NJ), as the latter often requires endoscopy or radiology expertise, the transfer of patients within the hospital, and a delay in starting feeding. However, NJ EN has been preferred to NG EN because of a fear about pancreatic stimulation. Pancreatic response to feeding was studied in human volunteers, and it was shown that all forms of EN, with the exception of NJ feeding, stimulate pancreatic secretion (O'Keefe et al, 2003). By contrast, a study in patients with acute pancreatitis showed a significantly lower rate of secretion of trypsin, amylase, and lipase in comparison with healthy subjects (O'Keefe et al, 2005). Moreover, it was shown that the greater the severity of acute pancreatitis, the greater the reduction in pancreatic enzyme secretion as a response to duodenal feeding, probably reflecting greater injury of acinar cell mass. The possible clinical implication of these findings is that NG EN may not aggravate the course of acute pancreatitis, as was previously suggested.

Two RCTs have compared NG EN with NJ EN in patients with severe acute pancreatitis (Eatock et al, 2005; Kumar et al, 2006). These studies demonstrated the feasibility, safety, and tolerance of NG EN, but a meta-analysis did not demonstrate a statistically significant reduction in risk of death (Petrov et al, 2008b). Before NG EN can be considered the standard of care in the nutritional support of patients with AP, a well-designed and adequately powered RCT comparing mortality and morbidity of NG EN and NJ EN is required. A practical compromise is to start EN through an NG tube after the patient has been resuscitated and for the tube to be advanced when endoscopic or radiologic assistance is available.

Type of Enteral Feeding

The concept of "pancreatic rest" has also influenced decisions about the type and content of enteral feeding. The preferred formulations, elemental and semi-elemental formulas (Roberts, 2001; Petrov, 2007), did not require pancreatic enzymes for digestion and absorption. However, the major disadvantage of elemental and semi-elemental formulas is the cost, which is reportedly threefold to sevenfold higher than that of polymeric formulas. A recent meta-analysis of RCTs compared these two formula types in terms of feeding intolerance, infectious complications, and mortality and found that the use of polymeric over elemental and semi-elemental feedings did not result in reduced tolerance in patients with acute pancreatitis and appeared to reduce the risk of infectious complications and death (Petrov et al, 2009a). Thus the use of elemental and semi-elemental formulas confers no apparent advantage over relatively inexpensive polymeric formulas.

Because the gastrointestinal tract is the largest immune organ, containing approximately 65% of the immune tissue in the body, it has been considered that the use of immune-enhanced enteral formulations might increase the beneficial effects of EN in acute pancreatitis (Bengmark, 1999; Schloerb, 2001). Several trials were performed in different clinical settings, which suggested that immunonutrition might have the potential to modify the inflammatory response. The results of RCTs that compared the use of immune-enhanced and standard enteral formulas were statistically aggregated in several meta-analyses (Beale et al, 1999; Heyland et al, 2001; Heys et al, 1999). The most recent and comprehensive systematic review of 2419 patients from 22 RCTs (Heyland et al, 2001) found that the effect of immune-enhancing EN may depend on the subset of the analyzed patients. In particular, no effect of immunonutrition on the risk of infectious complications or death was reported within the subgroup of critically ill patients. At the same time, administration of a formula high in arginine in a combined group of critically ill and elective surgery patients was associated with a statistically significant reduction in infectious complications and a trend toward lower mortality rates in comparison with other immune-enhancing diets. A recent meta-analysis of RCTs in patients with acute pancreatitis did not show any clinical beneficial effect of immunonutrition when compared with standard EN (Petrov et al, 2008a).

Tolerance of Enteral Feeding

Dieticians generally agree on the caloric target in patients with acute pancreatitis: 30 kcal/kg and 1.5 g/kg of protein daily based on ideal body weight (Andersson et al, 2009; Olah & Romics, 2008). To ensure tolerance of EN, it is usually commenced at a low rate of 25 to 30 mL/h and increased incrementally over a day or more, until the desired caloric intake is reached. Despite this approach, EN can be associated with feeding intolerance in some patients with acute pancreatitis. Most commonly, the intolerance manifests as abdominal distension, delayed gastric emptying, gastroesophageal reflux, and diarrhea, all of which may develop in the presence of sepsis or with a significant clinical deterioration. In general, tolerance is achieved when EN is provided without development of one of these complications (Bankhead et al, 2009; Mallampalli et al, 2000). Various strategies to improve tolerance to EN require clinical studies, which are also needed to investigate markers of gut motility, absorption, and blood flow that can be easily applied at the bedside.

Timing of Enteral Feeding

The best time to start EN in patients with acute pancreatitis has never been studied. The indirect evidence in regard to this is derived from trials of EN versus PN only. Some authors have demonstrated clinical benefits of early enteral nutrition, but others have demonstrated the favorable effects of delayed enteral feeding (Petrov et al, 2009b). Early EN should help maintain gut integrity (enterocyte population) and function (motility) and reduce bacterial translocation and ileus. It should also help to achieve caloric targets more quickly. But early nutrition is not without risk, particularly in hemodynamically unstable patients and in those requiring inotropic support. These patients appear to be at an increased risk of nonocclusive mesenteric ischemia, and it is best to commence EN after adequate resuscitation.

Therapeutic Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy (ES) has been promoted as a proven intervention in patients with acute biliary pancreatitis since the early 1990s (see Chapters 18 and 27). This was based on the findings of two RCTs, from the United Kingdom and Hong Kong, of early ERCP (within 24 to 48 hours of admission) with or without ES versus conservative treatment (Neoptolemos et al, 1988; Fan et al, 1993). Both trials demonstrated that early ERCP was associated with a reduction in complications, but not in mortality, and only in patients with predicted severe acute pancreatitis.

Some evidence suggests that the duration of biliary obstruction, rather than the predicted severity of acute pancreatitis, is the most important determinant of outcome (Acosta et al, 1997, 2006). This is probably due to concomitant cholangitis secondary to the obstruction and probably best explains the usefulness of ERCP in the context of acute biliary pancreatitis (Petrov, 2009). The first multicenter RCT to examine the role of ERCP in acute pancreatitis was designed to include only patients without evidence of biliary obstruction (Folsch & Neoptolemos, 2002). This German study did not find any benefit of early ERCP (within 72 h after onset of symptoms) over conservative treatment. The most recent RCT, from Argentina, found that early ERCP in patients with biliary obstruction, defined by laboratory and radiologic criteria, and without evidence of acute cholangitis conferred no benefit (Oria et al, 2007).

Two important meta-analyses were published in 2008. The first found that compared with conservative treatment, early ERCP in patients with both predicted mild and predicted severe acute pancreatitis did not decrease the incidence of local pancreatic complications or mortality rate (Petrov et al, 2008d). The second meta-analysis was designed to negate the confounding effect of acute cholangitis and demonstrated no benefit of early ERCP over conservative treatment in terms of complications and mortality in patients with predicted mild and predicted severe acute pancreatitis (Petrov et al, 2008e). The conclusion to be drawn from these studies is that early ERCP is indicated in patients with acute pancreatitis if acute cholangitis is evident (see Chapter 43) but not for those with just cholestasis (Petrov, 2009). Although cholestasis can reflect a persisting main bile duct stone, it might also be due to edema of the ampulla secondary to stone passage to the duodenum and may thus be expected to improve over the first few days of admission. Persistent cholestasis without cholangitis may require an ERCP but not usually in the acute setting.

Cholecystectomy

Recurrent attacks of gallstone pancreatitis carry a morbidity rate of up to 40% (Banks & Freeman, 2006), and an early laparoscopic cholecystectomy is widely advocated within the same hospital admission (see Chapter 30). The optimal timing of cholecystectomy has been controversial. The U.K. guidelines for the management of acute pancreatitis recommend that all patients with biliary pancreatitis undergo definitive management of gallstones during the same hospital admission (index cholecystectomy; Working Group, 2005). However, some surgeons have concerns that early surgery may be associated with an increase in operative difficulty and hence morbidity and conversion rate; therefore they advocate cholecystectomy after a period of 4 to 6 weeks to allow resolution of the inflammatory process (interval cholecystectomy; Green, 2008; Larson et al, 2006). These two approaches have been compared in several RCTs, which demonstrated no difference in complication rates between index and interval cholecystectomy; however, index cholecystectomy resulted in a significantly shorter length of hospital stay (Siddiqui et al, 2008). It is worth mentioning that patients with acute biliary pancreatitis were excluded from these trials. An adequately powered RCT of index versus interval cholecystectomy is needed to draw a firm conclusion about the optimal timing of cholecystectomy in patients with acute biliary pancreatitis.

MANAGEMENT OF SYSTEMIC COMPLICATIONS

Most patients with acute pancreatitis have an initial sudden inflammatory respiratory syndrome response, others develop multiple organ dysfunction syndrome (MODS) in the first few days, and some develop MODS later in response to infectious complications (see Chapters 52 and 53). Patients with severe and critical acute pancreatitis are best managed in an intensive care environment to allow for optimal monitoring of fluid resuscitation and organ function and the early identification of life-threatening local or systemic complications. Systemic complications and organ failure are not an all-or-nothing phenomenon, rather a continuous spectrum exists between normal function of an organ system and its complete failure (Table 54.5; Marshall et al, 1995).

Some of the systemic complications of acute pancreatitis—coagulation abnormalities that may range from intravascular thrombosis to disseminated intravascular coagulation, metabolic disturbances (hyperlipidemia, hypocalcemia), liver failure, encephalopathy, and Purtscher retinopathy—are rare in clinical practice and beyond the scope of this chapter. In contrast,

Table 54.5

Modified Marshall Scoring System

Organ System	0	1	2	3	4
Respiratory (Pao_2/Fio_2)	>400	301-400	201-300	101-200	<101
Cardiovascular (systolic blood pressure [mm Hg])	>90	<90; fluid responsive	<90; not fluid responsive	<90; pH <7.3	<90; pH <7.2
Renal					
Serum creatinine (μmol/L)	<134	134-169	170-310	311-439	>439
Serum creatinine (mg/dL)	<1.4	1.4-1.8	1.9-3.6	3.6-4.9	>4.9

From Marshall JC, et al, 1995: Multiple organ dysfunction score: a reliable descriptor of a complex clinical outcome. Crit Care Med 23(10):1638-1652.

respiratory, cardiovascular, renal, and intestinal dysfunction are the most common systemic complications (Banks & Freeman, 2006; Pandol et al, 2007).

Respiratory failure is the most common systemic complication. The pathogenesis involves inflammatory cytokines released from the pancreas and the action of phospholipase A_2 and other pancreatic catabolic enzymes on the lung. The clinical diagnosis of incipient respiratory failure is based on tachypnea and low oxygen saturation. A chest radiograph may confirm pleural effusions, pulmonary edema, and features of acute respiratory distress syndrome. Management is supportive, with oxygen supplementation and analgesia, and some patients will ultimately require endotracheal intubation and mechanical ventilation. Lung-protective ventilation strategies should be instituted, such as adequate positive end-expiratory pressures, permissive hypercapnia, and tidal volumes of 6 mL/kg ideal body weight (Nathens et al, 2004).

Patients with severe and critical acute pancreatitis can develop hypotension (arterial pressure <90 mm Hg) secondary to vasodilation and decreased systemic vascular resistance, and sometimes as a result of cardiotoxicity. Appropriate management consists of close hemodynamic monitoring, intravenous fluid resuscitation, and inotropic medications—dopamine at 2 to 10 µg/kg/min or dobutamine at 2 to 10 µg/kg/min—if indicated (Tonsi et al, 2009).

In the setting of acute pancreatitis, acute renal failure is usually secondary to decreased renal perfusion pressure with hypovolemia and is sometimes secondary to ischemic acute tubular necrosis. The clinical diagnosis is based on acute oliguria and an acute elevation in blood urea nitrogen and serum creatinine (>0.5 mg/dL or 44 mmol/L; Nathens et al, 2004; Tonsi et al, 2009). Treatment is supportive and focused on restoring renal perfusion and providing dialysis if required.

The failure of the intestine is usually due to ischemia secondary to hypovolemia and reflex splanchnic vasoconstriction. The clinical diagnosis is based on the development of nausea and vomiting, increased NG losses, tympanic distension of the abdomen, reduced bowel sounds, and reduced tolerance to EN. Intestinal failure with the breakdown in intestinal barrier function and bacterial translocation can result in bacteremia and the infection of pancreatic necrosis.

MANAGEMENT OF LOCAL COMPLICATIONS

Because local complications can develop at any time, frequent assessment and continuous monitoring of patients is necessary. When a local complication occurs, it is necessary to make an accurate diagnosis and to decide whether intervention is required, when it is required, and what intervention is appropriate. Managing the local complications of acute pancreatitis requires a number of considerations.

Type of Complication

The first consideration is the type of local complication and its prognostic significance. Early peripancreatic fluid collections often resolve without intervention and usually have little bearing on disease course. As such, this is more a manifestation of the disease than a complication per se. Fluid collections may persist, often to the result of ductal injury and pancreatic leak; they may cause symptoms because of a mass effect (e.g., gastric outlet obstructions) and from secondary infection. Patients with pancreatic necrosis show signs of clinical deterioration: persistent abdominal discomfort, intolerance to oral feeding, and failure to thrive. The local complication in these patients is often a mature (thick-walled) collection predominantly filled with sterile necrosis. In these patients, intervention might expedite recovery. Intervention is very rarely indicated in patients with sterile necrosis but may be required in those who continue to deteriorate despite maximal supportive care. In contrast, patients with extensive infected pancreatic or peripancreatic necrosis almost always require intervention, as this complication is the most significant determinant of outcome. Although infected pancreatic necrosis has been considered an absolute indication for surgical intervention, cases successfully managed nonsurgically have been reported. Any necrotizing process, regardless of the infectious status, may cause significant hemorrhage (e.g., pseudoaneurysm) or bowel perforation (e.g., duodenum or transverse colon), both of which require urgent intervention. Thus the type of local complication has a direct bearing on the indication for treatment.

Trajectory of Patient

The second consideration is the clinical status and trajectory of the patient. If supportive measures, such as those discussed above, bring about clinical improvement—evidenced by serial clinical assessment and inflammatory markers, such as C-reactive protein (CRP)—intervention is unnecessary. If, however, the patient continues to deteriorate despite maximum intensive care support, survival will depend on effective intervention. Related to this is a consideration of the physiologic reserve of the patient. Elderly patients with significant preexistent morbidity have less physiologic reserve to withstand prolonged severe illness and invasive interventions.

Timing of Intervention

The timing of intervention is an important consideration and one of the most difficult decisions to make in the management of patients with acute pancreatitis. Early intervention of local complications is often fraught with difficulty in patients with more severe necrotizing pancreatitis because of the risk of hemorrhage when necrotic tissue is less well demarcated from viable tissue. Delaying intervention allows this demarcation and thus reduces the risks of bleeding, dissemination of infection, and collateral damage to adjacent organs as the necrotic process has stopped extending, and infected necrotic tissues become organized and "walled off." Appreciation of this has resulted in a notable trend toward delayed intervention, which is uncommonly performed before 4 weeks from the onset of symptoms.

Another emerging concept related to timing is the increasing use of percutaneous catheter drainage in patients with infected fluid collections and those with infected necrosis. Preemptive drainage with one or more catheters often produces an improvement in the patient's overall clinical status, or at least it arrests clinical deterioration. In this way drainage buys time and allows the more definitive necrosectomy to be delayed, until the patient is more stable, and the lesion is better defined. If required, repeat intervention can be undertaken on a programmed basis (e.g., every second day) or with an on-demand strategy, wherein the intervention is repeated only if and when it is clinically indicated. The former is often necessary if intervention has occurred

earlier in the disease course, when immature necrosum does not readily debride.

Type of Intervention

Another important consideration is the type of intervention. There are many different interventions, and the challenge is to select the intervention that is appropriate for the particular local complication, taking into account the anatomic location, infection status, complexity of any target lesions, the physiologic status and comorbidity of the individual patient, and the availability of expertise with the type of intervention. A review of current guidelines highlights the absence of level 1 evidence to guide decision making regarding the types of intervention (Loveday et al, 2008). Two broad philosophies are evolving in this regard. Many consider open surgical drainage with necrosectomy to be the gold standard in the management of infected pancreatic necrosis, and they reserve less invasive interventions for subsequent complications, such as percutaneous tube drainage of residual fluid complications. Such a *step-down approach* contrasts with the approach that advocates starting with less invasive interventions, such as percutaneous or endoscopic drainage, and only employing open surgical techniques later in the disease course in those who fail to respond (i.e., the *step-up approach*). These two approaches have been subjected to an RCT demonstrating that a minimally invasive step-up approach results in a reduced rate of the composite endpoint of major complications or death in patients with necrotizing pancreatitis and suspected or confirmed infected necrotic tissue (van Santvoort et al, 2010).

There are a number of variations to open surgical necrosectomy. More recently a number of less invasive approaches to treatment have been developed. The advocates for a less invasive approach argue that open surgery adds insult to injury and pushes a patient closer to or beyond their physiologic reserve; they point to the need to tailor treatment to specific lesions in individual patients and to the opportunities afforded by the development and convergence of minimally invasive technologies. Enthusiasts must be cautious not to overstate the benefits of less invasive approaches in the absence of high-level evidence. The reported improvement in outcomes with less invasive approaches might be due to a number of factors, including improvements in the early management of acute pancreatitis, such as resuscitation and EN; better intensive care to prevent and treat organ failure; more aggressive and appropriate use of percutaneous drainage; and better timing and selection of patients for intervention.

Classification of Interventions

In response to the need to standardize the description of invasive interventions to facilitate communication, comparison, and controlled trials (Windsor, 2007), progress has been made with the introduction of the VRP classification system, based on the ICD-10 approach (Loveday et al, 2011). It uses three dimensions, combining the method of *visualization* of the lesion, *route* taken to reach the lesion, and the *purpose* of the intervention (Table 54.6). Visualization includes open procedures, in which the operative site is exposed through the skin incision; endoscopic procedures, in which the operative site is

Table 54.6

VRP Classification of Invasive Procedures

V1 Radiologic	Using only radiologic modalities (e.g., fluoroscopy, CT, US, MR) to visualize and assist entering the target lesion
V2 Endoscopic	Using any white-light endoscopic instrument (e.g., flexible or rigid endoscope, urologic endoscope) to visualize the target lesion
V3 Combined	Using an endoscopic technique as the primary mode of visualization, assisted by a real-time radiologic modality
V4 Open	Using any method in which skin and any other body layers are cut to expose the site of the procedure
Vx	Insufficient information
Vz	Other visualization technique
R1 Per os transpapillary	External orifice entry point, internal route traversing papilla to enter pancreatic duct
R2 Per os transmural	External orifice entry point, internal route traversing gastrointestinal wall
R3 Percutaneous retroperitoneal	Skin external entry point, internal route traversing retroperitoneum
R4 Percutaneous transperitoneal	Skin external entry point, internal route traversing peritoneum
R5 Percutaneous transmural	Skin external entry point, internal route traversing gastrointestinal wall
Rx	Insufficient information
Rz	Other route
P1 Drainage	Letting out fluid and/or solid necrotic matter, externally out of the body or internally into the gastrointestinal tract
P2 Lavage	Flushing away solid necrotic matter with fluid to facilitate external or internal drainage
P3 Fragmentation	Breaking down solid necrotic matter by instrumental or mechanical disruption to facilitate external or internal drainage
P4 Debridement	Taking or cutting out solid necrotic matter with either sharp or blunt dissection
P5 Excision	Cutting out all or part of the pancreas, including healthy tissue, with the intention to fully remove all necrotic matter
Px	Insufficient information
Pz	Other purpose

Procedures should be classified using a single value from each component, and the highest applicable value should be selected.
CT, computed tomography; US, ultrasound; MR, magnetic resonance

Loveday BP, et al, 2011: A comprehensive classification of invasive procedures for treating the local complications of acute pancreatitis based on visualization, route, and purpose. *Pancreatology* 11:406-413.

visualized with an endoscope (gastroscope, laparoscope, or nephroscope); radiologic procedures that use computed tomography (CT), ultrasound, or fluoroscopy to visulalize lesions; and hybrid procedures that combine endoscopic and radiologic techniques. The routes taken by these interventions include the *external* route into the body, by mouth or gastrostomy tube, or the *percutaneous route,* through the skin; the *internal routes* used to reach a target lesion might pass through the gastrointestinal wall, peritoneum, or retroperitoneum.

The overall purpose of treatment is to eliminate areas of necrotic and infected tissue or fluid and inflammatory and enzyme-rich exudates. However, the way in which this is achieved varies considerably, and some procedures are much more aggressive than others. Therefore the purpose of individual treatment procedures for PN may be to effect simple drainage alone or to lavage the necrotic cavity to assist drainage of necrotic debris, fragment necrotic tissue to facilitate its drainage, debride necrotic tissue, or excise or resect the pancreas. The overall aim of intervention is to control the septic focus and preserve pancreatic function.

Open Surgical Necrosectomy

Three general variations of open necrosectomy are currently practiced: 1) open necrosectomy with open or closed packing, 2) open necrosectomy with continuous closed postoperative lavage, and 3) programmed open necrosectomy. Although these are broadly similar in terms of the necrosectomy, they differ in terms of how they provide egress routes for infected fluid, debris, and tissue. The abdomen is entered though a midline or bilateral subcostal incision. The latter is preferred, as it minimizes contamination of the greater sac and allows easy access to the extremities of the gland. The pancreas is exposed by dividing the gastrocolic omentum or gastrohepatic omentum to access the pancreas through the lesser sac. The body and tail of the pancreas (Fig. 54.1) can also be exposed by elevating the transverse colon and gaining access to the lesser sac via the transverse mesocolon (Fig. 54.2). Inflammatory adhesions may exist between the pancreas and stomach or transverse mesocolon, and great care is required during exposure. It is generally useful to take down both the hepatic and splenic flexures, if possible, as this will facilitate exposure and reduce the risk of colonic fistula secondary to drain erosion. When the process involves the head of the pancreas, access might require medial mobilization of the duodenum.

Open Necrosectomy with Closed Packing

The goal of necrosectomy with closed packing is to perform a single operation by performing a thorough debridement and removal of necrotic and infected tissue to minimize the need for reoperation or subsequent drainage (Pezzilli et al, 2007). Primary closure of the abdomen is the intention. Once the necrotic cavity is opened, fluid collections are drained, and the exposure is enlarged to allow debridement of all areas of necrosis, including those in the perirenal and paracolic spaces. Early advocates used gauze-stuffed Penrose drains placed via separate stab incisions, but many variations are in practice with regard to the type and number of drains. Between 2 and 12 drains are placed with the intention to fill the cavity and provide some compression. Additional silicone drains (Jackson-Pratt) are placed in the pancreatic bed and lesser sac for fluid drainage. The stuffed Penrose drains are removed one every other day, starting 5 to 7 days postoperatively, allowing a slow collapse of the cavity. The silicone drains are removed later.

Open Necrosectomy with Open Packing

The difference with this approach is that the abdomen is left open after debridement and packing of the pancreatic bed, lesser sac, and retroperitoneum (Gotzinger, 2008). Drains are placed in addition to the packing. Sometimes the abdomen is closed, and the packing is accessed via separate flank incisions (Nakasaki et al, 1999). Open packing techniques have been reported to have higher incidences of fistulae, bleeding, and incisional hernias as well as a slightly higher mortality rate (Heinrich et al, 2006). However, it should be noted that no prospective trials have compared open packing with any other technique.

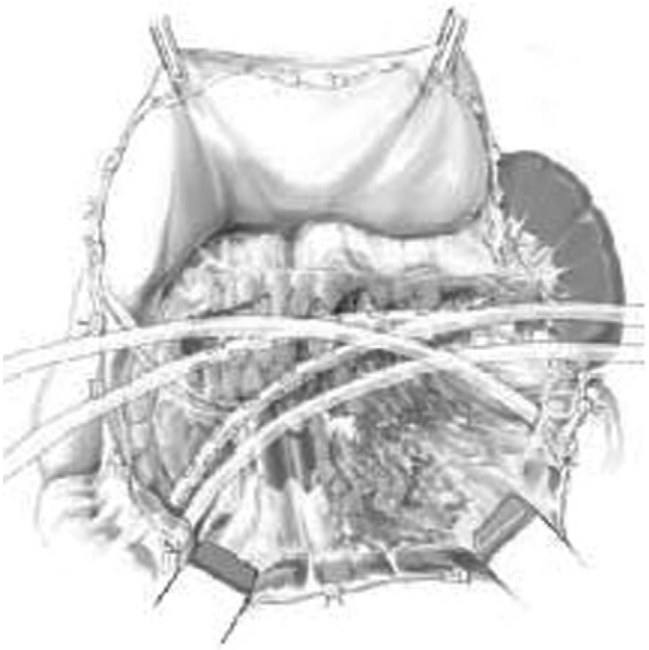

FIGURE 54.3. Open necrosectomy with continuous closed postoperative lavage. *(From Uhl W, et al, 2007: Necrosectomy. In Clavien P-A, et al (eds): Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 893-915.)*

Open Necrosectomy with Continuous Closed Postoperative Lavage

In this approach, debridement is followed by continuous peripancreatic lavage to remove infected necrotic debris, peripancreatic exudates, and extravasated pancreatic exocrine fluid (Fernandez-del Castillo et al, 1998). The large silicone drainage catheters are placed into the pancreatic bed to inflow and outflow isotonic irrigation fluid (Fig. 54.3). During closure, a closed peripancreatic compartment is made by resuturing the gastrocolic and duodenocolic ligaments. Postoperative continuous lavage is instituted at 1 to 10 L per day and should be continued until the effluent is clear and the patient shows improvement in clinical and laboratory parameters (Wig et al, 2004). No evidence is available to suggest the best irrigation fluid, the optimal number or caliber of drains, or the duration of irrigation.

Programmed Open Necrosectomy

The principle of this approach is to be more conservative with debridement, particularly if necrosum has not fully demarcated, with the intention of performing repeat procedures every 48 hours until debridement is no longer required. The pancreatic bed is drained or packed, and the abdomen is closed by suturing mesh or a zipper to the fascial edges of the wound. This allows multiple reentries and helps to prevent wound retraction, which aids in later delayed primary wound closure. In a proportion of patients, primary closure is not possible, and secondary intention healing is allowed to occur, accepting that this may require elective scar excision and repair of an incisional hernia. This procedure may be modified with the addition of intra-abdominal vacuum sealing (negative pressure 50 to 75 mm Hg) to encourage granulation of the pancreatic bed, potentially reducing the number of operations and mortality (Olejnik et al, 2008).

Several approaches to open surgical necrosectomy are possible. Comparing them has limited value in the absence of controlled trials because of variations in referral patterns, selection criteria, patient comorbidities, and the use of presurgical percutaneous management. Most techniques are associated with a 15% to 25% mortality rate, but this can be higher in patients with multiple organ failure and in those who have had early surgery. The important principles are adequate exposure guided by high-quality preoperative CT scanning, gentle debridement of demarcated dead tissue, preservation of viable pancreatic tissue, and thorough irrigation of the pancreatic bed, lesser sac, and retroperitoneum. Packing is probably best reserved to control hemorrhage, as it is associated with an increased risk of enteric fistulae. The placement of wide-bore dependent drains allows further egress of necrotic and infected material, aided by continuous irrigation, which may reduce the need for reoperation. In rare cases, when a necrosectomy is indicated within the first 2 weeks, an open approach should be considered because of the higher probability of requiring multiple procedures.

Endoscopic Techniques

In 1996, Gagner described the first true endoscopic treatment of necrotizing pancreatitis, in which the pancreas was debrided using a laparoscopic approach. Over the last decade, a wide range of endoscopic approaches for pancreatic necrosectomy have been described, including infracolic laparoscopy, transgastric laparoscopy, hand-assisted laparoscopy, retroperitoneal laparoscopy, transgastric flexible endoscopy, flexible endoscopy via a percutaneous endoscopic gastrostomy, and retroperitoneal nephroscopy (Ammori, 2002; Baron & Morgan, 1999; Charnley et al, 2006; Cuschieri et al, 1998; Horvath et al, 2001; Parekh, 2006). This array of endoscopic techniques can be classified by the type of scope that is used: laparoscope, nephroscope, or flexible endoscope (Windsor, 2007). Although some endoscopic procedures do not utilize radiologic modalities, many are hybrid procedures that incorporate fluoroscopy or endoscopic ultrasound into the procedure.

Laparoscopic Techniques

Most laparoscopic techniques are minimally invasive versions of open surgical techniques, and they use an anterior or lateral approach. In Gagner's original (1996) description of laparoscopic necrosectomy, two anterior routes—*retrogastric retrocolic* and *transgastric*—and one lateral route were described. In the retrogastric retrocolic route, a 30-degree laparoscope is introduced through the umbilical port following CO_2 insufflation (15 mm Hg). Placement of additional ports depends on the location of the necrosis. Following necrosectomy, large sump drains are placed in the necrotic beds, and continuous lavage may be established to remove peritoneal contaminants. In the transgastric route, the stomach is opened anteriorly and posteriorly. Endoluminal ports are used, which maintain the tip of the port inside the stomach. Debridement is performed internally through the posterior stomach wall, in a technique akin to an open cystogastrostomy. It is also possible to use a transduodenal route for necrosis of the pancreatic head, although this can be more difficult. No drains are left in the stomach, but a drain may be placed over the incision in the anterior gastric wall. With the retroperitoneal route, the patient is placed in the

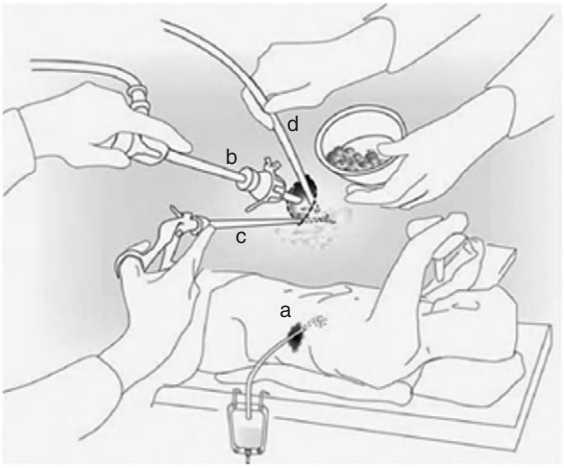

FIGURE 54.4. Videoscopic-assisted retroperitoneal debridement technique. *(From van Santvoort HC, et al, for the Dutch Acute Pancreatitis Study Group, 2007: Case-matched comparison of the retroperitoneal approach with laparotomy for necrotizing pancreatitis. World J Surg 31:1635-1642.)*

left or right lateral position, and a small flank incision made. The three muscle layers of the abdominal wall are split, and a trocar is inserted. Using a 0-degree laparoscope and CO_2 insufflation (10 to 15 mm Hg), a tract is made through to the pancreas. Once the necrotic areas have been identified, necrosectomy proceeds as when approached via a retrogastric retrocolic route.

These techniques have subsequently been modified. Of the lateral approaches, one of the most widely used laparoscopic techniques is *videoscopic-assisted retroperitoneal debridement* (VARD; Fig. 54.4), which was first described by Horvath and colleagues in 2001. The purpose of this procedure differs from those of open necrosectomy. Rather than performing complete removal of all infected and necrotic tissue, the purpose of VARD is to facilitate percutaneous drainage. In this technique, radiologic drainage of the lesion is first instituted. In the operating room, the patient is placed in a modified left lateral decubitus position, and a 4- to 5-cm incision is made in the left flank at the site of the drain. A finger is used to probe and confirm entry into the necrotic cavity. Fluid and loose necrotic debris are removed by suction, and two ports (10 to 12 mm) are inserted through the incision. The incision is sealed with wet sponges and towel clips to allow insufflation with CO_2. Debridement of necrotic tissue is performed with hydrodissection and 10 mm forceps. Drains are placed for postoperative continuous lavage: a 10-Fr red rubber drain is brought through a separate anterolateral incision, and two 1.3-cm (0.5-inch) Penrose drains are placed in the original skin incision. An ostomy bag is then positioned over the flank incision and Penrose drains, and continuous lavage is performed through the red rubber drain at 200 mL/h for 5 days or until the effluent is clear.

Variations of the anterior laparoscopic approaches are well described. In addition to the retrogastric, recolic, and transgastric routes, a transmesocolic route may be used, in which the transverse colon is elevated to expose the pancreatic lesion in the lesser sac (Cuschieri et al, 1998). Laparoscopic ultrasound may be used to confirm the position of the lesion, and the transverse mesocolon is usually opened to the left of the middle colic vessels. Following necrosectomy, two or more drains are placed in the pancreatic bed for postoperative lavage of the lesser sac. Anterior approaches may also incorporate a hand-assist device; this is termed *hand-assisted laparoscopic surgery* (HALS; Parekh, 2006). Another recent publication described single-port laparoscopic necrosectomy (Bucher et al, 2008). Port placement (12 mm) is through postlaparotomy drain tracts, allowing introduction of both a 4-mm laparoscope and 5-mm instruments. Insufflation pressures are kept to 8 mm Hg, as higher pressures may promote bacterial translocation from the cavity. Debridement is performed with both hydrodissection and atraumatic grasping forceps, hemostasis is achieved with monopolar diathermy, and a sump drain is placed for continuous postoperative lavage.

Nephroscopic Techniques

Nephroscopic techniques utilize warmed fluid to expand the necrotic cavity, irrigate turbid fluid, and maintain a clear visual field. Carter and colleagues (2000) were the first to describe the use of a nephroscope during necrosectomy, terming the procedure *percutaneous necrosectomy*. The principle underlying this procedure is the same as for an open procedure: debridement of devitalized tissue and establishment of a system for continuous postoperative lavage—with reduced physiologic stress on the patient. Percutaneous necrosectomy may only be used when the area of necrosis is accessible to percutaneous puncture, and it is contraindicated in the presence of bowel ischemia, perforated viscus, or significant preoperative hemorrhage. The first step is to insert a drainage catheter into the pancreatic lesion under CT guidance. The preferred path for drainage is between the lower pole of the spleen and the splenic flexure (Fig. 54.5), although in right-sided necrosis, a path through the gastrocolic omentum, anterior to the duodenum, may occasionally be used. The patient is then transferred to the operating room and positioned in the left lateral position, or for right-sided necrosis, in the right lateral position. A nephrolithotomy drape is used to collect irrigant fluid, and the drain tract is dilated to allow insertion of a 34-Fr Amplatz sheath. A nephroscope is inserted through the sheath into the cavity, and lavage is used to clear away debris and suppurative fluid (Fig. 54.6). Following necrosectomy, a 32-Fr soft drainage tube is left in the cavity. A smaller (8-Fr) catheter can be inserted through or alongside the larger drain to allow continuous postoperative lavage. This might be commenced at 250 mL/h with warmed dialysis fluid. Repeat procedures are often required after 2 to 10 days (Carter & Wysocki, 2008).

Flexible Endoscopic Techniques

The use of flexible endoscopy to treat patients with PN has a long history. In 1991, Prinz and Olen recognized that some areas of the abdomen were difficult to access during open necrosectomy as a result of the inflammatory process, therefore a choledochoscope was passed through the open abdomen to debride necrosis located in the lower retroperitoneum following open necrosectomy (Prinz & Olen, 1991). Since that time, the use of flexible endoscopes has developed considerably, with many different techniques currently available, as discussed below. In these procedures, the endoscope is either inserted via an external orifice, usually the mouth, or a skin incision is made.

Peroral flexible endoscopic techniques follow an internal route through either the gastric/duodenal wall or duodenal papilla, and some authors consider this to be a form of natural orifice transluminal endoscopic surgery (Friedland et al, 2009). Initial descriptions of flexible endoscopic treatment of PN used

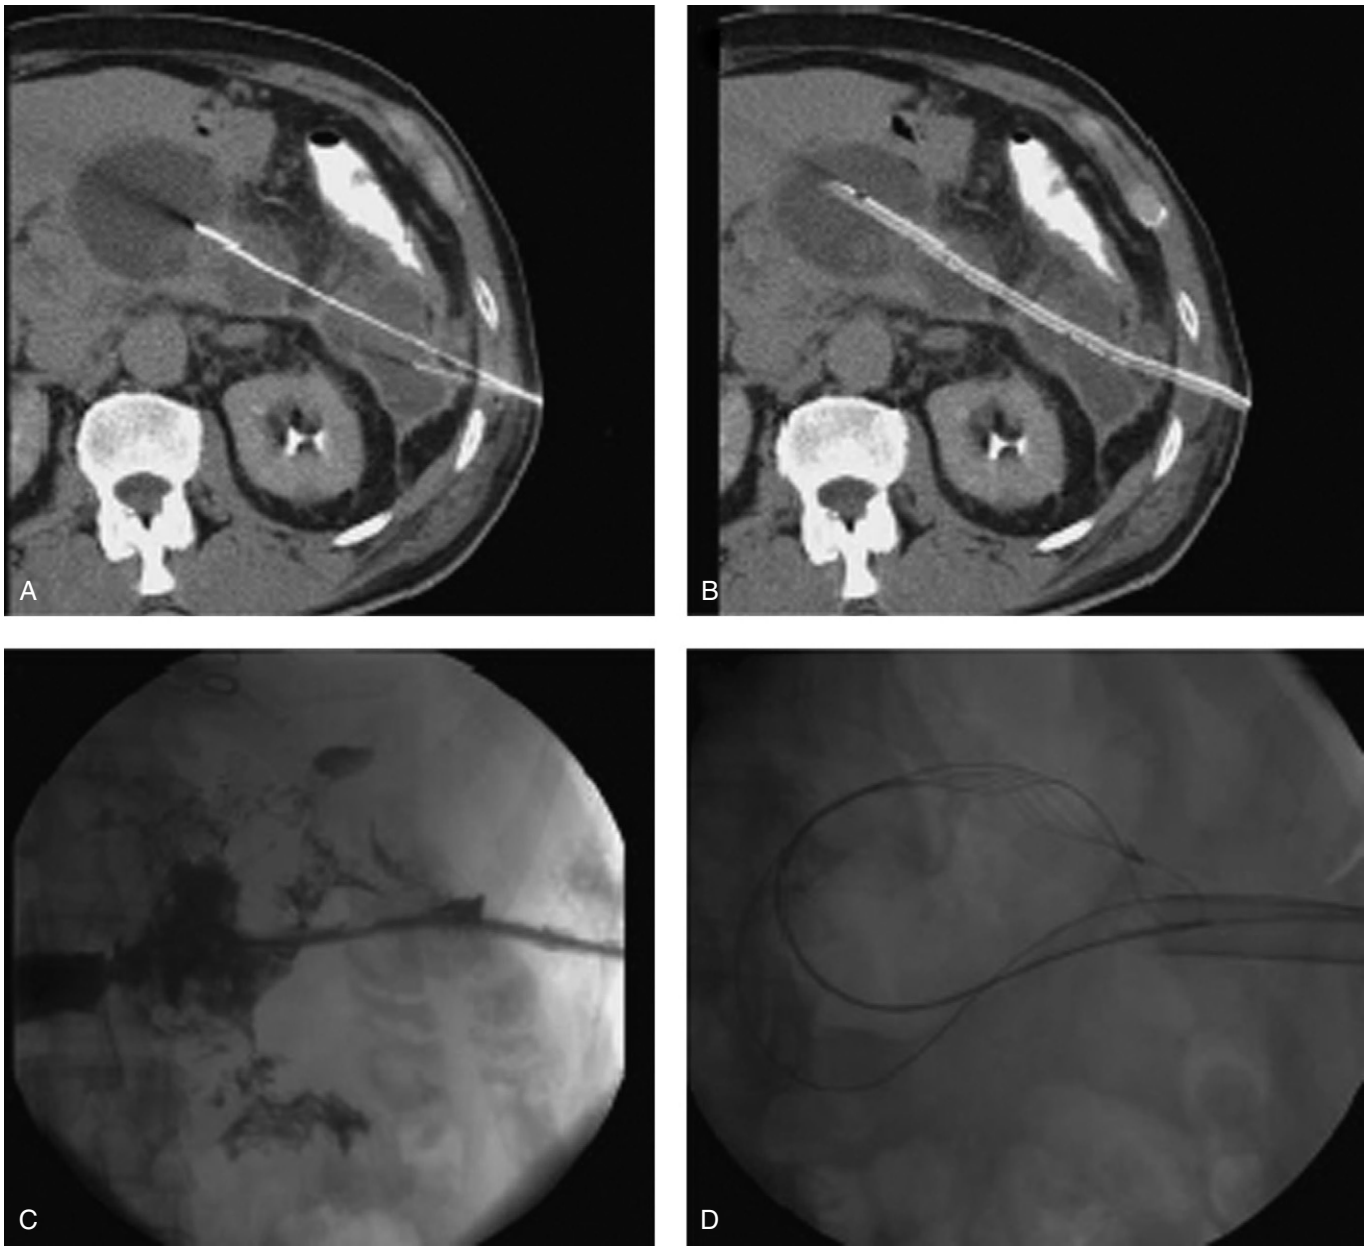

FIGURE 54.5. Insertion of a drainage catheter under CT guidance. *(From Bruennler T, et al, 2008: Percutaneous necrosectomy in patients with acute, necrotizing pancreatitis. Eur Radiol 18[8]:1604-1610.)*

lavage and drainage without instrumental debridement (Baron et al, 1996). A more aggressive approach was subsequently introduced, which demonstrated that necrotic tissue may be debrided with baskets, snares (Fig. 54.7), forceps, and suction (Seewald et al, 2005). A recent long-term multicenter study of transluminal endoscopic necrosectomy described 93 patients who underwent a mean of six interventions, starting at a mean of 43 days after the onset of severe acute pancreatitis (Seifert et al, 2009). Initial clinical success was obtained in 80% of patients but with a complication rate of 26% over 43 months of follow-up; 16% developed recurrent pancreatitis, 10% required further endoscopic procedures, 4% required surgical treatment, and the mortality rate was 7.5% at 30 days. Surgical necrosectomy was required in 12% of patients.

Endoscopic retrograde pancreatography (ERP) can be used to diagnose any communication between the duct and cavity or duct stenosis or disruption, and transpapillary stenting can be employed to decompress the duct. Puncture of the posterior gastric wall into the pancreatic lesion may be performed at the point of maximal bulging, although confirmation of the location with endoscopic ultrasound helps achieve correct placement of the perforation and avoids injury to vessels. A successful puncture is confirmed with aspiration of suppurative fluid from the cavity.

The injection of contrast with fluoroscopy can be used to determine the extent of the cavity. The gastric perforation is dilated with balloons up to 20 mm. For lavage and drainage, a 7-Fr nasocystic (lavage) and a 10-Fr pigtail drain (drainage) are

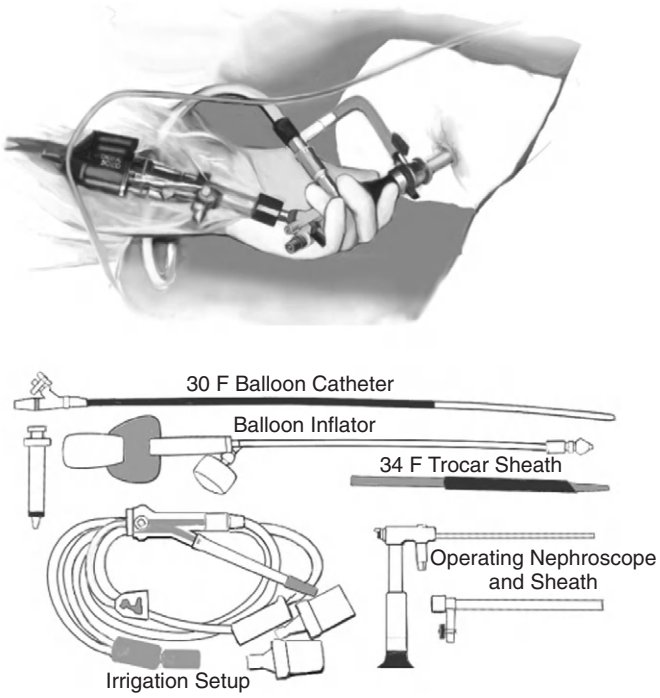

FIGURE 54.6. Percutaneous necrosectomy technique. *(From Uhl W, et al, 2007: Necrosectomy. In Clavien P-A, et al (eds): Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 893-915.)*

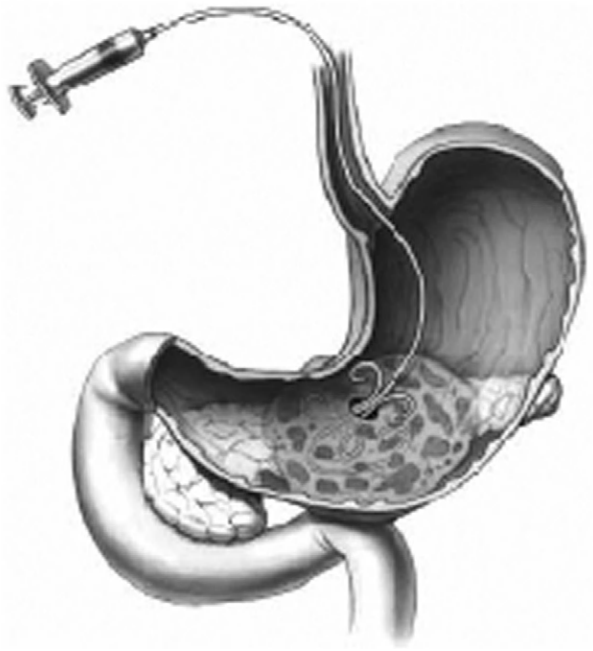

FIGURE 54.8. Transmural drainage of organized pancreatic necrosis. *(From Baron TH, et al, 2002: Outcome differences after endoscopic drainage of pancreatic necrosis, acute pancreatic pseudocysts, and chronic pancreatic pseudocysts. Gastrointest Endosc 56[1]:7-17.)*

placed in the cavity (Fig. 54.8). Continuous lavage with 1500 mL/day saline is established. Necrosectomy may be performed with endoscopic instruments, such as a Dormia basket or polypectomy snare, and introduction of a forward-viewing endoscope into the necrotic cavity can be used for better visualization during the necrosectomy. Multiple necrosectomy procedures are usually required to clear the cavity of necrotic tissue. A similar procedure may be performed with external entry into the body via a percutaneous endoscopic gastrostomy (PEG) tube (Baron & Morgan, 1999).

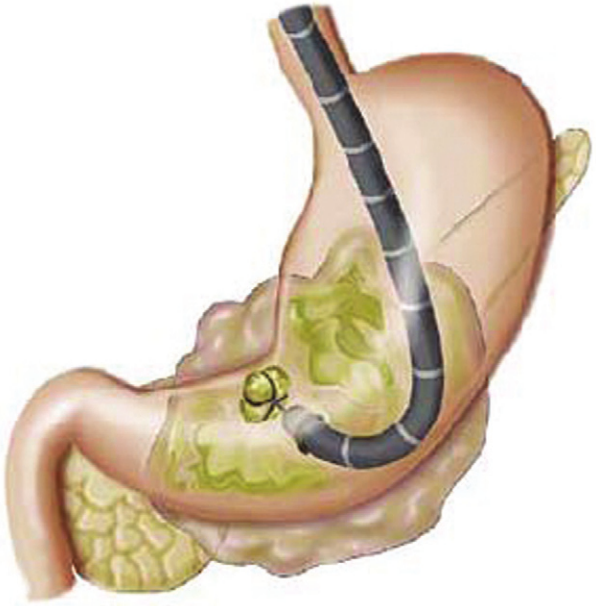

FIGURE 54.7. Pancreatic necrosis debridement with the use of flexible endoscope. *(From Seewald S, et al, 2005: Aggressive endoscopic therapy for pancreatic necrosis and pancreatic abscess: a new safe and effective treatment algorithm [videos]. Gastrointest Endosc 62[1]:92-100.)*

Several techniques using flexible endoscopy through skin incisions have been described. The first was by Prinz and Olen (1991) after open necrosectomy, as detailed above. Following percutaneous necrosectomy with a nephroscope, subsequent debridement may be undertaken using a flexible endoscope, a so-called *sinus-tract endoscopy* (Carter et al, 2000). The drain tract is dilated to 45 Fr, and a flexible endoscope is inserted into the cavity for necrosectomy. A similar technique has been described following open necrosectomy via a translumbar incision, in which a flexible endoscope is inserted into the cavity for debridement of ongoing necrosis (Jakobs et al, 2000). These endoscopic debridements were initiated 10 days after the open necrosectomy and were carried out every 3 days for 4 weeks (approximately 8 to 10 sessions).

The plethora of endoscopic approaches to necrosectomy and the absence of formal comparison make a recommendation for the optimal approach problematic. The selection of an endoscopic technique will be influenced by training, experience, and the availability of equipment, but it will also be determined by the location and complexity of the target lesion and the clinical status of the patient.

Radiologic Techniques

Interventional radiology techniques are assuming greater importance, particularly for initial sepsis control to allow definitive necrosectomy to be performed more electively (Jakobs et al, 2000). Ultrasound, fluoroscopy, or CT is used to guide the interventional radiologist into the pancreatic lesion. These

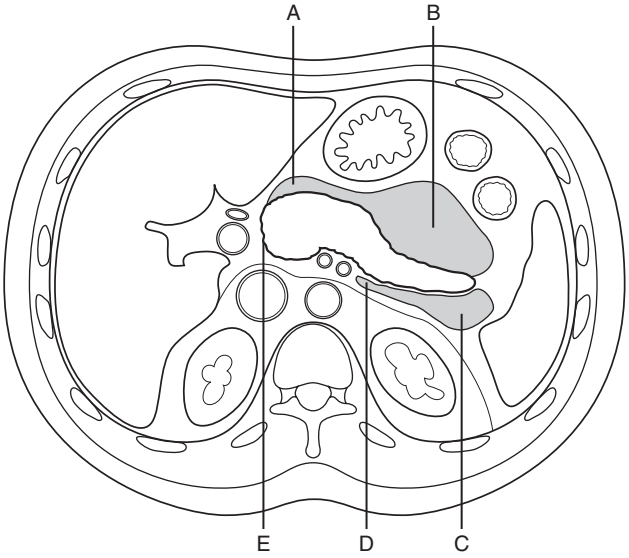

FIGURE 54.9. Common percutaneous access routes for drainage of pancreas and peripancreatic sites. **A,** Transhepatic. **B,** Transgastric. **C,** Retroperitoneal from left flank. **D,** Paravertebral. **E,** Subhepatic. *(Modified from Lee MJ, Wittich GR, Mueller PR, 1998: Percutaneous intervention in acute pancreatitis. Radiographics 18[3]:711-724.)*

radiologic modalities are also used to define the extent and composition of the lesion, visualize the instruments used, and determine the efficacy of the treatment procedure. The purpose of radiologic techniques may be to achieve either drainage, with or without lavage, or debridement.

Radiologic Drainage Techniques

Drainage techniques are most effective if target lesions have a significant fluid component. They can be located in many sites but are most often in the lesser sac, anterior and left pararenal spaces, and other parts of the retroperitoneum (Fig. 54.9; Jakobs et al, 2000). Image-guided needle puncture of the lesion may involve a retroperitoneal or transperitoneal route and may be transmural (transgastric or transduodenal), but a retroperitoneal approach is preferred to reduce the risk of contamination and possible peritonitis (Jakobs et al, 2000). A guidewire is passed down the needle, and the tract is dilated to accommodate a catheter. Because catheters readily block with necrosum and debris, it is advisable to maximize catheter diameter to improve patency. Typically, catheters should have multiple sideholes and a minimum diameter of 12 Fr (Jakobs et al, 2000). Drain tracts may be serially dilated to accommodate larger catheters (20 to 24 Fr). Often multiple catheters are required, especially for large or complex lesions. To increase the efficacy of the drainage procedure, remove toxic factors, and help maintain catheter patency, lavage should be considered (Eatock et al, 2005; Jakobs et al, 2000). Theoretical concerns have been raised that lavage may spread infection, either from infected fluid spilling over into previously sterile cavities or from the increased intracavity pressure, resulting in translocation of bacteria into surrounding tissues. However, this has not been demonstrated as a major problem clinically, most likely because the pancreatic lesion is walled off in a fibrous capsule 4 to 6 weeks after the onset of acute pancreatitis.

The efficacy of radiologic drainage procedures is reduced with more solid lesions. In patients with PN treated with percutaneous catheter drainage, approximately half will be successful and will not require surgical intervention (Jakobs et al, 2000). Indications for surgical intervention in patients who have undergone percutaneous catheter drainage include persistent systemic or local manifestations of infected PN, physiologic deterioration despite the placement of a patent drain, persistent abdominal pain, and intolerance of oral intake after the systemic inflammatory response syndrome has resolved (Jakobs et al, 2000).

Radiologic Debridement Techniques

In some specialized centers, radiologic techniques have been used to debride PN. These procedures are similar to percutaneous catheter drainage, as described above, but they also include removal of necrotic material with snares, baskets, or even by applying suction to a catheter during its removal (Economou & Ward-McQuaid, 1971; Jakobs et al, 2000; Thompson, 2001). Necrotic tissue may be fragmented with wires before attempting its extraction (Blamey et al, 1984; Jakobs et al, 2000), and lavage is recommended to flush out loosened necrotic debris.

A tailored approach to the treatment of the local complications of acute pancreatitis is required and must take into account the specific lesion, the patient's status, and the operator's expertise. Strong trends toward delayed intervention and less invasive intervention have been seen. Radiologic drainage has assumed a more important role for the definitive treatment of predominantly fluid-filled lesions and to delay definitive necrosectomy, either by minimally invasive or open methods. The convergence of technologies is apparent, and the plethora of minimally invasive techniques can now be classified to facilitate accurate description and much needed RCTs.

CONCLUSION

The management of acute pancreatitis remains a formidable challenge and continues to evolve. Although specific treatments for acute pancreatitis remain elusive, progress has been made in the management of pain, fluid resuscitation, antibiotic prophylaxis, enteral nutrition, therapeutic ERCP, and cholecystectomy. Progress has also been made in the intensive care management of systemic complications and in the development of less invasive interventions for the treatment of local complications, particularly infected pancreatic necrosis. This chapter has highlighted the need for more evidence to guide decision making, quell persisting controversies, and reduce variations in practice, particularly in patients with severe and critical acute pancreatitis.

CHAPTER 55A

Chronic pancreatitis: etiology, pathogenesis, and diagnosis

Klaus Mönkemüller, Stefan Kahl, and Peter Malfertheiner

OVERVIEW

The most common etiology of chronic pancreatitis (CP) in adults in Western societies is long-term alcohol abuse, which accounts for 70% of cases. Although many of the etiologies of CP are well known, as are the clinical and morphologic characteristics, the pathogenic mechanisms of CP have remained elusive. Major scientific progress has been made in the understanding of the underlying genetic, cellular, and molecular aspects of CP, but ongoing debate continues regarding the initiating events of the various factors of CP. Multiple hypotheses have been proposed to explain the pathophysiology in subgroups of patients with CP, but to date no single, unifying theory exists. The best known hypotheses about the pathogenesis of CP include necrosis-fibrosis, toxic-metabolic causes, oxidative stress, plug and stone formation with duct obstruction, primary duct obstruction, and the sentinel acute pancreatitis event (SAPE).

CP is a well-defined disease on histopathologic grounds, but histology is rarely available for diagnosis; therefore the diagnosis is reached by using a combination of clinical, laboratory, and imaging criteria. The correct diagnosis of CP is easy in late stages but difficult in early stages of the disease. Several imaging methods are available for patients with known or suspected CP. In early stages of the disease, both endoscopic retrograde pancreatography (ERP; see Chapter 18) and endoscopic ultrasonography (EUS; see Chapter 14) are methods with reliable diagnostic accuracy. Initial studies have shown superiority of EUS over ERP for the diagnosis of CP in its early stages. Transabdominal ultrasonography (US) is less sensitive for diagnosis of CP and is limited only to patients with advanced disease. In patients with an early stage of disease, we believe that EUS is the method of choice. In the absence of EUS, the combination of ERP and computed tomography (CT; see Chapter 16) provides the most reliable morphologic information. Among all imaging methods, magnetic resonance imaging (MRI), includingmagnetic resonance cholangiopancreatography (MRCP), has seen the most rapid development over the last years (see Chapter 17). With further improvement of hardware and software, it is likely that these methods will be capable of visualizing even early stages of the disease in the near future. The most common pancreatic function tests do not detect mild to moderate exocrine pancreatic insufficiency with adequate accuracy, therefore functional investigation techniques of the pancreas play only a complementary role in the routine clinical evaluation of CP but are important methods used in clinical research and in specialized pancreatic disease centers.

This chapter is divided into three sections. The first part presents the known etiologies of CP; the second part is a discussion of the most important pathogenic mechanisms of CP. The etiology and pathogenesis of CP are presented based on the TIGAR-O classification (***t***oxic–metabolic, ***i***diopathic, ***g***enetic, ***a***utoimmune, ***r***ecurrent severe, ***o***bstructive) proposed by Etemad and Whitcomb (2001) and elegantly delineated by Stevens and colleagues (2004). It is inevitable that data must be provided on the pathogenesis of CP while presenting its etiology and vice versa; in this manner, the reader will have a better comprehension of the disease process. The third part of this chapter discusses an approach to the diagnosis of CP, with emphasis on the use of radiologic diagnostic methods, and a brief discussion of the most commonly used pancreatic function tests.

ETIOLOGY OF CHRONIC PANCREATITIS

The classification of CP has evolved during the last several decades, and the basis for such classification stems from three consensus conferences: Marseille in 1963, Marseille-Rome in 1986, and Cambridge in 1984 (Axon et al, 1984; Sarles, 1986, 1991; Singer et al, 1985). Subdivisions of CP are based mainly on imaging characteristics, but newer classification systems such as the TIGAR-O categorize CP based on the various known etiologic factors and mechanisms jointly considered to be risk modifiers (Chari & Singer, 1994; Etemad & Whitcomb, 2001). It is likely that these risk modifiers, as well as multiple genetic and environmental cofactors, interact to produce expression of the disease in a given individual (Bourliere et al, 1991; Cavallini et al, 1994; Cavestro et al, 2003; Cohn et al, 1998; Ichimura et al, 2002; Whitcomb, 2001). It is clear that an individual, whose genetic composition is unique, will respond or not respond to an insult of similar etiology in a different morphologic pattern (inflammation or no inflammation) giving rise to disease. Response to an insult results in presence or absence of disease and progression or regression of the disease. Progression is likely to be closely related to the individual's genetic characteristics and to ongoing environmental toxic or infectious insults. This general concept explains why individuals respond differently to the same amounts of a toxin, such as alcohol, or why less amounts of the same toxin produce disease in a susceptible individual. Furthermore, the low prevalence of CP among alcoholics would seem to suggest other cofactors at play in many with diagnosed "alcoholic" pancreatitis. In fact, the presence of multiple risk factors may be required for progression to fibrosis. The various etiologies of CP based on the TIGAR-O system (Stevens et al, 2004) provide a further advancement in the etiologic and mechanistic classification of CP, although we anticipate it will likely require revision in the future. For example, the category of "idiopathic" will tend to decrease or even disappear as other etiologies are being discovered (Jansen

Table 55A.1

Etiopathogenesis of Chronic Pancreatitis

Etiology/Mechanism of Injury	Pathogenesis	Etiology/Mechanism of Injury	Pathogenesis
Toxic-Metabolic		**Autoimmune and Immunologic**	
Alcohol i (genetic mutations) Tobacco Hypercalcemia (hyperparathyroidism) Lipoprotein lipase deficiency Apolipoprotein C-2 deficiency Chronic renal failure (uremia) Protein deficiency Trace element deficiency Dietary toxins Medicinal products (phenacetin)	Protein plug obstructive hypothesis Toxic-metabolic hypothesis Necrosis-fibrosis Oxidative stress (detoxification insufficiency)	Viral infection Hepatitis B Coxsackie Autoimmune diseases Primary AIP Associated with Sjögren syndrome, Crohn disease, ulcerative colitis, primary biliary cirrhosis	Large duct
Idiopathic		**Recurrent and Severe Acute Pancreatitis**	
Early onset Late onset Tropical form (*SPINK1* mutations) Tropical calcific pancreatitis Fibrocalculous pancreatic diabetes	Necrosis-fibrosis Protein plug	Vascular disease Ischemia Postradiation therapy	Necrosis-fibrosis
Genetic/Hereditary		**Obstructive Mechanical Causes**	
Autosomal dominant mutations, cationic trypsinogen gene (*PRSS1*) Autosomal-recessive mutations: *SPINK1*, cationic trypsinogen (codons 16, 22, 23) Cystic fibrosis transmembrane conductant regulator (*CFTR*) defects α_1-Antitripsin deficiency	Necrosis-fibrosis	PD with insufficient accessory papilla Annular pancreas Papillary stenosis Ductal scarring Malignant PD stricture (pancreatic, ampullary, or duodenal carcinoma) Duodenal obstruction (diverticulum, duodenal) Stricture of the pancreatic duct after severe acute pancreatitis or trauma Stones Sphincter of Oddi dysfunction Choledochocele	Stone and duct obstruction Protein plug

AIP, autoimmune pancreatitis; PD, pancreas divisum

et al, 2002; Mahlke et al, 2005; Teich et al, 2005; Whitcomb, 2001; Whitcomb et al, 1996a; Whitcomb & Schneider, 2002; Witt et al, 2000, 2001).

Toxic and Metabolic

Table 55A.1 shows the multiple toxic and metabolic etiologies involved in CP. The association of alcohol and CP was first described almost 60 years ago by Comfort and colleagues (1946). Alcohol is still the most common cause of CP in Western industrialized countries, but interestingly, only 5% to 10% of alcoholics develop clinically apparent CP; at autopsy, 10% to 20% of alcoholics are found to have evidence of CP (Ammann, 1997; Ammann et al, 1994; Ammann et al, 1999; Angelini et al, 1993; Bernades et al, 1983; Layer & Melle, 2004; Sarles et al, 1989). Therefore, the majority of alcohol abusers never develop CP. Most patients (60% to 90%) with CP have a history of 10 to 15 years of heavy alcohol consumption, but some individuals have drunk less during a shorter period and still develop CP. This is especially true for patients who began to drink alcohol during puberty (Layer & Melle, 2004). The critical threshold of daily alcohol intake has been estimated to be about 40 g daily for women and 80 g daily for men, regardless of the quality or type of the alcoholic beverage (Layer & Melle, 2004; Papachristou & Whitcomb, 2004). Because the tolerance limits for alcohol differ substantially among individuals, smaller amounts of alcohol may be sufficient to induce pancreatic damage in susceptible individuals.

In the past it was believed that at the time of the initial attack, most patients with alcohol-induced CP already had underlying fibrosis and calcifications of the pancreas, but the Zürich group has demonstrated that acute attacks preceded the development of chronic disease (Ammann & Muellhaupt, 1994). Because only a fraction of alcoholics develop CP, involvements of other factors are actively being investigated. Several lines of evidence have shown that in addition to the direct effects of alcohol, various predisposing factors, such as genetics, smoking, intestinal infection, high-fat diet, compromised immune function, gallstones, gender, hormonal factors, and drinking patterns, may render the pancreas more susceptible to alcohol-induced tissue injury (Angelini et al, 1993; Lankisch et al, 2002; Levy et al, 1995; Lowenfels et al, 1994; Sahel et al, 1986). Many patients thought to have CP as a result of alcohol abuse, may indeed have a higher inherited susceptibility to alcohol-induced pancreatic damage or genetic defects that cause pancreatitis independent of alcohol exposure (Malats et al, 2001; Stevens et al, 2004).

There is convincing evidence that smoking is also independently associated with increased risk for CP, with odds ratios as high as 17.3 (Talamini et al, 1996). CP induced by smoking is particularly associated with pancreatic calcifications. By mechanisms similar to alcohol, tobacco produces alterations in the secretion and composition of pancreatic juice mainly as a result of decreased pancreatic juice and bicarbonate secretion and induction of oxidative stress (Bynum et al, 1972; Cavallini et al, 1994; Crowley-Weber et al, 2003; Stevens et al, 2004). In a large study involving 146 patients with CP, 52 patients with pancreatic cancer, and 235 healthy controls, Ockenga and colleagues (2003) analyzed the genomic DNA for expression of uridine 5′-diphospho (*UDP*) glucuronosyltransferase (*UGT1A7*) genes. These proteins are vital biochemical factors for detoxification and cell defense. The incidence of this mutation was much more common in patients with CP and tobacco abuse but not in

patients with nonalcoholic CP. This study establishes the possible connection between genetic predisposition and external triggering factors. It is possible that smoking is the main factor of CP in some patients, whereas in others smoking may increase the damage induced by alcohol, and in another group it might potentiate an as yet unidentified factor or pathogen (Crowley-Weber, 2003).

Calcium plays a central role in trypsinogen secretion and trypsin stabilization. Hypercalcemia as a result of primary or secondary hyperparathyroidism results in recurrent acute pancreatitis, which progresses to CP, likely due to trypsinogen activation, which in turn results in necrosis and fibrosis of the parenchyma (Goebell, 1976; Noël-Jorand et al, 1981). Increased serum calcium concentration is believed to induce direct damage to acinar cells, and increased secretion of calcium results in intraductal stone formation. It also appears that hypercalcemia modifies pancreatic secretion and leads to protein plug formation (Goebell, 1976; Noël-Jorand et al, 1981), in turn resulting in varying degrees of pancreatic fibrosis with calcifications. This is likely due to hypercalcemia related to secondary hyperparathyroidism, but other mechanisms msy nr involved, including toxicity of uremic substances to the pancreatic parenchyma (Karanjia et al, 1992; Owyang et al, 1982).

Idiopathic

Up to 30% of patients with CP have no known risk factors; therefore the CP they have is called *idiopathic*. It is likely that many of these patients are mislabeled because of underreported alcohol abuse, an underlying genetic abnormality, or other unknown factors (Truninger et al, 2002; Witt, 2000). Pfützer and colleagues (2000) and Witt and colleagues (2000) have described mutations of the serine protease inhibitor Kazal type 1 (*SPINK1* gene) in up to 25% of patients with idiopathic CP. Based on the bimodal age of onset of the clinical symptoms, idiopathic pancreatitis is separated into two distinct entities: *Early idiopathic CP* is seen during the first 2 decades of life, with abdominal pain being the predominant clinical feature, whereas pancreatic calcifications and exocrine and endocrine pancreatic insufficiency are very rare at the time of first diagnosis (Layer et al, 1994). In contrast, the clinical presentation of *late-onset idiopathic CP* is in patients during their fifth decade of life, usually following a rather painless course but associated with significant exocrine and endocrine pancreatic insufficiency and pancreatic calcifications (Layer et al, 1994; Papachristou & Whitcomb, 2004). Histologically, many cases of idiopathic chronic pancreatitis have T-lymphocyte infiltration, ductal obstruction, acinar atrophy, and fibrosis, raising the possibility of autoimmune etiology.

Tropical or *nutritional pancreatitis* is considered a form of idiopathic CP. It is the most common form of CP in certain parts of the world, such as India, sub-Saharan Africa, and Brazil, where it is a disease of youth and young adulthood (Schneider et al, 2002). The disease is subdivided into *tropical calcific pancreatitis,* characterized by severe recurrent and chronic abdominal pain and extensive pancreatic calcifications and fibrocalculous pancreatic diabetes with significant pancreatic endocrine insufficiency. This form of CP is clearly related to mutations in the *SPINK1* gene (Chandak et al, 2002). Based on this important fact, this form of CP is likely going to be categorized as genetic. The *SPINK1* pancreatic secretory trypsin inhibitory (*PSTI*) gene, is responsible for the encoding of *SPINK1* (Chandak et al, 2002; Schneider et al, 2002). *PSTI* has the main function of inhibiting activated trypsin. *SPINK1* is the major intrapancreatic "deactivator" of activated trypsinogen (Kukor et al, 2002; Teich et al, 2005). Trypsin has a central role in the digestion of dietary proteins and in the activation of other digestive enzymes. If the trypsin inhibitory protein malfunctions or cannot bind itself to trypsin, then trypsin is not properly deactivated or destroyed, and it remains active for a longer period of time. This is called a *gain of function* of trypsin (Gorry et al, 1997; Kukor et al, 2002; Pfützer et al, 2000; Sahin-Tóth, 2000; Stevens et al, 2004; Whitcomb et al, 1996a). Other genetic alterations have been described in patients with idiopathic CP. Cohn and colleagues (1998) and Durie (1998) independently demonstrated the strong association between cystic fibrosis transmembrane regulator (*CFTR*) mutations and idiopathic CP. In patients without evidence of cystic fibrosis, the frequency of *CFTR* mutations was six times that of patients without mutations. Subsequently, Cavestro and colleagues (2003) reported that one third of all patients with idiopathic CP have *CFTR* mutations. In the future, many patients categorized under idiopathic CP will fall into the categories of the other risk factor groups, specifically in the genetic category. In fact, leading pancreatologists speculate that most CP might be a genetic disease with multifactorial triggering factors (Papachristou & Whitcomb, 2004; Stevens et al, 2004; Whitcomb et al, 1996b).

Genetic

Until a few years ago, data on the genetic basis of CP were scarce. The only well-studied hereditary form of chronic pancreatic insufficiency was cystic fibrosis (Cohn et al, 1998; Durie, 1998). Many cases of CP represent a variable part of the cystic fibrosis syndrome, which is caused by mutations in the gene coding for the cystic fibrosis transmembrane conductance regulator. Several groups have reported an increased prevalence of *CFTR* mutations in patients with chronic pancreatitis of different etiologies. Later studies demonstrated that the mutations associated with cystic fibrosis (*CFTR* mutations) were also found with increased frequency in patients with CP (Teich et al, 2005). Interestingly, this mutation was also found to be more frequent in patients with CP thought to be secondary to pancreas divisum (Gelrud et al, 2004).

Other genetic variants predispose for CP. Research has focused on the *SPINK1-N34S* gene mutation, which is also closely associated with tropical (50%), alcoholic (6%), or idiopathic (20%) CP (Schneider et al, 2002; Sahin-Tóth & Tóth, 2000). One of the major discoveries in CP was the description of the point mutation in patients with autosomal dominant hereditary pancreatitis (HP) (Gorry et al, 1997). Several variants of the mutation of the cationic trypsinogen gene exist, all of which lead to a malfunction of trypsinogen (Chandak et al, 2002; Chen et al, 2000; Kukor et al, 2002; Sahin-Tóth, 2000; Teich et al, 2004). Consequently, premature intracellular activation of trypsinogen within the pancreatic acinar cell leads to activation of other enzymes, which may ultimately result in autodigestion (Kukor et al, 2002). Genetic abnormalities have been described more commonly in HP, which present typically in a bimodal pattern of childhood and adulthood (Teich et al, 2004, 2005). Associated with trypsinogen gene mutations, HP is an autosomal dominant disease that carries an 80% penetrance (Howes et al, 2004; Keim et al, 2001; Sossenheimer et al,

1997). HP is characterized by recurrent episodes of acute pancreatitis or familiar aggregation of CP, but most patients with this genetic mutation are asymptomatic (Teich et al, 2005). The progression of CP is faster in patients with *SPINK-N34S* mutation than in patients with cationic trypsinogen mutations (Howes et al, 2004; Keim et al, 2003). Patients with HP have a more than 50-fold increased risk of pancreatic ductal cancer compared with the general population (Howes et al, 2004; Lowenfels et al, 1987). Despite great advances in the knowledge of genetics in pancreatitis, currently it is only advised to evaluate for mutations in patients with HP. The genetic-phenotyping correlation of *SPINK1* or *CFTR* mutations has not been studied well enough to allow for guidelines and recommendations to be established regarding its use in general clinical practice (Ellis et al, 2001; Teich et al, 2005).

Autoimmune

Autoimmune pancreatitis (AIP) is a rare but distinct form of CP characterized by specific histopathologic and immunologic features (Klöppel et al, 2005; Külling et al, 2003; Montefusco et al, 1984). In recent years, it has been established as a special type of CP whose morphologic hallmarks are periductal infiltration by lymphocytes and plasma cells and granulocytic epithelial lesions with consequent destruction of the duct epithelium and venulitis (Klöppel et al, 2003).

The pathogenesis of AIP involves both a cellular (CD4+ and CD8+ T cells) and humoral immune-mediated attack to the ductal cells and pancreatic ducts that results in cytokine-mediated inflammation and periductular fibrosis with subsequent obstruction of the pancreatic ducts (see *primary duct hypothesis*) (Okazaki, 2002). AIP is commonly associated with other autoimmune diseases such as Sjögren syndrome, primary sclerosing cholangitis, and inflammatory bowel disease (Külling et al, 2003; Montefusco et al, 1984). Nevertheless, more than a third of patients with AIP do not have other extrapancreatic autoimmune disorders.

AIP is clinically characterized by minimal abdominal pain and diffuse enlargement of the pancreas without calcifications or pseudocysts, and it most commonly involves the head of the pancreas and the distal bile duct. On occassion, masses have been described as *inflammatory myofibroblastic tumors* (Klöppel et al, 2005). On laboratory examination patients have hypergammaglobulinemia and autoantibodies, such as antinuclear and anti–smooth muscle antibodies (Bovo et al, 1987; Okazaki et al, 2000). Histopathologic examination of the pancreas reveals inflammatory infiltration of lymphocytes and plasma cells around the pancreatic duct, as well as fibrosis, in a pattern similar to primary sclerosing cholangitis (Montefusco et al, 1984; Okazaki et al, 2000).

In 2002, the Japan Pancreas Society was the first in the world to propose diagnostic criteria for autoimmune pancreatitis. These criteria were revised by an Asian consensus conference a few years later (Otsuki et al, 2008).

Recurrent and Severe Acute Pancreatitis

Recurrent acute pancreatitis can result in CP. This form of pancreatitis is discussed in more detail in the chapter on acute pancreatitis, but it is mentioned here as part of the TIGAR-O classification, in which the *R* is for recurrent and severe acute pancreatitis.

Obstructive

Obstruction of the main pancreatic duct is well known to result in CP. The most common etiologies causing CP as a result of obstruction of the pancreatic duct include scars of the pancreatic duct, tumors of the ampulla of Vater and head of the pancreas, and trauma (see Table 55A.1). Other disorders, such as sphincter of Oddi dysfunction and pancreas divisum, have a more tenuous connection with CP. Obstruction of the main pancreatic duct produces changes of CP within weeks in several animal models (Boerma et al, 2003; Reber et al, 1999). Main pancreatic duct obstruction may lead to stagnation and stone formation of pancreatic juice (stone and duct obstruction theory) or acute recurrent pancreatitis and periductular fibrosis (necrosis-fibrosis theory). Histopathologic characteristics of human CP as a result of obstruction include uniform distribution of interlobular and intralobular fibrosis and marked destruction of the exocrine parenchyma in the territory of obstruction, without significant protein plugs and calcifications (Suda et al, 1990). Experiments in cats with obstructive chronic pancreatitis have demonstrated impaired pancreatic blood flow in addition to elevated tissue pressure (Karanjia et al, 1992; Reber et al, 1992). In contrast to the normal hyperemic response, these cats show a decrease in blood flow after secretin injection that constitutes a form of compartment syndrome, as the normal postprandial augmentation of blood flow and oxygen supply is prevented because of decreased tissue compliance and increased interstitial pressures.

PATHOGENESIS OF CHRONIC PANCREATITIS

In the past 50 years, several hypotheses have been postulated to explain the pathogenesis of CP. Debate is ongoing as to which of these hypotheses bests explains the origins of CP, and although each proposes a specific mechanism to explain the pathophysiology, none of them explains the entire pathogenic process in all cases. Thus far, no hypothesis or theory has been able to unify the concepts of the known pathways of CP, and no reported hypothesis convincingly demonstrates the first molecular steps in the development of CP. Six major theories are described, and the reader will no doubt notice that many of the hypotheses share similarities, especially later in the disease process, once the initiating factors of each mechanism have "opened the flood gates" for the amplification and continuation of the process of CP. A close interaction is known to exist between underlying genetic predisposition, triggering factors, inflammatory processes mediated through cytokines, the immunologic process, oxidative and toxic-metabolic stress, changes in the consistency and flow of pancreatic juice, and fibrosis and obstruction of the ducts that play a role in almost every case of CP. Furthermore, every year, new information on cellular, genetic, and molecular mechanisms of pancreatic inflammation and fibrosis emerge, and it is likely that other pathogenic models or the unification of existing models will come into existence.

Necrosis-Fibrosis Hypothesis

The hypothesis originally proposed by Comfort and colleagues almost 60 years ago (Comfort et al, 1946) fits most with the understanding of the pathogenesis of chronic pancreatitis. The histologic changes and pathogenesis of CP have been

extensively studied by Klöppel and Maillet (1991, 1992). The hypothesis of necrosis-fibrosis views the development and course of CP as a consequence of acute pancreatitis, emphasizing that fibrosis is a late development resulting from repeated attacks of acute (alcoholic) pancreatitis, which initially lead to inflammation and necrosis (Demols, 2002; Klöppel & Maillet, 1991). Ongoing inflammation is replaced by fibrosis in the parenchyma and in the area around the pancreatic ducts, resulting in scarring and sacculations of the ducts, which in turn obstruct the flow of juice and facilitate the precipitation of proteins and subsequent calcification (Kennedy et al, 1987). This process in turn leads to further stasis, plugging, and stone formation, further obstruction, additional fibrosis, and, finally, atrophy of the gland (Klöppel & Maillet, 1992). The necrosis-fibrosis hypothesis has significant supporting evidence from epidemiologic and large follow-up studies that have shown CP to result from recurrent attacks of acute pancreatitis. Several histopathologic studies have demonstrated that mild perilobular fibrosis is common in resolving acute pancreatitis; marked fibrosis with ductal distortion is seen more frequently in patients with advanced CP (Ammann et al, 1984, 1994, 1996). In one study by Ammann and colleagues (1984), 245 patients were prospectively followed after their first episode of alcoholic pancreatitis, and investigators found that the higher the severity and frequency of attacks, the more rapid the progression to CP. Studies of *ERBB2* oncogene expression also support the acute pancreatitis–CP sequence (Standop et al, 2002). The recurrent attacks of acute pancreatitis in HP are also supportive of the necrosis-fibrosis hypothesis. One important aspect that partially negates this hypothesis is the fact that the type of fibrosis that follows acute attacks of pancreatitis involves short-lived collagen type III and procollagen type IV, not the long-lasting collagen types I and IV (Casini et al, 2000).

Protein-Plug (Stone/Ductal Obstruction) Hypothesis

Sarles of France has proposed and extensively studied the hypothesis that states that CP results from plugging of the pancreatic duct (Multigner et al, 1985; Sarles, 1986). These investigators proposed that the origin of CP was within the lumen of the pancreatic ductules, in contrast to the origins of acute pancreatitis, which tends to be inside the acinar cell. The investigators proposed that increased lithogenicity of pancreatic fluid leads to the formation of eosinophilic proteinaceous aggregates that precipitate and obstruct the pancreatic ductules (Guy et al, 1983). These plugs then become rich in calcium and precipitate in the ductules because of deficiency of lithostatin or pancreatic stone protein (PSP); this protein is synthesized in the acinar cell and is an important factor in avoiding calcification within the ductules (Bimmler et al, 2001; Cavallini et al, 1998; Guy et al, 1983; Sarles, 1986; Sarles et al, 1990). Indeed, several studies have proven that alcohol decreases the formation and secretion of pancreatic juice, making it more viscous; lower in bicarbonate; richer in protein, enzymes, and calcium crystals; and deficient in lithostatin (Sarles et al, 1989; Suda et al, 1990).

The mechanism by which heavy alcohol use leads to a decrease in PSP synthesis has not been fully elucidated. Alcohol has also been shown to mediate the release of gastrointestinal hormones by increasing cholecystokinin (CCK)-releasing factor, which in turn affects pancreatic juice formation and flow. The pancreatic stones and plugs are believed to produce ulceration of the ductal epithelial cells that results in inflammation, fibrosis, obstruction, stasis, and further stone formation. Parenchymal damage in the form of inflammation and fibrosis then follows and is usually worst proximal to the obstruction (Boerma et al, 2003).

Another protein believed to induce pancreatic plug formation is glycoprotein 2 (GP-2), a major component of the zymogen granule cell membranes (Fukuoka et al, 1991). The chain of events of decreased flow, decreased lithostatin production, plug formation, calcification, stone precipitation, ductal ulceration, parenchymal and periductular inflammation, stenosis, and stasis repeats itself in a constant vicious cycle (Guy et al, 1983; Reber et al, 1992). Although pancreatic stones and plugs are found in late stages of pancreatitis, it has not been proven whether their formation represents a primary event or is only part of the sequence of CP.

Oxidative Stress Theory

Braganza (1983) from England postulated that the original pathogenic mechanism of CP was a dysregulation and overactivity of the hepatic mixed-function oxidases, mechanisms leading to oxidative stress. This theory places the major area of injury by oxidative stress at the acinar cell, usually as a result of steady exposure of xenobiotics that induce the cytochrome P-450 enzymatic system and deplete glutathione (Braganza, 1998). The hepatic mixed-function oxidases are part of the hepatic detoxification system, and as a consequence of the metabolization process, several "waste products"—such as toxic epoxides, free radicals, and lipid peroxidation products—are produced and are then released into the systemic circulation and reach the pancreatic parenchyma; or they are secreted into the bile and end up refluxing into the pancreatic duct, where they induce inflammatory damage of the acinar and ductular cell. Each burst of oxidative stress affects exocytosis, resulting in fragility of the lysozomes. Pancreatitis is triggered through interference of the methionine–glutathione transulfuration pathway, resulting in diversion of free radicals into the pancreatic tissue with subsequent activation of inflammation and fibrosis of the ductules and resultant low flow of pancreatic juice, inhibition of lithostatin, and precipitation of proteins and calcium (Braganza, 1998; Wilson et al, 1990). Alcohol may also contribute to oxidative stress as a result of the depletion of scavengers such as selenium, vitamins E and C, and riboflavin; such depletion helps to induce or propagate the damage (Atten et al, 2003; De las Heras Castano et al, 2000; Wilson & Apte, 2003).

Toxic-Metabolic Theory

Bordalo and colleagues from Portugal (1977) have proposed the toxic-metabolic hypothesis of CP. They described how alcohol and its toxic metabolites cause accumulation of intracellular lipids and fatty acid ethyl esters, which damage the acinar cell. The alterations of intracellular lipid metabolism lead to fatty degeneration, apoptosis, and scarring of the pancreatic parenchyma with impairment of the pancreatic microcirculation. In a landmark study, biopsies from 42 chronic alcoholics with and without established CP were evaluated by histology and electron microscopy (Bordalo et al, 1977). Even though many of these patients did not have CP, many changes were found to be due to cellular damage, such as cytoplasmic fat droplets of the acinar cells, decreased zymogen granules, and increased mitochondrial size.

Several studies in animals, as well as in human pancreatic tissue, have demonstrated that the toxic or metabolic insult to the fat cells (Kupffer cells) plays an important role in the pathogenesis of pancreas fibrosis in a similar fashion as Ito cells do in the liver (Jaskiewicz et al, 2003; Luttenberger et al, 2000; McCarroll et al, 2003; Phillips et al, 2003). It was demonstrated that these fat cells exist in the human pancreas; they can migrate into the periacinar spaces, and they are activated by alcohol and acetylaldehyde, transforming into scar-producing cells (Vogelmann et al, 2001; Xie et al, 2001; Yokota et al, 2002). As demonstrated in immunohistochemical analysis of pancreatic tissue, a clear correlation exists between the expression of activated Kupffer cells and the degree of fibrosis. These cells have been shown to deposit collagen very early in the process of CP (Haber et al, 1999); therefore an analogy with cirrhosis of the liver can be made when talking about macronodular and micronodular fibrosis in CP.

Primary Duct Hypothesis

Cavallini (1993) from Italy proposed that CP represents a primary autoimmune or inflammatory condition beginning in the pancreatic duct and suggests that the primary pathogenic factor leading to CP is an outflow obstruction, likely the result of duct inflammation, destruction, and fibrosis; these are likely the result of an immunologic attack to a specific genetic, structural, or acquired antigen of the periductular epithelium. The target of this attack may be some specific genetic or acquired antigen on the duct epithelium. Cavallini proposes that the immune-type mechanism occurs via two channels; one is due to aberrant expression of major histocompatibility antigens by the ductal epithelium, the other to infiltration of activated lymphocytes that produce a periductular cytotoxic response. Several reports have shown a defect of ductal epithelial aberrant expression, which leads to periductular lymphocyte infiltration (Bedossa et al, 1990; Bovo, 1987; Jaskiewicz et al, 2003). Therefore, it appears that CP is an autoimmune or "duct-destroying" disease, analogous to primary sclerosing cholangitis (PSC). This is supported by several observations: the radiologic and histologic similarity of chronic PC and PSC, the activation of cytotoxic T lymphocytes in the periductular areas of the pancreas in patients with alcoholic CP, and the occasional association of CP and PSC (Külling et al, 2003; Montefusco et al, 1984; Okazaki, 2001).

Sentinel Acute Pancreatitis Event Hypothesis

Introduced by Whitcomb (1999), the sentinel acute pancreatitis event (SAPE) hypothesis is fascinating because it incorporates much of the knowledge about the molecular and cellular mechanisms of CP pathogenesis in an effort to put previous hypotheses together. The SAPE hypothesis tries to provide a "final common pathway" for the many etiologies for pancreatitis. According to Whitcomb, a SAPE is essential to initiate the inflammatory and immunologic process of CP. In addition, it is necessary for multiple risk factors or insults—agents, toxins, and infections—to propagate CP through membrane and mitochondrial injury as well as through the release of inflammatory cytokines. Susceptibility is essential, either genetic or through some other mechanism, such as ongoing injury (i.e., alcohol toxicity). Then the critical sentinel event appears, triggers the process, and causes acute pancreatitis and CP. Further activation of the immunologic system and the stellate cells propagates CP, and the end result is fibrosis and calcification. Most studies demonstrate that an acute attack of pancreatitis tends to be self-limited; other studies have also demonstrated that the continued oxidative stress cannot cause pancreatitis under normal conditions. Even patients with genetic mutations (susceptibility) known to be associated with CP do not develop the disease spontaneously. Nevertheless, this hypothesis has the merits of placing several of the previous theories under one umbrella.

DIAGNOSIS OF CHRONIC PANCREATITIS

Diagnosis of CP is made by imaging studies. For many years, the gold standard for diagnosing CP has been ERP. In advanced stages, the diagnosis is easy, but diagnosis is challenging in the early stages. In a clinical setting, diagnosis of CP is based on a thorough history and physical examination, laboratory data, and imaging study evaluation, which will reflect the imaging abnormalities as well as functional impairments of the pancreas. The most exact method for diagnosing CP is histologic evaluation of the gland, but this method is rarely used in clinical practice, given the gland's retroperitoneal location and the risks involved in the procedure. Because alcohol is the most common etiology of CP, most studies have based their data on the clinical presentation of alcohol-related CP. Abdominal pain is the most common initial symptom, but it may be absent in up to 15% of patients with alcohol-related CP and in up to 23% of patients with nonalcoholic CP. Steatorrhea is a later symptom because 90% of exocrine function must be lost before steatorrhea develops. Patients can have symptoms of bloating discomfort, abdominal pain, or a change in bowel habits when 60% to 90% of pancreatic function is lost.

CP is a dynamic disease characterized by a progressive loss of pancreatic parenchyma caused by inflammation and tissue destruction and subsequent synthesis of fibrotic tissue (Braganza et al, 1982; DiMagno et al, 1973; Lankisch, 1993; Malfertheiner & Büchler, 1989). According to Amman, the course of the disease can be classified in three distinct stages (Table 55A.2). *Stage A* is the early stage, characterized by recurrent acute attacks, without any or with only mild impairment of pancreatic function. *Stage B* comes later in the course of the disease, when complications are seen—pseudocysts, cholestasis, segmental portal hypertension—along with increasing intensity of pain, more frequent acute painful attacks, and significantly impaired pancreatic function. *Stage C* represents end-stage disease, characterized by less frequent episodes and less intense pain but with marked impairment of endocrine and exocrine pancreatic function ("burnout").

In all stages of the disease, clinical symptoms, such as pain, weight loss, steatorrhea, diabetes mellitus, and local complications, can be observed in various combinations and degrees. Abdominal pain is usually located in the epigastrium and radiates to the back. Weight loss is due to two factors: at first, patients fear eating because of the accompanying pain, whereas later in the disease process, weight loss occurs as a result malabsorption related to pancreatic insufficiency (Mahlke et al, 2005). Close correlation between morphologic changes and impairment of pancreatic function is demonstrated in late stages of the disease, but in the early course of CP, no correlation is seen between morphologic changes and pancreatic function (Antman et al, 1994). In various stages of the disease,

Table 55A.2

Stages of Chronic Pancreatitis: Typical Clinical and Morphologic Pictures, Pancreatic Function, and Recommended Diagnostic Procedures

	CLINICAL PICTURE				
Stage	**Pain**	**Complications**	**Morphology**	**Pancreatic Function**	**Diagnostics**
Early	Recurrent acute attacks	No complications	Morphologic changes detectable with imaging procedures directed to pancreatic parenchyma and ductal system	Normal pancreatic endocrine and exocrine function	EUS, ERP/MRP, CT, secretin
Moderate	Increasing number of attacks and increased intensity	Pseudocysts, cholestasis, segmental portal hypertension	Progredient morphologic changes detectable in several imaging procedures	Impairment of pancreatic function in several degrees, but rarely steatorrhea	Transabdominal US, ERP/MRP, EUS, CT, fasting blood glucose, oral glucose tolerance test
Advanced	Decreasing pain ("burnout" of the pancreas)	Pseudocysts, cholestasis, segmental portal hypertension	Calculi	Marked impairment of pancreatic function, more often steatorrhea than in other stages; diabetes mellitus	Transabdominal US, ERP/MRP, CT, FE-1, fasting blood glucose, oral glucose tolerance test

CT, computed tomography; ERP, endoscopic retrograde pancreatography; EUS, endoscopic ultrasound; FE-1, fecal elastase-1; MRP, magnetic resonance pancreatography

different morphologic examinations and function tests are necessary to establish the diagnosis of CP (Glasbrenner et al, 1997). In all cases, a complete staging of the disease is only possible by the assessment of the clinical setting and evaluation of morphologic changes and functional impairment. For patients presenting with advanced CP after lifelong alcohol abuse, staging is not difficult; most patients are initially seen in earlier stages of the disease, and the diagnosis of CP in these cases is challenging. Idiopathic CP is diagnosed by exclusion of known causes of CP, including nutritional or hereditary causes, hypercalcemia, trauma with residual duct injury, hyperlipidemia, autoimmunity, pancreas divisum, ampullary and duodenal diseases that cause obstructive CP, and primary pancreatic tumors that cause obstructive pancreatitis.

Two scoring systems are widely used for aiding in the diagnosis of CP: the Luneburg and Mayo Clinic scores. The Luneburg score appears to provide a more complete evaluation than the Mayo score, because it includes more aspects, such as US, EUS, CT, and indirect pancreatic function tests (Mahlke et al, 2005).

Imaging Methods

Noninvasive imaging methods are preferred for diagnosing CP in most cases (Malfertheiner & Büchler, 1989). Sensitivity and specificity of different imaging methods vary significantly, depending on the imaging modality used, the stage of the disease, and the experience of the investigator. ERP is still the gold standard among all imaging methods, but in the future, it may be replaced by other methods, such as EUS (see Chapter 14), or after a further significant refinement by magnetic resonance cholangiography (MRC; see Chapter 17).

Plain Abdominal Radiographs

Although plain abdominal radiographs cannot exclude the diagnosis, the presence of focal or diffuse pancreatic calcification, seen in 30% to 40% of cases, makes the diagnosis of advanced CP almost certain and in most cases obviates the need for additional testing. However, calcification is not always found in early CP. In addition, the clinician must be certain that the calcifications are within the pancreas, that they do not simply represent vascular calcifications, and that they are not associated with neoplasms.

Transabdominal Ultrasonography (See Chapter 13)

Transabdominal ultrasonography (US) is an essential tool to visualize the entire pancreas. It is useful for the detection of calcifications and pseudocysts (Figs. 55A.1 to 55A.4). It is inexpensive, simple, noninvasive, widely distributed, well tolerated, and therefore often the first imaging method in patients with abdominal complaints. The sensitivity of US to detect CP is low: it varies from 48% to 96% and increases in advanced stages of CP; the specificity is described between 75% and 90% (Bolondi et al, 1987, 1989b; Freeny & Lawson, 1982; Hessel et al, 1982; Table 55A.3). If US detects changes of CP,

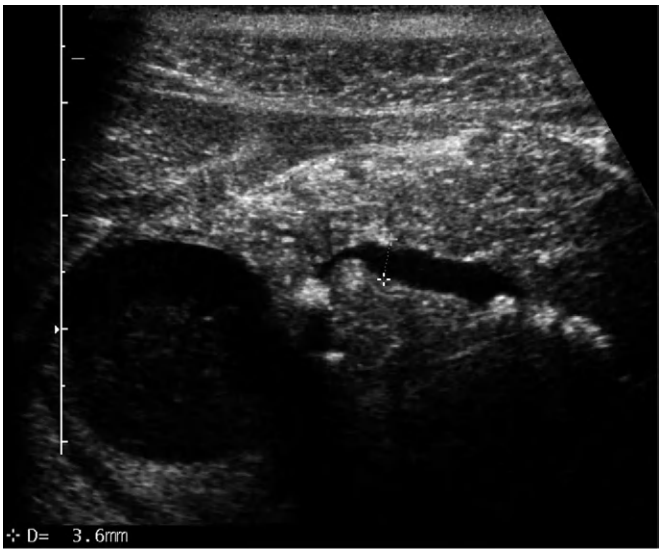

FIGURE 55A.1. Transabdominal ultrasound showing typical changes of chronic pancreatitis. Note the multiple intrapancreatic calcifications and the dilated pancreatic duct. A large pseudocyst is also present in the region of the head of the pancreas.

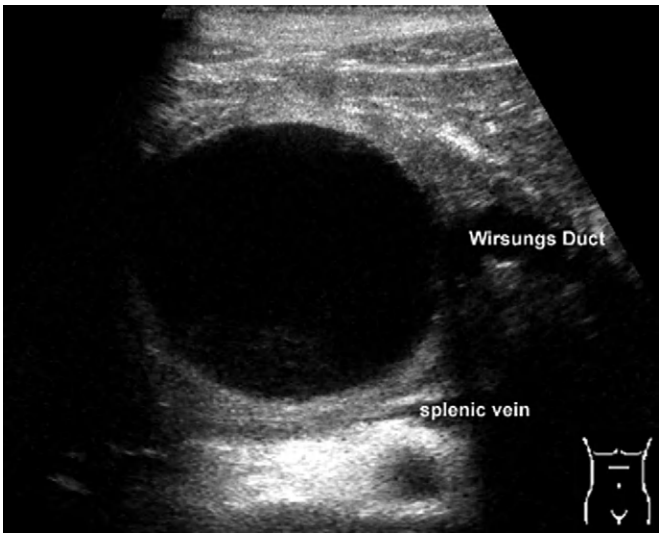

FIGURE 55A.2. Ultrasound showing a large solitary pancreatic pseudocyst complicating chronic pancreatitis.

diagnosis is certain (high specificity), but if the pancreas is not completely visualized or appears normal, further examinations are necessary (low sensitivity). US is the easiest method to detect complications of CP and to follow up patients with CP. The major disadvantage of US is the difficult examination based on poor visualization of the pancreas, mainly because of overlying gas-filled bowel loops and technical and operator-dependent factors, such as experience of the operator and the stage of disease. Reliance on US for the diagnosis of CP is therefore limited to advanced stages (see Fig. 55A.2). Diagnostic criteria for the diagnosis of CP by transabdominal US are 1) irregular contour (lobulation), 2) pancreatic duct dilation and irregularity of the main pancreatic duct, 3) loss or reduction of pancreatic parenchyma echogenicity (echo-poor or echo-rich areas), 4) cysts or cavities, and 5) calcifications (Alpern et al, 1985; Niederau & Grendell, 1985).

FIGURE 55A.3. Ultrasound of a cystlike structure in the pancreas in a 56-year-old woman with chronic pancreatitis and sudden anemia without evidence of gastrointestinal blood loss. This pseudoaneurysm is one of the most dreadful complications of chronic pancreatitis.

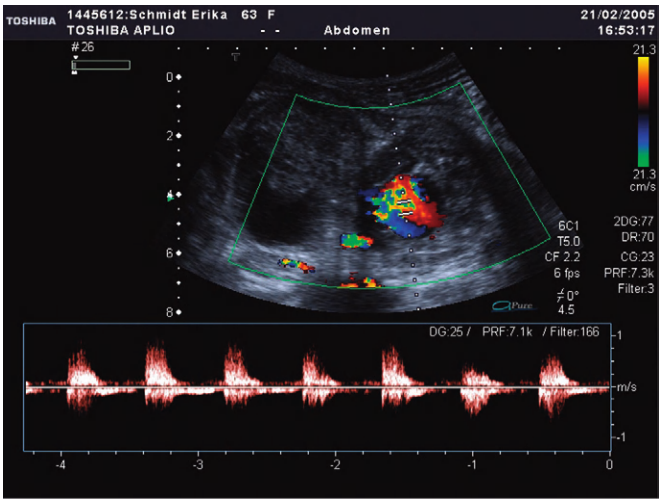

FIGURE 55A.4. Ultrasound with Doppler flow studies demonstrating blood flow inside a pseudocyst-like structure. This study confirmed the presence of a pseudoaneurysm. The patient underwent percutaneous angiographic therapy with release of an endocoil, which completely obliterated blood flow to the aneurysm, therefore averting its rupture.

Computed Tomography (See Chapter 16)

CT findings of CP include pancreatic duct dilatation, calcifications, and cystic lesions (Fig. 55A.5). Other significant findings include heterogeneous density of the pancreatic gland with atrophy or enlargement. CT is as specific as US but is more sensitive (80%). Early parenchymal changes and effects on small pancreatic ducts cannot be detected by CT, but advanced stages and complications of the disease can be evaluated with high reliability. After oral and intravenous administration of contrast medium, the pancreas can be completely visualized with spiral CT and an optimal scanning technique using a slice thickness of 5 mm (Lieb & Dragonov, 2008). In this technical setting, CT is the most sensitive method to detect calculi. Dilation of the main pancreatic duct is visualized with high sensitivity, whereas side branches are only detectable in advanced stages of the disease. CT is an excellent method to detect advanced stages, but discrete changes of the early stages of CP can be easily missed. In summary, CT shows a sensitivity of 56% to 95% with a specificity of 85% to 100% (Robinson & Sheridan, 2000; Lieb & Dragonov, 2008) (see Table 55A.3).

Endoscopic Retrograde Pancreatography (See Chapter 18)

Endoscopic retrograde pancreatography (ERP) is the gold standard among all imaging methods for diagnosis and staging of CP, because it has 90% sensitivity and 100% specificity in

Table 55A.3

Sensitivity and Specificity of Imaging Methods

	Sensitivity (%)	Specificity (%)
Transabdominal ultrasound	48-96	75-90
Computed tomography	56-95	85-100

diagnosis (Axon et al, 1984; Forsmark & Toskes, 1984). An ERP staging system based on pancreatic ductal changes has been developed for the diagnosis of CP, and international definitions are based on ERP findings published in 1984 as the Cambridge criteria (Table 55A.4; Axon et al, 1984). Nevertheless, it is important to mention that changes of early CP may not be seen on ERP, which may assess ductal changes that occur in advanced CP, such as irregularity, dilation, tortuosity, stenosis, cysts, and calculi (see Fig. 55A.5). These findings may culminate in a "chain of lakes" appearance in the main pancreatic duct with intermittent points of obstruction in a dilated pancreatic duct (Figs. 55A.6 and 55A.7). In large multicenter trials, the sensitivity of ERP was described to be 68% to 100%, with a specificity of 89% to 100% (Braganza et al, 1982; Malfertheiner & Büchler, 1989; Sica et al, 1999).

It must be kept in mind, however, that ERP is an invasive method with a low but important rate of post-ERP pancreatitis in 3% to 7% (Sherman & Lehman, 1993). For successful ERP, specially trained personnel are necessary to perform the procedure and to interpret the pancreatograms. In special cases, typical changes of CP detected by ERP are not pathognomonic for CP: in patients examined early after AP, ductal changes might be reversible; in patients older than 65 years, these changes can be obvious without having CP (Lieb & Dragonov, 2008). In general, correlation is good between the changes observed on ERP and results of a secretin stimulation test. ERP may also be useful in distinguishing CP from pancreatic cancer. A dominant stricture as opposed to ductular ectasia—with multiple stenosis, irregular branching ducts, and intraductal calculi—is highly suggestive of pancreatic cancer rahter than CP.

Abnormal pancreatograms in patients with upper abdominal pain should not always lead to a diagnosis of CP. Occasionally, patients have suffered a previous episode of acute pancreatitis that resulted in fibrotic damage to the pancreatic duct. In these patients, it is likely that the pancreatic changes are from the initial acute inflammatory episode, and they do not have CP (Mahlke et al, 2005).

In summary, the advantages of using ERP for the diagnosis of CP are standardization, evaluation of the method in multicenter trials with large patient groups, and the possibility of

Table 55A.4

Cambridge Criteria of Chronic Pancreatitis

Stage	Typical Changes
Normal	Normal appearance of side branches and main pancreatic duct
Equivocal	Dilation or obstruction of less than three side branches; normal main pancreatic duct
Mild	Dilation or obstruction of more than three side branches; normal main pancreatic duct
Moderate	Additional stenosis and dilatation of main pancreatic duct
Severe	Additional obstructions, cysts, and stenosis of main pancreatic duct; calculi

Endoscopic Ultrasound Criteria of Chronic Pancreatitis

Parenchymal Features
Gland size, cysts
Echo-poor lesions (focal areas of reduced echogenicity)
Echo-rich lesions >3 mm in diameter
Accentuation of lobular pattern
Ductal Features
Increased duct wall echogenicity
Narrowing or dilation (main pancreatic duct, side branches)
Calculi

From Wiersema MJ, et al, 1993: Prospective evaluation of endoscopic ultrasonography and endoscopic retrograde cholangiopancreatography in patients with chronic abdominal pain of suspected pancreatic origin. Endoscopy 25(9):555-564.

interventions. The disadvantages are complications, costs, and invasiveness.

Endoscopic Ultrasonography

Endoscopic ultrasonography (EUS) visualizes both the pancreatic ducts and the parenchyma (see Chapter 14; Nattermann et al, 1993, 1995; Tenner et al, 1997; Vazquez & Wiersema, 2000; Wiersema et al, 1993). Wiersema and colleagues (1993) described diagnostic criteria of CP detectable by EUS (Stevens & Parsi, 2011; Table 55A.5). These Milwaukee criteria were further refined with the Rosemont classification (Catalano et al, 2009). Parenchymal and ductal changes were divided into major and minor criteria, based on their importance. To diagnose CP based on the Rosemont classification criteria, a sum score consisting of different major and minor changes must be calculated. The advantage of this classification system, compared with further descriptions, is to support the endosonographer with weighted criteria.

In contrast to other imaging methods, which detect CP only in its advanced stages, EUS has the ability to detect CP in patients with early stages of the disease as well as in those with advanced CP (Wiersema et al, 1993; Mönkemüller et al, 2004). EUS features of CP include ductal and parenchymal changes,

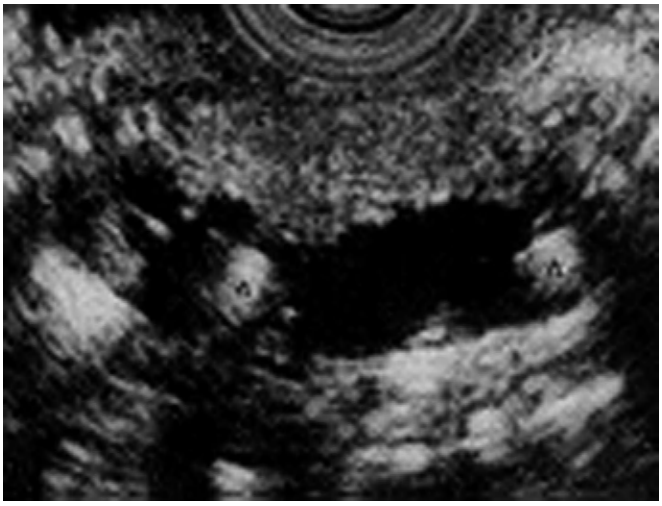

FIGURE 55A.8. Endoscopic ultrasound in 54-year-old patient with chronic pancreatitis as a result of alcohol abuse. Note the marked dilation of the pancreatic duct, with its echo-rich changes and calcifications.

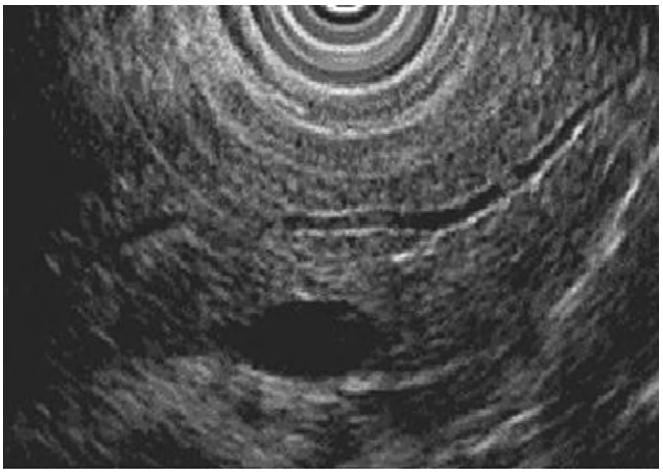

FIGURE 55A.9. EUS in a 48-year-old female with idiopathic pancreatitis. Note the echo-rich changes of the pancreatic duct, which is not pathologically dilated. This EUS is characteristic for early changes of chronic pancreatitis.

such as echotexture of the gland, calcification, lobulation, and bands of fibrosis (Figs. 55A.8 and 55A.9). A prospective evaluation comparing EUS with ERP and a secretin stimulation test in the diagnosis of CP showed good correlation in normal subjects and in patients with moderate disease, showing three or four features, or severe disease, in which more than five features are evident. The agreement was poor for mild EUS changes (one to two features) compared with ERP and a secretin stimulation test; moderate EUS criteria for CP also correlated poorly with secretin test results but had a 92% concordance with ERP in moderate disease. In summary, compared with ERP, EUS is accurate and at least as sensitive for detection of moderate to severe CP.

In early stages of CP, EUS has a number of advantages compared with other imaging modalities. In a series of patients with a history of chronic alcohol abuse and recurrent abdominal pain with normal ERP, we detected typical changes of CP by EUS. These patients were included in a follow-up program. After a median follow-up of 18 months, we detected typical changes of CP by repeat ERP in 68.8% of patients initially presenting with normal ERP but who showed typical changes of CP on EUS. Our conclusion is that EUS has a higher sensitivity to detect CP compared with ERP in a typical clinical and patient history setting (Kahl et al, 2002). The disadvantage of this method is the need for expert EUS endoscopists and a dedicated EUS unit. The advantages of EUS are the reliable visualization of the pancreatic parenchyma and ductal system without any risk for pancreatitis.

Magnetic Resonance Pancreatography (See Chapter 17)

Combining magnetic resonance tomography (MRT) and magnetic resonance pancreatography (MRP) provides an imaging method that allows visualization of the ductal and parenchymal changes of CP. Hardware and software for MRT and MRP are under ongoing, intensive development. Several possibilities of this method have been developed but have yet to be evaluated in patients with inflammatory pancreatic diseases. The major disadvantage is that changes of side branches are not visualized with the same accuracy as in ERP, therefore MRP is not sensitive enough to detect early stages of CP. The future benefit of MRP in patients with CP will depend on patient selection.

Table 55A.6

Sensitivity and Specificity of Imaging Methods and Tests of Exocrine Pancreatic Function

	Sensitivity (%)	Specificity (%)
Invasive Tests		
Spiral computed tomography	≥90-100	>90
Noninvasive Tests		
Pancreolauryl	70-85	75
Fecal elastase-1	35-85	83

Tests of Exocrine Pancreatic Function

Today, function tests play only a minor, complementary role in the diagnosis of CP. The two main reasons are that noninvasive tests of exocrine pancreatic function show high sensitivity only in advanced stages of CP (Glasbrenner et al, 1997; Lankisch, 2000; Leodolter et al, 2000) and any clinical manifestation of an exocrine pancreatic insufficiency occurs late in the course of the disease, after approximately 90% of the exocrine parenchyma has been destroyed (DiMagno et al, 1973). The two types of function tests are *direct* (invasive) and *indirect* (noninvasive) (Table 55A.6; Mahlke et al, 2005). Nevertheless, one of the most sensitive tests to detect exocrine insufficiency is an invasive test, which requires duodenal intubation and aspiration of duodenal juice after pancreatic stimulation. Only this test is able to detect functional impairment in early stages of CP (Malfertheiner & Büchler, 1989), but invasive tests are time consuming, expensive, and require additional manpower and technical equipment to provide little information that is of use in the clinical routine. Therefore such tests are only used in specialized centers or to answer scientific questions. For clinical decision making, such as that regarding enzyme supplementation, pancreatic function tests can provide important information and can allow follow-up of patients with CP (Malfertheiner & Büchler, 1989). In clinical routine today, noninvasive tests, such as the pancreolauryl test and determination of fecal elastase-1 (FE-1) play a more relevant role. With the exception of secretin cerulein test function, tests of exocrine pancreatic function do not play any role in the initial diagnosis of CP because of their decreased sensitivity to detect early functional impairment (see Table 55A.6).

Invasive Function Tests

Duodenal intubation to measure pancreatic juice production after humoral stimulation of the pancreas (secretin-cerulein test, Lundh test) is the only test able to detect functional impairment in all stages of disease (Mahlke et al, 2005). Even though this test has some limitations, it is considered the gold standard in the evaluation of exocrine pancreatic function, because of its acceptable sensitivity and specificity (75% to 95%; see Table 55A.5). The secretin stimulation test, with or without concomitant cholecystokinin (CCK 8) or cerulein administration, measures the volume of secretion and the concentration of output of bicarbonate and pancreatic enzymes via aspiration of duodenal contents in response to injection of secretin. Bicarbonate levels less than 50 mEq/L are consistent with CP; levels greater than 50 mEq/L but less than 75 mEq/L are normal. The disadvantages of this test are its invasiveness, as it requires duodenal tube insertion for collection of secretions. False-positive results may be associated with primary diabetes mellitus, Billroth II gastrectomy, celiac sprue, and cirrhosis.

Until recently, standardization of the secretin-cerulein test has not been done. Most of the investigators use a maximal stimulation of the pancreas with CCK 8 or cerulein, which leads to maximal pancreatic stimulation and output over 60 to 90 minutes (Lankisch, 1993). Direct function tests are not widely employed in clinical routine despite the fact that the costs and time involved in their performance are similar or less than imaging tests such as ERCP, MRCP, or CT (Mahlke et al, 2005).

Noninvasive Function Tests

In contrast to invasive tests, noninvasive pancreatic function tests are more applicable in clinical routine. Most indirect tests of pancreatic function measure the absorption of some compound that first requires digestion by pancreatic enzymes, thereby indirectly assessing pancreatic function. These tests have the disadvantage of a lesser sensitivity in early stages of the disease. The diagnostic accuracy increases slightly when mild to moderate disease is present.

The pancreatolauryl and bentiromide tests are only of historical interest because neither is currently available or useful for clinical practice (Malfertheiner et al, 1987a, 1987b; Dominguez-Munoz & Mlafertheiner, 1998). The only noninvasive function tests that play a potential role in the evaluation of chronic pancreatitis are stool tests, such as measurement of fat and/or pancreas elastase, and the mixed trigylceride C breath test.

Measurement of stool quantity and weight over a period of 72 hours has been considered essential for the diagnosis of CP with malabsorption, but this complicated and malaodorous process has not gained popularity in clinical routine (Mahlke et al, 2005). Stool tests for the quantification of fat (with subsequent correction after pancreatic enzyme replacement), chymotrypsin, and FE-1 have been well studied. Today, evaluation of stool fat plays no further role in the diagnosis of CP, because fat malabsorption occurs only in later stages, after more than 90% of the exocrine pancreatic parenchyma has been destroyed (DiMagno et al, 1973). Therefore only a minority of patients will have significant steatorrhea even with marked exocrine insufficiency (DiMagno et al, 1973). Two stool tests are commercially available for use in clinical routine: chymotrypsin (Immunodiagnostik AG, Bensheim, Germany), and Elastase-1 (ScheBo Biotech, Wettenberg, Germany, and BioServ Diagnostics, Rostock, Germany). Measurement of fecal chymotrypsin is still popular today, but the diagnostic accuracy of this test is not acceptable. Before performing this test, it is important to discontinue pancreatic enzyme supplement therapy. The best accuracy among all stool tests is obtained by measurement of FE-1. Besides high stability of pancreatic elastase during passage throughout the intestine, the commercial test measures only human elastase. This is of advantage in cases of therapeutic oral enzyme supplementation, because this lipase is of porcine origin. Even if FE-1 measurement is superior to other stool tests, its diagnostic value should not be overrated; sensitivity and specificity are low in early stages of the disease, with only mild to moderate exocrine insufficiency (Lankisch et al, 1998; Leodolter et al, 2000).

The ^{13}C breath tests are based on the fact that, after oral administration, the ^{13}C-marked substrates are cleaved by

specific pancreatic enzymes. Exhalation of $^{13}CO_2$ can then be measured and indirectly reveals exocrine pancreatic function. Several tests are available to detect different pancreatic enzyme systems. Lipase activity is detected by ^{13}C mixed-triglyceride breath tests or triolein breath tests, a ^{13}C-cholesteryl-octanoate breath test detects pancreatic cholesterol-esterase, and a ^{13}C-starch breath test is directed to amylase activity. All these tests are mainly used under research conditions in scientific laboratories and currently do not play any role in the clinical management of CP; they are expensive and have been neither standardized nor sufficiently evaluated. Tests able to detect specific pancreatic enzymes secreted in amounts lower than amylase or lipase would be useful in the future.

Endocrine Pancreatic Function

For clinical decision making, the differentiation between normal endocrine function, impaired oral glucose tolerance, and overt diabetes mellitus is sufficient. This differentiation succeeds with determination of fasting blood glucose level and, if normal, with an oral glucose tolerance test (Glasbrenner et al, 1997).

SECTION II Neoplastic

A. General

CHAPTER 56

Pancreatic and periampullary tumors: classification and pathologic features

N. Volkan Adsay and David S. Klimstra

TUMORS OF THE PANCREAS

Pancreatic neoplasms are classified based on the degree to which they recapitulate one of the cellular components of the pancreas (Hruban et al, 2007; Klimstra & Adsay, 2009; Klimstra et al, 2007b). To appreciate the various tumor types that occur in the pancreas, basic functional and histomorphologic characteristics of the elements that constitute this gland, both neuroendocrine and exocrine, must be recognized. The neuroendocrine component consists of the islets of Langerhans, small nests of up to a few hundred cells, scattered throughout the pancreas, usually forming round, well-delineated units amid the exocrine elements. Islet cells synthesize hormones (i.e., insulin, glucagon, and somatostatin) and store them in neurosecretory granules; under appropriate stimuli, these hormones are released into the surrounding capillary network. Pancreatic neoplasms that recapitulate the islet cells were previously referred to as *islet cell tumors* but are now called *pancreatic neuroendocrine tumors* (PanNETs; see Chapter 61).

Pancreatic acini—which are responsible for the production of digestive enzymes such as amylase, lipase, trypsin, and others—constitute most of the organ, and acinar neoplasms are uncommon. Acinar cells are arranged in small, rosette-like clusters packed back to back to form compact lobules separated by thin, fibrous septa. To achieve their laborious secretory activity, acinar cells have abundant rough endoplasmic reticulum. The enzymes produced here are transferred to the zymogen granules concentrated in the apical cytoplasm, ready to be secreted into the ductal system.

The ductal component of the pancreas is responsible for most of the neoplasms (see Chapter 58), but it is perhaps the least sophisticated. Ducts are responsible for transporting the acinar secretions to the duodenum. The ductal system starts with the centroacinar cells, and through intralobar and interlobar ducts, the enzymatic secretions are carried to the main pancreatic duct and eventually to the duodenum through the ampulla of Vater. The larger ducts produce and secrete mucins for lubrication and protection, to aid the passage of acinar products, and to create the proper milieu for the enzymes during transportation. However, intracellular mucin is not normally detectable in cells of the interlobular or smaller ducts. Recapitulating the normal ducts, ductal neoplasms are characterized by gland, duct, or cyst formation with or without papillary structures. Production of variable amounts of mucin is also typical and ranges from focal intracellular to abundant intracystic or stromal. As in any organ of the body, supportive tissues (mesenchymal elements) and neighboring organs may also give rise to tumors in the pancreas, although these are very rare. This section reviews the general characteristics of pancreatic neoplasms.

Invasive Ductal Adenocarcinoma

Invasive ductal adenocarcinoma is the most common neoplasm of the pancreas. Its clinical characteristics are discussed in detail elsewhere in this text (see Chapter 58). Most are solid, ill-defined masses; conversely, most solid, ill-defined lesions in the pancreas also prove to be ductal adenocarcinoma. Ductal adenocarcinomas have a remarkable tendency for rapid dissemination and insidious infiltration. Typically, it spreads in the abdomen in a multinodular fashion (intraabdominal carcinomatosis) or is already widely metastatic by the time the primary tumor grows to 5 to 6 cm in size. This feature is so characteristic that a larger solitary pancreatic mass is unlikely to be ductal adenocarcinoma. Interestingly, however, despite the high frequency of distant metastases, some ductal carcinomas cause

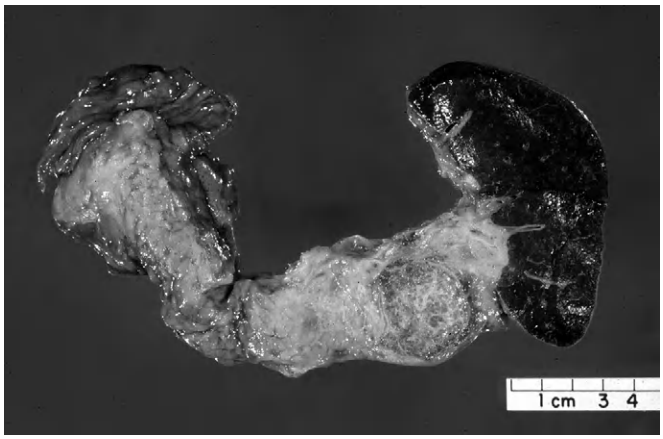

FIGURE 56.1. Ductal adenocarcinoma, gross appearance at autopsy. The solid tumor diffusely involves the pancreatic tail with extension into splenic hilar soft tissues. The periphery of the tumor is poorly defined.

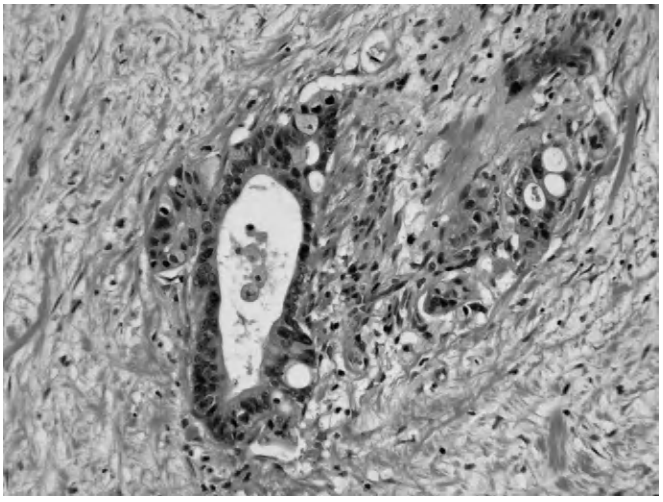

FIGURE 56.2. Infiltrating ductal adenocarcinoma. The tumor is composed of well-formed glands, individual cells, and small, solid cellular clusters. Desmoplastic stroma is abundant.

death of the patient as a result of predominantly local extension; such cases appear to be molecularly distinctive.

Macroscopically, ductal adenocarcinoma is a scirrhous (scar-forming) type of carcinoma; it is associated with abundant desmoplastic stroma, in which the neoplastic glands are widely scattered. This creates a challenge in the diagnosis of ductal adenocarcinoma, because often only a few cancer cells are present, if any, for evaluation in biopsy specimens. This is also a problem for cancer researchers, because most procured "tumor" specimens may in fact contain much more host tissue than carcinoma cells. Also, because ductal adenocarcinoma is typically very sclerotic, it can be difficult to distinguish from fibrosis of chronic pancreatitis, not only radiologically and intraoperatively but also for pathologists examining the gross specimen. The characteristics that distinguish ductal adenocarcinoma are its firm, gray, and gritty cut surface rather than the rubbery, milky white appearance of benign fibrotic lesions (Fig. 56.1).

Most ductal adenocarcinomas are located in the head of the pancreas and infiltrate the neighboring structures, especially the common bile duct, and obstructive jaundice is a common finding at presentation. For this reason, it is often difficult to distinguish pancreatic carcinoma from a carcinoma of the distal common bile duct, especially given that the two are microscopically similar. Some pancreatic ductal adenocarcinomas infiltrate and ulcerate the duodenum or ampulla of Vater and may mimic a primary duodenal or ampullary neoplasm, and the classification of such cases may have to be based on arbitrary criteria such as the epicenter of the mass.

Microscopically, ductal adenocarcinoma is characterized by infiltrating tubular glands, often widely scattered, embedded in a desmoplastic stroma of variable cellularity (Fig. 56.2). The ducts are lined by cuboidal to columnar cells, with variable amounts of intracellular mucin and nuclear atypia (Klimstra & Adsay, 2009). The columnar cells may form cords or nests, or they may grow as individual cells. Perineural invasion is present in more than 60% of cases and is often identifiable in the retroperitoneal region or around the common bile duct, even away from the grossly evident tumor (Fig. 56.3). Neoadjuvant therapy seems to cause substantial alterations in the morphology of the tumor cells. Also, residual foci of previously treated ductal adenocarcinoma may be patchy and may require more careful examination. Recently, scoring systems have been devised in an attempt to evaluate the efficacy of chemotherapy; however, the relevance of these proposals requires further study.

The difficulty in distinguishing ductal adenocarcinoma from chronic pancreatitis (see Chapter 55) also applies to the microscopic diagnosis and is regarded to be one of the most difficult distinctions in diagnostic pathology (Adsay et al, 2004a). Chronic pancreatitis may be associated with epithelial atypia, both architectural and cytologic, in pancreatic tissue; conversely, ductal adenocarcinoma is notorious for its deceptively bland appearance. Features favoring a malignant diagnosis include abnormal location of glands (adjacent to muscular arteries, within the duodenal muscularis, adjacent to adipocytes in the peripancreatic tissue, or around nerves), architectural abnormalities in the shape of the glands (cribriforming, angulation, or incomplete gland formation), and nuclear

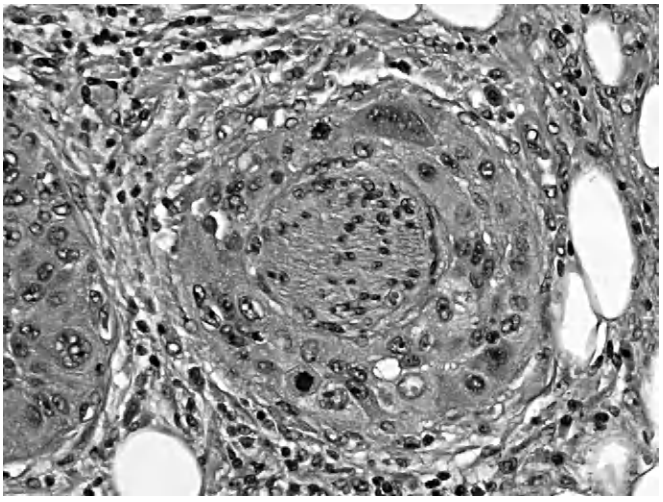

FIGURE 56.3. Infiltrating ductal adenocarcinoma with perineural invasion. The poorly differentiated adenocarcinoma cells completely encircle a small nerve.

abnormalities (variation in the shape and size of nuclei among the cells within an individual gland). A fourfold variation in nuclear volume between adjacent cells, otherwise known as the *4-to-1 rule,* is helpful to recognize carcinoma. Diagnostic difficulty also extends to the differential diagnosis of ductal adenocarcinoma in metastatic sites, because ductal adenocarcinoma often retains its well-differentiated appearance and mimics benign or low-grade neoplasms of these sites. Common pitfalls include misinterpretation of metastatic ductal adenocarcinoma in the ovary as a primary borderline ovarian cystadenoma (Young, 2007); in the lung, as bronchioloalveolar carcinoma; and in the liver, as bile duct adenoma. In the last instance, the converse—misinterpretation of bile duct adenoma as metastatic ductal adenocarcinoma—seems to be more common.

No uniformly applied pathologic grading system exists for ductal adenocarcinoma. Schemes advocated by Western and Asian experts show major philosophical differences in principle and results. The current American Joint Commission on Cancer–endorsed tumor-node-metastasis (TNM) grading system (Edge et al, 2010) is similar to the grading of other adenocarcinomas of the gastrointestinal (GI) tract: *well differentiated* means 95% or more composed of glandular structures; *moderately differentiated,* 50% to 95% glandular in pattern, the remainder occurring as solid nests or individual cells; and *poorly differentiated,* with more than 50% solid nest and individual cells. The World Health Organization (WHO) has adopted the complex grading scheme proposed by Klöppel and colleagues, which is difficult to employ and not widely used in daily practice (Fukushima, 2010). Intratumoral heterogeneity seems to be an important problem in the grading of ductal adenocarcinoma, and for this reason, a simpler, more practical, and more clinically relevant grading scheme that accounts for this heterogeneity by scoring the patterns of infiltration has been proposed (Adsay et al, 2005).

The pathologic evaluation of a pancreatectomy specimen is important both for staging and in determining the adequacy of resection (Lüttges et al, 1998; see Chapter 58). Extrapancreatic extension and involvement of neighboring organs are documented in the pathology report, and determination of tumor size is important. As stated earlier, it is often difficult to appreciate the boundaries of ductal adenocarcinomas; careful macroscopic examination and close correlation with the microscopic findings are necessary to establish the correct size of the tumor. Microscopic foci of carcinoma are often present within the pancreas distant from the main tumor (Bandyopadhyay et al, 2009). Metastasis to lymph nodes is considered one of the most important predictors of outcome in resected ductal adenocarcinomas. Generally, at least 12 lymph nodes should be identified in a simple pancreatoduodenectomy specimen (Adsay et al, 2009). Most of these lymph nodes are embedded in the surfaces of the pancreas or in the groove between the pancreas and duodenum.

Proper identification of margins and their adequate sampling also are important components in the pathologic evaluation of a pancreatoduodenectomy specimen (Ferrone et al, 2008). For pancreatic ductal adenocarcinoma, the most important margin seems to be the retroperitoneal margin, also termed the *uncinate, superior mesenteric vein,* or *vascular margin* (Staley et al, 1996; Lüttges et al, 1998). The retroperitoneal margin at the posteroinferior aspect of the head of the pancreas can be distinguished by its nodular, granular, and irregular appearance, with the vascular bed of the superior mesenteric vessels appearing as a groove to its left. Studies have shown that the retroperitoneal margin should be sampled thoroughly, because this margin is often microscopically positive for grossly undetectable disease. Common bile duct, distal pancreatic (pancreatic ductal), and GI mucosal margins also should be evaluated.

As expected, ductal adenocarcinoma shows immunohistochemical evidence of ductal differentiation. Mucin-related glycoproteins and oncoproteins, including carbohydrate antigen 19-9 (CA19-9), carcinoembryonic antigen (CEA), B72.3, DUPAN2, MUC1, and MUC5AC are commonly detected in ductal adenocarcinoma (Basturk et al, 2010b; Hruban et al, 2007; Klimstra, 1998). Expression of these and the differential labeling for cytokeratins (CK7 positive, CK20 variable) sometimes may help distinguish ductal adenocarcinoma from other carcinomas, although no profile of immunohistochemical markers is specific for ductal adenocarcinoma. Scattered cells with neuroendocrine differentiation may be present, and acinar enzymes typically are not expressed.

Substantial developments have occurred in understanding the molecular carcinogenesis of ductal adenocarcinoma (see Chapter 8A). Mutation in codon 12 of the *KRAS* oncogene is found in more than 90% of ductal adenocarcinoma and seems to be an early event (Hruban & Adsay, 2009). Mutation of *P16* or methylation of the promoter also is common (>80%) and represents the pathogenetic link with the familial atypical multiple mole–melanoma syndrome (Hruban et al, 2001a). Overexpression of *TP53* (Barton et al, 1991; Hameed et al, 1994) and loss of *SMAD4*/*DPC4* are detected in about half of cases (Tascilar et al, 2001). The latter appears to have a modest degree of specificity for pancreatic ductal adenocarcinoma. Immunohistochemical demonstration of these abnormalities may be useful in the diagnosis of carcinoma (Fig. 56.4). *BRCA2* and Peutz-Jeghers gene mutations have been implicated in about 5% of ductal adenocarcinoma cases (Hruban & Adsay, 2009). Fanconi anemia gene alterations also have been identified (van der Heijden et al, 2003). Abnormalities in mismatch repair proteins and microsatellite instability are uncommon, although pancreatic ductal adenocarcinomas can occur as one of the less common manifestations of Lynch syndrome.

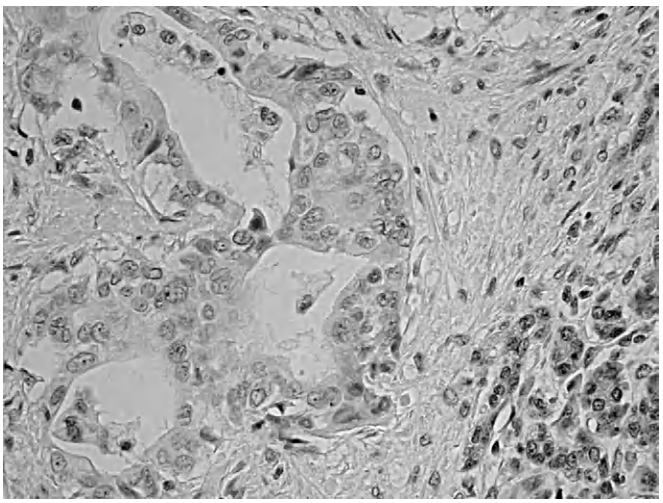

FIGURE 56.4. Infiltrating ductal adenocarcinoma immunohistochemical staining for *SMAD4*. The neoplastic cells have completely lost immunolabeling, whereas the adjacent normal cells show nuclear and cytoplasmic positivity.

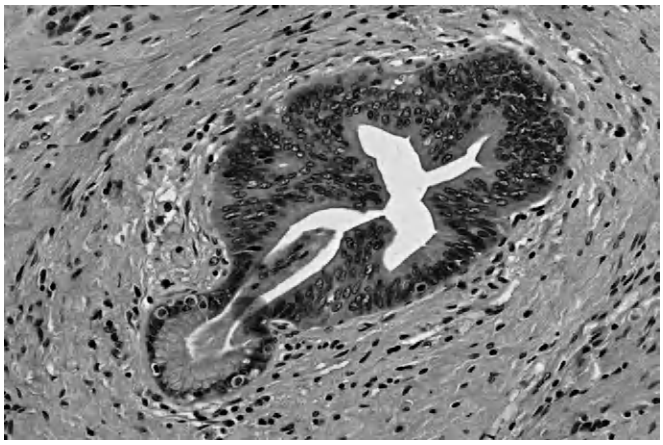

FIGURE 56.5. Pancreatic intraepithelial neoplasia. In this example (PanIN2), full-thickness nuclear pseudostratification and mild cytologic atypia are seen.

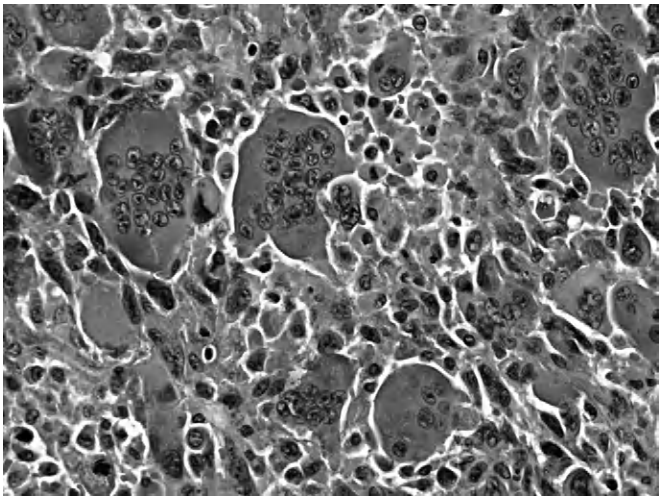

FIGURE 56.6. Undifferentiated carcinoma with osteoclast-like giant cells. Neoplastic cells are mononuclear and dyscohesive, with moderate to marked nuclear atypia. Nonneoplastic, osteoclast-like giant cells contain numerous nuclei that show more uniform cytologic features.

Pancreatic Intraepithelial Neoplasia (PanIN)

It has been speculated for decades that proliferative lesions in the ducts precede the development of invasive ductal carcinoma (Klöppel et al, 1980). These proliferations have been referred to by a plethora of terms, including *hyperplasia* and *dysplasia,* but these are now designated *pancreatic intraepithelial neoplasia* (Hruban et al, 2001b) in recognition of their neoplastic nature (Fig. 56.5). The spectrum of changes is classified in three grades (Hruban et al, 2001b). Replacement of the normal cuboidal, nonmucinous ductal epithelium with columnar cells that contain abundant apical mucin, but without architectural complexity (e.g., papilla formation) or cytologic atypia, is regarded as *PanIN1A*. Cytologically similar lesions that form papillae constitute *PanIN1B*. When a substantial pseudostratification of the cells and some degree of cytologic atypia are seen, the lesion is *PanIN2*. When irregular papillary architecture is present with tufting, cytologic atypia, necrosis, suprabasal mitoses, and loss of cell polarity, it is regarded as *PanIN3*.

A progressive accumulation of molecular alterations is reported from PanIN1 to invasive carcinoma (Hruban & Adsay, 2009). Some alterations, such as *KRAS* mutations, are early events; others, such as *TP53* overexpression, occur at the more advanced end of this spectrum. Low-grade PanINs are very common incidental findings in the normal population (Andea et al, 2003); therefore they are generally believed to not to require any further clinical attention, if encountered in isolation or at resection margins. PanIN3, on the other hand, is seldom seen in the absence of an invasive carcinoma (Andea et al, 2003), and for this reason, if PanIN3 is encountered in a pancreas, the likelihood of pancreas cancer elsewhere in the gland is very high.

Other Invasive Carcinomas Related to Ductal Adenocarcinoma

Certain types of carcinomas are closely related to, and often seen in association with, ductal adenocarcinoma (Klimstra & Adsay, 2009). *Undifferentiated carcinoma* can be regarded as the least differentiated form of ductal adenocarcinoma, in which characteristic tubule formation is no longer evident or only focal. Such tumors are rare, and their demographics do not seem to differ from ordinary ductal adenocarcinoma, except that they may have even more aggressive behavior. Undifferentiated carcinomas include sarcomatoid (spindle cell) carcinoma, anaplastic giant cell carcinoma, and carcinosarcoma. Rarely, the sarcomatoid components of these tumors may show aberrant differentiation, including bone and cartilage formation.

Also known as *osteoclastic giant cell carcinoma, undifferentiated carcinoma with osteoclast-like giant cells* is the name commonly used for a distinctive tumor type characterized by an abundance of such cells in the background of a sarcomatoid carcinoma (Fig. 56.6; Hoorens et al, 1998; Westra et al, 1998). Studies have shown that the osteoclastic giant cells are nonneoplastic histiocytic cells (Westra et al, 1998); the reasons for this chemotaxis are unknown. The true neoplastic cells in this tumor type are the sarcomatoid mononuclear cells. An adenocarcinoma component or, in some cases, high-grade PanIN or mucinous cystic neoplasm precursors may be present. Undifferentiated carcinomas with osteoclast-like giant cells often appear well demarcated and form a large solitary mass. If examined carefully, many such tumors appear to have substantial intraductal growth. These are clearly malignant neoplasms, most exhibiting an aggressive clinical course; however, some examples with minimal ductal adenocarcinoma components have a protracted clinical course.

Squamous differentiation is seen in some conventional ductal adenocarcinomas (i.e., adenosquamous carcinomas; Fig. 56.7; Kardon et al, 2001), but rare pure examples of squamous cell carcinoma without any glandular components also may be seen. They may have variable degrees of keratinization. Squamous cell carcinoma and adenosquamous carcinoma of this region are highly aggressive tumors (Kardon et al, 2001) with a prognosis that is even worse then that of ordinary ductal adenocarcinoma.

Colloid carcinoma, pure mucinous or mucinous noncystic carcinoma (Adsay et al, 2001; Hruban et al, 2007; Seidel et al, 2002), is characterized by extensive stromal mucin deposition (Fig. 56.8). Those tumors composed almost exclusively of the

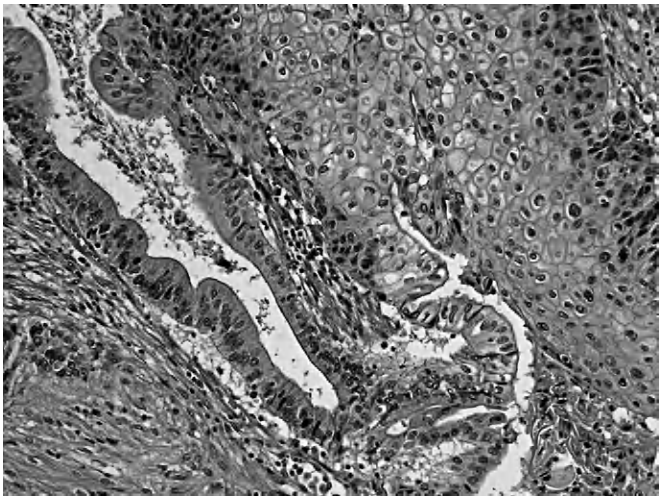

FIGURE 56.7. Adenosquamous carcinoma. Glandular differentiation and pavement-like squamous morphology are apparent.

colloid pattern—in which the mucin/epithelium ratio is very high, and most carcinoma cells are floating within the mucin (detached from the stroma)—have a different biology with an unusually protracted clinical course. Anecdotal evidence suggests that open biopsy of colloid carcinomas may contribute to dissemination, presumably owing to the adherent nature of the mucin. Colloid carcinomas also tend to be larger and better demarcated than ductal adenocarcinomas, and their molecular alterations seem to be somewhat unique. They usually are associated with intraductal papillary mucinous neoplasms (IPMNs) of the intestinal type (see Chapter 57) and also exhibit immunohistochemical evidence of intestinal differentiation (see later).

Medullary carcinomas, akin to those seen in the GI tract associated with microsatellite instability, also have been reported in the pancreas (Goggins et al, 1998; Wilentz et al, 2000). Syncytial nodules of large, poorly differentiated epithelioid cells with a pushing pattern of invasion characterize medullary carcinomas. In one study (Goggins et al, 1998), these tumors were found to have a more protracted clinical course, but further data are necessary to define the prognosis of these rare tumors.

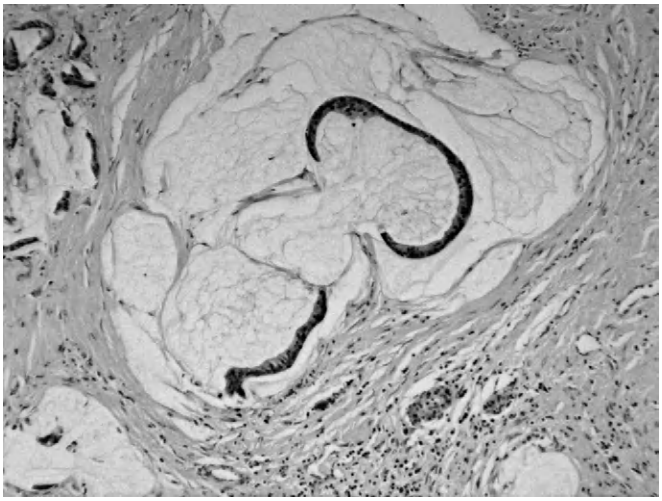

FIGURE 56.8. Colloid carcinoma. Strips of cytologically bland mucinous epithelium are suspended in large pools of extracellular mucin.

Intraductal Neoplasms

Intraductal neoplasms constitute an increasingly encountered and important category of pancreatic tumors of ductal origin, characterized by intraductal polypoid/papillary nodules that are often associated with cystic dilatation of the ducts (Basturk et al, 2009). Intraductal neoplasms constitute a wide spectrum of morphologic variants, but they are all regarded to represent precursors to invasive carcinoma; that is, they may be associated with, or may progress to, invasive carcinoma. As preinvasive neoplasms, they are similar to PanINs; but in contrast to PanINs, which are incidentally detected microscopic forms of dysplasia, intraductal tumors form clinically detectable masses (defined as >1.0 cm), conceptually similar to adenomas of the GI tract. It is estimated that about 2% of invasive adenocarcinomas in the pancreas arise from these tumor types. The neoplasms that are included under this umbrella are intraductal papillary mucinous neoplasms and intraductal tubulopapillary neoplasms.

Intraductal Papillary Mucinous Neoplasms (See Chapter 57)

Intraductal papillary mucinous neoplasms (IPMNs) arise predominantly in the head of the gland and occur more commonly in elderly men (males ≥ females; mean age, 64 years; Basturk et al, 2009). The mucin produced by these tumors may exude from the ampulla of Vater, a finding that is virtually diagnostic of an IPMN. Radiographic findings of ductal dilatation with irregularities also are often diagnostic. A history of pancreatitis is noted in some patients. An adenoma-to-carcinoma progression is seen in IPMNs, which are correspondingly classified as having low-, intermediate- or high-grade dysplasia based on the greatest degree of atypia (Hruban et al, 2007; Adsay et al, 2010); invasive carcinomas that arise in IPMNs are recognized separately and are graded and staged like other ductal-type carcinomas. IPMNs that predominantly involve the secondary ducts (branch duct type; Tanaka et al, 2006; Schnelldorfer et al, 2008; Nagai et al, 2009; Koizumi et al, 2009; Tanno et al, 2008, 2010; Terris et al, 2000) tend to be small (<3 cm) and noncomplex, and they generally prove to have low- to intermediate-grade dysplasia, with simple, gastric foveolar-type epithelium by microscopic examination. IPMNs that mostly involve the major ducts (main duct type; Fig. 56.9) (Tanaka et al, 2006) more commonly harbor high-grade dysplasia or invasive carcinoma (Salvia et al, 2004).

Distinctive pathologic subsets of IPMNs are emerging (Adsay et al, 2004b; Furukawa et al, 2005) with different histologic characteristics. In *intestinal-type IPMNs,* the papillary nodules are morphologically identical to colonic villous adenomas (Fig. 56.10), and the invasive carcinomas that develop in these tend to be of the relatively indolent colloid type (Adsay et al, 2001; Seidel et al, 2002). Intestinal-type IPMNs and colloid carcinomas typically express intestinal differentiation markers (MUC2 and CDX2) not found in ductal adenocarcinomas or in the nonintestinal subtypes of IPMNs discussed below, indicating that they represent a distinct "intestinal pathway" of carcinogenesis in the pancreas (Adsay et al, 2004b). Other IPMNs have more complex papillae that resemble papillary carcinomas of the biliary tree (Fig. 56.11). These *pancreatobiliary-type* IPMNs tend to be associated with tubular-type invasive

FIGURE 56.9. Intraductal papillary mucinous neoplasm, gross appearance. The main pancreatic duct is dilated and lined by friable, papillary excrescences. The surrounding parenchyma is diffusely fibrotic.

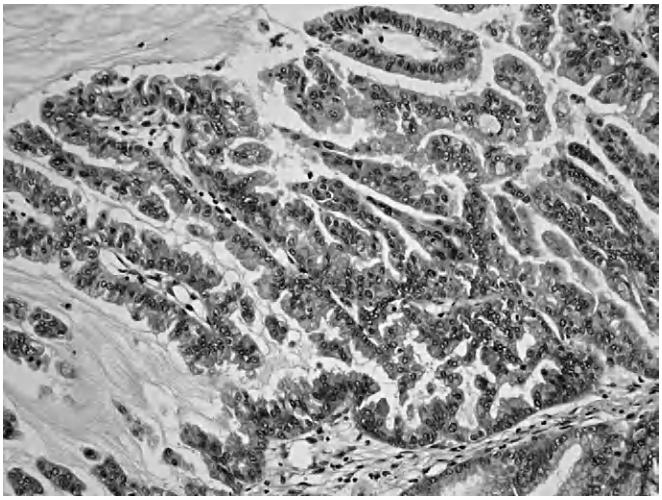

FIGURE 56.11. Intraductal papillary mucinous neoplasm, pancreatobiliary type. The papillae are markedly complex and are lined by cuboidal cells with a single layer of round nuclei, showing loss of cell polarity and moderate nuclear atypia.

carcinoma (conventional ductal adenocarcinoma) and appear to have more aggressive behavior (Sadakari et al, 2010). What is also known as *intraductal oncocytic papillary neoplasm* (Adsay et al, 1996) is now regarded as a distinct subtype of IPMN, characterized not only by the oncocytic nature of the cells but also by the complexity of the papillary nodules, which have an arborizing pattern. Oncocytic IPMNs are often large and very floridly proliferative; however, the carcinomas arising from them tend to be small, the incidence of metastasis is low, and the overall prognosis appears to be favorable. They also have different molecular changes from other IPMNs, with a much lower incidence of *KRAS* mutation and frequent expression of MUC6, suggesting a pyloropancreatic lineage distinct from the intestinal-type IPMNs (Basturk et al, 2010b).

FIGURE 56.10. Intraductal papillary mucinous neoplasm, intestinal type. The papillae resemble those of a villous adenoma of the large bowel, with pseudostratified, elongated nuclei with apical mucinous cytoplasm.

IPMNs can be multifocal in up to 40% of patients. They seem not only to be precursors but also "markers" of invasive adenocarcinoma (i.e., in some cases, invasive carcinoma is detected elsewhere in the gland, away from the IPMN; Fujii et al, 1996; Yamaguchi et al, 2002). Invasive carcinoma of either the colloid or tubular type (Adsay et al, 2004b) is present in more than one third of resected IPMNs. Colloid-type invasion occurs almost exclusively in intestinal-type IPMNs. It is generally believed that IPMNs proven devoid of high-grade dysplasia or invasive carcinoma by thorough histologic examination are innocuous, curable neoplasms. Patients with high-grade dysplasia may on occasion experience recurrences and metastases (White et al, 2007), presumably the result of undetected foci of invasive carcinoma; invasive carcinoma has a malignant clinical course, albeit often significantly more protracted than that of ordinary ductal adenocarcinoma. It should be kept in mind that most patients with IPMNs are older, often with comorbid diseases—including another malignant neoplasm in one third of patients (Eguchi et al, 2006; Sugiyama & Atomi, 1999; Adsay et al, 2002a; Adsay, 2008). The prognosis and management of IPMNs are discussed in detail elsewhere in this book (see Chapter 58).

Intraductal Tubulopapillary Neoplasms

Intraductal tubulopapillary neoplasm (Adsay et al, 2004b; Tajiri et al, 2005; Yamaguchi et al, 2009; Klimstra et al, 2007c) is a recently recognized category of mass-forming (>1.0 cm) intraductal neoplasm that is fairly similar to an IPMN, from which it is distinguished microscopically by its mucin-poor nature and distinctive tubular architecture. First reported by Tajiri and colleagues (2005) under the heading of *intraductal tubular adenocarcinoma,* the entity is now being designated *intraductal tubulopapillary neoplasm* in the new WHO classification. It is a rare tumor seen at an average age of 53 years, and it presents with nonspecific symptoms. The clinical findings are often indistinguishable from those of IPMNs. Most cases have cystic ducts

filled with tumor nodules. Intraductal tubulopapillary neoplasm occurs predominantly in the head of the pancreas but may involve any part. It is often large (mean, 7 cm; range, ≤15 cm).

The common characteristic present in all cases is intraductal nodular/polypoid growth of round, cuboidal *nonmucinous* cells in a tubular, or on occasion, tubulopapillary arrangement. Tubules are small to medium sized, typically well formed, with recognizable lumina of variable sizes, although more ill-defined, abortive tubular arrangements can be seen in some cases. The overall pattern closely mimics the intraductal variant of acinar cell carcinoma, but acinar differentiation is not evident by immunohistochemistry. Mitotic activity is often high, and a third of patients are seen with invasive carcinoma of the tubular type. Invasion, usually microscopic, is difficult to assess in these tumors because of the relative complexity of the intraductal component. The tumor cells express *MUC1* in the vast majority, and *MUC6* is present in 60% of patients, highlighting the similarities—and kinship—of this tumor type with the pancreatobiliary variant of IPMN. Limited follow-up suggests that these are indolent neoplasms with a protracted clinical course.

It should be noted that a variety of pancreatic neoplasms can show prominent intraductal growth, including acinar cell carcinomas (Basturk et al, 2007; Ban et al, 2010), pancreatic neuroendocrine tumors, osteoclastic giant-cell carcinomas (Basturk et al, 2010c), and even metastatic tumors; thus, they fall into the differential diagnosis of these intraductal neoplasms.

Mucinous Cystic Neoplasms (See Chapter 57)

Mucinous cystic neoplasms (MCNs) are seen almost exclusively in perimenopausal women (>95% female; mean age, 48 years; Tanaka et al, 2006; Thompson et al, 1999; Zamboni et al, 1999). One of the characteristic features, which essentially has become a requirement for the diagnosis, is an ovarian-type subepithelial stroma that is not only histologically similar to the ovarian cortex but that also expresses progesterone and estrogen receptors by immunohistochemistry. This distinctive mesenchyme helps distinguish MCNs from similar neoplasms, especially IPMNs (see above). MCNs typically form a thick-walled multilocular cyst in the body or tail of the pancreas (Fig. 56.12). Some examples may mimic pseudocysts, although the surrounding pancreatic tissue typically does not show evidence of chronic pancreatitis. In most cases, cysts do not communicate with the ductal system. The cyst fluid is rich in mucin-related glycoproteins and oncoproteins, such as CEA (Pitman et al, 2010; Deshpande et al, 2006), which may help distinguish these tumors from other cystic lesions. The cysts are lined by mucinous epithelium, which may exhibit varying degrees of cytologic and architectural atypia (Fig. 56.13), graded as low-, intermediate-, or high-grade dysplasia based on the most atypical region. Invasive carcinoma typically occurs in larger and more complex cases that show florid papillary nodules in the cysts.

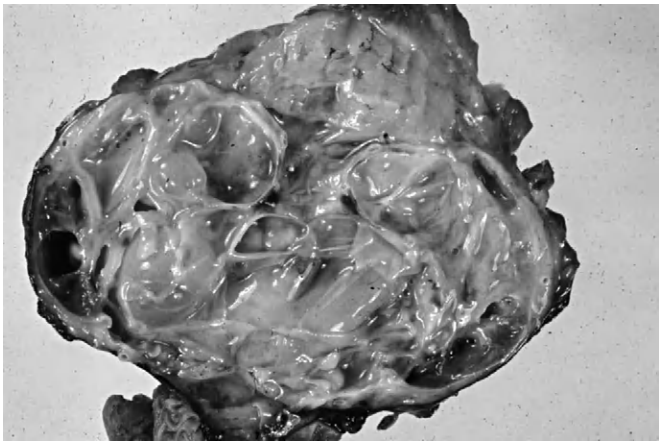

FIGURE 56.12. Mucinous cystic neoplasm, gross appearance. Multiple cystic locules are present, each measuring several centimeters. The intervening septa are thin and translucent.

FIGURE 56.13. Mucinous cystic neoplasm. A layer of hypercellular ovarian-like stroma underlie columnar mucinous epithelium that lines the cystic spaces.

Invasive carcinomas are found in 10% to 15% of MCNs (Pitman et al, 2010; Zamboni et al, 1999; Reddy et al, 2004). The carcinoma may be limited to microscopic foci within the septa of the cysts, or it may invade out of the cyst into the peripancreatic tissues. Invasive carcinomas resemble ductal adenocarcinoma histologically, including the occasional occurrence of an uncommon histologic variant such as sarcomatoid or giant-cell carcinoma. Although some studies have questioned the utility of grading MCNs, it has become clear recently that if these tumors are examined thoroughly, and the presence of invasive carcinoma is ruled out by rigorous pathologic examination, patients typically are cured by complete excision (Zamboni et al, 1999; Sakorafas & Sarr, 2005; Hruban & Zamboni, 2009). Because all MCNs have the potential to harbor invasive carcinoma, most authors agree that these tumors should be completely resected.

Serous Cystic Tumors (See Chapter 57)

Serous cystadenomas (Bassi et al, 2003; Compton, 2000) form relatively large masses (mean size, 9 cm, some 25 cm) that tend to be well demarcated, predominantly in elderly women (mean age, 63 years; female/male ratio, 3:1). Typically, serous cystadenomas are composed of thousands of small cysts, each measuring only millimeters and creating the diagnostic macroscopic appearance of a spongelike configuration, hence the synonym *microcystic adenoma* (Fig. 56.14). Rare macrocystic and solid examples of serous adenomas also have been

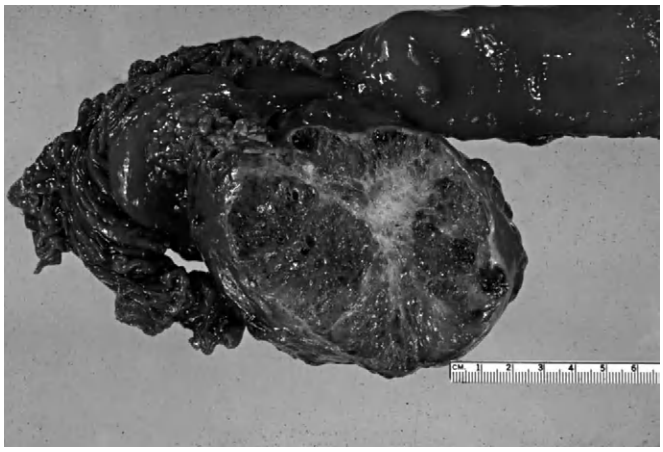

FIGURE 56.14. Microcystic serous cystadenoma, gross appearance. The tumor is well circumscribed with a central stellate fibrous scar. The cystic spaces are small, ranging from one to several millimeters.

described. Microcystic serous cystadenomas often have a central stellate scar. The defining microscopic feature is a simple, nonmucinous, cuboidal epithelium that contains intracytoplasmic glycogen, resulting in characteristic clear cytoplasm (Fig. 56.15). Serous cystic tumors are one of the few ductal neoplasms of the pancreas that do not produce mucin, possibly reflecting a recapitulation of the centroacinar cells that are nonmucinous. Along the same lines, the cyst contents are devoid of the mucin-related glycoproteins and oncoproteins that typically are found in mucinous pancreatic tumors, a feature that may help in the preoperative diagnosis (Brugge et al, 2004). Microscopically, these lesions are similar to the cysts seen in von Hippel–Lindau (VHL) disease, and some serous cystadenomas do show *VHL* gene alterations. Serous cystadenomas often are reported to coexist or "collide" with other pancreatic neoplasms and with congenital pathologic conditions (Compton, 2000).

Malignant serous tumors (serous cystadenocarcinomas) (Matsumoto et al, 2005; Shintaku et al, 2005; Strobel et al, 2003) are exceedingly rare. Only the presence of recurrence, metastases, or angioinvasive growth separates these tumors from their benign counterparts (i.e., the cytologic appearance is entirely bland). For practical purposes, serous cystadenomas limited to the pancreas are regarded as uniformly benign.

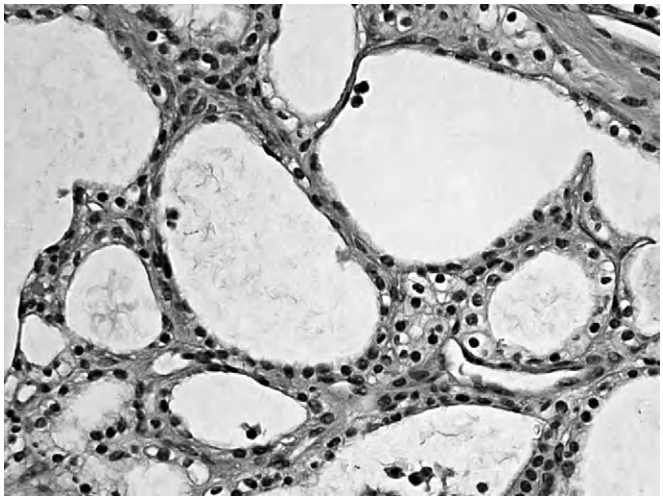

FIGURE 56.15. Microcystic serous cystadenoma. The individual cysts are lined by a flattened-to-cuboidal layer of uniform epithelial cells with clear cytoplasm and round hyperchromatic nuclei.

FIGURE 56.16. Pancreatic neuroendocrine tumor, gross appearance. This example involves the tail and consists of a relatively circumscribed, multinodular, uniform, yellow-tan mass.

Pancreatic Neuroendocrine Tumors (See Chapter 61)

Most neuroendocrine-type tumors of the pancreas are well-differentiated, low- to intermediate-grade neuroendocrine tumors, previously referred to as *islet cell tumors* and now designated as *pancreatic neuroendocrine tumors* (PanNETs) by the World Health Organization (WHO) (Klimstra et al, 2010a; Solcia et al, 1991), with low-grade malignant behavior (Hochwald et al, 2002). Grossly, PanNETs are usually solid, circumscribed, and fleshy tumors, although multinodular and sclerotic examples occur (Fig. 56.16). Rarely, cystic degeneration may be seen (Adsay & Klimstra, 2000; Deshpande & Lauwers, 2007), with a central unilocular cyst lined by a cuff of viable tumor; this occurs more often in the setting of multiple endocrine neoplasia (MEN) syndrome type I. PanNETs recapitulate the morphologic features of islet cells by forming nested, gyriform, trabecular, or rarely acinar or glandular patterns (Fig. 56.17). The cells have characteristic neuroendocrine features, including round, monotonous nuclei with a coarsely stippled chromatin pattern and moderate amounts of cytoplasm (Fig. 56.18).

Almost half of PanNETs are clinically functional, and patients come to medical attention with signs or symptoms of inappropriate production and serologic activity of one or more hormones. These functional PanNETs are named based on the hormonal syndrome: *insulinoma*, *glucagonoma*, *gastrinoma*, *somatostatinoma*, and *VIPoma* (vasoactive intestinal peptide tumor) for example. The correlation of serum hormone levels and expression of the corresponding hormone in the tumor itself by immunohistochemistry is often imperfect. Nonfunctional PanNETs (Hochwald, et al, 2001; Klimstra & Adsay, 2009; La Rosa et al, 1996) constitute an ever-enlarging proportion of PanNETs because they are being detected more commonly as incidental findings on abdominal imaging studies.

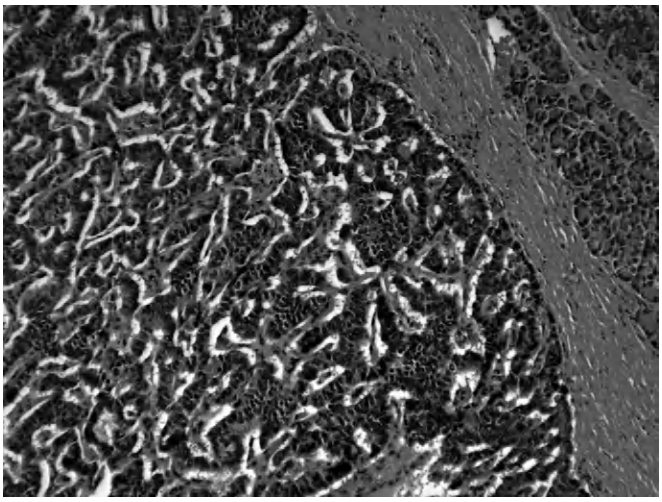

FIGURE 56.17. Pancreatic neuroendocrine tumor. The uniform cells are arranged in nests, and trabecula and are separated by a richly vascular stroma.

Most insulinomas follow a benign clinical course, likely because insulinomas typically are highly symptomatic, even when they are small, which leads to their early detection. Glucagonomas, on the other hand, tend to be large at diagnosis and have a more aggressive course. PanNETs associated with MEN type I or other syndromes tend to be multifocal and less aggressive (Anlauf et al, 2006, 2007; Klimstra & Adsay, 2009; Perigny et al, 2009). In addition to grossly evident and usually functional PanNETs, patients with MEN type I have numerous neuroendocrine microadenomas, defined as PanNETs (<0.5 cm). Most sporadically occurring functional and nonfunctional PanNETs are clinically low-grade malignancies. More than half of patients have recurrence or metastasis after resection, and many patients come to attention only after the development of metastatic disease. Nonetheless, there may be a relatively protracted clinical course even in patients with metastatic disease. It has been difficult, as in neuroendocrine tumors of other organs, to determine which PanNETs are more likely to metastasize and which metastatic cases are likely to progress most rapidly (Pelosi et al, 1996; White et al, 1994). Findings associated with more aggressive behavior include size greater than 3 cm, a functional PanNET other than insulinoma, extrapancreatic or vascular invasion, high mitotic activity, high proliferation index (based on immunohistochemical staining for Ki-67) (Jamali & Chetty, 2008; Rindi et al, 2007; Chatzipantelis et al, 2009), CK19 expression (La Rosa et al, 2007), and c-KIT expression (Zhang et al, 2009); however, some PanNETs lacking all of these features still may metastasize.

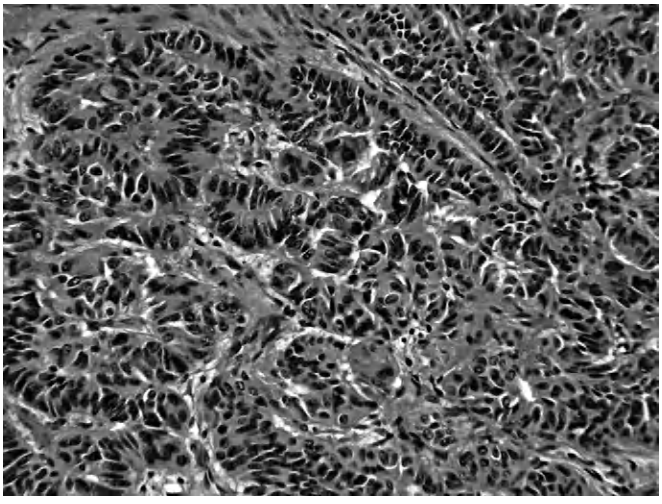

FIGURE 56.18. Pancreatic neuroendocrine tumor. Although the nuclei show some variation in size and shape, the chromatin pattern is uniformly granular with no evident mitotic figures.

The 2004 WHO classification (Heitz et al, 2004) separated *well-differentiated pancreatic neuroendocrine tumors*, those lacking metastases or gross local invasion, from *well-differentiated pancreatic neuroendocrine carcinomas,* with metastases or gross local invasion; they further predicted "benign behavior" or "uncertain behavior" in the former group based on size less than 2 cm, mitotic rate below 2/10 high-power fields (HPFs), Ki-67 labeling index below 2%, and absence of vascular or perineural invasion. However, studies have demonstrated that the patients who fall in the uncertain behavior group still experience recurrence and metastasis in long-term follow-up in up to 40% of the cases (Schmitt et al, 2007); therefore it is clear that even this group represents a low-grade malignancy.

Another more recent proposal (Ferrone et al, 2007) divides PanNETs into low-grade and intermediate-grade groups based on the mitotic rate (2 mitoses per 50 HPFs) and necrosis. The two groups exhibit a highly significant difference in prognosis, although no subset specifically is regarded to be utterly benign. Recently, a multidisciplinary group of international experts have proposed a set of parameters to be included in pathology reports (Klimstra et al, 2010a). It was emphasized that PanNETs ought to be evaluated by the approach used for any other malignancy, and accordingly, the grade and stage should be reported separately (Klimstra et al, 2010b; Klöppel et al, 2010a). For grading, in 2010 the WHO adopted the system originally devised and tested by the European Neuroendocrine Tumor Society (ENETS), which grades PanNETs based on the mitotic count and Ki-67 labeling index. *Grade 1* if the mitotic rate is less than 2/10 HPFs *and* the Ki-67 index is below 3%; *grade 2* if the mitotic rate is 2 to 20/10 HPFs *or* the Ki-67 index is 3% to 20%; and *grade 3* if *either* is above 20. For staging, the AJCC has adapted the TNM-based staging system used for adenocarcinomas, but the ENETS system is somewhat different (Klöppel et al, 2007).

On the other end of the spectrum of neuroendocrine neoplasia, very rarely, poorly differentiated neuroendocrine carcinoma, related to small cell carcinoma, may be encountered in the pancreas (Tranchida et al, 2000). Some are composed of large cells with more abundant cytoplasm (high-grade neuroendocrine carcinomas of a "large cell" type). According to WHO, high-grade neuroendocrine carcinomas are classified as *grade 3* PanNETs, although the true nature of such tumors is difficult to characterize because of their rarity, and they appear to be a distinct tumor type with morphology and behavior usually very similar to that of high-grade neuroendocrine carcinomas of the lung rather than being advanced forms of well-differentiated PanNETs. In fact, especially when the small cell morphology is present, poorly differentiated neuroendocrine carcinomas must be distinguished from metastases to the pancreas from a pulmonary primary.

Acinar Neoplasms

Although acinar tissue constitutes most of the pancreas, acinar neoplasms are rare. Acinar neoplasms are characterized by the production of pancreatic enzymes, such as trypsin, chymotrypsin, and lipase. Solid acinar cell neoplasms are carcinomas; although a benign cystic variant exists, known as *acinar cell cystadenoma*, no solid acinar cell adenoma has been defined in the pancreas.

Acinar cell carcinomas (Kitagami et al 2007; Klimstra, 2007; Wisnoski, 2008) form relatively large tumors (mean, 10 cm), usually in older men (mean age, 63 years), although some occur in children (Shorter et al, 2002). In a small percentage of cases (10%), patients experience a "lipase hypersecretion syndrome" (Klimstra & Adsay, 2001) characterized by subcutaneous fat necrosis, polyarthralgia, and peripheral eosinophilia. Serum α-fetoprotein (AFP) levels may be elevated in some cases (Cingolani et al, 2000). Half of acinar cell carcinomas have metastases at the time of diagnosis, usually in the liver and/or regional lymph nodes (Holen et al, 2002). Once believed to be almost as aggressive clinically as ductal adenocarcinomas with a 5-year survival of 10% (Holen et al, 2002), more recent studies place acinar cell carcinomas in a somewhat more indolent category (Klimstra et al, 1992) with some studies reporting a 5-year survival over 40% (Kitagami et al, 2007; Wisnoski et al, 2008). In contrast to ductal adenocarcinomas, acinar cell carcinomas are stroma-poor cellular tumors composed of sheets of cells and small glands (acini) composed of polygonal cells with prominent nucleoli (Labate et al, 1997) and cytoplasmic eosinophilia (Fig. 56.19), often with periodic acid-Schiff (PAS)-positive granules. Acinar enzymes, especially trypsin and chymotrypsin, are demonstrable by immunohistochemistry in essentially all cases (Klimstra et al, 1992). A subset of acinar cell carcinomas is characterized by prominent intraductal growth; such cases are reportedly associated with a more protracted clinical course (Basturk et al, 2007; Ban et al, 2010). Molecular genetic findings of acinar cell carcinomas markedly differ from those of ductal adenocarcinomas (Cao et al, 2005), with absence of the common alterations of ductal adenocarcinoma in genes such as *KRAS, TP53, P16,* or *SMAD4*.

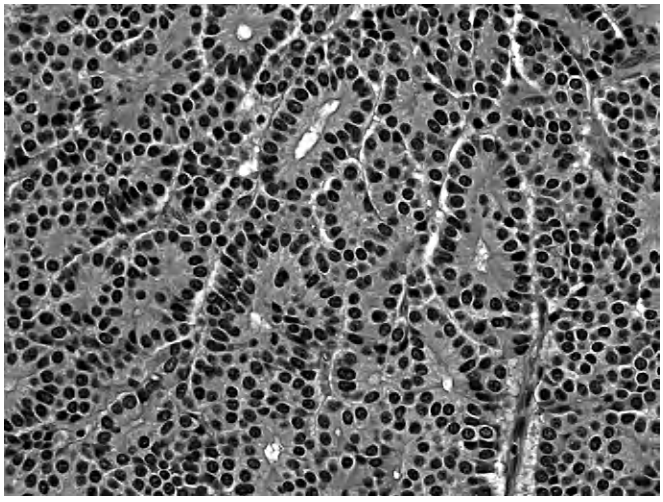

FIGURE 56.19. Acinar cell carcinoma. The cells are arranged in nests and acinar formations. The cytoplasm is eosinophilic and granular, especially in the regions surrounding the pinpoint luminal spaces.

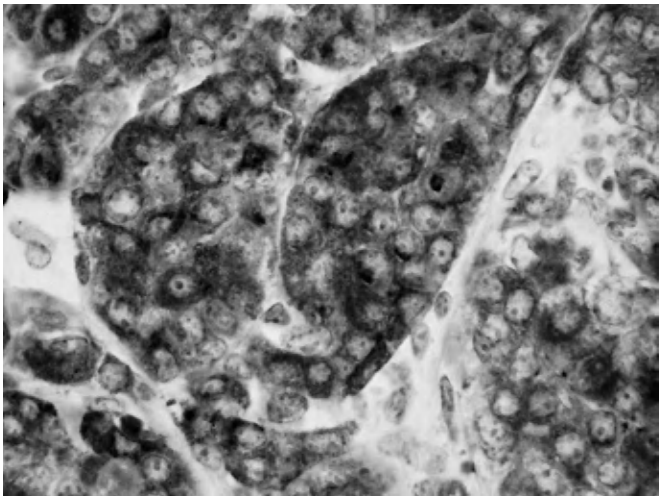

FIGURE 56.20. Mixed acinar-neuroendocrine carcinoma. Immunohistochemical labeling for trypsin and chromogranin shows participation of acinar and endocrine cells in this mixed neoplasm.

Immunohistochemistry discloses scattered neuroendocrine cells in 30% to 40% of acinar cell carcinomas. Some cases have a significant neuroendocrine component that may be evident microscopically (Klimstra et al, 1992). If the latter constitutes more than 25% of the tumor, it is classified as *mixed acinar-neuroendocrine carcinoma* (Fig. 56.20), a tumor that seems to be biologically similar to pure acinar cell carcinoma (Klimstra et al, 1994; Ohike et al, 2004). Similarly, acinar cell carcinomas with more than 25% ductal differentiation are classified as *mixed acinar-ductal carcinoma* (Stelow et al, 2010). Rarely, acinar cell carcinomas may show a grossly cystic pattern and are designated *acinar cell cystadenocarcinoma* (Cantrell et al, 1981; Stamm et al, 1987).

Acinar Cell Cystadenoma

Acinar cell cystadenoma, also referred to as *acinar cystic transformation,* is a rare entity (Albores-Saavedra, 2002; Zamboni et al, 2002). Acinar cell cystadenomas are usually small, incidental cysts lined by benign-appearing acinar cells, although some may form a mass that measures a few centimeters. Some examples have a patchy distribution that spans to a large segment of the organ. They are considered to be benign.

Pancreatoblastoma

Pancreatoblastoma is an extremely rare childhood tumor of the pancreas (mean age of 4 years, with a second small peak in the third decade) (Dhebri et al, 2004; Klimstra et al, 1995; Shorter et al, 2002). Pancreatoblastomas are usually large (7 to 18 cm). Some cases are associated with elevated serum AFP levels, and occasional cases are seen in association with Beckwith-Wiedemann syndrome (Drut & Jones, 1988; Kerr et al, 2002) or familial adenomatous polyposis (FAP) syndrome (Abraham et al, 2001). Pancreatoblastomas are malignant tumors with a 5-year survival of about 25%, although children diagnosed before the development of metastases have been cured. Pancreatoblastomas are predominantly acinar neoplasms. Microscopically, they have sheets of primitive-appearing epithelial cells and acinar formations. A characteristic and peculiar

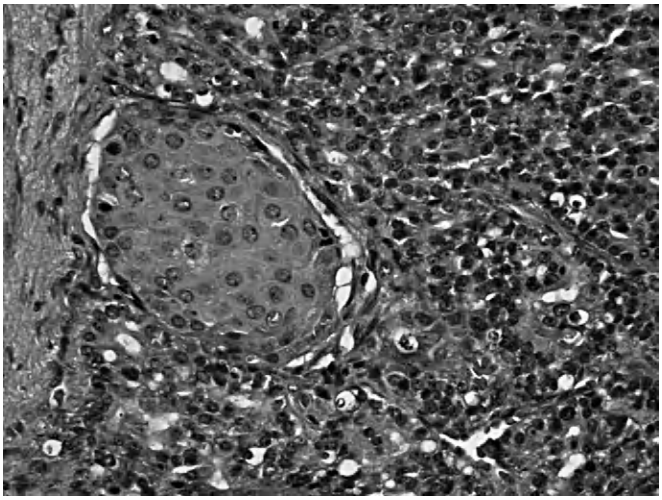

FIGURE 56.21. Pancreatoblastoma. Solid nests and small acinar formations are composed of uniform small cells. In addition, larger cells form circumscribed squamous corpuscles, and a cellular stromal component is present.

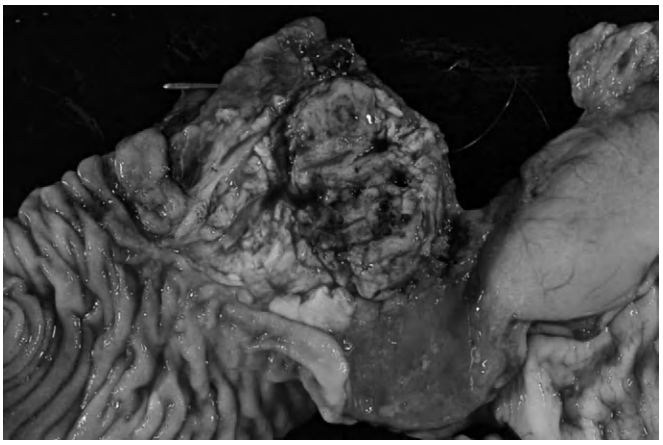

FIGURE 56.22. Solid pseudopapillary neoplasm, gross appearance. The tumor is grossly circumscribed and composed of soft, tan tissue with areas of hemorrhage. No gross cystic change is apparent in this relatively small example.

microscopic finding is the squamoid nest, which is a small morular arrangement of squamoid cells specific for this tumor type in the pancreas (Fig. 56.21). Typically, pancreatoblastomas exhibit all three lines of pancreatic differentiation—*acinar, neuroendocrine,* and *ductal*—with acinar elements being the most consistently present (Klimstra et al, 1995). Molecular genetic findings of pancreatoblastomas differ from the findings of ductal adenocarcinoma; they are associated with β-catenin pathway alterations (Cao et al, 2005). The squamoid nests (morules) are interesting in this regard because they are also often encountered in other cancer types in which this pathway is abnormal (Nakatani et al, 2004).

Solid Pseudopapillary Neoplasm

Solid pseudopapillary neoplasm is seen predominantly in young women (mean age, 25 years; >80% female) (Klimstra et al, 2000; Kosmahl et al, 2000; Papavramidis & Papavramidis, 2005; Tang et al, 2005). It is a peculiar neoplasm of unknown origin, and its obscure nature is reflected in the various descriptive names assigned to this tumor in the past, including *papillary cystic tumor, solid and papillary tumor, solid and cystic tumor,* and *Frantz tumor* (Klöppel et al 1981; Lieber et al, 1987; Pettinato et al, 1992; Stommer et al, 1991). It is an indolent malignant neoplasm for which complete resection is curative in most cases. In a small percentage (approximately 15%), metastases are noted, usually to liver or peritoneum and often at the time of diagnosis. Even patients with metastases have a protracted clinical course, and death as a result of this tumor is rare; however, a few highly aggressive solid pseudopapillary neoplasms have been reported that exhibit high-grade malignant transformation from a conventional solid pseudopapillary neoplasm (Tang et al, 2005).

Solid pseudopapillary neoplasms are relatively large tumors (mean, 8 to 10 cm). Although they are typically solid cellular neoplasms, cystic degeneration is common (Fig. 56.22). Degenerative changes combined with the preservation of the cells around the microvasculature create the pseudopapillary microscopic pattern (Fig. 56.23). The cells are round to oval and often show nuclear grooves. Intracytoplasmic hyaline globules and aggregates of foamy macrophages are characteristic findings, and calcifications may also be seen. Overall, the histologic picture may resemble closely that of PanNETs. The immunophenotype of this tumor is quite distinctive but fails to disclose the line of differentiation of the cells. The tumor typically expresses vimentin, progesterone receptors, CD10, and some of the neuroendocrine markers, CD56 and synaptophysin (Klimstra et al, 2000; Kosmahl et al, 2000; Ladanyi et al, 1987). Chromogranin, the most specific neuroendocrine marker, is negative, which is important for the differential diagnosis with PanNETs, and pancreatic enzymes are not expressed. β-Catenin and cyclin D1 expression have been found in these tumors, suggesting an alteration in the *WNT* signaling pathway. E-cadherin and n-cadherin expression are also abnormal (Abraham et al, 2002; Tiemann et al, 2007).

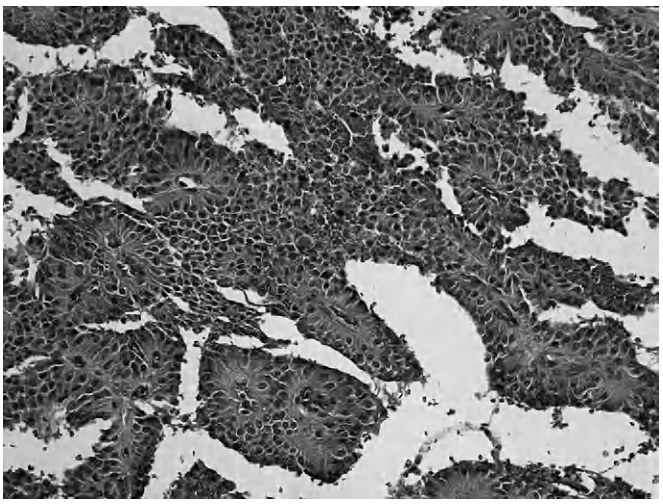

FIGURE 56.23. Solid pseudopapillary neoplasm. The pseudopapillae are formed by a cuff of cells adherent to a central small vessel. Many of the cells contain large eosinophilic globules, and the nuclei have longitudinal grooves.

Miscellaneous Cystic Pancreatic Lesions

Other uncommon cystic lesions occur in the pancreas in addition to pseudocysts, intraductal cyst-forming neoplasms, mucinous cystic neoplasms, and serous cystic tumors (Adsay et al, 2000; Kosmahl et al, 2004). Lymphoepithelial cysts (Adsay et al, 2002b) are usually peripancreatic rather than intrapancreatic, and they occur predominantly in men (mean age, 52 years; male/female ratio, 3 : 1). In contrast to their salivary gland counterparts, pancreatic lymphoepithelial cysts do not show associations with autoimmune syndromes, human immunodeficiency virus (HIV), or lymphoma. Lymphoepithelial cysts may occur in any part of the pancreas and may be unilocular or multilocular. They are characterized by variably keratinized, squamous-lined cysts immediately surrounded by a rim of lymphoid tissue, some with lymphoid follicles and a capsule (Fig. 56.24). The cyst contents may extrude into the cyst wall and cause an inflammatory reaction, including granulomas. Dermoid cysts are similar to lymphoepithelial cysts but lack the lymphoid tissue and show skin adnexal elements, including sebaceous glands. Lymphangiomas (Paal et al, 1998) are seen in young women (mean age, 29 years; male/female ratio, 1 : 3) and form endothelial-lined cysts surrounded by a rim of lymphoid tissue. Congenital cysts and intestinal duplications also may form cystic lesions in the vicinity of the pancreas and periampullary region. These may have a variable lining, including respiratory type, intestinal, squamous, or transitional.

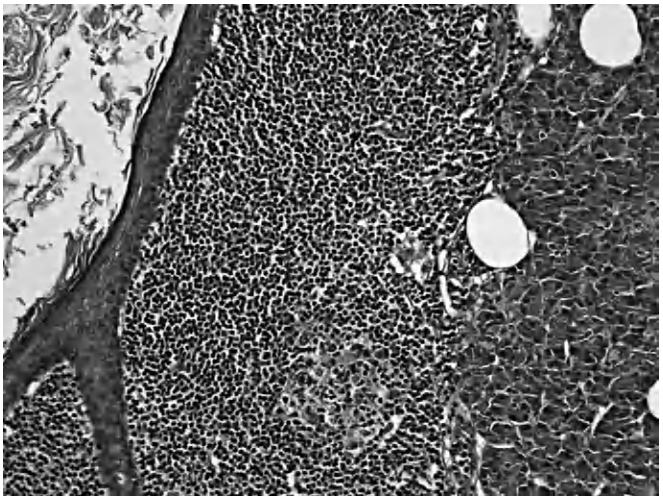

FIGURE 56.24. Lymphoepithelial cyst. The cyst is lined by stratified squamous epithelium with keratinization, and a band of lymphoid cells separates it from the pancreatic parenchyma.

Pseudotumors

As discussed in the section on ductal adenocarcinoma, benign chronic inflammatory and fibrosing conditions of the pancreas may be difficult to distinguish from carcinomas both clinically and pathologically. Chronic pancreatitis of any cause—including alcohol, obstruction, and even causes with granulomatous inflammation—may lead to segmental fibrosis and a tumorous mass (see Chapter 55; Adsay et al, 2004c; Klöppel & Maillet, 1991). However, certain subtypes of chronic pancreatitis are especially prone to form pseudotumors and mimic carcinomas, as discussed below (Adsay et al, 2004c; Klöppel, 2007; Levenick et al, 2009).

Autoimmune pancreatitis (AIP), also called *lymphoplasmacytic sclerosing pancreatitis* (Zamboni et al, 2004), is often misdiagnosed as carcinoma preoperatively (see Chapter 55). AIP typically is seen in patients in their 30s to 50s, and high serum immunoglobulin G4 (IgG4) levels are helpful in the preoperative diagnosis (Dhall et al, 2010; Morselli-Labate & Pezzilli, 2009; Sanchez-Castanon et al, 2009; Tabata et al, 2009). It may be associated with other autoimmune disorders, such as Sjögren syndrome, and with components of the multifocal fibrosclerosis syndrome: retroperitoneal and mediastinal fibrosis, Riedel thyroiditis, inflammatory pseudotumor of the orbit, and sclerosing cholangitis. Microscopically, dense periductal lymphoplasmacytic infiltrates, interstitial fibrosis with abundant myofibroblasts arranged in a storiform pattern, and obliterative venulitis are characteristic (Fig. 56.25).

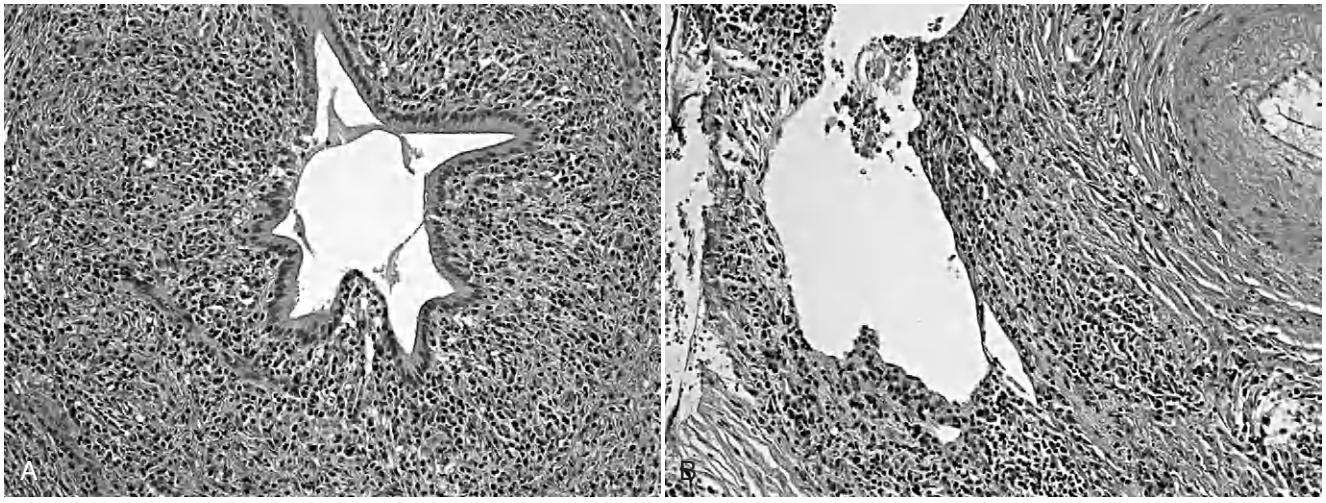

FIGURE 56.25. Autoimmune pancreatitis. **A,** Dense inflammation is evident and includes lymphocytes, plasma cells, and eosinophils arranged in a periductal pattern. **B,** The inflammatory infiltrate also involves the walls of small veins.

Recently, a variant of AIP has been recognized (Klöppel et al, 2010b) and termed variably as *type 2 autoimmune pancreatitis* or *pancreatitis with granulocytic epithelial lesions* (GELs). This type is more commonly seen in patients with ulcerative colitis and does not seem to be associated with IgG4-producing plasma cells but rather shows neutrophilic destruction of the duct epithelium (Klöppel et al, 2010b).

Paraduodenal pancreatitis (Adsay & Zamboni, 2004; Coban et al, 2009) is the name recently proposed for a distinct but poorly recognized subset of chronic pancreatitis that creates a clinical picture often indistinguishable from pancreatic or periampullary carcinoma. This entity is also known as *groove pancreatitis* (Badia Bartolome et al, 2009; Castell-Monsalve et al, 2008; Ishigami et al, 2009; Levenick et al, 2009; Triantopoulou et al, 2009) or *cystic dystrophy of heterotopic pancreas* (Casetti et al, 2009; de Madaria et al, 2009). Affected patients are predominantly men in their 50s with a history of alcohol abuse. Endoscopically, in the second portion of the duodenum, proximal to the ampulla, mucosal nodularities are present that microscopically reveal inflamed mucosa, Brunner gland hyperplasia, or myoid spindle cell proliferation in the submucosa that can also extend to the mucosa. These pseudotumors are typically centered around the minor papilla or accessory duct and thus invade into the region between the common bile duct, duodenum, and pancreas (i.e., the "groove" region) (Badia Bartolome et al, 2009; Castell-Monsalve et al, 2008; Ishigami et al, 2009; Levenick et al, 2009; Triantopoulou et al, 2009). The process often exhibits a dense myofibroblastic proliferation within which lobules of pancreatic tissue are scattered, and cystic ducts contain inspissated enzymatic secretions. In some cases, cystic change in the duodenal wall can be prominent (cystic dystrophy of the duodenum) and may become large (paraduodenal wall cyst) (Casetti et al, 2009; de Madaria et al, 2009), mimicking pseudocysts, congenital cysts, or intestinal duplication. Some of the cysts are lined by granulation tissue without any epithelium.

Some developmental abnormalities also may lead to pseudotumors. A solid and cystic hamartoma and a cellular hamartoma (Pauser et al, 2005a, 2005b) have been reported to present as pancreatic tumors in adults. *Lipomatous pseudohypertrophy* (Altinel et al, 2009) of the pancreas also may lead to a mass that could be mistaken for carcinoma. Adenomyomatous hyperplasia (Handra-Luca et al, 2003) of the ampulla—a common finding in the general population, reported in 40% of autopsies—has been implicated as a cause of biliary obstruction that mimics a periampullary carcinoma.

Mesenchymal Tumors

Primary mesenchymal tumors of the pancreas are rare (Khanani et al, 2003; Lüttges et al, 1997), but mesenchymal tumors from neighboring sites may secondarily involve the pancreas. In particular, GI stromal tumors and retroperitoneal sarcomas may appear to be centered in the pancreas. A variety of benign mesenchymal tumors, including fibromatosis (desmoid tumor), solitary fibrous tumor (Lüttges et al, 1999b), and schwannoma (Paal et al, 1998), have been reported in the pancreas. Primary sarcomas include primitive neuroectodermal tumor (Movahedi-Lankarani et al, 2002), synovial sarcoma, desmoplastic small round-cell tumor, leiomyosarcoma, and malignant fibrous histiocytoma, all of which are largely documented in single case reports.

Secondary Tumors

A widely metastatic malignant neoplasm commonly may involve the pancreas; however, most of these are clinically undetected lesions identified only at autopsy (see Chapter 60; Adsay et al, 2004d). Autopsy studies have shown that most secondary tumors involving the pancreas are of pulmonary origin, followed by GI carcinomas; however, a few metastatic tumors are prone to involve the pancreas in the absence of other metastatic foci, mimicking a primary carcinoma. Lymphomas and renal cell carcinomas (Adsay et al, 2004d; Temellini et al, 1989) seem to be the most common tumor types responsible for such cases. Renal cell carcinomas in particular are known to form polypoid ampullary nodules or even to grow within the ducts (Klimstra & Adsay, 2009).

TUMORS OF THE AMPULLA OF VATER (SEE CHAPTER 59)

Although the ampulla of Vater is anatomically a small structure, it and the surrounding periampullary duodenum give rise to a surprising number and variety of neoplasms that often present with dramatic symptoms because of the strategic location of the ampulla at the confluence of the pancreatic and biliary ducts. The ampulla itself includes several kinds of epithelia: the duodenal mucosa, covering the papilla; the pancreatic ductal epithelium and that of the distal common bile duct; and the epithelium lining the common channel—the short, if not hypothetical, union of the two ducts within the duodenal wall. The epithelia lining the ducts and the common channel are histologically similar pancreatobiliary-type epithelium, whereas the papilla is covered by intestinal-type epithelium (Klimstra et al, 2007a). Different cell types can be observed intimately admixed in the transitional region. Neoplasms arising in the ampulla may have predominantly intestinal or pancreatobiliary features, or patterns may be mixed. Most ampullary neoplasms are adenocarcinomas (Klimstra & Adsay, 2009), although some neuroendocrine tumors also affect this region. Benign neoplasms also arise in the ampulla, and techniques for local treatment, such as endoscopic polypectomy or transduodenal ampullectomy (Roggin et al, 2005) have introduced new challenges into the pathologic analysis of ampullary tumors (Klimstra & Adsay, 2009). This section reviews the pathologic features of these ampullary neoplasms.

Adenoma and Noninvasive Papillary Carcinoma

These tumors can be regarded in two categories: 1) those that arise from the duodenal surface of the ampulla, which are nearly identical to colonic-type adenomas and may occur in association with FAP syndrome (Albores-Saavedra et al, 2000; Alexander et al, 1989; Domizio et al, 1990; Klimstra & Adsay, 2009; Noda et al, 1992; Odze et al, 1994); and 2) those that arise *within* the ampulla (Fig. 56.26), which are not only of an intestinal type, similar to colonic-type adenomas, but are also of a pancreatobiliary type, referred as *noninvasive papillary carcinomas* in the WHO classification (Klimstra et al, 2010c). For the latter group, those occurring within the ampulla, the designation of *intraampullary papillary tubular neoplasm* (IAPN), akin to pancreatic IPMNs and intraductal tubulopapillary neoplasms, also has been recently proposed (Ohike et al, 2010a).

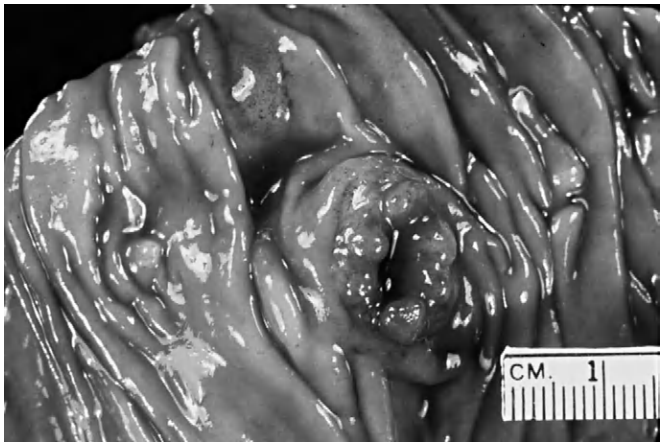

FIGURE 56.26. Intrampullary papillary tubular neoplasm, gross appearance. This predominantly intraampullary tumor produces a bulging ampulla with a nodular orifice.

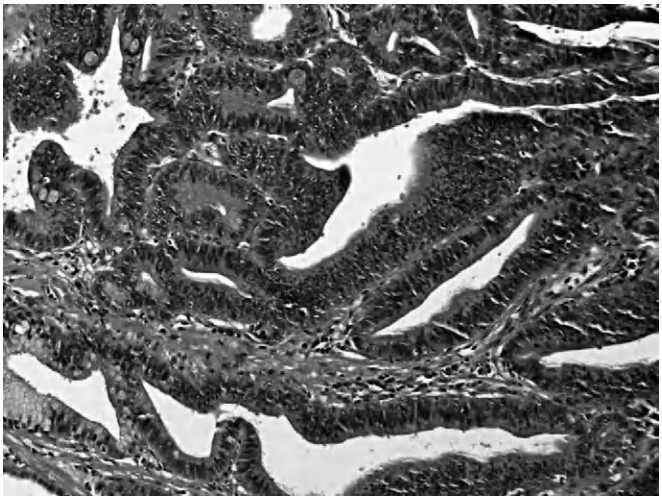

FIGURE 56.27. Ampullary adenoma. The histologic appearance resembles that of an adenoma of the large bowel, with predominantly tubular glands showing pseudostratified, elongated nuclei.

Adenomas of the Duodenal Surface of the Papilla of Vater

Adenomas of the duodenal surface of the ampulla are morphologically and genetically similar to adenomas of the large bowel. Although in most clinical studies, invasive carcinomas outnumber pure adenomas, residual adenomas are commonly found associated with invasive carcinomas. Most ampullary adenocarcinomas, especially those with an intestinal phenotype, are thought to arise from adenoma precursors. Conversely, many adenomas of the ampulla contain foci of invasive carcinoma, requiring a thorough histologic evaluation (Perzin & Bridge, 1981).

A significant percentage of adenomas of the small intestine involve the ampulla or the surrounding duodenal mucosa (Perzin & Bridge, 1981). They may occur sporadically, or they may be associated with FAP. The ampulla and periampullary duodenum are the most common sites of extracolonic adenomas in patients with FAP (Alexander et al, 1989; Domizio et al, 1990; Klimstra & Adsay, 2009; Noda et al, 1992; Odze et al, 1994). Sporadic ampullary adenomas are generally solitary, whereas those arising in patients with FAP usually are accompanied by numerous adenomas in the periampullary duodenum, sometimes forming a carpet of polyps. Ampullary adenomas in patients with FAP usually are detected at a younger age (mean, 41 years) compared with sporadic ampullary adenomas (mean, 62 years) (Albores-Saavedra et al, 2000). Symptomatic patients are generally seen initially with biliary obstruction, although ampullary and duodenal adenomas are increasingly detected in asymptomatic patients with FAP owing to endoscopic screening (Shemesh & Bat, 1985). The risk of an invasive carcinoma being found within an ampullary adenoma is proportional to the size of the adenoma, and it is greater for a given size compared to adenomas of the large bowel.

Microscopically, ampullary adenomas resemble their large bowel counterparts and may be tubular, villous, or mixed (tubulovillous) (Albores-Saavedra et al, 2000). The intestinal-type epithelium shows pseudostratification of elongated nuclei, and additional cytologic atypia and architectural complexity may be evident, depending on the degree of dysplasia (Fig. 56.27). Areas of high-grade dysplasia are characterized by complex, cribriform glands with considerable nuclear atypia and loss of epithelial polarity. Immunohistochemical stains often reveal abundant neuroendocrine cells and Paneth cells in ampullary adenomas (Fig. 56.28; Albores-Saavedra et al, 2000; Mora et al, 2004), and these two cell types may be prominent enough to be recognized in routinely stained material.

In some instances, ampullary adenomas may be treated effectively by endoscopic resection or transduodenal ampullectomy rather than pancreatoduodenectomy (see Chapters 27 and 62C; Bohra et al, 2002; Saurin et al, 2003). When this procedure is performed, it is essential for the pathologist to evaluate the lesion carefully to determine the completeness of

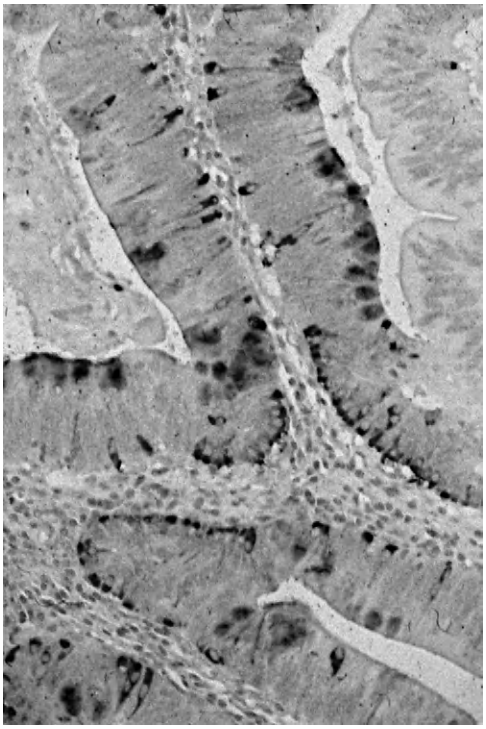

FIGURE 56.28. Ampullary adenoma. Immunohistochemical labeling for chromogranin and lysozyme shows abundant endocrine and Paneth cells.

resection and to search for subtle foci of invasive carcinoma. Sometimes this evaluation must be performed on frozen sections.

Intraampullary Papillary Tubular Neoplasms

Intestinal-type preinvasive neoplasms (adenomas), similar to those occurring on the duodenal surface, may also occur *within* the ampulla; however, in addition, *noninvasive pancreatobiliary-type neoplasms* (Klimstra et al, 2010c) may also be encountered in this region. Recently, the term *intraampullary papillary tubular neoplasm* (Ohike et al, 2010a) was proposed to unify all the tumoral intraepithelial neoplasms that arise predominantly within the ampulla—or the very terminal, intraampullary ends of the two ducts—under one category to avoid confusion and also to establish their kinship with IPMNs and intraductal tubulopapillary neoplasms of the pancreas. As in IPMNs, IAPNs occur predominantly in men at a mean age of 64 years. They form exophytic masses within the ampulla that lead to a protuberant ampulla with a widened orifice (see Fig. 56.26) through which a granular, polypoid tumor can be appreciated within the ampulla. Cut sections show friable, granular lesions with a mean size of 2.5 cm filling the ampullary lumen. Microscopically, half of the cases exhibit a mixture of papillary and tubular growth pattern, and in the remainder, one of the two patterns predominates. About three quarters of the cases have a more intestinal-type appearance, and the remainder have gastropancreatobiliary features; however, overlaps and hybrid types are common, presumably owing to the transitional nature of ampullary epithelium, which harbors different cell types. This is reflected also in the immunophenotype, which often shows discrepant and unexpected profiles using markers that are putatively lineage-specific. High-grade dysplasia is detected in the majority of the cases, and invasive carcinoma is found in more than 75%. Conversely, from the invasive carcinoma perspective, IAPNs are detected in the background of about 30% of invasive ampullary carcinomas. Invasive carcinoma often but not always follows the cell phenotype of the preinvasive component. Noninvasive carcinomas have a very good prognosis; however, they may occasionally develop recurrence in long-term follow-up. Invasive carcinomas arising from IAPNs have a malignant course but one that is significantly more protracted than that of invasive carcinomas unaccompanied by IAPNs (Ohike et al, 2010a).

Flat-Type Intraepithelial Neoplasia (Dysplasia and Carcinoma in Situ)

Much less common preinvasive neoplastic lesions of the ampulla include *flat dysplasia* (Albores-Saavedra et al, 2000), a lesion with epithelial dysplasia that does not form a grossly polypoid mass. Microscopically, a low papillary pattern may be apparent, because the epithelia of the papilla of Vater and the common channel normally have papillae. Otherwise, the dysplastic epithelium involves the native architecture of the ampulla.

Adenocarcinoma (See Chapter 59)

Adenocarcinomas are the most common malignancies of the ampulla. Their precise incidence is difficult to determine because of definitional differences. Many carcinomas arising in the common bile duct, pancreas, or duodenum secondarily invade into the ampulla and can be mistaken as a primary. If defined stringently as tumors with their epicenter at the ampulla, with more than 75% of the tumor confined to the ampulla, or with a convincing preinvasive neoplasm within the ampulla, the incidence of ampullary carcinomas becomes fairly low, typically comprising less than 20% of carcinomas in pancreatoduodenectomy specimens.

Similar to the adenomas and IAPNs from which many of them arise (Stolte & Pscherer, 1996), adenocarcinomas are more common in the ampulla than in other sites in the small bowel (Klimstra & Adsay, 2009). Also, they are prevalent in patients with FAP (Harned & Williams, 1982), generally presenting later than the large bowel carcinomas that these patients also have. The classic presentation of ampullary adenocarcinoma is considered to be biliary obstruction accompanied by a distended, palpable gallbladder (the Courvoisier sign); in truth, a palpable gallbladder is an uncommon finding. Accurate preoperative diagnosis depends on the extent of the invasive carcinoma, relative to any residual adenoma, and on the technique of endoscopic biopsy (Elek et al 2003; Rodriguez et al, 2002). The invasive components are commonly deeply situated within the adenoma, so superficial biopsy specimens may fail to reveal invasion. Especially for carcinomas located within the common channel, endoscopic papillotomy may be helpful to reach the diagnostic areas.

Ampullary adenocarcinomas are often relatively small when detected, presumably because of early symptoms. Nearly 20% are less than 1 cm, and more than 75% are less than 4 cm at diagnosis (Albores-Saavedra et al, 2000; Tajiri et al, 2009a). Because about a third of the cases arise in an adenoma or IAPN, the overall tumor size is often misleading. The gross configuration depends on the specific epithelia involved. Some ampullary carcinomas have the bulk of the lesion at the duodenal surface of the ampulla, forming a polypoid or ulcerated mass readily recognizable endoscopically, whereas other intraampullary carcinomas are covered by intact duodenal mucosa (Fig. 56.29). Larger tumors may replace the normal ampullary structures completely, making it difficult to determine precisely where the tumor arose. A subset of ampullary carcinomas forms schirrous, constrictive lesions in the wall of the distal tips of the ducts, in particular the common bile duct, without causing an overt exophytic mass in the ampulla or on the duodenal surface.

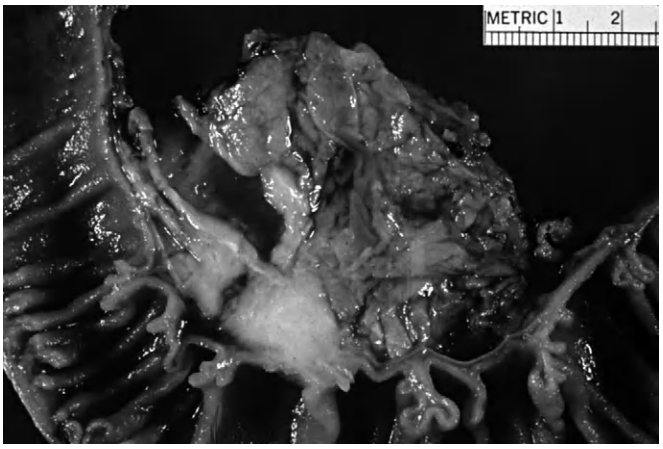

FIGURE 56.29. Ampullary adenocarcinoma, gross appearance. This intraampullary carcinoma forms a sclerotic, infiltrative mass situated in the wall of the duodenum, with associated dilation of the common bile duct and invasion into the head of the pancreas.

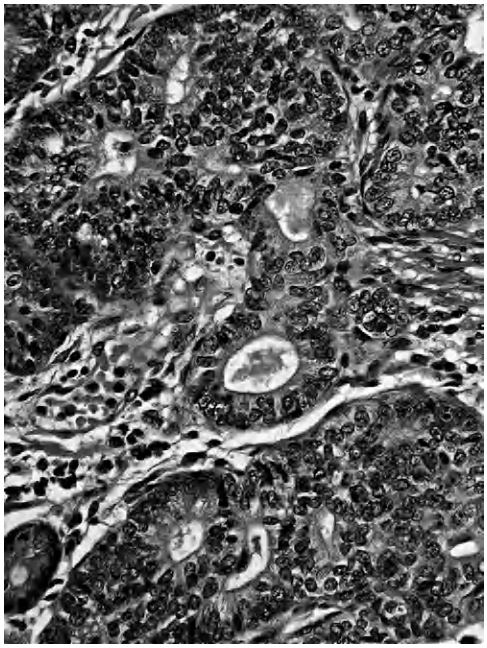

FIGURE 56.30. Ampullary adenocarcinoma, intestinal type. This invasive carcinoma is formed of cribriform, tubular glands with pseudostratified nuclei, resembling a carcinoma of the large intestine.

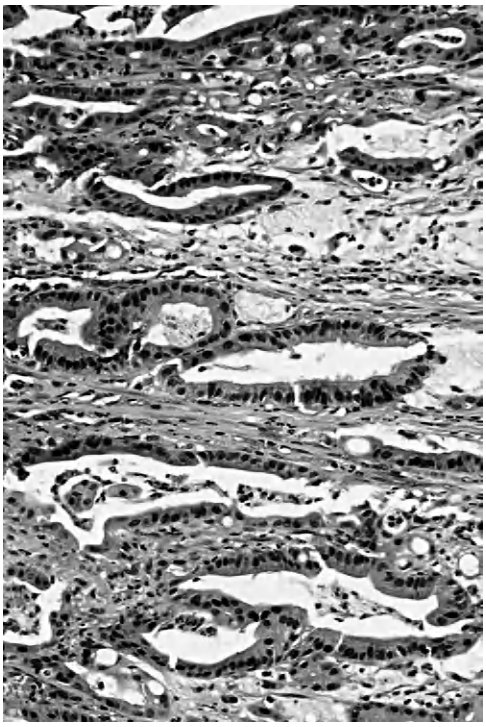

FIGURE 56.31. Ampullary adenocarcinoma, pancreatobiliary type. The glands are arranged individually, with a single layer of round nuclei and mucinous cytoplasm. Abundant desmoplastic stroma is present, resembling a primary ductal adenocarcinoma of the pancreas.

Microscopically, some ampullary adenocarcinomas resemble carcinomas of the large bowel and are referred to as *intestinal type* (Albores-Saavedra et al, 2000; Kimura et al, 1994). They are composed of individual, complex, cribriform glands with pseudostratified, elongated nuclei, commonly exhibiting extensive luminal necrosis (Fig. 56.30). Another subset of ampullary adenocarcinomas resembles ductal adenocarcinoma of the pancreas or common bile duct; these are referred to as a *pancreatobiliary type,* which show simple and relatively small glands with a single layer of cells with round nuclei and abundant stromal desmoplastic cells (Fig. 56.31). Most commonly, intestinal-type ampullary adenocarcinomas arise in association with a preinvasive neoplasm, although many pancreatobiliary-type adenocarcinomas appear to arise without a recognizable preinvasive lesion (Albores-Saavedra et al, 2000). Recent sudies have shown different biologic behavior for intestinal versus pancreatobiliary adenocarcinomas; however, it is also clear that a substantial portion of the cases has either hybrid or unclassifiable patterns, making this distinction highly subjective (Balci et al, 2010). Small, infiltrative clusters at the advancing edge of the tumor, so-called *tumor budding,* is seen quite commonly in ampullary adenocarcinomas when examined carefully and has been found to be an indicator of aggressive behavior (Ohike et al, 2010b). Perineural invasion is less common than it is in pancreatic cancer and may also be an indicator of adverse behavior (Lowe et al, 2009).

Ampullary adenocarcinomas typically invade into the muscularis of the sphincter of Oddi, extend through the duodenal submucosa and muscularis propria, and invade the pancreatic parenchyma or peripancreatic soft tissues. However, it is often difficult to determine the precise extent of the tumor at the three-dimensional level because of the anatomic complexity of this region. This may be partly responsible for the better survival recorded for stage pT2 cases compared with pT1 cases in the data from the National Cancer Database of American College of Surgeons (Edge et al, 2010). Furthermore, even relatively small invasive carcinomas can extend to the peripancreatic soft tissues, which creates problems in staging such cases (Tajiri et al, 2009a). Lymph node metastases may be found even in superficially invasive carcinomas and are detected in about 40% of patients, far less than the 75% associated with pancreatic ductal adenocarcinomas.

Numerous histologic variants of ampullary adenocarcinoma have been described, including adenosquamous carcinoma, clear cell carcinoma, mucinous adenocarcinoma, signet ring cell carcinoma, and micropapillary carcinoma, often associated with tumor infiltrating neutrophils (Albores-Saavedra et al, 2000; Hara et al, 2002; Khayyata et al, 2005; Ueno et al, 2002). Although the morphologic features of each of these subtypes are distinctive, specific clinical or genetic differences from the more common histologic types have yet to be described. Unusual carcinoma types, such as acinar, medullary, and osteoclastic giant cell, can also occur in the ampulla (see the discussion on other invasive carcinomas related to ductal adenocarcinoma).

The molecular genetic changes involved in the development of ampullary adenocarinomas roughly parallel those that occur in colorectal carcinomas: mutations in the *KRAS* oncogene are found in approximately 40% and include mutations in codon 12 and codon 13 (Scarpa et al, 1993). More than half of cases have mutations in *TP53* (Albores-Saavedra et al, 2000; Howe et al, 1997; Kubota et al, 2003; Matsubayashi et al, 1999; Takashima et al, 2000; Younes et al, 1995), and loss of *SMAD4* has been shown (McCarthy et al, 2003). However, abnormalities of DNA mismatch repair genes are uncommon in ampullary carcinomas (Park et al, 2003).

Ampullary carcinomas have a relatively favorable survival compared with ductal carcinomas of the pancreas; patients with localized disease have a 5-year survival of 50%, and patients with lymph node metastases have a 5-year survival of 28% (Albores-Saavedra et al, 2000; Howe et al, 1998; Tajiri et al, 2009b). Although some authors have questioned whether this outcome reflects a different biology for ampullary carcinoma, as opposed to simple detection at an earlier stage because of earlier onset of symptoms, even ampullary carcinoma patients with positive lymph nodes have a better survival than any group of pancreatic carcinoma patients (Howe et al, 1998).

High-Grade Neuroendocrine Carcinoma

Although high-grade neuroendocrine carcinomas of the ampulla are rare, they are more common in this location than in the pancreas (see Chapter 61). The clinical findings are the same as those of ampullary adenocarcinomas; hormonal symptoms are uncommon (Nassar et al, 2005). Many high-grade neuroendocrine carcinomas arise in association with an adenoma, and some contain mixed components of adenocarcinoma. Two histologic types occur, including *small cell carcinoma* (Zamboni et al, 1990) and *large cell neuroendocrine carcinoma* (Albores-Saavedra et al, 2000; Nassar et al, 2005). Small cell carcinomas have fusiform small cells with minimal cytoplasm, finely granular chromatin, and nuclear molding (Fig. 56.32). Large cell neuroendocrine carcinomas have moderate amounts of cytoplasm and round nuclei with prominent nucleoli. Both are distinguished from well-differentiated neuroendocrine tumors by their high mitotic rate (>20 per 10 HPFs) and abundant necrosis. Immunohistochemical evidence of neuroendocrine differentiation is generally identifiable and is required for the diagnosis of the large cell type, but staining for chromogranin and synaptophysin is less widespread than in carcinoid tumors (Fig. 56.33). Some of the molecular genetic abnormalities are different from those of ampullary adenocarcinomas, including frequent loss of retinoblastoma gene product expression (Nassar et al, 2005). High-grade neuroendocrine carcinomas are highly aggressive. Most patients are seen initially with lymph node involvement and suffer early recurrence and death from the tumor.

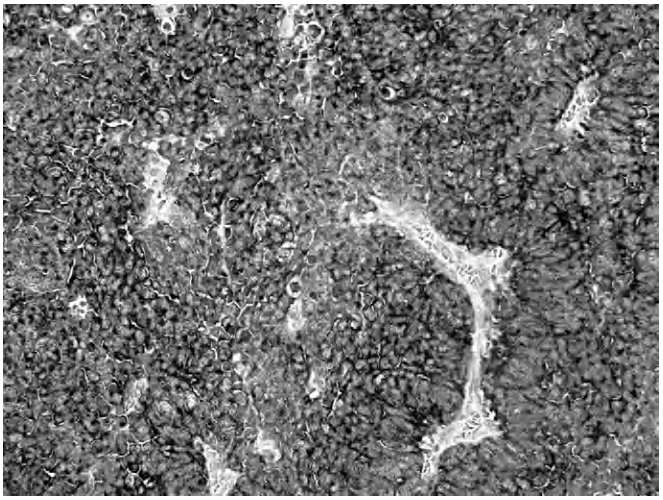

FIGURE 56.33. Large cell neuroendocrine carcinoma of the ampulla. Immunohistochemical labeling for synaptophysin confirms the endocrine nature of this carcinoma.

Well-Differentiated Neuroendocrine Neoplasms

Carcinoid Tumors

A family of well-differentiated neuroendocrine tumors occurs in and around the ampulla of Vater. Most of these have also been designated *carcinoid tumors,* although *neuroendocrine tumor* (NET) is now the preferred term (Burke et al, 1989; Hartel et al, 2005; Hatzitheoklitos et al, 1994; Niido et al, 2005). Ampullary NETs are distinguished from high-grade neuroendocrine carcinomas by their strikingly organoid growth pattern, with nests and ribbons of cells; their low mitotic rate (<20 mitoses per 10 HPFs); and their relative paucity of necrosis. They predominantly involve the submucosa and muscularis of the duodenum and ampulla, although extension into the mucosa is generally present, and endoscopic mucosal biopsy specimens usually yield diagnostic tissue (Bornstein-Quevedo & Gamboa-Dominguez, 2001). Most periampullary NETs are relatively small, ranging from a few millimeters to several centimeters. Tumors that directly involve the ampulla of Vater manifest early with biliary obstruction, whereas tumors situated in the surrounding duodenum are often asymptomatic unless associated with a neuroendocrine paraneoplastic syndrome. Periampullary NETs are associated with several hereditary genetic syndromes, including neurofibromatosis type 1 and MEN type I (Burke et al, 1989). Some NETs arising in these patients have distinctive clinical or morphologic features, representing either gastrinomas or so-called *glandular duodenal carcinoid tumors.* Most periampullary NETs are not associated with a clinical syndrome or distinctive morphology, however, and they only rarely give rise to the carcinoid syndrome, generally after the development of hepatic metastases. These NETs, not otherwise specified, resemble NETs of the stomach and upper GI tract, with a predominately solid, nested architecture; cytologic uniformity; coarsely granular chromatin pattern; and moderate amounts of amphophilic cytoplasm (Fig. 56.34; Makhlouf et al, 1999). By immunohistochemistry, the tumors strongly express the general neuroendocrine markers chromogranin and synaptophysin, and most express keratin as well (Albores-Saavedra et al, 2000; Burke et al, 1989). The low proliferative rate correlates with a low rate of immunolabeling for

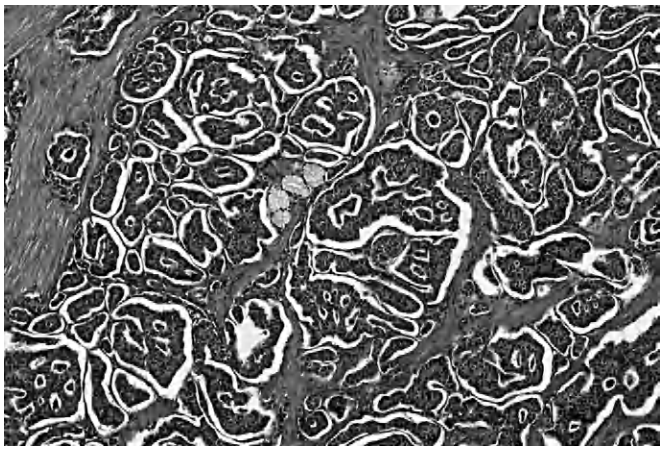

FIGURE 56.34. Well-differentiated neuroendocrine tumor of the ampulla. This neoplasm is composed of nests of uniform epithelial cells predominantly involving the submucosa and muscularis propria.

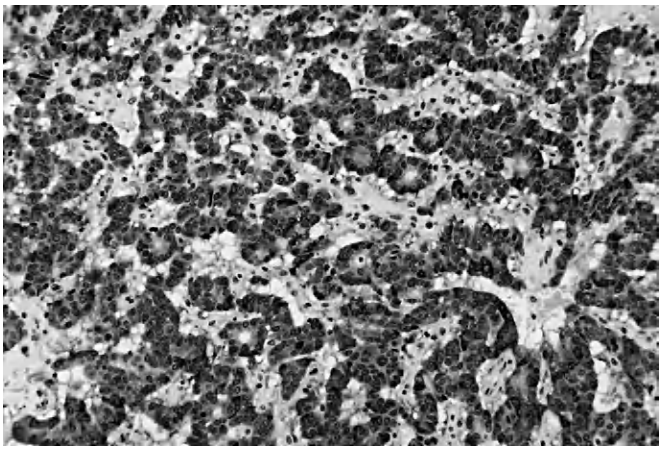

FIGURE 56.35. Gastrinoma of the ampulla. Immunohistochemical staining for gastrin shows positivity in the neoplastic cells that otherwise have characteristic features of a neuroendocrine tumor.

Ki-67, defined to be less than 20% and usually less than 5%. Small NETs (<1 cm) limited to the mucosa and submucosa generally lack lymph node metastases, and some may be treated effectively by local excision (Pyun et al, 2004); however, the lesion often proves to be more advanced than originally appreciated, and even small tumors may on occasion have metastases, thus these tumors can require pancreatoduodenectomy. As the size increases, the risk for nodal metastases also increases. Patients with nodal or hepatic metastases are difficult to cure, but the disease has a protracted clinical course, and survival for many years in the presence of liver metastases is not unusual.

Gastrinomas of the periampullary region are NETs associated with hypersecretion of gastrin, resulting in peptic ulceration (Zollinger-Ellison syndrome). Periampullary gastrinomas are particularly prevalent in patients with MEN type I, and they outnumber pancreatic gastrinomas as the source of Zollinger-Ellison syndrome (Donow et al, 1991). In contrast to the pancreatic primaries, periampullary gastrinomas are often small (<1 cm), and regional lymph node metastases from these tumors may be larger than the primaries; and in some cases, the primary tumor is difficult to identify (Anlauf et al, 2008). For this reason, some authors advocate pancreatoduodenectomy for patients with gastrinoma syndrome with an unidentified primary to remove the most plausible culprit region, the "gastrinoma triangle." Processing of such specimens in the pathology laboratory may require special protocols (Anlauf et al, 2008). Histologically, gastrinomas are indistinguishable from nonfunctioning NETs, but gastrin production is usually demonstrable by immunohistochemistry (Fig. 56.35). Although regional lymph node metastases are commonly present, periampullary gastrinomas have a better long-term prognosis than pancreatic gastrinomas, which are usually considerably larger at the time of diagnosis.

Glandular duodenal carcinoid tumors, also known as *ampullary somatostatinomas* or *psammomatous somatostatinomas,* are well-differentiated NETs with an exquisitely glandular growth pattern (Thirabanjasak et al, 2008). These tumors are highly characteristic of the periampullary region and are closely associated with neurofibromatosis type 1, although sporadic examples occur (Burke et al, 1990). Many of these tumors produce somatostatin (Dayal et al, 1983), and they almost never cause the somatostatinoma syndrome, in contrast to pancreatic somatostatinomas. In addition to their gland-forming architecture, glandular duodenal carcinoid tumors often exhibit psammoma bodies (Fig. 56.36; Albores-Saavedra et al, 2000; Dayal et al, 1983). By immunohistochemistry, expression of general neuroendocrine markers, such as chromogranin and synaptophysin, is consistent, and somatostatin is usually detectable. Although the nuclear features are those of a well-differentiated NET, the glandular architecture of glandular duodenal carcinoid tumors may cause confusion for adenocarcinoma. Also, abundant, lightly eosinophilic cytoplasm causes resemblance of the neoplastic glands to submucosal Brunner glands of the duodenum on endoscopic biopsy specimens. Glandular duodenal carcinoid tumors are relatively aggressive in their spread and are frequently associated with lymph node and hepatic metastases; however, limited data in the literature indicate that they may still be indolent neoplasms like other ampullary-region NETs (Thirabanjasak et al, 2008).

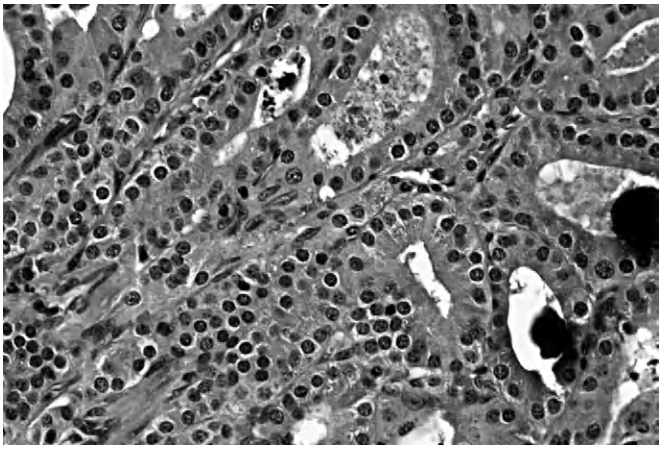

FIGURE 56.36. Glandular duodenal carcinoid of the ampulla. The uniform endocrine cells are arranged in well-formed glands with granular eosinophilic cytoplasm. Calcified psammoma bodies are a characteristic feature.

Gangliocytic Paraganglioma

A pathologically distinctive tumor that is essentially limited to the ampullary region, gangliocytic paraganglioma contains a variety of different cell types that have defied a logical histogenetic explanation. Most patients are adults who present with minimal symptoms, unless the tumor is close enough to the ampulla to cause biliary obstruction. Some cases are associated with neurofibromatosis type 1 (Burke & Helwig, 1989; Castoldi et al, 2001), but the association is less strong than for glandular duodenal carcinoid tumors. Gangliocytic paragangliomas are situated in the submucosa, similar to NETs, and some are polypoid or pedunculated and usually measure 1 to 3 cm. Microscopically, three different cellular components vary in proportion from case to case (Fig. 56.37; Albores-Saavedra et al, 2000; Burke & Helwig, 1989). Nests of epithelioid neuroendocrine cells are usually predominant. Individual ganglionic cells have abundant cytoplasm and large, round nuclei with prominent nucleoli. Finally, a spindle cell component represents Schwann cells. The neuroendocrine cells stain for chromogranin and synaptophysin and variably express keratin (Collina et al, 1991); this last finding establishes a relationship with NETs and distinguishes them from true paragangliomas. The ganglion cells express synaptophysin and neurofilaments, and the schwannian component stains for S100 protein. Most gangliocytic paragangliomas also produce pancreatic polypeptide (Altavilla et al, 2001). The origin of these tumors has been debated, because they contain endodermally derived (NET-like elements) and neural crest–derived (schwannian) components (Perrone, 1986). Most gangliocytic paragangliomas are benign, but rare metastases have been reported.

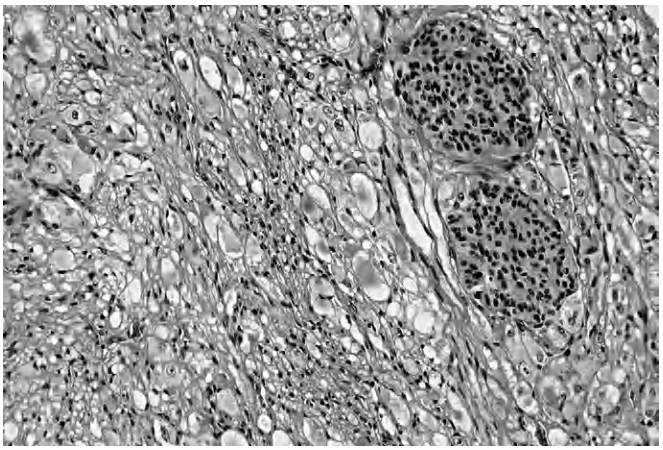

FIGURE 56.37. Gangliocytic paraganglioma of the ampulla. The neoplasm has three characteristic elements: the nested neuroendocrine tumor–like epithelial component, the large ganglion cells with abundant granular cytoplasm, and the intervening spindled Schwann cell component.

CHAPTER 57

Cystic neoplasms of the pancreas: epidemiology, clinical features, assessment, and management

James J. Mezhir and Peter J. Allen

OVERVIEW

Cystic neoplasms of the pancreas have become a well-defined radiographic entity over the last decade. With increasing use of cross-sectional imaging, nearly 2.6 cystic lesions per 100 individuals are encountered per year (Brugge et al, 2004a; Gorin & Sackier, 1997; Kimura et al, 1995). These lesions have a broad histologic differential, which has been well characterized by Klöppel and Kosmahl (2001) and others (Table 57.1; Kosmahl et al, 2004). This differential includes benign nonneoplastic pancreatic pseudocysts and also cystic neoplasms, which comprise benign entities such as serous cystadenoma, premalignant cysts such as intraductal papillary mucinous neoplasms (IPMNs), and cystic lesions with invasive carcinoma. The ability to differentiate among neoplastic pancreatic cystic neoplasms without the need for resection continues to evolve. Serous cysts can often be differentiated from mucinous cysts by cross-sectional imaging and endoscopic ultrasound (EUS) with cyst fluid analysis (Allen et al, 2003, 2006; Allen & Brennan, 2007; Brugge et al, 2004b; Carpizo et al, 2008; Ferrone et al, 2009). However, diagnostic dilemmas continue, and the ability to predict future progression to malignancy within the premalignant group is currently limited (Lee et al, 2008).

As shown in Table 57.1, these lesions remain a diagnostic challenge. As their incidence increases, so does the differential diagnosis. With an increasing knowledge of the clinicopathologic variables predictive of malignancy and an improved understanding of the natural history of many of the common cystic lesions, management has changed to one of selective resection. Despite the improvement in diagnostic capability, there still remain a significant number of lesions that are indeterminate; in this setting the clinician must balance the risk of malignancy with the morbidity and mortality associated with pancreatic resection.

Following is a summarization of the current literature on the diagnosis and management of patients with cystic neoplasms of the pancreas.

CLINICOPATHOLOGIC VARIABLES

The majority of patients with pancreatic cysts will have nonneoplastic inflammatory pseudocysts that develop as a complication of acute pancreatitis (see Chapter 54; Brugge et al, 2004a; Cannon et al, 2009). A *pseudocyst* is a fluid collection that is devoid of an epithelial lining. Pseudocysts have been reported to develop in up to 50% of patients who have acute pancreatitis (Cannon et al, 2009; Grace & Williamson, 1993; O'Malley et al, 1985). Because of the frequency of pancreatitis, some studies have reported that pseudocysts comprise up to 85% of all cystic pancreatic lesions. Pseudocysts can be managed with observation, endoscopic drainage, or operative drainage (Cannon et al, 2009). The particulars of the management of patients with pancreatic pseudocysts are beyond the scope of this chapter.

Cystic neoplasms are a heterogeneous group of lesions carefully described by Klöppel and Kosmahl (see Table 57.1; Klöppel & Kosmahl, 2001; Kosmahl et al, 2004). They comprise approximately 10% to 15% of cystic lesions of the pancreas and are a heterogeneous group of lesions that range from benign to malignant. Despite the fact that numerous neoplasms can present as a cystic lesion, the most common cystic neoplasms encountered by surgeons include serous cystadenoma (SCA), mucinous cystic neoplasm (MCN), and intraductal papillary mucinous neoplasm (IPMN). In a study by the French Surgical Association of 372 resected cystic neoplasms from 73 institutions, these three lesions comprised 87% of all lesions (Le Borgne et al, 1999). More recent series of pancreatic cystic neoplasms are outlined in Table 57.2. The clinicopathologic

Table 57.1

Classification of Cystic Neoplasms of the Pancreas

Neoplastic	Nonneoplastic
Epithelial	**Epithelial**
Benign	Congenital cyst (in malformation syndromes) Lymphoepithelial cyst Mucinous nonneoplastic cyst Enterogeneous cyst Retention cyst Periampullary duodenal wall cyst Endometrial cyst
Serous adenoma (microcystic) Serous adenoma (oligocystic, poorly demarcated) MCN IPMN Acinar cell cystadenoma Dermoid cyst Cystic hamartoma Von Hippel–Lindau–associated cystic neoplasm	**Nonepithelial**
Borderline	Pseudocyst Parasitic cyst
MCN IPMN Solid pseudopapillary tumor	
Malignant	
MCN-associated carcinoma IPMN-associated carcinoma Ductal adenocarcinoma, cystic Serous cystadenocarcinoma Pancreatoblastoma, cystic Cystic metastatic epithelial neoplasm Neuroendocrine carcinoma, cystic	
Nonepithelial	
Benign neoplasm (i.e., lymphangioma) Malignant neoplasm (i.e., sarcoma)	

IPMN, intraductal papillary mucinous neoplasm; MCN, mucinous cystic neoplasm

Modified from Kosmahl M, et al, 2004: Cystic neoplasms of the pancreas and tumor-like lesions with cystic features: a review of 418 cases and a classification proposal. Virchows Arch 445(2):168-178.

factors associated with the more common cystic neoplasms are shown in Table 57.3.

Serous Cystadenomas

Serous cystadenomas (SCA) were first characterized by Compagno and Oertel in 1978 as microcystic and glycogen rich, and they distinguished these lesions from mucinous cysts (MCNs and IPMNs) (Compagno & Oertel, 1978a). SCAs occur with variable size, and when large (>10 cm) may cause symptoms from local compression. Grossly, these cysts are characterized by septations and thick fibrous walls and have what appear to be innumerable small cysts containing clear, thin fluid. A classic honeycomb appearance is often present, as is a calcified central scar with or without hemorrhage (Fig. 57.1A and B). On imaging, these lesions may appear as a single, large cyst (oligocystic) (Fig. 57.1C and D); if so, they are very difficult to distinguish from mucinous lesions. Because of the fibrous nature of this lesion, a solid component is often visualized; if noted in the presence of the other characteristic findings of SCA, this should not be concerning for malignancy. Histologically these lesions are characterized by a bland, cuboidal epithelial lining without nuclear polymorphism or mitoses. Typically, no mucin is present in the epithelial lining, but glycogen may be detected in the cytoplasm or in the amorphous cellular material.

SCAs are generally considered benign lesions, and only 25 cases of serous "cystadenocarcinoma" have been reported in the world literature as of 2010 (King et al, 2009; Matsumoto et al, 2005). Many of these case reports describe the "malignant" serous cystadenoma as locally invasive, and only 9 (36%) of 25 cases had evidence of metastasis. Despite the presence of metastasis, long-term prognosis remains excellent in these patients; it appears that the true incidence of malignancy within SCA is less than 1%. The institutional database at Memorial Sloan-Kettering Cancer Center (MSKCC) includes approximately 200 patients who have had resection for SCA, and none has developed or presented with metastatic disease. The more common problem caused by these lesions is local invasion that results in symptoms such as early satiety, obstructive jaundice, and pain. It stands to reason that large lesions are more likely to produce symptoms; however, many patients with lesions greater than 10 cm in diameter will have their lesion identified incidentally; for example, with a mean diameter of 11 cm, 71% of patients had symptoms compared with a mean diameter of 5 cm, with which 53% had symptoms (Compagno & Ortel, 1978a; Tseng et al, 2005).

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCNs) are mucin-producing cystic tumors that lack communication with the pancreatic duct and contain mucin-producing columnar epithelium. Ovarian-like stroma surrounding the columnar epithelium is considered a pathognomonic finding and is the presumed reason that MCNs are almost exclusively found in females. The stroma is a characteristic that pancreatic MCNs share with some mucinous

Table 57.2

Single-Institution Series of Patients with Resected Cystic Neoplasms of the Pancreas

Reference	Years (Inclusive)	No. Patients	SCA N (%)	MCN N (%)	IPMN N (%)	SPT N (%)	Pseudocyst N (%)	Other N (%)	Malignancy N (%)*

SCA, serous cystadenoma; MCN, mucinous cystic neoplasms; IPMN, intraductal papillary mucinous neoplasm; SPT, solid pseudopapillary tumor

*Includes ductal adenocarcinoma, serous cystadenocarcinoma, mucinous cystadenocarcinoma, neuroendocrine neoplasm, and cystic neoplasms with high-grade dysplasia.

Table 57.3

Characteristics of Common Cystic Neoplasms of the Pancreas

Cystic Neoplasm	Mean Age (Yr)	Gender (M/F)	Gross Features	Macroscopic Features	Imaging Characteristics	Cyst Fluid Characteristics	Cyst Fluid Cytology
Serous cystadenoma	61-65	7:3	Variable size, microcystic, stellate scar	Clear cytoplasm, well-defined borders, uniform nuclei, glycogen-rich cells	Microcystic, characteristic honeycomb pattern, stellate scar	Low viscosity, CEA low, amylase low	Cuboidal cells, clear glycogen-rich cytoplasm
Mucinous cystic neoplasm	45-55	>10:1	Large size, multilocular, thick walled	Tall, columnar mucin-producing epithelial; ovarian-type stroma	Macrocystic, body/tail location, does not communicate with duct, peripheral calcifications	High viscosity, CEA elevated, amylase low	Variable cellularity with columnar cells with or without atypia
Intraductal papillary mucinous neoplasm	65-75	1:1	Variable size, multilocular, involves main or branch ducts	Mucin-producing epithelium with papillae	Macrocystic ductal involvement	High viscosity, CEA elevated, amylase high	Variable cellularity with columnar cells with or without atypia
Solid pseudopapillary tumor	25	9:1	Irregular cystic cavities with hemorrhage	Solid sheets of variable cells, hyaline globules neuroendocrine features	Macrocystic areas of hemorrhage	Bloody necrotic debris	Polygonal cells, eosinophilic cytoplasm
Ductal adenocarcinoma with cystic degeneration	60-80	1:1.3	Mass with cystic degeneration	Ductal adenocarcinoma	Cyst with solid component, ductal dilation	Bloody necrotic debris	Malignant cells
Pseudocyst	Variable	1:1	Fibrous, thick-walled capsule	No epithelial lining	Unilocular, associated with pancreatitis	Low viscosity, CEA low, CA19-9 elevated, amylase elevated	Inflammatory cells, no mucin, epithelial cells

Modified from Carpizo et al, 2008: Current management of cystic neoplasms of the pancreas. Surgeon 6(5):298-307.

cysts of the ovary and the liver. Pancreatic MCNs are most commonly found in the body and tail and can range in size from small (2 cm) to large (25 cm). Despite their distal location, patients are often symptomatic (76% in a review of multiple series) at the time of diagnosis (Goh et al, 2006).

Any macrocystic lesion in the distal pancreas of a female patient should be highly suspicious for MCN. These lesions are often unilocular but may contain septa within the primary lesion (Fig. 57.2A to C). When these lesions are multilocular, they are typically macrocystic, in contrast to serous cystadenomas. These lesions may also have peripheral "eggshell" calcifications. Any evidence of mural nodularity in these lesions should be concerning for invasion (Fig. 57.2D). Upon gross inspection, these tumors are round, with a smooth surface and fibrous pseudocapsule.

Unlike serous cystadenomas, MCNs have a risk for harboring malignancy. Rates of invasive disease range from 10% to 50%, which may be an underestimate because of the fact that both benign and malignant epithelium may coexist within the same cyst. Only an extensive pathologic evaluation will detect both entities, which is critical for accurate diagnosis. Clinical factors that increase the risk for malignancy in MCNs are not well characterized, but one study found that older age was more often associated with cancer (Crippa et al, 2008). Factors on imaging associated with malignancy within MCNs include the presence of septations, larger size, and mural nodularity (Allen et al, 2006; Zamboni et al, 1999). Because these lesions are so rare, their natural history is not well defined, although the extent of invasion was demonstrated to be associated with recurrence and death from disease in one study (Allen et al, 2006; Zamboni et al, 1999). In one of the largest studies of MCNs to date, 5-year disease-specific survival for patients with malignancy was 57% (Goh et al, 2006).

Intraductal Papillary Mucinous Neoplasms

Before the first classification system published by the World Health Organization (WHO) (Klöppel et al, 1996), IPMN was described under a variety of names, including *mucinous ductal ectasia*, *papillary carcinoma*, and *villous adenoma*. In contrast to other mucinous and cystic tumors, IPMNs occur equally in men and women and are more often found in older individuals, with the peak incidence between 60 and 70 years of age (Brugge et al, 2004a). Among cystic neoplasms diagnosed in large series, IPMNs represent approximately 15% to 30% of all lesions (see Table 57.2; Allen et al, 2006; Ferrone et al, 2009; Kosmahl et al, 2004; Spinelli et al, 2004). Because of the recent evolution in the understanding of IPMNs, many early reports may include a mixture of patients with IPMNs and MCNs and should be interpreted with caution.

Current nomenclature as defined by the WHO divides IPMN into the categories of *adenoma* (low-grade dysplasia), *borderline* (moderate dysplasia), *carcinoma in situ* (high-grade dysplasia), and *carcinoma* (Furukawa et al, 2005). As clinical experience with IPMN increases, it is becoming more evident that the underlying process presents as a spectrum of neoplasia with significant variation (Schnelldorfer et al, 2008). The clinical and radiologic presentation, malignant potential, and

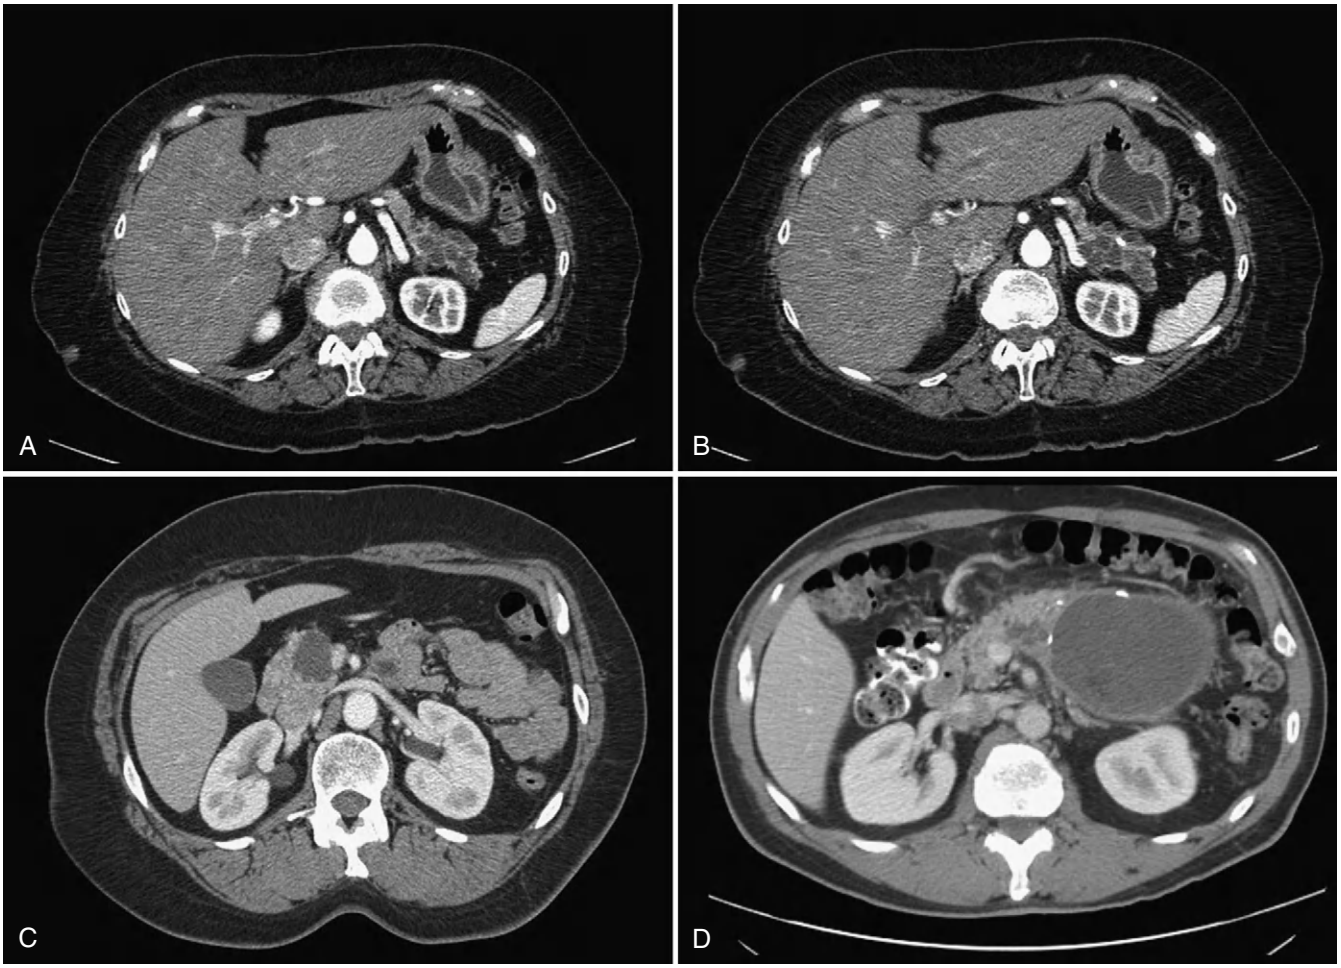

FIGURE 57.1. Imaging characteristics of serous cystadenoma. **A,** Classic honeycomb appearance. **B,** Central calcification. **C,** Oligocystic serous cystadenoma. **D,** Large cystic neoplasm with peripheral calcification, a thickened wall, and pancreatic ductal dilation. This patient underwent distal pancreatectomy and splenectomy because of the inability to exclude malignancy. Final diagnosis was serous cystadenoma.

disease-specific outcomes are highly variable. There also appears to be a progression from adenoma to intraductal carcinoma to invasive carcinoma that can be predicted based on molecular studies.

IPMN is indeed a process that involves the entire pancreas; however, radiographically detectable disease may involve the main duct alone, branch ducts alone, or both (mixed variant). The main duct variant of IPMN is typically seen with diffuse ductal dilation (Fig. 57.3). The presence of a discrete mass or solid component should be concerning for malignancy. Branch duct IPMNs, particularly when smaller than 3 cm, do not have any defining features. They may be unilocular, multilocular, and may be present without dilation of the main pancreatic duct. In the absence of septations, mural nodules, or a solid component, branch duct IPMNs may be indistinguishable from pancreatic retention cysts, MCNs, small cystic endocrine tumors, or even pancreatic pseudocysts.

IPMNs are now a well-characterized mucinous cystic tumor of the pancreas evidenced by ductal involvement and mucin production. Recently, a histopathologic consensus conference defined IPMN as a grossly visible, noninvasive, mucin-producing neoplasm arising from either the main or side branches of the pancreatic duct with variable degrees of ductal dilation (Fig. 57.4A; Furukawa et al, 2005). On histologic analysis, IMPN lesions are characterized by papillary projections of columnar lined epithelium with varying degrees of dysplasia. Mucin is typically abundant both within the cytoplasm of the lining epithelial cells as well as within the acellular fluid matrix (Fig. 57.4B).

IPMN-Associated Malignancy

Malignancy arising from IPMN is well documented, and several large series have been reported in the literature (Table 57.4; D'Angelica et al, 2004; Nara et al, 2009; Salvia et al, 2004; Schnelldorfer et al, 2008; Shin et al, 2010; Sohn et al, 2004; Woo et al, 2009). Invasive cancer is found in 20% to 50% of resected IPMN specimens, which is the reason that these lesions are typically resected. Factors shown to be associated with the presence of invasive cancer in large series include symptoms at presentation, large size, mural nodularity, main duct dilation, and elevated levels of carbohydrate antigen 19-9 (CA19-9).

The reported outcome associated with invasive cancer in patients with IPMN of 5-year survival of 43% to 60% is better than that of ductal adenocarcinoma (15%) (see Chapter 58) following resection. Poultsides and colleagues (2010) reported the Johns Hopkins experience of IPMN-associated invasive cancers and found that compared with patients with ductal

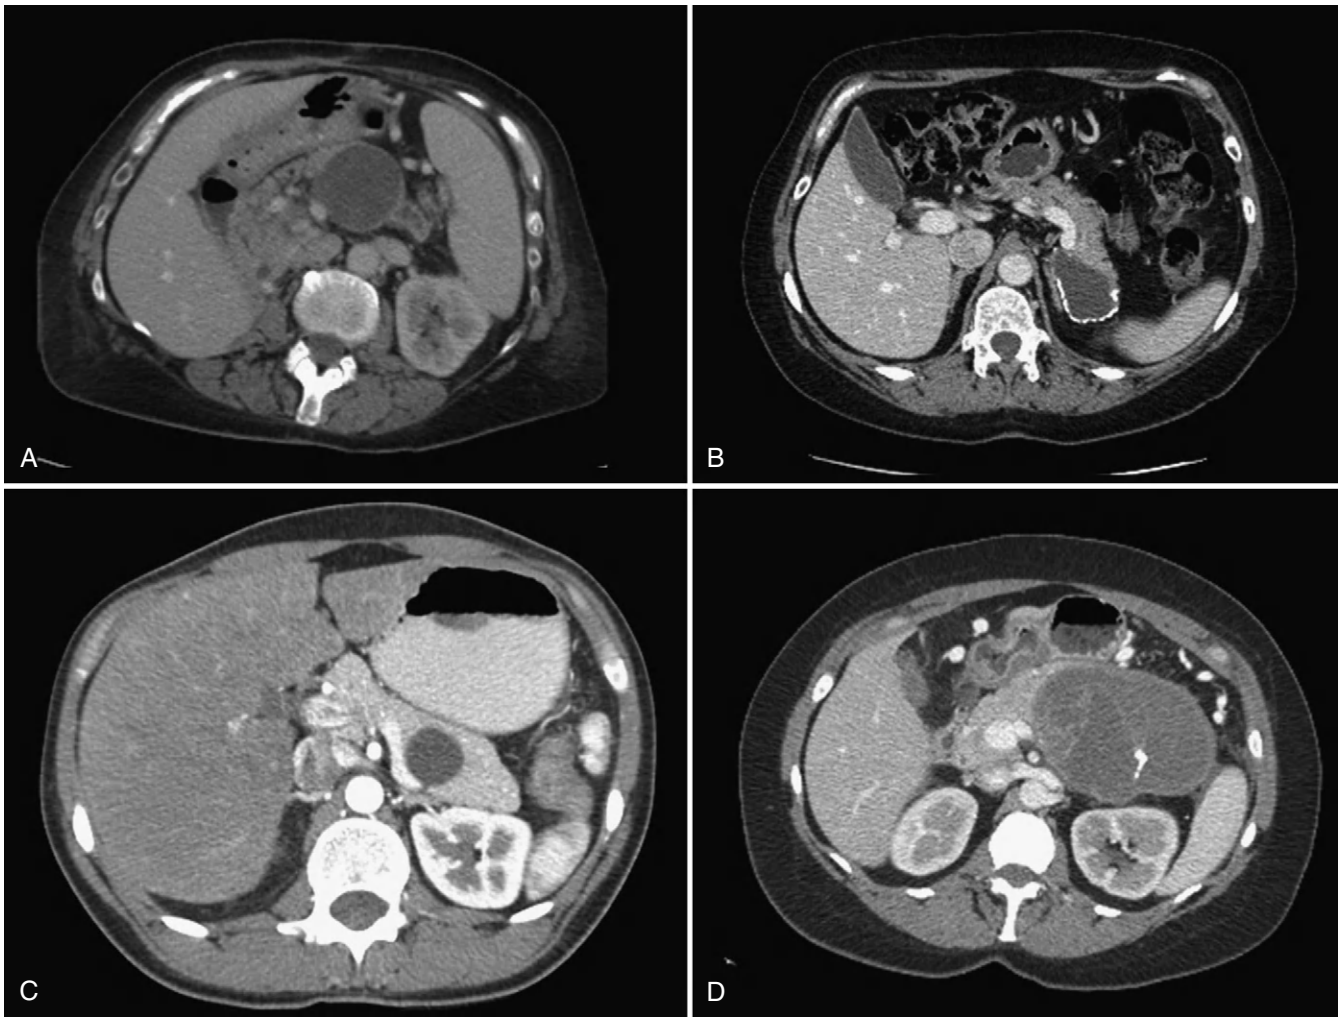

FIGURE 57.2. Imaging characteristics of mucinous cystic neoplasm. **A,** Unilocular lesion in the tail of the pancreas in a young female. **B,** Peripheral "eggshell" calcifications. **C,** Oligocystic lesion in tail of pancreas. **D,** Large macrocystic lesion with central calcification and mural nodularity.

adenocarcinoma, IMPN patients had a lower rate of advanced T stage and lymph node metastasis. Patients with ductal adenocarcinoma more often had high-grade lesions and evidence of perineural invasion, vascular invasion, and positive margins. Despite patients with IPMN-associated cancers having an overall better outcome, if any of the adverse tumor-related factors were present, outcome was similar to patients with ductal adenocarcinoma. It can be inferred from this study that the improved outcome of IPMN-associated cancers is a factor of earlier stage of disease at resection.

Variants of IPMN-associated cancer also have different prognoses. A matched controlled study from our institution demonstrated that patients with colloid-subtype invasive IPMN had significantly better survival than both matched patients with conventional pancreatic carcinoma and patients with invasive tubular IPMN. Fifty-nine patients with IPMN-associated cancer were matched one-to-one with patients with ductal adenocarcinoma with factors from the MSKCC pancreatic cancer nomogram (unpublished data). Among IPMN-associated cancers, tubular histology (compared with the colloid variant) and lymph node involvement were negative prognostic factors associated with outcome. Patients with conventional adenocarcinoma more often presented with obstructive jaundice and had more specimens with evidence of perineural/vascular invasion and regional lymph node metastasis. Survival among patients with colloid variant carcinoma (87% estimated 5-year survival) was significantly better compared with patients with tubular cancers (55%) and ductal adenocarcinoma (23%) (Fig. 57.5).

DIAGNOSTIC EVALUATION OF PANCREATIC CYSTIC NEOPLASMS

High-quality cross-sectional imaging is the key to the diagnostic evaluation of any cystic lesion of the pancreas (see Chapter 16; Sahani et al, 2005). Multidetector computed tomography (CT) allows thin-section imaging of the pancreas and is the most common method at our institution for evaluation of pancreatic cysts. A high-quality CT scan can carefully delineate and characterize the pancreatic parenchyma near a cystic lesion, which is critical in assessing for a radiographically occult malignancy causing adjacent dilation of a pancreatic duct (Allen et al, 2006). In addition, careful visualization of the cystic lesion allows evaluation of septations, mural nodules, and

calcifications. Magnetic resonance cholangiopancreatography (MRCP) can also be used to define cyst morphology and may actually be better than CT for determining a communication with the pancreatic duct and to diagnose branch duct IPMN (Koito et al, 1998; Sainani et al, 2009).

An improvement in endoscopic techniques has significantly improved the clinician's ability to evaluate pancreatic cystic neoplasms (Michael & Gress, 2002). EUS with or without cyst aspiration is a valuable diagnostic tool in the assessment of indeterminate cystic lesions (see Chapter 14). Because this procedure is operator dependent, a gastroenterologist with expertise in performing EUS is highly valuable (Ingram & Arregui, 2004). Careful evaluation with EUS can provide detailed images of the cyst wall and internal cyst architecture. Fine-needle aspiration and biopsy can be performed with EUS and may include both biopsy of the cyst and aspiration of cyst fluid for cytology and analysis for tumor markers (Linder et al, 2006).

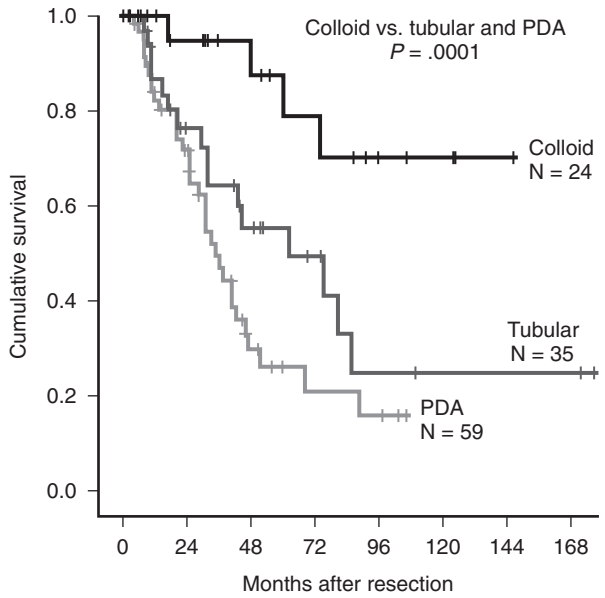

FIGURE 57.5. Outcome of intraductal papillary mucinous neoplasm–associated malignancy *(Memorial Sloan-Kettering Cancer Center, unpublished data). PDA, pancreatic ductal adenocarcinoma.*

Cyst fluid analysis has been extensively studied as a diagnostic tool in assessment of cystic lesions of the pancreas (Allen et al, 2009; Brugge et al, 2004b; Hammel et al, 1995, 1997; Sand et al, 1996). Numerous markers have been evaluated including CA19-9, CEA, CA15-3, MUC proteins, K-Ras, and amylase. In a landmark study by Brugge and colleagues (2004b), cyst fluid CEA greater than 192 ng/mL was the best predictor of a mucinous lesion, which accurately defined these lesions in 79% of patients. An elevation of cyst fluid CEA in combination with the presence of extracellular mucin has been shown to have a positive predictive value as high as 85% in some series. The ability to predict the presence of invasive disease, however, has not been demonstrated by measurement of cyst fluid CEA. SCA and pancreatic retention cysts uniformly have undetectable levels of CEA (Lewandrowski et al, 1993; van der Waaij et al, 2005).

One of the most significant diagnostic challenges is to delineate serous from mucinous cysts. Unfortunately, cyst fluid evaluation for both cytology and tumor markers is limited in this evaluation. The limitations of cyst fluid cytology stem from the very small volume of evaluable fluid and the low cellular content of aspirates. Furthermore, the samples are often contaminated with mucin and mucin-producing cells from the stomach or duodenum, where the EUS needle is passed to reach the cyst.

TREATMENT OF PANCREATIC CYSTIC NEOPLASMS

If the histopathology of a cystic neoplasm can be diagnosed by clinical and imaging criteria, treatment recommendations can be made based on the known behavior of that specific histologic

entity. In some instances, most often in patients with small cysts, the exact histopathologic diagnosis cannot be determined without formal pancreatectomy. It is under these circumstances that treatment recommendations are based on the radiographic and *inferred* histopathology, once a comprehensive diagnostic evaluation is complete.

Serous Cystadenoma

When radiographic and/or endoscopic findings are characteristic of SCA, resection should be reserved for young patients with significant growth or for those whose lesion is clearly symptomatic. As previously discussed, asymptomatic patients have a risk of malignancy of less than 1%. For these lesions the risk associated with pancreatectomy is much greater than the risk of cancer, and it is well documented that the risk of malignancy in SCA is exceedingly rare. The scenario that presents a challenge is the young asymptomatic patient because the natural growth history of SCA is not well defined.

Tseng and colleagues (2005) radiographically followed 24 patients with SCA for a median of 23 months and reported a 0.6 cm per year median growth rate for these lesions and noted that larger lesions (≥4 cm) had a higher growth rate (1.98 cm/year) compared with lesions smaller than 4 cm (0.12 cm/year). The authors recommended that all patients with SCAs larger than 4 cm be resected, regardless of symptoms. At MSKCC, we have noted a growth rate for SCA of approximately 0.5 cm per year but have not found an association between larger size and faster growth (Allen et al, 2006). It is our current practice to observe asymptomatic patients, regardless of lesion size, with the possible exception of those patients who have large lesions that are marginally resectable at presentation, where tumor growth would preclude the ability to perform resection. However, even in the latter circumstance, resection of asymptomatic SCA is difficult to justify given its benign nature.

Mucinous Cystic Neoplasms

Because of the malignant potential of MCNs, it is recommended that these lesions be resected in most cases. MCNs are more often located in the distal pancreas and therefore may be amenable to splenic preservation and laparoscopic resection, which has been demonstrated to be safe and feasible. The remnant pancreas is not known to be at risk following resection of MCN, and therefore patients do not require long-term follow-up. Patients with features concerning for malignancy should have a formal pancreatectomy. Patients with mucinous cystadenocarcinomas should undergo postoperative surveillance the same as patients with pancreatic cancer.

Intraductal Papillary Mucinous Neoplasms

Resection is reserved for selected patients with IPMNs. When radiographic or endoscopic studies identify dilation of the main pancreatic duct and/or any other concerning features, the standard approach is resection. Concerning radiographic features in the setting of branch duct IPMN include a solid component or mural nodule, septations, or size greater than 3 cm (Allen et al, 2006). Lesions in the head of the pancreas are resected with pancreatoduodenectomy, and in the tail, distal pancreatectomy with or without splenectomy is used. In centers where pancreatectomy is commonplace, central pancreatectomy may be considered for lesions in the body of the pancreas. Total pancreatectomy is reserved for fit patients with diffuse IPMN; however, this procedure should be reserved for highly selected patients, in whom surveillance of the affected remnant duct would not be feasible.

The goal of resection of IPMN is to achieve a complete resection. One of the controversies that exist is the extent of pancreatic resection (Lai & Lau, 2005). IPMN is considered a diffuse process; therefore some concern has been raised that removal of only part of the pancreas would be inadequate. The clinical significance of a glandular recurrence in a patient with invasive IPMN is small because invasive IPMN is a disease characterized more by distant recurrence, similar to that of ductal adenocarcinoma. However, patients who undergo resection of noninvasive IPMN are at risk for recurrence in the remnant pancreas. In a recent report from MSKCC, White and colleagues (2007) reviewed 78 patients who had a resection for noninvasive IPMN; at a median follow-up of 40 months, a recurrence rate in the remnant pancreas of 8% was reported. Only 2% of patients (1 in 50) with a negative margin had recurrence, but 17% of those (4 of 23) with a margin positive for IPMN had recurrence ($P = .02$). Because 92% of this cohort of patients did not have a recurrence, it would seem that the risk associated with total pancreatectomy outweighs the risk for recurrence. However, routine surveillance of these patients with cross-sectional imaging is recommended. In this study, recurrences occurred at a median of 22 months (range, 8 to 62 months) from the time of initial resection and were noninvasive. Completion pancreatectomy is indicated for treatment of any detected recurrence.

One of the challenges of managing patients with IPMN is that many patients are young and are seen with small cysts in the head of the pancreas. Our institution and others have demonstrated the exceedingly rare incidence of invasive malignancy in cysts smaller than 3 cm (Allen et al, 2006; Lee et al, 2008; Sahani et al, 2006). We have not seen invasive IPMN less than 3 cm in the setting of isolated branch duct disease without concerning radiographic features. Because of the low risk of invasive cancer in small mucinous cysts, our current approach to these lesions is selective. Resection is indicated for patients with symptoms, which are infrequently present in patients with cystic neoplasms. A second indication for resection is for cysts with concerning features, such as a solid component or increasing size (Fig. 57.6; Allen et al, 2006). If the decision is made for nonoperative management, our current surveillance protocol includes high-quality cross-sectional imaging with multidetector CT scan or magnetic resonance imaging (MRI) every 6 months for 2 years (Landa et al, 2009). After 2 years of demonstrable stability, patients can graduate to annual imaging. Indications for resection in patients undergoing surveillance include significant tumor growth or development of other features concerning for malignancy.

Solid Pseudopapillary Tumor and Other Cystic Pancreatic Neoplasms

Solid pseudopapillary tumors (SPTs) are also known as *Frantz tumors* or *Hamoudi tumors* after the pathologists who first described this unique entity (Frantz, 1959; Hamoudi et al, 1970). SPTs are rare tumors that account for up to 2.5% of resected pancreatic neoplasms. They predominate in young women and are often discovered when patients have symptoms. In a review of SPTs, Papavramidis and Papavramidis (2005) described the clinicopathologic factors of 718 patients collected from the English literature. The female/male ratio was 9.8:1,

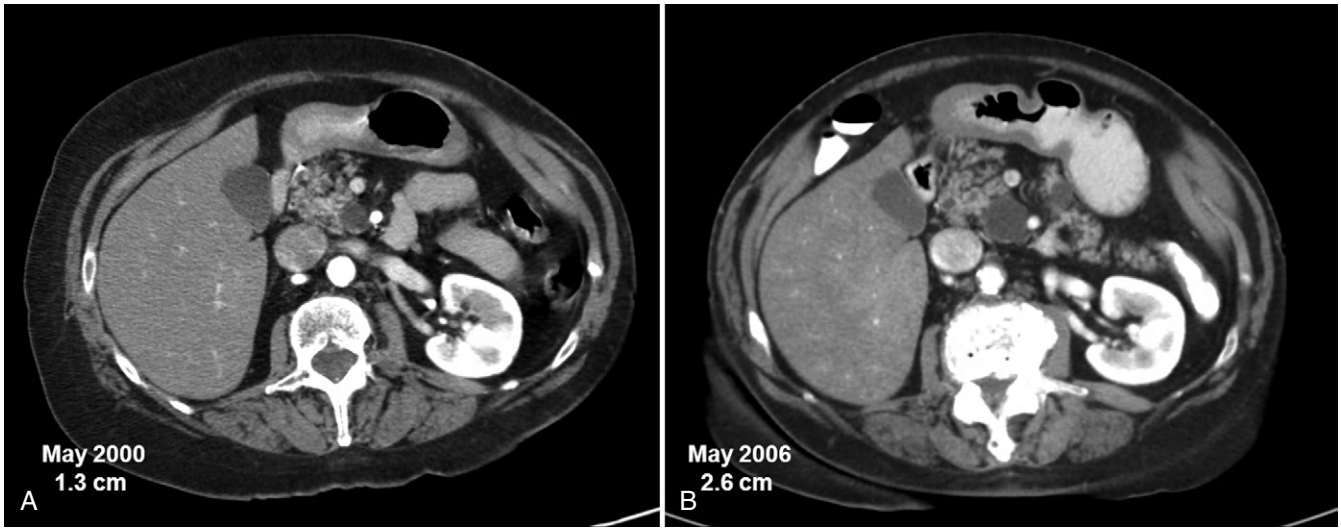

FIGURE 57.6. A, Intraductal papillary mucinous neoplasm (IPMN) in the head and uncinate process of the pancreas in a 68-year-old woman. Because the lesion was small without associated concerning features, the patient was initially only monitored. **B,** Over time, the lesion increased in size, and the patient underwent pancreatoduodenectomy. Final pathology revealed a main duct IPMN with moderate dysplasia.

and the mean age was 22 years. Only 15% of the patients in the review were asymptomatic at presentation; 47% had pain, and 35% had a mass. Tumors were often large, and 34% were greater than 10 cm in diameter. The most common location for SPT was the tail (36%) and head (34%) of the pancreas, and metastases were present in approximately 20% of patients.

Cross-sectional imaging characteristically reveals encapsulated lesions with irregular areas of hypodensity secondary to necrosis or hemorrhage (Fig. 57.7). The wall often reveals calcifications. Because of the cystic degeneration exhibited by these lesions, they are often difficult to differentiate from pseudocysts or other pancreatic cystic neoplasms. What differentiates these lesions from other cystic tumors is a combination of solid and cystic components with gradual degenerative changes resulting in pseudopapillae formation (Tang et al, 2005). SPTs are distinct from the normal pancreatic parenchyma, and like other cystic neoplasms, they rarely cause ductal dilation because of the lack of invasion.

Grossly, tumors appear tan or yellow and are well circumscribed and smooth on palpation. When opened, the tumors show irregular cystic cavities with some areas of necrosis or hemorrhage (Fig. 57.8). Most SPT can be diagnosed with routine histologic evaluation by the presence of polygonal epithelial cells arranged in a discohesive pattern; the boundaries resemble a mass effect as opposed to being invasive. Immunohistochemical staining for vimentin, keratin, neuron-specific enolase, CD10, and progesterone is common (Martin et al, 2002). These lesions rarely express chromogranin or estrogen. In contrast to ductal adenocarcinoma, abnormal β-catenin expression has been shown to be present in SPTs, but *KRAS*, *TP53*, and *SMAD4* appear to be unaltered (Abraham et al, 2002). Aggressive phenotypes of SPT have been demonstrated and histologically exhibit a high mitotic rate, nuclear atypia, spindling of tumor cells, and anaplastic giant tumor cells consistent with sarcomatoid carcinoma (Tang et al, 2005).

Clinically, SPTs are indolent and are typically cured with complete surgical extirpation. Many series have demonstrated long-term survival after resection (Lam et al, 1999; Martin et al, 2002; Reddy et al, 2009). Significant vascular invasion is the most common reason for the inability to resect these lesions, and metastatic disease has been noted to be present in up to 15% of patients. Criteria for defining SPTs as "malignant" may be locally advanced disease with vascular invasion precluding resection or lymph node or hepatic metastasis. Long-term survival is often possible despite the presence of malignant factors, such as metastatic disease, and should not preclude resection in selected cases (Lam et al, 1999; Martin et al, 2002; Reddy et al, 2009).

Indeterminate Cystic Neoplasm

The spectrum of cystic lesions discussed above represents many of the incidental lesions seen on cross-sectional imaging. However, a significant number of patients present with lesions that lack diagnostic certainty. Because of the inability to determine the exact histologic diagnosis without pancreatectomy, and because of the risk for malignancy of some cyst subtypes, some authors advocate a routine resection of pancreatic cysts (Horvath & Chabot, 1999; Ooi et al, 1998; Siech et al, 1998; Spinelli et al, 2004). Advocates of this approach argue that the clinical distinction between benign and malignant lesions is unreliable, and that there is a risk for the development of cancer; therefore all medically fit patients should undergo pancreatic resection. Despite the fact that this approach allows definitive treatment of all malignant lesions, it exposes patients with benign lesions to the risk associated with pancreatectomy without known benefit.

A selective approach to resection of pancreatic cystic neoplasms has been advocated by several reports, including those from our institution (Allen et al, 2003, 2006; Fernandez-del Castillo et al, 2003). Advocates of this approach argue that with improved knowledge of specific histologic subtypes and with the advances in diagnostics, a group of patients can be identified who are at very low risk (<1%) of harboring malignancy. Most authors who have reported their experience with this approach have recommended radiologic surveillance over resection for small, incidentally discovered cysts that lack a solid component or that have other concerning features of malignancy. Although this approach avoids the risks associated with pancreatectomy in patients with benign lesions, it does not

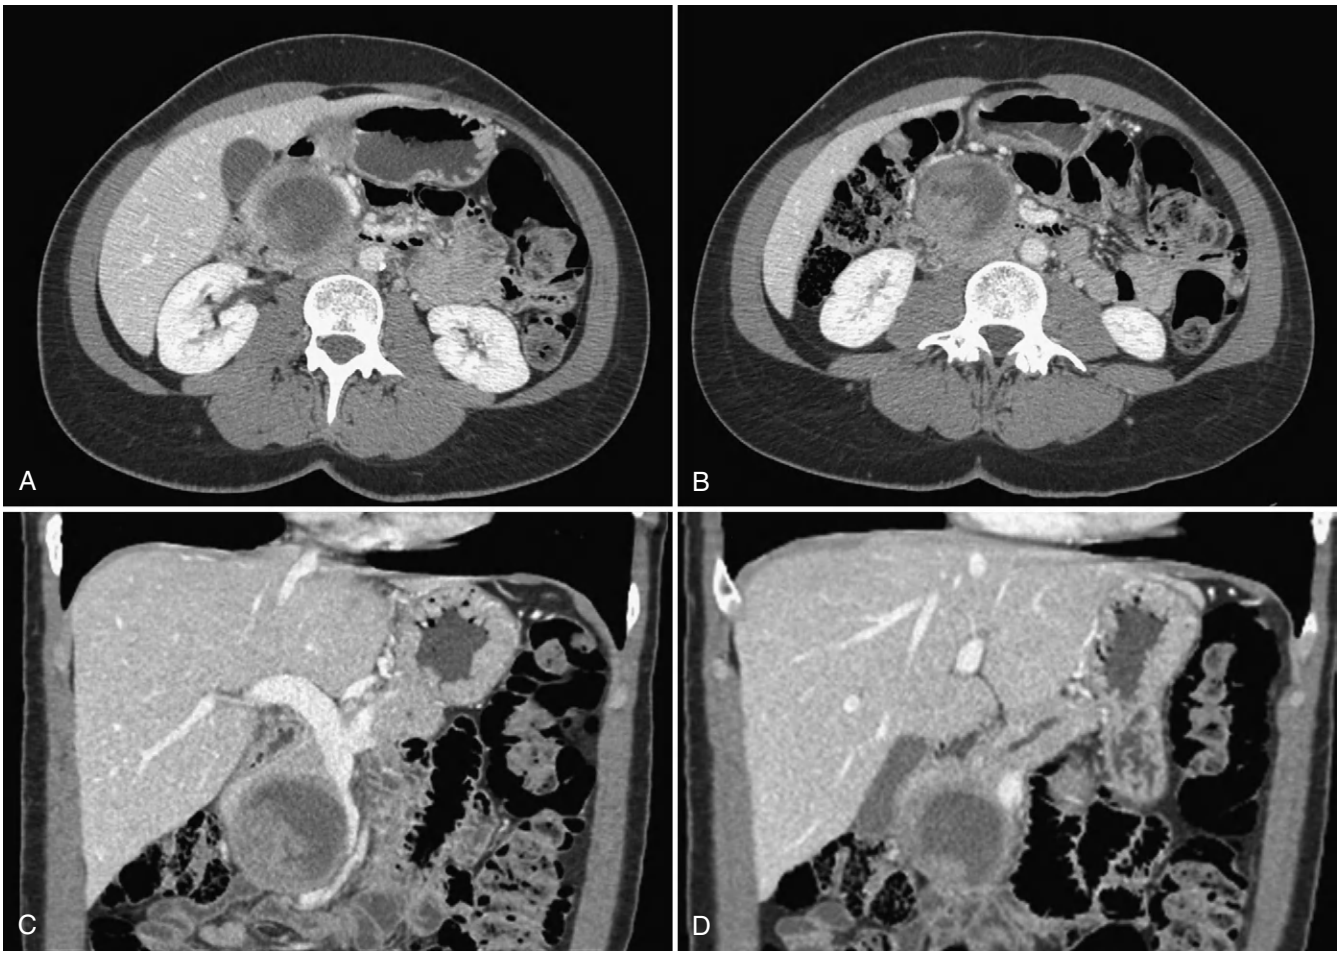

FIGURE 57.7. Imaging characteristics of solid pseudopapillary tumor (SPT) in the pancreas of a 35-year-old woman. A large lesion in the head of the pancreas was causing chronic abdominal pain; note the thickened wall and area of hemorrhage classic for SPT (**A** to **D**). This patient underwent endoscopic ultrasound to confirm SPT prior to pancreatoduodenectomy.

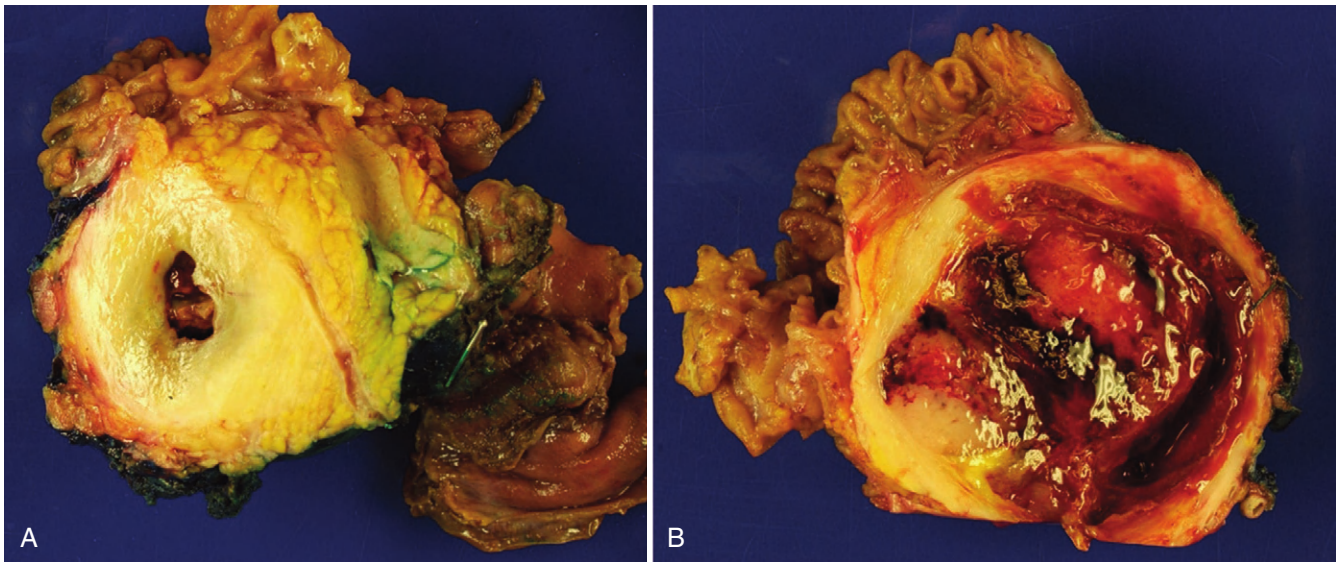

FIGURE 57.8. Gross appearance of solid pseudopapillary tumor (resected specimen from patient in Fig. 57.7).

guarantee that a cancer is being mistakenly observed. Operative morbidity following pancreatectomy is consistently as high as 45%, and mortality rates range from 2% to 10% (Büchler et al, 2000; Mezhir et al, 2009; Muscari et al, 2006; Winter et al, 2006). Published data suggest that with current imaging and endoscopic techniques, a group of patients with pancreatic cysts can be identified with a malignancy rate of less than 3% (Allen et al, 2006). It is in this select group of patients that the risk of death from pancreatectomy approaches or exceeds the risk of the lesion harboring a malignancy.

Despite the well-characterized lesions described above, many patients are seen with a cystic neoplasm that does not fit a specific diagnosis. In these patients, a nonoperative histologic diagnosis may not be made; therefore treatment recommendations for these patients are primarily based on imaging findings. The majority of patients who fit into this category have small, asymptomatic lesions, and their management is controversial. Our approach to such patients has been published in recent reports (Allen et al, 2003, 2006). Allen and colleagues (2006) reviewed 539 patients, the majority of which (369 [68%]) were followed up without operative intervention. Compared with patients treated with resection, observed patients were more likely to have small (median diameter, 2.4 cm) asymptomatic cysts without a solid component. At a median follow-up of 24 months, the average change in diameter of the observed lesions was 0.2 cm. Changes leading to resection developed in 29 patients (8% of 369 initially observed), and no patients with malignant mucinous tumors were reported in this group. Eight patients (2%) who did not undergo immediate resection developed malignancy, which is lower than the mortality rate associated with pancreatic resection, even in high-volume centers. Of note, in five of the eight patients who developed malignancy in the observed group, the cysts appeared to have represented retention cysts that developed adjacent to a radiographically undetectable malignancy. The decision-tree analysis illustrating the approach used is shown in Fig. 57.9.

As a result of our findings from this retrospective review, our current approach to patients with incidental cysts less than 2.5 cm in diameter is to initially obtain high-quality cross-sectional imaging with triphasic multidetector CT with 2-mm cuts through the pancreas or an MRCP. The imaging is reviewed at a multidisciplinary hepatopancreatobiliary conference by surgeons, gastroenterologists, and radiologists with expertise in pancreatic diseases. A detailed analysis of the cyst characteristics and the adjacent parenchyma is undertaken. Any findings concerning for malignancy—such as a solid component, mural nodules, or any pancreatic parenchymal abnormality—should result in EUS for further diagnosis or resection.

The importance of evaluating the adjacent pancreatic parenchyma cannot be overstated in that a number of patients in our series who developed adenocarcinoma in the observed group had small retention cysts adjacent to invasive cancer. Incidentally discovered cystic neoplasms smaller than 3 cm without solid component of main duct dilation are typically followed radiographically every 6 months for 2 years and then annually thereafter.

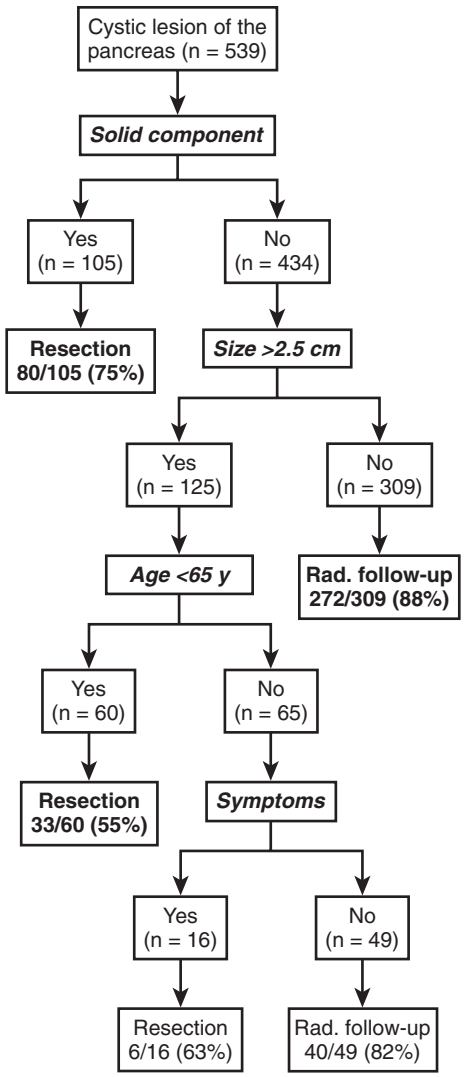

FIGURE 57.9. Selective management of cystic neoplasms of the pancreas. Rad., radiologic. *(From Allen PJ, Brennan, MF, 2007: The management of cystic lesions of the pancreas. Adv Surg 41:211-228.)*

CONCLUSIONS

The diagnosis of cystic lesions of the pancreas is increasing, and the most common lesions are SCAs, MCNs, and IPMNs. SCAs should be considered benign, and in the asymptomatic patient, they can be followed radiographically. Most patients with mucinous lesions should undergo resection, especially in the setting of concerning features such as size greater than 3 cm, solid component, and ductal dilation. The initial evaluation of a small, benign-appearing cyst should include one early interval image to ensure no occult malignancy is present that has resulted in a retention cyst.

As more clinicians are adopting a selective approach, improvements have been made in the ability to determine histopathologic subtypes without resection. High-quality cross-sectional imaging and EUS with cyst fluid analysis can help subtype many pancreatic cystic neoplasms. Advancements are also being made in the development of biomarkers from cyst fluid. Continued improvements in all of these modalities should lead to better identification of mucinous subtypes, obviating the need for resection.

CHAPTER 58A

Epidemiology of pancreatic cancer

Theresa P. Yeo and Charles J. Yeo

OVERVIEW

Pancreatic ductal adenocarcinoma (PDA) accounts for 6% of all cancers in the United States. It is the fourth leading cause of cancer death in men, after lung, prostate, and colorectal cancer, and the fifth leading cause of cancer death in women, following lung, breast, colorectal, and ovarian cancer (Jemal et al, 2009). More than 42,000 incident cases of pancreas cancer are predicted annually, with about 35,240 deaths. Although mortality rates from pancreas cancer have improved slightly in the last decade, the diagnosis of PDA still confers an unfavorable prognosis.

Traditionally, PDA has been considered a predominantly male cancer; however, in 2009 the number of incident cases in women (21,420) exceeded the number of new cases in men (21,050) (Jemal et al, 2009). This suggests that the health consequences of increased smoking behavior by women over the last 3 decades are now becoming apparent. Pancreas cancer deaths remain higher in men (18,030) than in women (17,210), perhaps because of the presence of increased comorbidities or delayed diagnosis in men or greater genetic susceptibility to cancer, which limits treatment responsiveness in men (Jemal et al, 2009).

In the United States, the peak incidence of pancreas cancer occurs in the seventh and eighth decades of life (Horner et al, 2009). The U.S. population risk for pancreas cancer is 13.1 per 100,000 for men and 10.4 per 100,000 for women. The main risk for PDA occurs with advancing age. Between 2002 and 2006, the median age at diagnosis for cancer of the pancreas was 72 years, and the median age at death was 73 years according to Surveillance Epidemiology and End Results (SEER) data (Horner et al, 2009; SEER, 2010). Fifty-six percent of new PDA cases occur between the ages 65 and 84 years. The incidence of PDA remains highest for black Americans, with rates of 15.4 per 100,000 in men and 12.4 per 100,000 in women. The lowest risk of PDA is among Asian/Pacific Islander men and women (8.1 and 7.0 per 100,000, respectively). PDA is also a common second malignancy in both men and women who have had a prior smoking-related malignancy, such as lung or head and neck cancers (Neugut et al, 1995). The annual incidence rate worldwide for all histologic types of pancreas cancer is approximately 9 new cases per 100,000 persons (0.009), ranking it eleventh among all cancers.

In 2000, 217,000 new cases of pancreas cancer were reported globally, with 213,000 resultant deaths (Hariharan et al, 2008). The highest incidence of PDA in the world has been reported among Maoris in New Zealand, native Hawaiians, and black American populations; India and Nigeria have the lowest reported incidence (Boyle et al, 1989; Mack et al, 1985). In Europe during the same period, there were 60,139 incident cases with 64,801 deaths (Parkin et al, 2001). In Japan, PDA is the fifth leading cause of cancer death. Between 1950 and 1995, the worldwide incidence rates of PDA increased ninefold in men (1.4 to 12.5 per 100,000) and women (0.8 to 6.8 per 100,000), but rates have leveled off since 1985 (Lin et al, 1998). China reported 1619 deaths from pancreas cancer between 1991 and 2000, with rates higher in men and in urban areas compared with rural communities (Wang et al, 2003). No cases of PDA are reported in many African nations, reflecting the absence of an organized cancer registry system and an increased focus on more predominant causes of death in these nations. Incidence rates vary between 6 and 12 per 100,000 for the five Scandinavian countries, with Iceland having the lowest rates (Engholm et al, 2009).

RACE AND ETHNICITY

African Americans

Combining all types of cancer, African Americans have the highest death rate (Ward et al, 2004) at 1.4 times higher than that of white males and 1.2 times higher than that of white females. In a 2004 study, Chang and colleagues (2004) used the California Cancer Registry of the Cancer Surveillance Section of the California Department of Health Services to determine the incidence of PDA between 1988 and 1998. African Americans had a higher age-adjusted incidence rate (8.8 per 100,000) for PDA when compared with all other races and ethnicities

combined. African Americans were more likely to be seen with advanced disease and were least likely to receive surgical treatment, regardless of stage of disease (82.9% had no surgery compared with 77% of Asians, 67.8% of Hispanics, and 62.5% of non-Hispanic whites). Interestingly, serum cotinine levels, the primary metabolite of nicotine, are consistently higher in African Americans than in whites and Mexican Americans, even after adjustment for the number of cigarettes smoked per day, the number of smokers in the home, the number of hours of environmental tobacco smoke (ETS) exposure at work, the number of rooms in the home, and the region of the country where the subject lived (Caraballo et al, 1998). This suggests that genetic differences in cigarette product metabolism may influence rates of PDA.

Asians

Asian patients with PDA tend to have less aggressive tumors than do non-Asians (either black or white patients) and higher survival rates when assessed on a stage-adjusted basis (Clegg et al, 2008). To determine whether Asians develop a histologically different type of PDA than Western populations, Longnecker and colleagues (2000) conducted a population-based study using three SEER geographic areas: Hawaii, San Francisco, and Seattle. They compared PDA cases in Japanese, Chinese, Filipino, Hawaiian, black, and white patients. The study revealed that Japanese patients had the highest fraction of localized tumors with the lowest grade, and that Chinese, Filipino, and Japanese women had longer survival times than did whites, although survival time was significantly different for Japanese women only. Race-related genetic and environmental exposure factors may be involved in these survival discrepancies.

Ashkenazi Jews

Pancreatic cancer occurs in excess in Jews, particularly Jews of Ashkenazi heritage (Lynch et al, 1996). The age-standardized rates for PDA in Jews in Israel significantly exceed the rates for Israeli non-Jews (7.2 per 100,000 for all Jewish men and 5.7 per 100,000 for Jewish women vs. 4.0 per 100,000 for non-Jewish men and 2.9 per 100,000 for non-Jewish women). Approximately 5% to 10% of this discrepancy is attributed to the *BRCA2* mutation, which is associated with breast, gastric, ovarian, and bile duct cancers.

RISK FACTORS FOR PANCREATIC DUCTAL ADENOCARCINOMA

Our understanding of the risk factors for PDA continues to evolve. PDA is characterized by multiple germline and somatic genetic mutations (Hruban et al, 1998). This topic is covered extensively in Chapter 8A. It is estimated that less than 3% of pancreatic cancers are truly hereditary and due to inherited germline mutations and their respective syndromes (Wang et al, 2009). Other reported risk factors for PDA include cigarette, cigar, and pipe smoking; ETS exposure, also known as *second-hand smoke* or *passive smoke exposure*; exposure to occupational and environmental carcinogens; African American race; Ashkenazi Jewish heritage; high-fat, high-cholesterol diet; obesity; alcohol abuse; chronic pancreatitis; and long-standing diabetes (Table 58A.1; Gold et al, 1998; Everhardt et al, 1995; Silverman et al, 1994; Wynder, 1975).

Table 58A.1

Risk Factors Associated with Cancer of the Pancreas: Summary of Previous Reports

Lifestyle and Environmental Factors

Cigarette smoking (dose-response relationship)
Environmental tobacco smoke exposure, particularly early in life
Alcohol
Residential radon

Race/Ethnic Factors

African-American men and women
Native female Hawaiians
Ashkenazi Jews

Inherited Predisposition

Hereditary pancreatitis
Hereditary nonpolyposis colorectal cancer
Hereditary breast and ovarian cancer
Familial atypical multiple mole melanoma syndrome
Peutz-Jeghers syndrome
Ataxia-telangiectasia
Fanconi anemia
Cystic fibrosis

Medical Conditions

Cirrhosis
Diabetes mellitus
Chronic pancreatitis

Dietary Factors

High fat/cholesterol
Overweight and obesity
Nitrosamines in food

Occupational Exposure to Carcinogens

Asbestos, 2-naphthylamine, benzidine, gasoline products, PAHs, dry cleaning agents, DDT, radon

Selected High-Risk Occupations

Dry cleaning or chemical plant work, sawmill work, electrical equipment manufacturing work, mining and metal working occupations

Height

RR = 1.81 (CI, 1.31 to 2.52) when comparing tallest and shortest height categories for men and women

Previous Surgery

Cholecystectomy

Not all listed factors have been definitively proven to cause pancreatic cancer.
PAHs, polyaromatic hydrocarbons; CI, confidence interval; DDT, dichlorodiphenyltrichloroethane; PDABs, p-dimethylaminobenzaldehydes; RR, relative risk

Data from Ahlgren, 1996; Efthimiou et al, 2001; Ekbom et al, 1994; Garabrant et al, 1993; Gold et al, 1998; Hruban et al, 1998; Kogevinas et al, 2000; Lowenfels et al, 1997; Lynch et al, 1996; Michaud et al, 2001; Silverman et al, 1998; and Yeo et al, 2009.

Familial Pancreatic Cancer

Family history of pancreatic cancer is a strong risk factor in 5% to 10% of cases (Lowenfels et al, 2005). When a history of PDA exists in a close relative, a number of responsible genes have been identified (Wang et al, 2009). In the National Familial Pancreas Tumor Registry (NFPTR) at Johns Hopkins, prospective studies of family members of pancreas cancer kindreds found a twofold increased risk of pancreas cancer in the first-degree relatives of persons with sporadic pancreas cancer and a ninefold increased risk in first-degree relatives of those with familial pancreatic cancer (Klein et al, 2004; Wang et al, 2009). Germline mutations of *BRCA2* are found in 6% to 19% of familial pancreatic cancer patients (Murphy et al, 2002). When a more stringent definition of familial pancreas cancer is used, a 57-fold increased risk of PDA was reported in kindreds with three or more family members affected with PDA (Tersmette et al, 2001). This corresponds to an incidence rate of 301 cases per 100,000 per year compared with the SEER age-adjusted rate for the entire U.S. population of 8.8 cases per 100,000 per year. A recent report identified a germline truncating mutation of the *PALB2* gene in 3% of familial pancreas cancer patients (Jones et al, 2009; Blackford et al, 2009). Despite these many advances in the understanding of the mutations involved in the pathogenesis of PDA, no single "pancreas cancer gene" has been identified.

Table 58A.2

High-Risk Genetic Disorders Associated with Familial Pancreatic Cancer

Genetic Syndrome	Gene/Chromosomal Mutation Region	Estimated Increased Risk of PDA
Hereditary pancreatitis	*PRSS1* (7q35)	50 to 80 times
Hereditary nonpolyposis colorectal cancer (Lynch II variant)	*hMSH2, hMSH1, hPMS2, hMSH3, hPMS1, hMSH6/GTBP*	Undefined
Hereditary breast and ovarian cancer	*BRCA2* (13q12-q13)	3.5 to 10 times
FAMMM syndrome	*p16* (9p21)	20 to 34 times
Peutz-Jeghers syndrome	*STK11/LKB1* (19p13)	75 to 132 times
Ataxia-telangiectasia	*ATM* (11q22-23)	Rare

FAMMM, Familial atypical multiple mole melanoma; PDA, pancreatic ductal carcinoma

Six Genetic Syndromes Associated with Pancreatic Ductal Adenocarcinoma

Six genetic familial syndromes and their respective predisposing genes have been identified and linked to the development of PDA; these are described briefly below (see also Table 58A.2). Although individuals with these syndromes have an increased risk of developing PDA, collectively these syndromes account for less than 5% of the familial aggregation of PDA. The mean age of onset of familial PDA is similar to that of nonfamilial cases: 65.8 years versus 65.2 years (Hruban et al, 1998). Familial cases have also been noted to have a somewhat increased incidence of secondary primary cancers (23.8%) when compared with their nonfamilial counterparts (18.9%).

Hereditary Pancreatitis

Children and adolescents with hereditary pancreatitis (HP) may develop severe pancreatitis at a young age, often in childhood or adolescence, with a resultant 50-fold to 80-fold increased risk of PDA developing over their lifetime. HP results from germline or new somatic mutations in the *PRSS1* cationic trypsinogen gene (Lowenfels et al, 1997). Approximately 40% of those with HP will develop PDA when the additional risk factor of cigarette smoking is added. The risk of cancer seems to be limited to pancreatic cancers and not tumors in other organs.

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC) is an autosomal dominant inherited disease that predisposes affected persons to colorectal cancer and PDA (Hruban et al, 2002). It is usually caused by germline mutations in a number of DNA mismatch repair genes. Of the inherited syndromes associated with an increased risk of PDA, HNPCC is the least strongly linked to PDA.

Hereditary Breast and Ovarian Cancer

Patients with germline *BRCA2* mutations have up to a 10-fold increased risk (range, 3.5 to ×10) of PDA developing even in patients without a strong family history of breast cancer. Goggins and colleagues (1996) identified germline *BRCA2* mutations in 7% of sporadic (nonfamilial) PDA patients screened, none of whom had a family history of breast cancer or PDA.

Familial Atypical Multiple Mole and Melanoma Syndrome

Familial atypical multiple mole and melanoma (FAMMM) syndrome is rare condition associated with *p16* germline mutations, a tumor suppressor gene that may be mutated or may have its expression altered by posttranscriptional methylation. The syndrome predisposes affected individuals to melanomas, multiple nevi, atypical nevi, and PDA (Lynch et al, 1990). Those with FAMMM have a 20- to 34-fold increased risk of PDA over their lifetime.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is a rare autosomal dominant disease associated with alterations in the *STK11* gene, in which affected individuals develop hamartomatous polyps of the gastrointestinal tract and lip freckles referred to as *mucocutaneous melanocytic macules* (Hruban et al, 2002). Individuals with this syndrome have a roughly 100-fold increased risk of developing PDA (Giardiello et al, 2000), and they also appear to have a tendency to form intraductal papillary mucinous neoplasms (IPMNs).

Ataxia-Telangiectasia

Ataxia-telangiectasia is an autosomal recessive inherited disorder associated with *ATM* gene mutations, in which affected persons present with cerebellar ataxia, conjunctival telangiectasias, a hypofunctioning thymus gland, and oculomotor abnormalities. An association between ataxia-telangectasia and the subsequent development of PDA has been reported, but it is less well established than with the other five familial syndromes (Lynch et al, 1996).

Tobacco Exposure

Cigarette smoking is a contributing factor in approximately 20% to 25% of the cases of PDA and is the most consistently reported risk factor (Iodice et al, 2008; Jemal et al, 2009). Smoking has been associated with increased risk of PDA in at least 29 epidemiologic studies (Silverman et al, 1994), and smokers have a 70% increased risk of PDA compared with nonsmokers. Smoking habits in the 15 years preceding the diagnosis of PDA appear to be more relevant to increased risk, whereas former smokers who have quit for more than 13 years decrease their PDA risk to that of a lifetime nonsmoker (Howe et al, 1991).

Prospective and retrospective studies have found that the risk of PDA increases consistently with cigarette smoking but only inconsistently with cigar or pipe smoking (Wynder, 1975), suggesting perhaps that smoke must be deeply inhaled to exert its carcinogenic effects. A dose-response relationship between PDA and the number of cigarettes consumed has been documented in several investigations (Ahlgren, 1996; Howe et al, 1991). For current smokers who also have a family history of PDA, the relative risk of PDA has been reported to be as high as 8.23 (Schenk, 2001). Lowenfels and colleagues (1997) found that individuals with familial PDA tend to smoke more than those with sporadic PDA. These observations raise the possibility that smoking is interactive, perhaps multiplicatively, with genetic mutations known to be present in persons with familial PDA. Postmortem examinations of the pancreatic ducts of smokers have found widespread ductal hyperplasia, now called *pancreatic intraepithelial neoplasia* (PanIN), considered to be a premalignant lesion. Neugut and associates (1995)

found a relationship between cigarette smoking and the development of PDA as a second malignancy in patients with a smoking-related first malignancy, such as lung, head and neck, or bladder cancer. This relationship is likely due to overlapping smoking-related genetic mutations among these different malignancies.

The socioeconomic status (SES) gap among smokers is widening in the United States and globally. Decreases in smoking prevalence in the U.S. population as a whole have not been realized in those from a lower SES background (Gilman et al, 2003). In a 2003 study of 657 adults aged 30 to 39 years that used parental occupation, adult educational attainment, and household income as indicators of SES, those of a lower SES were more likely to start smoking and to become regular smokers and were less likely to quit smoking than their higher SES counterparts.

The carcinogenic components of cigarette smoke are usually cleared from the bloodstream and excreted into bile; they reach the pancreas from the bile duct through biliary-pancreatic reflux, or they may be carried into the pancreatic parenchyma directly by the bloodstream. Cigarette smoke contains more than 60 known carcinogens, including polycyclic aromatic hydrocarbons (PAHs), nitrosamines, benzo[a]pyrene, β-napthylamine, methylfluoranthenes, and arylamines (Hecht, 2003). These carcinogens may bind to DNA and form adducts, which increase the risk of somatic mutations and cancer if unrepaired. Nitrosamines are known to be organ specific, causing pancreatic carcinomas in hamsters that are histologically similar to the type found in humans (Wang et al, 2009). Little research has been conducted on the other carcinogens in cigarette smoke and their relationship to PDA. Another possible mechanism by which cigarette smoke leads to PDA is unrelated to the carcinogens in the smoke. Rather, higher cholesterol (lipid) levels are measured in smokers than in nonsmokers. The pathophysiologic mechanism of hypercholesterolemia may be partially due to nicotinic stimulation of circulating catecholamines, which increase serum cholesterol levels. Elevated lipid levels may be causative in the induction of PDA (Wang et al, 2009).

Mulder and colleagues (1999) developed multicountry computer-based models to estimate the impact of smoking cessation on the incidence of PDA in the European Union (EU). According to these models, the EU would reach a projected 600,000 new cases of PDA per year by 2020 if the present smoking levels were to continue. If all current smokers quit smoking, the predicted number of incident cases of PDA per year in the EU would be 175,000 by 2020. If 45% to 50% of smokers were able to successfully quit smoking, the reduction of new cases would still be a substantial 68,000 cases per year.

Environmental Tobacco Smoke

ETS is related to the development of PDA, with a possible dose-response relationship (Ahlgren, 1996; Villeneuve et al, 2004). A mildly elevated odds ratio (OR, 1.2.1; confidence interval [CI], 0.60 to 2.44) has been reported, suggesting a weak association between PDA and ETS exposure in nonsmokers who reported ETS exposure both as an adult and in childhood. The effect was more pronounced in smokers who reported ETS exposure. Recently published findings from a retrospective case-only analysis of familial and sporadic PDA indicate that nonsmokers with PDA who were exposed to ETS early in life (<21 years of age) were diagnosed with PDA at a significantly younger mean age (64.0 years) when compared with nonsmoker, non–ETS-exposed cases (66.5 years) (Yeo et al, 2009). Moreover, both cigarette smoking and ETS exposure in nonsmokers younger than 21 years is associated with a younger mean age of diagnosis in both familial, sporadic, and Ashkenazi Jewish cases of PDA.

High-Risk Occupations

The evidence linking occupational exposures to PDA is inconsistent, reflecting the difficulty of quantifying workplace exposure to carcinogens and of differentiating these exposures from other risk factors. A number of epidemiologic investigations have suggested excess risk of pancreatic cancer in certain occupations. Definitively establishing certain occupations as high risk for the development of PDA is difficult because of the problems with self-reported exposures, lack of objective quantitative monitoring data, personal comorbidities, and the presence of other confounding and modifying risk factors. The available studies are summarized in Table 58A.3.

Occupational Exposures

Studies examining occupational exposures that increase a worker's risk of developing PDA have been conducted both in the United States and in Europe, particularly in the Scandinavian countries. Occupational exposures linked to PDA are summarized in Table 58A.4. Overall the occupational etiologic fraction for PDA was estimated at 12% in a meta-analysis of 20 occupational studies conducted between 1969 and 1998 (Ojajarvi et al, 2000). A retrospective analysis of more than 22 occupational and environmental studies reported by people with PDA found that exposure to asbestos, pesticides and herbicides, residential radon, coal products, welding products, and radiation were the most commonly reported exposures (Yeo et al, 2009).

Calvert and colleagues (1989) conducted a review supported by the National Institute for Occupational Safety and Health (NIOSH) of five cohort studies reporting an association between the use of metalworking fluids (MWFs) used in industrial machining and grinding operations and the development of all types of cancer, including PDA (Acquavella et al, 1993; Hoppin et al, 2000; Porta et al, 1999; Rotimi et al, 1993; Tolbert et al, 1992). More than 1 million workers are exposed to MWFs according to NIOSH estimates (Calvert et al, 1989). Substantial evidence was found for an increased risk of cancer at several sites, including the pancreas, larynx, rectum, skin, scrotum, and bladder. MWFs contain a number of compounds suspected to be cancer initiators or promoters including long-chain aliphatics, polyaromatic hydrocarbons, nitrosamines, sulfur-containing compounds, formaldehyde-releasing biocides, and heavy metals (Tolbert et al, 1992).

Diabetes Mellitus

Two theories regarding the relationship between type 2 diabetes mellitus (DM) and PDA have been postulated; in one theory, DM is viewed as a predisposing risk factor for PDA; in the other theory, type 2 DM and its attendant altered glucose homeostasis are considered a consequence of PDA (Yalniz et al, 2005). The majority of PDA patients (80%) have either subclinical

Table 58A.3

Occupations Associated with Excess Risk of Pancreatic Cancer

Reference	Occupation	Risk Estimate	95% CI
Falk et al, 1994	Chemical processor	1.22 OR	NR
	Chemical fertilizer	1.20 OR	NR
Li et al, 1969	Chemist	10.2 MH	NR
Lin et al, 1981 Falk et al, 1990	Auto mechanic (gasoline exposure)	5.1 RR if >10 years exposure	NR
	Service station worker	1.6 SMR	NR
	Machine repairer	2.45 OR	NR

Data from references cited in Table 58A.3.

impaired glucose tolerance or type 2 DM. Many investigators regard DM as a clinical manifestation of PDA rather than a risk factor, a result of the alteration of islet cell function—specifically, the loss of β-cell mass from tumor growth—or a result of disruptions in acinar–islet cell interactions.

A meta-analysis of epidemiologic studies focused on DM and the risk of PDA found that the pooled relative risk (RR) of PDA in people diagnosed with DM 5 years or more prior to the PDA diagnosis was twice the risk (RR, 2.0; 95% CI, 1.3 to 2.2) of those without DM (Everhardt et al, 1995). In a population-based case-control study of 484 PDA cases and 2099 controls in three geographic areas of the United States, those diagnosed with DM at least 10 years prior to the development of PDA had a 50% increased risk of PDA compared with the control group (Silverman et al, 1998). Insulin treatment did not appear to alter the risk of development of PDA (OR, 1.6 with insulin and 1.5 without).

During an 18-year follow-up study of 88,802 women in the Nurses' Health Study (NHS), 180 incident cases of PDA were reported (Michaud et al, 2001). A positive association was observed between fructose intake and impaired glucose metabolism and increased PDA risk. The risk was most apparent in women with an elevated body mass index (BMI) above 30 kg/m^2 and low physical activity. A diet high in glycemic load (GL), the glucose response to each unit of carbohydrate-containing foods, may increase the risk of PDA in women with underlying insulin resistance as a result of obesity. Chronically elevated plasma glucose levels and increased PDA risk were also observed by Gapstur and colleagues (2000), further suggesting that impaired glucose tolerance, insulin resistance, and hyperinsulinemia may be involved in the etiology of PDA.

Chronic Pancreatitis

Chronic pancreatitis has been linked to the development of PDA. It is not clear whether chronic pancreatitis is a risk factor or if it represents an indolent presentation of PDA. The standardized incidence ratio of PDA in individuals with a diagnosis of chronic pancreatitis was 16.5 compared with the 1.76 expected number of cases (Lowenfels et al, 1993). Because PDA may mimic chronic pancreatitis, misdiagnosis is a possibility. A review of the records of patients with acute, chronic, or unspecified pancreatitis was conducted on all inpatient medical institutions in Sweden from 1965 to 1983. In 7956 patients with pancreatitis, 46 pancreas cancers were diagnosed compared with 21 expected cases—a standardized incidence ratio of 2.2 (CI, 1.6 to 2.9) (Ekbom et al, 1994). Although it seems reasonable to conclude that the cellular destruction and glandular dysfunction caused by pancreatitis may yield an environment favoring the initiation of tumor growth, it remains

problematic that some premalignant lesions may be initially incorrectly diagnosed as chronic pancreatitis.

Cholecystectomy

A history of cholelithiasis and/or cholecystectomy may precede the diagnosis of PDA, yet cholecystectomy per se is not believed to promote its development. Individuals who underwent cholecystectomy in the year preceding the diagnosis of PDA had an exceedingly high risk of developing PDA (OR, 57.9) in one investigation (Everhardt et al, 1995). This finding is most likely explained by the misdiagnosis of gallbladder disease, either cholelithiasis or cholecystitis, in the setting of cryptic PDA, often prompting gallbladder removal with an undetected tumor being left in place. However, when data subset analyses were performed in patients with a history of cholecystectomy 20 years or more prior to the diagnosis of PDA, a 70% excess risk of PDA was still evident.

Hormonal Factors

In recent years, a link between female reproductive factors and PDA has been hypothesized. A case-control study of 52 postmenopausal women with PDA and 233 matched controls was conducted as a component of the Canadian Enhanced Cancer Surveillance Project (Kreiger et al, 2001). A questionnaire focused on reproductive history, cigarette smoking, physical activity, diet, occupation, residential history, and sociodemographic information was mailed to eligible patients diagnosed with PDA. Multiparity, defined as three or more children, and use of oral contraceptives were associated with a decreased risk of PDA (OR, 0.22 and 0.36, respectively). Late age at birth of first child significantly increased the risk of PDA (OR, 4.05; CI, 1.50 to 10.92 for ages 25 to 29 years; for women 30 or older, OR, 3.78; CI, 1.02 to 14.06). No relationships were found between age of menarche or menopause and PDA. The inverse relationship between parity and PDA suggests that PDA may be partially an estrogen-dependent transformation, or that estrogen may act in an inhibitory manner upon pancreatic carcinogenesis.

Lifestyle Factors and Height

Michaud and associates (2001) reported on the relationship between BMI, height, physical activity, and smoking and the risk of PDA in two large, prospective cohort studies: the Health Professional Follow-up Study (HPFS) and the NHS. Activity levels and body weight were ascertained prospectively. A higher risk of PDA was found among obese men and women, as was a direct association between above-average height and risk of PDA. An additional 2.54 centimeters of height above average increased the risk of PDA by 6% in the HPFS and by 10% in the NHS. The association between height and cancer risk in general has been identified in other studies (Giovannucci et al, 1995; Smith et al, 1998). Height may serve as a proxy for calorie intake or exposure to growth factors, such as insulin or insulin-like growth factor-1, in childhood.

Furthermore, an inverse relationship between moderate physical activity and PDA was observed. Walking or hiking 1.5 hours or more per week in the overweight cohort was associated with a 50% reduction in PDA risk, but physical activity had no effect on PDA risk for participants who were not overweight. Likewise, BMI had no effect on risk if the participant was a moderate exerciser. However, individuals with a BMI of at least 30 kg/m^2 had an elevated risk of PDA (RR, 1.72; CI, 1.19 to 2.52) compared with those with a BMI of less than 23 kg/m^2. The authors speculated that the PDA risk associated with obesity might be linked to glucose intolerance, peripheral insulin resistance, and/or hyperinsulinism.

Diet

It is estimated that 30% to 50% of pancreatic cancers may be attributable to dietary factors. Both butter consumption and saturated fat intake were positively associated with PDA (hazard ratio [HR], 1.40; CI, 0.87 to 2.25; and HR, 1.60; CI, 0.96 to 2.64, respectively) in the Finnish Cancer Registry (Stolzenberg-Solomon et al, 2005). Fat entering the duodenum stimulates cholecystokinin secretion, and it is possible that chronic hypercholecystokininemia may be associated with an increased susceptibility of the pancreas to carcinogens. Other possible explanations include that the increased intake of saturated fat may lead to insulin resistance and the development of DM, or foods with a high soluble fat content may be contaminated with carcinogenic organochloride compounds from the environment.

Processed meats have been linked to the development of PDA. In a prospective study of more than 200,000 people, 482 individuals developed PDA during 7 years of follow-up (Nöthlings et al, 2007). Those who had consumed the greatest amount of processed meats had a 67% increased risk of PDA. Diets laden with pork and red meat intake were associated with a 50% increase in PDA risk, but poultry, fish, dairy product, and egg consumption conferred no additional risk. Heterocyclic amines and polycyclic aromatic hydrocarbons that form during high-temperature cooking are known to be carcinogenic and may be responsible for the increased risk of PDA observed with processed and barbecued meats. These compounds have also been linked to the development of other cancers.

Several recent investigations have focused on the relationship between *glycemic load* and *glycemic index*. Consumption of fruit juices and soda has been evaluated in six studies to date with conflicting results (Michaud et al, 2002; Mueller et al, 2010; Nöthlings et al, 2007; Silvera et al, 2005; Stolzenberg-Solomon et al, 2005). Two studies found no relationship between PDA and glycemic load, carbohydrate intake, or sugar, sucrose, or fructose intake (Johnson et al, 2005; Silvera et al, 2005). Three studies reported mixed findings (Michaud et al, 2002; Nöthlings et al, 2007; Stolzenberg-Solomon et al, 2005). In the Multiethnic Cohort Study, BMI modified the effect of high sucrose intake and the occurrence of PDA, with elevated BMI increasing the risk and normal BMI decreasing the risk (Nöthlings et al, 2007). A positive association with PDA was also observed with high fructose intake, but no association was observed with consumption of soft drinks (diet or regular).

Mueller and colleagues (2010) conducted a retrospective analysis of the Singapore Chinese Health Study regarding soft drink and fruit consumption and the risk of PDA. Among 63,257 participants, 142 incident PDA cases were identified. However, only 56.4% of the PDA cases were histologically confirmed, 5% were reported from death certificate data, and 38.8% were identified by signs and symptoms possibly related to PDA but not proven. The finding of an elevated HR for PDA

in those who drink two to three soft drinks per week is suspect in this setting and requires further evaluation.

Coffee and Alcohol Consumption

Cohort studies from the 1970s and 1980s indicating that heavy coffee and alcohol consumption led to an excess risk of PDA were often confounded by excessive smoking among the heavy coffee and alcohol drinkers (Michaud et al, 2001). Three subsequent investigations have attempted to clarify this issue while controlling for smoking (Ghadirian et al, 1991; Lagergren et al, 2002; Michaud et al, 2001). Ghadirian and colleagues (1991) conducted a case-control study of residents of greater Montreal, obtaining all information through questionnaires administered to either the patient or a proxy. The results indicated that those who consumed alcohol were, in general, at lower risk for PDA (OR, 0.65; CI, 0.30 to 1.44). This was true for beer, white wine, and hard liquor. The odds ratio for red wine drinkers was elevated at 1.57, but it did not achieve statistical significance. Likewise, coffee drinkers had a lower overall risk of developing PDA (OR, 0.55; CI, 0.19 to 1.62), regardless of whether they drank caffeinated or decaffeinated coffee. The increased risk when coffee was taken on an empty stomach or between breakfast and lunch (OR, 1.30 and 1.15, respectively) was not statistically significant.

Lagergren and colleagues (2002) hypothesized that because heavy alcohol intake often causes chronic pancreatitis, which may be a risk factor for PDA, the ideal group to examine would be those with a diagnosis of alcoholism, alcoholic chronic pancreatitis, and alcoholic liver cirrhosis. Using the Swedish National Board of Health and Welfare, data were collected on 178,688 patients over a 30-year period. A total of 305 incident cases of PDA were identified in the group, representing a 40% excess risk in observed compared with expected cases. Alcoholics with chronic pancreatitis or cirrhosis had a twofold increased risk of PDA. A major limitation of the study was the lack of information on smoking. The authors estimated that the observed excess risk of PDA in the alcoholic group "may be almost totally attributable to the confounding effect of smoking" (Lagergren et al, 2002).

Michaud and colleagues (2001) examined data on coffee and alcohol consumption and other dietary factors obtained at baseline in two large, national cohort studies. The HPFS, initiated in 1986, includes 51,529 men aged 40 to 75 years who responded to a mailed questionnaire; the NHS began in 1976 and includes 121,700 registered nurses. Follow-up information was gathered via a mailed questionnaire from both groups on age, marital status, weight, height, medical history, medication use, smoking status, physical activity, and intake of coffee and alcohol. The results regarding coffee and alcohol are compelling: during 1,907,222 person-years of follow-up, 288 incident cases of PDA were diagnosed. Data were analyzed separately for each of the cohorts and then pooled to compute overall RR estimates. The results revealed that neither coffee consumption nor alcohol consumption conferred an excess risk of PDA; a pooled RR of 0.62 was reported (95% CI, 0.27 to 1.43) for more than 3 cups of coffee per day versus no coffee, and a pooled RR of 1.00 (95% CI, 0.57 to 1.76) for more than 30 g alcohol per day versus no alcohol were found.

Most recently, Brand and colleagues examined data on 29,239 histologically confirmed cases of pancreas cancer from 350 U.S. hospitals between the years 1993 and 2003 by cigarette smoking and alcohol consumption self-reported history (Brand et al, 2009). Current smokers were diagnosed with PDA at significantly younger ages (6.3 to 8.6 years) than nonsmoking counterparts. Among nonsmokers, age at diagnosis of PDA progressed linearly according to the amount of alcohol consumed, from 6 years younger for minimal drinkers to 8.7 years younger for self-described heavy alcohol consumers.

CHAPTER 59

Pancreatic cancer: duodenal adenocarcinomas

Cristina R. Ferrone and Carlos Fernandez-Del Castillo

OVERVIEW

The first case of duodenal adenocarcinoma was described by Hamburger in 1746 (Hamburger, 1775). In the United States, approximately 5000 patients are diagnosed with small bowel cancer every year, and 1000 of them have duodenal adenocarcinoma (Howe et al, 1999). Duodenal adenocarcinomas are rare tumors that account for approximately 0.3% of all gastrointestinal (GI) malignancies (Spira et al, 1977). Despite the duodenum representing only about 10% of the length of the small bowel, duodenal adenocarcinomas comprise 25% to 45% of small bowel tumors (Alwmark et al, 1980; Sohn et al, 1998); up to half occur near the ampulla of Vater, which explains why some studies group them with other periampullary cancers (Joesting et al, 1981). The incidence of small bowel cancers is estimated to be 1.4 per 100,000, with duodenal adenocarcinoma in approximately 0.17 per 100,000 (DiSario et al, 1994). Other malignant tumors such as carcinoid, gastrointestinal (GI) stromal tumor, lymphoma, and sarcoma can also occur in the duodenum but are far less common there than in the rest of the small intestine.

PRESENTATION

Duodenal adenocarcinoma has a slight male predominance. The median age at presentation is in the sixth and seventh decades of life (DiSario et al, 1994; Rose et al, 1996). Approximately half of the patients with duodenal adenocarcinoma are initially seen with symptoms of abdominal pain or gastric outlet obstruction: nausea, vomiting, early satiety, and anorexia. Duodenal cancers often present as circumferential napkin-ring type lesions (Fig. 59.1). However, patients can also be seen with bleeding, melena, or jaundice. Bauer and colleagues (1994) noted a 21% incidence of a palpable mass on physical exam. A small proportion of patients are asymptomatic; the lesion is identified during the workup of an unrelated medical problem or as a result of screening for familiar adenomatous polyposis (FAP).

EVALUATION

The evaluation of any duodenal mass must assess for possible metastases and for resectability of the lesion (see Chapters 16 and 17). Depending on the patient's presenting symptoms, the initial study that identifies the lesion will vary (see Fig. 59.1). Radiologic findings highly suggestive of malignancy include central necrosis or an intraluminal exophytic mass or intramural mass with ulceration (Fig. 59.2). Patients will need either a computed tomography scan or magnetic resonance imaging to assess resectability and rule out metastatic disease. For the tumor to be considered potentially resectable, there should be no evidence of major vascular encasement, distant lymphadenopathy, or distant metastases (e.g., liver, peritoneum, lung). If patients undergo upper GI endoscopy, the lesion can be biopsied at that time. Additionally, if a segmental resection is being considered, an upper GI series is helpful, and the relationship of the tumor to the ampulla should be evaluated by endoscopy.

RISK FACTORS

The biology of duodenal adenocarcinoma is poorly understood. An adenoma-to-carcinoma sequence similar to that seen in colon cancer has been suggested. In various series of endoscopically resected adenomas, the incidence of malignancy varied from 10% to 42%, with villous adenomas being at higher risk for malignant transformation (Seifert et al, 1992; Witteman et al, 1993). Carcinoma in situ can be adequately treated with a local submucosal excision; however, it is generally impossible to know the maximal depth of invasion of the entire lesion before resection, and a more extensive procedure should be performed for any patient with invasive carcinoma (Bjork et al, 1990).

Patients with FAP are at significant risk for duodenal or ampullary adenomas, with an incidence as high as 88% (Church et al, 1992), and they have an increased relative risk of duodenal cancer of 330 compared with the general population (Offerhaus et al, 1992). Groves and colleagues (2002) prospectively followed 114 patients with FAP for 10 years, beginning at a median age of 42 years. Patients underwent upper endoscopy three times a year with a side-viewing duodenoscope. During this time three patients developed duodenal adenocarcinoma and three developed ampullary cancers. This occurred at a median of 6 years' follow-up and at a median age of 68 years. All patients were classified according to the Spigelman classification: 3 were stage 0, 15 were stage I, 44 were stage II, 41 were stage III, and 11 were stage IV. Stage progression was seen in 0, 3, 7, 5, and 4 patients, respectively. Of the patients who developed invasive carcinoma, 4 were classified as Spigelman IV, but 2 were classified as Spigelman II and III, underscoring the need for surveillance in this population. Soravia and colleagues (1997) prospectively screened 74 patients over 5 years, during which time 11 patients (15%) developed advanced polyposis, and one patient developed duodenal cancer. The patient with adenocarcinoma presented at age 66 years, and the median age for duodenal polyposis for the group was 69 years (range, 38 to 66 years). All the patients in the study who underwent local resection of duodenal polyps developed recurrent polyps at sites of previous local resection. Duodenal and ampullary carcinomas are the second most common cause of death after colon cancer

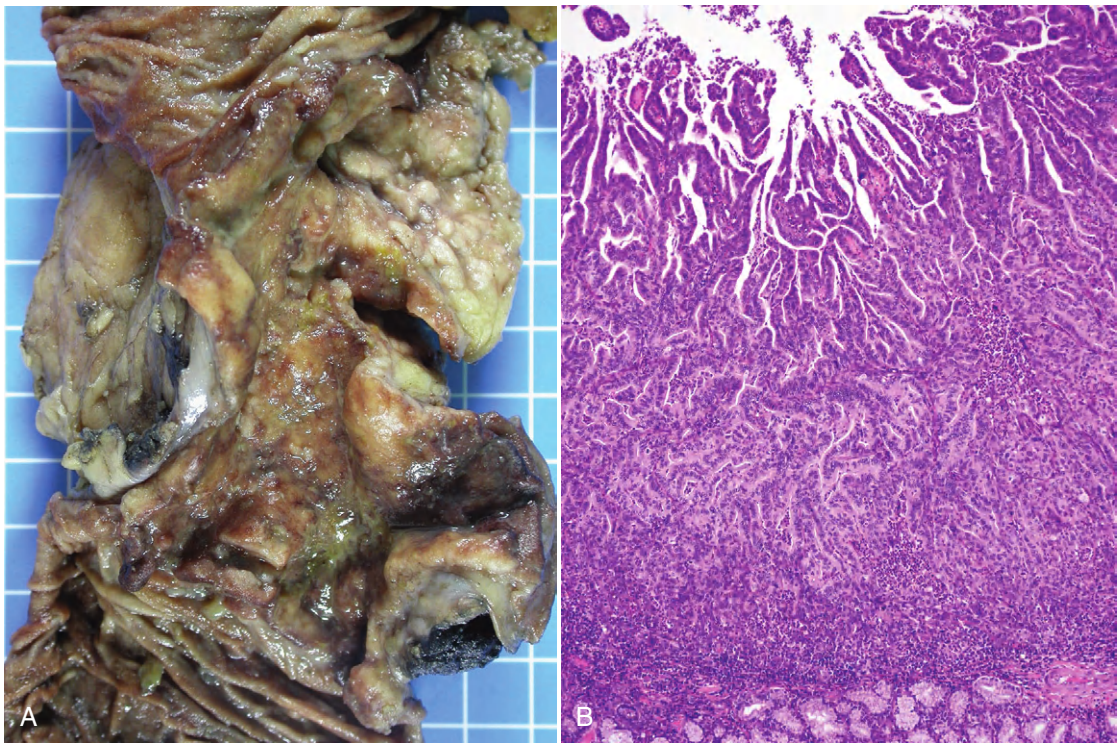

FIGURE 59.1. A, Macroscopic photograph of a resected duodenal adenocarcinoma. **B,** Microscopic image of duodenal adenocarcinoma.

in patients with FAP, underscoring the need for aggressive surveillance.

Gardner syndrome is another condition associated with a high risk for duodenal adenocarcinoma. Patients present with GI polyposis, osteomas, and soft tissue tumors. The risk of malignant degeneration in duodenal polyps is between 3% and 12%, requiring these patients to also undergo an aggressive surveillance program (Sinha & Williamson, 1988). Patients with Peutz-Jehgers syndrome are also at risk, but it is lower than that seen in patients with Gardner syndrome or FAP.

The pathogenesis of duodenal adenocarcinoma is poorly understood. It appears to have a biology similar to, yet distinct

from, colon cancer and other pancreatohepatobiliary tumors. Oncogenes and tumor suppressor genes that appear to contribute to the malignant progression include *KRAS, TP53, ERBB2,* and *TGFBRII* (Achille et al, 1998; Younes et al, 1997; Zhu et al, 1996). In patients with FAP, the normal duodenal mucosa and duodenal polyps have a higher *COX-2* expression than patients with sporadic duodenal adenomas (Brosens et al, 2005). This increased expression may explain the poorer response to inhibitory COX-2 chemoprevention in these lesions.

THERAPY

Surgical

Surgical resection is the strongest predictor of long-term survival. Most series of resected duodenal carcinoma document a 5-year overall survival of more than 40%, which is twofold better than that of pancreatic ductal adenocarcinoma (Table 59.1).

The optimal extent of resection of duodenal cancers remains the subject of some debate and perhaps confusion. Superficial lesions may be amenable to endoscopic resection. In such cases, careful examination of the resected specimen is required to exclude the presence of invasive disease and the need for a more extensive operation. Transduodenal resections, even those that include the ampulla (i.e., ampullectomy), are inadequate in the face of invasive carcinoma. Such lesions generally require a pancreatoduodenectomy to achieve an R0 resection, particularly when in proximity to the ampulla. For patients in whom the entire duodenal mucosa is at risk, such as patients with FAP, a pancreatoduodenectomy should be performed.

Debate is active and ongoing as to the role of segmental resection of the duodenum in patients with duodenal adenocarcinoma not involving the ampulla. This consideration is typically germane only to lesions in the distal aspect of the duodenum. A number of clinical series from Massachusetts General Hospital (MGH), Memorial Sloan-Kettering Cancer Center, M.D. Anderson Cancer Center, and Duke University have shown no difference in survival between pancreaticoduodenectomy and a segmental resection (Cecchini et al, 2011; Rose et al, 1996). On the other hand, some series suggest that a more radical resection may improve overall survival (Alwmark et al, 1980; Dabaja et al, 2004). It is not unexpected that multiple small series of patients demonstrate no adverse effect of performing local en bloc resections for lesions in the third or fourth portions of the duodenum; because the lymphatic drainage to this area should be into the small bowel mesentery and not via the pancreatoduodenal lymphatic basins. Whether a pancreatoduodenectomy or a segmental resection is performed depends on the tumor's location with respect to the ampulla and the ability to achieve a complete resection, which ultimately is the most important prognostic factor.

Unlike many other GI tumors, metastatic disease to regional lymph nodes is not a consistent predictor of poor outcome. In the series by Joesting and colleagues (1981) and Ouriel and Adams (1984), lymph nodes did not predict an adverse outcome. More recent series from MGH and the Mayo Clinic, on the other hand, have identified that lymph node involvement was associated with an adverse outcome (Cecchini et al, 2011; Bakaeen et al, 2000). In both series, overall survival decreased from 65% to 25% in the MGH series and from 68% to 22% in the Mayo Clinic series when lymph nodes were involved. The MSKCC group evaluated lymph node status in the setting of the number of nodes evaluated. Similar to gastric cancer, resection and assessment of more than 15 lymph nodes assessed improved the disease staging and the prognostic value of finding no lymph node metastases (Sarela et al, 2004). The modern series from MGH was the first to identify perineural invasion as the most powerful independent predictor of survival (Cecchini et al, 2011). The 5-year overall survival was 56% versus 19% for patients with and without perineural invasion, respectively.

Neoadjuvant and Adjuvant Therapy

The role of neoadjuvant or adjuvant therapy for duodenal adenocarcinoma has not been studied in a Phase III prospective randomized trial. Duodenal cancers were treated in the cohort of periampullary tumors in a European Phase III adjuvant trial without any evidence of improved survival. However, a high rate of chemotherapy and radiation therapy noncompliance was reported, and the duodenal cancers were not analyzed separately; therefore the results must be interpreted with caution. The largest retrospective review from the National Cancer Database documented that only 15% of patients received adjuvant radiation therapy, and 21% received chemotherapy (Howe et al, 1999). The study from Johns Hopkins included 14 node-positive patients who underwent pancreatoduodenectomy and adjuvant chemoradiation therapy who had improved local control and median survival, but no difference was reported in 5-year overall survival (Swartz et al, 2007). Therefore no conclusive decisions can be made based on the current data in the literature regarding the role of adjuvant chemotherapy or radiation therapy.

Patterns of Recurrence

The patterns of recurrence have not been well defined in duodenal adenocarcinoma. Approximately 17% to 44% of patients will be seen with locoregional recurrences, mainly in the operative bed and retroperitoneal lymph nodes. In the MGH series, the first site of recurrence was distant in 21%, locoregional in 19%, and both in 5% at a median follow-up of 14.5 months. In the MDACC series, 17% of patients had locoregional recurrences and 33% had distant recurrences (Barnes et al, 1994). In the series from Duke, 44% of patients were seen with locoregional recurrences (Kelsey et al, 2007).

CHAPTER 60

The pancreas as a site of metastatic cancer

Oliver Strobel, Markus W. Büchler, and Jens Werner

OVERVIEW

Resection has become an established part of the standard therapy for liver and lung metastases of several primary tumors (Fong et al, 1999; Quiros & Scott, 2008). Unlike liver and lung, the pancreas is an uncommon site of metastases. In autopsy series, 3% to 12% of patients with diffuse metastatic disease have pancreatic involvement (Showalter et al, 2008), and metastases account for only about 2% to 4% of malignant lesions in the pancreas (Showalter et al, 2008; Strobel et al, 2009). However, this number is increased up to 40% in patients with a pancreatic mass and a history of malignant disease (Roland & van Heerden, 1989; Z'Graggen et al, 1998).

Metastases to the pancreas may occur as isolated lesions or with additional extrapancreatic metastases that are technically resectable; isolated pancreatic metastases are very rare. Until recently the available data on resection for pancreatic metastases were based only on small series and multiple case reports. However, recent larger series and meta-analyses suggest that resection for pancreatic metastases is safe and associated with a favorable long-term outcome in appropriate patients (Reddy et al, 2008; Reddy & Wolfgang, 2009; Strobel et al, 2009; Tanis et al, 2009). This is best documented for metastastic renal cell carcinoma (RCC), the most frequent primary tumor of isolated pancreatic metastases (Sellner et al, 2006; Tanis et al, 2009). Based on these recent data, pancreatic resection can be recommended as part of an interdisciplinary treatment in metastatic disease to the pancreas.

This chapter summarizes the recent literature on surgery for pancreatic metastases and discusses the surgical approach, including diagnostic workup, patient selection, and technique of resection.

RESULTS OF SURGERY FOR PANCREATIC METASTASES

Because isolated pancreatic metastases and metastases with localized, treatable extrapancreatic disease are uncommon, the results of pancreatic resection for metastases are not as well documented as for the liver or lung (Fong et al, 1999; Internullo et al, 2008). Until recently, the available literature was based only on smaller series and multiple case reports, which inherently tend to be biased toward the report of favorable results. However, in recent years, resection for metastases to the pancreas has been used more frequently, resulting in several larger series and, most recently, meta-analyses. This change occurred for several reasons. In the last decades, morbidity and mortality rates of pancreatic surgery decreased considerably, and pancreatic surgery can now be considered a safe procedure when performed by experienced surgeons (see Chapter 62). With the development of more effective drugs and tailored chemotherapy, the prognosis of metastatic disease has largely improved for several tumor entities. Also, with standardized follow-up programs after resection for cancer and with broader use of cross-sectional imaging, pancreatic metastases are more frequently detected at a resectable stage. Finally, the decision for resection of a pancreatic metastasis is more frequently made in an interdisciplinary setting, such as by tumor boards, which are established in most centers.

Safety of Resection for Pancreatic Metastases

In a recent review of 19 series, a mortality rate of 1.2% and a morbidity rate of 38.3% were reported for resection of isolated pancreatic metastases (Reddy & Wolfgang, 2009). Resections for metastatic disease may be more difficult than resections for primary pancreatic tumors because of the necessity of extensive adhesiolysis after previous surgery in approximately 80% of patients and because of the necessity of multivisceral resections. Our series, which included 41% multivisceral resections, reported a mortality rate of 4.4% and a morbidity rate of 33% (Strobel et al, 2009). These findings are comparable to the data reported for primary pancreatic malignancies and show that resection for pancreatic metastases can be performed safely by specialized surgeons.

Oncologic Outcome of Resection for Pancreatic Metastases

The follow-up results of the largest studies of resection for pancreatic metastases are summarized in Table 60.1 and show a very favorable outcome. However, most series include several primary tumor entities, and conclusions about individual tumor types must be made with great caution. RCC is, by far, the most frequent primary tumor associated with resectable, isolated pancreatic metastases. The frequency of various primary tumors derived from surgical series is given in Table 60.2. The data for resection of RCC metastatic to the pancreas are summarized in Table 60.3; they show considerably longer survival rates compared with the mixed group of other histologies (see Table 60.1). Two systematic reviews of 236 and 311 published cases of surgery for RCC pancreatic metastases (Sellner et al, 2006; Tanis et al, 2009) report 5-year survival rates of about 75% after radical resection. However, because both reviews included case reports and smaller series, they may overestimate survival rates because of publication bias. However, RCC histology was also associated with improved outcome in several of the published series, including that of the authors (Eidt et al, 2007; Hiotis et al, 2002; Reddy et al, 2008; Strobel et al, 2009).

Table 60.1

Outcome in the Largest Series of Pancreatic Resection for Metastases (≥15)

Reference	No. Patients	Median Survival (mo)	5-Year Survival (%)

Hiotis et al, 2002	16	39.6	NR

Survival is calculated from time of resection of the metastasis.
*Exclusively RCC metastases.
NR, not reported.

Although 57% of cases in our series had extrapancreatic metastatic disease, the overall 5-year survival rate was 56.8%, and the 5-year survival rate was 67.3% after resection of RCC metastases. The 5-year survival rate after resection of isolated pancreatic metastases was as high as 75% (Strobel et al, 2009).

Efficacy of Resection for Pancreatic Metastases

Although comparison of the survival data after metastasectomy with the historic results of conservative treatment suggests a benefit of surgery, the efficacy of surgical resection and its superiority over conservative treatment alone cannot be formally proven because of the lack of controlled trials. However, for RCC, three studies observed longer survival in patients after resection compared with noncontrolled groups with irresectable disease (Sellner et al, 2006; Tanis et al, 2009; Zerbi et al, 2008). Furthermore, the survival data after pancreatic resection for RCC metastases compare very favorably to the survival reported for resection of RCC metastases in other organs (Kavolius et al, 1998). Another point supporting resection for pancreatic metastases is good local tumor control. In our series, local tumor control after 5 years was 87%, but disease-free survival was only 33% because of distant metastases (Strobel et al, 2009). This underlines the importance of interdisciplinary therapy with consideration of adjuvant treatment in these patients.

A major limitation of the literature concerning pancreatectomy for metastatic disease is the heterogeneity of patients, with most series including metastases from several different primary tumors. Except for RCC, the number of patients with other diagnoses is too small to draw reliable conclusions about the outcome and value of pancreatic resection for metastases. Thus, surgical decision making is generally based on the overall experience with resection for pancreatic metastases and on the reported outcome for each tumor type.

Table 60.2

Pathologic Diagnosis in Patients with Pancreatic Resections for Metastases

Primary Tumor Type	No. Patients	% of Total
Renal cell cancer	181	63.1
Colorectal cancer	22	7.7

SURGICAL APPROACH IN PATIENTS WITH PANCREATIC METASTASES

Presentation of Patients with Pancreatic Metastases

Patients with pancreatic metastases can be divided into two groups: those with symptoms and those without. Patients in the first group experience typical symptoms caused by a pancreatic tumor, and the diagnostic workup reveals a pancreatic mass that

often has features atypical for primary pancreatic cancer (Palmowski et al, 2008). In the second group of patients, the lesion is found during standardized follow-up exams for the primary tumor or by imaging for other reasons. Within the past few decades, the distribution has shifted from symptomatic to asymptomatic patients, most likely as a result of standardized follow-up programs and broad use of cross-sectional imaging techniques. In studies that include patients from previous decades, 60% to 90% of patients were seen because of symptoms (Reddy et al, 2008; Sellner et al, 2006; Tanis et al, 2009); in the authors' recent series, only 18% of metastases were diagnosed because of symptoms, and 82% were detected during oncologic follow-up (Strobel et al, 2009). Patients with symptoms appear to have a worse prognosis, as has been shown for RCC metastases (Tanis et al, 2009). These findings suggest that symptoms eventually develop as local complications during progression of pancreatic metastases and present another point in favor of surgery for resectable metastatic disease.

Interestingly, pancreatic metastases frequently are identified long after resection of the primary tumor. This is best documented for RCC metastases, which are diagnosed at a median interval of 10 years after resection of the primary tumor (Sellner et al, 2006; Strobel et al, 2009). This long disease interval must be taken in account in the design of oncologic follow-up programs.

Diagnostic Workup for Suspected Pancreatic Metastases

Usually, a pancreatic mass is first detected by contrast-enhanced computed tomography or magnetic resonance imaging. Pancreatic metastases have features different from primary pancreatic malignancies (see Chapters 16 and 17). In contrast to pancreatic adenocarcinoma, most metastatic entities exhibit contrast enhancement, as shown in Figure 60.1 (Palmowski et al, 2008), particularly mestastatic RCC. Another feature of metastases is their multifocality within the pancreas: 40% in pathologic workup in our series. Perhaps because of the long interval between the primary tumor resection and the pancreatic metastases, these lesions are often misdiagnosed as primary pancreatic malignancy.

Clearly, if a pancreatic lesion is detected in a patient with a history of cancer, the serum tumor markers for the previous malignancy, if relevant, should be determined, and state-of-the-art restaging should be performed to rule out local recurrence and extrapancreatic systemic disease. The importance of a thorough workup is highlighted by the high frequency of additional, extrapancreatic lesions in patients with pancreatic metastases. If additional extrapancreatic disease is suspected, positron emission tomography is recommended to identify patients with diffuse spread who will not benefit from surgery. In contrast, preoperative tissue diagnostics are usually not needed, especially in patients with disease confined to the pancreas, because it does not alter the indication for operation, which would also be offered for a primary pancreatic malignancy without evidence of spread. Only in cases with extrapancreatic spread or features that would otherwise contraindicate resection should a tissue diagnosis be pursued because it may be helpful to rule out metastatic pancreatic cancer.

Patient Selection for Surgery

As discussed, solid data regarding the outcome of resection for pancreatic metastases are lacking for tumor types other than RCC. Decision making and selection of patients for surgery must therefore be considered on an individual basis and by using several clinical parameters, including type and history of malignant disease, pattern of metastatic spread, patient comorbidities, and operative risk. Ideally, the decision process should involve both medical oncologists and experienced pancreatic

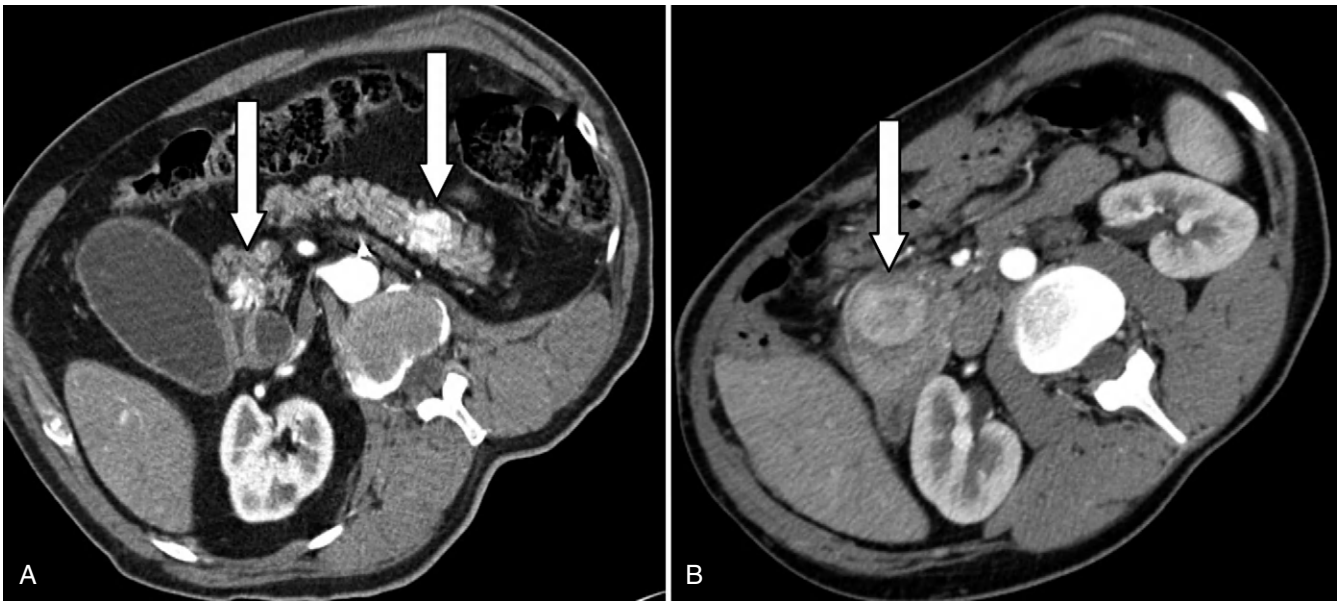

FIGURE 60.1. Typical radiologic features of pancreatic metastases. On contrast-enhanced computed tomography, pancreatic metastases typically appear as lesions with contrast enhancement in the arterial phase. **A,** Metastases of renal cell cancer to the pancreatic head and tail (*arrows*) exhibit intense contrast enhancement in the arterial phase. **B,** Metastases of soft tissue sarcoma to the pancreatic head (*arrow*) with contrast enhancement and central hypodensity.

surgeons and does not differ much from decision making for resection of other metastatic sites, such as liver and lung.

Primary Tumor Type

Clearly, the biology of the primary tumor is a key factor influencing the outcome. Patients with RCC metastases have a significantly better outcome than patients with other malignancies (Strobel et al, 2009), likely the result of a relatively slow tumor biology and, more recently, of more effective chemotherapy. Although the expected outcome in other malignancies, such as melanoma, is much worse, the decision for surgery can be based on the lack of effective nonoperative treatment in some tumor entities. Thus the decision for pancreatectomy for metastatic disease, as from other metastatic sites, can only be based on the experience with metastasectomy, per se, in each specific tumor entity.

History of the Disease

In our recent series, a prolonged interval (>36 months) between the primary tumor and the occurrence of the pancreatic metastasis was associated with improved survival. Of importance, a previous recurrence only affected disease-free but not overall survival (Strobel et al, 2009).

Pattern of Recurrent Disease

As expected, the presence of extrapancreatic disease is associated with shorter disease-free and overall survival (Strobel et al, 2009). This further highlights the importance of a thorough diagnostic workup to rule out local or extrapancreatic systemic recurrence of the primary tumor, as previously discussed. However, the survival results show that additional extrapancreatic disease should not necessarily preclude a patient from resection if the pattern is not multifocal/diffuse and if a complete resection can be expected.

Local Resectability, Patient Comorbidities, and Operative Risk

Given the lack of studies to evaluate factors that determine local resectability of pancreatic metastases, the same parameters used for primary pancreatic malignancies can be applied and typically involve assessment of mesenteric vascular and/or adjacent organ involvement (see Chapter 62A).

Of course, the same applies to patient-related factors that influence the operative risk, but consideration should also be given to the overall life expectancy related to the underlying disease and the efficacy and risk related to resection of extrapancreatic disease, if present. Clearly, medical comorbidities, functional status, and age have to be thoroughly considered.

Technique of Resection for Pancreatic Metastases (See Chapter 62A)

No studies have compared different techniques of pancreatic resection, and most larger studies only describe radical resections. However, in one report, a high rate of pancreatic recurrence was observed after limited resections (Bassi et al, 2003).

FIGURE 60.2. Pancreatic metastases of sarcoma. Cross-sections through the pancreas revealed two independent lesions located in different parts of the pancreas.

In our series, we performed standard partial resections but avoided total pancreatectomy whenever possible and observed only two pancreatic recurrences after 30 partial (6.7%) pancreatectomies (Strobel et al, 2009). Because pancreatic metastases are frequently multifocal (Fig. 60.2), a thorough exploration of the pancreatic remnant by palpation and ultrasound is mandatory whenever a partial pancreatectomy is performed (Zerbi et al, 2008). Because the two largest series showed that pancreatic metastases are associated with peripancreatic lymph node metastases in 26% to 30% of patients (Reddy et al, 2008; Strobel et al, 2009), a standard peripancreatic lymphadenectomy should be performed during pancreatic resection for metastases. To achieve curative resection, multivisceral resections should be performed if the operative risk and potential benefit are acceptable.

CONCLUSION

Rather than limited local resections, standard partial pancreatectomy combined with standard lymphadenectomy is recommended for treatment of pancreatic metastases. If complete tumor resection can be achieved with acceptable risk, total pancreatectomy and multivisceral resections may be performed in selected patients.

CHAPTER 61

Endocrine tumors of the pancreas: clinical picture, diagnosis, and therapy

Tricia A. Moo-Young and Richard A. Prinz

OVERVIEW

Pancreatic endocrine tumors (PETs) are rare neoplasms that comprise 2% to 4% of all clinically detected pancreatic tumors (see Chapter 56). The origin of these tumors is not completely understood. Based on the most recent evidence, it has been suggested that these tumors arise from an endocrine cell–derived gastrointestinal epithelium. The pathogenesis of these tumors is not completely understood. Earlier theorists and modern geneticists have suggested that PETs arise from omnipotent endocrine stem cells present within the gastrointestinal epithelium. PETs are frequently divided into two groups based on the presence or absence of hormone function. *Nonfunctioning, or non–hormone producing, tumors* account for up to 30% or more of all neuroendocrine tumors; they express neurosecretory granules but are not associated with a clinically evident endocrinopathy, and most are discovered incidentally through the use of imaging studies done for other reasons or because of nonspecific abdominal symptoms. *Functional tumors* produce hormones that result in well-described endocrinopathies directly attributable to the hormones they secrete. The majority of PETs are sporadic, but they can be associated with hereditary syndromes, such as multiple endocrine neoplasia type 1 (MEN-1), von Hippel–Lindau (VHL) syndrome, tuberous sclerosis complex (TSC), and neurofibromatosis 1 (NF-1). The genetic predisposition for pancreatic endocrine tumors is strongest with MEN-1, which is characterized by the development of multigland parathyroid hyperplasia, pancreatic islet cell tumors, and pituitary adenomas. Almost half of all patients with MEN-1 develop symptomatic pancreatic endocrine tumors, and 100% of patients are shown to harbor small, nonfunctioning pancreatic endocrine neoplasms when the gland is examined histologically (Muscarella & Ellison, 2004).

Clinical management of PETs involves a multidisciplinary approach. Biochemical diagnosis and radiologic localization are the cornerstone of preoperative planning. Surgical resection is the only treatment that is curative, especially in an early stage of disease, but as many as 75% of patients present with advanced disease. Nonoperative therapies include chemotherapy, radiofrequency ablation (RFA), radionuclide therapy, biotherapy, and chemoembolization (see Chapters 81B and 83). These therapeutic modalities are useful for patients with unresectable or metastatic disease in whom symptomatic control of the hormonal effects and arrest of tumor progression can provide palliation and in some instances prolong survival.

CLASSIFICATION AND PROGNOSIS

Pancreatic endocrine tumors arise from the islets of Langerhans, and human islet cells display wide varieties in cellular composition and morphology. The molecular pathogenesis of PETs is poorly characterized, but they are associated with genetic syndromes such as VHL, MEN-1, NF-1, and TSC. The genetic makeup of these syndromes may help elucidate the molecular pathways from which PETs arise, although the majority of PETs are sporadic in origin. The broad heterogeneity of these tumors presents a challenge with regard to their correct classification. PETs are commonly classified by the presence or absence of a syndrome caused by hormone hypersecretion; however, neither of these classification systems offers any valuable predictive information regarding the biology or prognosis of these tumors.

The World Health Organization (WHO) developed a classification of pancreatic tumors that predicts malignant behavior based on histologic criteria (Heitz et al, 2004). This classification system assesses tumor localization, extension, proliferative capacity, and the presence of vascular or perineural invasion (Table 61.1). Some authors have challenged the clinical relevance of the WHO classification system (Schindl et al, 2000). Other studies have shown to have strong prognostic value and the ability to predict response to adjuvant treatments (Artale et al, 2005; Bajetta et al, 2005). The tumor-node-metastasis

Table 61.1

WHO Classification of Pancreatic Endocrine Tumors

Well-Differentiated Endocrine Tumor

Type 1: Benign Behavior	*Type 2: Uncertain Behavior*
Confined to the pancreas	Confined to the pancreas and *one* of the following:
<2 cm in diameter	>2 cm in diameter
<2 mitoses per high-powered field	>2 mitoses per high-powered field
<2% Ki-67–positive cells	>2% Ki-67–positive cells
No vascular or perineural invasion	Vascular or perineural invasion

Well-Differentiated Endocrine Carcinoma

Low-grade malignant
Gross local invasion
Metastases

Poorly Differentiated Carcinoma

High-grade malignant
>10 mitoses per high-powered field

(TNM) staging system for pancreatic exocrine adenocarcinoma has been applied to the staging of PETs and was recently revised to include grades relative to mitotic counts or Ki-67 index (Table 61.2). This was recently validated in a retrospective study looking at 202 foregut neuroendocrine tumors, of which 131 were PETs. This system was found to be equivalent but not superior to the WHO classification system (Pape et al, 2008).

The prognostic value of newer systems has yet to be validated in a prospective way. In a large retrospective study of PET patients from the National Cancer Database, variables predictive of outcomes included age, grade, type of resection, distant metastases, and tumor functionality. Tumor size, nodal status, and margins were not associated with survival (Bilimoria et al, 2008). The limitations of retrospective studies, usually with a small cohort size, and heterogeneity among these tumors likely explain why a standard classification system for PETs still does not exist.

Table 61.2

TNM Classification for Pancreatic Neuroendocrine Tumors

T: Primary Tumor	
T0	No evidence of cancer
Tis	Carcinoma in situ
T2	Tumor limited to the pancreas, size >2 cm
T3	Tumor extends beyond the pancreas but does not involve the celiac axis or superior mesenteric artery
T4	Tumor involves celiac axis or superior mesenteric artery (unresectable primary tumor)
N: Regional Lymph Nodes	
N0	No regional lymph nodes involved
N1	Regional lymph nodes involved
M: Distant Metastases	
M0	No distant metastases
M1	Distant metastases
Stages	
0	TisN0M0
IA	T1N0M0
IB	T2N0M0
IIA	T3N0M0
IIB	T1N1M0, T2N1M0, T3N1M0
III	T4, any N, M0
IV	Any T, any N, M1

INSULINOMA

Insulinomas represent the most common type of functioning pancreatic endocrine tumor. They can occur sporadically or in association with the hereditary MEN-1. Patients typically are women (2 : 1) in the fifth or sixth decade of life. Among the functional PETs, insulinoma has the most favorable prognosis because the majority of these lesions are benign. Sporadic insulinomas are typically unifocal, but MEN-1 patients who develop insulinomas (approximately 10%) may present with multifocal disease.

Clinical Picture

Insulinomas are characterized clinically by fasting hypoglycemia and neuroglycopenic symptoms. Patients typically have episodic attacks of weakness, sweating, and tachycardia; however, the most notable symptoms are associated with central nervous system dysfunction. Neuroglycopenic symptoms include altered mental state, weakness, diplopia, seizures and, in late stages, coma. The stress of hypoglycemia causes a release of catecholamines responsible for the symptoms of anxiety, sweating, and palpitations. As a result, patients can be erroneously given cardiovascular, neurologic, or psychiatric diagnoses. Whipple described a triad of signs and symptoms associated with insulinomas that includes hypoglycemic symptoms after a fast or exercise, a blood glucose level less than 45 mg/dL when symptomatic, and relief of those symptoms by intravenous or oral glucose administration. The symptoms of hypoglycemia can be relieved or diminished by increasing oral intake, and appetite is stimulated by the sympathetic adrenergic surge. Because of this, patients with insulinomas often develop hyperphagia and have new-onset weight gain.

Diagnosis

The differential diagnosis of hyperinsulinemic hypoglycemia includes postprandial dumping syndromes, insulin receptor gene mutations, factitious hypoglycemia, chronic adrenal insufficiency, and hypopituitarism. In adults with symptoms of hypoglycemia, a 72-hour fast can elucidate the cause of hypoglycemia, defined as a plasma glucose level of 50 mg/dL or less. A monitored fast until symptoms of hypoglycemia develop, or until 72 hours elapse, is commonly performed, with measurement of the plasma concentrations of insulin and glucose at set intervals, especially when the patient becomes symptomatic. An insulin/glucose ratio greater than 0.4 is consistent with an insulinoma.

Insulin is synthesized in the β-cells as a larger molecule called *proinsulin*. C-peptide is cleaved from proinsulin to make the active form of insulin. Elevated levels of insulin with undetectable proinsulin and C-peptide indicate factitious hypoglycemia from the exogenous administration of insulin. Factitious hypoglycemia can also be caused by the ingestion of sulfonylureas, which cause elevated levels of all the β-cell polypeptides.

Table 61.3

Diagnostic Criteria for Insulinoma

Monitored fast for <48 hours with documented blood glucose <50 mg/dL with hypoglycemic symptoms
Relief of symptoms after oral glucose load
Elevated insulin level (>5 to 10 μU/mL)
Increased serum proinsulin level (>22 pmol)
Absence of urinary or plasma sulfonylureas
Elevated C-peptide levels

Factitious hypoglycemia often occurs in health care workers who have access to insulin or oral hypoglycemics. So, during a monitored 72-hour fast, both C-peptide and sulfonylureas should also be measured in the patient's plasma and urine. Monitored testing can detect up to 99% of insulinomas (Table 61.3; Service et al, 2000). Provocative testing with tolbutamide, glucagon, or intravenous calcium is rarely required for the diagnosis of insulinoma; furthermore, their use can cause harmful hypoglycemia with permanent neurologic damage. Autoimmune syndromes are rare causes of hypoglycemia that result from elevated levels of insulin in the presence of antiinsulin antibodies or antiinsulin receptor antibodies. Screening for these rare conditions can be done with serum measurements of the respective antibodies. Treatment is nonsurgical and sometimes warrants plasmapheresis.

Localization

Imaging for preoperative localization of insulinomas should take place only after the biochemical diagnosis has been confirmed. Most patients with insulinomas have a solitary benign adenoma (Friesen, 1982). Patients with familial syndromes, however, are more likely to have multifocal disease. Adenomas occur with equal frequency in the head, body, and tail of the pancreas. The majority of lesions are less than 1.5 cm in size and can be below the limit of detection for many conventional imaging modalities. Localization of insulinomas preoperatively remains a challenge for present-day clinicians. Traditional imaging techniques include ultrasound (US), computed tomography (CT) (see Chapter 16), and magnetic resonance imaging (MRI) (see Chapter 17). Transabdominal US, although widely available and used routinely, has low sensitivity in detecting insulinomas because of limitations from body habitus, surrounding intraabdominal organs, and the retroperitoneal depth of the pancreatic head.

Endoscopic ultrasound (EUS) (see Chapter 14) has substantially improved preoperative imaging of pancreatic neoplasms, but it is invasive. The sensitivity of EUS for localizing insulinomas has been reported to be 65% to 94%, with a mean sensitivity of 84% to 89% (Sotoudehmanesh et al, 2007). EUS visualization of the pancreatic head and uncinate process is superior to that of conventional US and provides the option of image-guided biopsy. The sensitivity of EUS is variable and depends on the location of the tumor. Sotoudehmanesh and colleagues (2007) reported sensitivity of EUS for detection of lesions in the pancreatic head, body, and tail as 92.6%, 78.9%, and 40.0%, respectively. This is understandable because of a blind spot in the distal body and tail where the stomach does not directly overly the pancreas.

Because of its wide availability, CT is usually the first localizing study performed; it can detect up to two thirds of lesions. When available, multidetector-row CT has been shown to be more sensitive for detecting small insulinomas (Liu et al, 2009). Most insulinomas are vascular and can be visualized on arterial phase imaging. One series comparing the use of CT, EUS, and the two in combination found the sensitivity of CT with EUS was superior to either modality done separately (Gouya et al, 2003). MRI alone or in combination with other imaging modalities has demonstrated higher sensitivity and rates of detection than were originally reported. More recent use of rapid triphase breath-holding imagery allows better fat suppression and reduction in motion artifact in both the arterial and venous phases (Catalano et al, 1999; Thoeni et al, 2000). At present, MRI is considered a second-line modality in the evaluation of insulinomas because of its greater expense and more limited availability.

Because only 30% of insulinomas possess somatostatin type II receptors, the value of somatostatin receptor scintigraphy (SRS) is limited in this tumor type (Kisker et al, 1997). Intraarterial calcium stimulation with hepatic venous sampling is one of the most sensitive localization modalities but also one of the most invasive (Guettier et al, 2009). It is a modification of the selective arterial secretin injection test developed by Imamura and colleagues (1993) and used to localize gastrinomas. This technique involves selective infusion of calcium into branches of the celiac axis and superior mesenteric artery with sampling of the hepatic venous effluent for insulin. It is an invasive, expensive, time-consuming, and technically difficult procedure that should be reserved for patients with persistent or recurrent disease, or when other tests are unsuccessful.

Despite these advances, preoperative localization may still not be successful in up to a third of patients. Current research suggests that future improvements will continue. A recent study showed that glucagon-like peptide-1 (GLP-1) receptor was expressed in more than 90% of insulinomas and at twice the density of somatostatin receptors (Reubi et al, 2003). Exendin-3, the analogue of GLP-1, is known to enhance insulin secretion in β-cells and has been introduced in the treatment of type 2 diabetes (Gallwitz et al, 2006). In a pilot trial of six patients, scintigraphy done with GLP-1 radioligands was able to identify all the insulinomas prior to operative exploration (Christi et al, 2009).

The extent of imaging necessary to ensure operative cure has not been clearly defined. Some institutions have suggested that preoperative localization is not necessary beyond the evaluation for metastatic disease (Hashimoto et al, 1999). This philosophy is based on the observation that the combination of surgical exploration and intraoperative US can identify more than 90% of insulinomas.

Therapy

Although the definitive treatment for patients with insulinomas is resection of the tumor, presurgical therapy to alleviate the symptoms and neurologic affects of hypoglycemia should be instituted. The medical management of insulinomas consists of dietary measures to minimize the occurrence of dangerous hypoglycemia. This involves taking small, frequent meals and closely monitoring blood glucose levels throughout the day. A number of insulin antisecretagogues can be used, such as diazoxide, verapamil, octreotide, or dilantin. Diazoxide, the most commonly prescribed drug, works by directly inhibiting the release of insulin from β-cells by stimulating their α-adrenergic receptors. Diazoxide also promotes glycogenolysis

by inhibiting cyclic adenosine monophosphate phosphodiesterase. It can offer symptom control in up to 50% to 60% of patients (Boukhman et al, 1998). Octreotide, a somatostatin analogue, has had variable results and alleviates symptoms in approximately 40% of patients (Arnold et al, 2002). Its use is limited by side effects such as bloating, malabsorption, cholelithiasis, and eventual tachyphylaxis. Dilantin and verapamil have been used alone or in combination with other drugs, but their duration of action and side effects limit their efficacy for long-term medical therapy.

Definitive treatment for an insulinoma is operative removal of the tumor. Before proceeding to surgery, it is important to exclude the presence of any familial syndromes and their other associated problems, such as pituitary tumors and hyperparathyroidism. Intraoperative glucose monitoring is done to ensure normoglycemia. Dextrose infusions should be stopped just prior to surgical resection to permit intraoperative glucose measurements as an indicator of biochemical cure. The glucose levels should be monitored frequently to be sure hypoglycemia does not persist.

Most sporadic adenomas are amenable to enucleation regardless of their location. Surgical exploration starts by gaining access to the pancreas in the lesser sac. Lesions located in the head of the pancreas should be explored via a wide kocherization of the duodenum. In experienced hands, intraoperative US in combination with palpation detects up 98% of insulinomas (Norton et al, 1988). Care must be taken not to injure the pancreatic duct when performing an enucleation or segmental resection. Intraoperative US is useful to identify the location of the pancreatic duct for lesions in the head that are being enucleated. The insulinoma can be approached anteriorly or posteriorly depending on findings from palpation and intraoperative US. After an insulinoma is fully enucleated, it is essential to inspect the area for ductal leaks. Should a leak be identified, a suture repair should be attempted if feasible, and a suction drain should be left in place; postoperative management of the drain is identical to that for any pancreatic leak. The most common complication following resection for an insulinoma is a pancreatic leak. Rates of pancreatic fistula have been reported between 18% and 38% (Espana-Gomez et al, 2009; Nikfarjam et al, 2008). Fistulas are seen more commonly among patients treated with enucleation procedures than those undergoing formal resection.

Most insulinomas are solitary, but in patients with MEN-1, multifocal lesions are typical. In MEN-1 patients—in whom multiple, subcentimeter tumors often coalesce—segmental resection rather than enucleation is preferred (see Chapter 62A). The goal of surgery in MEN-1 patients is to remove only the tumors, preserving as much normal pancreas as possible. After preoperative imaging, if the tumor cannot be identified by operative exploration with complete mobilization of the pancreas—including kocherization to allow bimanual palpation of the entire gland—or intraoperative US, blind resection is not recommended. When the lesion is not found, a pancreatic biopsy specimen should be obtained to rule out adult nesidioblastosis, which generally can be treated successfully by subtotal pancreatectomy. The biopsy specimen is obtained by removing a small portion of the most distal tail.

Numerous studies have shown that laparoscopy is a safe and feasible approach for the treatment of pancreatic insulinomas (see Chapter 62B). Solitary lesions localized preoperatively are ideally suited for this approach. In the absence of bimanual palpation, laparoscopic US assists in tumor localization. Whereas preoperative localization has an accuracy rate of 45% for laparoscopic resection alone, when combined with laparoscopic US, the accuracy rises to 96% (Luo et al, 2009). Conversion rates to an open procedure range between 7% and 44% (Ayav et al, 2005; Jaroszewski et al, 2004; Luo et al, 2009), and the most common reason for conversion is failure to localize the tumor. Limited data suggest that fistula rates are lower among patients treated by laparoscopic compared to open approaches (Cunha et al, 2007).

The rarity of malignant insulinoma limits definitive statements about therapeutic strategies and outcome. In patients with metastatic disease, surgical resection of the tumor and metastatic lesions should be considered for palliation of symptoms of hypoglycemia. Because of the often indolent nature of malignant insulinomas, extended survival is possible. Multimodal therapy that includes surgical debulking, chemoembolization, radiofrequency thermoablation, and liver transplantation has been shown to prolong survival (Begu-Le Corroller et al, 2008). Median disease-free survival has been reported to be approximately 4 years in patients who underwent curative resection for malignant disease (Danforth et al, 1984; Hirshberg et al, 2005). Chemotherapy of malignant insulinomas consists of streptozotocin in combination with other agents, including 5-fluorouracil or doxorubicin. Reports regarding the success of these agents in clinical trials are understandably scarce given the rarity of this condition.

GASTRINOMA (ZOLLINGER-ELLISON SYNDROME)

Gastrinomas are the second most common functioning islet cell tumor of the pancreas. The overall incidence of gastrinomas is 0.5 to 3 per million population per year (Jensen et al, 2006). The peak age of onset is 50 years, and there is a slight male predominance. Despite their slow-growing nature, more than 60% of gastrinomas are malignant. Because of their indolent growth pattern, even in the presence of metastases, the 10-year survival approaches 90%. Approximately two thirds of gastrinomas are sporadic, with the remainder associated with familial MEN-1. Gastrinomas in MEN-1 patients tend to be multifocal, and as many as 50% of patients have lymph node, liver, or distant metastases at the time of presentation (Andersen, 1989).

Clinical Picture

Gastrinomas are so named because they produce excess levels of the gastrointestinal hormone gastrin. This results in acid hypersecretion and the subsequent development of intractable gastrointestinal ulcers. Zollinger-Ellison syndrome (ZES) is the name given to this condition, and it includes the presence of a gastrin-producing tumor in the presence of acid hypersecretion. With the advent of effective antisecretory medications, patients may or may not have intractable ulcer disease at the time of diagnosis. ZES patients come to medical attention with symptoms of abdominal pain, heartburn, nausea, and often weight loss. Diarrhea is a common problem in ZES, occuring in close to 80% of patients (Jensen et al, 2006), and 70% of patients being seen for evaluation of ZES have a confirmed history of peptic ulcer disease. Patients with ZES are also likely to exhibit sequelae of gastric acid hypersecretion, such as esophageal stricture or prominent gastric folds, documented by endoscopic

Table 61.4

Diagnostic Criteria for Gastrinoma

Fasting gastrin level	>100 pg/mL *or* >10 times higher than upper limit of normal
Basic acid output level	>15 mEq/h
Secretin stimulation testing	Increase of >200 pg/mL
Calcium infusion provocative testing	Rise >395 pg/mL

Patients should be off antisecretory agents a minimum of 3 to 7 days.

gastroduodenoscopy (EGD). A suspicion of ZES is not appropriate for all patients who present with peptic ulcer disease (PUD). Approximately 0.2% of patients with PUD will have ZES, whereas 2% of patients with recurrent PUD will have ZES (Modlin et al, 1982). Other than recurrent ulcers, a higher suspicion of ZES should be held in patients who present with 1) PUD with diarrhea; 2) ulcers in unusual locations, including the distal duodenum and jejunum; 3) ulcers that are refractory to medical management or those associated with complications, such as bleeding and perforation; 4) disease at a young age; and 5) hyperparathyroidism, pituitary disorders, or a familial history of endocrinopathies. Given the nonspecific symptoms and relative rarity of this disorder, the mean time from the onset of symptoms to diagnosis is 5.9 years (Roy et al, 2000; Berna et al, 2006a). A high index of suspicion is necessary to diagnose these patients.

Diagnosis

The diagnosis of ZES is established by measuring a fasting serum gastrin (FSG) level and documenting the presence of acid hypersecretion (Table 61.4). Prior to testing, patients should be off all antisecretory medications at least 3 to 7 days. Proton pump inhibitors should be stopped for at least 1 week, and H_2 receptor antagonists should be stopped for 2 days prior to testing. A fasting serum gastrin (FSG) level above 100 pg/mL or 10 times greater than the upper limit of normal (ULN) is highly suggestive of ZES. However, only one third of ZES patients have an FSG level 10 times higher than the ULN, and a number of conditions that are not associated with ZES can cause an elevated FSG level (Table 61.5). To help differentiate these conditions, the presence of gastric acid hypersecretion should be documented. Excess gastric acid production is demonstrated by having a gastric pH of less than 2.1 or a basal acid output level greater than 15 mEq/h.

The magnitude of the increased FSG has been shown to correlate with certain tumor features (Berna et al, 2006a). Patients with pancreatic primary tumors are more likely than those with duodenal primary tumors to have an FSG level higher than 10 times the ULN (50% of pancreatic vs. 25% of duodenal primaries). FSG level also correlates with tumor size and extension. Patients with larger tumors (>3 cm) are more likely to have an FSG level greater than 10 times the ULN when compared with smaller tumors (40% vs. 23%, respectively). Fifty percent of patients with liver metastases will have an FSG level more than 10 times the ULN, compared with only a third of those who do not.

Two thirds of ZES patients will have equivocal FSG testing, and provocative testing should be performed. Three types of provocative tests are available for the diagnosis of ZES: 1) the secretin stimulation test, 2) the calcium infusion test, and 3) the standard meal test. The secretin stimulation test is performed by intravenously administering a 2 IU/kg bolus of secretin to the patient and serially measuring serum gastrin levels at specific time points. A serum gastrin rise of 200 pg/mL (range, >100 to 335 pg/mL) is consistent with ZES (Frucht et al, 1989b; McGuigan et al, 1980). The secretin stimulation test is highly sensitive and useful in patients who cannot tolerate being off their antisecretory medications. The calcium infusion provocative test is performed by administering an intravenous infusion of calcium gluconate 5 mg/kg/h over a 3-hour period (Deveney et al, 1977). Serial time points of gastrin and calcium are measured. A rise of more than 1.5 mEq/L of calcium is used to validate the test. A rise in serum gastrin above 395 pg/mL is considered diagnostic (range, 326 to 450 pg/mL). This test should be avoided in patients with renal disease, hypercalcemia, and cardiac disease. The standard meal test is performed by serving the patient a meal composed of 30 g protein, 20 g fat, and 35 g carbohydrate (Frucht et al, 1989a). Serum gastrin levels are again measured serially and are considered diagnostic of ZES if levels rise to either more than 50% of the zero time point level or to a maximal gastrin level greater than 500 pg/mL. This test is not performed in patients who have had a prior gastrectomy or those who cannot tolerate oral feedings.

Berna and colleagues (2006b) compared these three provocative tests for ZES and showed that the secretin test was more sensitive than the calcium infusion test (94% vs. 62%). However, 38% to 50% of patients with normal secretin test values went on to have positive calcium infusion tests. Fewer than 25% of ZES patients had an appropriate rise in their postprandial serum gastrin levels with provocative meal testing. The authors concluded that secretin stimulation should be the first-line provocative test, followed by calcium testing if the secretin test results are normal in the presence of a strong suspicion for ZES. Meal provocative testing should not be used given the high percentage of equivocal studies. Once a diagnosis of ZES is established, all patients should be screened for MEN-1 by measuring serum calcium, parathyroid hormone, and prolactin levels.

Table 61.5

Differential Diagnosis of Hypergastrinemia

High Acid Output	Normal Acid Production
Zollinger-Ellison syndrome	Atrophic gastritis
G-cell hyperplasia	Proton pump inhibitors

Gastric outlet obstruction	Renal failure

Localization

Once the biochemical diagnosis of ZES has been established, the next step is to localize the primary lesions and determine the presence or extent of tumor spread. The modalities for localization are similar to those used for insulinoma and include transabdominal and endoscopic US, CT, and MRI along with selective visceral angiography, selective venous sampling of the portal venous tributaries, intraarterial secretin with hepatic venous sampling for gastrin, and somatostatin receptor scintigraphy (SRS).

In contrast to insulinomas, SRS has proven effective in detecting gastrinomas. A radiolabeled form of the somatostatin

analogue octreotide can localize tumors that express high-affinity somatostatin receptors. SRS can also identify metastatic lesions elsewhere in the body. Current improvements in CT imaging have raised reported localization sensitivities from 30% to 55% through the increased use of multiphase detector CT scanning and the use of thin-slice imaging (Klose et al, 2007; Noone et al, 2005). CT imaging provides anatomic information, and it is useful for identifying metastatic disease. With MRI, gastrinomas have high signal sensitivity on T2-weighted fat-suppressed sequences. MRI can localize lesions smaller than 1 cm, but its overall sensitivity for gastrinomas is only 20% to 30% (Klose et al, 2007). Arterial angiography is now rarely used and has highly variable sensitivities because of its user-dependent variability.

As with insulinomas, EUS is extremely useful in detecting lesions within the pancreatic head but is less sensitive at identifying duodenal lesions (75% vs. 50%; Ruzzniewski et al, 1995). One promising technology being investigated for use with positron emission tomography is (68)Ga-DOTATOC, a somatostatin tracer (Hofmann et al, 2001). Preliminary studies have shown that 68 Ga-DOTATOC positron emission tomography has a higher sensitivity for detecting pancreatic endocrine tumors compared with both CT and SRS (Gabriel et al, 2007). Gastrinoma patients should first be evaluated by SRS and cross-sectional imaging (CT or MRI). If these tests fail to localize the lesions, EUS or angiography with secretin stimulation can be considered. When preoperative localization studies fail to detect the gastrinoma, surgical exploration with intraoperative palpation, US, and endoscopy with transillumination of the duodenum should be attempted, especially with sporadic gastrinomas.

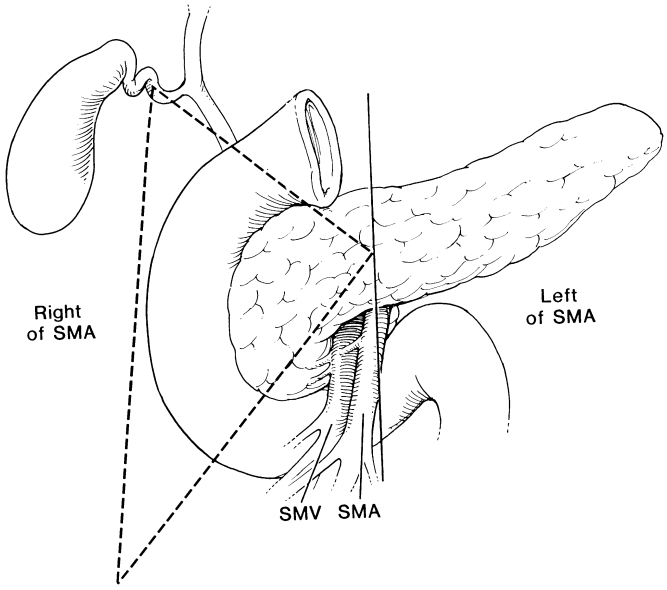

FIGURE 61.1. Gastrinoma triangle. SMA, superior mesenteric artery; SMV, superior mesenteric vein. *(From Howard TJ, et al, 1990: Anatomic distribution of pancreatic endocrine tumors. Am J Surg 159:258-264.)*

Therapy

Surgical resection is the recommended treatment for patients with sporadic, resectable disease (see Chapter 62A). As with all PETs, the only chance for cure is complete surgical resection. This is achieved in only a minority of patients (Norton et al, 1999). The majority of gastrinomas are located within the "gastrinoma triangle," as was described by Stabile and colleagues (Stabile et al, 1984; Howard et al, 1990). The *gastrinoma triangle* is defined by a line that joins the confluence of the cystic and common bile duct superiorly, the junction of the second and third portion of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially (Fig. 61.1). More than 80% of gastrinomas are located within this anatomic triangle (Abood et al, 2009).

The primary goal of treatment in ZES is to control acid production, remove the primary tumor, and prevent malignant progression. Historically, ZES patients were offered total gastrectomy to control acid production, but this has become unnecessary since the development of effective pharmacologic therapies for gastric hypersecretion. Resection of the primary is undertaken by performing a complete exploration of the gastrinoma triangle, which begins with an extended Kocher maneuver to mobilize the duodenum, gaining full exposure of the pancreas in the lesser sac. Bimanual palpation with the use of intraoperative US assists in identifying small and multifocal lesions located within the pancreas. Lesions within the pancreatic head should be treated with enucleation, and those in the tail or body should be treated with spleen-preserving distal pancreatectomy or enucleation. A duodenotomy should be performed routinely in all patients undergoing operative exploration for ZES (Morrow et al, 2009). Routine duodenotomy in the exploration for ZES doubles the cure rate from 30% to 60% (Morrow et al, 2009; Norton et al, 2004, 2006). Duodenal tumors less than 5 mm can be enucleated, but larger tumors should be resected by full-thickness excision of the duodenal wall. Laparoscopy has been attempted in patients with sporadic gastrinomas. Because more than 50% of these lesions occur in the duodenum or tend to be larger than other PETs, its use is limited to patients with lesions localized to the distal pancreas or those amenable to enucleation (Fernandez Cruz et al, 2008; Pierce et al, 2007).

The operative role and appropriate procedure in MEN-1 patients with ZES is controversial. This is because more than 50% of these patients are initially seen with evidence of metastases; thus MEN-1 patients are rarely cured by surgery. The goal of surgery in MEN-1 patients is not cure but prevention of metastatic disease. Surgical resection of the primary tumor may prevent the development of liver metastases and prolong disease free-survival among patients with MEN-1 ZES (Fraker et al, 1994; Motellaro et al, 2009). The larger the tumor, the more likely the patient is to develop liver metastases. Among patients with tumors less than 1 cm, only 4% are likely to have liver metastases compared with more than 60% of patients with tumors greater than 3 cm (Bartsch et al, 2007; Weber et al, 1995a).

The main predictor of survival in MEN-1 patients is the extent of liver metastasis (Weber et al, 1995b). ZES patients with MEN-1 who have tumors smaller than 2 cm may be observed. Tumors larger than 2 cm should have resection of their primary tumors with full duodenal and pancreatic exploration for multifocal disease. The use of pancreatoduodenectomy remains controversial in the management of MEN-1 ZES. This approach is recommended for young patients or those who have large isolated pancreatic head tumors (Fendrich et al, 2007; Morrow et al, 2009).

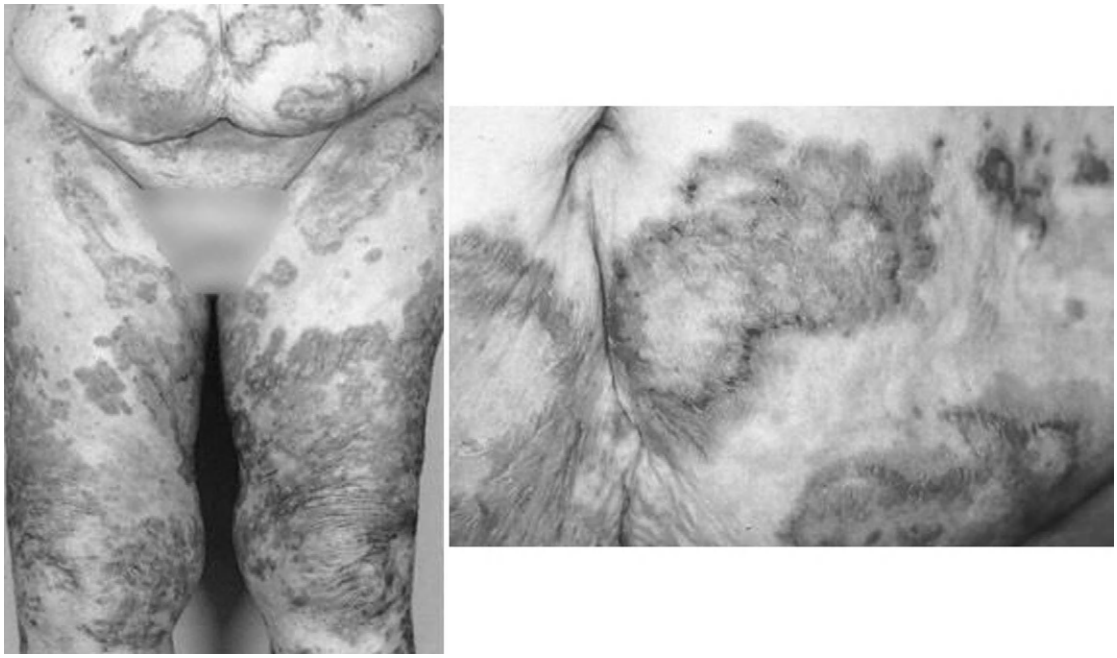

FIGURE 61.2. Necrolytic migratory erythema of glucagonoma. *(From Lebwohl MG [ed], 2002: Treatment of Skin Disease: Comprehensive Therapeutic Strategies. St. Louis, Mosby, p 416.)*

The effects of hyperparathyroidism on gastrin and acid hypersecretion should not be overlooked in MEN-1 patients. Those with both ZES and hyperparathyroidism should undergo parathyroidectomy prior to surgical treatment for their ZES.

GLUCAGONOMA

The first patient with a glucagonoma was described in 1942 by Becker and colleagues, who reported a 45-year-old woman with a diffuse, erythematous, vesicular, necrotic dermatosis in addition to diabetes mellitus, stomatitis, anemia, weight loss, and thromboembolism. Her autopsy revealed a pancreatic islet cell tumor. More than 20 years later, with the benefit of radioimmunoassay techniques, McGavran and colleagues (1966) showed elevated glucagon levels in the blood and pancreatic islet α-cell tumor tissue in a similar patient with "bullous and eczematoid dermatitis," diabetes, and anemia. Glucagonomas are rare, frequently large (>4 cm) at diagnosis, and almost always found within the pancreas. Patients typically are seen in their 40s, with an equal distribution between genders (Wermers et al, 1966). Most of the tumors (60% to 70%) are malignant, and association with MEN-1 is rare.

Clinical Picture

The clinical manifestations of a glucagonoma encompass what is sometimes referred to as the "four D syndrome," which includes ***d***iabetes mellitus type 2, ***d***ermatitis (necrolytic migratory erythema), ***d***eep vein thrombosis (30% of patients), and ***d***epression. Other symptoms can include chronic anemia, stomatitis, weight loss, and generalized weakness. Less common features include mental changes, diarrhea, arterial thrombosis, and neurologic abnormalities (Prinz et al, 1981). Necrolytic migratory erythema (NME) is present in 70% of patients (Fig. 61.2). This rash is characteristic of a glucagonoma but not definitively diagnostic. The distribution of NME is highly variable across regions of the body. It typically occurs where there is frequent friction or inadvertent trauma, such as the feet, lower legs, buttocks, or perineum, but lesions can be present anywhere. The rash is commonly confused with psoriasis, pemphigus, or eczema. To differentiate NME from these other rashes, a biopsy can be performed. Histopathology shows necrolysis, pallor of the epidermis, and mild lymphocytic and histiocytic infiltration. The biopsy should be taken from an early lesion and preferably from its edge. The reason for this is that older lesions with blisters in various stages of healing reveal nonspecific findings of dyskeratosis and acanthosis (Kovacs et al, 2006). These features make it more difficult to distinguish NME from other causes of subacute dermatitis. After resection, patients can have complete regression of NME.

Diagnosis and Localization

Laboratory findings of a glucagonoma include elevated plasma glucose level, normochromic normocytic anemia, and a generalized decrease in plasma amino acids. The diminished levels of amino acids stem from the stimulation of gluconeogenesis and amino acid oxidation by glucagon. Fasting serum glucagon levels greater than 1000 pg/mL (normal is 0 to 150 pg/mL) are virtually diagnostic. Other conditions that can cause elevated glucagon levels (usually <500 pg/mL) include fasting, sepsis, pancreatitis, abdominal surgery, Cushing syndrome, and renal or hepatic failure. Because the diagnosis is often delayed, patients with glucagonomas typically are seen with large tumors (>5 cm). CT scan with intravenous contrast administration is often sufficient for localization and has been reported to detect 86% of tumors (Wermers et al, 1966). Abdominal CT is also useful for identifying metastatic disease, which can be present in

up to 50% of patients at the time of presentation (Stacpoole, 1981). EUS is usually unnecessary for localization, but it can be useful for US-guided needle biopsy. SRS has been used more for long-term follow-up of these patients and can demonstrate metastatic disease (Lipp et al, 2000). Other imaging modalities, such as angiography and portal venous sampling, are rarely needed for localization purposes.

Therapy

Glucagonomas cause a prolonged and profound catabolic state. Preoperative nutritional status should be assessed, and the patient's metabolic deficits should be corrected before operation. Somatostatin analogues should be considered for the preoperative preparation because they can markedly diminish circulating levels of glucagon and consequently lessen or reverse its catabolic effects. The majority of tumors are located in the body or tail of the pancreas and are potentially amenable to laparoscopic spleen-preserving distal pancreatectomy, if diagnosed early. Unfortunately, most are very large at diagnosis. Glucagonomas are malignant in 60% to 70% of patients, and the likelihood of cure is small. An R0 resection is achievable in only 30% of patients (Abood et al, 2009). Nevertheless, resection of the primary and even metastatic lesions can offer substantial palliation if the tumor tissue can be removed safely. Like most islet cell carcinomas, glucagonomas frequently have an indolent course. Thus, reoperative surgery for recurrent disease is a reasonable option if the resection can be performed safely. Control of the hormonal effects through debulking procedures can help manage symptoms and prolong survival (Altimari et al, 1986). When widely metastatic disease is present and surgical debulking is not possible, medical therapy can alleviate hormonal symptoms (Nightingale et al, 1999). Somatostatin analogues such as octreotide can reduce serum glucagon levels and improve NME, diabetes, diarrhea, and neurologic symptoms. Dacarbazine and streptozotocin have been used to treat metastatic glucagonomas with some success. As with other pancreatic endocrine cell tumors, metastatic disease to the liver has been treated by resection, hepatic artery embolization, and liver transplantation (Dousset et al, 1995).

VASOACTIVE INTESTINAL PEPTIDE TUMOR

Vasoactive intestinal peptide (VIP) tumors are rare, with an annual incidence in the United States of 1 in 100,000,000 people. The majority of VIP tumors are benign and typically consist of a solitary lesion with a mean size of 3 to 5 cm. The mean age at presentation is 48 years, with a slight male predominance (Peng et al, 2004). In 1958, Verner and Morrison first described this syndrome of watery diarrhea (WD), hypokalemia (H), and achlorhydria (A) associated with a non–β-cell tumor of the pancreas (Verner & Morrison, 1958). As a result, this complex is often referred to as *WDHA syndrome* or *Verner-Morrison syndrome*, and 98% of patients are first seen with diarrhea. Hypokalemia is present in 67% to 100% of patients. The prevalence of flushing and weight loss is much more variable. The secretory diarrhea is high in volume (6 to 8 L/day) but painless and odorless; its color resembles tea, and it characteristically persists despite fasting. In VIP tumors, the diarrhea does not decrease with nasogastric fluid aspiration, whereas in ZES diarrhea will cease (Mansour & Chen, 2004). Over time, with large-volume gastrointestinal fluid losses, patients become hypokalemic and acidotic. The fluid and electrolyte deficits in VIP tumor patients can be profound and must be corrected before proceeding to surgical or other treatment.

The differential diagnosis for diarrhea is very long, so the diagnosis of a VIP tumor is typically made several months to years after the onset of symptoms. The average duration of symptoms before diagnosis is 3 years (Thomason et al, 2000). To confirm the diagnosis, a fasting serum VIP level should be greater than 200 pg/mL; average levels are close to 1000 pg/mL in patients with VIP tumors (O'Dorisio et al, 1989). The majority of pancreatic VIP tumors are located within the tail of the pancreas (72%) and thus are readily identified by conventional imaging. Radiologic examination begins with a CT scan of the abdomen and pelvis. Because of their relatively large size, sensitivity for localizing these lesions approaches 100%. Other radiographic adjuncts include MRI and SRS. Unlike insulinomas, more than 85% of VIP tumors are somatostatin receptor positive. SRS can be useful in detecting primary lesions outside the pancreas, where one third of VIP tumors are located. Compared with pancreatic tumors, extrapancreatic lesions are typically smaller, less likely to be malignant (33% vs. 64%), and less likely to present with metastases (29% vs. 56%) (Ghaferi et al, 2008).

While the diagnosis and localization of the tumor is being confirmed, electrolyte imbalances are corrected with oral or intravenous supplements when necessary. In some patients with longstanding diarrhea refractory to standard replacement strategies, it is necessary to start somatostatin therapy to reduce the amount of daily electrolyte losses. When radical resection is not possible, palliation can usually be achieved by debulking of the metastatic tumor in combination with the use of somatostatin analogues. Prognosis for these patients is largely determined by the presence or absence of metastatic disease at the time of presentation.

SOMATOSTATINOMA

Somatostatinomas are rare, representing only 1% of all pancreatic neuroendocrine tumors (O'Toole et al, 2006). In 1977, Ganda and colleagues and Larsson and colleagues independently reported the first patients with a somatostatinoma. Somatostatinoma syndrome was described by Krejs and coworkers in 1979 and includes hyperglycemia, cholelithiasis, steatorrhea, and diarrhea. The mean age of patients at diagnosis is 50 years, with an equal distribution between men and women. In most patients (>90%), the lesions are solitary and generally average between 5 and 6 cm. Extrapancreatic somatostatinomas occur in 44% of patients, most commonly within the duodenum, but they have also been reported to arise from the biliary tract or other parts of the small bowel. The inhibition of insulin secretion leads to mild hyperglycemia, and decreased gallbladder contractility from the inhibition of cholecystokinin results in the formation of gallstones. The inhibition of pancreatic enzyme and bicarbonate secretion and intestinal absorption causes diarrhea and steatorrhea. Patients also may have gastric hypochlorhydria from the inhibition of gastrin release (Jensen & Norton, 1995). These clinical manifestations are rarely present with somatostatinomas arising in the duodenum. Instead, patients with duodenal somatostatinomas are initially seen with obstructive symptoms that include abdominal pain and jaundice. Duodenal somatostatinomas often are identified as an incidental finding (Mao et al, 1995). They are malignant in

60% to 70% of patients, with nearly two thirds of patients having evidence of metastases at diagnosis (Nesi et al, 2007). Lesions greater than 2 cm are more likely to be associated with metastatic disease (Tanaka et al, 2000).

Most tumors located in the head of the pancreas are large. Localization of pancreatic somatostatinomas often can be accomplished by CT or US, whereas EUS, MRI, and SRS play a role in localization of smaller or metastatic tumors. Because many duodenal somatostatinomas are small (<1 cm), EUS can be especially useful for their localization. Surgical resection offers the only chance for cure, but many somatostatinomas have metastasized by the time they are discovered. Debulking can provide symptomatic relief, and cholecystectomy should be performed at the time of operation because of the high incidence of cholelithiasis. In unresectable disease, octreotide and interferon-alfa may improve symptoms. In patients without metastatic disease, the mean 5-year survival is 100%. Those patients with metastatic disease who undergo radical resection or debulking procedures have a mean 5-year survival of 60% (Abood et al, 2009).

NONFUNCTIONAL PANCREATIC ENDOCRINE TUMORS

Nonfunctional pancreatic neuroendocrine tumors (NF-PETs) histologically express endocrine differentiation but lack a clinical syndrome of hormone overproduction (Prinz et al, 1983). They represent more than 75% of all pancreatic endocrine tumors (Halfdanarson et al, 2008). The mean age at presentation is 45 years, and an equal distribution is found between men and women. Traditionally, NF-PETs are described as large tumors, and more than 60% to 80% are metastatic at the time of diagnosis. With the widespread use of high-resolution abdominal imaging, however, these lesions are being increasingly identified as small, asymptomatic tumors. Approximately 60% are malignant at the time of diagnosis (Ehehalt et al, 2009), and 8% of NF-PETs occur in association with MEN-1; of patients with MEN-1, approximately 55% of tumors will be NF-PETs (Thomas-Marques et al, 2006).

Clinical Picture

The diagnosis of an NF-PET is typically delayed by the lack of a clinical syndrome. These lesions are typically discovered on routine radiographic imaging done for nonspecific abdominal complaints. As these tumors grow larger and begin to compress surrounding structures, patients may develop symptoms of pain or obstruction.

Diagnosis and Localization

Although these tumors are hormonally "silent," they often release inert precursor hormones into the systemic circulation. Blood testing for such inert tumor markers include pancreatic polypeptide, neurotensin, protein S, neuron-specific enolase, and chromogranin A. Measurement of these levels prior to resection may help establish a baseline for tumor burden and provide a possible marker for follow-up for tumor recurrence. Localization of the primary tumor and establishment of the extent of metastatic disease is best achieved with a triple-phase—arterial, portal, and venous phase—CT scan (see Chapter 16). Because these tumors are typically large, EUS is only necessary for biopsy or to identify subcentimeter disease. SRS is recommended to determine receptor expression status for the postsurgical treatment with somatostatin analogues. Because a small percentage of these lesions can be associated with MEN-1, patients who have a medical or family history suggestive of MEN-1 should undergo testing for this familial syndrome's associated endocrinopathies.

Therapy

In patients with sporadic NF-PETs, resection should be geared toward cure when possible. When the lesion is limited to the pancreas, a standard oncologic resection should be performed (see Chapter 62A). In the presence of limited, synchronous hepatic metastases, concomitant liver resection should be considered if the patient is a good surgical candidate. In patients with extensive liver disease, resection of the primary tumor may be considered in conjunction with partial hepatectomy combined with locoregional ablative techniques, such as transarterial chemoembolization (TACE) and radiofrequency ablation (RFA).

In MEN-1 patients, the indications and approach to surgery remain controversial. MEN-1 patients have a field defect that makes the entire pancreas at risk of neoplastic disease, such that resection of a primary lesion does not necessarily prevent recurrence in the remnant gland. The goal of surgery for MEN-1 NF-PETs should be to resect all gross disease while also trying to preserve pancreatic function. Surveillance EUS performed in these patients often reveals small PETs of uncertain importance. The threshold for operation varies across institutions. Bartsch and colleagues (2005) advocate that patients undergo early resection at a size threshold of 10 mm, based on the observation that lesions greater than 10 mm carry a 20% risk of having locoregional metastases. Some groups advocate surgical exploration based on biochemical evidence alone, even if imaging studies fail to localize lesions (Skogseid et al, 1991). The recommended procedure includes enucleation of lesions in the pancreatic head followed by prophylactic spleen-preserving distal pancreatectomy.

METASTATIC DISEASE

Unlike exocrine pancreatic neoplasms, patients with endocrine tumors may benefit from reoperation for resectable recurrences or metastatic disease. This is likely because of the relatively indolent nature of these tumors. Observational studies have shown that many patients live for several years with untreated metastatic disease (Weber et al, 1995a). The debilitating aspects of these tumors are related to the excess hormone secretion in patients with functional PETs or to obstructive symptoms caused by large NF-PETs. The predominant site of metastatic spread is the liver. Resection, chemotherapy, and other treatment modalities may not cure the patient, but they do offer substantial palliation and may extend survival. Compared with medical management, patients treated surgically or with ablative therapy have improved overall survival (see Chapter 81B; Chamberlain et al, 2000).

Resection

With advanced metastatic disease that includes hepatic metastases, resection remains the gold standard of treatment in these patients when feasible. The biochemical response rate is 96%,

and the 5-year survival is reported as 80% (Steinmuller et al, 2008). Patients with advanced disease at initial presentation should undergo radical resection with an attempt at cure if it can be done safely. In study by Norton and colleagues (2003), in which the mean tumor size was 8 cm and 40% of patients had liver metastases, a curative resection was achieved in 75% of patients. Procedures included pancreatoduodenectomy, liver resection, nodal dissection, and total pancreatectomy. No perioperative deaths were reported, and the mean follow-up period was 19 months. During that time the actuarial overall 5-year survival rate was 80%, which supports the conclusion that patients with advanced disease at presentation may benefit from a complete resection or a debulking procedure. Musunuru and colleagues (2006) retrospectively reviewed 48 patients with neuroendocrine liver metastases only and evaluated their 3-year survival based on medical management, ablation, and surgical resection. The surgical group had a 3-year survival of 83% compared with 31% in the patients treated with medical therapy or embolization. No difference was reported in the palliation of symptoms among the three treatment groups.

Because of the limited patient population, none of these studies is likely to be validated by a prospective randomized controlled trial. Case-based studies and retrospective reviews are the basis for the current recommendations. Such studies recommend that curative resection in conjunction with an anatomic liver resection should be attempted, when it appears that at least 90% of the tumor burden can be removed based on preoperative imaging (Morrow et al, 2009).

Liver transplantation is an effective therapy for patients with hepatocellular cancer. In PET patients with isolated liver metastases, organ transplantation remains controversial. Lehnert (1998) reported 103 patients with metastatic neuroendocrine tumors who received liver transplants. The overall survival at 1 and 5 years was 61% and 30%, respectively, for the 48 patients with pancreatic islet cell tumors. Recurrence-free survival for all 103 patients was 24% at 5 years. Pretransplant treatment with a somatostatin analogue was found to be a favorable prognostic factor (Lehnert, 1998). The morbidity associated with these procedures can be high as a result of opportunistic infections, and a 10% operative mortality rate has been reported (Marin et al, 2007). There is a high risk of recurrence in the transplanted liver, and liver transplantation is generally reserved for young patients with unresectable isolated liver metastases as the single site of disease and for those who have poor symptom control on medical therapy.

Ablative Therapies for Neuroendocrine Hepatic Metastases

Although surgery remains the most effective therapy for PETs, many patients will be seen later with recurrent disease. The median time to recurrence is 21 months, with 5-year recurrence rates of 84% (Atwell et al, 2005; Sarmiento et al, 2003). At the time of recurrence, less than 10% of patients are candidates for reoperative surgery (Schurr et al, 2007). For this subset of unresectable patients, ablative cytoreductive measures have been attempted. Ablative therapies that include RFA, cryoablation, TACE, and radioembolization have been effective in reducing tumor burden in marginally resectable patients (see Chapters 83, 84A, and 85A through D; Maithel et al, 2009).

Ablative techniques are most efficacious when used for tumors smaller than 4 cm and for deep lesions, for which resection would sacrifice a great deal of normal liver parenchyma; ablative techniques are also beneficial as an adjunct in patients with bilobar disease who undergo anatomic resection of the lobe with the greatest tumor burden. The largest series on RFA therapy showed 95% symptom relief and a 5-year survival rate of 48% (Maithel et al, 2009). This was comparable to resections in which Sarmiento and colleagues (2003) showed a 5-year survival of 61% after aggressive operative removal. Hepatic artery embolization with or without direct infusion of chemotherapeutic agents has been used as an alternative therapy for patients who are not candidates for hepatic resection. Tumors of the liver receive most of their blood supply from the hepatic artery, whereas normal hepatic parenchyma can be sustained mainly from the portal venous circulation. Chemotherapeutic agents used include doxorubicin, cisplatin, mitomycin C, streptozotocin, and 5-fluorouracil (Mansour & Chen, 2004). In retrospective reviews of patients treated with TACE for unresectable liver metastases, response rates range from 66% to 100%, and 5-year survival rates of up to 83% are reported (Roche et al, 2003; Kim et al, 1999). A comparison between simple arterial embolization versus chemoinfused embolization showed no difference in symptom improvement or median overall survival between the two groups (Pitt et al, 2008).

Somatostatin Analogues and Systemic Chemotherapy

Approximately 80% of PETs express somatostatin receptors, and treatment with somatostatin analogues can alleviate symptoms associated with excessive hormone activity in patients with functional PETs. Subtypes of PETs most amenable to treatment with octreotide are glucagonomas, VIP tumors, and, to a lesser extent, gastrinomas and insulinomas. Positive SRS imaging may help predict which patients will respond to somatostatin analogue therapy (Oberg et al, 2004). The most commonly prescribed regimen starts with subcutaneous administration of 50 μg dosed three times per day. Lanreotide, a long-acting somatostatin analogue administered every 10 to 14 days, has been shown to have efficacy similar to that of octreotide (Ricci et al, 2000; Scherubl et al, 1994). Depot formulations of somatostatin analogues are also available that can be administered no more frequently than 4 to 6 weeks apart. These drugs are more difficult to titrate given their long-acting effects. It is not uncommon for patients treated with depot formulations to have "breakthrough" symptoms such that immediate, shorter acting medications must be given until a steady state is achieved.

Somatostatin analogues such as octreotide are generally well tolerated, safe, and have minimal side effects, although an increased incidence of cholelithiasis (up to 50%) is reported with continuous use of these drugs. However, the incidence of acute cholecystitis requring emergent cholecystecomy is rare (0% to 12%). Although it remains controversial, mounting evidence suggests that somatostatin analogues have cytoreductive properties in addition to their ability to control hormone symptoms (Clements et al, 1985; Imtiaz et al, 2000). An interim report at 6 months from an ongoing multiinstitutional, randomized, placebo-controlled trial has shown that 67% of patients receiving therapy had radiographic evidence of stable disease compared with 37% in the placebo group (Rinke et al, 2009). Of the patients included in this trial, 66% had undergone resection of the primary tumor, 74% were octreoscan positive, and 62% had some evidence of liver involvement.

When unresectable disease is found at laparotomy and it is likely that a somatostatin analogue will be used later, cholecystectomy should be considered.

Several trials have studied the role of interferon (IFN) in the treatment of pancreatic endocrine neoplasms. In one series, 57 patients treated with monotherapy IFN had a radiologic response of only 12% and biochemical control in 47%. IFN-alfa stimulates T-cell function and can control hormone secretion by the tumor. Oberg (2000) pooled 13 studies that examined a total of 383 patients with malignant neuroendocrine tumors; the biochemical and tumor response rates were 44% and 11%, respectively, with a disease stabilization rate of 35%. A randomized, prospective study of 80 patients with metastatic neuroendocrine gastroenteropancreatic tumors showed comparable antiproliferative effects among patients treated with somatostatin analogues, IFN-alfa, or a combination of the two (Faiss et al, 2003).

The role for systemic chemotherapy in the treatment of PETs is still undefined. Several different chemotherapeutic agents have been studied, both as single agents and in combination regimens. The most common single agents include streptozotocin, doxorubicin, capecitabine, fluorouracil, and dacarbazine. In the early trials, overall response rates for these single-agent regimens ranged from 20% to 50% (Broder et al, 1973; Moertel et al, 1982; Ramanathan et al, 2001). Combination regimens have shown even more promising outcomes, with overall response rates as high as 81% (Strosberg et al, 2011a). A newer agent, temozolomide, has been shown to have promise in Phase II trials. The combination of this drug with capecitabine in chemo-naive patients illustrated an objective radiographic response rate of 70%, with a median progression-free survival of 18 months (Strosberg et al, 2011b). The limitation of these drugs, either in combination or as single agents, is their associated toxicity. In several of these trials, patients were unable to tolerate the regimens because of complications such as lymphopenia or development of opportunistic infections.

Ki-67 is an immunohistochemical marker of high tumor proliferation. The Ki-67 index has been used to determine tumor grade and prognosis. In fact, a high Ki-67 index has been suggested as a measure to predict which patients would do better with antiproliferative or chemotherapy, even as a first-line treatment (Vilar et al, 2007).

New Drugs and Targeted Therapies

External-beam radiation has been used for the treatment of bulky hepatic metastases. The normal liver has a low tolerance for the levels of radiation needed to kill tumor cells. To minimize this, patients have been treated with targeted radiotherapy through the use of radiolabeled somatostatin analogues. These agents are conjugated to an injectable microsphere that allows high-dose intraarterial administration of the radiolabeled drug in a fashion similar to that used for TACE/transarterial embolization. Results of these studies are highly variable, but partial response rates ranging from 32% to 87% have been reported (Kennedy et al, 2008; King et al, 2008; McStay et al, 2005; Safford et al, 2004). Complete responses were seen in 5% to 18% of patients, and symptomatic improvement occurred in 49% to 61% of patients. The most common symptoms associated with toxicity were fatigue and nausea (Kennedy et al, 2008).

Novel molecular targets are also being studied for their therapeutic potential. PETs are highly vascular tumors that may be inhibited by the use of angiogenesis inhibitors such as bevacizumab, an antibody to vascular endothelial growth factor. In a Phase II trial of 44 patients with advanced carcinoid tumors, the reported progression-free surival rate over 18 weeks was 95% with bevacizumab versus 67% in those treated with IFN (Yao et al, 2008). In a Phase II study, rapamycin, a serine threonine kinase known as mTOR (mammalian target of rapamycin), was recently reported to achieve stable disease in 80% of patients treated during a 9-month period. The median progression-free survival was 17 months. As more is understood about the tumor biology of pancreatic endocrine neoplasms, it is likely more multimodal therapies will be developed.

POSTOPERATIVE SURVEILLANCE

Monitoring for recurrence after therapy is mainly based on serial measurement of tumor-specific markers and imaging. Regardless of the tumor subtype, almost all PETs express some level of chromogranin A (CgA). Every 6 months to 1 year, patients with PETs should have lab tests consisting of a CgA level and blood chemistry tests specific to their endocrine subtype. Patients with gastrinomas should be followed with serial gastrin levels and periodic SRS if their gastrin levels begin to trend upward. Insulinoma patients need only spot glucose checks; further testing should be done if glycopenic symptoms recur. Imaging is indicated when biochemical markers change during the patient's period of surveillance. This is begun by obtaining a baseline CT scan approximately 6 months after resection. Subsequent imaging is done when there is an alteration in the patient's symptom profile as it relates to the type of functional tumor for which the patient was originally treated. SRS is useful in patients with an index suspicion for metastatic disease and when receptor status is not yet known. This latter piece of information can be useful when trying to decide whether the patient is likely to benefit from somatostatin analogue therapy.

CHAPTER 62B

Surgery of the pancreas: minimally invasive approaches

Stefan Fritz, Markus W. Büchler, and Jens Werner

OVERVIEW

In recent years, an increasing number of laparoscopic pancreatic surgical procedures have been performed and reported from centers around the world. Even operations that were once considered impossible to perform laparoscopically, such as pancreatoduodenectomy or segmental pancreatic resection, are gaining momentum in a number of centers. With improving surgical techniques and experience, it has become crucial to reevaluate proper indications for laparoscopic pancreatic surgery. Limitations for a minimally invasive approach are often due to technical difficulties and particularly to the characteristics of pancreatic diseases.

Open pancreatic resection is commonly performed through an upper abdominal incision, whereas laparoscopic pancreatic resection is performed through four or five small abdominal incisions. The exposure during open pancreatic surgery involves the use of abdominal wall retractors and mechanical retraction of the abdominal viscera. In contrast, exposure during laparoscopic pancreatic resection is achieved with pneumoperitoneum. By reducing the length of surgical incisions and eliminating the need for mechanical retraction of the abdominal wall and viscera, operative trauma to the abdominal wall during laparoscopic pancreatic surgery can be minimized. However, the lack of direct haptic feedback, fewer degrees of freedom, a narrow working space, and a sometimes difficult orientation conspire to limit the indications for laparoscopic pancreatic surgery. Moreover, the intraabdominal surgical trauma is identical to the open technique and exceeds by far the relatively minor trauma to the abdominal wall. Within this context, the relative benefits of laparoscopic pancreatic resection must be examined critically.

Laparoscopic pancreatic surgery represents one of the most sophisticated applications for laparoscopy currently in use. Recent advances in technology and techniques have opened new gates to a wide range of applications in patients with pancreatic diseases. This chapter describes the laparoscopic techniques available today, including diagnostic laparoscopy, laparoscopic resection techniques, and new technical developments such as robotic approaches.

DIAGNOSTIC LAPAROSCOPY

Diagnostic laparoscopy is a procedure that allows the surgeon to examine directly the contents of a patient's abdomen or pelvis, including the peritoneum, small bowel, large bowel, liver, pancreas, or gallbladder (see Chapter 21). Pancreatic cancer is characterized by an aggressive, infiltrating local tumor growth and early manifestation of metastasis. Consequently, resection with curative intent can be performed in only 10% to 20% of patients with newly diagnosed pancreatic cancer.

Although staging of pancreatic cancer is critical to the planning of therapy and has improved over the past decades, especially as a result of better imaging techniques, there are still some patients in whom liver or peritoneal metastases are not detected during preoperative testing. Even with modern thin-sliced computed tomography (CT) or magnetic resonance imaging (MRI), detecting hepatic or peritoneal metastases smaller than 5 mm is difficult and often impossible. Likewise, assessing local tumor extent and the degree of infiltration into adjacent organs remains challenging. In these cases, diagnostic laparoscopy is useful for assessing whether the patient is a candidate for curative resection or radiotherapy. In addition to the possibility of obtaining peritoneal fluid for cytology, following instillation of saline into the peritoneal cavity, laparoscopic ultrasonography (US) can be performed. This technique enables the detection of locally advanced disease and intraparenchymal liver involvement and gives a good indication of vascular involvement (Menack et al, 2001). Consequently, in many cases a primarily planned surgical pancreatic resection can be aborted with minimal surgical trauma. At the same time, tissue samples for histologic evaluation can be achieved from distant metastases and from large tumors, particularly when the body or tail of the pancreas is involved.

Overall, the indications for a staging laparoscopy in pancreatic cancer are 1) large primary lesions in the neck, body, or tail of the pancreas; 2) radiographic findings suggestive of occult metastases or a possible carcinomatosis; 3) small, hypodense regions in the hepatic parenchyma suspicious for liver metastases; and 4) subtle clinical and laboratory findings suggesting more advanced disease (Pisters et al, 2001). In eliminating nontherapeutic laparotomy and redirecting treatment plans, laparoscopy contributes significantly both to the proper management of patients with pancreatic cancer and to increased efficiency of resource utilization (Warshaw et al, 1986).

HISTORY OF LAPAROSCOPIC PANCREATIC SURGERY (SEE CHAPTER 62A)

The slow progress of laparoscopy in pancreatic surgery in the past has been attributed to the retroperitoneal location of the gland, its proximity to various important vascular structures and organs, the friable nature of the gland, and the difficulty in its exposure. Similar to experiences with sigmoid colon resections, which were first performed in benign diseases such as recurrent sigma diverticulitis, laparoscopic pancreatic resections were initially performed for benign tumors. In particular, benign endocrine tumors less than 1 cm (e.g., insulinomas) or

small cystadenomas predominantly located in the distal body and tail of the pancreas were ideally suited for the laparoscopic approach. In such cases, the surgical specimen is relatively small and contrasts greatly with the size of the abdominal incision required to access this retroperitoneal gland at conventional open surgery. Furthermore, enucleation or atypical resection can often be performed to remove small pancreatic lesions without the need for an anastomosis (Ammori, 2003).

Currently, laparoscopic resection can be performed both for benign and malignant pancreatic diseases. For benign tumors, left resections or enucleations can be often performed without difficulty. On the other hand, resections that require an anastomosis or those for malignant tumors that require an adequate margin and associated lymph node dissection remain tremendously challenging. Because lymphadenectomy in pancreatic cancer is technically difficult, especially along the celiac trunk and the superior mesenteric artery, few surgeons perform laparoscopic resections for malignant disease on a routine basis. Although many reports have demonstrated technical feasibility, it must be stated that not everything that can be done should be done. Sophisticated pancreatic resections such as pancreatoduodenectomy are only performed in highly select cases by exceptionally skilled laparoscopic surgeons to achieve a satisfying postoperative outcome (Gagner & Palermo, 2009). Because the challenge in pancreatic surgery for malignant disease is to achieve an R0 resection, even in advanced cases requiring vascular and/or multivisceral resections, we feel that the potential benefit of laparoscopic resections does not outweigh the risk in patients with cancer.

LAPAROSCOPIC PANCREATIC RESECTIONS

Pancreatic Left Resection

Surgical Technique

Distal pancreatic resection has been performed for the treatment of patients with chronic pancreatitis and benign and malignant tumors in the tail or body of the pancreas. Initially, distal pancreatectomy was performed en bloc with the resection of the spleen. This technique was preferred by surgeons for technical as well as oncologic reasons. Because resection of the spleen has been reported to impair the immune system and could predispose to infective complications after distal pancreatectomy and splenectomy (Holdsworth et al, 1991), Kimura and colleagues (1996) developed a technique of preserving both the splenic artery and vein. In addition, Warshaw (1988) described a technique of distal pancreatectomy in which splenic vessels are ligated both at the level of transection of the pancreas and again at the splenic hilum, leaving the spleen to survive on blood flow through the short gastric vessels.

Over the past few years, the technique of laparoscopic pancreatic left resection has been introduced and refined. Many different methods have been described for trocar placement and surgical technique. In the technique used in Heidelberg, the patient is placed in a half-lateral position with the left side up. The surgeons stand on the right side of the patient, and the camera operator and scrub nurse stand on the opposite side. Four 10- to 12-mm trocars are inserted in the abdominal wall 3 to 4 cm above the umbilicus on the xiphoid area, subcostal on the midaxillary line, and subcostal to the midclavicular line. The first step is dissection of the splenorenal ligament; the splenic flexure of the colon is then mobilized downward. The gastrocolic omentum is widely opened along the gastroepiploic arcade up to the level of the mesenteric vessels, and the body and tail of the pancreas are then visualized (Fig. 62B.1). The inferior border of the pancreas is dissected, and the body and tail of the pancreas are completely detached from the retroperitoneum (Fig. 62B.2). This mobilization of the left pancreas allows visualization of the posterior wall of the gland, where the splenic vein is easily identified (Fig. 62B.3). The splenic vein is pushed away from the posterior pancreatic wall by gentle blunt dissection, and a tunnel is created between the splenic vein and the pancreas. The splenic artery is identified through this space by using careful blunt dissection with a curved dissector. Alternatively, the artery can be identified at the superior margin of the pancreas (Fig. 62B.4).

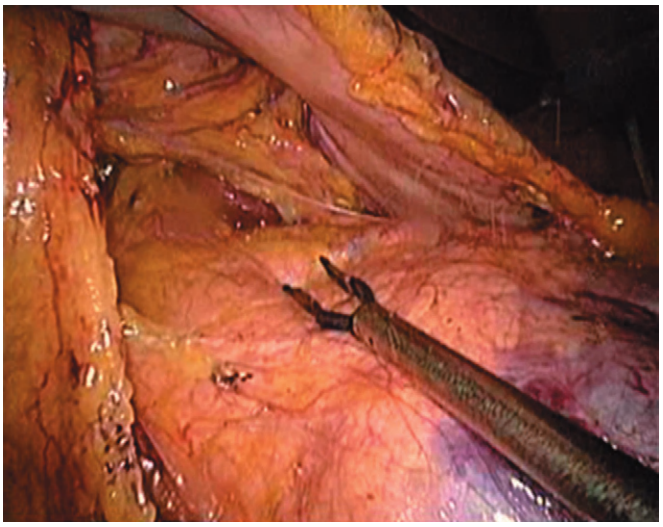

FIGURE 62B.1. Division of the gastrocolic ligament and entry into the lesser sac allows visualization of the body of the pancreas. *(Courtesy Dr. Bryce Gayet.)*

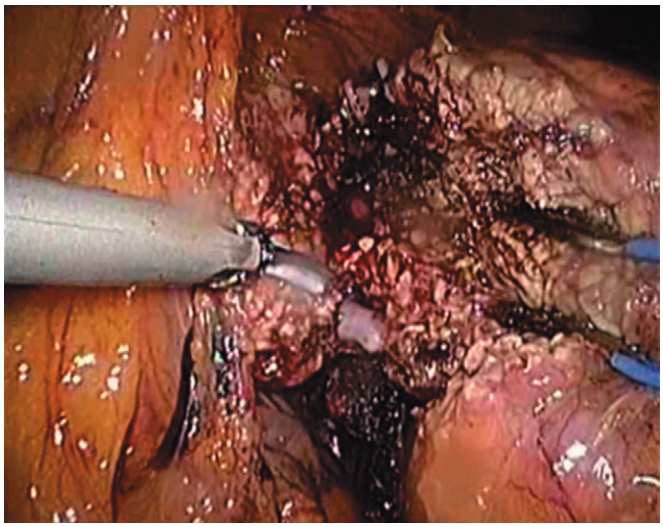

FIGURE 62B.3. Dissection of the splenic vein. In this view, the pancreas has already been divided. *(Courtesy Dr. Bryce Gayet.)*

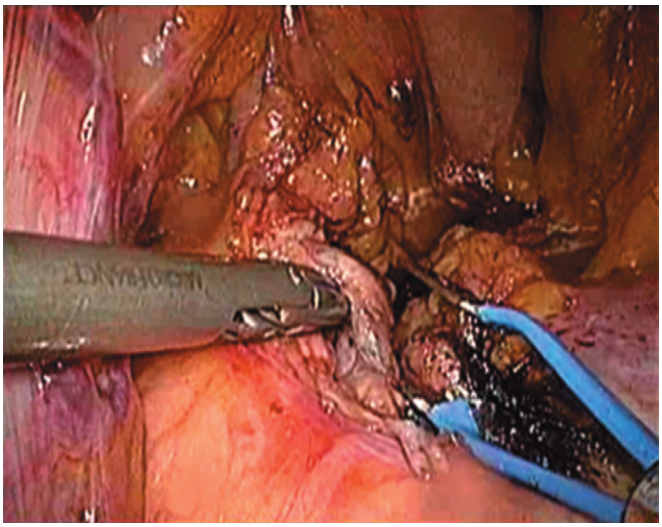

FIGURE 62B.4. The splenic artery is identified above the pancreas and is dissected in preparation for division. *(Courtesy Dr. Bryce Gayet.)*

Next, the tail of the pancreas is grasped and retracted anteriorly. Traction is applied to expose the small branches of the splenic artery and vein, which are coagulated with the LigaSure device (Covidien, Mansfield, MA). The vascular area connecting the end of the tail of the pancreas and the spleen is transected. The left pancreas is then lifted up and mobilized posteriorly with the splenic artery and vein, which are clipped and divided or transected with an Endo-GIA stapler (Covidien) as they emerge from the pancreatic tail to enter the hilum of the spleen (Fernandez-Cruz, 2006). At the end, the pancreas is transected with an endoscopic linear stapler when the pancreas is soft and not too thick. Alternatively, the pancreas may be cut with scissors or with a LigaSure, with a separate suture applied directly to pancreatic duct.

Outcome of Laparoscopic Pancreatic Left Resection

It has been convincingly shown that laparoscopic distal pancreatectomy is feasible with short- and long-term outcomes similar to open distal pancreatectomy (Kooby et al, 2010). Table 62B.1 gives an overview of recent series of more than 50 laparoscopic left pancreatic resections. In experienced hands, the laparoscopic approach has been associated with shorter operating times, early return of bowel function, minimal narcotic requirements, and early resumption of normal activities (Fernandez-Cruz et al, 2002). Sufficient experience and data confirm that laparoscopic distal pancreatectomy can be recommended as the treatment of choice for benign and noninvasive lesions in experienced hands when clinically indicated (Rosok et al, 2010); however, it is difficult to make a clear statement concerning malignant pancreatic tumors because of the lack of conclusive data (Merchant et al, 2009). An important problem leading to conversion in many studies has been the difficulty in localizing small tumors by laparoscopy or laparoscopic US.

Tumor Enucleation

Surgery is the only potentially curative treatment for pancreatic endocrine tumors amenable to resection. With the exception of gastrinomas and somatostatinomas, which are frequently localized in the head of the pancreas, neuroendocrine tumors are located predominantly in the body and tail of the pancreas. This location makes these tumors suitable for a laparoscopic surgical approach. In many cases, especially in sporadic insulinomas and if tumor size does not exceed 2 cm, laparoscopic enucleation can be performed safely (Bozbora et al, 2004). Other functioning and nonfunctioning neuroendocrine tumors should be managed with extended pancreatic resection, including peripancreatic lymph node dissection, because the malignant potential must be considered. In preoperative examination, a combination of dynamic CT and selected angiography leads to a correct diagnosis in 70% to 90% of patients (Cuschieri et al, 1996). Tumors located in the pancreatic body and tail, distant from the splenic vessels and the main pancreatic duct, are good

Table 62B.1

Published Series of More than 50 Cases of Distal Pancreatectomy

candidates for laparoscopic enucleation if no findings of malignancy are detected on preoperative staging (Tihanyi et al, 1997).

Surgical Technique

The position of the patient and the trocar sites are the same as for distal pancreatectomy. Intraoperative US is required to confirm the location of the tumor and the absence of other lesions. If the tumor is located close to the splenic vessels, the main pancreatic duct, or the bile duct, enucleation should be abandoned in favor of a formal resection (Kano et al, 2002). For dissection of the tumor from the pancreatic parenchyma, some surgeons prefer the use of a Harmonic Scalpel (Ethicon, Somerville, NJ) or Ligasure. Because enucleations have a high risk of postoperative fistula, mainly type A fistula, a drain should be placed adjacent to the side of the enucleation.

Pancreatoduodenectomy (See Chapter 62A)

Although the first successful pancreatoduodenectomies were performed in 1912 and 1934 by Walter Kausch and Allan Whipple, respectively, the first attempt at laparoscopic pylorus-preserving pancreatoduodenectomy (PPPD) has been credited to Gagner and Pomp (1994). Today, a number of laparoscopic pancreatoduodenectomies or Whipple procedures have been performed in different centers with reasonable outcomes; therefore, no doubt remains that the Whipple procedure can be performed by laparoscopy.

Surgical Technique

The laparoscopic technique for a Whipple procedure represents a modification of the Traverso and Longmire (1978) description of the PPPD. Under general anesthesia, the patient is placed in a supine position with the legs abducted. An endoscope is inserted over a trocar at the umbilicus to examine the peritoneal cavity, liver, stomach, and mesentery vessels, and four to six more trocars are inserted under direct vision in the epigastrium and upper quadrants. The surgical dissection is performed with the usual laparoscopic devices: Harmonic Scalpel, LigaSure, bipolar cautery, and clips.

The main difficulty of the resection phase is the complete lymphadenectomy, especially along the celiac trunk and superior mesenteric artery. The major difficulty with the operation, however, is the reconstruction. The pancreatojejunostomy or pancreatogastrostomy are the most problematic anastomoses, even in the conventional open technique. The soft pancreas with a small duct is especially problematic because the haptic feedback during the anastomosis is missing in laparoscopic surgery. Thus some surgeons use a hybrid technique with a small abdominal incision for the reconstruction.

A positive correlation has been shown between postoperative mortality and morbidity and the experience of a surgeon and volume of a center (Birkmeyer et al, 2002). This is probably also true for the laparoscopic pancreatic resection; however, larger series that investigate this relationship have yet to be undertaken.

Outcome of Laparoscopic Pancreatoduodenectomy

The first laparoscopic PPPD was performed in 1992 and took at least 10 hours, even for a highly skilled endoscopic surgeon (Gagner & Pomp, 1994). The patient's postoperative course was complicated by delayed gastric emptying, resulting in a 30-day hospitalization. Cuschieri (1994) also reported two cases of PPPD with disappointing postoperative outcomes, including pancreatic fistula and delayed gastric emptying. Nevertheless, several centers with expert surgeons continued to perform this complicated procedure, and between 1994 and 2008, a total of 146 laparoscopic Whipple procedures were reported in scientific literature.

Reviewing the existing literature, Gagner and Palermo (2009) have shown that this complex surgical procedure can be performed laparoscopically with acceptable complication rates in selected patients. In the series described, the mean operating time was 439 minutes, average blood loss was 143 mL, and median hospital stay was 18 days. Postoperative complications included 2 hemorrhages, 4 bowel obstructions, 1 stress ulcer, 1 delay of gastric emptying, 4 pneumonias, and 11 leaks. Although laparoscopic pancreatoduodenectomy and laparoscopic duodenum-preserving pancreatic head resection are technically feasible, laparoscopic reconstruction after proximal pancreatectomy is not yet generally practiced because performance is limited to highly skilled endoscopic surgeons. To justify the performance of laparoscopic proximal pancreatectomy, it is mandatory to demonstrate the potential clinical benefits and safety of such a complicated procedure (Takaori & Tanigawa, 2007). Furthermore, in patients with pancreatic cancer, it yet has to be validated whether radical lymph node dissection is feasible in the same manner and extent as open surgery.

LAPAROSCOPIC PALLIATIVE PROCEDURES FOR PANCREATIC CANCER (SEE CHAPTER 63B)

Currently, endoscopic biliary stenting is the most widely performed procedure for palliation in patients with malignant biliary obstruction as a result of pancreatic cancer. However, patients with endobiliary prostheses who survive for a long time have a significant risk of stent obstruction. In patients expected to have a prolonged survival, laparoscopic biliary decompression can be performed and is a reasonable consideration. The main types of surgical palliation of malignant biliary obstruction are choledochoenterostomy and cholecystoenterostomy. With regard to outcomes and complications, choledochoenterostomy has been shown to be better than cholecystoenterostomy (Sarfeh et al, 1988). Although both procedures have been described to be feasible laparoscopically, the cholecystoenterostomy is technically easier to perform (Sussman et al, 1996). Nevertheless, because cholecystoenterostomy would never be used in conventional open surgery, this compromise should not be accepted in laparoscopic surgery either, and an inferior operation should not be performed only because it is easier.

In patients with locally advanced and inoperable pancreatic cancer, whether associated with gastric outlet obstruction or not, a retrocolic gastrojejunostomy should be added to a biliary bypass. Today, gastroenterostomy can be performed laparoscopically with acceptable outcomes (Rhodes et al, 1995). Where it is not feasible or meaningful to perform a gastroenterostomy because of extensive peritoneal disease, particularly that involving the bowel in the lower abdomen, a palliative stoma must be considered to ensure gastrointestinal patency. It has been reported that a palliative stoma done laparoscopically has significantly better outcomes in terms of postoperative morbidity and mortality compared with the open surgical procedure

(Scheidbach et al, 2009). However, laparoscopic palliation of locally advanced pancreatic cancer always demands a high level of technical expertise and should be limited to performance by experts in specialized centers (Gentileschi et al, 2002).

ROBOTIC APPROACHES FOR PANCREATIC RESECTIONS

Recently, it has been reported that laparoscopic pancreatic surgery can be performed with robotic assistance. A single-center study analyzed the charts of 134 patients who underwent robotic-assisted surgery for different pancreatic pathologies with the DaVinci system (Intuitive Surgical, Sunnyvale, CA) (Giulianotti et al, 2010). The authors showed that complication and mortality rates were comparable to those of open surgery but with the advantages of minimally invasive surgery. In another series of 17 robotic-assisted distal pancreatectomies, a shorter length of stay in robotic versus laparoscopic or open approaches has been reported. Furthermore, in this study, spleen preservation rates improved with a robotic approach at the expense of increased operative time. The authors conclude that robotic distal pancreatectomy is safe and cost effective in selected cases (Waters et al, 2010), although the indication for robotic surgery in pancreatic disease has been controversial, particularly considering the cost of robotic procedures compared with laparoscopic resection. Further experience and randomized clinical trials are clearly needed to evaluate the benefit of this surgical approach. In addition, the cost-benefit comparison needs to be assessed for this expensive method.

CHAPTER 63A

Chemotherapy and radiotherapy for pancreatic and periampullary cancer: adjuvant, neoadjuvant, and palliative

Christopher M. Halloran, Paula Ghaneh, and John P. Neoptolemos

ADJUVANT CHEMORADIOTHERAPY

Early studies examining the role of combined external-beam radiotherapy (EBRT) with 5-fluorouracil (5-FU) as a radiosensitizing agent in advanced, unresectable pancreatic adenocarcinoma showed an increased median survival over that of solo EBRT (Douglas et al, 1979; Moertel et al, 1981). Subsequently, combination chemoradiotherapy (CRT) was used in patients who had undergone potentially curative resection for pancreatic adenocarcinoma. The Gastrointestinal Tumor Study Group trial 9173 (Kalser & Ellenberg, 1985) randomized 43 patients to either CRT (40-Gy EBRT, combined with 5-FU and follow-on 5-FU) or no adjuvant treatment after potentially curative pancreatic resection; recruitment was slow and only 43 patients were enrolled after 8 years instead of the intended 150. Median, 2-year, and 5-year survival rates were all increased in the treatment group (Table 63A.1). This trial had several problems, chief among them being poor compliance and inadequate quality assurance, with only 9% of patients completing the intended 2 years of chemotherapy; 32% had violations of the radiation therapy. To increase numbers, another 30 patients were entered into the treatment group without randomization (Douglas et al, 1987). Several subsequent studies have all shown similar advantages (Conlon et al, 1996; Neoptolemos et al, 1998; Yeo et al, 1998), although all were underpowered.

Two studies, however, have countered these results. Bakkevold and colleagues (1993) prospectively randomized 61 patients who had undergone radical pancreatic resections (including 14 patients with periampullary lesions) to adjuvant combination chemotherapy with 5-FU, adriamycin, and mitomycin-C versus observation; no postoperative EBRT was used. Although the median survival and 2-year survival were increased in the treatment groups, the overall long-term cure rate was unaffected (see Table 63A.1).

Later, on behalf of the European Organisation for Research and Treatment of Cancer (EORTC), Klinkenbijl and colleagues (1999) randomized 218 patients following potentially curative resection for pancreatic cancer to CRT (40-Gy EBRT and 5-FU, no follow-on 5-FU) or no adjuvant treatment. This included 114 patients with pancreatic head cancer and 93 with periampullary cancer. Of the patients with pancreatic head cancers, no significant increase in median survival was found between the two groups (see Table 63A.1).

These early studies set the scene for the European Study Group for Pancreatic Cancer (ESPAC) to conduct a randomized trial of adjuvant chemotherapy and chemoradiotherapy in resected pancreatic cancer. The design was as a 2×2 factorial trial in which patients were randomized twice to either chemotherapy (bolus 5-FU for six cycles) or no chemotherapy *or* to chemoradiation (fractionated 20-Gy EBRT plus an intravenous bolus of 5-FU) or no chemoradiation. This totaled 549 patients from 61 cancer centers in 11 countries, thus making it, at the time, the largest adjuvant therapy trial in pancreatic cancer ever completed. A total of 289 patients were randomized into the 2×2 factorial design, and 261 additional patients were randomized to either chemotherapy or chemoradiation versus observation outside the original design (ESPAC-1 plus).

ESPAC-1 has been criticized largely because of confusion over the 2×2 trial design; nonetheless, data from both patient datasets are relevant (Neoptolemos et al, 2001, 2004) and are suggestive of the benefit of chemotherapy (Table 63A.2 and Fig. 63A.1), evident in resection margin–positive (R1) as well as resection margin–negative (R0) patients. Two subsequent meta-analyses have confirmed this advantage, suggesting a reduction in risk of death in postresection pancreatic cancers of 25% (hazard ratio [HR], 0.75; 95% confidence interval [CI], 0.64 to 0.90; $P = .001$) (Stocken et al, 2005) and an advantage of postresectional chemotherapy in patients with an R0 margin over those with an R1 margin (Butturini et al, 2008). Moreover, the reported that survival advantage for adjuvant chemotherapy was maintained when adjusted for quality of life over the 24-month period after resection (Carter et al, 2009).

Since the usurpation of 5-FU as the gold standard of chemotherapy for pancreas cancer, current focus has centered on the use of gemcitabine as a radiosensitizer and also on the use of biologic agents. The Radiation Therapy Oncology Group (RTOG) (Regine et al, 2006) conducted a Phase III trial, study 9704, of 538 patients (443 analyzed, with 388 having cancer in the head of the pancreas) based on chemoradiation (50.4-Gy EBRT with 5-FU) combined with either 5-FU or gemcitabine, 3 weeks before CRT and 12 weeks after. Although both the median and 3-year survival rates were increased in the group receiving gemcitabine, these increases were not significant. Analysis of the 388 patients with pancreatic head cancer suggested a 21% reduction in risk of death in the gemcitabine arm (HR, 0.79; 95% CI, 0.63 to 0.99; $P = .047$). Although this was

suggestive of the advantage of gemcitabine, a greater proportion of T3 tumors and higher toxicity were reported in this arm. In response, the EORTC 40013 Phase III trial plans to randomize 538 patients after R0 pancreatic resection to either gemcitabine or two cycles of gemcitabine followed by CRT (gemcitabine and 50.4-Gy EBRT).

A phase III trial of postoperative cisplatin, interferon alpha-2b, and 5-FU combined with external radiation treatment versus 5-FU alone for patients with resected pancreatic adenocarcinoma randomized 110 patients after pancreatectomy to either 5-FU, cisplatin, interferon-$\alpha_2\beta$, and EBRT (50.4 Gy) with two follow-on cycles of 5-FU post-CRT (arm A) or 5-FU/folinic acid (arm B). Median overall survival of patients treated in arm A was 32.1 months (95% confidence interval [CI], 22.8 to 42.2) compared with 28.5 months (95% CI, 19.5 to 38.6) for arm B. Unfortunately, this underpowered trial was not able to address satisfactorily the significance of adjuvant chemoradiation plus interferon. Further trials are required to confirm these effects.

Finally, RTOG0848 is opening a Phase III trial, recruiting 950 patients with resected adenocarcinoma of the pancreas, including intraductal papillary mucinous neoplasms (IPMNs), to either five cycles of gemcitabine or five cycles of gemcitabine with erlotinib. Patients with no progression will receive either one further cycle of chemotherapy or one cycle of chemotherapy followed by EBRT plus either 5-FU or capecitabine.

Overall, the use of chemoradiation remains controversial, but many U.S. centers continue to support adjuvant chemoradiotherapy as standard treatment (Twombly, 2008).

ADJUVANT CHEMOTHERAPY

ESPAC-1 has provided the clearest evidence to date that adjuvant chemotherapy is advantageous (see Table 63A.2) when based on regimens of biomodulated 5-FU. The advance made by ESPAC-1 has driven forward the next generation of adjuvant chemotherapy trials, notably ESPAC-3 (v2) and ESPAC-4 in addition to translational run-offs (ESPAC-T plus and ESPAC-4T).

Evidence that emerged during the 1990s showed the usefulness of gemcitabine in pancreatic cancer, initially in the setting of advanced disease (Berlin et al, 2002; Burris et al, 1997; Carmichael et al, 1996; Casper et al, 1994; Hertel et al, 1990; Huang et al, 1991; Rothenberg et al, 1996). Recently, a large, multicenter, Phase III randomized trial of 386 patients was undertaken to determine the influence of adjuvant gemcitabine

versus observation following resection of pancreatic cancer on disease-free survival (CONKO-001) (Oettle et al, 2007; Neuhaus et al, 2008). Median disease-free survival for the gemcitabine group was 13.4 months compared with 6.9 months for the observation arm ($P < .001$); these data are summarized in Table 63A.3. The estimated disease-free survival at 3 and 5 years was 23.5% and 16.5% in the gemcitabine group versus 7.5% and 5.5% in the observation group, respectively. In addition, a significant improvement in median overall survival of 24.2 months was reported with gemcitabine compared with observation alone (20.5 months; $P = .02$). Estimated overall survival at 3 and 5 years was 34% and 22.5% for gemcitabine patients versus 20.5% and 11.5% for observation patients, respectively. These results were suggestive of prolonged disease-free survival in patients undergoing R0 or R1 resection for pancreatic cancer. These earlier studies formed the basis for the ESPAC-3 study.

ESPAC-3 initially was designed with three arms: six cycles of 5-FU versus six cycles of gemcitabine versus observation, with a recruitment target of 330 patients. With the publication of the ESPAC-1 results, a definite survival advantage for adjuvant chemotherapy after resection of pancreatic ductal adenocarcinoma was apparent over observation alone; the trial design was therefore amended, with the observation arm being dropped. The recruitment targets for the remaining two arms were increased to 515 patients each for a total of 1030 patients with pancreatic ducal adenocarcinoma, and the trial was renamed ESPAC-3 (v2). ESPAC-1 had been underpowered to determine the role of adjuvant therapy in less common malignancies such as bile duct cancers and ampullary tumors; therefore the observation arm of ESPAC-3 was continued for these patients. The trial closed after having recruited 1583 patients, with 1088 having ductal adenocarcinoma. Overall, no difference was

found between 5-FU/FA and gemcitabine by treatment ($P = .39$), treatment effect by R status ($P = .56$), or by progression-free survival ($P = .44$). However, significant advantages were found from the use of gemcitabine, notably its significantly reduced side effects and toxicity profiles (Neoptolemos et al, 2009a, 2009b); thus the current recommendation for adjuvant chemotherapy in pancreatic ductal adenocarcinoma is gemcitabine (see Table 63A.3).

Currently, interest lies in the use of capecitabine, a prodrug for 5-FU. It is sequentially metabolized into active 5-FU by enzymes highly expressed in both liver and tumor, notably the last enzyme in this cascade, thymidine phosphorylase. This has four potential advantages: 1) systemic side effects are reduced, 2) high concentrations are achieved in the vicinity of the tumor, 3) oral capecitabine has a pharmacokinetic profile similar to that of a continuous systemic infusion 5-FU, and 4) patients tolerate it better than 5-FU. Unfortunately, the effects of solo capecitabine seem minimal: clinical response in 24% and tumor response in 7% (Cartwright et al, 2002). Better responses have been observed when capecitabine and gemcitabine were combined. Eighty-three patients were randomized to either biweekly gemcitabine or biweekly gemcitabine and daily oral capecitabine for a duration of 6 months (Scheithauer et al, 2003). Although no increase was seen in median survival, a 33% increase in clinical benefit response was reported in the combination group.

This effect will be explored in the forthcoming ESPAC-4 study, which aims to recruit 1080 patients who have undergone curative resection for pancreatic ductal adenocarcinoma within the previous 12 weeks. Randomization will be either to six cycles of gemcitabine or to six cycles of gemcitabine plus 24 weeks of capecitabine. The primary end point is length of survival with secondary end points of toxicity, quality of life, 2-year survival, 5-year survival, and relapse-free survival.

The effects of combining chemotherapeutic agents are measured against the solo effects of the current gold standard drugs. Bakkevold and colleagues (1993) randomized patients who had undergone pancreatic resection to FAM (5-FU, adriamycin, and mitomycin-C) or observation. Although a significant increase was reported in median survival (23 vs. 11 months; $P = .04$), no increase in 3- or 5-year survivals was reported. Excessive toxicity was noted, and only 56% of the treatment group completed the six courses of chemotherapy (see Table 63A.3). Takada and colleagues (2003) enrolled 508 patients with mixed pancreatobiliary cancers (173 with pancreatic cancer) and randomized them to either surgery alone or surgery with combined mitomycin-C and 5-FU. The 5-year survival rates were 18 months and 11.5 months, respectively. Of note was the use of oral 5-FU, which has lower efficacy as a result of first-pass hepatic metabolism when compared with intravenous administration.

Kosuge and colleagues (2006) undertook a multicenter, randomized trial of surgery versus surgery and combination cisplatin and 5-FU. They concluded that although cisplatin and 5-FU were safe and well tolerated, the combination conferred no clear survival benefit over monotherapy (see Table 63A.3). As yet, no convincing evidence shows any benefit of combination chemotherapy over standard monotherapy based on either or both of these agents (Magee et al, 2002), and good evidence shows increased severity of side effects in combined regimens (Ghaneh et al, 1999).

INTRAOPERATIVE RADIOTHERAPY

The effect of EBRT on the pancreatic bed is limited by the immediacy of radiosensitive structures; the use of intraoperative radiotherapy (IORT) should reduce this effect. Studies that have explored IORT are small and have heterogenous populations, such that conclusions are hard to reach (Coquard et al, 1997; Fossati et al, 1995; Hiraoka et al, 1990; Reni et al, 2001; Shibamoto et al, 1996; Showalter et al, 2009; Zerbi et al, 1994). RTOG gave 20 Gy of IORT with EBRT (a total of 50.4 Gy) to 51 patients with advanced pancreatic cancer. Results showed a disappointing median survival of 9 months (Tepper et al, 1991). Sindelar and Kinsella (1986) similarly showed a median survival of only 12 months in patients treated with surgery or surgery and IORT. There are reports (Valentini et al, 2009), however, of long-term control and survival in operated patients receiving IORT, although such data are contaminated, with 24% of patients receiving preoperative and postoperative EBRT. Nonetheless, preoperative chemotherapy with surgery and

Magnin et al, 2003	30- to 45-Gy EBRT 5-FU, cisplatin	32	19	19		30	59% at 2 years; 2-year DFS, 43.7%
Mornex et al, 2006	50-Gy EBRT, 5-FU, cisplatin	41	36	26	80% R0	9.4	20% at 2 years
Le Scodan et al, 2009	5-FU, cisplatin, 50-Gy EBRT	41	27	26	80% R0	9.4	22% at 2 years

nCRT, neoadjuvant chemoradiotherapy; ERBT, external-beam radiation therapy; R/LN, resection margin/lymph node positivity; R0, negative resection margin; R1, positive resection margin; LN–, no metastatic tumor in lymph nodes; 5-FU, 5-fluorouracil; FA, folinic acid; PR, potentially resectable; LA, locally advanced; IORT, intraoperative radiotherapy; DFS, disease-free survival

IORT gave a 5-year local control of 23.3%, although IORT is unlikely to become mainstream treatment outside specialized centers undertaking this modality because of the limited number of appropriate patients.

NEOADJUVANT CHEMORADIOTHERAPY, CHEMOTHERAPY, AND BIOLOGIC TREATMENT

Broadly speaking, medical treatments are either directed at known borderline resectable disease, with the aim of downsizing a tumor in contact with or encasing vascular structures, or to patients with staged resectable disease. The presumption of both is acceptance of the rationale for neoadjuvant chemoradiotherapy (nCRT). Early studies implied the advantage of CRT in advanced pancreatic cancer (Moertel et al, 1969, 1981), hence the extrapolation to neoadjuvant regimens. These can be categorized into studies using 5-FU (Table 63A.4) or gemcitabine (Table 63A.5) as the radiosensitizing agent.

Overall, great heterogeneity exists between studies, with mixing of preoperative and postoperative chemoradiation, lack of standardized regimens, and in some cases poor outcome data. However, a few points are worthy of discussion. First, the majority of these studies are from the United States and use multimodal therapy, which is less common in Europe. Patients are restaged after nCRT; hence, a prognostically better subgroup is the result. In addition, current histologic assessment would change the assessments of R0 resection in some of these studies. Of those receiving nCRT, the rate of tumor resection is less than 60% for those receiving 5-FU–based treatment, but it is up to 85% in those receiving gemcitabine-based therapy. Gemcitabine-based neoadjuvant therapy would appear safe and is likely to be the emerging central agent in these modalities. The addition of biologic agents would appear counterintuitive at the moment, but the literature base is currently lacking. Hence this field is in need of powered trials. A randomized, multicenter study (ESPAC-5) is being planned.

PALLIATIVE CHEMOTHERAPY

Until the landmark study by Burris and colleagues (1997), 5-FU had been considered the gold standard of palliative chemotherapy despite its poor response rates, but gemcitabine has subsequently been shown to be more beneficial than 5-FU when used as monotherapy in advanced pancreatic cancer (Carmichael et al, 1996; Casper et al, 1994; Hertel et al, 1990; Huang et al, 1991). Better response rates, longer median and 1-year survival, and enhanced clinical benefit response were achieved. The cornerstone study exploring these advantages (Burris et al, 1997) randomized patients with advanced pancreatic cancer to receive either 5-FU or gemcitabine. Those

receiving gemcitabine had a modest but significant increase in median survival (5.56 vs. 4.41 months; $P = .0025$) and improved clinical benefit (23.8% vs. 4.8%; $P = .0022$). A follow-on study by the same group showed advantage for patients with advanced pancreatic cancer previously treated with 5-FU in whom there had been disease progression. The patients were subsequently given gemcitabine (Rothenberg et al, 1996), and a 27% clinical benefit response was achieved for a median of 14 weeks, with an overall median survival of 3.85 months. The Eastern Cooperative Oncology Group randomized 322 patients with advanced pancreatic cancer to receive solo gemcitabine or gemcitabine followed by 5-FU (Berlin et al, 2002). This regimen achieved a nonsignificant rise in median survival, although it did show a significantly improved progression-free survival for gemcitabine plus 5-FU ($P = .022$).

Overall, combining 5-FU with gemcitabine has little to offer over monotherapy with gemcitabine (Berlin et al, 2002; Crown et al, 1991; DeCaprio et al, 1991; Di Costanzo et al, 2005; Hansen et al, 1988; Maisey et al, 2002; Riess et al, 2005). Alternately, combining gemcitabine with platinum compounds has a better overall response rate and to some extent better median and progression-free survival (Alberts et al, 2003; Cascinu et al, 2003; Colucci et al, 2002; Heinemann et al, 2000, 2006; Philip et al, 2001; Poplin et al, 2006); however, it is associated with more toxicity side effects. The same is true for most other cytotoxic agents.

Combination of gemcitabine with capecitabine has shown promise in Phase II (Scheithauer et al, 2003) and Phase III (Herrmann et al, 2007) trials. The largest Phase III trial to date (Cunningham et al, 2009) has recently reported and is summarized in Table 63A.6. In this study, 533 patients were randomized to either gemcitabine (G) or gemcitabine and capecitabine (GC). Those receiving GC had significantly better objective response rates (19.1% GC vs. 12.4 G; $P = 0.034$) and progression-free survival (HR, 0.78; 95% CI, 0.66 to 0.93). Although not reaching significance, a trend toward increased overall survival was reported for GC. Median survival and 1-year survival for GC and G were 7.1 months versus 6.2 months and 24.3% versus 22%, respectively. This study also includes a meta-analysis of this report and directly comparable Phase II and III trials (Herrmann et al, 2007; Scheithauer et al, 2003), all of which show a significant survival benefit from gemcitabine combined with capecitabine (HR, 0.86; 95% CI 0.75 to 0.98; $P = .02$). The initial excitement regarding combining gemcitabine with biologic agents—such as erlotinib, an epidermal growth-factor receptor tyrosine kinase inhibitor, or bevacizumab, monoclonal antibody to vascular endothelial growth factor A—have not shown the expected promise in recent phase III trials and appear no better than combination gemcitabine and capeciabine (see Table 63A.6).

Several other Phase III trials of novel agents are in progress or have recently closed, notably TeloVac, RC-57, and IPC-BAYPAN. Also under development is the VIP study, a Phase II, randomized, multicenter trial comparing gemcitabine and vandetanib with solo gemcitabine in advanced pancreatic cancer.

It is vital to remember that patients with advanced pancreatic cancer are looking for improvement in quality of life, which should not be sacrificed for modest increases in survival.

PALLIATIVE RADIOTHERAPY

Much of the poor reputation of palliative radiotherapy may be unjustified in the modern era. This is because of a recent dramatic shift in radiotherapy delivery techniques from fractional or low doses (e.g., 2 Gy over 6 weeks with a radiation holiday of 2 weeks in the middle) to a continuous-course fraction with a higher overall dose (e.g., 50.4 Gy compared with 40 Gy in fractionated low-dose EBRT). This has the advantage of faster completion of treatment and better overall local control (Lim et al, 2003; Regine et al, 2006). Radiation field size has decreased with the use of intensity-modulated radiation therapy (IMRT), in which smaller fields are targeted by "pencil" beams to reduce the traditional scatter effect to surrounding tissues (Bai et al, 2003; Ben-Josef et al, 2004; Crane et al, 2001; Landry et al, 2002; Milano et al, 2004). This has the added advantage of potentially reducing side effects of combination agents.

Stereotactic radiotherapy (CyberKnife; Accuray, Sunnyvale, CA) uses focused radiotherapy with controlled organ movement via implanted metallic markers. Unfortunately, both Phase I (25 Gy, 15 patients) (Koong et al, 2004) and Phase II trials (45-Gy IMRT with a 25 Gy stereotactic boost, 19 patients) (Koong et al, 2005) have failed to show any great effect, with median survivals of 11 and 7.6 months, respectively. Median time to progression with sole 25-Gy stereotactic radiation was 2 months. Despite the lack of evidence for this technique, which involves a specialized setup, it is gaining some popularity as a result of recent high-profile cases.

PALLIATIVE CHEMORADIOTHERAPY

Palliative radiotherapy has been used in conjunction with chemotherapeutic agents, mainly 5-FU, which allows radiosensitization of tissues. Early work by Moertel and colleagues (1969) suggested a survival advantage for those patients given CRT (35 to 40-Gy EBRT + 5-FU) over those given only EBRT (35 to 40 Gy), with a median survival of 10.4 versus 6.3 months and a 1-year survival of 22% versus 6.3%, respectively. Several small, historic trials have addressed the role of 5-FU and EBRT and show median survival times of 10 to 15 months (Gunderson et al, 1987; Haycox et al, 1998; Ikeda et al, 2001), although these studies may be subject to patient selection bias. The larger GITSG trial (Moertel et al, 1981) randomized 194 patients with advanced pancreatic cancer to either ERBT (60 Gy), ERBT + 5-FU (40 Gy), or EBRT + 5-FU (60 Gy). Concomitant EBRT with 5-FU increased median survival from 23 to 42 weeks. Unfortunately, none of these trials had a control arm. A smaller, follow-on GITSG trial (1988) of 48 advanced pancreatic cancer patients randomized to either 5-FU plus 54-Gy EBRT with follow-on ***s***treptozotocin, ***m***itomycin-C, and 5-***F***U (SMF) versus SMF only. The combination regimen was seen to increase median survival from 32 weeks in the SMF group to 42 weeks in the combination SMF group.

Contrary to this, the Eastern Cooperative Oncology Group (Klaassen et al, 1985) randomized 91 patients to either 5-FU plus 40-Gy EBRT versus 5-FU alone and found no difference in survival in either arm. At present, there seems to be little difference between chemotherapy based on 5-FU and the radiosensitizer EBRT in the treatment of advanced pancreatic cancer (Haycox et al, 1998). A recent multicenter, randomized, Phase II trial by Wilkowski and colleagues (2009) failed to elicit any advantage of CRT regimens. In this trial, 95 patients were randomized to either 5-FU with 50-Gy EBRT (RT–5-FU arm); gemcitabine and cisplatin with 50-Gy EBRT (RT-GC arm), or gemcitabine and cisplatin with 50-Gy EBRT with follow-on gemcitabine and cisplatin (RT-GC + GC arm). Median survivals of 9.6, 9.3, and 7.3 months for RT–5-FU, RT-GC, and RT-GC + GC, respectively, with corresponding progression-free survival at 4, 5.6, and 6 months. The authors conclude that such CRT is no better than solo gemcitabine.

Overall, despite the success of gemcitabine in the adjuvant setting, there would appear to be significant side effects, especially in terms of toxicity, when combined with radiotherapy. As yet there is no clear way forward, but palliative CRT seems to have few advantages over solo chemotherapy for advanced, unresectable pancreatic carcinoma.

PART 7: Hepatic Disease

SECTION I
Inflammatory, Infective, and Congenital

A. Hepatitis

CHAPTER 64

Chronic hepatitis: epidemiology, clinical features, and management

Christopher D. Anderson and Jeffrey S. Crippin

OVERVIEW

Surgery in the patient with chronic hepatitis can create multiple dilemmas in the preoperative, perioperative, and postoperative phases. Preoperatively, assessment of the stability of the patient's liver disease can be crucial in decisions regarding a surgical procedure. Intraoperatively, both technical and anesthesiology considerations will potentially affect the outcome. Postoperative care involves strategies to prevent or treat acute hepatic decompensation, bleeding, and infection. This chapter covers the chronic hepatitides and addresses, the issues facing the hepatologist and hepatobiliary surgeon.

CHRONIC HEPATITIS

Hepatitis, in general, means liver inflammation. Most associate the term with a viral infection; however, a number of different processes and agents can lead to an inflamed liver. Other than viral infections, other relatively common causes of hepatitis include alcohol, hepatotoxins (including medicines), autoimmune disorders, and fat (i.e., steatosis). The other important definition, for purposes of this discussion, is *chronic* versus *acute* hepatitis. Chronic hepatitis implies the presence of hepatic inflammation for longer than 6 months. Routinely, this is based on the presence of elevated transaminases: aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Although liver inflammation can certainly occur in the absence of transaminasemia, establishing the diagnosis of chronic hepatitis depends on elevations of the AST and ALT for at least 6 months. Thus the finding of elevated transaminases during an evaluation of a potential patient for surgery should lead to a careful assessment because it pertains to the clinical issues at hand. However, the presence of a single set of elevated transaminases does not necessarily imply an acute or chronic process. For example, a patient with transaminases in the range of 1000 to 1500 IU/L in the face of a common bile duct gallstone causing obstruction is distinctly different from a patient with acute cholecystitis presenting with a history of transaminasemia in the range of three to four times the upper limit of normal and an ultrasound showing fatty infiltration of the liver. Thus the clinical setting and history for any particular patient is of crucial importance when evaluating a patient for hepatobiliary surgery. Having a basic working knowledge of each of the chronic hepatitides facilitates evaluation of the patient facing surgery.

Chronic Hepatitis C

Epidemiology

Hepatitis C is an RNA virus and a member of the family *Flaviviridae* and affects approximately 1.6% of the American population, with estimates at 3 to 4 million infected (Armstrong, 2006). Most commonly, the disease is transmitted by blood-to-blood to contact. Before the availability of the hepatitis C antibody test in the early 1990s, posttransfusion hepatitis C was a common means of contraction. However, the availability of reliable assays has led to a marked decrease in the incidence of posttransfusion hepatitis C (Alter, 1997). Currently, the risk of posttransfusion hepatitis C is approximately 1 in 2 million transfusions. The much more common means of contracting hepatitis C is by intravenous drug use. Other needle-stick exposures, such as with tattoos and occupational exposure, account for a much lower percentage of cases. Sexual transmission is likewise a low risk, particularly among monogamous partners. However, the prevalence of hepatitis C is much higher at

sexually transmitted disease clinics, affecting nearly 10% of nonintravenous drug–using patients (Thomas et al, 1994), presumably related to sexual promiscuity and/or traumatic sex, with increased risk of blood to blood exposure. Inhalation of cocaine has been raised as a potential risk factor, based on the transmission via blood on straws used to snort the inhaled agent (Hepburn & Lawitz, 2004). This risk factor has been questioned, with the issue that inhaled cocaine may be associated with other high-risk behaviors that are, in fact, the modes of transmission.

Presentation

Patients with chronic hepatitis C are frequently asymptomatic, although many have nonspecific symptoms, usually related to fatigue, myalgias, arthralgias, and/or right upper quadrant discomfort. Most patients are only diagnosed when they seek medical care for other reasons or with the above symptoms and are found to have mild elevations of the transaminases. However, up to 30% of patients will have normal transaminases at any one time because transaminase levels may wax and wane over time (Piton et al, 1998). Thus a history of any of the risk factors outlined above should lead to serologic testing to rule out hepatitis C.

Diagnosis

The standard screening study for hepatitis C is an enzyme-linked immunosorbent assay (ELISA) for antibody to hepatitis C. This is the standard test used by blood banks around the country; it has a sensitivity and specificity in high-risk populations ranging from 98% to 100% (Vrielink et al, 1995). If a patient has a known risk factor and elevated transaminase levels, a positive hepatitis C antibody study by ELISA is consistent with the diagnosis of hepatitis C. The presence of hepatitis viremia is checked with a reverse transcriptase polymerase chain reaction (PCR). Unfortunately, the PCR may take days to a week to get results, depending on the frequency of testing at the local lab. Patients can have a positive antibody study without viremia if the acute infection spontaneously resolved, an event that occurs 15% to 40% of the time (Herrine, 2002). Antibody positivity frequently persists indefinitely, but it does not imply infection if viremia is absent, based on an undetectable viral load by PCR. Patients will have one of six genotypes, variants in the hepatitis C genome that mainly reflect responsiveness to antiviral therapy (McHutchison et al, 1998). If screening for hepatitis C, and background on a patient being considered for surgery is all that is needed, a genotype need not be checked. However, if antiviral therapy is being considered, a genotype will provide important information regarding the chance of a virologic response and the length of therapy. Genotype 1 is the most common genotype in the United States, accounting for 70% of cases. Genotype 2 accounts for 15% of cases, and genotype 3 accounts for another 10% (McHutchison et al, 1998). Genotype 4 is occasionally seen in the United States, although it is more commonly seen in the Middle East and northern and central Africa. Genotypes 5 and 6 are seen in the United States, although rarely; prevalence of each is higher in South Africa and Southeast Asia, respectively.

Natural History

The course of hepatitis C is quite variable and can be influenced by a number of factors. Progression of the disease is routinely measured over decades. One commonly quoted figure is that 20% of those with the disease for at least 20 years will have cirrhosis. It is important to keep in mind that this implies that 80% of those with the disease for 20 years do not have cirrhosis. Another important consideration in determining the extent of the disease at the time of surgical evaluation is knowledge of when the disease was contracted. For example, if the patient knows he or she received a blood transfusion at the time of a motor vehicle accident 35 years ago, the patient has probably had the disease for 35 years. Likewise, a patient with an extensive history of intravenous drug use as a young adult has likely had the disease for several decades by the sixth or seventh decade of life. The disease takes an accelerated course in patients who ingest excessive amounts of alcohol (Wiley et al, 1998), contract the disease at a later age, and are coinfected with HIV or hepatitis B (Ragni & Belle, 2001; Tsai et al, 1996).

Treatment

Hepatitis C treatment is centered around the use of pegylated interferon and ribavirin. Routinely, the patient with chronic hepatitis C is started on therapy for one of several reasons; without question, the presence of hepatitis C viremia is the primary consideration for therapy, but careful consideration is also given to genotype, histologic changes, and potential relative and absolute contraindications. For example, patients with genotype 1 have a 45% to 50% chance of achieving a sustained virologic response, or "cure," if they can complete a course of therapy. However, the profound fatigue and flulike symptoms commonly associated with antiviral therapy often lead to a decision to delay therapy if histologic changes are mild. For example, if a patient has genotype 1 with a high viral load, the most common demographic in American patients, a liver biopsy showing low-grade inflammation and fibrosis often leads to a period of observation that often lasts for years, or until therapeutic breakthroughs occur. If additional comorbidities associated with a poor response are added to this scenario, such as obesity (Charlton et al, 2006) and/or insulin resistance (D'Souza et al, 2005), and the patient is African American (Jeffers et al, 2004), the potential for successful treatment can drop to 20% to 25%, usually leading clinicians to delay therapy until factors that can be modified are changed. In the face of a disease that potentially may not lead to cirrhosis for 20 to 30 years, if ever, the wisdom of such an approach becomes obvious. Genotype 2 and 3 patients, however, respond in the range of 70% to 80% of the time, routinely requiring only 24 weeks of therapy versus the 48 recommended for genotype 1 patients. This higher response rate can be affected by the same cofactors outlined above.

Absolute contraindications to antiviral therapy include anemia, neutropenia, and severe thrombocytopenia. Because of a type of hemolytic anemia that can be induced by ribavirin, patients with a baseline hemoglobin less than 10 to 12 g/dL must be carefully evaluated if treatment is considered. A 2- to 3-g drop of hemoglobin is expected in the face of ribavirin; thus severe anemia is possible if the baseline hemoglobin level is low. Although reduced doses of ribavirin can be given with the hope of minimizing the anemia, reduced doses also lead to lower response rates; thus most experienced clinicians avoid dose reductions and use erythropoietin to increase hemoglobin levels. Neutropenia and thrombocytopenia are due to pegylated interferon and may improve with dose reduction, although similar lower levels of response can be expected. Granulocyte colony-stimulating factor or filgrastim can maintain neutrophil

levels and obviate the need for dose reduction. Eltrombopag, a nonpeptide thrombopoietin receptor agonist, has been approved for patients with thrombocytopenia secondary to immune thrombocytopenic purpura and is under study for the treatment of thrombocytopenia secondary to pegylated interferon treatment. This will potentially allow thrombocytopenic patients to receive antiviral therapy.

Other potential contraindications to antiviral therapy include uncontrolled psychiatric illness, renal insufficiency, severe cardiopulmonary disease, and alcohol or substance abuse. Pegylated interferon and ribavirin can induce and exacerbate depression (Renault et al, 1987); thus recent suicidal ideation is an absolute contraindication to therapy. Well-controlled psychiatric disease can be successfully treated with careful follow-up. Renal insufficiency is a relative contraindication because of renal excretion of both interferon and ribavirin (Bino et al, 1982; Glue, 1999). The ribavirin dose must be decreased to avoid severe hemolytic anemia. Unfortunately, strict guidelines are not available, so dosing is often started at a low level, then increased based on patient tolerance. The anemia induced by ribavirin can exacerbate cardiac and pulmonary disease; these patients must therefore be carefully assessed before starting therapy. For example, a patient with congestive heart failure and a left ventricular ejection fraction of 40% may decompensate in the face of a drop in hemoglobin from 14 to 7 g/dL. Finally, patients with a history of alcohol or substance abuse are usually not treated until a period of abstinence can be maintained. Studies have shown a decreased response rate in patients with ongoing alcohol abuse (Pessione et al, 1998). Whether alcohol has a direct effect on drug pharmacokinetics and/or efficacy is unclear; however, the potential effect on compliance is obvious.

Once a patient is deemed an appropriate candidate for therapy, one of two pegylated interferon products is started: pegylated interferon alfa-2a at 180 μg subcutaneously weekly or pegylated interferon alfa-2b at 1.5 μg/kg/week. Although no head-to-head studies have been performed, the agents appear to be equivalent in efficacy and side effects, although clinicians usually have a personal preference. Ribavirin is dosed at 13 mg/kg/day, given orally in divided doses. Because of the myalgias, arthralgias, fever, chills, and sweats that frequently occur after administration of pegylated interferon, patients frequently take an over-the-counter analgesic before the injection. Fatigue and flulike symptoms are usually at their worst in the 24 to 48 hours following the pegylated interferon injection, with milder symptoms for the remainder of the week, until the next scheduled injection. That said, many patients are affected by these symptoms on a nearly daily basis, but others have minimal discomfort. Most patients can maintain their usual activities with only scattered absences. However, a small percentage of patients are nearly disabled, requiring frequent absences from their usual responsibilities. Discontinuation of therapy as a result of intolerable side effects occurs in 5% to 10% of treated cases.

On treatment, laboratory work is followed at least monthly and more often if needed. Thyroid function is assessed quarterly because of the potential for development of hypothyroidism or hyperthyroidism (Marcellin et al, 1992). The addition of growth factors for cytopenias is often clinician dependent. Most clinicians start supplemental erythropoietin with a hemoglobin level less than 10 g/dL, although many clinicians start erythropoietin if a patient has severe fatigue in the face of a drop in hemoglobin of 25% to 40% (e.g., from 18 to 11 g/dL). Absolute neutrophil counts less than 500 mm^3 usually lead to supplemental filgrastim, although many clinicians start filgrastim in response to an absolute neutrophil count of less than 1000 mm^3. Drops in hemoglobin, absolute neutrophil counts, and platelet counts may lead to dose reduction of pegylated interferon and/or ribavirin, although the current standard of care is to attempt to maintain patients on standard doses unless all other measures fail.

Viral loads are monitored at 4, 12, and 24 weeks of therapy (Ghany et al, 2009). An undetectable viral load after 4 weeks of therapy is associated with an 85% to 90% response rate, if the patient can complete the course of therapy, regardless of genotype (Ferenci et al, 2005). Thus a response at 4 weeks should lead to maximal efforts to maintain a patient at standard doses and a full course of therapy. An undetectable viral load observed at 12 weeks drops the rate of a sustained virologic response to 67% to 80% (Davis et al, 2003), whereas patients with a "late" response at week 24 only respond approximately 18% to 30% of the time (Berg et al, 2006; Pearlman et al, 2007). In patients with the first undetectable viral load at 24 weeks, recent studies suggest that extending therapy for an additional 24 weeks may improve the rate of response by 20%, although patient tolerance for this extended therapy is poor (Berg et al, 2006; Pearlman et al, 2007).

If undetectable viremia is achieved during therapy, viral load is routinely checked 3 to 6 months following the end of therapy. An undetectable viral load at that point is consistent with a sustained virologic response. Long-term studies have shown this response is durable, with undetectable viral loads persisting indefinitely (Desmond et al, 2006), unless the patient is reinfected. Patients who do not respond to antiviral therapy do not benefit from another treatment trial unless specific circumstances resulted in underdosing. New classes of medicines are under study, and when used in combination with pegylated interferon and ribavirin, protease inhibitors appear to increase response rates.

Surgery in the Patient with Hepatitis C

In the noncirrhotic patient with hepatitis C undergoing hepatopancreatobiliary surgery, no special precautions need be taken. The risk of decompensation postoperatively is solely related to the presence of advanced fibrosis and is not related to the presence of the hepatitis C virus itself. If a patient is undergoing antiviral therapy at the time of surgery, the best advice is to ask a hepatologist to assess the situation. In the vast majority of cases, antiviral therapy need not be stopped in the face of surgery. Obviously, antiviral therapy can be stopped if more pressing issues require treatment. Stopping antiviral therapy for a period of weeks may necessitate starting over from the beginning.

Hepatitis B

Epidemiology

Hepatitis B is a DNA virus that represents the number one cause of chronic viral hepatitis worldwide, with more than 2 billion people infected at some point and more than 350 million infected chronically (World Health Organization, 2008). More than 45% of the world's population lives in endemic areas, particularly in Asia and sub-Saharan Africa (Mahoney, 1999).

More than 8% of the population in these areas is positive for hepatitis B surface antigen (HBsAg). The prevalence is much lower in North America, affecting less than 2% of the population overall. In the United States, approximately 73,000 new cases occur each year, with approximately 1.25 million patients infected chronically (McQuillan et al, 1999). However, because of the mobility of the world's population, the possibility of acute or chronic hepatitis B must be considered in patients who have come to the United States. These changes in patterns of immigration will likely increase the prevalence of the disease by as much as a factor of two.

Transmission

In the United States, the most common means of transmission is via percutaneous or permucosal exposure to blood or body fluids (Gust, 1996); thus sexual transmission and parenteral exposure via needle sticks account for the majority of cases. Vertical transmission is relatively rare in this country because of the identification of HBsAg-positive mothers and the administration of hepatitis B immune globulin and the hepatitis B vaccine at the time of birth. Failure to administer these agents frequently leads to chronic infection in the neonate because of the inability of an immature immune system to eradicate hepatitis B virus (Lok, 2002).

Presentation

Acute hepatitis B has a wide range of presentation, from subclinical disease to acute liver failure. The disease tends to be associated with more severe symptoms as the age of the patient increases, and malaise, arthralgias, jaundice, and anorexia may be present. Chronic hepatitis B is usually not associated with symptoms, although vague, nonspecific symptoms may be present. Differentiating fatigue, arthralgias, and myalgias from other systemic diseases may be difficult.

Diagnosis

The presence of acute or chronic hepatitis B requires the presence of HBsAg. If this test is negative, the patient does not have hepatitis B. On occasion, a patient with acute hepatitis B can present without HBsAg and without hepatitis B surface antibody (HBsAb) because the virus is being eradicated. This is referred to as the *core window.* During this phase, only the immunoglobulin M (IgM) hepatitis B core antibody (IgM HBcAb) is present, thus explaining its presence on acute hepatitis panels available through commercial laboratories. Chronic hepatitis B is only diagnosed when HBsAg is present more than 6 months following the onset of the acute infection. If HBsAg is positive, the evaluation includes assessment for the presence of the hepatitis B e-antigen (HBeAg), hepatitis B e-antibody (HBeAb), and hepatitis B viremia with a hepatitis B virus DNA level by the polymerase chain reaction. Along with the transaminases, these tests guide decisions regarding the need for antiviral therapy. Imaging studies are only required if advanced fibrosis is suspected, based on the presence of complications of end-stage liver disease, including hypoalbuminemia, a prolonged prothrombin time, and/or thrombocytopenia. Sonography is a reasonable first step, although other cross-sectional imaging studies may be indicated, depending on the sonographic findings. Similar to hepatitis C, there are different hepatitis B genotypes: eight have been found to exist, with genotypes A and C most common in the United States. Routine checks of the genotype are unnecessary with regard to screening, however, the genotype can be useful in predicting the response to antiviral agents.

Natural History

Acute hepatitis B resolves spontaneously in 90% of patients. The other 10% with persistent HBsAg require careful assessment and follow-up. Within the past decade, the natural history of chronic hepatitis B has been rewritten. Previously, patients either were "chronic carriers" or had "chronic hepatitis B," which is now defined more as a spectrum of disease that slowly evolves from one phase to another. Patients who contract hepatitis B in the perinatal period frequently maintain high levels of hepatitis B viremia with normal transaminases (Lok & Lai, 1988), which may persist for decades. This "immune tolerant" phase is characterized by the absence of liver injury, or at most only minimal injury.

Current guidelines recommend observation with regular follow-up of liver biochemistry panels, hepatitis B serology, and viral load. Spontaneous HBeAg to HBeAb seroconversion occurs at a rate of 8% to 12% of patients per year (Hoofnagle et al, 1981). An exacerbation of hepatitis B may accompany seroconversion, with marked elevations of the transaminases. Many of these patients (67% to 80%) enter the *inactive carrier state,* with absent or low-level viral replication, normal transaminases, and minimal histologic damage (Hoofnagle et al, 1981). However, 10% to 30% of HBeAb-positive patients continue to have elevated transaminases, viral replication, and histologic damage (Davis et al, 1984). Up to 20% of HBeAb-positive patients may revert back to an HBeAg-positive phase, with elevated viral loads and transaminases (Davis et al, 1984).

Treatment

Patients with acute hepatitis B are treated supportively. Because 90% of cases resolve spontaneously, antiviral therapy is not indicated, and two studies have shown no benefit to the use of lamivudine (Kumar et al, 2007; Tassopoulus et al, 1997). Cases of chronic hepatitis B must be carefully assessed to determine the appropriate treatment for the patient, and guidelines have been published by several professional societies. The key themes throughout all of the published guidelines include certain principles: 1) if transaminase levels are normal, observe, even if there is a detectable viral load; 2) consider treatment if transaminase levels are elevated or if significant histologic damage is evident; and 3) consider treatment in all patients with cirrhosis who have chronic hepatitis B.

Medical management is centered around the use of nucleoside/nucleotide analogues or pegylated interferon. The nucleoside/nucleotide analogues are relatively nontoxic and easy to take, although years of treatment may be necessary before seroconversion occurs. Entecavir, tenofovir, and telbivudine are potent suppressants of hepatitis B viral replication, although telbivudine is associated with a high rate of hepatitis B viral resistance (Lok & McMahon, 2009). Lamivudine, the mainstay of therapy for over a decade, is not considered first-line therapy because of high levels of drug resistance. Pegylated interferon offers a defined treatment length of 48 weeks; however, weekly subcutaneous injections and significant side effects make it less attractive to many. The nucleoside/nucleotide analogues lead to eradication of viral replication in approximately 80% of patients, with HBeAg seroconversion in up to

22%; pegylated interferon leads to HBeAg seroconversion in up to 34% (Lok & McMahon, 2009).

Surgery in the Patient with Chronic Hepatitis B

No special precautions are necessary in patients with chronic hepatitis B unless a patient has cirrhosis. Otherwise, surgery can proceed as scheduled. If the patient is undergoing antiviral therapy, discontinuation of the antiviral agent can lead to replicative rebound, resulting in acute hepatitis and potential liver failure. Thus antiviral agents should not be suddenly stopped until the situation can be discussed with a hepatologist. Any HBsAg-positive patient not taking an antiviral agent should be considered for prophylactic antiviral therapy if immunosuppressive therapy or chemotherapy is started (Lok & McMahon, 2009). Flares of hepatitis, even to the point of hepatic decompensation and death, have been reported in patients without evidence of viral replication (Yeo & Johnson, 2006).

Nonalcoholic Steatohepatitis

Epidemiology

Nonalcoholic steatohepatitis (NASH) is slowly becoming the most common liver disease worldwide. Nonalcoholic fatty liver disease (NAFLD) has a prevalence of 3% to 23% of the North American population (Clark et al, 2002; McCullough, 2005). The prevalence of fatty liver disease has paralleled the increase in body weight seen globally. Nearly 75% of those with obesity or type 2 diabetes mellitus have NAFLD (McCullough, 2005), and approximately 20% of obese subjects have NASH (Wanless & Lentz, 1990). The increase in body mass seen in the United States over the last 25 years suggests the prevalence will rise before it falls.

Presentation

Patients are usually without symptoms. During routine physical examinations and health screenings, abnormal transaminase levels are a frequent problem. Right upper abdominal quadrant fullness or pain is a common symptom, and patients routinely have multiple features of metabolic syndrome, including hyperlipidemia, hyperglycemia/diabetes mellitus, and hypertension. All these issues appear to be related to the development of insulin resistance (Grundy et al, 2004).

Diagnosis

The definitive diagnosis of NAFLD is made histologically; however, this does not imply that a biopsy must be obtained in all cases. The finding of elevated transaminases in an obese patient is consistent with the diagnosis, but other causes of chronic liver disease must be ruled out. Alcoholic steatohepatitis is the first consideration, although this may be limited by the honesty of the patient and whether family members are aware of the patient's alcohol consumption. If heavy alcohol use is unlikely, viral hepatitis serologies, autoimmune serologies, iron studies, and ceruloplasmin measurements should be performed. If the studies results are normal, the next step is imaging of the liver, either sonographically or with cross-sectional imaging.

Fatty infiltration of the liver is only detected if more than 30% of the parenchyma is infiltrated with fat (Saadeh et al, 2002). If fat is detected, a liver biopsy is not absolutely required. Many hepatologists proceed with biopsy if there is any suspicion of another liver disease, such as borderline autoimmune serologies or mildly elevated iron studies, or if there is some question as to the presence of moderate to severe fibrosis. The biopsy can be used to rule out other liver diseases and as a means of staging the amount of fibrotic tissue. The latter is seen as an incentive to patients to begin a dedicated weight loss program. Biopsies from patients with NASH show fat and inflammation, although distinguishing the findings from alcoholic steatohepatitis may be difficult.

Natural History

Hepatic steatosis occurs with minimal or no inflammatory changes histologically, but NASH is associated with necroinflammatory changes; both may progress to fibrosis and cirrhosis. Natural history studies are relatively few in number, because of small patient numbers and limited long-term follow-up. However, NASH progresses to cirrhosis in 15% to 20% of patients (Edmison & McCullough, 2007). Progression is obviously shorter in patients presenting with advanced fibrosis, although 30% of patients will have progression of fibrosis over 5 years (Fassio et al, 2004).

Treatment

In spite of multiple trials of medical treatments, the mainstay of therapy for NASH remains weight loss (Hickman et al, 2004). Decreased dietary intake, ideally complemented by an exercise program, will lead to weight loss, a decrease in hepatic fat, and lower transaminase levels. Weight loss in the amount of 10% to 15% of the current body weight over the course of a year is a reasonable and attainable goal for most patients. However, bariatric surgery and its frequent accelerated weight loss is not harmful and has been associated with histologic improvement (Kral et al, 2004).

Medical therapy for NASH has been the subject of multiple drug trials. Thiazolidinediones have been associated with improvement of transaminase levels and a decrease in histologic fat (Aithal et al, 2008). However, weight gain is a potential side effect; thus use of this class of medications solely to improve NASH is not standard practice. If a patient is diabetic and has NASH, pioglitazone or rosiglitazone may be considered. Agents such as vitamin E, betaine, metformin, and pentoxifylline have also been used in small trials without remarkable improvement. Thus weight loss remains the foundation of NASH treatment.

Surgery in the Patient with Nonalcoholic Steatohepatitis

Routinely, no special precautions need be taken for the operative candidate with NASH in the absence of cirrhosis. However, large hepatic resections in patients with fatty livers have been associated with decompensated liver disease postoperatively (Kooby et al, 2003; Parikh et al, 2003). Thus careful assessment of the patient being considered for hepatic resection must take all of these factors into account. A liver biopsy may provide the necessary information regarding baseline hepatic histology, the extent of fatty infiltration and fibrosis, and the presence of other lesions that may lead to postoperative decompensation.

Autoimmune Hepatitis

Epidemiology

Autoimmune hepatitis is a chronic, usually progressive liver disease with an incidence among Northern Europeans of 1.9 per 100,000 population (Boberg et al, 1998) and 1 per 200,000 in the United States (Manns et al). Although often characterized as a disease of middle-aged women, all ages can be affected,

including the very young and the elderly, but women are affected more often than men. Patients frequently have a coexistent autoimmune disease; a history of thyroid disease, rheumatoid arthritis, psoriasis, or other autoimmune disease should raise the possibility of the diagnosis in a patient who presents with elevated liver biochemistry results (Abdo et al, 2004).

Presentation

Patients present in a number of ways, ranging from relatively asymptomatic elevations of the transaminases to cirrhosis to acute liver failure, the latter two preceded by relatively nonspecific symptoms of fatigue and malaise of varying duration. Up to 40% of patients present with systemic symptoms and an acute illness with possible fever, arthralgias, myalgias, and skin rash. This can progress to acute liver failure with hepatic encephalopathy within 8 weeks of the onset of symptoms, potentially leading to death or to the need for liver transplantation. Autoimmune hepatitis historically accounts for 5% to 6% of liver transplantations done in the United States.

Diagnosis

No single test or finding leads to the diagnosis of autoimmune hepatitis. Other causes of acute and chronic liver disease must be ruled out; thus viral serologies, iron studies (hereditary hemochromatosis), serum ceruloplasmin measurements (Wilson disease), α_1 antitrypsin level, and phenotyping must be performed, and drug-induced hepatotoxicity, alcoholic liver disease, and nonalcoholic steatohepatitis must be ruled out based on historic, serologic, radiologic, and histologic data. Autoimmune serologies are helpful, particularly when present at a titer of more than 1:80. Antinuclear antibodies (ANAs) and anti–smooth muscle antibodies (ASMAs) are frequently present, although their absence does not rule out the disease. The anti–liver/kidney microsomal antibody is much less common in the United States, representing fewer than 5% of cases. Other autoimmune serologies occur even less commonly and are not routinely checked in clinical practice.

Histologic features are the foundation of the diagnosis; however, serologic and clinical findings may lead to the diagnosis, even in the absence of classic histologic findings. Characteristic histologic findings include interface hepatitis, previously known as *piecemeal necrosis,* and a portal plasma cellular infiltrate. However, other liver diseases such as Wilson disease, chronic hepatitis C, and drug-induced hepatotoxicity can have similar histologic features. Thus the issues outlined above regarding careful assessment and evaluation for other acute and chronic liver diseases cannot be forgotten. Histologic features of other autoimmune liver diseases, such as primary biliary cirrhosis, may suggest the presence of an overlap syndrome in which serologic and histologic features of both diseases are present.

Natural History

Autoimmune hepatitis is often a progressive disease, with death occurring in 40% of untreated patients. In those surviving the initial illness, another 40% progress to cirrhosis with the potential manifestations of end-stage liver disease, including ascites, portal hypertension, and hepatic encephalopathy. Not unexpectedly, severe histologic damage on the initial liver biopsy is a poor prognostic factor. Although transaminase elevations do not always correlate with the degree of liver damage or prognosis in other liver diseases, persistent transaminase elevations greater than 10 times the upper limit of normal are associated with higher early mortality rates. Patients with milder laboratory and histologic findings have a less severe course; however, cirrhosis still develops in 49% of patients over a period of 15 years (Czaja & Freese, 2002). Thus early diagnosis and treatment are key to prolonging long-term survival.

Treatment

Indications for treatment must be individualized, although in more severe cases, patients should be started on therapy immediately. Those with significant histologic changes and transaminase levels greater than 10 times the upper limit of normal should be treated. Lower level transaminase elevations in combination with bridging necrosis and/or lobular necrosis should also be treated. The potential risks and benefits of treatment should be considered in patients without the above findings; however, because of the progressive nature of the disease, most experienced hepatologists routinely treat patients with transaminase elevations and even mild histologic changes.

Immunosuppressive therapy is the key to controlling this progressive disease. Although treatment protocols vary by center and clinician, corticosteroid-based treatment is most common. A 30- to 60-mg daily dose of oral prednisone is usually started in most cases, even in patients with coexistent diseases that potentially could be affected, such as diabetes mellitus. Because of the adverse effects associated with long-term high-dose corticosteroid therapy, the dose is tapered over varying amounts of time, ranging from weeks to months. Because of the potential for disease flares as the corticosteroid dose is tapered, most patients start azathioprine at a dose of 50 mg daily along with corticosteroids, or azathioprine is started within 2 to 3 months of the initiation of treatment (Czaja & Freese, 2002). Azathioprine is usually not effective for 4 to 8 weeks after initiation; thus many clinicians start it with prednisone rather than delaying. Although 90% of adults show marked improvement in laboratory studies and symptoms within 2 weeks of starting therapy, disease remission is uncommon in less than 12 months. Thus azathioprine is continued after prednisone is tapered off. As the prednisone is tapered, elevations in transaminases can be addressed with an increase in dose; however, the long-term side effects associated with corticosteroids make this a less than ideal choice. Thus doses of azathioprine incrementally increased to a maximum dose of 2 mg/kg/day are routinely used, if the disease flares during the steroid taper.

Depending on the severity of the histologic damage seen initially, most clinicians continue the azathioprine for at least 1 to 2 years. Even with normal transaminase levels, a significant number of patients have ongoing interface hepatitis on immunosuppressive therapy. Thus any attempt to stop immunosuppressive therapy should be preceded by a liver biopsy to assess the histologic response to therapy. As a rule, more severe initial changes will take longer to correct and will lag behind biochemical improvement. Many clinicians see autoimmune hepatitis as a chronic disease that inevitably flares off therapy, although some patients go into remission and can remain off therapy without histologic progression. Patients tapered off therapy should be followed up with liver biochemistry measurements at least twice a year because relapses may occur without symptoms. Reinstitution of immunosuppressive therapy leads to improvement in most patients within 2 years and should lead to indefinite immunosuppressive therapy with azathioprine, and in some cases prednisone, based on liver biochemistries (Czaja & Freese, 2002).

The complications of long-term corticosteroid therapy are well known and need not be outlined. However, the short- and long-term consequences associated with azathioprine are less well known and worth listing. Bone marrow suppression—with anemia, leukopenia, and thrombocytopenia—is the most common laboratory abnormality. Symptomatically, nausea, vomiting, and abdominal pain may lead to cessation of therapy as a result of intolerance. Acute pancreatitis is rare, as is hepatotoxicity, typically marked by sinusoidal obstructive syndrome or cholestasis, both of which usually respond to drug cessation. Long-term treatment can result in malignancy, usually a lymphoma or leukemia (Kandiel et al, 2005). However, one series of patients with autoimmune hepatitis followed for more than 20 years showed no incidence of malignancy (Johnson et al, 1995).

Of note, allopurinol should never be used in patients taking azathioprine because it inhibits xanthine oxidase, an enzyme necessary for the breakdown of azathioprine. If this enzyme is inhibited, the half-life of azathioprine is prolonged and can lead to profound bone marrow suppression.

Other agents have been used for the treatment of autoimmune hepatitis, although the experience is predominantly anecdotal. Mycophenolate mofetil, another lymphocyte inhibitor used in solid organ transplant recipients, can be substituted for azathioprine with comparable efficacy in cases of intolerable side effects based on a relatively limited experience.

Surgery in the Patient with Autoimmune Hepatitis

No special precautions need be taken in patients with autoimmune hepatitis requiring surgery. Patients with acute autoimmune hepatitis with signs of acute liver failure or cirrhosis clearly are at risk, and indications for surgery in this setting should include only those of an emergent nature. All the risks and benefits of surgery must be carefully considered. In patients with well-controlled autoimmune hepatitis on maintenance immunosuppression, the risk of liver decompensation and/or a disease flare is small as long as patients are maintained on their medications. Stress doses of corticosteroids should be considered if a patient is taking corticosteroids or has recently been tapered off. If a patient is undergoing azathioprine monotherapy preoperatively, the dose should be restarted as soon as possible postoperatively. A prolonged absence of gut motility should lead to discussion with a hepatologist regarding the need for intravenous steroids to keep the disease in remission. Routinely, a few days off immunosuppressive therapy will not lead to a disease flare; the potential risks and benefits associated with corticosteroids therefore must be carefully considered. Patients with advanced cirrhosis routinely are not surgical candidates except in cases of emergent and/or life-threatening events requiring surgical intervention.

APPROACH TO SURGERY IN PATIENTS WITH LIVER DISEASE

Partly because of the epidemic of obesity and NAFLD, increasing numbers of patients with chronic liver disease are undergoing nonhepatic and nontransplant operations. Liver disease, especially significant fibrosis or cirrhosis, represents a significant risk factor for perioperative morbidity and mortality. Any clinically evident signs of liver dysfunction should raise concern, particularly for intraabdominal operations. Although no absolute consensus on risk quantification has been reached, the perioperative risk in patients with liver disease clearly increases with the severity of liver dysfunction (Teh et al, 2007). Perioperative risk in these patients can be quantified using the Child-Turcotte-Pugh (CTP) score and/or the Model for End-Stage Liver Disease (MELD) score (Teh et al, 2007; Muilenburg et al, 2009; del Olmo et al, 2003), which can discriminate risks to a finer degree than the CTP score and has evolved as the best predictor of 30- and 90-day operative mortality rate (Teh et al, 2007). Furthermore, perioperative mortality risk greatly increases in patients with MELD scores higher than 10 to 15 (Costa et al, 2009; Morisaki et al, 2010; Northup et al, 2005; Telem et al, 2010; Teh et al, 2007), and there also is utility in MELD-based variants in making more refined predictions regarding surgical risk (Costa et al, 2009; Telem et al, 2010).

Ultimately, the indication for surgery, whether elective or emergent, along with the patient's estimated operative risk from liver disease must be considered as the operative plan is developed. These factors should clearly influence the informed consent for the patient and family. When possible, patients should be referred to a specialty liver care center, where preoperative optimization should be carried out by a multidisciplinary team approach.

CHAPTER 65

Hepatic steatosis, steatohepatitis, and chemotherapy-related liver injury

Carlo M. Contreras, Antoine Brouquet, Dipen M. Maru, and Jean-Nicolas Vauthey

OVERVIEW

Hepatic parenchymal damage from chemotherapy can be divided into two main categories: *nonalcoholic fatty liver disease* (steatosis and steatohepatitis) and *sinusoidal injury.* Both types of injuries may be caused by chemotherapy or other factors; however, hepatic injuries become relevant in the context of preoperative chemotherapy and can be a concern for the hepatic surgeon. Steatosis is linked to an increased body mass index (BMI) and to the use of chemotherapy agents, such as 5-fluorouracil (5-FU) and irinotecan. Steatohepatitis is observed in 5% to 10% of patients undergoing irinotecan-based chemotherapy, and sinusoidal injury is related to the use of oxaliplatin-containing regimens.

In patients undergoing liver resection, severe steatosis and high-grade sinusoidal injury increase the overall postoperative complication rate, and steatohepatitis can increase the 90-day posthepatectomy mortality rate, including death from postoperative liver failure. In the context of preoperative chemotherapy, preventive measures—such as limiting the duration of chemotherapy to 2 to 3 months—reduce the risk of hepatic injuries and therefore reduce surgical complication rates.

With the expansion of the indications for liver surgery in patients with hepatic malignancies, liver surgeons have become concerned with steatosis, steatohepatitis, and other liver damage from chemotherapy. Preoperative chemotherapy is widely used before resection of colorectal cancer liver metastases (see Chapters 81A and 87), and can induce different types of hepatic parenchymal injuries. Although most of these changes can be observed outside the context of preoperative chemotherapy, they have become more relevant in patients receiving preoperative chemotherapy for colorectal cancer liver metastase because they can affect perioperative outcome after hepatic resection. This chapter focuses on risk factors and prevention of chemotherapy-related liver damage as it affects liver resection.

TYPES AND ETIOLOGY OF LIVER PARENCHYMAL DAMAGE

Hepatic parenchymal damage from chemotherapy (see Chapter 87) can be divided into two main categories: *nonalcoholic fatty liver disease* (NAFLD) and *sinusoidal injury*. NAFLD describes a large spectrum of histologic liver changes unrelated to alcohol consumption. It is important to note that these lesions may also be observed in the context of alcohol abuse. Steatosis is defined by an intracellular hepatocyte lipid accumulation, and it is the hallmark of NAFLD. Histologic evidence of an inflammatory component associated with steatosis defines *steatohepatitis.* Upon operative exploration, a liver that has undergone steatotic changes is recognized by its yellow-tan color, often referred to as *yellow liver.* NAFLD is typically graded according to the scoring system of Kleiner and colleagues (2005), which considers the degree of steatosis (0 to 3 points), lobular inflammation (0 to 3 points), and hepatocellular ballooning (0 to 2 points; Fig. 65.1). A score of 5 or more indicates steatohepatitis.

Increased BMI is the main risk factor of nonalcoholic steatosis (Brouquet et al, 2009; Kooby et al, 2003; Vauthey et al, 2006). The use of chemotherapy may increase the risk of steatosis (Kooby et al, 2003), which can be detected in 30% to 47% of patients who have received systemic chemotherapy (Peppercorn et al, 1998; Sorensen et al, 1995). Although no specific chemotherapy regimen has been definitively linked to the occurrence of steatosis, it is generally attributed to the use of 5-FU or irinotecan in patients with liver metastases (Moertel et al, 1993; Sorensen et al, 1995; Vauthey et al, 2006). However, in these patients, it is difficult to ascertain whether chemotherapy directly induces steatosis or more likely aggravates preexisting NAFLD.

Steatohepatitis has long been described as a "second hit" in patients with preexisting steatosis, but the continuum between these two different types of NAFLD is uncertain. Macroscopically, no specific features distinguish the steatohepatitis from other types of NAFLD. Chemotherapy-related steatohepatitis was initially believed to be related to the use of any chemotherapy (Bilchik et al, 2005; Fong et al, 2006), but only irinotecan has been confirmed as a risk factor for steatohepatitis (Vauthey et al, 2006). The effect of an elevated BMI on the development of chemotherapy-associated steatohepatitis is additive to the risk imposed by the use of irinotecan (Vauthey et al, 2006), and this risk can rise to up to 25% in patients with a BMI of 25 kg/m^2 or more who received irinotecan-based chemotherapy (Attal et al, 1992).

Sinusoidal injury is a variant of the sinusoidal obstruction syndrome first described in association with bone marrow transplantation. In the operating room, a liver that has sustained sinusoidal injury is characterized by vascular ectasia, commonly referred as *blue liver.* The initial damage affects endothelial cells of the sinusoids, leading to a rupture of the continuity of the sinusoidal wall, which triggers a coagulation cascade and induces the deposition of coagulation factors, erythrocyte aggregates, and cytoplasmic fragments into the perisinusoidal space, ultimately leading to sinusoidal obstruction (Attal et al, 1992; Rubbia-Brandt et al, 2004).

Histologically, the severity of sinusoidal injury can be graded according to a scoring system developed by Rubbia-Brandt and colleagues (2004). This system evaluates the proportion of

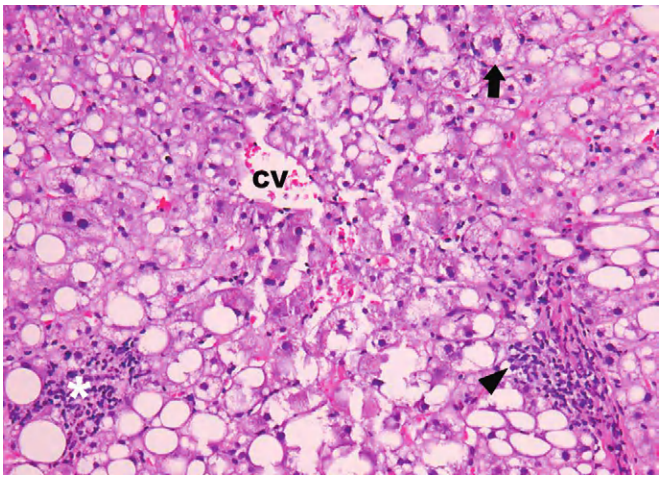

FIGURE 65.1. Steatohepatitis. Moderate steatosis (40% to 50% of hepatocytes), hepatocyte-ballooning degeneration (*arrow*), lobular inflammation (*asterisk*), and portal inflammation (*arrowhead*) can be seen in this specimen, which has a Kleiner score of 6 for nonalcoholic fatty liver disease. *CV,* central vein. centrilobular involvement relative to the entire lobular surface (Fig. 65.2). A score of 0 indicates no sinusoidal dilation; 1 indicates mild sinusoidal dilation, characterized by centrilobular changes limited to one third of the lobular surface; 2 indicates moderate sinusoidal dilation, characterized by centrilobular changes extending to two thirds of the lobular surface; and 3 indicates severe sinusoidal dilation, characterized by evidence of complete lobular involvement. There is strong evidence that sinusoidal injury is caused by the use of platinum compounds, including oxaliplatin (Aloia et al, 2006; Brouquet et al, 2009; Nakano et al, 2008; Rubbia-Brandt et al, 2004; Vauthey et al, 2006), and the incidence of sinusoidal injury can range from 19% to 52% in patients who have received preoperative oxaliplatin-based chemotherapy (Aloia et al, 2006; Brouquet et al, 2009; Nakano et al, 2008; Rubbia-Brandt et al, 2004; Vauthey et al, 2006).

PATHOPHYSIOLOGY OF CHEMOTHERAPY-ASSOCIATED LIVER DAMAGE

Although histologically distinct, the NAFLD and sinusoidal injury pathways both involve chemical damage by reactive oxygen species (ROS) (Fig. 65.3). The initial event in the NAFLD sequence is likely drug-related damage to the mitochondrial membrane that interferes with oxidation of fatty acids and ultimately leads to the accumulation of ROS within hepatocytes (Laurent et al, 2004; Pessayre et al, 2001). Fluoro-β-alanine, a fluorouracil metabolite, is also believed to impair metabolism in hepatocytes, thus prolonging their exposure to toxic substances (Miyake et al, 2005).

The pathophysiology of sinusoidal injury also involves the accumulation of ROS. Wang and colleagues (2000) developed a rodent model of sinusoidal injury using exposure to pyrrolizidine alkaloids, which deplete the sinusoidal endothelial cells' glutathione stores, leaving them susceptible to subsequent ROS injury. Pyrrolizidine alkaloids also decrease nitric oxide concentrations, resulting in the upregulation of matrix metalloproteinase activity, which can be prevented by pretreatment with a nitric oxide donor (DeLeve et al, 2003). Damage induced by exposure to pyrrolizidine compounds can also be abrogated in a dose-dependent manner by pretreating sinusoidal endothelial cells with exogenous glutathione or N-acetyl-L-cysteine in this model (Wang et al, 2000). However, these preventive pharmacologic strategies have not yet been tested in humans.

PREOPERATIVE DETECTION OF LIVER INJURY

The definitive diagnosis of hepatic injury relies on the pathologic examination of non–tumor-bearing liver tissue after liver resection. The preoperative detection of liver injury is useful to devise the best surgical strategy in patients with severe hepatotoxicity (Fig. 65.4). Numerous modalities have been proposed to detect chemotherapy-related liver injuries preoperatively, but no consensus has been reached. Although abnormal liver function tests may suggest hepatic injury, assessment of the severity of hepatic injury is not possible based only on these laboratory values (Brouquet et al, 2009; Nakano et al, 2008). The combination of macroscopic and microscopic examinations of the liver provided by preoperative laparoscopy with intraoperative liver biopsies probably offers the best assessment of the effects of preoperative chemotherapy in patients at high risk for surgical complications (Vauthey et al, 2006). However, this is an invasive approach, which limits its routine use. Image-guided liver biopsy has also been proposed to assess liver injuries; however, the practicality of such an approach is questionable because of the heterogeneity of hepatic lesions and because of interobserver variations in the histologic identification of chemotherapy-related liver injuries.

A number of noninvasive imaging methods have been evaluated to preoperatively determine the presence and degree of liver injuries. Ultrasound (US) is ineffective in differentiating hepatic steatosis from fibrosis because it is highly operator dependent and therefore prone to interobserver variations (Mazhar et al, 2009). Computed tomography (CT) offers the

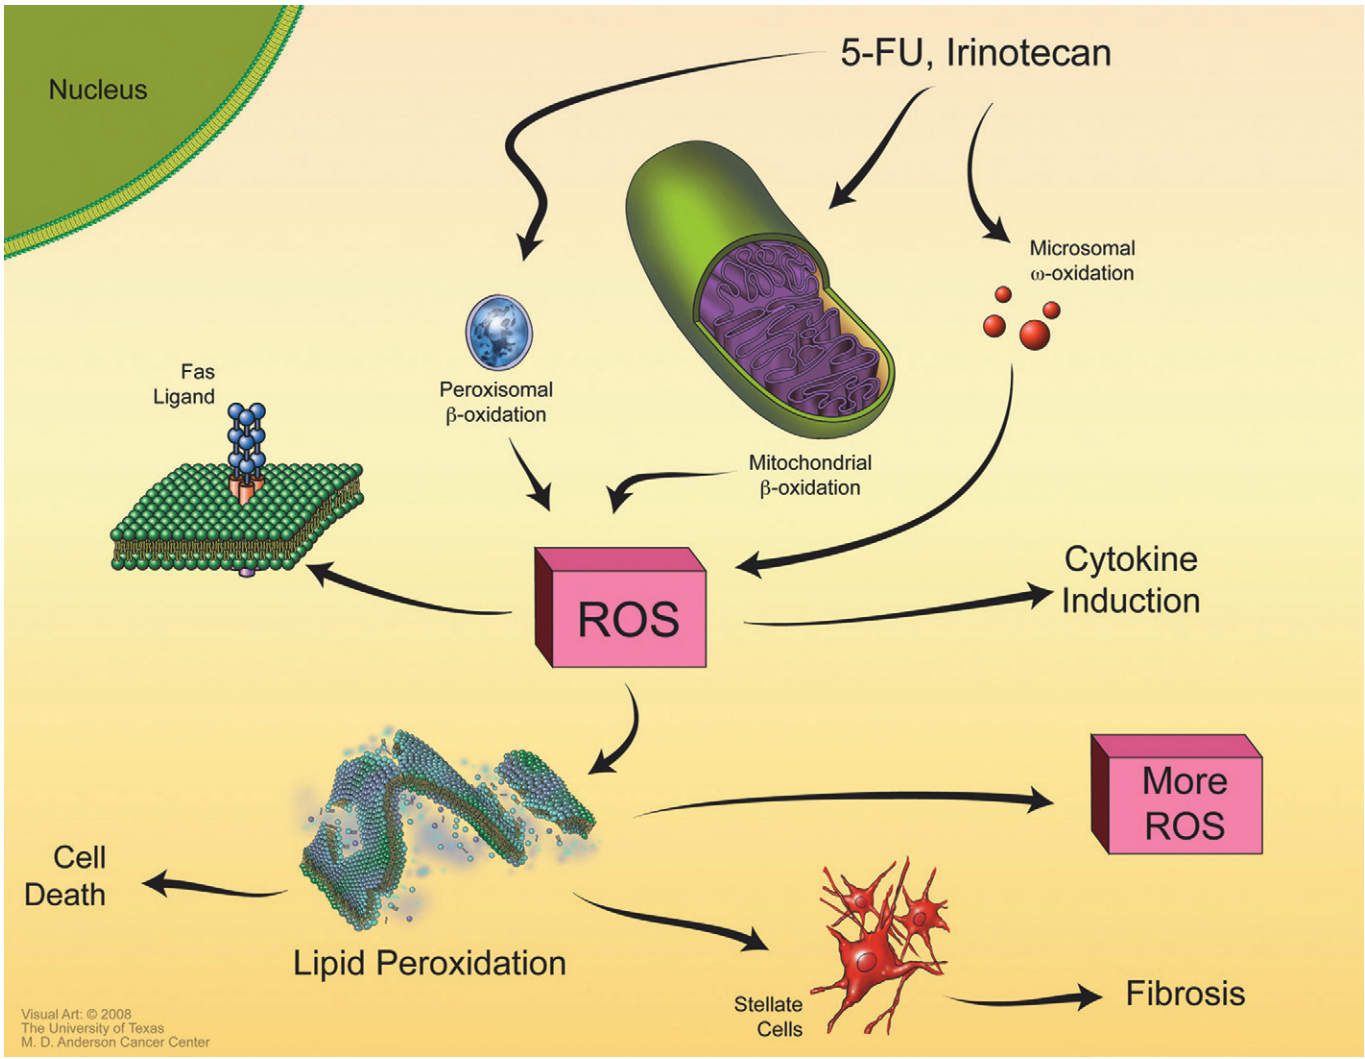

FIGURE 65.3. Cytotoxic drugs impair mitochondrial oxidation, leading to reactive oxygen species production, Fas ligand death receptor expression, and cytokine induction. Lipid peroxidation results in cell death, stellate cell activation, and fibrosis. 5-FU, 5-fluoruracil; ROS, reactive oxygen species. *(From Chun YS, et al, 2009: Management of chemotherapy-associated hepatotoxicity in colorectal liver metastases. Lancet Oncol 10:278-286.)*

advantage of being part of the preoperative workup of liver metastases, and its performance to detect steatosis has been evaluated (Kodama et al, 2007; Cho et al, 2008). Non–contrast-enhanced CT images more accurately estimate hepatic steatosis than do contrast-enhanced images. Unenhanced liver parenchyma with an attenuation value less than 40 Hounsfield units (HU) is indicative of more than 30% hepatic steatosis. However, marked steatosis cannot be excluded on non–contrast-enhanced CT (Cho et al, 2008; Kodama et al, 2007).

Magnetic resonance imaging (MRI) can also be useful for characterizing certain types of liver injuries. Super paramagnetic iron oxide (SPIO) agents are preferentially taken up in Kupffer cells (Ward et al, 2008) and can be used to increase the accuracy of MRI to detect sinusoidal injury because this lesion is associated with a change in Kupffer cell phagocytic behavior. Ward and colleagues (2008) evaluated the performance of SPIO-enhanced MRI for the assessment of sinusoidal injury and found a sensitivity of 87% and specificity of 89%; however, these MRI techniques are investigational and therefore have limited utility. Furthermore, MRI lacks specificity (63%) and is less accurate than non–contrast-enhanced CT for detecting steatosis (Cho et al, 2008). Because of these limitations and the high cost, MRI is not routinely used to detect hepatic injury.

CHEMOTHERAPY-ASSOCIATED LIVER DAMAGE AND SURGICAL RESECTION

Table 65.1 summarizes the results of several studies on the relationship between the presence of hepatic injury and the postoperative complication rate. Although the presence of steatosis does not increase 90-day postoperative mortality rates (Vauthey et al, 2006), Kooby and colleagues (2003) reported in a series of 485 patients that marked steatosis was an independent risk factor for postoperative infectious complications. In this study, the presence of marked steatosis was independently associated with preoperative chemotherapy.

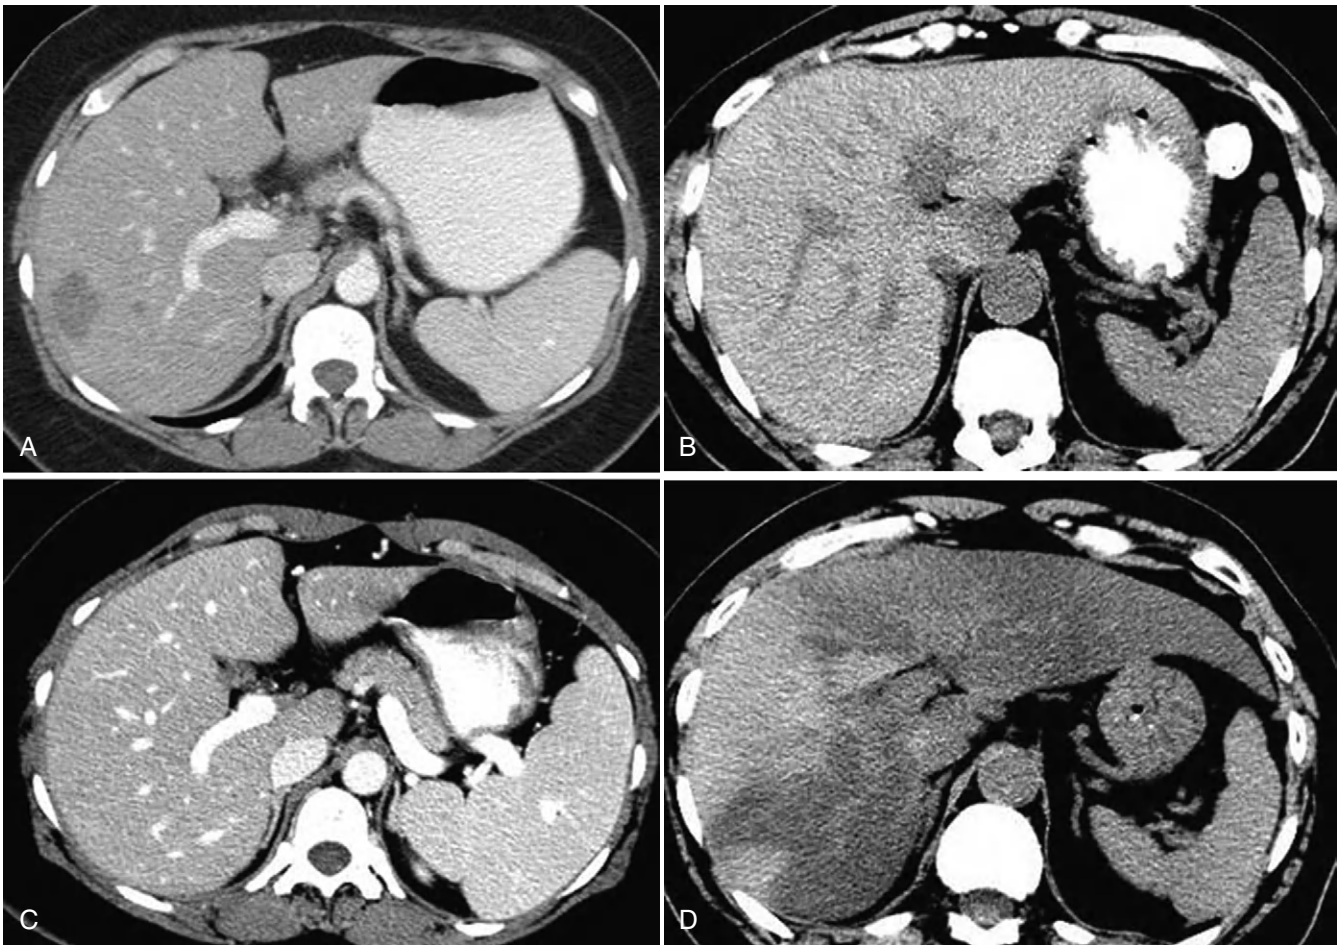

FIGURE 65.4. Radiographic manifestations of chemotherapy-related injury. Computed tomography (CT) images taken before (**A**) and after (**C**) 6 months of FOLFOX (folinic acid, fluorouracil, oxaliplatin) therapy show the resolution of colorectal cancer liver metastasis and interval development of splenomegaly. CT images taken before (**B**) and after (**D**) 2 months of FOLFIRI (folinic acid, fluorouracil, irinotecan) therapy show the interval development of contiguous areas of hepatic parenchymal steatosis.

Irinotecan-related steatohepatitis, although less frequent, is potentially more dangerous in candidates for liver resection. Vauthey and colleagues (2006) evaluated the outcomes of 406 patients who underwent liver resection for colorectal cancer liver metastases; 248 of them had received preoperative chemotherapy, and 158 had not. The presence of steatohepatitis, observed in 8.4% of patients, was associated with an increase in the 90-day postoperative mortality rate as a result of liver failure (15% in patients with steatohepatitis vs. 2% in those without; $P = .001$). The presence of severe sinusoidal injuries has been reported to be closely associated with the risk of bleeding and the requirement for blood transfusion during resection in patients who received oxaliplatin-based chemotherapy for more than 6 months (Aloia et al, 2006). Others have suggested that sinusoidal injuries increase the risk of postoperative complications after major liver resection (Nakano et al, 2008).

Overall, the effect of a sinusoidal lesion on posthepatectomy outcome is real but probably less severe than steatohepatitis, as demonstrated in the European Organisation for Research and Treatment of Cancer (EORTC) 40983 trial (Nordlinger et al, 2008). In this prospective randomized trial comparing patients treated by surgery plus perioperative FOLFOX (folinic acid, fluorouracil, oxaliplatin) versus surgery alone for resectable colorectal liver metastases, the 151 patients randomized to receive perioperative FOLFOX were more likely to develop reversible postoperative complications than the 152 patients who underwent resection without chemotherapy (25% vs. 16%, respectively; $P = .04$; Nordlinger et al, 2008). However, perioperative mortality rate was low (1%), and it was similar in the two groups.

In addition to increasing the risk for postoperative complications, chemotherapy-related liver injuries appear to impair the radiographic detection of liver metastases. Angliviel and colleagues (2009) assessed the ability of CT to detect liver metastases in patients with or without preoperative chemotherapy before planned liver resection. Preoperative CT findings were compared with intraoperative and histologic findings. In this study, preoperative chemotherapy, more than three liver metastases, and steatosis greater than 30% were independent risk factors of inaccurate CT staging.

MINIMIZING THE RISKS AND CONSEQUENCES OF HEPATIC INJURY

A better knowledge of the determinants of chemotherapy hepatotoxicity has led to various measures proposed to minimize the incidence and consequences of hepatic injury. The duration of chemotherapy exposure and the time interval between the cessation of chemotherapy and liver resection have been recognized as risk factors of hepatic injury (Aloia et al, 2006; Karoui et al, 2006; Kishi et al, 2010; Nakano et al, 2008). In a series of 45 patients who underwent major liver resection, Karoui and colleagues (2006) showed that receiving six or more cycles of preoperative chemotherapy was a predictor of postoperative morbidity (54% vs. 19%; $P = .047$). Another study found that when compared with shorter duration treatment, preoperative chemotherapy of more than 12 cycles increased the risk of reoperation (11% vs. 0%, respectively; $P = .04$) and resulted in a longer hospital stay (11 vs. 7 days; $P = .02$) after liver resection for colorectal liver metastases (Aloia et al, 2006). In this study, hemorrhagic centrilobular necrosis was more common in patients treated with more than 12 cycles of chemotherapy than in patients with a shorter chemotherapy duration (50%, 25%, and 10%, respectively; $P = .01$). Prolonged preoperative chemotherapy has been confirmed as an independent risk factor for grade 2 and grade 3 sinusoidal injuries in a series of 90 patients who underwent liver resection for colorectal cancer liver metastases (Nakano et al, 2008). Prolonged chemotherapy is associated with an increased rate of postoperative morbidity, but it does not appear to increase the rate of major or complete pathologic response (Kishi et al, 2010); therefore it is desirable to pursue liver resection after a short course (e.g., six cycles or less) of preoperative chemotherapy and to cease chemotherapy as soon as the lesions are resectable in patients with initially unresectable liver metastases.

The time interval between cessation of chemotherapy and liver resection also influences the risk of postoperative complications and the incidence of hepatic injury (Brouquet et al, 2009; Welsh et al, 2007). Welsh and colleagues (2007) found in a series of 497 patients who underwent resection of colorectal cancer liver metastases with and without preoperative chemotherapy that an interval of 4 or fewer weeks between chemotherapy and surgery was a risk factor for the development of postoperative complications. More recently, a time interval of less than 4 weeks was identified as an independent risk factor for chemotherapy-related liver injury in a series of 146 patients who received preoperative chemotherapy for colorectal cancer liver metastases (Brouquet et al, 2009). The influence of the time interval on the severity of hepatic injury supports the current recommendation to wait at least 5 weeks between the cessation of chemotherapy and liver resection.

Other strategies to minimize liver injury have focused on the use of additional pharmacologic agents. Bevacizumab is a monoclonal antibody directed against the vascular endothelial growth factor receptor (VEGF-R); when used with 5-FU–based chemotherapy for metastatic colorectal adenocarcinoma, it is associated with improvements in both radiologic response rates and survival (Hurwitz et al, 2004). However, bevacizumab increases the risk of various tumor-related complications, including bleeding and perforation (Chen et al, 2006; Shah et al, 2005); therefore its use during the perioperative period in patients with colorectal cancer liver metastases was initially thought to be potentially deleterious. Several studies have since shown that the addition of bevacizumab to preoperative chemotherapy is safe, provided a sufficient time interval is allowed to elapse between the cessation of chemotherapy and liver resection (i.e., 6 weeks, which is two half-lives) (D'Angelica et al, 2007; Gruenberger et al, 2008; Kesmodel et al, 2008).

Ribero and colleagues (2007b) evaluated the influence of bevacizumab in a series of 105 patients who underwent liver resection for colorectal liver metastases after preoperative chemotherapy. They found that preoperative bevacizumab with oxaliplatin had higher rates of pathologic response, assessed by the proportion of patients with less than 25% viable tumor cells (45% with bevacizumab vs. 23% without bevacizumab) and a lower incidence of sinusoidal injury (any grade: 27.4% with bevacizumab vs. 53.5% without; moderate or severe: 8.1% with bevacizumab vs. 27.9% without; both $P < .01$) (Fig. 65.5). This protective effect of bevacizumab against oxaliplatin-induced sinusoidal injury has been confirmed in two other studies (Gruenberger et al, 2008; Rubbia-Brandt et al, 2010).

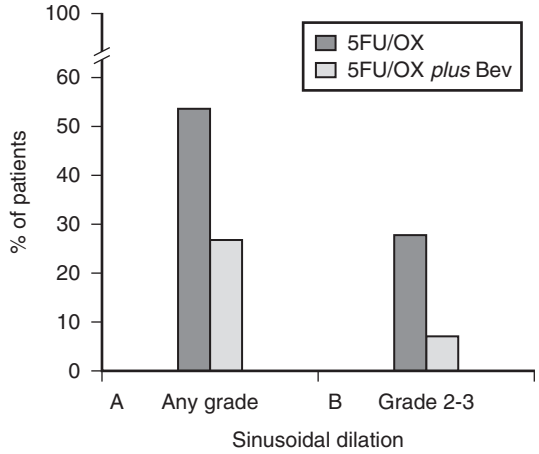

FIGURE 65.5. Frequency and grades of sinusoidal dilatation observed in non–tumor-bearing livers by type of preoperative chemotherapy regimen. *5FU/OX,* 5-fluorouracil and oxaliplatin; *Bev,* bevacizumab. *(Modified from Ribero D, et al, 2007b: Bevacizumab improves pathologic response and protects against hepatic injury in patients treated with oxaliplatin-based chemotherapy for colorectal liver metastases. Cancer 110: 2761-2767.)*

Other pharmacologic agents may also have a protective effect against liver injury. Brouquet and colleagues (2009) retrospectively explored the risk factors for chemotherapy-related

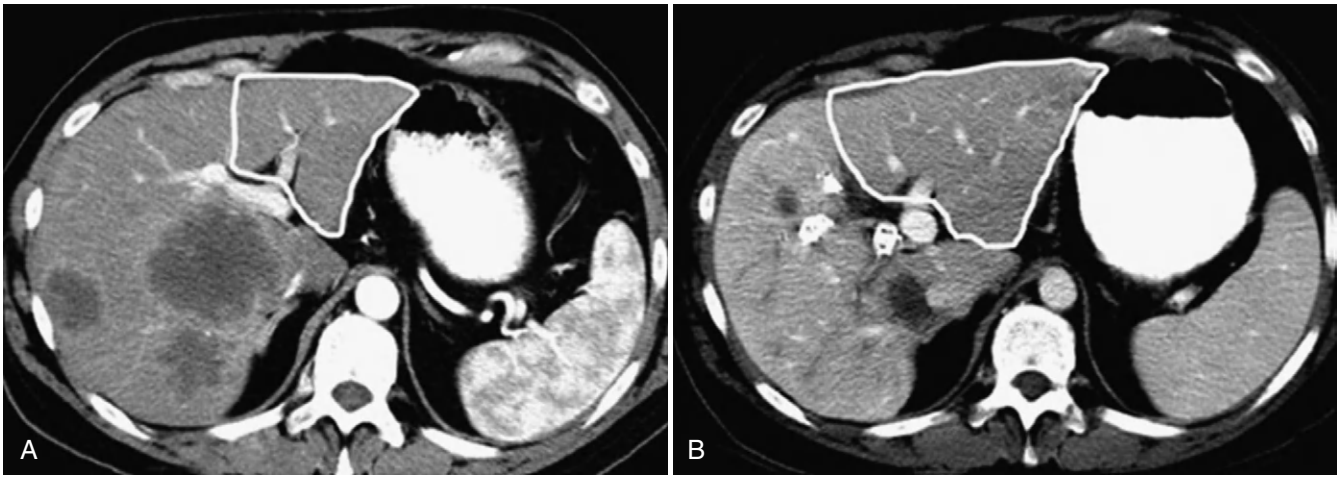

FIGURE 65.6. Computed tomography (CT) images from a patient with multiple, large metastases who required extended right hepatectomy. **A,** The measured volume of the future liver remnant (FLR; bisegments II and III, outlined in *white*) was 291 cm^3, and the standardized FLR (sFLR) was calculated as 17% of the estimated total liver volume (TLV). To downsize metastases and induce hypertrophy in the FLR before hepatectomy, chemotherapy was administered, followed by portal vein embolization. **B,** This led to an increase in the FLR volume to 510 cm^2 and in sFLR to 30% of the estimated TLV. *(From Chun YS, Vauthey JN, 2007: Extending the frontiers of resectability in advanced colorectal cancer. Eur J Surg Oncol 33[suppl 2]:S52-S58.)*

liver injuries in a group of 146 patients who had undergone resection of liver metastases within 3 months of preoperative chemotherapy and found that low, daily "cardiac prophylaxis" doses of aspirin (75 to 360 mg) may have a protective effect against sinusoidal injury and other chemotherapy-related liver injuries. This beneficial effect of aspirin has yet to be confirmed by other studies.

In patients with advanced liver disease who receive prolonged chemotherapy, hepatic injury cannot be avoided, and the objective is to minimize its consequences. Portal vein embolization (PVE) was initially proposed to increase resectability in patients who require extended resections but with an inadequate liver remnant (see Chapter 93). It can also be used to increase the hepatic reserve in patients suspected to have hepatic injury who may require extended liver resection (Fig. 65.6) (Abdalla et al, 2002; Azoulay et al, 2000; Kishi et al, 2009; Ribero et al 2007a). Hypertrophy of the liver remnant after PVE seems to not be significantly affected by the preoperative chemotherapy even if associated with bevacizumab (Goere et al, 2006; Zorzi et al, 2008). This is a test to assess the regenerative capacities of the liver because the degree of hypertrophy correlates with the postoperative mortality rate (Farges et al, 2003; Ribero et al 2007a). At the University of Texas M.D. Anderson Cancer Center, in patients who have received extended chemotherapy (>4 months) or in those with a preexisting hepatic injury, PVE is performed if the future liver volume is 30% or less of the total liver volume. A degree of hypertrophy of 5% or less after PVE is considered a contraindication to major liver resection (Ribero et al, 2007a).

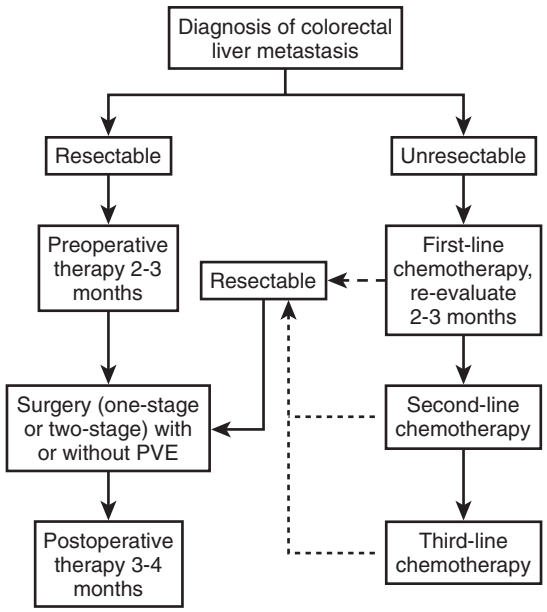

FIGURE 65.7. Treatment recommendations for colorectal cancer liver metastases when preoperative chemotherapy is used. Portal vein embolization is considered if the future liver remnant is 20% or less of the total volume in a healthy liver, 30% or less after extensive chemotherapy (>4 months), or 40% or less in patients with cirrhosis. It should be noted that not all patients with resectable disease require preoperative treatment, and proceeding directly to resection is an alternative approach. *(Modified from Kopetz S, Vauthey JN, 2008: Perioperative chemotherapy for resectable hepatic metastases. Lancet 371:963-965.)*

CONCLUSION

The increasing use of preoperative chemotherapy has led to an increased incidence of hepatic injury, including NAFLD and sinusoidal injury. Although the consequences of hepatic injury can vary widely according to its severity, it is of major concern to liver surgeons. Overall, hepatic injury rarely affects surgical outcomes if the lesions are identified preoperatively. In patients receiving preoperative chemotherapy who are at risk for developing hepatic injury, the use of simple guidelines regarding the duration of the treatment (2 to 3 months in patients with resectable metastases) and the time interval between chemotherapy and surgery (>5 weeks) should optimize surgical outcomes (Fig. 65.7).

PART 7: Hepatic Disease

SECTION I: Inflammatory, Infective, and Congenital

B. Liver Infection and Infestation

CHAPTER 66

Pyogenic liver abscess

Oscar M. Mazza and Eduardo De Santibañes

OVERVIEW

Pyogenic liver abscess (PLA) may be defined as solitary or multiple collections of pus within the liver, the result of bacterial infection. In 1938, Ochsner and coworkers reported the first series of patients with hepatic abscesses in the modern surgical era treated by surgical drainage. This study included 47 patients and reported an overall survival of 67%. The advent of antibiotic therapy marked the basis of the contemporary treatment of liver abscesses, becoming a major part of the therapy, combined with surgical drainage. The first landmark report in minimally invasive treatment of liver abscess was that of McFadzean and colleagues in 1953. They presented a group of 14 patients who underwent percutaneous drainage for PLAs with no deaths within the group. Although potentially effective for dealing with the liver problem, such approaches present the disadvantage of overlooking the underlying abdominal pathology because of the lack of surgical exploration.

The development of clinical ultrasound (US) in the 1960s and the introduction of computed tomography (CT) in the 1970s represent the two major advances in the diagnosis and treatment of PLAs. Surgical exploration as a diagnostic tool was replaced by abdominal imaging, thus allowing minimally invasive techniques to become the first choice of treatment. Currently, percutaneous needle aspiration (PNA) and percutaneous catheter drainage (PCD) have become standard methods for both single and multiple PLAs (see Chapter 28). Surgical debridement, done either in an open or laparoscopic fashion, has a limited therapeutic role for patients in whom nonoperative treatment fails or in those requiring surgical treatment for the underlying cause of the abscess. In addition, surgical exploration may be indicated as the initial procedure when coexistence of peritonitis is suspected as result of abscess rupture into the peritoneal cavity.

ETIOLOGY

During the nineteenth century, PLAs were well known as a complication of acute appendicitis. Since then, etiology and presentation have dramatically changed. Inflammatory abdominal diseases are no longer the most common underlying conditions for PLAs, being replaced in later decades by a higher incidence of biliary causes, including malignancies, immunocompromised status, and advanced age (Branum et al, 1990). In 1996, Huang and colleagues (1996) presented a review that spanned more than 40 years in the treatment of PLAs. They analyzed and compared patterns of clinical presentation in 80 patients treated between 1952 and 1972 with a second group of 153 patients treated from 1973 to 1993. The authors concluded that the increased incidence of biliary malignancies as a cause of PLAs was due to a more aggressive approach in the treatment of this pathology, which includes more frequent instrumentation of the biliary tree (see Chapters 28 and 50D). Hilar cholangiocarcinoma was the most frequent single condition found during the second period reviewed, with the use of biliary stents and broad-spectrum antibiotics leading to the emergence of mixed bacterial and fungal infections. Biliary malignancy was an important risk factor for hospital mortality (Lok et al, 2008).

Elucidating the subjacent condition that caused a liver abscess is as important therapeutically as the correct treatment of a PLA. In a simplified schema, infection may get to the liver by five different avenues: 1) portal vein, 2) hepatic artery, 3) biliary tree, 4) adjacent organ infection, and 5) direct trauma to the liver. The term *cryptogenic PLA* applies when no underlying pathology is identified (Box 66.1).

Portal pyemia is often a consequence of intraabdominal infection, such as acute appendicitis or diverticulitis. The incidence of this mechanism as a cause of PLA has markedly decreased in the past years. However, portal vein patency must be evaluated with Doppler US or dynamic CT scan in patients with PLAs. Gastrointestinal malignancies, such as colorectal adenocarcinoma or even gastric carcinoma, may also lead to a disruption of the mucosal barrier, leading to pyemia and liver abscess in the absence of liver metastasis (Tzur et al, 2003). This phenomenon should be particularly considered in the evaluation of patients with a cryptogenic PLA (Lim & Lim, 2004). Adequate investigation of etiology after PLA treatment may lead to a diagnosis of an underlying disease previously unknown for the patient (Mohsen et al, 2002).

Box 66.1

Classification of PLA According to the Underlying Mechanism of Dissemination

Hepatobiliary

Cholelithiasis
Benign strictures
Acute cholangitis
Periampullary tumors
Gallbladder cancer

Portal

Diverticulitis
Anorectal suppuration
Pelvic suppuration
Postoperative sepsis
Intestinal perforation
Pancreatic abscess
Appendicitis
Chronic inflammatory bowel disease
Colonic cancer
Gastric cancer

Arterial

Endocarditis
Vascular sepsis
Ear, throat, nose, or dental infection

Traumatic

Open or closed abdominal trauma
Chemoembolization
Percutaneous ethanol injection or radiofrequency ablation

Adjacent Abdominal Pathology

Acute cholecystitis
Gastroduodenal perforation
Colonic perforation

Cryptogenic

PLA, pyogenic liver abscess

Hematogenous spread of infection through the hepatic artery may also cause PLA. Frequent examples are bacterial endocarditis and intravenous drug abuse, but certain immunosuppressive conditions may also be associated with this mechanism. Liver cirrhosis is often associated with immunodeficiency, and the incidence of liver abscesses in cirrhotic patients compared with the general population is increased (see Chapter 9; Molle et al, 2001). Loss of hepatic filter function, impaired immunity, and frequent abdominal infections may also be responsible factors. Immunosuppressive drug use, alcoholism, chronic pancreatitis, pyelonephritis, and acquired immune deficiency syndrome are also associated with PLA (Huang et al, 1996).

The incidence of diabetes mellitus varies among different series, but its presence is associated with a 10-fold increased risk for PLA compared with that of the general population. Diabetes mellitus was the most common comorbidity in a report of PLA from Taiwan and was present in 41 (16%) of 253 patients with PLA (Chen et al, 2008a). Biliary pathology has become the most identifiable cause of PLA in recent decades (Alvarez et al, 2001a). In this group of patients, infection may have different etiologies. Bile duct strictures, common bile duct stones, and hepatolithiasis are benign conditions that may cause PLA (see Chapters 43 and 44). Benign diseases are more commonly reported in Asia (Lok et al, 2008); in Western countries, however, biliary malignancy is a more prevalent condition. Instrumentation of bile duct obstruction by endoscopic stenting or percutaneous drainage is a frequent cause of cholangitis and PLA. Malignancy is a predictor of higher recurrence and mortality rates. The mortality rate of PLA caused by underlying malignant disease is almost twice as high as that of nonmalignant disease (Yeh et al, 1998).

Direct liver contamination by adjacent organ infection may produce a PLA, with acute cholecystitis being the most common example (see Chapter 31). However, gastric and duodenal perforation directly into the liver may also give rise to a PLA. Perforation secondary to foreign bodies, mainly from fish bones, have been also reported. In addition, liver parenchyma may become infected after direct damage. Intrahepatic biloma, hematoma, and necrotic parenchyma are favorable conditions for development of a PLA. This is a well-known consequence of blunt or penetrating liver trauma and liver resections.

In recent decades, local treatments for liver tumors have become a widespread alternative for many patients. These local techniques include ethanol injection, transarterial chemoembolization (TACE), selective internal radiation therapy, and radiofrequency ablation (RFA) (see Chapters 83 through 85), which induce tumor necrosis either by chemical or thermal tissue destruction. In all these patients, PLA is a potentially life-threatening complication that may occur up to 5 months after a successful procedure. Transarterial liver embolization may be helpful in patients with hepatocellular carcinoma or liver metastases of gastrointestinal sarcomas and neuroendocrine tumors. The incidence of liver abscess after this procedure is low. Ong and colleagues (2004) reported PLAs in 0.26% of 3878 embolizations; the mortality rate in these patients was 33%. Patients with bilioenteric anastomosis are at particular risk for this complication. The odds ratio (OR) for developing PLA in this population was 894 in a series from Philadelphia (Kim et al, 2001). Subjacent pathology is not a predisposing factor for this complication (Song et al, 2001), but RFA of liver tumors may also cause a PLA. In a multicenter study from Italy, Livraghi and coworkers (2003) reported 2320 patients with 3554 lesions, with a 0.3% incidence of PLA. This incidence was slightly higher (1.7%) in another group of patients with hepatocellular carcinoma treated by RFA (Choi et al, 2005). De Baere and colleagues (2003) reported a 100% incidence of liver abscess in patients with prior bilioenteric anastomosis who underwent RFA. A further prospective analysis showed an incidence of PLA of 50% in patients with biliary diversions, but the risk was not increased if this diversion was performed synchronously with the ablation procedure (Elias et al, 2006).

In some patients with a PLA, no underlying cause is identified; they are considered to have a cryptogenic PLA. These cases account for up to 67% in some published data (Chen et al, 2008a). Etiology and presentation are summarized in Table 66.1.

INCIDENCE

PLA is a rare disease, and actual incidence rates are poorly described in the literature. However, recent investigations demonstrated a marked increase of PLA incidence in the general population in the last few years. Huang and colleagues (1996) showed that PLA accounted for 13 per 100,000 hospital admissions in 1973, which increased to up to 20 per 100,000 only 20 years later. In a recent study from a teaching hospital in the

Table 66.1

Demographics, Origin, and Mortality Rates of PLAs in Eastern and Western Series

Reference	No. Patients	Age (Years)	Diabetes (%)	Biliary (%)	Cryptogenic (%)	Solitary (%)	Right Lobe (%)	Mortality (%)

PLAs, pyogenic liver abscesses

United Kingdom, PLA had an incidence of 18.5 per 100,000 hospital admissions, with an estimated crude incidence of 2.3 cases per 100,000 the general population (Mohsen et al, 2002).

Two recent studies demonstrated this tendency in both Eastern and Western countries. In 2008, Tsai and colleagues published an analysis of PLA in the Taiwanese population from 1996 through 2004. The incidence of PLA rose from 11.15 to 17.59 cases per 100,000 inhabitants over the period of study, with more than 30,000 cases occurring in this period. Of these patients, 62% were male; the age of highest incidence in men was 80 to 84 years, and for women it was 85 to 89 years. Factors associated with PLA were diabetes, malignancy, renal disease, and pneumonia. Mortality rates, however, decreased from 12.33% in 1996 to 9.72% in 2004.

The second, a national series from Denmark (Jepsen et al, 2005), analyzed 1448 cases in a 25-year period; 54% were male. The incidence of PLA in Danish men was 6 per million in 1977 and 18 per million in 2002. In women, the incidence rose from 8 per million to 12 per million in the same period. Mortality rates in 1977 were 40% and 50% for men and women, respectively, and decreased to a global 10% in 2002.

CLINICAL PRESENTATION

Liver abscesses may have a broad array of symptoms and physical findings, which may vary according to the patient's underlying condition. Cryptogenic lesions are often found after several days of nonspecific symptoms. The most frequent clinical features include fever of more than 38° C and chills. Other symptoms that may be present are general malaise and anorexia. Patients may also have abdominal pain, nausea and vomiting, diarrhea, and weight loss. Although more often found with abscesses of biliary origin, jaundice may be an indicator of systemic sepsis response, and septic shock may be a dramatic form of the presentation. There are no significant differences in clinical presentation between single and multiple lesions, although single PLAs are more frequent in the right lobe of the liver. These symptoms may be present from several days up to several weeks before hospital admission (Chou et al, 1997; Seeto & Rockey, 1996). In another group of patients, PLA is a consequence of an underlying pathologic process that may lead to a faster diagnosis. Benign or malignant biliary disease, intraabdominal infections, and abdominal surgery are frequent causes of abscesses, and imaging studies should be systematically carried out to exclude the presence of a PLA in a septic patient.

Finally, some patients may be seen with systemic complications as a result of metastatic septic lesions that originate from a PLA. Although rare, cases of endophtalmitis; meningitis; cellulitis; lung abscess; prostate, kidney, and joint infections; pulmonary embolisms; and even cardiac tamponade due to pericardic effusion have been reported in the literature (Cahill et al, 2000; Vong et al, 2007). Infection by *Klebsiella pneumoniae* genotype K1 and an underlying condition of immunosuppression resulting from diabetes mellitus and alcoholism may be predisposing factors for these complications (Chen et al, 2006; Fang et al, 2007).

DIAGNOSIS

The most common laboratory findings are nonspecific alterations as a result of infection. In a large series from Hong Kong, low albumin levels were found in 92.8% of patients presenting with PLAs (Lok et al, 2008). Leukocytosis (74.8%), increased alkaline phosphatase (72.1%), and elevated alanine aminotransferase levels (ALT; 58.6%) were frequent laboratory abnormalities also present in these patients. Jaundice may be seen in up to 50% of patients, and alkaline phosphatase, gamma-glutamyl transferase, erythrocyte sedimentation rate, and glutamic oxaloacetic transaminase levels are usually elevated (Cosme et al, 2010). Alvarez and colleagues (2001) analyzed laboratory data obtained from patients younger than and older than 60 years. The only significant difference between these two groups was that older patients tended to present with higher blood urea nitrogen and serum creatinine levels. Hemoglobin level, serum C-reactive protein, blood urea nitrogen, creatinine levels, prothrombin time, and total bilirubin levels must be part of systematic laboratory tests in patients with PLA.

Some findings at presentation may be prognostic and associated with increased mortality rate. Chen and colleagues (2008b) presented a review of 72 patients admitted to the intensive care unit. Low levels of serum albumin, increased serum creatinine, and prolonged prothrombin time were significant risk factors for death. These authors' findings are shown in Table 66.2.

The clinical investigations used to evaluate liver abscesses have changed in recent decades. Plain radiographs may be part of the routine evaluation, but these play a minor role in PLA diagnosis. Indirect findings in chest and abdominal radiographs may include atelectasis, an elevated right hemidiaphragm, pleural effusion, enlargement of the liver shadow, and exceptionally an air-fluid level in gas-forming bacterial infections.

US imaging is usually the first diagnostic approach in these patients. Although US examination may not detect small lesions and those located on the dome, it has several advantages. It is fast, inexpensive, and provides information about biliary tract

Table 66.2

Laboratory Data of 72 Patients with PLA on the First Day of Intensive Care

Variable	Survivors (n = 52)	Nonsurvivors (n = 20)	*P* Value
WBC count (103/mm^3)	16.5 ± 18	16.4 ± 14	.99
Hemoglobin (g/dL)	11.3 ± 2	10.4 ± 3	.17

PYA, pyogenic liver abscess; *WBC*, white blood cell; *ALK-p*, alkaline phosphatase; *AST*, aspartate aminotransferase; *ALT*, alanine aminotransferase; *BUN*, blood urea nitrogen

From Chen SC, et al, 2005b: Comparison of pyogenic liver abscesses of biliary and cryptogenic origin: an eight-year analysis in a University Hospital. Swiss Med Wkly 135:344-351.

and gallbladder pathology, the most prevalent conditions that predispose to PLA. The images obtained by this procedure vary according to different stages of evolution of the disease. Anechoic images are infrequent, with most lesions being hypoechoic; most abscesses present with a smooth wall, which thickens with chronicity. Some abscesses have inhomogeneous content, and if pus becomes thick, the lesion may be confused with liver parenchyma. Gas within an abscess is hyperechoic and casts shadows. Doppler scan should be routinely performed; this may help in differentiating solid tumors, show vessels surrounding the abscess, and, most importantly, evaluate portal vein patency.

CT has a sensitivity of more than 97% in detecting PLA and is considered the most important imaging modality. Examination should be routinely performed with intravenous contrast enhancement. During the arterial phase, parenchyma surrounding the abscess may show segmental enhancement as a result of altered portal microcirculation in the infected tissue. The typical CT image description of PLA is that of a target-like sign (see Chapter 16) that appears as a single or multiloculated mass with a central hypodense region and peripheral contrast enhancement during the portal phase of examination.

CT scan offers the advantage of detecting other intraabdominal pathology that may be the cause of the abscess, such as acute diverticulitis or appendicitis. It may also provide information about portal vein patency and may demonstrate local complications that may include pleural effusion, vascular complications, and spontaneous rupture into the peritoneal cavity, retroperitoneum, and even the pericardium (Yang et al, 2004b). Finally, CT scan is generally necessary to guide percutaneous drainage of the abscess (Fig. 66.1).

Magnetic resonance imaging (MRI) is an alternative to CT for the diagnosis of PLA. In MRI sequences, PLA appears much the same as other fluid-containing lesions: hypointense in T1-weighted and hyperintense in T2-weighted images. After contrast administration, most PLAs show a hyperintense enhancement rim, which may persist in later phases (Balci et al, 1999). Infected tumors or metastases may show the same pattern, and differentiation by MRI may be difficult, although diffusion techniques may play a role in distinguishing between benign and neoplasic lesions. MRI is not widely accepted as a first-line diagnostic approach for several reasons: examinations take more time, patient cooperation is needed, and MRI cannot be used as guidance for percutaneous treatment. Nevertheless, it has the advantage of providing data regarding the biliary tract in patients with underlying biliary pathology, findings that could change the therapeutic approach (Fig. 66.2).

Nuclear medicine has a limited role in PLA diagnosis, but in case of doubt, it may be helpful for detecting intraabdominal abscesses. This may be important, for example, in a patient with polycystic liver disease and suspected infection of a single lesion. Indium-111 leukocyte scintigraphy readily detects most hepatic abscess. Gallium-67 may also be used, but it is normally taken up by the liver, making interpretation of the results more difficult. In both cases, prior technetium-99m sulfur colloid scan provides more diagnostic accuracy (Youssef et al, 2005).

Conflicting results have been reported regarding PLA characteristics according to different origins (Chen et al, 2005). Single lesions tend to be cryptogenic, whereas multiple abscesses are more likely to have a biliary origin (Alvarez et al, 2001). Regardless of etiology, patients are most commonly seen initially with a single lesion (Chan et al, 2005). In both single and multiple forms, abscesses are more frequently located in the right hepatic lobe, followed by a left and bilateral distribution (Chen et al, 2008a; Seeto & Rockey, 1996).

A PLA less than 2 cm in diameter is described as a *microabscess*. Multiple microabscesses may present as widely scattered lesions or with a cluster pattern that tends to aggregate focally (Ralls, 2002). The diffuse miliary pattern of pyogenic microabscesses is usually staphylococcal in origin, the result of hematogenous spread of an endovascular infection. The cluster pattern is often associated with coliform and enteric organisms and may occur in cholangitic abscesses secondary to biliary obstruction. It is probable that the clustering of pyogenic microabscesses is an early stage of an evolving pyogenic abscess cavity, and the tendency of coliform microabscesses to coalesce into a larger abscess with intercommunicating cavities explains the success of single-catheter drainage of multiseptate PLAs.

MICROBIOLOGY

Although PLAs may originate from a broad spectrum of microorganisms, the underlying etiology and geographic location of PLAs are often related to specific pathogens. Identification of pathogens may be achieved by direct puncture of the abscess or by blood cultures. The positive abscess culture rates are higher than those of blood culture samples, and only up to 50% of patients with PLA have both cultures positive (Chen et al, 2005). Moreover, negative abscess cultures may be found in 20% of patients (Lok et al, 2008). Poor culture technique may be the reason in some cases, but negative cultures can also be caused by the use of broad-spectrum antibiotics before cultures are obtained. Patients with cryptogenic PLAs are more likely to have negative cultures from the blood, whereas patients with PLAs secondary to biliary tract disorders are more likely to have positive cultures from blood and aspirated pus (Seeto & Rockey, 1996).

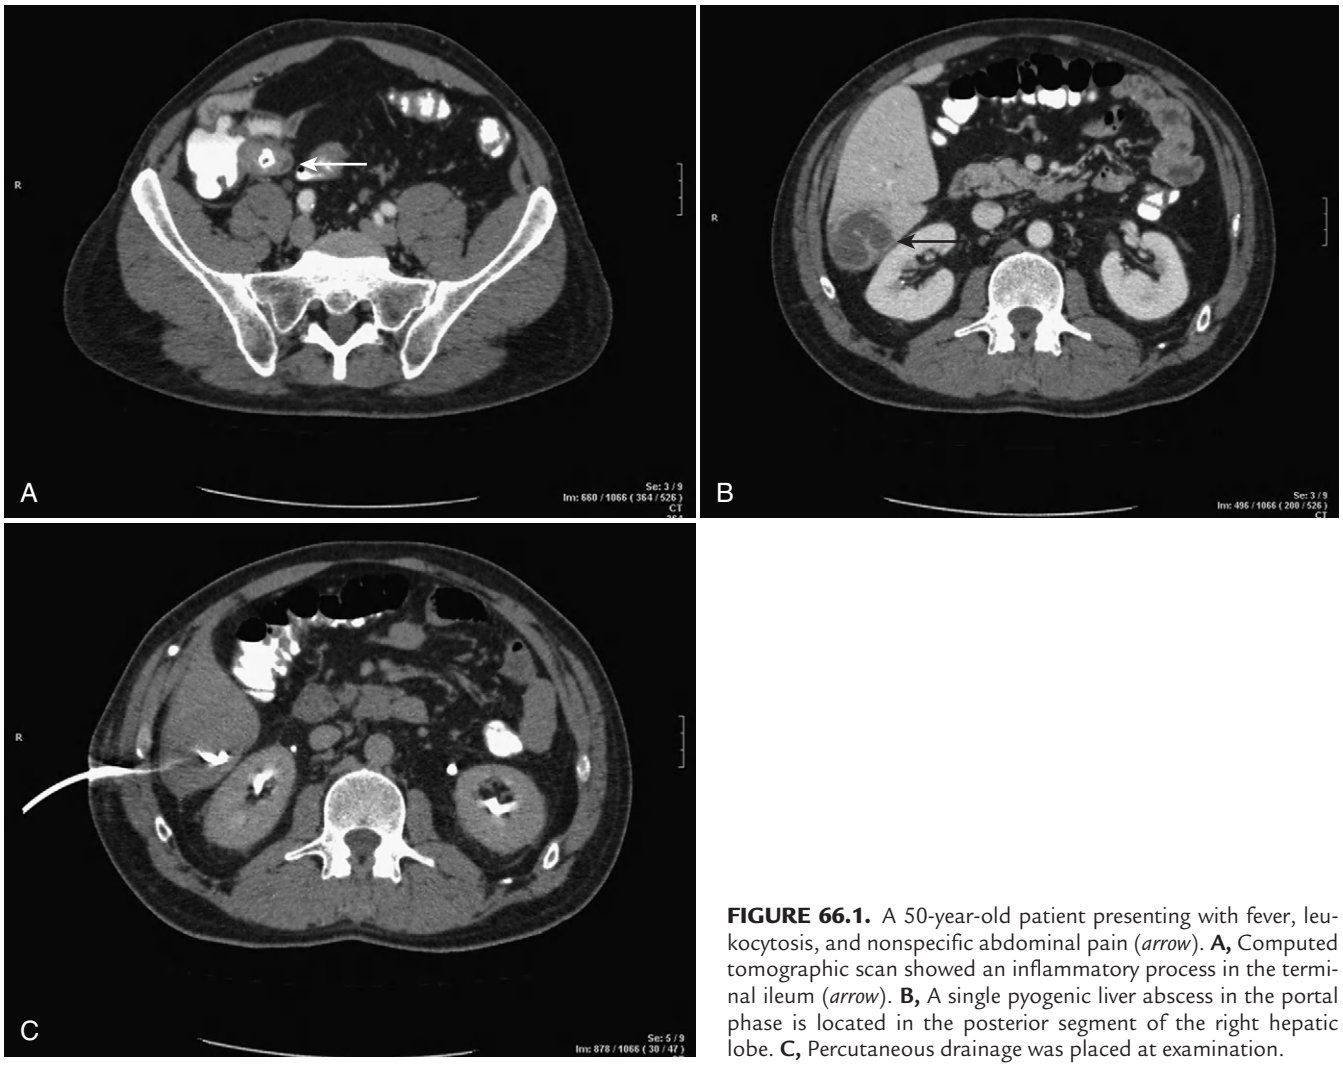

FIGURE 66.1. A 50-year-old patient presenting with fever, leukocytosis, and nonspecific abdominal pain (*arrow*). **A,** Computed tomographic scan showed an inflammatory process in the terminal ileum (*arrow*). **B,** A single pyogenic liver abscess in the portal phase is located in the posterior segment of the right hepatic lobe. **C,** Percutaneous drainage was placed at examination.

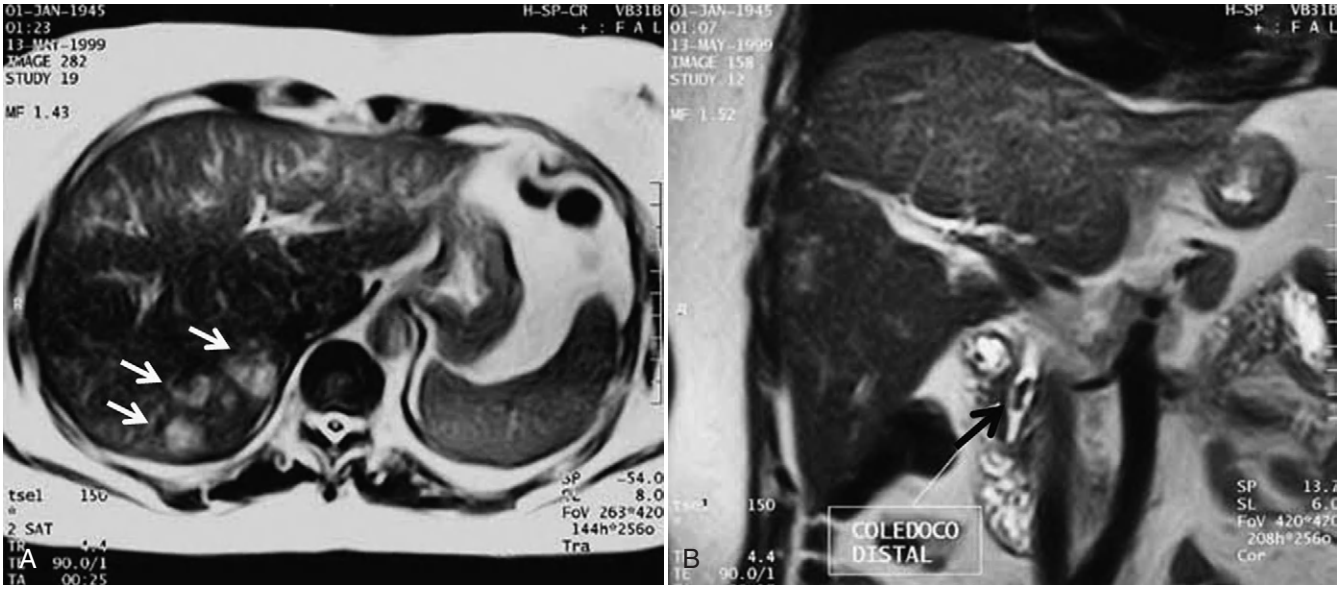

FIGURE 66.2. **A,** Magnetic resonance (MR) image of the liver showing three small pyogenic liver abscesses (PLAs) in the right posterior segment of the liver (*arrows*). **B,** MR cholangiopancreatography demonstrates a stone in the distal common bile duct originating the PLAs (*arrow*).

In Asian populations, *Klebsiella pneumoniae* is the most frequent pathogen associated with cryptogenic PLAs. The incidence of infection with *K. pneumoniae* appears to have markedly increased in this population, ranging from 50% to 88% of all cases occurring in Taiwan in the last few decades to become an endemic disease. Diabetes mellitus is suggested to be an important risk factor, but the pathogenesis is still unclear. No mutations or clonal spread strains have been found. Environmental or host factors may be responsible for the different incidence rates in Asia compared with Western series (Cheng et al, 2002). Although PLAs secondary to *K. pneumoniae* infections are associated with an increased risk of septic metastases, overall mortality, even in diabetic populations, is decreased in this group of patients (Tsai et al, 2008; Yang et al, 2004a).

Gas-forming PLAs are uncommon and often associated with compromised immunity in diabetic patients, and they present higher mortality rates than non–gas-forming PLAs. *Escherichia coli, Enterobacteriaceae,* and *K. pneumoniae* are well-known gas-forming microorganisms. The mechanisms of gas formation involves mixed acid fermentation of glucose, increased production of gas, impaired transportation of gas, and equilibrium between the gas in local tissues and that in abscesses (Lee et al, 2004).

E. coli is the most common pathogen in Western countries, in both monomicrobial and polymicrobial isolates, followed by *Streptococcus milleri.* Anaerobes may also be cultured from PLAs, and *Bacteroides* spp. are the most common isolated organism (Alvarez et al, 2001b; Mohsen et al, 2002).

An abscess secondary to biliary tract disease or originating from a gastrointestinal source is more likely to be polymicrobial with aerobic gram-negative organisms and anaerobes. PLAs that result from hematogenous spread, on the other hand, are more likely to be monomicrobial, and staphylococci and streptococci are the most frequent bacteria isolated in these patients. A summarized spectrum of possible pathogens is listed in Box 66.2.

PLAs, pyogenic liver abscesses

TREATMENT

The basis for treatment of PLAs relies on complete drainage of pus and infected debris, initiation of adequate antibiotic therapy, and resolution of the underlying cause. Modern imaging techniques allow accurate diagnosis, localization, and assessment of dimensions and actual number of lesions. US is usually performed as the initial diagnostic approach, and CT scan should be routinely performed, either in cryptogenic suspected lesions or in secondary abscesses. The aim of CT examination is to achieve a complete evaluation of the abdominal cavity to asses any underlying condition that may need further or concomitant treatment. If a biliary origin is suspected, MR cholangiopancreatography may be useful to assess the hepatic abscess and completely evaluate the biliary tree. Abdominal imaging has replaced surgical exploration as a diagnostic tool, making possible the high success rates of the percutaneous approach.

Over the past several years, treatment of PLAs has shifted toward minimally invasive percutaneous treatment. Nevertheless, treatment options include a wide spectrum that ranges from antibiotic therapy alone to major operative interventions that could include liver debridement and/or resection. Adequate antibiotic selection is critical in the treatment of PLAs. Blood samples should be obtained before starting antibiotics, if possible, but not at the expense of treatment delay in an unstable patient. Broad-spectrum parenteral therapy must begin as soon as possible. Fine needle aspiration (FNA) or percutaneous drainage may increase the risk of bacteremia, even in stable conditions, so close monitoring of the patient during and after the procedure is always indicated.

The choice of the antimicrobial agent depends of the epidemiology, the patient's background, and the underlying disease if present, and should be adjusted according to geographic differences and local antimicrobial treatment policies. Empiric treatment of a cryptogenic abscess should be directed to cover the most commonly found organisms: gram-negative bacilli, anaerobes, and microaerophilic streptococci. A classic regimen of ampicillin, an aminoglycoside, and metronidazole may be a first therapeutic approach. Other options include combinations of third-generation cephalosporins or quinolones with metronidazole.

Patients who come to medical attention with secondary PLAs should be treated according to epidemiology and risk factors. Abscess secondary to acute cholangitis after biliary instrumentation and postoperative abscess after abdominal surgery should be treated as nosocomial infections, with a distinct epidemiology and flora compared with cryptogenic lesions. Antibiotic selection should be based primarily on the patient's clinical history and local resistance patterns. Imipenem-cilastatin, vancomycin, and piperacillin-tazobactam therapies should be considered in these cases. A sample culture, whenever possible, is mandatory, and when information regarding the organism and antibiotic sensitivity becomes available, modifications can be instituted.

PLAs must be treated with a prolonged course of antibiotics. Initially, antibiotics should be administrated parenterally. This therapy must be maintained until stabilization of the patient's condition is achieved and for at least 2 weeks thereafter. Criteria for clinical stability include subjective and objective evidence of improvement in the inflammatory response produced by the infection. The patient should be afebrile, with a white cell count

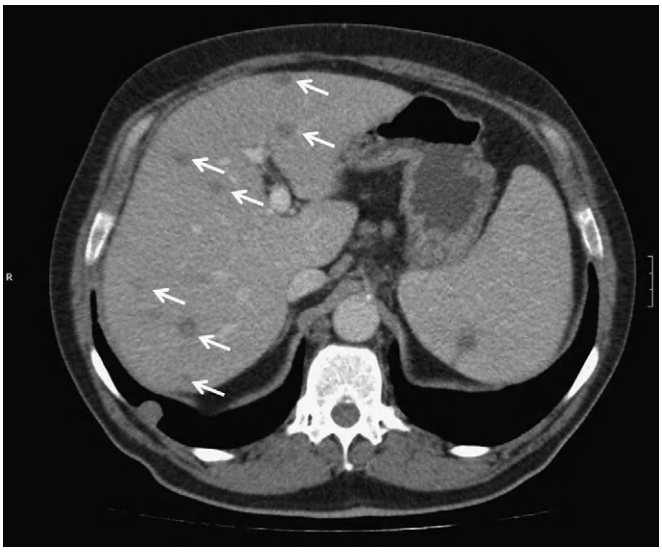

FIGURE 66.3. Multiple microabscesses (*arrows*) in a patient after left colectomy as a result of colon carcinoma. He received intravenous antibiotic therapy for 6 weeks and recovered.

trend toward normal and adequate oral intake and gastrointestinal absorption. The patient may then be switched to oral antibiotic therapy, perhaps even continued on an outpatient basis for at least 2 more weeks. This sequential modality has proven effective in the treatment of PLAs compared with continuous intravenous administration, reducing both the cost of therapy and the length of hospital stay (Ng et al, 2002).

Drainage of all lesions may not be possible in patients with multiple small abscesses. In such cases, percutaneous puncture of any of the abscess may be indicated for isolation of the causative bacteria for a rational antibiotic therapy (Fig. 66.3). If a biliary origin of these lesions is suspected, biliary decompression is mandatory, either by endoscopic, percutaneous, or surgical means (see Chapters 27 through 29). The mortality rates reported in patients with multiple liver abscesses are high, ranging from 22% to 44%. However, Giorgio and colleagues (2006) reported 0% mortality in 39 patients treated with an aggressive approach consisting of percutaneous needle aspiration of all visible lesions under sonographic guidance and antibiotic therapy.

Drainage of pus is usually necessary for an effective resolution and to shorten the duration of antibiotic therapy, especially in lesions greater than 5 cm in diameter. Drainage can be achieved by nonsurgical methods, such as percutaneous catheter drainage (PCD) or percutaneous needle aspiration (PNA). Either open drainage or laparoscopic drainage approaches can be used surgically.

PERCUTANEOUS TREATMENT

Percutaneous drainage is a safe and effective treatment for almost all PLAs (Pearce et al, 2003; see Chapter 28). This procedure can be performed under sonographic or CT guidance. The US exam provides real-time guidance of the needle, and it is fast and reliable (Fig. 66.4). Fluoroscopy control and operating theaters under aseptic conditions are recommended. The freehand technique allows dynamic changes in the needle pattern and does not have the limitations of attached needle guides. CT guidance is recommended for multiple abscess drainage, when multiple catheters may be placed or in cases of hazardous anatomic locations. Local anesthesia and minimal sedation is used for most of these procedures (Giorgio et al, 2006).

After aspiration of a PLA to obtain samples for culture and to confirm the diagnosis, the treatment options are complete aspiration of pus (PNA) or catheter drain insertion (PCD). Controversy persists regarding the optimal procedure, particularly for small abscesses. The first randomized trial conducted by Rajak and colleagues in 1998 showed 100% resolution of PLAs in the PCD group with a 60% success rate in the FNA group. Although FNA patients were given only a second chance of aspiration before placing a PCD, the thickly viscous nature of the pus was considered a major cause of failure in this group. In a subsequent randomized study conducted by Yu and colleagues in 2004 using intermittent needle aspiration, no significant differences were found between PCD and FNA, suggesting that FNA may be as effective as catheter drainage. However, a tendency toward a shorter hospitalization and lower mortality rate was found in the FNA group. Finally, a third trial randomized 60 patients to FNA or PCD (Zerem & Hadzic, 2007). The authors succeeded in all 30 patients undergoing one or two PCDs. In the FNA group, a 33% failure rate was reported after three aspiration procedures. None of the patients with multiloculated lesions was effectively treated by FNA. The authors recommended PCD as first-line treatment option but considered FNA a valid alternative in simple abscesses smaller than 50 mm in diameter. Several nonrandomized studies report experiences with both therapeutic approaches with good results. The clinical experience of the treating physicians is important in the evaluation of each patient. FNA could be considered as an alternative to routine PCD in patients with small uniloculated lesions, no viscous content, and with no communication with the biliary tree.

Placement of a PCD may cause bacteremia in spite of antibiotic administration. The most important preventive measure is to avoid excessive manipulation of infected pus. Overdistension of the abscess with contrast agents during the procedure and saline injections to wash the cavity are associated with an increased risk of bacteremia and are therefore not recommended (Thomas et al, 2006). Flushing the catheter may be useful for maintaining its patency, especially in cases of viscous pus. Furthermore, in such cases, larger catheters may be needed to drain the cavity efficiently. In some cases, after apparent successful drainage, imaging may show incomplete evacuation of the abscess cavity, and repositioning of the catheter or even placement of additional catheters may be necessary. An intercostal approach may cause pneumothorax, pleural effusion, or contamination of the pleural space, and a chest tube should be placed without removal of the abscess drain.

Failure of PCD may occur in up to 10% of patients, and the chronicity of a PLA may result in a thick, fibrous rind that will not collapse. In other cases, a cluster of abscesses may be misinterpreted as a multiloculated PLA on imaging, and the absence of communication with the main cavity results in incomplete drainage. Persistent drainage of bile through the catheter after several days or weeks is commonly seen when the abscess communicates with the biliary tree (Fig. 66.5). Endoscopic retrograde cholangiopancreatography with endoscopic sphincterotomy and transpapillary stent may help resolve this problem.

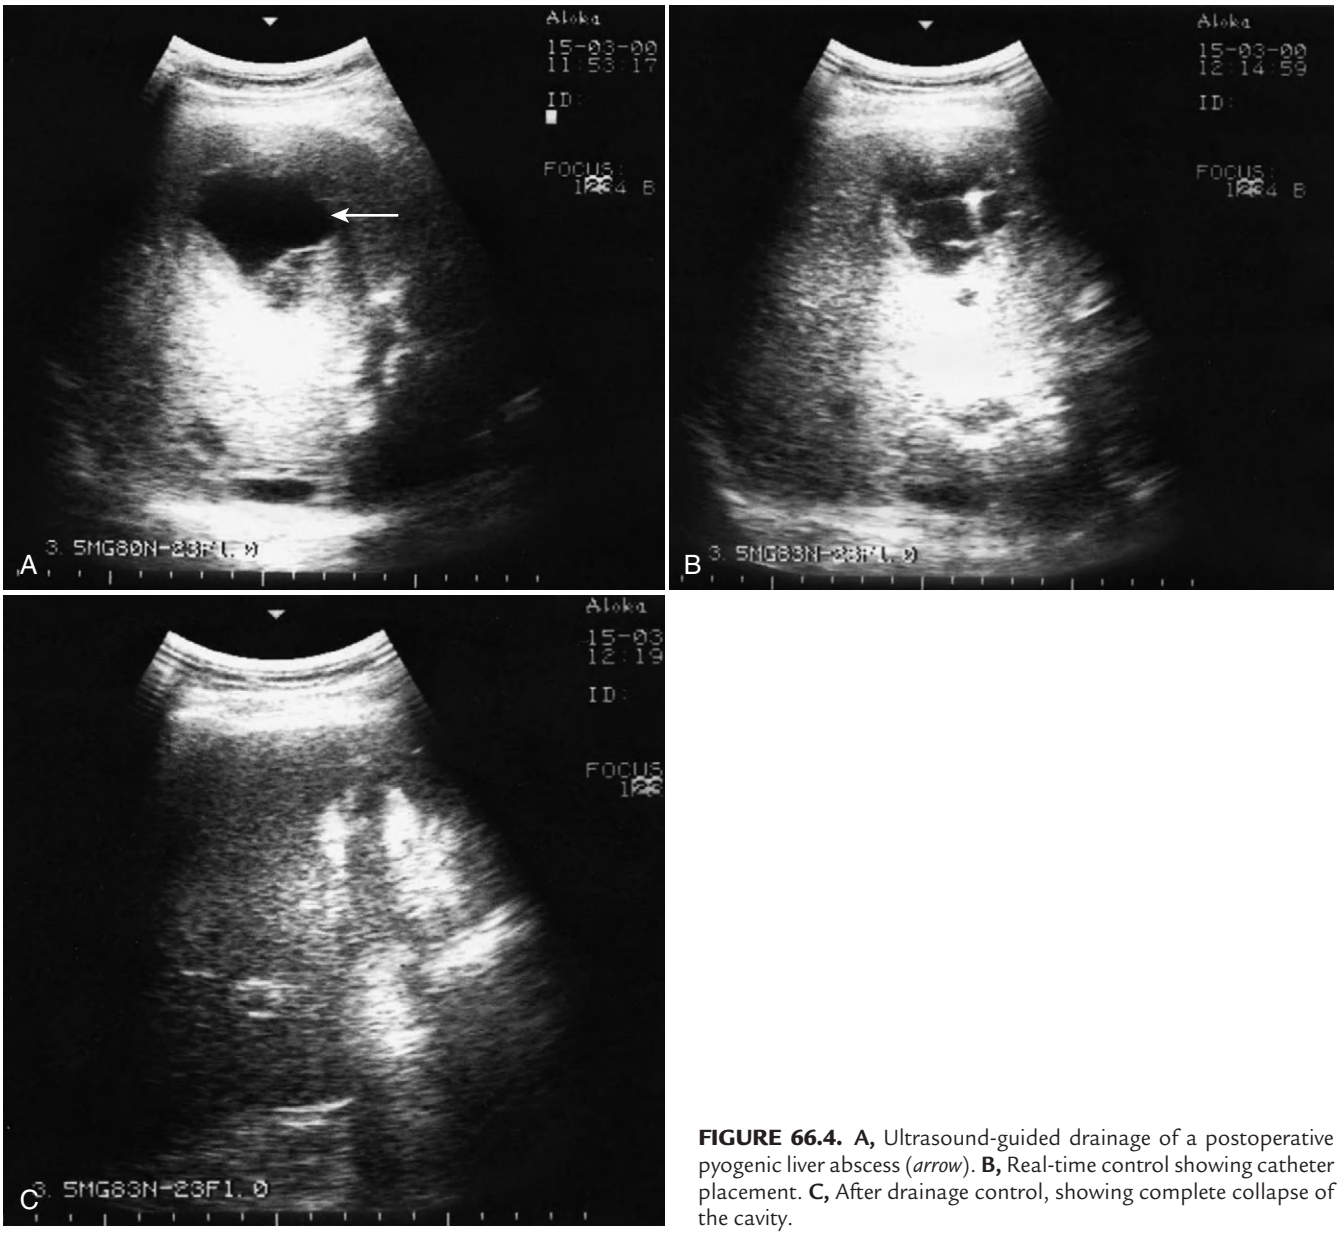

FIGURE 66.4. **A,** Ultrasound-guided drainage of a postoperative pyogenic liver abscess (*arrow*). **B,** Real-time control showing catheter placement. **C,** After drainage control, showing complete collapse of the cavity.

Sugiyama and Atomi (2002) found that in all cases of biliary communication, complete cure of abscesses after PCD required additional treatment to relieve the obstruction.

SURGICAL TREATMENT

Surgical treatment of PLAs as a first therapeutic approach is not usually indicated. Percutaneous procedures have been increasingly performed, leaving surgical drainage to salvage cases where percutaneous treatment fails (Tan et al, 2005). However, surgical treatment of PLAs may be indicated in certain specific clinical situations.

Primary surgical therapy is indicated in patients with intraperitoneal rupture, in which complete exploration and lavage of the abdomen are indicated. Laparoscopic approach combined with intraoperative US examination appears to be a minimally invasive therapeutic option for this rare condition (Siu et al, 1997). In some other patients, surgery may be indicated for the treatment of complications of the percutaneous drainage, such as bleeding or intraperitoneal leakage of pus.

Patients with an underlying pathology that needs surgical resolution can undergo treatment for the liver abscess during the same operation, such as cases of acute cholecystitis presenting with an adjacent abscess. It must be emphasized, however, that percutaneous drainage is indicated if surgery must be delayed for further stabilization of a critically ill patient.

Large, multiloculated abscesses containing thick pus are more prone to not respond to percutaneous treatment. In these patients, complete evacuation and removal of necrotic tissue and debris may be more easily achieved surgically (Hope et al, 2008). Percutaneous drainage may, on the other hand, delay effective treatment, which would increase the number

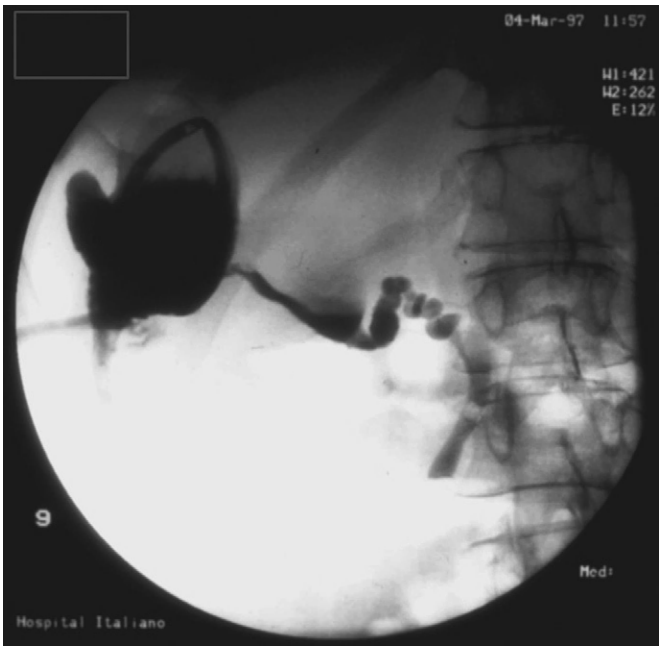

FIGURE 66.5. Percutaneous fistulogram showing a pyogenic liver abscess in communication with the gallbladder and the presence of a common bile duct stone.

of treatment failures, secondary procedures, and the length of hospital stay (Tan et al, 2005). Failure to institute appropriate surgical treatment in a timely fashion could be harmful in critically ill patients who require urgent resolution of the septic illness (Hsieh et al, 2008) and in whom salvage surgery may be associated with a mortality rate of 46% (Ng et al, 2008). However, a multidisciplinary team of surgeons and interventional radiologists is mandatory for treating patients in these complex situations. Laparoscopic drainage may play an important role in diminishing wound-related complications. With a laparoscopic approach, intraoperative US plays an important role to assess location and extension of the lesion (Yeh et al, 2007); however, it should be emphasized that an open approach should be used if there is any question regarding the adequacy of drainage achievable laparoscopically. No prospective studies compare open versus laparoscopic approach in the treatment of PLAs. Wang and colleagues (2004) presented a retrospective comparison of five patients treated with open drainage with 18 patients who underwent laparoscopic approach. Although mortality rate in the series was 0%, the laparoscopic group had shorter operating times and earlier oral intake in the postoperative period with less intraoperative blood loss and shorter hospitalization. Given the bias associated with patient selection, these results cannot be taken as evidence of the superiority of the laparoscopic approach but only as evidence that laparoscopic treatment is feasible in selected patients.

In all cases, when operating on a patient with a PLA, localization of the abscess should be assisted by means of intraoperative US for a complete examination of the liver to exclude associated lesions. In superficial lesions, the pus can be evacuated with needle aspiration to avoid peritoneal contamination, and the abscess cavity can then be opened to break up loculations and remove any debris from the cavity wall. Closed suction drainage should be considered in most cases. In lesions located deep within the liver parenchyma, an extended hepatotomy to reach the lesion may be necessary, but this maneuver may increase the risk of postoperative bile leak; for these cases, the placement of intrahepatic catheter drainage under US guidance may be an effective alternative.

Liver resection for the treatment of PLAs is rare because almost all PLAs can be cured by either percutaneous or operative drainage, but in some cases, PLAs with different physical and etiologic characteristics may need a different surgical approach. Liver atrophy and multiple abscesses may be the consequences of chronic obstruction of a segmentary bile duct branch as a result of hepatolitiasis or intrahepatic strictures (see Chapters 39, 42, and 44). Resection of the affected liver segments is the recommended treatment for these patients. Although more frequent in the left lobe, this condition may also be present in the right lobe of the liver. This aggressive approach is also indicated for multiple pyogenic abscesses with severe destruction of surrounding liver parenchyma (Chou et al, 1997). In an impressive series, Strong and colleagues (2003) reported 49 patients who underwent liver resections for PLAs over a 15-year period. Indications for surgery were failure of medical treatment or underlying hepatobiliary pathology. Two deaths (4%) occurred after intraperitoneal rupture of the PLA.

TREATMENT SUMMARY

Parenteral antibiotic therapy should be started as soon as possible in patients with PLAs. In stable patients, blood specimen samples for culture before therapy can be useful, but delaying therapy is not advisable. A combination of ampicillin, aminoglycoside, and metronidazole or a third-generation cephalosporin plus metronidazole are both effective schemes for therapy. In multiple small lesions, FNA under CT or US guidance is advised to obtain samples for culture. Solitary nonloculated cysts smaller than 50 mm can be treated by puncture and aspiration alone, but biliary tree communication must be excluded in these cases; otherwise, a PCD must be placed.

Imaging and clinical response are good indicators of treatment success. On occasion, a residual cavity may persist despite drainage. In this situation, if the patient remains asymptomatic and the lesion imaging is stable, no further procedure may be needed (Johannsen et al, 2000). After clinical stabilization, antibiotics may be switched to oral administration. A complete course of 4 weeks of antibiotics is recommended, although some authors suggest 2 weeks of treatment (Bowers et al, 1990).

Surgical debridement is indicated for the failure of nonoperative approaches for suspected intraperitoneal rupture of the abscess or in patients who need surgery to address underlying pathology. Laparoscopic drainage may be attempted in these cases. Finally, liver resection may be indicated in patients with hepatolithiasis, complex bile strictures, or liver atrophy.

OUTCOME AND PROGNOSIS

After successful treatment, recurrence of a PLA is rare; however, it is important to differentiate PLA recurrence from relapse as a result of incomplete treatment. Some patients with underlying risk factors may be at risk for recurrence. Cheng and colleagues (2008) reported 601 patients with PLAs with a median follow-up of 72 months. Recurrence rates were low in the cryptogenic (2%) and diabetes (4.4%) groups compared with those whose disease was of a biliary origin (23.8%). Except for

patients with biliary pathology, recurrences tended to be caused by the same organisms that generated the first PLA. However, the authors found no difference in recurrence rates comparing *E. coli* and *K. pneumoniae* organisms as causative agents.

PLA is a potentially life-threatening disease. Since the first report by Oschner in 1938, improvement in antibiotic therapy, new imaging techniques, and minimally invasive procedures have significantly decreased mortality. In series published in the last decades, mortality rates ranged between 6% and 20% (Chung, 2008). Although different prognostic factors have been identified in patients with PLAs, others remain controversial. Abscesses caused by *K. pneumoniae* have a higher risk of metastatic infection; however, mortality rates in these patients are lower compared with those whose PLA is caused by other organisms, even if compared with *E. coli* infections (Yang et al, 2004a). Diabetes is a well-known risk factor for PLA, but mortality rates in patients with diabetes are not increased compared with the general population in both Eastern and Western series (Alvarez et al, 2001; Tsai et al, 2008). Liver cirrhosis is a strong risk factor for developing PLA and is associated with poor prognosis and high short-term mortality rates (Molle et al, 2001). In general, the prognosis of patients with malignancy is poor, but in the absence of comorbidities, age is not associated with worse prognosis (Alvarez et al, 2001a).

Systemic response to septic injury is a major determinant of outcome. This may be indicated by the presence of septic shock, clinical jaundice, coagulopathy, leukocytosis, and hypoalbuminemia. An Acute Physiologic, Age, and Chronic Health Evaluation (APACHE II) score at admission of 15 or higher, multidrug-resistant isolates, gas-forming abscess, anaerobic infections, and a blood urea nitrogen level of 7.86 mmol/L or greater have been identified as high mortality–associated risk factors (Chen et al, 2008a).

CHAPTER 67

Amebiasis and other parasitic infections

Hany Dabbous, Hosein Shokouh-Amiri, and Gazi Zibari

AMEBIC LIVER ABSCESS

History

The earliest report of amebiasis is probably the Sanskrit document *Brigu-samhita,* written about 3000 BCE, referring to bloody mucoid diarrhea (Vaidya & Ray, 1982). Assyrian and Babylonian texts refer to blood in the feces, suggesting the presence of amebiasis in the Tigris-Euphrates basin before the sixth century BCE (Bray, 1996), and it is possible that hepatic and perianal abscesses described in both *Epidemics* and *Aphorisms* in the *Corpus Hippocratorum* refer to amebiasis (Jones et al, 1948; Jones & Whithington, 1953). After the death of Hippocrates in 356 BCE, Alexander the Great became king of Macedonia. In Alexander's eastern campaign, he reached an area where amebiasis was endemic, and he died on the return trip at the age of 33 years, probably of an amebic liver abscess (Saville, 1964).

In 1818, Ballingall described a surgical technique to drain liver abscesses. When Ballingall practiced in Madras, India, Napoleon Bonaparte was exiled on the tropical island of St. Helena by the British after his defeat at Waterloo, where bloody diarrhea—possibly amebiasis—was common. Napoleon died in 1821 after an attack suggestive of amebic liver abscess, with symptoms of fever, diarrhea, and painful, tender swelling in the epigastrium. At the postmortem, an ulcer was found at the small curve of the stomach, communicating with the liver, suspected to be due to rupture of an amebic liver abscess of the left lobe into the stomach (Chaplin, 1913). In 1828, James Annesley gave detailed descriptions of "hepatic dysentery" (Kapoor, 1979). The connection between amebic dysentery and liver abscesses was described by the English physician William Budd (1857), but Charles Morehead, professor of Medicine and first principal of Grant Medical College, Bombay, India, was the first to report a case of hepatic abscess in 1848 (Martinez Baez, 1986).

Entamoeba histolytica was discovered by Friedrich Lösch in 1873 in Russia (Lösch, 1975). Lösch recognized amebae in the colon and terminal ileum accompanying acute dysentery (Martinez Baez, 1986). He gave descriptions of amebae, including structure, size, motility, intracytoplasmic elements, and drawings. Lösch named the amebae after his patient; *Amoeba coli* was proved later on sequencing of the genome (Tovar et al, 1999), and a calreticulin-like protein and Golgi apparatus were detected in the amebae (Gonzalez et al, 2002).

Stephanos Kartulis, a Greek physician, found amebae in intestinal ulcers in patients from Egypt in 1885 and noted that he never found amebae from nondysenteric cases (Kartulis, 1886). In 1890, Osler reported a young physician who died of amebic liver abscess (ALA) after an attack of dysentery. The report by William Thomas Councilman and Henri Lafleur, working at Johns Hopkins in 1891, represents a definitive statement about the pathology of amebiasis, amebic dysentery, and ALA at the end of the nineteenth century (Faust, 1931). Schaudinn did differentiate between harmless *Entamoeba coli* and pathogenic *E. histolytica* (Martinez Baez, 1986). In 1901, Harris produced ALAs by intrarectal infection of puppies with *E. histolytica.* Musgrave and Clegg (1904) cultivated *E. histolytica* in vitro, introducing the term *amebiasis.* In 1952, Hoare reported that *E. histolytica* had three phases. Species of amebae found in human host; *E. gingivalis, Entamoeba coli, Iodamoeba bütschlii,* and *E. hartmanni* were discovered between 1849 and 1919 (Martinez Baez, 1986).

A plant alkaloid, concessine, was found to kill *E. histolytica* (Vaidya & Ray, 1982). The first effective treatment came from Brazil in the form of ipecac; emetine was isolated from ipecac in the nineteenth century. Leonard Rogers (1912), professor of pathology at Medical College Hospital in Calcutta, India, reported successful treatment of both intestinal and hepatic amebiasis by injectable salts of emetine. The 1930s witnessed the introduction of two important hydroxyquinolines introduced by Anderson and Koch in 1931 and by a number of others. Although largely replaced by imidazoles in the 1980s, hydroxyquinolines remain useful today. In 1966, Powell and his colleagues demonstrated the effectiveness of metronidazole as an amebicidal agent in both intestinal and extraintestinal amebiasis.

Epidemiology

Approximately one tenth of the world population is believed to be infected with *E. histolytica*, with 100,000 deaths worldwide each year due to invasive amebiasis (Haque et al, 2003; Petri et al, 2000; Walsh, 1986; World Health Organization [WHO] et al, 1997b). Amebiasis is the third most common parasitic cause of death worldwide (Li & Stanley, 1996). The prevalence of *E. histolytica* could be an overestimate because it dates before the separation of *E. histolytica* from the morphologically identical, nonpathogenic *E. dispar* (Diamond & Clark, 1993) and *E. moshkovskii* (Beck et al, 2008; Fotedar et al, 2008). However, recent prevalence and morbidity data obtained through molecular techniques allow construction of more reliable map of endemic regions of amebiasis around the world, such as on the Asian subcontinent (India, Bangladesh), Africa, Asian Pacific (Thailand, Japan), and South and Central America (Mexico, Colombia) (Ximenez et al, 2009).

Disease expression varies geographically; invasive disease seen in Egypt, predominantly amebic colitis, may vary in schistosomiasis-endemic versus nonendemic areas (Mansour et al, 1997), whereas in South Africa an excessive rate of amebic liver abscess is noted. Although amebic liver abscess has been encountered in epidemic form in temperate climates, as it was

in the water-borne epidemic in Chicago in 1933 (Munoz, 1986), it is a problem chiefly of the tropics and developing countries (Sepulveda, 1982). In developed countries, it continues to be encountered sporadically in immigrants or travelers from endemic zones, low socioeconomic groups, residents of institutions, and male homosexuals (Ravdin & Stauffer, 2005).

In the United States and Europe, homosexual males are principally colonized with *E. dispar,* and patients infected with the human immunodeficiency virus (HIV) had no increased risk of either intestinal or extraintestinal amebiasis (Petri & Singh, 2006). Invasive extraintestinal amebiasis (hepatic abscesses) are more frequent in HIV-infected patients in these countries (Hung et al, 2005), whereas the same is not true elsewhere (Moran et al, 2005). *E. histolytica* remains a significant cause of morbidity and mortality in developing countries, where infection is common through flies and food handlers. The annual incidence of amebic dysentery in children is 2.2% in Bangladesh (Haque et al, 2003), and annual incidence of amebic liver abscess averaged 21 cases per 100,000 inhabitants in Hue City, Vietnam (Blessmann et al, 2002). Ingestion of *E. histolytica* occurs where poverty facilitates deficiencies in sanitation and sewage treatment. In addition, a recent report suggests that parasite genotype plays a role in determining outcome of infection by *E. histolytica* (Ali et al, 2007).

Organism

E. histolytica is a protozoan with two forms: trophozoite and cyst. Cysts constitute the infective form through fecal-oral transmission via food, water, or direct person-to-person contact. Cysts survive the acid of the stomach and travel through the small intestine, and within the terminal ileum or colon, trophozoites emerge to complete the life cycle (Guerrant, 1986). Cysts can survive for 45 minutes in feces lodged under fingernails and for 1 month in soil at 10° C. They remain infective in fresh water, seawater, and sewage but are destroyed by drying, iodine, and heat. They are not killed by chlorination used to purify drinking water (Munoz, 1986). The genus *Entamoeba* includes the pathogenic species *E. histolytica* and nonpathogenic *E. hartmanni, E. coli, E. polecki* (in swine), and *E. moshkovskii* (from sewage) (Guerrant, 1986). *E. histolytica* is morphologically similar to *E. dispar*; therefore the study of zymodemes, patterns of the electrophoretic mobility of isoenzymes; genetic differences using RNA and DNA probes; and the use of polymerase chain reaction (PCR) amplification became more reliable in their identification (Tannich et al, 1989). Encoding genes for transcription factors have been cloned for *E. histolytica* (Castanon-Sanchez et al, 2009).

Community Screening Procedures

An effective community screening protocol includes 1) microscopic examination of unfixed fecal samples, 2) Ritchie's fecal concentration, 3) staining of alcohol-fixed stools, 4) Robinson's in vitro culture, 5) screening stool antigens, 6) serology (indirect hemoagglutination test [IHAT], enzyme-linked immunosorbent assay [EIA], and immunofluorescence test [IFT]), and 7) isoenzyme electrophoresis of stool for zymodeme identification (Thomas & Garg, 2007).

Direct microscopic examination is found to be more sensitive than serology; however, the sensitivity of both is lower than Robinson's culture and zymodeme identification, the gold standards (Gatti et al, 2002). DNA-based PCR is rapid and sensitive to detect cysts in the stool (<5) and in fluids aspirated from amebic liver abscess (Rivera et al, 1998). A PCR test for *E. moshkovskii* was developed with a high sensitivity and specificity using DNA from stool samples (Fotedar et al, 2007). In 2007, Helmy used nested PCR and restriction enzyme digestion (RED) to distinguish *E. histolytica* from *E. dispar.*

Host Factors

The major reservoir for *Entamoeba* spp. is the human being. Male homosexuals transmit the infection but usually harbor nonpathogenic *E. dispar,* which is more common in females (Gatharim & Jackson, 1987). *E. histolytica* can be transmitted by heterosexual activity as well as male and female homosexual activity (Salit et al, 2009), although menstruating women are protected against invasive infection. Breastfed neonates have a low incidence as a result of the presence of immunoglobin A (IgA) and low iron content in breast milk (Thomas & Ravindra, 2000). A diet rich in iron and carbohydrates predisposes to invasive amebiasis (Gatharim & Jackson, 1987), and *HLA-DR3* gene expression is an independent risk factor for amebic liver abscess (Arellano et al, 1996).

Although immunosuppression is considered an important risk factor for invasive amebiasis in Asian Pacific countries (Hsu et al, 2008; Hung et al, 2008), others maintain there is no particular susceptibility for developing invasive forms of amebiasis in immunosuppressed individuals. Nevertheless, some HIV infections have been detected during admission of amebic liver abscess patients. On the other hand, the natural history of the disease seems to be the same as in nonimmunosuppressed patients (Kershenobish & Corona, 2008).

Pathogenesis

The disease course is determined by three virulence factors: lectin (a surface protein), amebapores (small peptides), and cysteine proteases. Trophozoite adhesion to the colonic wall is mediated by lectin, which results in persistent infection, and caspase 3 activation, which is a crucial step in cell necrosis and abscess formation (Huston et al, 2003). Amebapores are inserted by the trophozoite into the host cell, where they puncture the lipid bilayer and form a portal of entry into the host. Amebapores result in colloid osmotic lysis of the cell (Leippe et al, 1991). Cysteine proteases contribute to degradation of the extracellular matrix proteins and disruption of cell monolayers (Que & Reed, 1997).

It is anticipated that antiamebic antibodies protective against invasive infection would block lectin binding and neutralize amebapore and cysteine proteases. It has been suggested that the proteophosphoglycans (PPGs) in the amebic glycocalyx may participate in *E. histolytica* pathogenicity because the closely related, nonpathogenic *E. dispar* lacks a significant glycocalyx surface layer (Bhattacharya et al, 2000). Furthermore, antibodies that bind to PPGs neutralize liver abscess formation (Marinets, 1997). PPGs are anchored into the parasite cell membrane by a glycosylphosphatidylinositol (GPI) moiety. Synthesis of the GPI anchor requires a cascade of enzymes, including mannosyl transferase 1 (PIG-M1), whose blockage reduces GPI synthesis and PPGs in trophozoites (Weber, 2008). In addition, experimental evidence suggests that liver cell necrosis is increased when neutrophils are present along with *E. histolytica* (Aikat et al, 1979).

Normal blood flow in the portal vein is about 1.4 L/min, blood pressure is 12 to 15 mm Hg, and erythrocyte velocity is 8

to 18 cm/s. In comparison, sinusoidal blood flow is extremely low (3.4 to 0.16 mL/min), as is red blood cell velocity (0.1 mm/s; Puhl et al, 2003). Forces exerted on a parasite that adheres to the endothelium are thus much lower in the sinusoids and may partly explain why the parasite crosses the endothelium within these structures. Lack of tight junctions in liver sinusoidal endothelial cells (LSECs) can facilitate crossing by the parasite, creating a larger breach when reaching the hepatic parenchyma (Blazquez et al, 2007).

Publication of the *E. histolytica* genome (Loftus et al, 2005) facilitated transcriptome studies of the parasite. Microarrays have been used to compare virulent and avirulent trophozoites (those unable to form liver abscesses) from the same strain (Santi-Rocca et al, 2008). Overexpression of peroxiredoxin and rubrerythrin genes in virulent parasites is of interest for ALA development because inflammatory cell recruitment and subsequent inflammation are features of liver infection by *E. histolytica* (Choi et al, 2005a).

Molecular Genetics

The Institutes for Genomic Research have recognized that *E. histolytica* has a small, highly repetitive genome rich in adenosine-thymidine and densely packed sequences, but it lacks introns (Mann, 2002). Although some regions of the genome encode highly conserved proteins, other areas exhibit high degrees of polymorphism (Haghighi et al, 2002). Sequencing of the *E. histolytica* genome has revealed at least 44 genes (Clark et al, 2007). The purification of trophozoites from different organs of the same patients revealed that their tropism was linked to different genotypes (Ali et al, 2007).

Host Defense and Potential for Vaccine Development

It has not been definitively established which mechanism is responsible for invasion or recurrence (Ravdin & Guerrant, 1982). The first line of defense is the innate immunity that recognizes pathogen-associated molecular patterns (PAMPs) that trigger an inflammatory response. Natural killer T cells activated by *E. histolytica* are important in the control of amebic liver abscess (Lotter et al, 2009). Interferon (IFN)-γ initiates inflammation through macrophage production of tumor necrosis factor (TNF) and nitrous oxide (NO) synthesis by polymorphonuclear cells and macrophages. In vitro, the effects of IFN-γ can be bypassed by the recognition of PPGs of *E. histolytica* by Toll-like receptors (TLR) 2 and 4, which results in direct production of TNF and interleukins (ILs)-12 and -8 (Maldonado-Bernal, 2005). This shows the importance of early recognition of PPGs and inflammatory cell recruitment during ALA onset (Ivory & Chadee, 2007).

Complement cannot prevent invasion because it is absent from gut mucosal secretions (Braga et al, 1992), and amebic cysteine proteases degrade C3a and C5a (Reed et al, 1995). Neutrophils fail in initial host defense (Salata et al, 1989), and trophozoites can infect the human liver for months before abscesses are diagnosed. The second line of adaptive immune response constituted by activated lymphocytes and macrophages is the important effector mechanism against *E. histolytica* (Vohra et al, 2003). *E. histolytica* infection elicits mucosal IgA and serum IgG response to lectin protein shown to be protective against infection (Abd-Alla et al, 2004; Haque et al, 2002) in addition to epitope-specific antibodies that inhibit adherence to target cells (Pillai et al, 1999). The galactose/GalNAc lectin isolates from three distinct areas of the world—Bangladesh, Republic of Georgia, and Mexico—retain remarkable sequence conservation (Beck et al, 2002), and is recognized as a potential vaccine target (Thomas & Garg, 2007). Serum immunoglobulin (Ig) G response to the lectin protein does not provide protection against infection (Haque et al, 2002). Oral vaccines that use amebic antigens have been developed and tested in animals (Lotter et al, 2003; Mann et al, 1997; Snow & Stanley, 2006). A codon-optimized DNA vaccine has been tested in a murine model and was found to be useful in stimulating type 1 cellular immune response and serum antibodies (Gaucher & Chadee, 2002). Cell-mediated immunity (CMI) may be sufficient for vaccine protection from intestinal amebiasis with significant IFN-γ, interleukin (IL)-2, IL-12, IL-10, and IL-17 production with recombinant vaccines (Guo et al, 2009). Gram-negative bacteria expressing *E. histolytica* antigens may constitute a suitable oral vaccine carrier against invasive ameobiasis (Lotter et al, 2008).

Pathology

The development of ALAs is a fatal feature of infection by *E. histolytica* and is the most common extraintestinal form of invasive amoebiasis. Indeed, an estimated 100,000 people succumb to ALA each year (WHO, 1997a). Trophozoites that successfully penetrate the colonic mucosal barrier cause invasive disease, enter the portal system, and travel to the liver. Amebic colitis and amebic liver abscess rarely occur simultaneously, and the colonic lesions are usually silent; direct extension to the liver and lymphatic spread do not occur. The cecum is the most common site of amebic colitis, and the right lobe of the liver is more commonly affected because of drainage of the right portal branch from the right side of the colon. The condition usually starts as diffuse amebic hepatitis; liver cells undergo liquefactive necrosis, starting in the center and spreading peripherally to produce a cavity full of blood (Fig. 67.1) and liquefied liver tissue resembling anchovy sauce; it has no odor and is sterile. The fluid itself is free from any amebae, which may be found at the expanding edge of the abscess cavity with little inflammation. Amebae are known to lyse neutrophils, and the release of neutrophilic mediators may promote hepatocyte death and extension of the abscess. Secondary bacterial infection may occur spontaneously, altering the color, odor, and consistency of the pus. Lack of fibrotic response by the surrounding tissue with centrifugal extension results in extention of the abscess to the Glisson capsule, which is resistant to the amebae. Typically, amebic liver abscesses are solitary, large, and located in the right liver. Left lobe abscesses are less common, but because of the smaller volume of the left liver, abscesses in this location are more prone to rupture the capsule (Thomas & Ravindra, 2000). Vascular and biliary structures may traverse the abscess cavity; because of the intrahepatic covering of the Glisson capsule, such structures are resistant to the process of liquefactive necrosis. However, these structures can be mistaken for septa within the abscess cavity, and fracturing of these strands can lead to hemorrhage or biliary leak, or it can create a communication between the vascular and biliary channels and result in hemobilia and jaundice (Singh et al, 2008). The abscess wall is typically ill defined with a minimal host response of fibrous tissue, but longstanding abscesses may develop a fibrous wall and may even calcify (Rogers et al, 1980). In treated cases, complete resolution is the rule, but it may take 6 months to 2 years or longer (Thomas & Ravindra, 2000) than the usual time for pyogenic abscesses to resolve (Sudhamshu & Sharma, 2009).

Clinical Presentation

The peak incidence of amebic liver abscess is between 20 and 60 years of age; thus it is predominantly a disease of young men. Amebic liver abscess is 10 times more common in adults than in children and is three to 10 times more common in males (Sepulveda & Manzo, 1986; Wells & Arguedas, 2004). Population groups that are not commonly affected—such as children (especially neonates), pregnant women, and women in the postpartum period—have an increased risk of severe disease and death. Treatment with steroids, malignancy, men having sex with men, advanced age, and malnutrition could be considered risk factors for severe disease (Guerrant, 1986; Li & Stanley, 1996).

Most *E. histolytica* infections are asymptomatic or present as mild, "noninvasive" disease. Asymptomatic carriers, or *cyst passers,* may excrete cysts for a short period, but the majority of these patients clear the infection within 12 months. Patients with confirmed *E. histolytica* infection, even if they are asymptomatic, should be treated to eliminate the organism and prevent further transmission (Stanley, 2003). The time between penetration of colonic mucosa and damage to hepatic parenchyma is unknown. Active diarrhea usually occurs in less than 30% of patients at any time before presentation despite intestinal infection by *E. histolytica.* In most cases, standard stool microscopy results are negative, but in research studies, cultures of stool were positive for *E. histolytica* in more than 75% of patients with amebic liver abscess (Irusen et al, 1992).

Concomitant hepatic abscess is found in only one third of patients with amebic colitis. The duration of symptoms is usually 10 days. In nonendemic regions, such as Western Europe and the United States, patients usually report travel to an endemic area in the previous 2 to 5 months (median, 3 months), although a prolonged latency may occur (Johnston et al, 2009; Wells & Arguedas, 2004). Patients with amebic liver abscess start reporting nonspecific symptoms such as anorexia, nausea, vomiting, and acute colitic illness. Abdominal pain and fever are the cardinal symptoms of the disease, seen in 90% of patients or more. Fever typically is between 38° C and 40° C and is seen in 87% to 100% of patients; rigors occur in 36% to 69%. Other signs and symptoms vary according to the site and the size of the abscess. The chief sympton is typically the abrupt onset of right hypochondrial pain radiating to the right shoulder and scapular area. The pain increases with coughing, deep breathing, and walking. If the abscess is in the left hepatic lobe, the pain may be epigastric, precordial, or retrosternal and may radiate to the left shoulder. Abscesses located on the inferior aspect of the liver may present in a manner similar to peritonitis resulting from any upper abdominal cause. On occasion, the presentation is insidious, lasting 2 or more weeks; in such patients, significant weight loss may occur (Thomas & Ravindra, 2000). One report has suggested that amebic liver abscesses can be silent and asymptomatic (Blessmann et al, 2003).

Abdominal examination usually reveals a tender, soft hepatomegaly accompanied by overlying muscle guarding and intercostal tenderness. On occasion, increased warmth and cutaneous edema may occur. Jaundice is often seen, although it was previously reported to be a prominent feature in only 5% to 8% of patients (Pitt, 1990); biliary communication of amebic liver abscess has been reported in up to 27% (Agarwal et al, 1995; Bayraktar et al, 1996). Because the right posterior-superior surface is the most common site of amebic liver abscess, it is always accompanied by right basal lung signs as a result of either pleural effusion, empyema, or lung abscess (Loulergue & Mir, 2009). On the other hand, left lobe abscess may be complicated by pericardial friction, and abscesses in this location can extend into the pericardium, a sign associated with a very high mortality rate (Wiwanitkit, 2008). Hepatic failure, ascites, and splenomegaly may occur in 15% of patients who have multiple abscesses. They present with fever, toxemia, deep jaundice, and encephalopathy; toxemia is suggestive of an added bacterial infection, leading to more severe disease. *Esherichia coli* and *Klebseilla pneumoniae* are the most commonly cultured organisms, and patients are seen with a clinical picture indistinguishable from hepatic encephalopathy as a result of acute hepatocellular failure. Hepatic encephalopathy in patients with amebic liver abscess may result from a combination of right hepatic vein occlusion, pylephlebitis, and occlusion of several portal vein radicles (Kapoor & Joshi, 1992). Clinically, the usual differential diagnosis includes acute cholecystitis, hepatitis resulting from viral or other causes, and pyogenic liver abscess. With atypical presentation, hepatocellular carcinoma, a hepatic hydatid cyst, or a simple cyst may be considered (Thomas &

Ravindra, 2000). Approximately three quarters of patients with an amebic liver abscess have leukocytosis. Leukocytosis most likely appears if symptoms are acute or complications have developed. Eosinophilia is rare, but mild anemia may occur in half of patients and is multifactorial. Hyperbilirubinemia is present in only a small proportion of cases.

In acute liver abscess, aspartate aminotransferase (AST) levels are high. In chronic liver abscess, the alkaline phosphatase level tends to be elevated, and the AST level tends to be within normal limits. Overall, the alkaline phosphatase level is elevated in about 70% of patients with amebic liver abscess. Similar complete blood count (CBC) and liver test abnormalities are found in patients with pyogenic liver abscesses and are not specific (Ravdin & Stauffer, 2005). Prolonged prothrombin time may occur. Chest radiography typically shows elevation of the right dome of the diaphragm with an anterior bulge on the lateral view (Debakey & Ochsner, 1951), atelectasis of the right lung, and pleural effusion. The liver shadow on plain abdominal radiographs is diffusely enlarged, and gas in the biliary tree or liver parenchyma is unusual unless there is communication of the hepatic abscess cavity with the lung or hollow viscus (Thomas & Garg, 2007).

Ultrasonography

Ultrasonography (US) is the preferable diagnostic test, with an accuracy of 90% (see Chapter 13; Sepulveda & Manzo, 1986). Abscesses are usually located in contact with the liver capsule (see Fig. 67.1) and are 2 to 21 cm in size, round or oval, with well-defined margins; they are hypoechoic and clearly defined from normal liver parenchyma with distal enhancement (Figs. 67.2 to 67.4; Ralls et al, 1982; Sukougj et al, 1989). In 80% of patients, the abscess is single in the right lobe; 10% in the left lobe and 6% in the caudate lobe are single, and the remaining are multiple abscesses (Ralls et al, 1979).

In early stages, amebic abscess appears as a subtle area of decreased echogenicity, and US diagnosis is not pathognomonic; complicated cysts, hematoma, metastases, and amebic abscess may mimic each other (Elzi et al, 2004; Kapoor, 1989). Only 40% of patients have typical US features of amebic liver abscess. Serial scanning tends to show no change despite adequate treatment with amebicidal drugs, complete aspiration of the abscess, or both (Ralls et al, 1979; Sukov et al, 1980). The mean resolution time is 7 months, and complete resolution may take up to 2 years. On occasion, percutaneous diagnostic aspiration may be needed to differentiate amebic from pyogenic liver abscess (Kurland & Brann, 2004). Although pyogenic liver abscesses tend to resolve earlier (within 2 to 4 months), amebic liver abscesses acquire a more echogenic and fibrous wall in 8 to 16 weeks and begin to resemble, but must be differentiated from, an encapsulated tumor. With time, resolution may be complete, or the result may be a residual cystic cavity that resembles a simple cyst of the liver (Ralls et al, 1983; Sheen et al, 1989).

Other Imaging Modalities

Computed tomography (CT) does not add to the diagnostic accuracy of US in acute stages, except in evaluation of imminent rupture of an abscess or for detection of small lesions (see Chapter 16; Kimura et al, 1997). Amebic liver abscesses usually appear on CT with contrast as rounded, well-defined lesions with complex fluid (Radin et al, 1988). The most characteristic finding is an enhancing wall with a peripheral

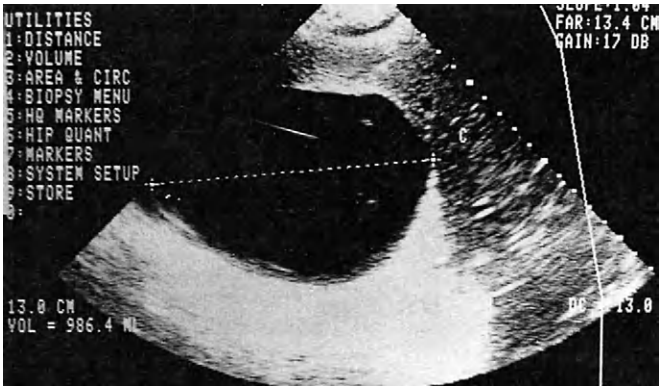

FIGURE 67.2. Ultrasound showing an abscess with more liquid contents in a 25-year-old man. The distal sonic enhancement has resulted in a "white out" of structures distal to the abscess cavity. *(Courtesy Professor M.S. Khuroo, Sher-I-Kashmir Institute of Medical Sciences, Srinagar, India.)*

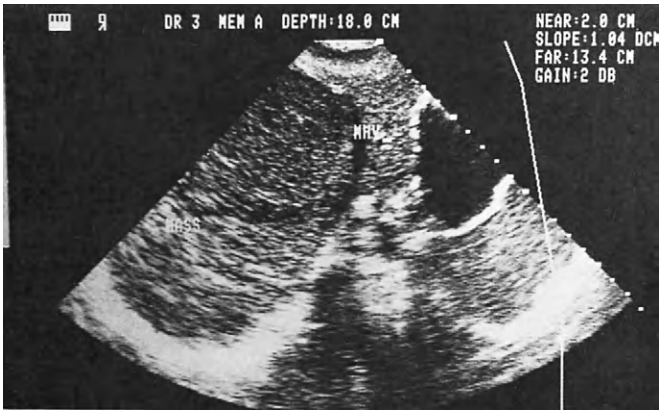

FIGURE 67.3. Ultrasound from a 50-year-old woman with a right liver mass initially mistaken for amebic liver abscess but proven on further investigation to be a tumor. There is a mixed-echo pattern with hyperechoic and medium-level echoes, no clear margin, and no distal sonic enhancement typical of an amebic abscess. *(Courtesy Professor M.S. Khuroo, Sher-I-Kashmir Institute of Medical Sciences, Srinagar, India.)*

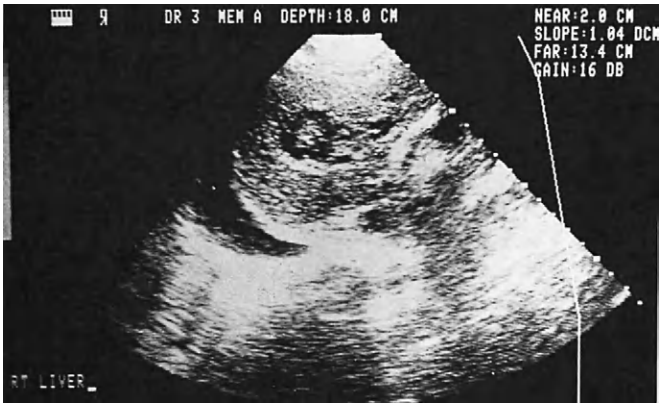

FIGURE 67.4. Ultrasound showing a typical metastatic "target" deposit in a 45-year-old woman. The central location, smaller size, and poor distal enhancement differentiate it from an amebic abscess. The presence of ascites is visible. *(Courtesy Professor M.S. Khuroo, Sher-I-Kashmir Institute of Medical Sciences, Srinagar, India.)*

FIGURE 67.5. Computed tomographic image showing a typical liver abscess with an enhancing wall and peripheral zone of edema. *(Courtesy Professor A.K. El Dory, Ain Shams University, Cairo.)*

zone of edema around the abscess (Fig. 67.5). The abscess cavity may show multiple septa (more with pyogenic abscesses), fluid and debris levels, air bubbles, or hemorrhage. CT may detect extension of amebic liver abscesses to other organs (Radin et al, 1988).

Magnetic resonance imaging (MRI; see Chapter 17) is not superior to CT in the diagnosis of amebic liver abscess, but it may be useful in differentiating it from a hepatic neoplasm. Amebic liver abscesses appear as heterogeneous cavities that are hypointense on T1-weighted images and hyperintense on T2-weighted MR images. The abscess margin may show incomplete hyperintense rings with perilesional edema on T2-weighted images. Following treatment, the abscess cavity becomes homogeneous, and complete concentric rings appear as a result of periabscess fibrosis and hemosiderin deposits (Mortelé & Ros, 2001).

Angiography is rarely required. When performed, it reveals a hypovascular or avascular mass displacing the hepatic artery and portal vein branches but may show portal vein thrombosis (Viana, 1975). Although its role is currently limited with gallium scanning, amebic liver abscesses appear as cold spots, whereas pyogenic lesions are seen as warm spots (Kapoor, 1989).

Amebic Serology

Amebic serology is highly sensitive and specific in the differentiation between pyogenic and amebic hepatic abscess. EIA is simple, rapid, inexpensive, and more sensitive, and it has now largely replaced IHAT and counterimmunoelectrophoresis (Restrepo et al, 1996). EIA detects antibodies specific for *E. histolytica* in approximately 95% of patients with extraintestinal amebiasis, 70% with active intestinal infection, and 10% who are asymptomatic cyst passers. Antibody response is related to the duration of illness and may be detectable 7 to 10 days after the onset of symptoms. Titers peak by the second and third months, decreasing to lower levels by 9 months; they revert to negative by 12 months (Munoz, 1986). Monoclonal antibody-based tests allow differentiation between invasive and noninvasive parasites (Kimura et al, 1997). Enzyme-linked immunosorbent assay (ELISA) and IHAT cannot differentiate acute from remote infection in endemic areas (Thomas & Garg, 2007).

Currently, ELISA for detection of the galactose-inhibitable adherence protein in serum and feces and IHAT appear to be the most reliable tests, with sensitivity and specificity greater than 95% (Hira et al, 2001), with a reversal rate of 82% after 1 week of treatment with metronidazole (Tanyuksel & Petri, 2003). Efforts are ongoing to identify antigens specific for acute infection (Ravdin, 1995). Rapid antigen and antibody tests are being evaluated and seem very promising (Leo et al, 2006).

Role of Aspiration

US-guided aspiration (Fig. 67.6) is often justified on the basis that the diagnosis would be "more certain," or that the abscess can be "aspirated to dryness" at the time of therapeutic aspiration. PCR may detect *E. histolytica* DNA in amebic liver abscess pus as well as in the saliva of patients (Khairnar & Parija, 2008; Khan et al, 2006). No randomized controlled trial has ever shown that aspiration is beneficial in survival, length of hospitalization, or time to become afebrile compared with treatment with antiamebic drugs alone (Chavez-Tapia et al, 2009; Sharma et al, 1989; Stanley, 2003; Van Allan et al, 1992), and aspiration may only confuse the diagnosis by revealing atypical pus or blood. The belief that aspiration hastens clinical recovery and may not involve significant procedure-related morbidity is widespread in clinical practice, however. This approach is supported by a small prospective study (Tandon et al, 1997) and continues to be advocated in reviews (Haque et al, 2002). Clinical improvement invariably occurs with antiamebic therapy alone in uncomplicated cases. When the differential diagnosis in a given case includes operable neoplasm or hydatid disease, aspiration is risky and may be contraindicated (Thomas & Garg, 2007).

Therapeutic aspiration should be reserved for the following situations (Ralls et al, 1982):

1. Serology is inconclusive and differential diagnosis is pyogenic liver abscess.
2. A therapeutic trial with antiamebic drugs is deemed inappropriate, as in pregnancy.
3. The liver abscess is secondarily infected, estimated to be true in 15% of cases (McDermott, 1995).
4. Fever and pain persist for more than 5 to 7 days after starting appropriate therapy.
5. Rupture is imminent in an extremely large abscess (>10 cm), especially if pericardial rupture from a left lobe abscess appears likely.

The following factors are predictive of the need for aspiration: 1) age 55 years or older, 2) an abscess 5 cm or more in diameter, and 3) failure of medical therapy after 7 days (Khan et al, 2008). In endemic areas, because of late presentation and existence of multiple abscesses, up to 50% of patients may require aspiration (Khanna et al, 2005). A single aspiration may be sufficient for diagnostic purposes, but it is inaccurate to recommend it because the characteristic "anchovy paste" characteristic of amebic abscess may not be found; when performed as part of therapy, it will likely be inadequate. Percutaneous catheter drainage (PCD) is better than percutaneous needle aspiration (PNA) for management of large liver abscesses (>10 cm) in

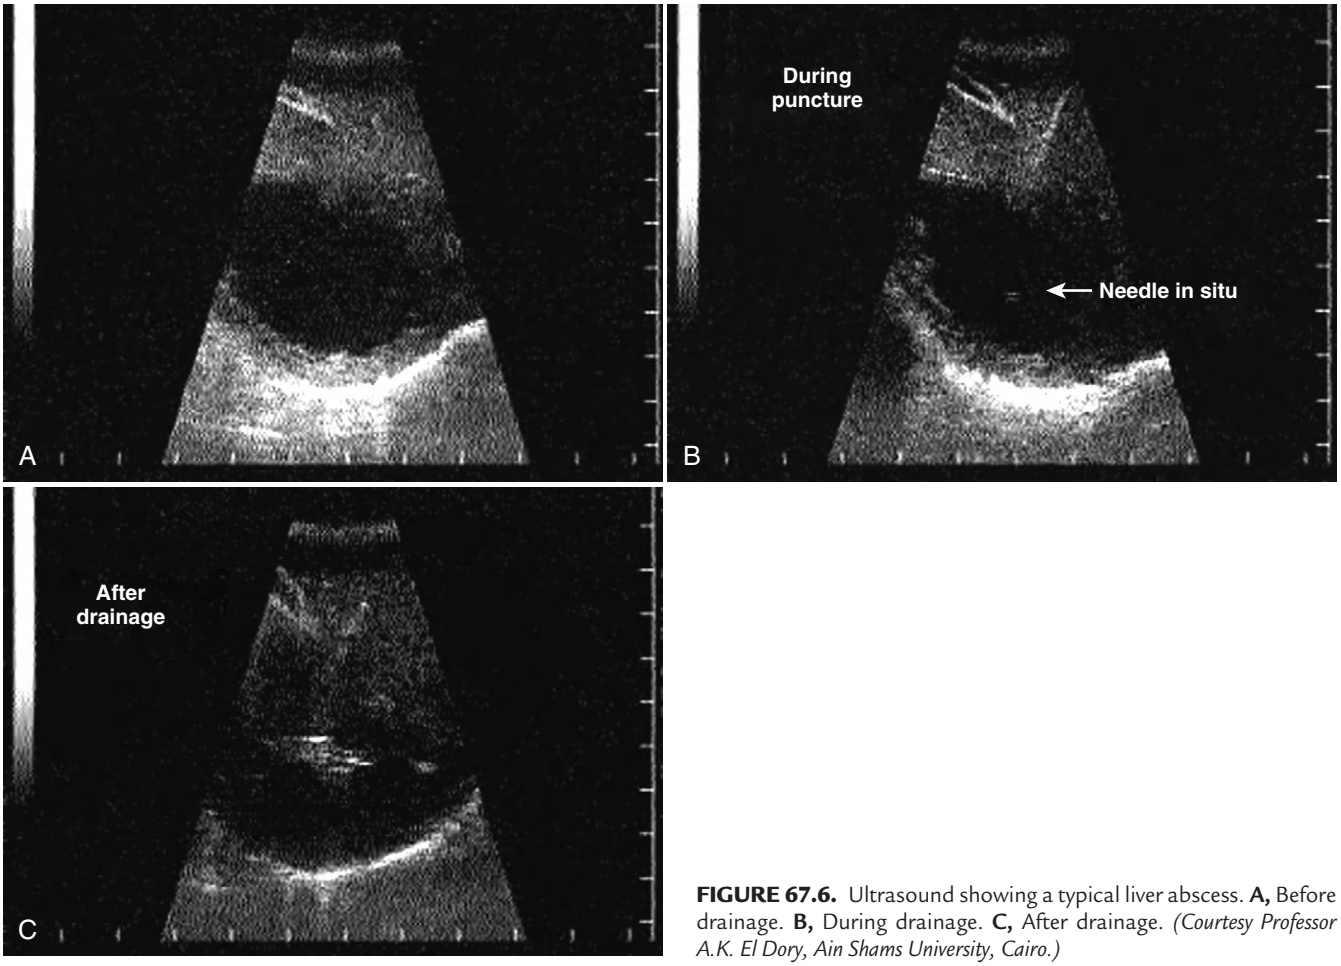

FIGURE 67.6. Ultrasound showing a typical liver abscess. **A,** Before drainage. **B,** During drainage. **C,** After drainage. *(Courtesy Professor A.K. El Dory, Ain Shams University, Cairo.)*

terms of duration to attain clinical relief and duration for which parenteral antibiotics are needed (Singh et al, 2009).

Complications

The most common complications of amebic liver abscess arise from rupture of the abscess into surrounding organs or anatomical spaces. Communication occurs into the peritoneum, viscera, and large vessels on one side of the diaphragm and the pleura, bronchi, lungs, and pericardium on the other.

Peritoneal and Visceral Involvement

Peritonitis with amebiasis is due to rupture of an amebic liver abscess in 78% of patients and perforated or necrotizing amebic colitis in the other 22% (Ken et al, 1989; Monga et al, 1976). Spontaneous rupture of amebic liver abscess may occur in 2.7% to 17% of cases (Eggleston et al, 1982; Monga et al, 1976; Sarda et al, 1989). Adherence of the liver abscess to the diaphragm, abdominal wall, omentum, or bowel tends to confine contamination and lead to rupture into hollow viscera, such as the stomach or colon (Angel et al, 2000).

A hepatogastric, hepatoduodenal, or hepatocolonic fistula and acute hepatic failure may occur. Free rupture into the peritoneal cavity is uncommon and usually only occurs in a nutritionally depleted patient (Rao et al, 2009). Patients present with abdominal pain, a palpable mass, or generalized distension. Bloody diarrhea may occur in colonic rupture, and hematemesis may occur in cases of hepatogastric fistula. Signs of peritonitis with tender hepatomegaly, intercostal tenderness, right basal lung signs, and clinical jaundice may lead to suspicion of the diagnosis, which can be confirmed on US. The diagnosis may be made only at laparotomy, with risk of bleeding from decreased prothrombin levels (Thomas & Garg, 2007). US and CT often show a perihepatic fluid collection in cases of amebic liver abscess that are reactive or with actual leaks from the abscess cavity (Radin et al, 1988). Management of abscesses that extended into the peritoneal cavity with aggressive surgical approaches were associated with increased mortality rates (Balasegaram, 1981; Eggleston et al, 1982) and have now been replaced by increasingly successful attempts at percutaneous drainage of the liver abscess and the extravasated pus (Ken et al, 1989; Sarda et al, 1989).

Absolute indications for laparotomy include a doubtful diagnosis; concomitant hollow viscus perforation with fistulization, resulting in life-threatening hemorrhage or sepsis; and failure of conservative management. At laparotomy, the liver abscess, which usually appears as a tan-colored bulge on the surface, must be handled gently. Septa running across the cavity are usually blood vessels and bile ducts traversing the abscess cavity. Hemorrhage can be difficult to control, and postoperative bile

leaks may result. Endoscopic stenting or nasobiliary drainage may be required in cases of biliary communication (Sandeep et al, 2006). Irrigation of the abscess cavity with saline is usually sufficient and may be followed by the installation for 3 to 5 minutes of a solution of 65 mg of emetine hydrochloride in 100 mL of normal saline. Tube drains are inserted and retained as necessary. Hollow viscus perforations must be dealt with on an individual basis, with exteriorization, proximal diversion, or serosal patch closure (Thomas & Garg, 2007). Postoperative intravenous metronidazole is combined with broad-spectrum antibiotics, and dehydroemetine is added if no cardiac contraindication exists. The mortality rate of viscus perforation ranges from 12% to 50% (Sarda et al, 1989).

Thoracic and Pleuropulmonary Involvement

Pulmonary complications occur in 7% to 20% of patients with amebic liver abscess (Stanley, 2003). A sympathetic right-sided effusion is the most common pulmonary complication and usually does not require treatment itself. Other thoracic complications include rupture of the abscess into the pleural cavity or into the bronchial tree. This condition manifests as dyspnea and dry cough with right basal crepitations and collapse of the right lung in addition to the abdominal signs. A pleural rub may also be found. Sudden onset of coughing with expectoration of copious quantities of chocolate-colored sputum occurs if the abscess ruptures into bronchi (Guarner, 1986). There are several routes of pulmonary infection, including direct hematogenous and inhalational amebiasis (Shamsuzzaman & Hashiguchi, 2002). Thoracocentesis is the main line of treatment. In case of aspiration and intercostal tube drainage, care is taken to go high on the right lateral side of the chest near the axilla. Ineffective early drainage of the amebic empyema is usually complicated by secondary infection that requires aggressive surgical procedures, such as pulmonary decortication, because the fibrous tissue can be dense enough to complicate thoracoscopic surgical techniques (Thomas & Garg, 2007).

Lung abscess rarely occurs, and it is walled off from the pleural and peritoneal cavities; surgical intervention is not required because postural drainage, bronchodilators, and antiamebic drugs may suffice. Metronidazole is effective, but emetine produces a rapid response and may be required in cases of metronidazole resistance (Jain et al, 1990).

Vascular and Pericardial Involvement

Some cases of vascular complications have been reported, such as Budd-Chiari syndrome (Mechai et al, 2009) and right atrial and inferior vena cava thrombosis, complicating multiple large amebic liver abscesses (Khan & Ameen, 2009; Sodhi et al, 2009). Surgical removal of the thrombus may be required.

Abscess rupture into pericardium is rare but serious, occurring in 1.3% to 2% of patients, with mortality rates from 30% to 60% (Shamsuzzaman & Hashiguchi, 2002). Abscesses of the left lobe of the liver or those more centrally located are more prone to pericardial complications that range from asymptomatic pericardial effusion to cardiac tamponade. Although left lobe abscesses resolve equally well with antiamebic drugs, as do right-sided abscesses (Thompson et al, 1985), the detection of pericardial thickening or pericardial effusion may constitute an indication for aspiration of a left-sided amebic liver abscess (Radin et al, 1988). In cardiac tamponade, pericardiocentesis must be performed, along with drainage of the liver abscess followed by antiamebic drugs, namely metronidazole. Dehydroemetine is used with caution because of its cardiotoxicity (Thomas & Garg, 2007).

Chemotherapy

Metronidazole

Metronidazole is the drug of choice for amebic liver abscess. The oral dose is 500 to 750 mg three times daily for 7 to 10 days, the same dose and duration used for intestinal amebiasis in adults, and 35 to 50 mg/kg in three divided doses for 10 days in children, with a cure rate of more than 90% (Li & Stanley, 1996). Hepatopulmonary amebiasis was found to respond equally to doses of 400 and 800 mg three times daily given over 5 days (Jain et al, 1990). The intravenous route is also highly effective at a recommended dose of 500 mg every 6 hours. Metronidazole reaches high concentrations in the liver and intestine, and it crosses the placenta and the blood-brain barrier. Its use is contraindicated in the first trimester of pregnancy and must be used cautiously in the second and third trimesters; breastfeeding should be discontinued during its use. The response of patients with amebic liver abscess to metronidazole is profound, with improvement in symptoms within 72 to 96 hours. However, a luminal agent such as paromomycin (30 mg/kg three times a day for 5 to 7 days), iodoquinol (650 mg orally three times a day for 20 days), or diloxanide furoate (500 mg orally three times a day for 10 days) should also be used to eradicate intestinal colonization (Stanley, 2003).

Medical therapy has a disulfiram-like action. The most common side effects are nausea, a metallic taste in the mouth, vomiting, and dark brown discoloration of the urine. Over 5 days, an 85% cure rate is achieved, which may increase to 95% after 10 days (Guarner, 1986). From 5% to 15% of patients with amebic liver abscess may be resistant to metronidazole (Thompson et al, 1985), but this may not be a major clinical problem (Li & Stanley, 1996); most reports of "drug resistance" reflect delayed resolution of either clinical symptoms or US findings and not a true resistance documented by drug failure. Experimental resistance may be related to inducing superoxide dismutase in vitro (Wells & Arguedas, 2004). Alternate medical therapy, percutaneous aspiration, or surgical intervention usually must be considered in patients who do not respond or show only modest improvement in 72 hours (Thompson et al, 1985). In countries where they are available, tinidazole, ornidazole, and nitazoxanide are alternative agents for the treatment of amebic liver abscess; these drugs are administered for only a few days (Lasserre et al, 1983; Quaderi et al, 1978; Vanijanonta et al, 1985). One study of a single 2-g dose of either tinidazole or ornidazole gave a success rate of 94% in both treatment arms (Lasserre et al, 1983). Other studies have shown a success rate of almost 100% for patients treated with tinidazole for 2 to 3 days (Khokhani et al, 1978; Quaderi et al, 1978; Vanijanonta et al, 1985). Tinidazole has been approved by the Food and Drug Administration (FDA) for the treatment of amebiasis, including amebic liver abscess. Secnidazole has a longer half-life, and a single daily dose of 2 g for 5 days is effective (Salles et al, 2003). Satranidazole showed lower incidence of side effects and better tolerance than metronidazole in a randomized, single-blind trial of 49 patients with amebic liver abscess (Muzaffar et al, 2006).

Other Medications

Emetine hydrochloride is effective against trophozoites and reaches amebicidal concentrations in tissues rather than

intestine. Emetine is administered by intramuscular or deep subcutaneous injection in a dose of 1 mg/kg/day (maximum 60 mg/day) for 10 days. The patient must be placed on complete bed rest. Tissue levels persist for 40 to 60 days, and readministration should be avoided for 6 weeks. Side effects include myositis at the injection site, hypotension, tachycardia, chest pain, dyspnea, and abnormalities on electrocardiogram, including T-wave inversion and prolonged Q-T interval. The drug is contraindicated in renal, cardiac, and muscular disease and is used cautiously in children and elderly patients (Thomas & Garg, 2007). Emetine or dehydroemetine is valuable in treatment of hepatopulmonary amebiasis (Guarner, 1986; Jain et al, 1990; Thompson et al, 1985).

Chloroquine phosphate is antimalarial and is effective in patients with resistance to emetine and pulmonary amebiasis (Guarner, 1986) but has no luminal amebicidal activity. Chloroquine is administered orally in a dose of 1 g (600 mg base) per day for 2 days followed by 500 mg (300 mg base) per day for 2 to 3 weeks. It is contraindicated in patients with retinopathy, but it has been used in pregnant patients (Guarner, 1986). Diloxanide is ineffective in invasive amebiasis and is used for treatment of asymptomatic carriers. The recommended dose is 500 mg three times a day for 10 days. No serious side effects are reported.

Nitazoxanide was effective in treating invasive amebiasis and eliminating colonization in intestine. Further studies are warranted in hepatic amebiasis (Rossignol et al, 2007). Trifluoromethionine is a lead compound, but a single subcutaneous or oral dose prevented the formation of amebic liver abscess in a rodent model (Sato et al, 2010).

Therapeutic Strategy

Oral metronidazole is administered as a single drug, with concomitant correction of hypoprothrombinemia, hypoproteinemia, and anemia. If dramatic improvement occurs in 48 to 72 hours, no therapy other than the complete course of metronidazole is required. A luminal agent, such as diloxanide furoate (500 mg three times a day for 10 days) or paromomycin (30 mg/kg/day in three doses for 10 days), must be administered after metronidazole therapy for eradication of intestinal infection as part of a complete treatment regimen (Irusen et al, 1992).

In patients who do not respond satisfactorily, emetine or dehydroemetine is added. Evidence of pulmonary, peritoneal, or pericardial extension is an indication for aspiration of the liver abscess with an intercostal tube or catheter drainage. Percutaneous catheter drainage is usually recommended for abscesses larger than 10 cm in diameter and for left lobe liver abscess, failure of medical treatment for 7 days, and failure to differentiate the abscess from a pyogenic abscess (Singh et al, 2009). The following are predictive of the need for aspiration: 1) age older than 55 years, 2) abscess greater than 10 cm in diameter, and 3) failure of medical therapy after 7 days (Khan et al, 2008). Late presentation with the existence of multiple abscesses may require aspiration (Khanna et al, 2005), but prompt medical care decreases the need. Laparotomy is usually reserved for patients with suspected peritonitis, fistulization, or secondary infection with sepsis after failure of above measures.

A meta-analysis of patients with amebic liver abscess showed that 4% died (Pitt, 1990). In patients treated with amebicidal drugs alone, the mortality rate was 2%. Independent risk factors for death include serum bilirubin greater than 3.5 mg/dL; encephalopathy; hypoalbuminemia, defined as less than 2 mg/dL; and multiple abscess cavities (Sharma et al, 1996) or total abscess volume greater than 500 mL (Wells & Arguedas, 2004). Rupture into the peritoneal cavity and the pericardium is responsible for most deaths. Patients treated with early and aggressive surgery as advocated by some authors (Balasegaram, 1981; Eggleston et al, 1982) did not show a remarkable improvement in mortality rate, although in Balasegaram's series, the hospital stay was probably reduced. Ruptured amebic liver abscess occurs in 2% to 17% of patients, with reported mortality rate of 6% to 50%. These patients usually constitute a major risk for surgery and anesthesia.

Prevention

In addition to regular sanitary measures that include proper washing of vegetables and fruits as well as drinking only bottled water in endemic areas, modern biologic techniques have helped characterize amebic antigens that show great promise in the development of a vaccine. No prophylactic vaccine is currently available for amebiasis, but efforts to better define antigenic candidates and wider use of animal models are encouraging. For example, a serine-rich *E. histolytica* protein (SREHP) has been expressed in avirulent vaccine strains of *Salmonella* (Stanley, 2006). *E. histolytica* galactose/N-acetyl-D-galactosamine (Gal/GalNAc) (Houpt et al, 2004) and a synthetic, enhanced, intranasal lectin-based amebiasis subunit have been extensively studied as attractive candidates for vaccine development (Abd Alla et al, 2007). In addition, Gal-inhibitable lectin shows promise in animal studies (Ivory & Chadee, 2007).

LIVER FLUKE DISEASE

Fasciola hepatica and *Clonorchis sinensis* are the primary liver flukes (see Chapter 45). They are unsegmented leaf-shaped trematodes. Although both have common features with respect to structure and life cycle, with accidental infection of humans, there are some epidemiologic differences. *C. sinensis* is endemic in East Asia, regions bordered by the South China Sea, and along the great rivers and streams of China, North Vietnam, and Korea. Disease results from eating contaminated raw freshwater fish. These areas also are endemic for viral hepatitis, and epidemiologic surveys of the population yield patients with common symptoms in whom the differential diagnosis must be made (Wang et al, 2004). *Opisthorchis viverrini* and *Opisthorchis felineus* are other liver flukes transmitted by the consumption of raw freshwater fish, but most of these cases are asymptomatic. The Western Hemisphere is free of the disease, but clinical manifestations may occur in natives of these areas several years after emigration to other countries. The first report of *C. sinensis* infection was described in a Chinese carpenter residing in Calcutta, India (McConnell, 1875).

Fascioliasis

Zoonotic disease is caused by *F. hepatica* (temperate) and *F. gigantica* (tropical), the causative agents of fascioliasis in cattle and sheep (see Chapter 45). Human infections with *F. hepatica* are found in areas where sheep and cattle are raised and where humans consume raw watercress, including Europe, the Middle East, and Asia (Thomas & Garg, 2007). Infections with *F. gigantica* have been reported in Asia, Africa, and Hawaii. Prevalence

is high in Bolivia (65% to 92%), Ecuador (24% to 53%), Egypt (2% to 17%), and Peru (10%). In hyperendemic areas of Bolivia, 68% of children are infected; 11% of Ethiopians who emigrated to Israel are also infected (Thomas & Garg, 2007). An estimated 2.4 million people are infected with liver flukes worldwide (Mas-Coma et al, 1999). The incidence in humans is estimated to be only 1%, and most patients are encountered as sporadic cases or in small community outbreaks (Ashton et al, 1970).

A distinct syndrome of fascioliasis, termed *halzoun* in Lebanon and *marrerra* in the Sudan, can result from consuming raw liver of an infected sheep, goat, or cow. The living fluke adheres to the posterior pharyngeal wall, causing severe pharyngitis and laryngeal edema. Similarly, disease can follow consumption of sashimi of bovine liver served in "yakitori" bars in Japan if the liver is contaminated with juvenile worms.

Morphology and Life Cycle

F. hepatica is a flat, leaflike, hermaphrodite trematode 15 to 30 mm long, 10 mm thick, and 3 mm wide that inhabits the bile ducts and gallbladder of the host. When the eggs in mammalian stool are deposited in tepid water (22° C to 26° C), miracidia appear, develop, and hatch in 9 to 14 days. These miracidia then invade many species of freshwater snails, in which they multiply as sporozoites and redia for 4 to 7 weeks. They leave as free-swimming cercaria that subsequently attach to watercress, water lettuce, mint, parsley, or khat. Free-swimming cercaria may remain suspended in the water and encyst over a few hours. When humans consume contaminated plants or water, larvae excyst in the duodenum, migrate through the bowel wall and peritoneal cavity, and penetrate the Glisson capsule, actions that initiate the acute larval, hepatic, and invasive stages of human infection, in which the parasites eat their way down to the bile ducts. Larvae sometimes also travel to ectopic body sites. This stage may last 3 to 4 months, during which the larvae mature and migrate through liver into large hepatic and common bile ducts. Mature flukes consume hepatocytes and duct epithelium and reside for years in the hepatic and common bile ducts and occasionally in the gallbladder; this is the chronic adult biliary stage of infection. Adult fluke worms produce eggs about 4 months (range, 3 to 18 months) after infection; these eggs traverse the sphincter of Oddi and intestine and then continue the cycle of infection. Acute and chronic stages can overlap, particularly in a high-level infection. The life cycle takes about 5 months, 3 months of which are required for the journey through the human host. The adult worms that develop in the bile ducts at the end of this period have a life span of 3 to 4 years. The parasite may invade other organs during migration, such as the urinary tract, and cause hematuria. Ectopic fascioliasis may affect the peritoneum, muscles, brain, and subcutaneous tissues (Jones et al, 1977).

Pathology

Early during infection, hepatic lesions may be white or gray nodules on the liver capsule, subcapsular tracts, and, rarely, a localized hepatic mass. Later, the worm enters the biliary system. *F. hepatica* is a relatively large parasite. In the intrahepatic ducts, the worms move to and fro, and the spinous nature of the integument causes extensive destruction of the biliary epithelium; in this way, the presence of the parasite stimulates fibrosis in the bile duct wall (Fig. 67.7). Serious infection may be associated with hepatic and biliary fibrosis, hepatic necrosis, abscess formation, cholangiohepatitis, impaired nutrition, and death. A liver biopsy may reveal a nonspecific round cell infiltration of portal tracts, and cholangiocarcinoma may occur in association with fascioliasis (Thomas & Garg, 2007).

Clinical Features

Eating watercress and drinking contaminated water in an endemic area are the likely routes of infection. Clinical symptoms and signs, together with radiologic findings, are the mainstay of diagnosis. The acute phase usually lasts 4 months and is caused by the migration of the immature fluke through the hepatic parenchyma, leading to hemobilia. Patients usually develop right upper quadrant pain, hepatomegaly, fever, vomiting, diarrhea, anemia, hypergammaglobulinemia (especially IgG and IgE), and allergic reactions (Aksoy et al, 2006).

On US examination of the intrahepatic and extrahepatic bile ducts, no motile echogenic images are seen (Saba et al, 2004). The findings in the liver parenchyma are nonspecific, although suspected nodules or cavitary lesions might warrant further imaging. CT is the most useful method for diagnosis; it can show peripherally located hypodense lesions, usually on the right lobe, with peripheral enhancement on contrast scans, arranged in a track like fashion with no coalescence into a larger abscess cavity, such as is seen in pyogenic abscesses. MRI usually adds nothing and cannot show the tracklike appearance of the lesions (Oto et al, 1999). After infection of the biliary tract or gallbladder, an asymptomatic clinical phase starts during which the flukes mature into adult form. This is followed by the chronic phase, caused by the adult fluke within the biliary system, during which the symptoms persist more than 4 months, are more discrete, and reflect intermittent biliary obstruction and inflammation. The main symptoms include recurrent episodes of biliary colic, cholangitis, and cholecystitis accompanied by constitutional upset, jaundice, anemia, hypoproteinemia, and edema. The liver may be tender and enlarged with

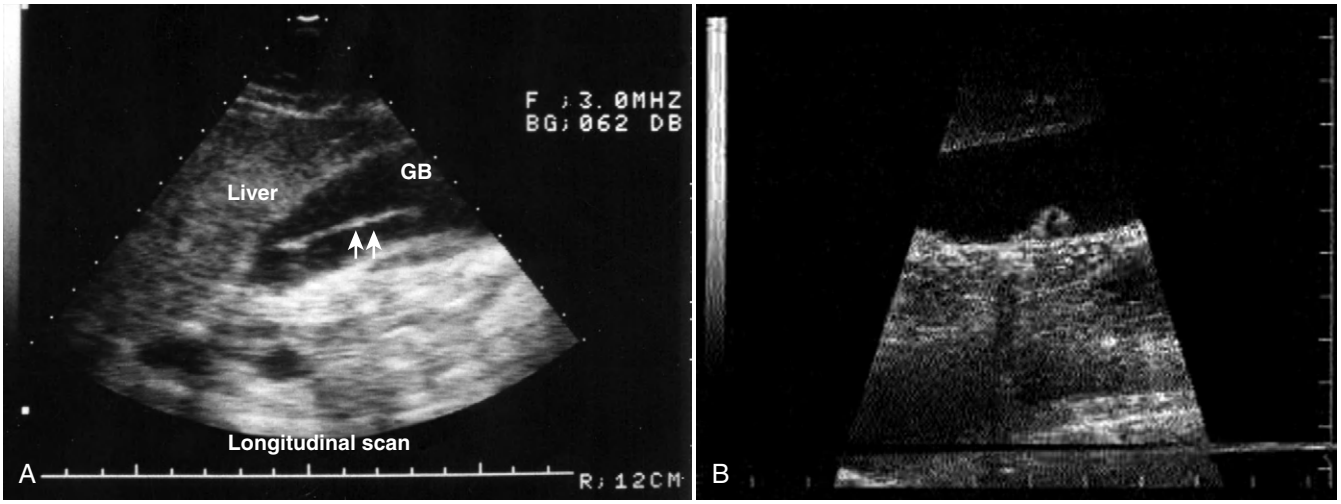

FIGURE 67.8. Ultrasound of *Fasciola hepatica* moving inside the gallbladder as an echogenic mass. **A,** Longitudinal view. **B,** Transverse view. *(Courtesy Professor A.K. El Dory, Ain Shams University, Cairo.)*

splenomegaly. Motile echogenic images with biliary mud can be seen in the gallbladder and bile ducts on US during this phase (Fig. 67.8). Real-time sonography may show the worm moving inside the gallbladder. Biliary duct dilation is common, and MRI cholangiography may show signal loss in the large bile ducts consistent with flukes or edema (LaPook et al, 2000). Diagnosis of fascioliasis by endoscopic ultrasound (EUS) (Fig. 67.9) has also been reported (Sotoudehmanesh & Yoonessi, 2003). Liver biopsy is not indicated for diagnosis and usually reveals necrotic debris, tracklike destruction of parenchyma, polymorphonuclear infiltration with abundant eosinophils, Charcot-Leyden crystals, granulomas with or without eggs, fibrosis, and bile duct proliferation (Acosta-Ferreira et al, 1979). Eosinophilia may be 50% or more of the total white blood cell count and is seen regardless of the clinical stage of infection; it may also be seen in asymptomatic contacts of the patient, who have latent infection (Saba et al, 2004; El-Shabrawi et al, 1997). It has been reported that eosinophilia could be absent in chronic cases in endemic areas (Marcos et al, 2008), and anemia is usually present (Bassiouny et al, 1991). Liver function tests show features of cholestasis. Hemoglobinuria is often present because the flukes can penetrate and lodge in the kidneys during migration through the peritoneal cavity. Adult flukes and eggs are absent from the feces and bile during the acute phase, and even in the chronic phase, so stool examination may not be diagnostic. Repeated stool analysis is required because of intermittent secretion of ova. Serologic modalities include complement fixation test (CFT), indirect fluorescent antibody test (IFAT), IHAT, and counterimmunoelectrophoresis (CIE) may be used with neither low specificity nor sensitivity (Marcos et al, 2008).

A specific serologic test to detect IgG antibodies to a crude *Fasciola* worm antigen preparation has been found to be positive in 97% to 100% of patients (Maher et al, 1999). Fas2-ELISA is more specific than Western blot and Arc II (Espinoza et al, 2005). The largest human diagnostic study has been carried out in Peru, where the Fas2-ELISA (cathepsin L1-based antibody) was validated, including 634 infected children from endemic areas. The sensitivity was 92.4% and specificity was 83.6%, with a negative predictive value of 97.2% (Espinoza et al, 2007).

The findings on imaging have already been described, and a differential diagnosis from necrotic hepatic neoplasms and liver abscesses must be made (see Chapter 66; LaPook et al, 2000). At laparoscopy or laparotomy, the characteristic features of hard, grayish white nodules on the liver surface with subcapsular channels may be seen in 55% to 75% of patients. Portal lymph nodes are often enlarged, and the common bile duct may be dilated. The diagnosis of fascioliasis should be considered in patients with a history of ingestion of raw watercress or other aquatic plants or those who have recently traveled to an endemic area and develop prostration, cholangitis, hepatosplenomegaly, anemia, and eosinophilia. The acute parenchymal phase is usually difficult to diagnose except by serologic tests for *Fasciola*. *Pseudofascioliasis* refers to the presence of eggs in the stool, which results not from an actual infection but from recent ingestion of infected liver containing eggs. This can be avoided by eating a liver-free diet several days before stool examination (Thomas & Garg, 2007).

Consequences of Chronicity of Infection in Fascioliasis

Recent studies have shown a strong association between fascioliasis and liver fibrosis (see Chapter 6). It seems that hepatic fibrosis may evolve in some susceptible hosts depending on the time and burden of infection. Liver cirrhosis has been reported in infected children (Marcos et al, 2005) and adults (Sanchez-Sosa et al, 2000), especially those with high-density infections (see Chapter 70). New data on the pathogenesis of hepatic involvement associated with *F. hepatica* infection have implicated cathepsin L1 and its collagenolytic function, associated with tissue invasion (Stack et al, 2007) with proteolytic activity, leading to collagen type I expression and ultimately hepatic fibrosis (Marcos, unpublished observation). On the contrary, chronic infection may also cause a persistent immunosuppressed status, suggesting that the infected host may be susceptible during chronic infection to other Th2-associated pathogens (Gironès et al, 2007).

Treatment

Emetine and chloroquine be may be successful in the short term, but recurrence is the rule because these drugs have no effect on the parasite. Fasciolae are also usually refractory to praziquantel. The drug of choice for both phases of *Fasciola* infection is triclabendazole, 10 mg/kg orally, repeated after 12 hours (El-Tantawy et al, 2007; Marcos et al, 2008), and it can be used even in the presence of biliary obstruction. Cure rates of 90% have been reported with no significant drug-related side effects. The most frequent adverse event is biliary colic caused by the passage of dead or dying parasites passing through the bile ducts. Bithionol is an alternative, available as 200-mg tablets at a daily dose of 30 mg/kg/day, to a total therapeutic dose of 150 mg/kg. The drug is administered on alternate days in three divided doses after meals. Nausea, abdominal pain, diarrhea, and photosensitivity are the most common side effects. Clinical improvement is gradual and occurs over 2 to 3 weeks (Thomas & Garg, 2007).

Surgical treatment may be indicated for diagnosis or for cholangitis (see Chapter 43). On occasion, a live worm may be found in the gallbladder or the bile duct, or the worm may find its way out through the T-tube placed at surgery (Nicholas, 1970). Endoscopic retrograde cholangiopancreatography (ERCP) may be used to relieve obstruction with removal of the worm. Rarely, percutaneous transhepatic cholangiography (PTC) may be an alternative with failed ERCP (Fig 67.10; see Chapter 18).

Proteomics and genomics have led to identification of molecules, including cathepsin L, glutathione S-transferase, leucine aminopeptidase, and fatty acid binding proteins (Dalton et al, 2003). The feasibility of inducing protective responses has been proven only in laboratory and large animals; human studies are lacking. Development of a vaccine for fasciolaisis still requires analysis of the protective effector mechanism provided by different vaccine candidates, vaccine formulations, doses, and route of administration.

Clonorchiasis

Epidemiology

C. sinensisis is endemic in northeast China, southern Korea, Japan, Taiwan, northern Vietnam, and the far eastern part of Russia (Lun et al, 2005; Rim, 2005). In general, the infection is acquired by eating raw or uncooked cyprinoid fish products in rural areas.

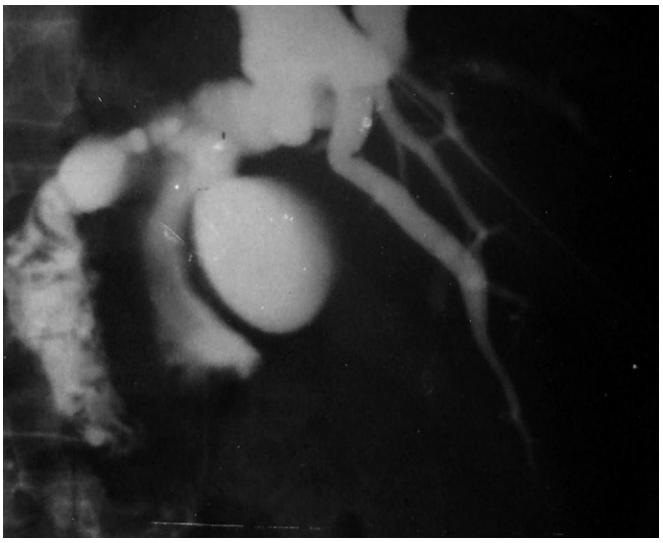

FIGURE 67.10. Percutaneous transhepatic cholangiography of *Fasciola hepatica* inside the common bile duct. *(Courtesy Professor A.K. El Dory, Ain Shams University, Cairo.)*

Morphology and Life Cycle

C. sinensis is 10 to 25 mm long, 3 to 5 mm wide, pink, and transparent when alive but hard, friable, and black when dead (Hou, 1956). Adult worms inhabit the intrahepatic ducts and may migrate down the common bile duct but tend to die in the gallbladder. In heavy infection, they may be found in the pancreatic duct. Cysts from infected fish are digested by gastric juice; larvae then migrate from the duodenum into the common bile duct upward until they lodge in a duct that is too small for further passage. Eggs laid in bile ducts reach the intestine to be excreted in feces, and the life cycle continues in fresh water in the snail, grass, or black carp, the intermediate hosts. The cercarial forms that emerge from the snail in fresh water attach to and penetrate the fish, with encysted metacercariae developing in the muscles; humans acquire the infection by ingesting the fish (Thomas & Garg, 2007).

Pathology

Irritation by the worm causes the biliary epithelium to undergo hyperplasia, which may progress to metaplasia and adenomatous hyperplasia. In the initial stages, periductal inflammation is mild, and dilation of the small- and medium-sized ducts in the periphery of the liver may occur (Choi et al, 2004; Hou, 1956). Metaplastic changes occur early in biliary epithelium, transforming normal cells into mucin-producing cells, which results in highly mucinous bile. This results in stagnation of bile with repeated cholangiohepatitis that eventually kills the worms. This may lead to ductal fibrosis and stricturing with formation of calcium bilirubinate calculi (Choi et al, 2004) and sepsis resulting from infection by *Escherichia coli* and anaerobic streptococci (Fung, 1961; Tandon, 1988). Progression to biliary cirrhosis is unusual, but there is an increased incidence of cholangiocarcinoma in patients infected with *C. sinensis* (see Chapter 50; Choi et al, 2004; Flavell, 1981; Hou, 1956). The etiology of cholangiocarcinoma is multifactorial. Carcinogens in infected individuals may be prone to malignant changes when hyperplasia of bile duct cells occurs (Flavell, 1981).

Relationship to Recurrent Pyogenic Cholangitis (See Chapter 44)

Of patients with Oriental cholangiohepatitis, 50% are infected with *C. sinensis* (Augustine et al, 1988; Tandon, 1988; Teoh, 1963). It is prudent to investigate patients with cholangitis or cholangiocarcinoma who reside in endemic areas for evidence of *Clonorchis* infection because screening for latent infection may be appropriate in relatives and close contacts of patients who test positive for *Clonorchis* (Thomas & Garg, 2007).

Clinical Features

The clinical features are independent of the severity of infestation. In an endemic area, 86% of 1091 patients screened by stool examination were found to have clonorchiasis. Only one patient had intrahepatic stones, and the 8% incidence of gallbladder stones was related more to ethnicity than to infection with *C. sinensis* (Hou et al, 1989). The classic signs associated with clonorchiasis are those of recurrent pyogenic cholangitis (Park & Son, 2008; Stunell et al, 2006). When clonorchiasis is acalculous, it is usually asymptomatic. Early symptoms include general malaise, abdominal discomfort, and diarrhea. Screening investigations may show eosinophilia with fluctuating jaundice or elevated liver enzymes (Choi et al, 2004). Clonorchiasis occurs equally in males and females, with peak incidence in the second and third decades of life (Fung, 1961). Another study showed that men are more commonly affected (Choi et al, 2004). Anemia and hypoproteinemia are common. Jaundice varies in intensity, and progression to cirrhosis results in splenomegaly. Serum bilirubin and alkaline phosphatase levels are high, and transaminase levels are slightly elevated. Evidence of pancreatitis may also be found. Plain radiographs of the abdomen may reveal gas in the biliary tree, but stones are rarely visualized. US and CT detect ductal dilation and calculi; however, contrast imaging of the biliary tract is essential to delineate the distribution of stones and strictures and to plan operative therapy. The common bile duct and hepatic ducts are usually dilated (Fung, 1961), but definite stenosis is seen in only 5%. Cholangiocarcinoma may be intrahepatic, hilar, or extrahepatic (Choi et al, 2006). The diagnosis of clonorchiasis with cholangitis depends on high index of suspicion. Elevated eosinophil counts warrant a search for the parasite, and fecal examination for eggs has been used for diagnosis of clonorchiasis (Choi et al, 2005b). Detection of specific antibodies (Kim, 1998; Lin et al, 1995) and circulating antigen by Dot-ELISA has been described (Wang et al, 2004). Other methods for diagnosis include intradermal test with diluted antigens of *C. sinensis* (Shin & Choi, 2000), radiologic studies of the liver (Choi et al, 2004), and bile examination for eggs, metacercariae, and cercariae. Of these, the intradermal test is the easiest to perform, but it has low specificity (Shin & Choi, 2000). Real-time PCR appears to be a powerful tool for both the detection and quantification of *C. sinensis* infections (Kim et al, 2009). Paramyosin (CsPmy) is a myofibrillar parasitic protein whose gene has been identified. Induction of host IgG suggests that CsPmy may be a diagnostic antigen or a vaccine for clonorchiasis (Park et al, 2009).

Treatment

Praziquantel (Biltricide) is the drug of choice. The dosage schedule is usually 25 mg/kg/day three times at 5-hour intervals in 1 day (total dose, 75 mg/kg) for 1 or 2 days, with a cure rate of 83% to 85% (Kaewpitoon et al, 2008). Antibiotics may be needed for associated pyogenic cholangitis, and interventional procedures are required in cases complicated by calculus formation and depend on the location of ductal stones and strictures. Endoscopic and minimally invasive techniques have the advantage of reduced morbidity over open surgery (Zhi et al, 2004). These procedures are usually adequate only in simple strictures, and patients referred to surgery are complicated cases in whom multiple endoscopic (ERCP) or percutaneous (PTC) procedures have failed.

Biliary Ascariasis

Epidemiology

Ascaris lumbricoides is a roundworm that commonly infects more than a quarter of the population in Asia, Africa, and Central America as well as those who have emigrated to the United States from these areas (Misra & Dwivedi, 2000). Clinical symptoms occur in individuals who have a heavy worm burden (Khuroo, 2001). When confined to the intestine, *Ascaris* infestation is usually asymptomatic, although ascariasis is an important cause of biliary disease in areas of the world where the rate of *Ascaris* infection is high. Tropical and subtropical regions with poor socioeconomic conditions and fecal contamination of the soil around dwellings and farms are main sources of infection (Khuroo et al, 1989a; Louw, 1966). Infection becomes symptomatic when the worms enter the biliary tract (Khuroo et al, 1989a, 1989b). Kamiya and colleagues (1993) reported that more than 11% of patients with gallbladder or biliary tract complications had *Ascaris* worms in their biliary tract. The incidence of gallstones in developing and developed countries is similar (Hou et al, 1989; Khuroo et al, 1989a), and it is unnecessary to consider ascariasis as an etiologic factor in all patients diagnosed with gallstone disease who hail from an endemic area.

The adult worm in humans inhabits the small intestine, mainly the jejunum, where the fertilized female lays eggs. These ova are excreted in host feces and can survive environmental conditions. In warm moist soil, the ova undergo maturation and are able to infect humans if the egg is swallowed. Mature ova hatch in the duodenum, releasing larvae that penetrate the mucosa of the proximal intestine to enter the portal venous blood, in which they are carried through the liver and via the right side of the heart to the pulmonary capillary bed. Here, larvae develop further, penetrating alveoli to travel up the trachea, enter the esophagus, and return to the intestine. In the jejunum, they mature to adults, reach 20 to 30 cm in length, and have a life span of 1 to 2 years (Thomas & Garg, 2007).

Pathology

The adult *Ascaris* reaches the duodenum either because of increased worm burden in the jejunum or as a consequence of increased intestinal motility (Khuroo, 1996). The ability of *A. lumbricoides* to enter the common bile duct, especially with heavy duodenal infection, is well known. Usually only one or two worms enter the biliary system, but massive infection may occur. The worm head moves first through the ampulla of Vater to the common bile duct, cystic duct, and intrahepatic ducts; because the length of the extrahepatic tree is only 4 to 10 cm, part of the worm may remain in the duodenum (Davies & Rode, 1982). In 2002, Kamiya and colleagues reported that 95% of the worms found in the biliary tract were located in the

hepatocholedochus, whereas only 3% were found in the gallbladder and even more rarely in the intrahepatic ducts. Migration into the biliary tract has been reported to be frequent after cholecystectomy, sphincterotomy, sphincteroplasty, choledochostomy, or biliary enteric anastomosis, presumably from increased space in the bile duct after gallbladder removal and increased release of cholecystokinin and secretin, which relaxes the sphincter of Oddi (Wani et al, 2000). Biliary migration is commonly seen in women, especially pregnant women; this is due to high levels of progesterone, which also relaxes the sphincter of Oddi (Shah et al, 2005). Children are at lower risk for biliary migration because of the small diameter of their ductal systems (Zargar & Khuroo, 1990).

The worm tends to move out of the biliary tract within 24 to 36 hours of inducing biliary or pancreatic symptoms, and the detection of live ascarids in the duodenal lumen is considered strong evidence of biliary ascariasis. The impacted worm causes spasm of the sphincter of Oddi, resulting in partial biliary obstruction and colicky pain, and cholangitis can occur after mechanical obstruction (see Chapter 43). Suppurative cholangitis may extend to intrahepatic ducts and cause multiple cholangiolitic liver abscesses. Acalculous cholecystitis, empyema of the gallbladder and, less commonly, necrosis and perforation of the bile duct may occur (Chang & Han, 1966). Dead worms cannot leave the bile duct; rather they disintegrate, providing a nidus for stones and provoking a chronic inflammatory response that leads to ductal strictures. Calculi associated with ascariasis are of the calcium bilirubinate type (Khuroo et al, 1989b; Maki, 1966), with the exception that ascarid ova or debris usually can be identified in the calculus. *Escherichia coli,* the pathogen usually identified with calcium bilirubinate stones, is frequently encountered in suppurative cholangitis (Maki, 1966). Another factor that may facilitate stone formation is the albuminoid membrane that covers most of the eggs and is not found in any other parasite. Worms reaching the intrahepatic ducts may become impacted or invade the liver parenchyma to form nests of worms (Lloyd, 1982). Unable to extricate themselves, the worms die. The resultant cholangiolitic abscess may enlarge and present on the surface or rupture into the peritoneal cavity. Extension of the abscess through the diaphragm can cause bronchopleural fistula and lung abscess, a well-known and potentially fatal complication (Chang & Han, 1966; Lloyd, 1981). The presence of dead worms in the bile duct also induces an intense eosinophilic inflammation that precipitates a fibromatous reaction. Eventually, the dead worms are surrounded by calcification, and the ongoing inflammation results in biliary stricture formation (Shah et al, 2006). Based on the aforementioned pathologic features, biliary ascariasis has been classified as *uncomplicated* and *complicated* (Thomas & Garg, 2007).

Clinical Features

Biliary ascariasis in the pediatric age group is most commonly seen in children aged 2 to 8 years. In endemic areas, adults are frequently affected, and mean age at presentation is 35 years. For unknown reasons, women are three times more likely to be affected than men; in children, a similar sex difference has not been noted. The mean duration of symptoms varies from 4 to 6 years, and 40% of patients may give a previous history of biliary surgery. In one large series, 80% of patients had undergone either cholecystectomy or endoscopic sphincterotomy (Sandouk et al, 1997a). Microscopic examination of stool and bile samples in these patients gives a positivity rate for *A. lumbricoides* of nearly 100% (Khuroo et al, 1990). Vomiting of worms is common, as well as a history of passing worms in the stool (Lloyd, 1981; Louw, 1966).

The most common presentation is usually with sudden severe upper abdominal colic with tenderness and guarding localized to the right upper quadrant or epigastrium. If present, fever is usually low grade, and jaundice, marked toxemia, and hepatomegaly are usually absent. Worms are rarely seen in the gallbladder, and the US finding of distension, wall edema, and intraluminal sludge completely resolves, usually within 2 weeks. Endoscopic examination is difficult to perform and unnecessary in the acute phase, but if done it may show duodenal or ampullary worms. ERCP has been commonly used for both diagnosis and removal of worms from the biliary tract (Fig. 67.11) and is particularly valuable when used with real-time US, with a sensitivity of 100% (Sanai & Al-Karawi, 2007).

ACUTE SUPPURATIVE CHOLANGITIS

Worms in the bile duct may block the cystic duct, leading to acute acalculous cholecystitis or empyema of the gallbladder. Biliary stasis as a result of spasm of the sphincter of Oddi coupled with intestinal contents carried by the worm into biliary tract lead to pyogenic cholangitis (Shah et al, 2006). This appears with right hypochondrial pain, fever, jaundice, tender hepatomegaly, and leukocytosis. Apathy, hypotension, metabolic acidosis, and electrolyte disturbances signify a grave prognosis. US may show worms in the biliary tree, and endoscopy may visualize pus, a tubular filling defect not suggestive of a tumor or stone on cholangiography, or a worm emerging from the ampulla (Fig. 67.12).

HEPATIC ASCARIASIS

No clinical features distinguish hepatic ascariasis from suppurative cholangitis. The diagnosis is usually made at US, and aspirated pus might yield the ova of *A. lumbricoides.* The right lobe is more commonly affected, and rupture into the peritoneal cavity is a recognized complication (Shah et al, 2006).

ACUTE PANCREATITIS

The character of the pain with acute pancreatitis varies, but an increase in serum amylase confirms diagnosis. Although encountered half as often as the purely biliary presentation (Louw, 1966), the condition was seen in only 31 of 500 patients in the series by Khuroo and colleagues (1990). Severe pancreatitis with progression to hemorrhagic pancreatitis or pancreatic fluid collections occurred in only one tenth of these cases. Sandouk and colleagues (1997a) reviewed 300 patients with pancreatic ascariasis in Syria and showed that US, along with clinical findings, was the mainstay of diagnosis, similar to another review of 14 patients (Misra & Dwivedi, 2000).

Late Complications

Late complications include intraductal calculi and biliary strictures.

Diagnosis

LABORATORY STUDIES

Stool analysis is usually the investigation of choice in the search for ascarid ova or remnants of dead worms, and results may approach 100% (Khuroo et al, 1990). Leukocytosis greater than 12,000/mm^3 usually denotes suppurative biliary and hepatic complications. The eosinophil count is seldom elevated

more than 5%. Hyperbilirubinemia occurs in hepatopancreatobiliary ascariasis (Lloyd, 1982). Elevation of alkaline phosphatase and transaminases may occur when cholangitis supervenes, and pancreatitis is suggested if serum amylase is greatly elevated. Normal liver enzymes and amylase levels have been reported in a case of recurrent ascaris related pancreatitis as a result of worm migration (Lee et al, 2009). Specific serologic tests are available that can be used to monitor successful treatment (Santra et al, 2001) but are not commonly used in clinical practice.

DIAGNOSTIC IMAGING

Abdominal radiographs may confirm the presence of intestinal worms in 90% of children. On occasion, air is seen in the biliary tree or in hepatic or subphrenic abscesses (Lloyd, 1982). US is the imaging modality of choice because it shows dilated bile

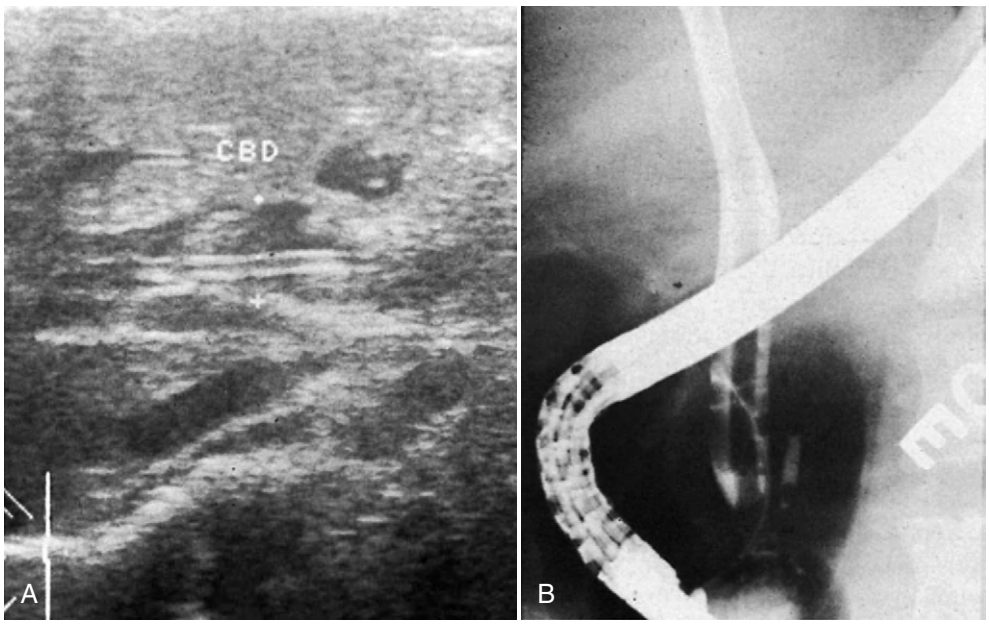

FIGURE 67.12. A, Ultrasound of a 30-year-old woman with biliary colic of 7 days' duration, showing the dilated common bile duct (*CBD*) with an echogenic tubular structure in the lumen and no distal shadowing. **B,** Endoscopic retrograde cholangiopancreatography in the same patient reveals the worm in the CBD and across the papilla. *(Courtesy Professor M.S. Khuroo, Sher-I-Kashmir Institute of Medical Sciences, Srinagar, India.)*

ducts containing linear or round areas of increased echogenicity representing worms (Desai & Tobin, 1995; Akhter et al, 2006'). Other findings were gallbladder distension with sludge inside, an edematous wall, and a mildly dilated biliary tree (Akhter et al, 2006). Real-time scanning may reveal the diagnostic movement of active worms within the biliary system. Multiple bile duct worms have a spaghetti-like appearance, with alternating echogenic and echolucent strips; if densely packed in the bile duct, they may appear as a hyperechoic pseudotumor (Shah et al, 2006). On transverse scanning, the biliary worm produces a bulls-eye appearance (Cremin, 1982). Other characteristic appearances include single or multiple long, linear echogenic strips within the bile duct without acoustic shadowing (Khuroo et al, 1987). US is useful for identifying intrahepatic worms and abscesses and for monitoring the response of lesions to therapy. Ascarid liver abscesses characteristically contain echogenic worm debris; CT does not offer significant advantage over real-time US, and it is less sensitive (Sandouk et al, 1997a). A thin line of dye is occasionally seen within the corpus of worm that has swallowed dye, and the worm is easily visualized on an unenhanced scan within the biliary tree (Sherman & Weber, 2005).

Endoscopy may reveal a worm in the duodenum, and occasionally a worm may be seen impacted in or protruding from the ampulla of Vater. ERCP has been done safely, even in the acute setting, and it shows worms in the extrahepatic and intrahepatic biliary tree, including liver abscesses (Lloyd, 1981) and cases of recurrent pancreatitis (Lee et al, 2009). Biliary strictures can be studied, and endoscopic extraction of worms and biliary decompression may succeed in aborting an attack of severe cholangitis (Khuroo et al, 1990). Magnetic resonance cholangiopancreatography (MRCP) is a useful modality in pancreaticobiliary ascariasis. The worms are described as linear, hyperintense tubular structures with a central hypointense area (Arya et al, 2005). EUS has been shown to document biliary ascariasis (Sriram et al, 2006). Percutaneous transhepatic cholangiography has been used in cases of failed ERCP to visualize and relieve obstruction in the abnormal biliary tree containing worms (Lloyd, 1982). Adult worms or debris may be identified in the aspirated bile.

Management

The management strategy for ascariasis includes conservative measures, endoscopic extraction, or surgical intervention. Without appropriate nonoperative management, worms spontaneously return to the duodenum in 98% of children (Chang & Han, 1966; Louw, 1966) and 94% of adults (Khuroo et al, 1990). Parenteral antispasmodic drugs and analgesics to relax the sphincter of Oddi and relieve biliary colic, nasogastric decompression, and intravenous fluids are recommended in the acute stage. Successful elimination of an adult *Ascaris* worm from the gallbladder 7 days after killing it with albendazole has been documented (Cha et al, 2002); however, oral antihelmintic drugs may not be helpful in the treatment of biliary ascariasis because of poor enterohepatic circulation (Khuroo, 1996). Administration of piperazine citrate through the nasobiliary catheter has been shown to be effective (Kamath et al, 1986). However, some investigators believe that this approach should not be used because it has been reported to cause paralysis or death of the worm in the bile duct, and this dead worm may act as a nidus for future stone formation (Shah et al, 2006). Albendazole (400 mg/day for 1 day) or mebendazole (100 mg twice daily for 3 days) and pyrantel pamoate (single dose of 11 mg/kg to a maximum of 1 g) are the preferred agents, and cure can be achieved in nearly 100% of cases. The safety of these drugs in pregnant women and children younger than 2 years is not established; in this situation, piperazine is safe in a single dose of 75 mg/kg (maximum 3.5 g) on 2 consecutive days. Stool examination is required to confirm eradication of the infection, and follow-up US is needed to look for intraductal worms. ERCP is recommended if symptoms or US abnormalities persist beyond 2 weeks with suspected pancreatobiliary ascariasis. To prevent reinfection in endemic areas, antihelmintic therapy must be repeated every 2 months in patients who are cured (Khuroo et al, 1990).

The problem of reinfection of the bile ducts after operative or endoscopic removal of worms has led to important modifications in the interventional approach previously advocated (Chang & Han, 1966; Louw, 1966). Preoperative eradication of intestinal worms ideally should be done before endoscopic or surgical manipulation of the common bile duct. Severe persistent pain unrespondive to antihelmintics is an indication for ERCP and endoscopic removal of intrabiliary worms. In an endemic area, multiple reinvasions of the bile ducts by worms is seen in patients who have undergone endoscopic sphincterotomy (Khuroo et al, 1990).

It would seem to be of paramount importance to preserve the sphincter of Oddi (Shah et al, 2006; Khuroo & Zargar, 1985; Khuroo et al, 1990). Failure of response to conservative management with increasing jaundice may indicate coexisting stones in the common bile duct (Khuroo & Zargar, 1985; Khuroo et al, 1990). When skilled endoscopic intervention has failed or is unavailable, PTC or surgery is recommended, a situation more likely to occur in children than in adults (Hangloo et al, 1989). Laparoscopic common bile duct exploration, with removal of the worm and a cholecystectomy, was reported by Astudillo and colleagues (2008).

Conservative management includes treatment of pain with analgesics, treatment of pyogenic cholangitis with antibiotics, and oral administration of antihelmintic drugs. The patients are subsequently allowed nothing by mouth and are given intravenous fluids. This management strategy is applied for a few days, and its success is judged by improvement in pain, fever, and jaundice with simultaneous disappearance of the worms from the bile duct. The symptoms usually resolve with this approach within 3 days in 60% to 80% of patients.

Worm extraction with biliary drainage may be lifesaving in patients with severe cholangitis, and it is successful in all patients from the papillary opening and in more than 90% of patients from the bile ducts (Shah et al, 2006). Biliary cannulation in these patients is easier to achieve because the passage of worms across the sphincter makes it patulous (Khuroo et al, 1990). Worms can be extracted across the papillary opening by using a grasping forceps or a dormia basket; polypectomy snares should be avoided because the snare may cut the worm, leaving a remnant that may lead to stone formation. The worms in the bile duct may protrude out of the papilla after injection of the contrast and thus may be extracted. If the worms are unable to come out or are dead, they can be pulled out using a dormia basket or a biliary occlusion balloon (Reddy et al, 2003). Total clearance of bile ducts may require multiple endoscopic sessions. Endoscopic papillary balloon dilation has been described in nonendemic areas to remove the worm and associated calculi (Misra & Dwivedi, 1998). When the worm cannot be reached

by conventional ERCP, Sandouk and colleagues (1997b) have suggested using the whirlpool jet technique. Early ERCP should be performed when pancreatobiliary ascariasis is suspected in cases of repeated pancreatitis following cholecystectomy and sphincterotomy, even with normal liver enzymes, because of worm migration (Lee et al, 2009).

Surgical intervention is required in patients after an unsuccessful endoscopic attempt; if the *Ascaris* organisms enter the intrahepatic ducts, leading to the formation of stones, strictures and abscesses; and when gallbladder ascariasis is present (see Chapters 39 and 44; Shah et al, 2006). Laparoscopic extraction of live worms from the bile duct has also been reported in the literature (Yoshihara et al, 2000). Overall, 20% of patients with biliary ascariasis need surgery (Wani & Chrungoo, 1992). An initial operative cholangiogram helps define the extent of the infection. Worms are removed through a longitudinal choledochotomy because compression of the liver often propels intrahepatic worms toward the common bile duct. Choledochoscopy is also valuable, especially if worms, debris, or stones are impacted in the intrahepatic ducts.

The evacuated biliary tree is irrigated with saline and closed over a large-bore T-tube. Intraoperative cholangiography through the T-tube is done to identify residual worms. The liver may contain granulomatous nodules or abscesses, and worms under the liver capsule can be extracted by incision and drainage of the abscess. Removal of all worms from the intestine via enterostomy is an important part of the operation to prevent biliary reinfestation, a serious complication that may require reoperation.

Postoperatively, a broad-spectrum antibiotic is prescribed. Worms identified in the bile duct at this point should be managed conservatively because the worm may spontaneously return to the intestine. Irrigation of the T-tube with saline may help, but antihelmintics should not be administered through the T-tube; this would kill the worm in the common bile duct and prevent spontaneous evacuation. Endoscopic extraction may be successful if the worm is impacted around the T-tube or can be removed by applying suction to a T-tube and gently withdrawing it with the worm. If these measures fail, reoperation is necessary with preoperative oral antihelmintics (Thomas & Garg, 2007).

Full recovery is the rule, with a mortality rate of 1% or less. Worm reinvasion after successful initial management is always symptomatic and may occur in 30% of those treated (Khuroo et al, 1989b, 1990). A careful search for biliary lithiasis in the intrahepatic and extrahepatic bile ducts and management of sepsis and biliary strictures should result in a good prognosis. MRCP and ERCP should always be considered in cases of repeated pancreatitis. Recurrent pyogenic cholangitis, liver abscesses, and granuloma necessitate surgery.

In endemic areas, school screening may be effective in the detection and early treatment of asymptomatic carriers. Health education, good sanitation, and early medical therapy of intestinal ascariasis are the best ways to prevent reinfection.

Biliary Opisthorchiasis (See Chapter 45)

Opisthorchiasis is caused by *Opisthorchis viverrini* and *O. felineus,* the latter of which is endemic in the Soviet Union, Kazakhstan, and Ukraine. The infection is acquired by eating raw or uncooked cyprinoid fish products in rural areas or dishes as *koi-pla* (Sayasone et al, 2007).

These small flukes migrate to the liver through the duodenum via the ampulla of Vater into the bile ducts, where they mature into adult worms in less than a month. The adult flukes reside in medium-sized and small intrahepatic bile ducts and occasionally in extrahepatic bile ducts, the gallbladder, and pancreatic duct, where they can live for many years; in the liver, they can live for decades (Marcos et al, 2008).

Clinical Features

Because *Opisthorchis* flukes do not penetrate the liver parenchyma, their disease manifestations are caused by the obstruction of the biliary tract, where they can cause prominent inflammation. Flukes can occasionally gain access to the pancreatic tract, where they can cause obstruction and pancreatitis.

OPISTHORCHIS VIVERRINI

In acute infection, only 5% to 10% of heavily infected patients have symptoms, such as right upper quadrant pain, flatulence, fatigue, and a hot sensation over the abdomen. In the chronic phase, mild hepatomegaly occurs. Jaundice and splenomegaly are rare, but intrahepatic duct stones and recurrent cholangitis are common. Whenever jaundice and ascending cholangitis are detected, fluke-related cholangiocarcinoma should be suspected (see Chapter 50B).

OPISTHORCHIS FELINEUS

In acute infection, symptoms occur 2 to 4 weeks after eating raw fish and include fever, nausea, vomiting, abdominal pain, malaise, arthralgia, lymphadenopathy, and skin rash (Tselepatiotis et al, 2003). Eosinophilia is common during the initial 2 to 6 weeks of infection, with raised liver enzyme levels. In chronic infection, eosinophilia is milder. Patients may come to medical attention with suppurative cholangitis and liver abscess because of biliary obstruction.

CONSEQUENCES OF CHRONICITY OF INFECTION IN OPISTHORCHIASIS

The higher the intensity and the higher the anti–*O. viverrini* antibody titres, the higher the risk for cholangiocarcinoma (Honjo et al, 2005). The International Agency for Research on Cancer recognizes this parasite as a category I carcinogen. The lesions that predispose to malignant changes in *O. viverrini* are dilation of subcapsular medium and large bile ducts with prominent fibrotic wall, periductal inflammatory cell infiltration, goblet cell metaplasia, epithelial and adenomatous hyperplasia, and periductal fibrosis. The pathogenesis of *O. viverrini*–mediated hepatobiliary changes may be due to mechanical irritation or its metabolic products (Sriamporn, et al, 2004). Several N-nitrosol compounds and their precursors occur at low levels in fermented food, such as preserved mud fish paste (*pla ra*), a condiment that is a ubiquitous component of the cuisine of northeastern Thailand and Laos (Sripa et al, 2007).

The study of *O. viverrini* genes should expedite molecular studies of cholangiocarcinogenesis and accelerate research focused on developing new interventions, drugs, and vaccines that might help in controlling *O. viverrini* and related flukes (Laha et al, 2007).

Diagnosis of Opisthorchiasis

Opisthorchiasis is diagnosed by detection of eggs in feces. In light infections, those with fewer than 10 adult worms in the biliary tract, a PCR detecting the DNA of the adult parasite in

stools may be helpful (Duenngai et al, 2008). Ruangsittichai and colleagues (2006) reported high sensitivity and specificity using a recombinant eggshell protein with potential for the serodiagnosis of human opisthorchiasis.

Treatment of Opisthorchiasis

Praziquantel is the drug of choice for *O. viverrini* and *O. felineus* treatment. For *O. viverrini,* a single dose (40 to 50 mg/kg) of praziquantel treatment is indicated, with a cure rate between 91% and 97% (Kaewpitoon et al, 2008).

BLOOD FLUKES

Schistosomiasis

Schistosomiasis is sometimes referred to as *bilharziasis* after Theodor Bilharz, who first identified the parasite in 1852. Schistosomiasis is caused by infection with blood flukes known as *schistosomes.* It can be associated with serious morbidity and mortality and may cause anemia, chronic pain, diarrhea, exercise intolerance, malnutrition, bladder cancer, portal hypertension, and central nervous system complications (King et al, 2005). Chronic complications usually occur in individuals who live in endemic areas and have recurrent exposure. However, schistosomiasis can also cause complications in people with even brief exposures, such as travelers (Blanchard, 2004). Three major species and two less common species produce infection in humans. Of the major species, *Schistosoma mansoni* is common in tropical and subtropical areas of sub-Saharan Africa, the Middle East, South America, and the Caribbean. *S. japonicum,* prevalent in Asia, can provoke intestinal and hepatic complications. *S. haematobium* is common in North Africa, sub-Saharan Africa, the Middle East, Turkey, and India and predominantly leads to renal and bladder sequelae, although on occasion it results in liver disease. The minor species include *S. mekongi* and *S. intercalatum,* both of which can also induce intestinal and liver disease. More than 200 million people worldwide are estimated to have schistosomiasis, a disease responsible for more than 200,000 deaths annually (Chistulo et al, 2004).

Life Cycle

The life cycle of schistosomiasis is complex and requires both intermediate and definitive hosts. The adult worms are approximately 1 to 2 cm in length with a cylindrical body, two terminal suckers, a blind digestive tract, and reproductive organs (Gryseels et al, 2006). The male schistosome forms a groove, where the female resides. Females produce hundreds to thousands of eggs per day. After contact with water, the ovum releases miracidium, which seeks an intermediate host in the snail. After 4 to 6 weeks, the miracida multiply asexually into sporocysts and later into cercariae. The cercariae leave the snail and seek a definitive host, where they develop into adult worms. As the definitive host, humans acquire schistosomiasis via contact with fresh water. Cercariae penetrate the intact skin of humans and become schistosomulae, which migrate from the skin into blood and lymph vessels and are carried to the heart and lungs. They then migrate through pulmonary capillaries into the left side of the heart and then into the arterial circulation, where they are carried to the mesenteric arteries, splanchnic arteries, and portal veins; they subsequently reach the liver, where they mature into adults over a period of 1 to 4 weeks.

Different species have a propensity to affect different organs. The adult worms migrate against portal blood flow to varying destinations: mesenteric venules of the small intestine (*S. japonicum* and *S. mekongi*), mesenteric venules of the colon (*S. mansoni* and *S. intercalatum*), and the vesical venous plexus (*S. haematobium*). Adults remain in these blood vessels for life, residing in permanent copulation and adhering to wall of blood vessels. Worms survive for 5 to 7 years but can persist up to 30 years (Arnon, 1990). Female worm begins to produce eggs, which travel hematogenously to other sites or traverse from vascular space through host tissues to the lumina of intestine or urinary bladder. The eggs are then variably excreted in the feces (*S. mansoni, S. japonicum, S. haematobium, S. intercalatum,* and *S. mekongi*) or the urine (*S. haematobium*).

Pathogenesis

Unless adult worms migrate to an unusual location, such as the spinal cord or brain, little damage occurs to the host, whereas cellular infiltrate is consistently found around the eggs (Keating et al, 2006). Eggs released into the bloodstream can invade local tissues, release toxins and enzymes, and provoke a Th-2–mediated immune response. Inflammation and granuloma formation occur around deposited eggs and lead to fibrosis of affected tissues (Cheever et al, 2000). *S. mansoni, S. japonicum, S, mekongi,* and *S. intercalatum* eggs tend to either penetrate the bowel adjacent to the mesenteric vessels or travel via the portal venous system to the liver. In the bowel, granulomatous inflammation around the invading eggs can result in intestinal schistosomiasis characterized by ulceration and scarring (Strickland, 1994).

In the liver, eggs lodge in presinusoidal radicles of the portal vein, where they elicit a granulomatous fibrosing reaction that blocks venous blood flow. Portal hypertension results, with compensatory portosystemic blood flow and late progressive liver damage. Symmers' pipestem fibrosis is pathognomonic. It is distinct from cirrhosis because there is no hepatocyte dysfunction; instead, the portal hypertension results from fibrosis within blood vessels. Eggs of *S. haematobium* usually affect urinary tract; however, this parasite may be associated with hepatic damage.

The interaction between the parasite and host immune response is complex. Immunity to infection with any schistosome species is both innate and acquired. It is the host's immune response to invading eggs that is the major cause of clinical disease. A host-mediated type 2 Th2 fibrogranulomatous inflammatory response occurs, which may result in activation of hepatic stellate cells, the mediators of fibrosis (Bartley et al, 2006).

The age-intensity curve in endemic areas characteristically shows a rise in intensity of infection during the first 2 decades of life, followed by a decline in adults, with possible acquired immunity to adult worms. The behavioral factors (e.g., walking barefoot and swimming) may play a role in the incidence of infections in children compared with adults.

Clinical Picture

Most patients are asymptomatic, and symptoms depend on the stage of disease. The different species of *Schistosoma* cause varying clinical complications. Acute symptoms may present as swimmer's itch or Katayama fever. Symptoms are also more

likely to occur in travelers and other nonimmune hosts. Lymphadenopathy, eosinophilia, and hepatosplenomegaly may be prominent findings. The diagnosis of Katayama fever relies upon appropriate epidemiology and consistent clinical findings (Gryseels et al, 2006).

Symptoms of chronic infection often begin insidiously and are progressive without treatment. Intestinal schistosomiasis may cause chronic or intermittent abdominal pain and diarrhea with iron-deficiency anemia secondary to ulceration and polyps. Acute appendicitis has also been described in one case report (Gabbi et al, 2006). Hepatic schistosomiasis can lead to hepatomegaly and severe splenomegaly in children and adolescents. Chronic hepatic schistosomiasis develops years later in young and middle-aged adults, with a long duration of intense infection, splenomegaly, and portal hypertension. However, hepatocellular function remains normal. Leading causes of morbidity and mortality include the formation of ascites and esophageal bleeding from varices. Urinary schistosomiasis may be asymptomatic or may cause hematuria, and symptoms related to anemia may be present. Squamous cell carcinoma of the bladder and nephritic syndrome may occur (Ross et al, 2002).

Schistosomiasis can sometimes be associated with serious neurologic complications. Pulmonary manifestations can also be seen in people with hepatosplenic disease as a result of heavy infections with *S. mansoni, S. japonicum,* or *S. haematobium* infection. Presinusoidal portal hypertension fosters the development of portosystemic collateral vessels that allow *Schistosoma* eggs to embolize into the pulmonary circulation, leading to granulomatous pulmonary endarteritis. Pulmonary hypertension and cor pulmonale gradually ensue with dyspnea as the principal symptom. As disease evolves, the heart enlarges and pulmonary arteries dilate to aneurysmal proportions, representing end-stage, irreversible alterations (Sarwat et al, 1986). Recurrent urinary tract infections or bacteremia as a result of *Salmonella* infection are classic complications of schistosomiasis (Elliott, 1996). It has been postulated that infection with *S. haematobium* may increase the risk of HIV infection (De Silva et al, 2006). Persons with hepatitis B or C viruses have more severe disease.

Diagnosis

Complete blood count may show anemia, leukopenia, or thrombocytopenia as a result of hypersplenism with hypercellular marrow, portal hypertension, or varices. The liver profile is usually normal except in cases of coinfection. Eggs in the stool or urine are often used as a test, and rectal snips as well as circulating antigen are specific and sensitive to detect active infection and assess treatment. Serology usually detects previous exposure, and abdominal US shows splenomegaly and periportal fibrosis.

Treatment

Praziquantel is the drug of choice for treatment of schistosomiasis. *S. haematobium, S. mansoni,* and *S. intercalatum* can be treated with 40 mg/kg in one or two doses, whereas the dosage for *S. japonicum* and *S. mekongi* is 60 mg/kg in two or three doses at least 3 hours apart. No serious side effects are reported, and treatment is efficacious in about 85% to 90% (Ross et al, 2002). In addition to antihelmintic therapy, patients with severe portal hypertension and esophageal varices may also benefit from treatment with propranolol and/or sclerotherapy band ligation or shunt procedures (see Chapter 70; Elliott, 1996).

Despite its demonstrated efficacy in decreasing recurrent variceal hemorrhage, enthusiasm for surgery has declined over the last 2 decades, due in part to the more easily administered techniques of endoscopic therapy or intervention. Orthotopic liver transplant is the only treatment that corrects the portal hypertension and also corrects the liver failure when it occurs. Endoscopic therapy or intervention and distal splenorenal shunting do not hinder transplantation but lengthen the time taken for surgery (Bismuth et al, 1995).

ACKNOWLEDGMENT

The authors acknowledge the contributions of P.G. Thomas and N. Garg to this chapter.

CHAPTER 68

Hydatid disease of the liver

Jake Krige, Phillipus C. Bornman, and Jacques Belghiti

OVERVIEW

Hydatid disease, or echinococcosis, is a widespread zoonotic parasitic disease caused by a tapeworm that continues to be a clinical and public health problem worldwide, especially in areas where animal husbandry and subsistence farming form an integral part of community life. Hydatidosis infects a large number of wild and domestic animals and humans, and the larval stage of the disease develops into a hydatid cyst. Hydatid disease is most frequently caused by *Echinococcus granulosus*, and the liver is the most commonly involved organ in two thirds of patients, although it may affect any part of the body, either as a primary or secondary event (Shaw et al, 2006). The life cycle of *Echinococcus* requires a definitive host, which is often a dog, and an intermediate host, which is commonly sheep. Humans become accidental intermediate hosts when they become infected after ingesting ova passed in dog feces.

During the natural history of hydatid cysts in the liver, several complications may occur, the most frequent and severe of which are secondary infection of the cyst cavity, biliary fistula causing jaundice and cholangitis, and rupture of the cyst into the peritoneal or pleural cavity. The diagnosis is confirmed by noninvasive radiologic imaging. Surgery is the treatment of choice for complicated cases, but uncomplicated cysts located in anterior liver segments have been treated successfully laparoscopically. Medical treatment alone for univesicular cysts, and in conjunction with surgical and percutaneous techniques, is effective in selected patients. Percutaneous treatment techniques represent an important therapeutic advance in the treatment of hydatid disease. Increasing migration and world travel requires that clinicians, radiologists, and surgeons in developed countries have a clear understanding of the diagnosis and treatment of hydatid disease. *Echinococcus multilocularis,* which causes alveolar echinococcosis, is discussed separately.

PATHOGENESIS AND ETIOLOGY

Although 16 species and 13 subspecies were originally described in the genus *Echinococcus,* molecular epidemiologic studies have led to the recognition of only four clinically important species: *E. granulosus, E. multilocularis (E. alveolaris), E. oligarthrus,* and *E. vogeli* (Thompson, 2001). Recently, a new strain, *E. shiquicus,* has been identified on the Tibetan plateau, but to date no human infection has been described (Shaw et al, 2006). The characteristics of the four *Echinococcus* species are summarized in Table 68.1. *E. granulosus* is the most common and is the main focus of this chapter. *E. multilocularis*, a rare and aggressive form of hydatid disease, is discussed separately at the end of the chapter.

E. granulosus is a small, hermaphroditic tapeworm about 5 mm in length. The tapeworm consists of a head, or *scolex,* and a body, or *strobila,* with three or four proglottids (Fig. 68.1). The last one is the largest and bears the mature eggs. The eggs contain a hexacanth embryo that has three pairs of lancet-shaped hooklets. The life cycle of *E. granulosus* requires two hosts, a carnivore and an herbivore (Fig. 68.2). The adult tapeworm lives in the intestine of the dog, which is the most common definitive host for *E. granulosus*. Worms release large numbers of infected eggs that pass out in the dog feces and contaminate soil, water, and plants. The eggs are ingested by the intermediate host (humans are accidental intermediate hosts), the eggs hatch, and the embryo migrates through the intestinal wall into the portal system. Most embryos lodge in the liver, mainly in the right lobe because of preferential portal flow; there they develop into hydatid cysts within months to years. Embryos may escape this first filter and lodge in the capillaries of the lung, where they develop. A small percentage of embryos find their way into the systemic circulation and involve other organs, including the spleen, kidney, brain, bone, or any other site. Most patients have single organ involvement. In the liver, the parasite develops into the larval stage, the hydatid cyst, which is filled with fluid and contains hundreds of protoscolices. For the life cycle to be complete, a canine host must ingest the hydatid cyst or its contents, which commonly occurs when infected sheep are slaughtered and organs containing hydatid cysts are fed to dogs (Krige & Beckingham, 2001).

EPIDEMIOLOGY

The disease occurs principally in sheep-grazing areas, especially where dogs are allowed to stray and eat uncooked viscera. Echinococcosis is endemic in many Mediterranean countries, the Middle and Far East, South America, and South and East Africa. The incidence of disease in humans in endemic areas depends on the level of health care and veterinary control. The incidence of human hydatidosis is often established by the number of surgically treated patients. The yearly incidence of human hydatidosis per 100,000 population ranges from 0.4 in Switzerland and Wales to 196 in Turkana in the northwest of Kenya. This high incidence is due to the close relationship the Turkana people have with their dogs: they sleep with them for warmth in the desert nights, and dogs are kept as "nurses" to lick babies clean after they vomit or defecate (Richards, 1992; Watson-Jones & Macpherson, 1988). This domestic intimacy results in many of the population becoming infected when very young (Morris, 1992).

Immigrants from endemic areas have a higher incidence of hydatid disease than native residents in Western countries. Indigenous people in endemic areas are the primary high-risk group, but aid workers and tourists are also at risk for becoming infected by hydatid disease, although infection in those groups is less frequent. Human infection results from eating raw

Table 68.1

Characteristics of Echinococcus Species

	E. Granulosus	*E. Multilocularis*	*E. Oligarthus*	*E. Vogelii*
Geographic distribution	Worldwide	Limited to Northern Hemisphere	Central and South America	Central and South America
Definitive hosts	Dog, fox, wolf, dingo, jackal	Fox, dog, cat	Wild felines (e.g., jaguar, puma)	Bush dog
Intermediate hosts	Sheep, cattle, pig, goat, camel, buffalo, human	Rodent, pig, horse, human	Rodent, human	Rodent, human
Cyst structure	Typically unilocular, spherical in shape	Multivesicular	Polycystic	Polycystic
Infiltration or metastasis	No	Yes	No	No
Location of cysts	Visceral, primarily liver and lungs	Visceral, primarily liver	Peripheral, primarily muscles	Visceral, primarily liver
Number of segments in worm (range)	3 (2 to 7)	5 (2 to 6)	3	3
Total length of worm (mm)	2 to 11	1.2 to 4.5	2.2 to 2.9	3.9 to 5.5

Modified from Thompson RCA, 2001: Echinococcosis. In Gillespie S, Pearson RD (eds): Principles and Practice of Clinical Parasitology. Chichester, UK, John Wiley & Sons, pp 587-612.

vegetables infected by the feces of dogs or by direct contact with dogs, mostly through the close contact of children with their pets. Some professions are particularly exposed, especially workers in slaughterhouses, veterinary stock breeders, shepherds, tanners, and butchers.

As a result of slow growth, cysts usually become symptomatic a few years after infection, in adolescence or early adulthood. Infected adults may become symptomatic later in life. Host immunity may overcome infection, resulting in a nonviable echinococcal cyst without the person ever becoming symptomatic. Humans are accidental hosts and play little part in the transmission of the disease, making them so-called *dead-end hosts,* and the disease is not transmitted from human to human (Shaw et al, 2006).

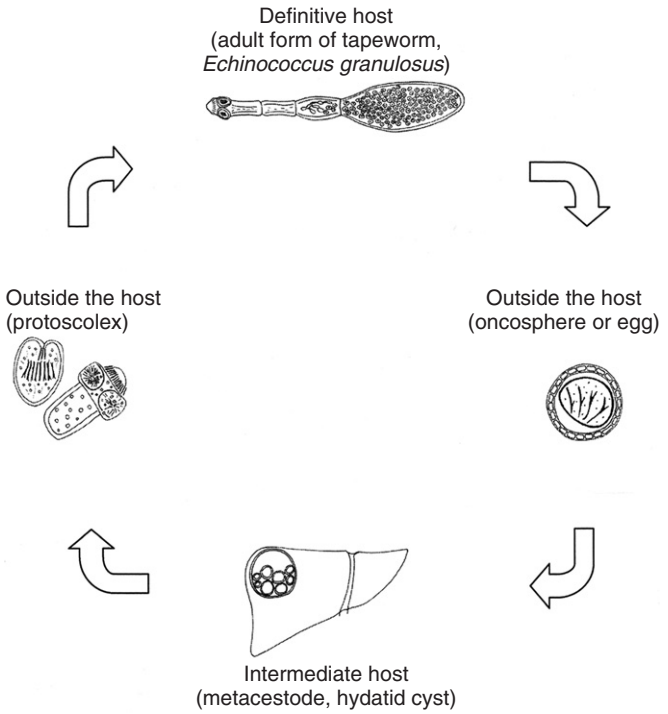

FIGURE 68.1. Life cycle of *Echinococcus granulosus.*

DEVELOPMENT OF A HYDATID CYST

When the parasite reaches the liver parenchyma, it develops into a cystic larval phase, which is visible within 3 weeks and may measure up to 3 cm in diameter after 3 months. The mature *E. granulosus* cyst consists of three layers: a *germinal layer,* a *laminated layer,* and an *ectocyst.* The inner, germinal layer surrounds the fluid-filled central hydatid cavity and in turn is surrounded by the laminated layer. These two layers together form the *endocyst.* Compression of the host tissue around the endocyst produces a fibrous layer known as the *ectocyst* or *pericyst* (Figure 68.3).

The germinal layer, also called the *germinative membrane,* is the living component of the parasite. Undifferentiated cells in the germinal layer produce invaginations into the cyst cavity, forming brood capsules that contain protoscolices, which are released into the cyst fluid. The germinal membrane secretes fluid into the cyst and is the source of daughter cysts (Fig. 68.4). The presence of daughter cysts creates multivesicular cysts, which are more common in adults than in children. Daughter cysts have a structure similar to the mother cysts, including a laminated and germinative membrane, cyst fluid, brood capsules, and protoscolices. The only difference is the absence of an adventitial layer (Krige & Beckingham, 2001).

The thin germinal layer is supported externally by a characteristic structural component of the parasite, the laminated layer, which is acellular, always separable from the pericyst, and usually 1 to 2 mm thick. Although the laminated layer is permeable to water, potassium, chloride, calcium, and urea, it protects the cyst from host enzymes, bile, and bacteria. The formation of daughter cysts is known as *endogenic vesiculation. Ectogenic vesiculation* occurs when there is a small leak or defect in the laminated membrane, and the germinal layer passes through to create a "satellite" hydatid cyst.

The ectocyst or pericyst is a fibrous capsule that develops from host tissue as an inflammatory reaction to *E. granulosus*. This thick fibrous layer is present in hydatid cysts in the liver and spleen but is absent in pulmonary and brain hydatid cysts.

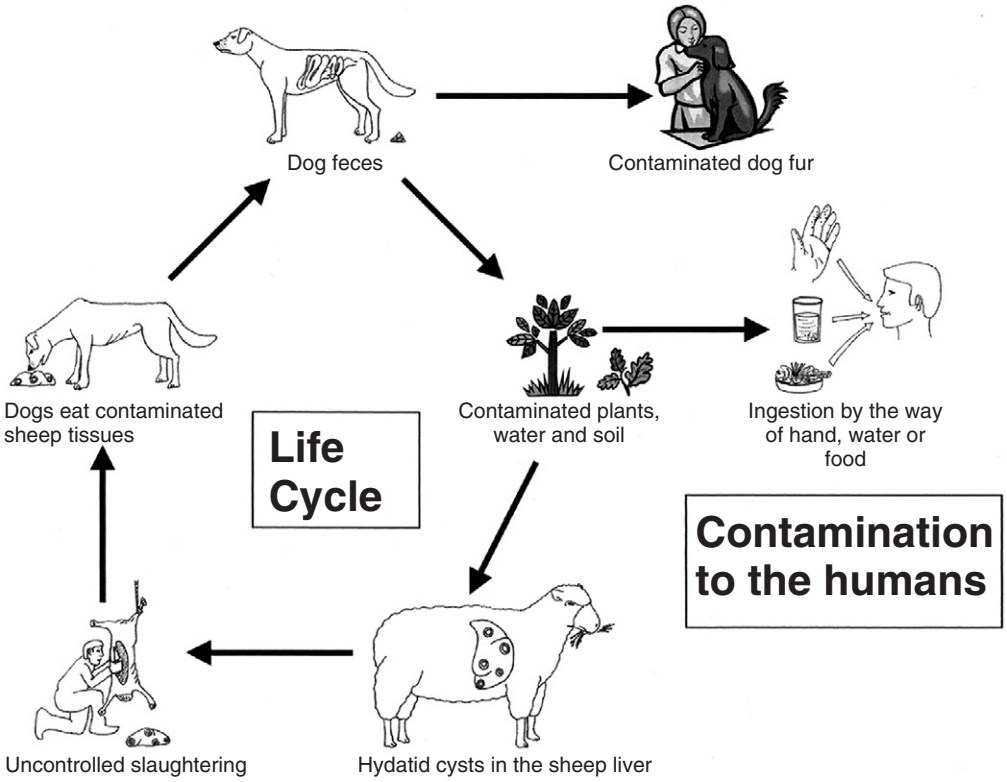

FIGURE 68.2. Usual route of *Echinococcus granulosus* and contamination of humans during the life cycle.

Vascular structures and bile ducts in the adventitial layer remain intact and patent despite enlargement of the cyst and may result in postoperative bleeding or bile leaks after partial pericystic resection. The blood supply of the adventitial layer is abundant and results in the appearance of a hypervascular rim or halo around the cystic cavity on computed tomography (CT) scans after contrast injection. No clear cleavage planes are apparent between the adventitial layer and the surrounding normal host tissue, and the cyst is not readily separable from the surrounding parenchyma. With time, the adventitial layer may calcify, either partially or totally (Krige & Beckingham, 2001).

An uncomplicated hydatid cyst typically contains a clear, colorless, odorless fluid secreted by the germinal membrane. Sodium, chloride, and bicarbonate concentrations are the same in the fluid as in the patient's plasma, whereas potassium and calcium levels are lower. In uncomplicated cysts, hydatid fluid is sterile. Bile-stained cyst fluid indicates a cystobiliary communication. When superadded infection is present, the cyst fluid appears frankly purulent; in degenerated cysts, the fluid becomes turbid. Spillage of hydatid fluid content as a result of traumatic or iatrogenic rupture produces implantation of protoscolices and secondary cysts on surrounding viscera, known as *secondary hydatidosis* (Krige & Beckingham, 2001). Although any segment

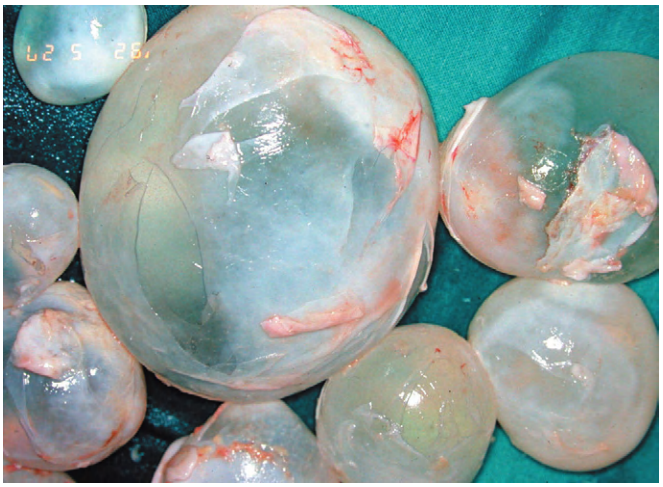

FIGURE 68.4. Hydatid daughter cysts.

of the liver can be involved, the location of liver hydatid cysts seems to be related to the respective volume of each lobe of the liver; thus a higher involvement of the right lobe is observed, especially in segments VII and VIII (Kayaalp et al, 2003).

COMPLICATIONS

Hydatid cysts in the liver may cause symptoms as a result of direct pressure, from the inflammatory reaction around the cyst, from distortion of neighboring structures or viscera, or as a result of erosion into the bile duct, pleural space, or peritoneal cavity. Rarely the cyst may communicate with the bronchial tree, pericardium, or digestive tract.

Compression

As the cyst grows, enlargement tends to occur toward the surface of the liver and Glisson's capsule, compressing the surrounding parenchyma and leading to compensatory hypertrophy of the remaining liver tissue. Sometimes an entire liver lobe can be replaced by a large cyst without any symptoms. Depending on the location, large cysts can cause compression of the adjacent bile ducts, portal or hepatic veins, or vena cava that causes obstructive jaundice, portal hypertension, or Budd-Chiari syndrome (Moreno-Gonzalez et al, 1994).

Cyst Infection

Cysts may become infected after an episode of bacteremia or via a communication with the bile ducts. Presentation is similar to a pyogenic liver abscess with right upper quadrant pain, high fever, rigors, leukocytosis, and elevated C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). Jaundice and cholangitis may occur if daughter cysts enter the bile duct. Fluid resuscitation, broad-spectrum antibiotics, and endoscopic and percutaneous drainage are the principal methods of treatment.

Rupture into the Biliary Tract

Intrabiliary rupture is the most common complication of liver hydatid cysts (Iscan & Duren, 1991; Yilmaz & Gokok, 1990). Cystobiliary communications that occur after rupture of a cyst into the bile ducts can be minor or major. Minor communications are usually asymptomatic and are revealed postoperatively by the presence of a bile leak, whereas major communications cause obstructive jaundice and cholangitis (Figure 68.5). In histologic studies of the pericyst wall, numerous biliary ducts of various sizes that communicate with the residual cavity have been demonstrated (Gahukamble et al, 2000), suggesting the existence of biliary communications in most hydatid cysts (Langer et al, 1984). The reported incidence of clinically evident cystobiliary communications rates vary from 2.6% to 28.6% (Langer et al, 1984; Ozmen et al, 1992). In a study by Kayaalp and colleagues (2003), the incidence of cystobiliary communications was 37% and the incidence of clinically apparent biliary leakage was 26%. The incidence of cystobiliary communications depends largely on the criteria used for defining the communications. Morel and colleagues (1988) showed a 36% rate of bile leaks when doing routine intraoperative cholangiography.

Preoperative and intraoperative determination of biliary communication is important. Kayaalp and colleagues (2002) found that the risk of biliary-cyst communication was higher in male patients (40.9% vs. 10.4%; $P < .01$) and in those with abnormal preoperative serum alkaline phosphatase and γ-glutamyltransferase (GGT); it was also higher in patients with multiple cysts, multilocular (23.8%) and degenerated cysts (24%) compared with unilocular cysts (12.5%); cysts near the biliary bifurcation, and in the presence of bile-stained or purulent cyst contents compared with others (61.9% vs. 2%; $P < .001$). Although the size of the cyst did not seem to be significant with regard to bile leakage in this study, Atli and colleagues (2001) found that a cyst diameter greater than 10 cm was an independent clinical predictor for the presence of intrabiliary rupture.

FIGURE 68.5. Computed tomographic scan showing a hydatid cyst biliary communication.

A *major biliary communication* has been defined as a fistula greater than 5 mm in diameter, a communication between the cyst and the main bile duct, or both (Bourgeon, 1985). The reported incidence of major biliary-cyst communications ranges from 5% to 10% (Zaouche et al, 2001). When large segmental ducts are involved, daughter cysts may enter the bile duct and cause obstructive jaundice or cholangitis or both. Ultrasound (US) and CT scans may show a detached membrane in the cyst cavity associated with dilated intrahepatic and extrahepatic bile ducts (see Fig. 68.5). Endosonography may also detect cystic material in the extrahepatic bile ducts. Endoscopic retrograde cholangiopancreatography (ERCP) is useful to confirm biliary obstruction that results from hydatid material and facilitate treatment with an endoscopic sphincterotomy and extraction of the hydatid debris with a balloon or basket (Fig. 68.6; Ozaslan & Bayraktar, 2002).

Rupture into the Bronchial Tree

A bile leak into large hydatid cysts in segments IVa, VII, and VIII of the liver with secondary infection results in inflammatory adhesions to the diaphragm and the pleurae, which may erode spontaneously into the pleural space, pulmonary parenchyma, and bronchi and lead to a bronchobiliary fistula. This classic presentation is confirmed when the patient reports coughing up "grape skins" (Krige & Beckingham, 2001).

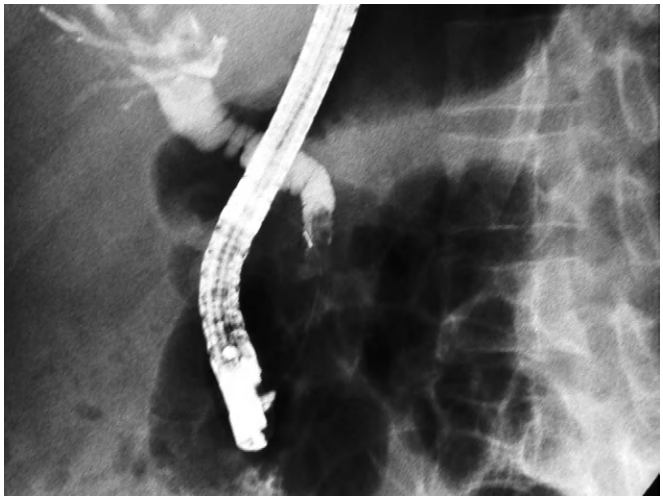

FIGURE 68.6. Endoscopic retrograde cholangiopancreatography demonstrating hydatid material within the lower common bile duct.

Rupture into the Peritoneum

Intraperitoneal rupture of a hydatid cyst is an uncommon clinical presentation, even in endemic regions, with an incidence ranging from 1% to 8% (Sozuer et al, 2002). Rupture can occur spontaneously. Although this complication may be totally silent (Abdel Hameed & Abu Aisha, 1987), abdominal pain, nausea, vomiting, and urticaria are the most common symptoms, and acute abdominal signs—such as guarding, rebound, and tenderness—are generally present. This complication should be included in the differential diagnosis of an acute abdomen in endemic areas. The release of brood cystic fluid into the peritoneal cavity leads to multiple cysts throughout the peritoneal cavity, ultimately resulting in gross abdominal distension, ascites, and intestinal obstruction. US and CT may be helpful in defining the cyst with a detached membrane and intra-abdominal fluid in patients with a ruptured hydatid cyst (Fig. 68.7).

FIGURE 68.7. Free peritoneal fluid and detached membrane, indicating perforation of a hydatid liver cyst into the peritoneal cavity.

Rupture into Other Cavities or Organs

Rupture into the gastrointestinal tract that involves the stomach and the duodenum has been reported (Diez Valladares et al, 1998). Isolated cases of rupture of liver hydatid cysts into the pericardium (Thameur et al, 2001) and into large vessels, including the inferior vena cava, have also been described (Karunajeewa et al, 2002).

DIAGNOSIS

The diagnosis of hydatid cyst is based on a careful history, imaging, and serology and a high index of suspicion in at-risk populations. The presence on cytology or histology of hydatid material or scolices in the cyst fluid confirms the diagnosis.

Symptoms

Small (<5 cm in diameter) and uncomplicated cysts usually are asymptomatic and detected incidentally during a radiologic examination of the upper abdomen or right upper quadrant. The expansion of larger cysts or the inflammatory reaction around a cyst causing irritation of the adjacent parietal peritoneum may cause moderate pain in the right upper quadrant or in the lower chest. Acute abdominal pain usually indicates an infected hydatid cyst or rupture into the peritoneal cavity. When antigenic cyst fluid is released into the circulation, especially after rupture into the peritoneal cavity, a variety of acute allergic manifestations may occur, such as urticaria, anaphylactic attacks, or episodes of asthma (Vuitton, 2004). Extrusion of cyst contents into the biliary tree may lead to absorption of the hydatid antigen in sensitized patients, resulting in similar allergic manifestations (Little, 1976). Clinical features of rupture into the biliary tree are recurrent colicky pain and jaundice, with or without resultant fevers and chills, mimicking obstructing bile duct stones. Bronchobilia resulting from a hepatobronchial fistula and ascites resulting from pressure on hepatic veins or inferior vena cava or both (Budd-Chiari syndrome) are rare clinical presentations.

Laboratory Tests

Even large hydatid cysts of the liver may not alter liver function tests, and transaminase levels are usually normal. Cholestatic enzymes, such as alkaline phosphatase and GGT, can be mildly elevated in about one third of patients, especially in patients with biliary compression (Kayaalp et al, 2002). Elevated bilirubin levels (>1 mg/dL) with elevated alkaline phosphatase and GGT levels are highly suggestive of a cystobiliary communication. White blood cell counts are elevated only if the cyst has become secondarily infected. Eosinophilia (>3%) occurs in 25% to 45% of patients with hydatid cysts in Western countries, but this is a nonspecific finding in endemic areas (Pitt et al, 1986). Serum immunoglobulin levels are elevated in 31% of patients with hydatid liver cysts (Kayaalp et al, 2002).

Radiology

Ultrasound and Computed Tomography

US and CT are standard investigations used for diagnosis, percutaneous treatment, and posttreatment follow-up of hydatid cysts. US is the preferred first-line imaging method for hydatid liver cyst visualization followed by CT, which gives more precise

Table 68.2

World Health Organization Classifications of Hydatid Cysts

Cyst Type	Status	Ultrasound Features	Remarks
CL	Active	Signs not pathognomonic, unilocular, no cyst wall	Usually early stage, not fertile; differential diagnosis necessary
CE 1	Active	Cyst wall, hydatid sand	Usually fertile
CE 2	Active	Multivesicular, cyst wall, rosette-like	Usually fertile
CE 3	Transitional	Detached laminated membrane, water-lily sign, less round, decreased intracystic pressure	Starting to degenerate, may produce daughter cysts
CE 4	Inactive	Heterogeneous hypoechogenic or hyperechogenic degenerative contents; no daughter cysts	Usually no living protoscolices; differential diagnosis necessary
CE 5	Inactive	Thick, calcified wall, calcification partial to complete; not pathognomonic, but highly suggestive of diagnosis	Usually no living protoscoleces

information regarding the morphology of the cyst, including size, location, number, and relationships to adjacent structures. CT shows exogenous daughter cysts and cysts in the rest of the peritoneal cavity and may also show evidence of complications, such as common bile duct dilation as a result of biliary obstruction in a jaundiced patient with cholangitis because of the hydatid content in the bile duct. CT is not as operator dependent as US, and it gives the surgeon an accurate roadmap of the sites of the cysts in the liver.

Hydatid cysts appear as well-defined, circumscribed cystic lesions with a clear membrane; they do not infiltrate surrounding liver tissue, and cysts are staged according to the content patterns. Staging is important for using a uniform nomenclature to allow a rational comparison of different management strategies. Although most staging protocols were based on US findings in the past, CT findings can be adapted easily to these systems. The World Health Organization (WHO) Informal Working Group on Echinococcosis (2003) described an ultrasound classification system that intended to follow the natural history of hydatid disease. Based on several studies and classifications, liver hydatid cysts can be divided into six types (Table 68.2; Beggs, 1983; Gharbi et al, 1981; McCorkel & Lewall, 1985):

1. *CL type:* a well-circumscribed liquid image with a clearly defined wall that is often difficult to differentiate from a simple biliary cyst and corresponds to an early stage of development
2. *CE 1 type:* a concentric, hyperechogenic halo around the cyst (Fig. 68.8), which may contain free-floating hyperechogenic foci called *hydatid sand.*
3. *CE 2 type:* multivesicular cysts that have the most characteristic appearance, with the "daughter" and "granddaughter" cysts identified by honeycomb, rosette, spoked-wheel, or cluster images; can also have some free cyst fluid within the main cavity or may be full of daughter cysts without any free fluid (Fig. 68.9).
4. *CE 3 type:* partial or total detachment of the laminated layer with floating and undulating hyperechogenic membranes showing the dual wall and "water lily," and "water snake" signs.
5. *CE 4 type:* cysts that contain cystic and solid components together without visible daughter cysts.
6. *CE 5 type:* cysts with a matrix or amorphous mass with a solid or semisolid appearance, often a limited amount of

FIGURE 68.8. Computed tomographic scan of a univesicular hydatid cyst shows a single cyst with clear cyst contents.

FIGURE 68.9. Computed tomographic scan of a multivesicular hydatid cyst with honeycomb or rosette appearance, containing minimal fluid and filled with daughter cysts.

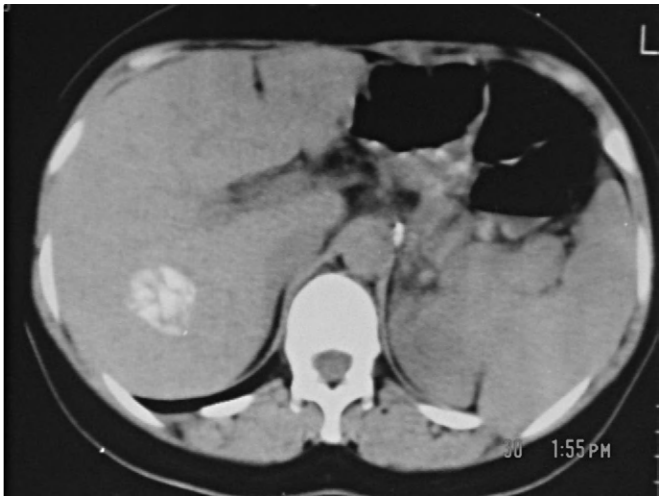

FIGURE 68.10. Computed tomographic scan of a calcified hydatid cyst.

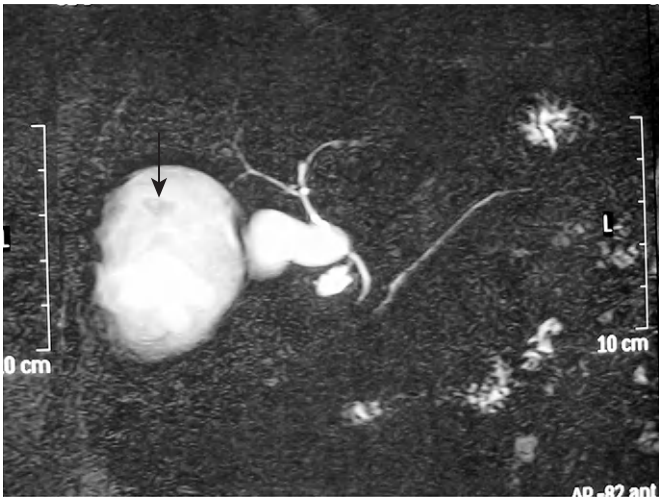

FIGURE 68.11. Magnetic resonance imaging cholangiography shows the relationship of the biliary system and the cyst along with intracystic fat density (*arrow*), suggesting cystobiliary communication.

calcification in the rim of the host adventitial tissue. This is the least typical of the cysts and may pose a diagnostic problem; they can be mistaken for a tumor, hepatic abscess, or hemangioma. Calcification in the cyst wall and hypoechogenic lacunar structures in the matrix do not indicate that the cyst is dead; a completely calcified cyst (eggshell appearance) is accepted as an effete or dead cyst (Fig. 68.10).

CL, CE 1, and CE 2 are considered active, fertile cysts. CE 3 is a transitional cyst believed to have begun degeneration. CE 4 is a degenerated cyst and CE 5 is a calcified cyst. The degree of calcification varies from partial to complete. CE 4 and CE 5 are accepted as inactive cysts (Shaw et al, 2006).

Other Imaging Studies

Plain radiography of the abdomen is of limited value in the diagnosis of hydatid liver cysts. A plain radiograph of the chest can reveal concurrent hydatid cysts of the lung. On T2-weighted magnetic resonance imaging (MRI), hydatid liver cysts may have a low signal intensity rim. This is a characteristic sign of hydatid disease that represents the outer, collagen-rich laminated membrane of the cyst. When present, daughter cysts are seen as cystic structures attached to the germinal layer that are hypointense relative to the intracystic fluid on T1-weighted images and hyperintense on T2-weighted images (Pedrosa et al, 2000). MRI is more specific than CT, especially if intracystic fat density is present, which suggests cystobiliary communication (Basaran et al, 2005). In cysts with biliary complications, MR cholangiography can provide good visualization of the intrahepatic and extrahepatic biliary tree and its relationship with the hydatid cyst and cystobiliary communications (Fig. 68.11; Little et al, 2002).

Serology

Serologic tests in hydatid disease are used for 1) the differential diagnosis of a cystic liver mass, 2) epidemiologic surveillance, and 3) posttreatment follow-up. Several serologic tests have been used in the diagnosis of human cases, and considerable differences in specificity and sensitivity are found among the various tests. Circulating *E. granulosus* antigens are small, and most are in the form of immune complexes. Detection of these antigens is less sensitive than antibody detection. At present, serologic tests usually are based on the reaction and precipitation of the test antigen and the circulating antibodies in the host. The sensitivity and specificity of the tests depend on the quality of antigens.

Immunoelectrophoresis

The diagnostic value of hydatidosis with immunoelectrophoresis ranges from 91% to 94% for hepatic cysts and 69% to 70% for pulmonary cysts (Varela-Diaz et al, 1983). Immunoelectrophoresis is not suitable for epidemiologic surveillance; rather, it is used for posttreatment follow-up.

Enzyme-Linked Immunosorbent Assay

Sensitivities for enzyme-linked immunosorbent assay (ELISA) vary from 64% to 100% depending on the antigens used (Coltorti, 1986; Iacona et al, 1980; Rickard, 1984). ELISA can also be automatized for large-scale epidemiologic studies. Selected test antibodies affect its value on posttreatment follow-up. Immunoglobulin (Ig) G assay may remain positive 4 years after successful treatment, so it is not a suitable test for posttreatment follow-up; IgM assay has been reported to be negative after 6 months of successful treatment (Zhang et al, 2003).

Blotting

Blotting allows molecular weight analysis of the antigens detected by the patient's serum. Western blotting with purified antigens has proved to be very useful in the diagnosis and postsurgical monitoring of hydatidosis patients (Doiz et al, 2001). The Arc 5 antibody test is a specific precipitation during electrophoresis of blood of hydatid cyst patients, with a specificity of 91%. Purification of antigens strongly affects the diagnostic value of the tests. Purified fractions enriched in antigens 5 and B and in glycoprotein yield a sensitivity of 95% and specificity of 100% (Sbihi et al, 1996).

TREATMENT INDICATIONS AND METHODS

Three treatment options are currently available for hydatid disease of the liver: surgery, which remains the most efficient treatment and the therapy of choice; percutaneous aspiration; and medical treatment. In general, hydatidosis is a public health problem, especially in developing countries, and the specific treatment selected may depend on social circumstances and the medical expertise available (Shaw et al, 2006).

Since the 1990s, percutaneous treatment has been increasingly used. Surgery has the advantage of removing the parasitic content of the cyst and the cyst wall and dealing with any associated complications. Although surgery may be technically demanding in patients with large and complicated hydatid cysts, advances in liver surgery have made complex operations safer and have reduced morbidity (Krige & Beckingham, 2001).

Conservative Management

Asymptomatic and small (<5 cm) CL-type cysts can be followed up with a wait-and-see policy with serial US examinations (Buttenschoen & Buttenschoen, 2003). Similarly, densely calcified hydatid cysts are accepted as dead cysts and can be monitored without any specific therapy.

Surgical Treatment

The literature on the surgical treatment of hydatid liver disease describes a variety of different techniques, ranging from simple evacuation to major liver resection. These techniques can be divided into two broad groups, *conservative* and *radical*. The conservative method involves inactivation of protoscolices and removal of the cyst contents; radical methods include total excision of the cyst and pericyst layers along with a portion of surrounding liver. Although no prospective randomized data compare radical and conservative surgery, most surgeons, especially in endemic areas, prefer conservative surgery, but some experienced liver surgeons may at times use pericystectomy or hepatectomy to deal with liver hydatid cysts. The principles of liver hydatid surgery include inactivation of protoscolices within the cyst fluid, evacuation of the cyst contents and prevention of spillage of the cyst contents, secure closure of any cystobiliary communications, and management of the residual cyst cavity (Terblanche & Krige, 1998).

Prevention of intraoperative spillage of the hydatid cyst contents is an important step during the procedure. Several methods have been described to avoid spillage. First introduced by Saidi and Nazarian (1971) and later by Aarons and Kune (1983), cone techniques allow the cyst to be entered in a safe and controlled manner with a funnel-shaped cone attached to the hydatid surface by suction or by freezing the contact area—although such an approach is not suitable for posterosuperior cysts attached to the diaphragm.

Preoperative Preparation

All patients undergoing surgery for hepatic hydatid cysts should have a detailed preoperative assessment that includes a chest radiograph to exclude pulmonary cysts (Figs. 68.12 and 68.13), an electrocardiogram, a complete blood count, international normalized ratio (INR), electrolyte and renal function tests, and liver function tests; in addition, blood should be grouped and screened. A recent CT scan of the abdomen should be reviewed before the operation to plan the surgical strategy and exclude hidden or occult pelvic, retroperitoneal, or hydatid cysts in other organs.

FIGURE 68.12. Chest radiograph showing lung hydatid cyst.

Surgical Incision

The position of the surgical incision depends on the location, size, and number of cysts in the liver and whether other extrahepatic intraabdominal cysts are present. Either a right subcostal incision with proximal midline extension or a bilateral subcostal incision will give adequate exposure to all liver hydatid cysts (Terblanche & Krige, 1998). A midline laparotomy is preferred in patients who have cysts in the left lobe of the liver and in those who have abdominal hydatidosis. Although thoracoabdominal incisions were used in the past for selected patients with large posterior liver hydatid cysts, a transthoracic approach is now used only for combined right lung and liver hydatid cysts, when a one-stage procedure can be done successfully for both cysts (Sahin et al, 2003).

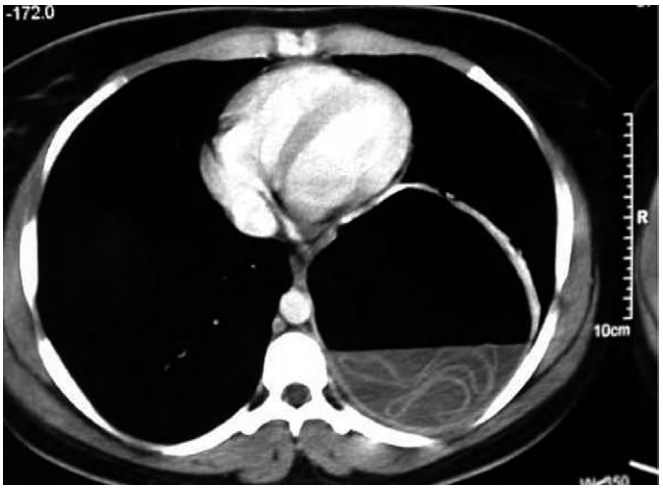

FIGURE 68.13. Chest computed tomography scan demonstrating a pulmonary hydatid cyst.

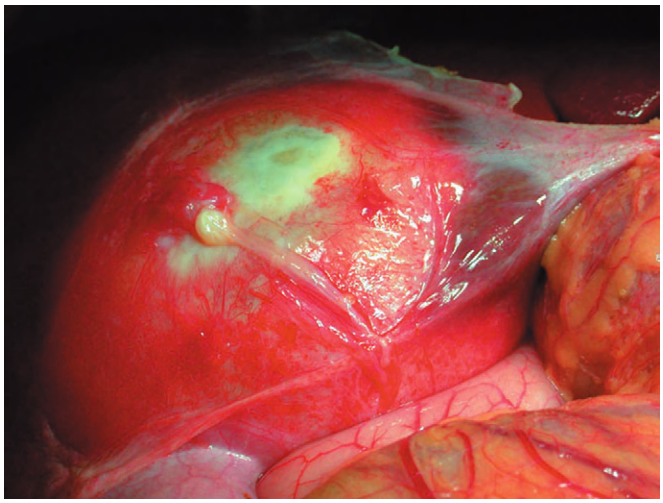

FIGURE 68.14. Shiny white appearance of the surface of a liver hydatid cyst.

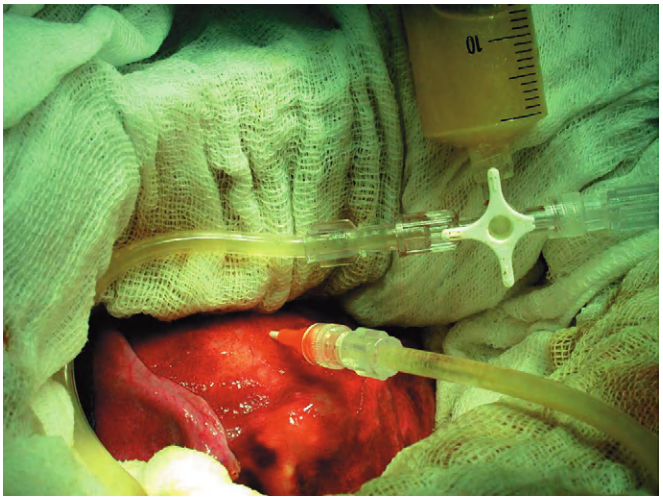

FIGURE 68.15. Aspiration of fluid from a hydatid cyst. Note the gauze packs soaked in scolicidal solution surrounding the aspiration site.

Conservative Surgery

Cystectomy is the safest and simplest surgical approach (Morris, 1992). After entering the abdomen, the skin wound is carefully protected with a plastic drape or a commercially available ring-shaped wound protector. A full laparotomy is performed, paying particular attention to potential sites of dissemination, including the omentum and pelvis (Morris, 1992). The characterisitic shiny white adventitial surface of a hydatid cyst is usually easily identified (Fig. 68.14). The position, size, and number of cysts in the liver are noted, as are the presence of complications and other extrahepatic intraabdominal cysts. It is important to assess the relationship of the cyst to the inferior vena cava, hepatic veins, and porta hepatis structures because large or multiple cysts frequently distort normal liver anatomy. For deeper cysts, palpation and intraoperative US help determine the most superficial part of the cyst suitable for aspiration and evacuation. Mobilization of the liver and the cyst should be minimal to avoid iatrogenic perforation of thin-walled cysts.

The area around the cyst is carefully isolated by gauze packs: the first layer is soaked with normal saline, and the second layer is soaked with a scolicidal solution; these act as a mechanical and a chemical barrier (Besim et al, 1998). An area 2 cm in diameter on the most prominent part of the exposed pericyst is left uncovered by the packs for insertion and evacuation. The cyst should be handled carefully because the contents of a viable cyst are usually under pressure. The point where the cyst is to be entered is identified, and the smallest possible working area is delineated by additional packing. At least two drains with powerful suction should be available, and one should have a sump cannula. The suction reservoir should have a large capacity, so that suction is not interrupted while changing reservoirs.

The cyst wall is pierced with a large-gauge needle connected to a 50-mL syringe and a three-way tap, and large-bore transparent plastic tubing is connected to a drain. The cyst is aspirated, and the volume and the color of the hydatid fluid are carefully noted (Fig. 68.15). As much fluid as possible is aspirated. If the cyst fluid is completely clear and not bile stained, turbid, or infected, scolicidal solution can be safely injected as long as the volume injected is less than what has been aspirated; the fluid is injected gently and not under pressure (Terblanche & Krige, 1998). A suction nozzle is kept at the needle puncture site at all times by the assistant to avoid any hydatid cyst fluid leaking out alongside the needle. The scolicidal fluid is left in the cavity for several minutes and then is reaspirated; this process is repeated twice. The cyst is decompressed again by aspiration; when the fluid level is sufficiently lowered, two stay sutures are placed close to the needle with upward traction on the stay sutures, which is maintained to allow the needle to be removed safely without spillage of residual cyst contents.

The objective is to remove the parasite totally, including both endocyst layers and the cyst contents. The cyst is incised between the sutures by electrocautery, a large-gauge sump suction cannula is inserted, and the contents are sucked out. The edges of the incision are grasped with Babcock tissue-holding forceps, and the stay sutures are removed. The incision is enlarged so that direct vision of the cyst cavity and its contents is obtained, and the sump suction can be moved freely around the cavity to evacuate the remaining fluid and cyst content. It is important to have a small opening of the cyst initially and to maintain constant upward traction on the edges of the incision, so that overflow or spillage does not occur. Warm saline solution is injected into the cavity intermittently to keep the suction tubing patent and to evacuate the hydatid sand.

Evaluation of the cyst content is important. The typical content of a viable cyst is clear fluid containing hydatid sand, daughter cysts, and the debris of brood capsules. Bile staining of the fluid implies a communication with the biliary tree and should warn against injection of scolicidal agents that may damage the biliary tree. Once the liquid has been drained, the laminated membrane collapses into the cavity, and the cyst contents can be evacuated. The incision is enlarged further, a kidney dish is brought close to the incision, and the evacuation of the daughter cysts begins (Fig. 68.16). Laminated membrane is best extracted with a ring forceps (Fig. 68.17), and small daughter cysts are best removed with a suction drain.

When all visible daughter cysts have been evacuated, the cavity is rinsed with warm saline, and the redundant portion of the cyst roof is excised. The adventitia and thinned-out liver are cut with electrocautery, and the cut edges are oversewn with a

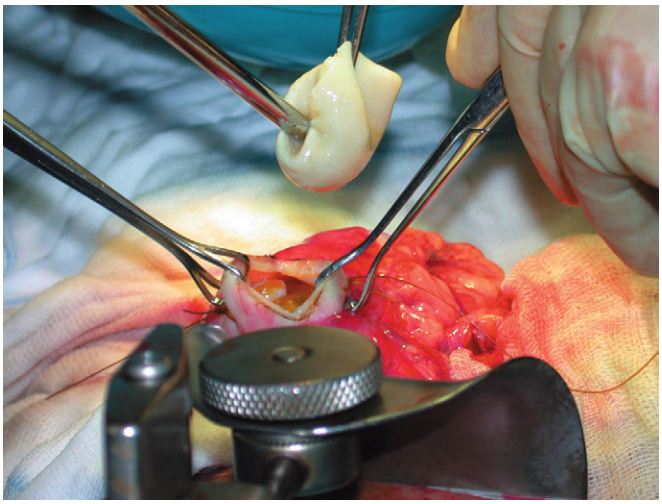

FIGURE 68.16. Removal of daughter cysts from the cyst cavity.

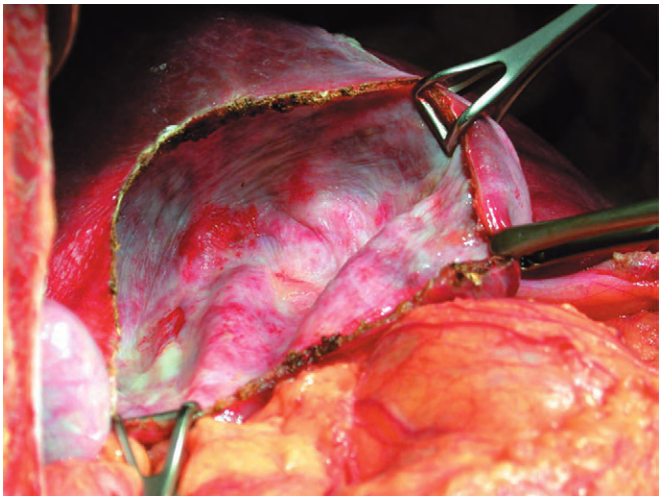

FIGURE 68.18. The residual hydatid cavity after extraction of the laminated membrane. The interior of the cyst is carefully inspected for bile leaks.

running mattress suture with an absorbable suture material; this is an important component of the operation because the cut edges contain blood vessels and small bile ducts. It is important to inspect the cavity for small daughter cysts that may be hidden in recesses of the main cavity. After removing the laminated membrane, the cavity is flushed with saline and inspected for bile leakage (Fig. 68.18). The cavity is packed with dry, white packs that are left in place for a few minutes and then removed. Bile stains are indicative of a bile communication.

If the aspirated contents are clear, scolicidal solutions are injected into the cyst, but never if the cyst has bile-stained or purulent content, which indicates a bile communication and hence the risk of causing caustic sclerosing cholangitis. Although some debate surrounds the efficacy and safety of protoscolicidal solutions injected into the cyst cavity, many consider injection of scolicidal solutions a prudent step when applying conservative surgery to reduce recurrence. Widely used scolicidal agents include hypertonic saline, fresh half-strength Eusol, 0.5% silver nitrate, and hydrogen peroxide. Hypertonic saline has been widely used in the past because of its availability and effective scolicidal properties (Kayaalp et al, 1999). Studies on different concentrations of hypertonic saline, ranging from 3% to 30%, have shown that the higher the concentration, the higher the scolicidal properties with a shorter contact time. In practice, 20% hypertonic saline is preferable, which has 100% scolicidal effect with an ideal contact time of 6 minutes (Besim et al, 1998). A danger of this practice is excessive absorption, which may result in hypernatremia, and the solution should be used with caution (Krige et al, 2002). A cetrimide (0.5%) and chlorhexidine (0.05%) combination (Savlex; Drogsan, Ankara, Turkey) used for 5 minutes is an effective scolicidal solution in laboratory and clinical studies (Besim et al, 1998). However, metabolic acidosis and methemoglobinemia have been reported as side effects (Baraka et al, 1980; Momblano et al, 1984).

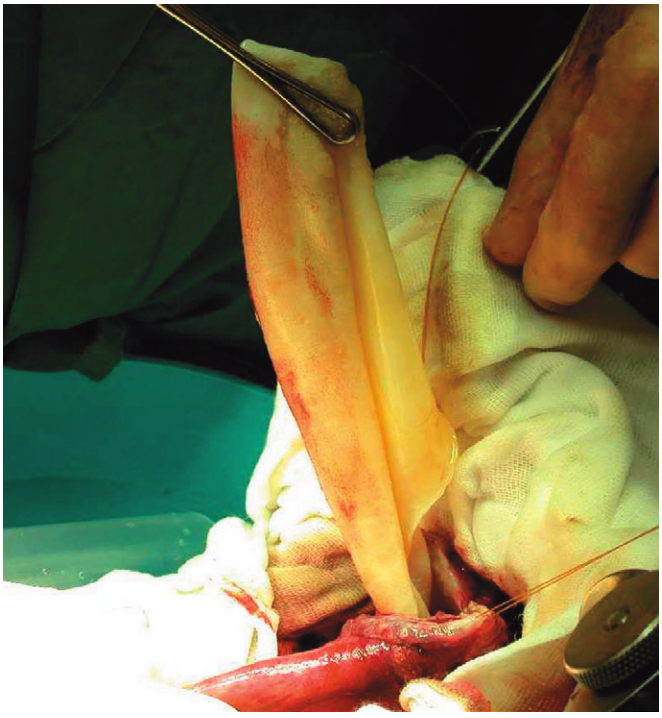

FIGURE 68.17. Removal of the laminated membrane from the cyst cavity.

Absolute alcohol has been used by interventional radiologists for the percutaneous treatment of hydatid cysts to produce sclerosis of the cyst cavity (Akhan & Ozmen, 1999), but it is not effective on protoscolices inside daughter cysts (Karayalcin et al, 1999). Disadvantages of absolute alcohol are the potential danger of caustic cholangitis and its flammable nature during surgical procedures when using electrocautery.

Povidone-iodine has been criticized because of an inappropriate animal model (Kolbakir & Erk, 1992). Gokce and colleagues (1991) reported that 1% povidone-iodine was superior to 20% saline. Landa Garcia and associates (1997) reported that 10% povidone-iodine was an effective agent for prevention of secondary hydatidosis in their in vivo study. The disadvantages of povidone–iodine are concentration dependency (Besim et al, 1998), induction of caustic cholangitis (Castellano et al, 1994), and coloring of the cyst cavity, which makes it difficult to identify the cystobiliary communications. Formalin is no longer used because of a high propensity to induce caustic sclerosing cholangitis. If a possible bile leak is suspected, the cyst is

carefully packed off and emptied by aspiration, and the contents are removed without injecting any scolicidal solutions to avoid the danger of inducing caustic sclerosing cholangitis (Shaw et al 2006).

Intraoperative Management of Biliary-Cyst Communication

Careful inspection for cyst-biliary communications should be done from a wide opening in the pericyst and should be confirmed by leaving a dry pad on the inner surface of the cyst and applying gentle pressure on the gallbladder. In cases of suspected biliary-cyst communication, intraoperative cholangiography is preferable to identify the communication site. After excision of the cyst, a methylene blue test through a transcystic duct tube is helpful in identifying small, overlooked biliary communications or leaks. Any obvious biliary orifices should be sutured to prevent postoperative biliary leakage, fistula, and cavity infections. On rare occasions, cyst communications involving a large duct may need drainage with a Roux-en-Y hepaticojejunostomy.

Management of the Residual Cavity

Although a variety of techniques have been described to prevent complications related to the residual cavity, depending on its size and shape and site, the safest way is to perform an omentoplasty. The omentum is mobilized from the transverse colon with sufficient mobility to pack the cavity and obliterate the dead space, and it is sutured to tether the omentum in place (Fig. 68.19). If the cavity has a large volume, a temporary drain is placed into the cavity alongside the omentum. Some put in two drains (Shaw et al, 2006). A closed, silastic suction drainage system is preferable; the tubes are removed as soon as drainage ceases. Omentum has a natural absorptive capacity that decreases the risk of infection and minimizes fistula formation. Older techniques, including capsulorrhaphy and capitonnage, are no longer used.

Postoperative Complications

Biliary Fistula

The incidence of biliary fistula after hydatid liver surgery varies from 1% to 10% (Abu Zeid et al, 1998; Barros, 1978). Endoscopic treatment is the main approach, and the aim of endoscopic drainage for biliary fistulas is to reduce the biliduodenal pressure difference to 0. The optimal endoscopic approach for managing external biliary fistulas resulting from hydatid liver disease has not been established. Sphincterotomy alone, stent or nasobiliary drain placement alone, and the combination of sphincterotomy and stenting or nasobiliary drainage have been used successfully for fistula healing. The overall success rate is 83.3% to 100%. Although closure time has been reported to be as short as 2 to 6 days, average duration of bile drainage after stent placement is generally 2 to 4 weeks (Ozaslan & Bayraktar, 2002; Simsek et al, 2003).

Biliary Stricture

Postoperative biliary strictures after surgical treatment of hepatic hydatid disease are uncommon. The most dramatic form is caustic sclerosing cholangitis, which is caused by the scolicidal solution entering the biliary tree from the cyst cavity (Belghiti et al, 1986). Diffuse caustic sclerosing cholangitis may result in secondary biliary cirrhosis, portal hypertension, and liver decompensation with ascites and bleeding esophageal varices, which may ultimately require liver transplantation (Loinaz et al, 2001). Minor passage of the scolicidal solution may cause a localized biliary stricture, which may be asymptomatic if the bile duct confluence is not involved (Belghiti et al, 1986). A bile duct stricture at the biliary confluence may result from a large biliary fistula treated by conservative surgery. Surgical repair is usually not feasible (Fig. 68.20), but long-term endoscopic stenting is a safe and effective method in these patients (Eickhoff et al, 2003; Yilmaz et al, 1998).

Recurrence

Recurrent disease is defined as the appearance of new active cysts after therapy of intrahepatic or extrahepatic disease (Sielaff et al, 2001). Failure to achieve permanent control of the primarily treated cyst is considered local recurrence, and the appearance of new cysts in the peritoneal cavity is regarded as disseminated disease. The incidence of local recurrence is approximately 10% after conservative surgery (Table 68.3). Intraoperative spillage of cyst contents, reduced effect of protoscolicidal agents, residual cyst content, and overlooked cysts lead to recurrence. All patients initially require close follow-up at 6-month intervals. Evaluation should include radiologic and serologic studies; complement fixation test, immunoelectrophoresis, counterimmunoelectrophoresis, ELISA, and blotting are used to detect recurrences. Even with complete removal of disease, blood titers may decrease slowly over months to years; therefore a positive serologic test during follow-up is not diagnostic of recurrence, but a rising titer is (Sielaff et al, 2001).

Pericystectomy

Also called *radical cystectomy, capsulectomy, total pericystectomy,* and *cystopericystectomy,* pericystectomy involves complete removal of the hydatid cyst. By creating a surgical plane just outside the pericyst layer without opening the cyst, the parasite and the adventitial layer are excised en bloc (Fig. 68.21). No clear anatomic plane exists, although the surgical approach of this plane does not differ from a classic liver parenchymal transection. The Cavitron ultrasonic aspirator (DentSply International,York, PA) is used to isolate the vessels and biliary ducts that are deviated and compressed by the cyst, and the parenchymal transection allows the suture of these vessels and bile ducts within the liver parenchyma. The aspirator should be used away from the pericyst to avoid fracture of the cyst, which can be responsible for spillage of the cyst contents.

Pericystectomy must be avoided for a cyst impinging on the major hepatic veins, inferior vena cava, or the liver hilum. On occasion, circumstances dictate a modified approach, and the surgeon may need to use a hybrid technique that uses both cystectomy with evacuation of hydatid contents and partial pericystectomy to resect peripheral liver parenchyma.

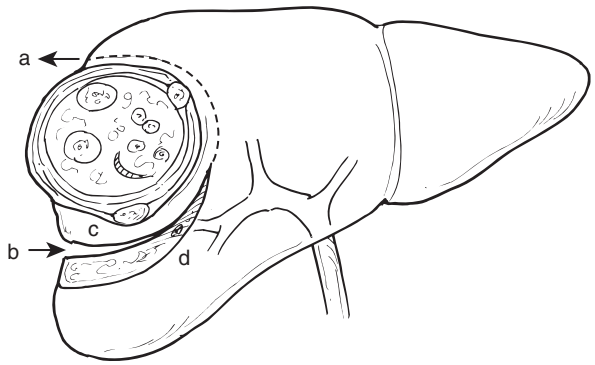

FIGURE 68.21. Closed pericystectomy. A line of parenchymal section passes close to the pericyst (*a*). A line of parenchymal section a little further from the pericyst (*b*); along the line, the liver parenchyma is shown as opened to some distance. Exogenous cyst just outside the pericyst layer (*c*). Suture of a biliary duct that communicated with the cyst (*d*).

Liver Resection

The indications for a formal hepatic resection for liver hydatid cysts are infrequent. Hepatic resection is the only surgical therapy for *E. multilocularis*, but it is inappropriately radical for *E. granulosus* (Morris, 1992). Other rare indications for liver resection are when the remaining parenchyma of a liver lobe is atrophic as a result of biliary obstruction, or when a large bile leak that cannot be safely managed with a Roux loop is present. Resection should be reserved for peripherally placed cysts, usually in the left lateral segment; for pedunculated lesions; or for extrahepatic intraabdominal cysts. Resection of small, pedunculated, and peripherally placed cysts is simple and safe, but in the majority of cases, cystectomy involves a major liver resection with its attendant increase in operative risk. Correct judgement is crucial because the operation may be complex as a result of distorted anatomy.

Radical surgery should not be standard procedure in the management of *E. granulosus* (Terblanche & Krige, 1998). In addition, a standard hepatic resection should not be done in

patients with large cysts that occupy the greater portion of the right lobe because the medial wall of such a cyst often involves the inferior vena cava and displaces the hepatic veins. Attempts to dissect outside the cyst are hazardous and unnecessary. Surgery for hydatid disease is done predominantly by general surgeons, frequently with limited resources. Surgeons who do not have extensive training and experience in liver resections should not be tempted to resect for hydatid disease. Meticulous and careful conservative surgery for this benign disease gives good results, and unnecessary operative mortality will certainly outweigh the merits of totally removing the cyst.

Laparoscopy

Although the laparoscopic approach to this disease offers some advantages, laparoscopic hydatid surgery has not gained a wide acceptance. Disadvantages of the laparoscopic approach are the limited area for manipulation, intricacy in controlling spillage during puncture, and difficulty in aspirating the thick, degenerated cyst contents. No prospective randomized clinical trials have compared laparoscopic treatment with conventional open treatment, and no reliable data are available on recurrence rates after laparoscopic treatment (Table 68.4).

Theoretically, a pneumoperitoneum can exert pressure on the hydatid cyst and increase the risk of hydatid fluid contamination during laparoscopic intervention. Bickel and colleagues (1998) examined the risk of spillage and found that laparoscopy had no disadvantages in the treatment of hydatid liver cysts. Berberoglu and colleagues (1999) used gasless laparoscopy for hydatid cyst surgery but found no significant advantage over the pneumoperitoneum method.

A supraumbilical port is the most frequent entry site for the scope, but the precise position of the trocars varies according to the position and size of the cyst. The puncture site into the cyst is protected by gauze soaked in a scolicidal solution. Several authors have developed special tools or techniques for safer and more effective evacuation of cyst contents, and some surgeons prefer puncture, aspiration, filling with a scolicidal solution, reaspiration, and evacuation of the cavity. During the procedure, the laparoscope can be introduced into the cyst cavity for magnified inspection and to ensure that no daughter cysts, laminated membranes, or bile leaks are overlooked.

Some groups have reported the use of a perforator-grinder and aspirator apparatus for insertion and evacuation (Alper et al, 1995; Saglam, 1996). An umbrella-shaped laparoscopic trocar for evacuation of the cysts has been used with a locking mechanism that enables the surgeon to suspend the cyst wall against the abdominal wall (Seven et al, 2000). Bickel and Eitan (1995) reported the use of a large, transparent cannula (12 mm) with a beveled tip for safe laparoscopic management of hydatid cysts of the liver. Suction is applied through the cannula onto the surface of the cyst, enabling oblique contact, and the cyst is aspirated through the cannula under a "vacuum." It is claimed that spillage was less with this method (Bickel & Eitan, 1995). Some investigators recommend washing the peritoneum with a scolicidal solution or creating a perihepatic scolicidal pool during laparoscopic hydatid surgery (Berberoglu et al, 1999; Palacios-Ruiz et al, 2002).

Percutaneous Treatment

Percutaneous aspiration and treatment of hydatid cysts has previously been discouraged because of the risk of anaphylaxis and intraperitoneal seeding. However, unintended percutaneous aspiration in sporadic cases were not associated with the expected side effects (McCorkell, 1984). These findings encouraged interventional radiologists to aspirate and treat hydatid cysts of the liver using US guidance. Mueller and associates (1985) were the first to report successful percutaneous drainage of hydatid cysts; since then, several authors have reported successful percutaneous treatment of hydatid liver cysts. With increased experience, successful percutaneous treatment of hydatid cysts for lung, kidney, peritoneum, and orbital cavity have also been reported (Akhan & Ozmen, 1999).

It now is generally accepted that the appearance of the cyst content on US and CT examination is an important determinant for percutaneous treatment. Indications for percutaneous treatment include univesicular cysts (type CE 1), univesicular cysts with detached membrane (type CE 3), and some multiple cysts (type CE 2). Aspiration is contraindicated in cysts that are inaccessible to puncture, in cysts in which puncture may damage important vascular structures, and in peripheral cysts that do not have a sufficient layer of hepatic tissue to permit safe transhepatic puncture. Percutaneous treatment is contraindicated in liver hydatid cysts that have ruptured into the bile ducts, peritoneum, or the pleural space. Recurrent cystic collections after surgery can be diagnosed and treated by percutaneous aspiration.

Three different techniques are used in percutaneous treatment of liver hydatid cysts. The first is the PAIR technique described by Ben Amor and associates (1986). PAIR is an acronym for ***p***uncture, ***a***spiration of cyst content, ***i***njection of protoscolicidal solution, and ***r***easpiration of the fluid. Patients are given albendazole before and after the procedure for prophylaxis. Under local anesthesia, a fine needle is inserted into the cystic cavity through normal liver tissue with US or CT guidance. As much fluid as possible is aspirated and, on completion, a protoscolicidal agent is injected into the cavity. After 15 minutes, as much fluid as possible is reaspirated and the needle is withdrawn. The most characteristic sonographic signs of involution at follow-up are heterogeneous reflections of cyst content (3 months), obliteration and pseudotumor appearance (5 months), and loss of echogenicity and disappearance of the cyst (9 months) (Bret et al, 1988; Khuroo et al, 1997). Direct microscopic examination of the aspirated fluid is used to identify protoscolices (Pelaez et al, 2000).

The second technique is a catheterization technique described by Akhan and associates (1993). A catheter is placed into the cavity by the Seldinger technique and, similar to the PAIR technique, the cyst is aspirated, injected with a protoscolicidal agent, and reaspirated, but the catheter is not removed at the end of the procedure and is instead left to facilitate drainage for 24 hours. If there is no biliary fistula within 24 hours, it is accepted that there is no communication between the biliary system and the cavity, which is also confirmed by obtaining a cystogram under fluoroscopic guidance. If the amount of drainage in 24 hours is less than 10 mL and free of bile, absolute alcohol (95%) is injected into the cavity (approximately 25% to 35% of the volume); after waiting 20 minutes, all the fluid is reaspirated and the catheter is withdrawn. If the amount of drainage in 24 hours is more than 10 mL or contains bile, the catheter is kept in place until the daily amount of drainage decreases to less than 10 mL. After that, the cystogram and sclerosis are performed as already mentioned. Alcohol instillation in cysts that have biliary communications is contraindicated. Some researchers suggest that all the liver hydatid cysts suitable for percutaneous technique should be treated by the PAIR technique. Others suggest that the cysts smaller than 6 cm in diameter (volume <100 mL) should be treated by the PAIR technique, and cysts larger than 6 cm in diameter (volume >100 mL) should be treated by the catheterization technique (Akhan & Ozmen, 1999).

In the PAIR and PAIR catheterization techniques, the ruptured daughter cysts and laminated membranes remain inside the cavity; both techniques are usually recommended for uncomplicated univesicular cysts, but not for multivesicular mother and daughter cysts. Each daughter cyst must be punctured separately, which is difficult and may be dangerous for the patient.

Saremi and McNamara (1995) developed an alternative method called *percutaneous evacuation of cyst content* (PEVAC). As in the PAIR catheterization technique, the cyst is first aspirated as much as possible and the catheter is left in place for drainage. In a second session, the catheter is replaced with a 14- to 18-Fr stiff sheath. A suction catheter is introduced into the cyst cavity through the sheath, and the cyst contents are evacuated by applying suction and directing the catheter toward the daughter cysts, endocyst, and undrainable material. A special cutting instrument is used to fragment and evacuate daughter cysts and laminated membrane, while the cavity is continuously irrigated with a protoscolicidal solution. After removal of the sheath, a catheter of the same size as the sheath is placed into the cavity, similar to the PAIR catheterization technique (Schipper et al, 2002). In the absence of bile leakage or any discharge, the catheter is removed.

The effectiveness and safety of percutaneous treatment are supported by the results of more than 2500 procedures carried out in several countries by different teams, with a low morbidity (4.1%) and mortality (0.08%) (Filice et al, 1999). The major risk of percutaneous drainage of hydatid cysts is spillage of hydatid fluid during the placement of the needle. With US or CT guidance, the position of the needle can be precisely monitored, and a transhepatic approach to the cyst, rather than a direct transperitoneal approach, can be used to minimize the possibility of spillage. Urticaria, itching, and hypotension are minor complications that may occur during or several hours after the procedure; these can be treated with antihistamines. In some patients, fever (>38.5° C) may occur, but this generally resolves spontaneously. Cavity complications, such as biliary fistula and infections, have been reported in 10% of patients (Akhan & Ozmen, 1999).

Chemotherapy

Benzimidazole carbamates (mebendazole and albendazole) are antihelmintic drugs that kill the parasite by impairing its glucose uptake. The first report of the successful treatment of four patients with hydatid liver cysts was in 1977 (Bekhti et al, 1977). Mebendazole was introduced first, but albendazole became the drug of choice because of its superior absorption in the gastrointestinal tract and better clinical results (Morris, 1992; Saimot et al, 2001). Benzimidazole treatment is contraindicated for patients with chronic liver diseases and in early pregnancy (Saimot, 2001). Albendazole absorption varies from person to person, and variability may be substantial even in the same individual. In clinical practice, albendazole should be administered in a dose of 10 mg/kg twice daily with a meal; it is wise not to give albendazole with medication that reduces gastric acidity. Adverse events including headache, nausea, anorexia, vomiting, abdominal pain, and itching have been reported in 5% to 10% of patients (Schipper et al, 2000). In the first weeks of treatment, a transient increase in liver enzymes may occur, and leukopenia is rare. Complete hair loss, which is reversible when albendazole is stopped, may also occur.

Although most studies were not well designed, prospective, or randomized, it has been shown that a success rate of 74% can be expected in patients with single cysts treated for 3 to 6 months (Franchi et al, 1999). Most relapses occur within 2 years after cessation of treatment, but more prolonged monitoring has shown that a significant number of relapses occur 2 to 8 years after completing initial treatment. A controlled study of 29 patients who received albendazole (400 mg twice a day in three cycles of 6 weeks with 2 weeks between cycles) or placebo showed that 82% of the patients in the treatment group had cure or improvement compared with 14% in the placebo group (Keshmiri et al, 2001).

Factors that influence the efficacy of benzimidazoles have not been well defined, but it is known that penetration of the drug across the cyst wall depends on several factors. Young cysts without pericystic fibrosis are more sensitive to drugs than thick, calcified cysts. Chemotherapy is less effective in daughter cysts within a mother cyst and in cysts with infection or a biliary communication. Small cysts (<8 cm) and secondary cysts are mostly sensitive to chemotherapy, and chemotherapy seems to be more effective in young patients (Teggi et al, 1993; Todorov et al, 1990).

The efficacy of preoperative albendazole treatment was established by two studies. In the first study (Wen et al, 1994), cyst viability after 3 months of albendazole pretreatment was 8% at the time of surgery, significantly lower than in the control group (100%). In the other study, 1-month and 3-month preoperative courses of albendazole significantly reduced cyst viability to 28% and 6%. Although no published data are available on the efficacy of perioperative prophylaxis, it is generally advised that albendazole is given for 1 week before surgery. Similarly, postoperative treatment is recommended for 6 months in cases of intraoperative hydatid spillage.

Treatment is usually administered in three or four courses lasting 4 weeks separated by a 2-week interval. Three courses are routinely recommended, in agreement with viability data

suggesting that a maximum benefit is not reached with less than 3 months of therapy, and more than 6 months of treatment is seldom necessary (WHO Informal Working Group on Echinococcosis, 1996). This cyclical method of treatment is recommended because of the limited toxicology data available at the time of the first treatment attempts, but more recent data on uninterrupted treatment show that this approach could have better efficacy (Saimot, 2001). The use of continuous treatment has been followed without evidence of increased adverse events, but controlled comparisons with intermittent treatment have not been carried out. Preoperative treatment with a benzimidazole should begin 1 week before surgery (WHO Informal Working Group on Echinococcosis, 1996). A new albendazole formulation has shown a fivefold to tenfold enhancement of bioavailability compared with classic albendazole (Rigter et al, 2004).

There are four objectives with medical treatment: definite cure, a reduction in cyst viability, preoperative treatment, and perioperative prophylaxis. Definite cure of univesicular cysts requires a 3- to 6-month course, which can achieve an 80% success rate with a 25% relapse rate. Most relapses occur within 2 years of treatment, but lifelong follow-up is advised. A reduction in cyst viability can be achieved in multivesicular cysts and preoperatively in univesicular cysts when percutaneous or elective surgery is planned. Perioperative prophylaxis should start 1 week before the procedure. Recommendations for posttreatment prophylaxis are 3 to 8 weeks for uncomplicated cases. In complicated cases with a higher risk of spillage of cyst contents, 3 to 6 months of treatment is arbitrarily advised.

ALVEOLAR HYDATID DISEASE

All four species of *Echinococcus* are potentially zoonotic, but *E. alveolaris* and *E. multilocularis* are the most pathogenic; both represent potentially fatal, chronically progressive hepatic infections, which is unusual for a parasitic helmintic infection. The fatal outcome may occur in 95% of untreated patients within 10 years after the diagnosis. These parasites occur within a large belt between the fortieth and forty-fifth degree of northern latitude (Ammann & Eckert, 1996). Surveys in central Europe have shown an increase in the known distribution of *E. multilocularis* from four countries at the end of 1980 to at least 11 countries in 1999 (Eckert & Deplazes, 1999). There is evidence that parasites have spread from endemic areas to previously nonendemic areas in North America, Japan, and China (Deplazes & Eckert, 2001).

Control of transmission of *E. alveolaris* is difficult because the definitive and intermediate hosts involved are usually wild animals. Risk factors for alveolar hydatid disease in endemic regions are complex and include seasonal fluctuations in the size of the fox population, the susceptibility and immunity of definitive hosts, and resistance of eggs to environmental factors (McManus et al, 2003).

The life cycle of *E. alveolaris* is similar to that of *E. granulosus*. After ingestion of an infected rodent, protoscolices transform into tapeworms. Maturation of the tapeworms to adult forms takes 28 to 35 days in the jejunum of the fox, and adult tapeworms live for 6 to 12 months in the fox intestine. Eggs in the gravid proglottis are released with fox feces and contaminate the environment. Eggs may remain viable for months, even under extreme climatic conditions. When they are ingested by the intermediate host, they are released from their capsule, and an active six-hooked embryo (oncosphere) penetrates the mucosa of the small intestine. Similar to *E. granulosus*, the eggs pass via the portal vein to the liver, where cysts are formed; about 98% of primary lesions occur in the liver. The laminated layer is secreted by the germinal layer of the parasite within 7 to 14 days after the postoncosphere period.

Humans can come into contact with the eggs accidentally, such as when skinning foxes, and ingestion of the eggs results in alveolar hydatid disease. The laminated membrane of an alveolar hydatid cyst is very thin, and brood capsules and protoscolices rarely are formed in the human host (<10%). In most cases, the germinal membrane is undetectable, or it appears as an isolated, thin form. This tissue still has the potential for proliferation, however, and it produces protoscolices when inoculated into a viable intermediate host (rodent). The growth rate of the alveolar hydatid disease in the liver is usually slow; calculated median growth rate is 14.8 mL/year (Luder et al, 1985).

The parasitic mass tends to be massive, infiltrating through the parenchyma of the liver, and it proliferates and metastasizes like a malignant tumor. Satellite lesions are common, and multiple vesicles are formed. The parasitic lesion exhibits dense granulomatous infiltration and microcalcifications. The center of the cyst may become necrotic and form a spongy mass that consists of small, irregular cavities filled with a gelatinous fluid. In addition, there is a risk of metastases in advanced alveolar echinococcosis, usually resulting in secondary lesions in the lungs, brain, or both, where necrotic and cavitating masses are found.

The symptoms are similar to those of a slowly growing liver carcinoma. Clinical symptoms vary, but initially there is a long asymptomatic period that may last for 5 to 15 years. One third of patients are diagnosed in this incubation period incidentally during examination for nonspecific symptoms, such as fatigue or weight loss. One third of patients have epigastric pain or dyspepsia, and another third have cholestatic jaundice. A palpable abdominal mass and enlarged liver are the most frequent signs. Patients are usually in a good general condition, although in advanced disease, jaundice, ascites, and hepatic failure may occur.

Routine laboratory tests do not yield specific findings. ESR is elevated in most cases, and eosinophilia is usually mild or absent (Ammann & Eckert, 1996). Alkaline phosphatase and GGT levels are usually increased, especially in advanced disease. US and CT demonstrate the lesions that appear as heterogenous, hypodense masses with irregular contours (Fig. 68.22). A necrotic cavity in the center of the mass without a well-defined wall is a frequent finding. Pressure on the portal or hepatic veins, or inferior vena cava may also occur, and calcification is common and appears as irregularly distributed clusters of microcalcifications or plaquelike foci (Fig. 68.23; Czermak et al, 2001). MRI demonstrates central necrosis better than CT but is less effective in showing microcalcification and small lesions. In most cases, T1-weighted images show the margins of the lesions more clearly (Harman et al, 2003). Alveolar hydatid disease is characterized clinically by a discrepancy between the often large, tumorlike lesions of the liver and the usually well general condition of the patient, which is in contrast to advanced malignancy.

Immunodiagnosis of alveolar hydatid disease is useful, effective, and more reliable than the diagnosis of cystic hydatid disease. The sensitivity in alveolar hydatid disease is 95% to 100%, and the specificity is high if purified and specific antigens

FIGURE 68.22. Heterogenous mass with irregular contours and necrotic cavity in the center in alveolar hydatid cyst.

are used. Native Em2 antigen, alone or mixed with recombinant Em10, is highly specific for alveolar hydatid disease using ELISA, and only a few cystic hydatid disease cases are cross-reactive (Silas-Lucas & Gottstein, 2001). Immunodiagnosis has a diagnostic sensitivity of 97.1% and overall specificity of 98.9%. The reported sensitivity of the recombinant Em18-ELISA was 87% with 97% specificity (Ito et al, 2002; Sako et al, 2002). The stage of the disease is the main prognostic factor, similar to malignant tumors. The so-called *PNM system* (***parasitic mass, involvement of neighboring organs, metastasis***) is a clinical staging system for alveolar hydatid disease (Box 68.1 and Table 68.5; Pawlowski et al, 2001).

Alveolar hydatid disease is more difficult to treat than cystic hydatid disease. Early diagnosis is crucial, and new imaging and serologic techniques, advances in surgery, and the introduction of chemotherapy have improved outcome. When alveolar hydatid disease is diagnosed, the patient should undergo treatment regardless of whether symptoms are present. The two treatment options are surgery and chemotherapy.

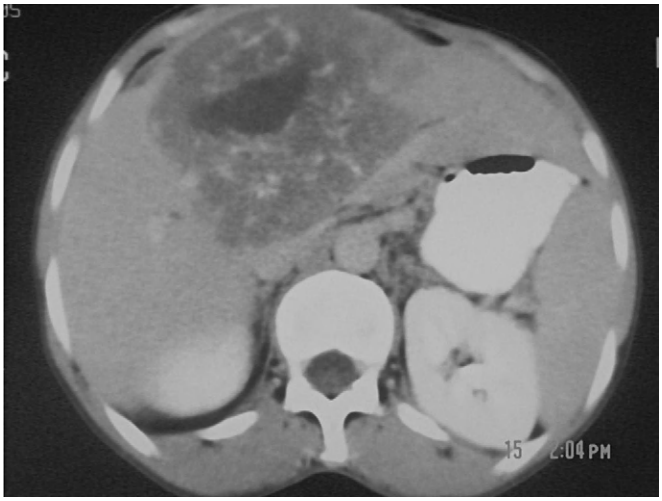

FIGURE 68.23. Plaque-like calcifications on the liver mass in an alveolar hydatid cyst.

Box 68.1

PNM Classification of Human Alveolar Echinococcosis

P: Hepatic Localization of Metacestode

PX Primary lesion unable to be assessed

P0 No detectable hepatic lesion

P1 Peripheral lesion without biliary or proximal vascular involvement

P2 Central lesions with biliary or proximal involvement of one lobe

P3 Central lesions with biliary or proximal vascular involvement of both lobes or two hepatic veins or both

P4 Any lesion with extension along the portal vein, inferior vena cava, or hepatic arteries

N: Extrahepatic Involvement of Neighboring Organs

NX Not evaluable

N0 No regional involvement

N1 Involvement of neighboring organs or tissues

M: Presence or Absence of Distant Metastasis

MX Not completely assessed

M0 No metastasis on chest radiograph and CT brain scan

M1 Metastasis present

CT, computed tomography

From Pawlowski I, et al, 2001: Echinococcosis in humans: clinical aspects, diagnosis and treatment. In Eckert J, et al (eds): WHO/OI Manual on Echinococcosis in Humans and Animals: A Public Health Problem of Global Concern. Paris, World Organisation for Animal Health, pp 20-71.

Curative liver resection is the treatment of choice for localized lesions. Because of the frequent involvement of the biliary bifurcation, liver resection often requires a biliary reconstruction using a Roux-en-Y jejunal loop. Most of the lesions occur in the right lobe of the liver; if adherent to the diaphragm, such lesions may require an associated diaphragmatic resection. Palliative resection has been proposed in patients with large bilobar involvement with extension to the portal vein or to the vena cava. This approach, combined with medical treatment, can result in long-term survival. In contrast, surgical external biliary drainage of cyst cavities is associated with poor outcome. Liver transplantation should be considered in patients who have unresectable disease, especially with massive involvement of the pedicle or coexisting chronic liver failure (Bresson-Hadni et al, 2003). The frequent extrahepatic extension of the disease—involving the hepatoduodenal ligament, vena cava, diaphragm, and pericardium—makes total hepatectomy technically difficult. In addition, hydatid disease may recur even after liver

Table 68.5

Staging of Alveolar Echinococcosis on the Basis of PNM Classification

Stage	P	N	M
I	P1	N0	M0
II	P2	N0	M0
IIIa	P3	N0	M0
IIIb	P1-3	N1	M0
IV	P4	N1	M0
	P4	N0	M0
	Any P	Any N	M1

transplantation (Bresson-Hadni et al, 1999). Adjuvant chemotherapy with albendazole should be added to posttransplant medication regimens to prevent recurrence (WHO Informal Working Group on Echinococcosis, 1996).

Albendazole (15 mg/kg/day) is probably the best drug currently available for alveolar hydatid disease. It is generally accepted that long-term albendazole therapy is primarily parasitostatic. Evidence of a parasiticidal effect of long-term albendazole has been reported, however, in a few cases (Ammann et al, 1998). More recent studies provide clear evidence that long-term chemotherapy of alveolar hydatid disease is effective. Oral albendazole resulted in an improved 10-year survival rate of 80% to 83% compared with 6% to 25% for untreated historic controls (Craig, 2003). Nitazoxanide, a broad-spectrum antihelmintic drug, has been tested for experimental alveolar hydatid disease. Nitazoxanide is better absorbed than albendazole after oral administration, and it provides an attractive potential alternative for medical treatment (Stettler et al, 2003).

CHAPTER 69A

Simple cysts and polycystic liver disease: clinical and radiographic features

Olivier Farges and Valerie Vilgrain

OVERVIEW

The entity common to simple cysts and polycystic liver disease (PCLD) is a malformation, lined by a nontypical biliary-type epithelium that does not communicate with the biliary tree. This differentiates these diseases from hydatid cysts (see Chapter 68), cystic hepatobiliary neoplasms (Chapter 79B), and cystic dilation of the intrahepatic bile ducts (Chapter 46).

Simple cysts and PCLD differ in more than just the number of cysts; simple cysts are frequently multiple, but the extent of disease in PCLD is highly variable. PCLD is currently a well-described genetic disease that comes in two forms, with and without autosomal dominant polycystic kidney disease (ADPKD). Most of what is known about the pathogenesis of PCLD comes from the study of animal models and of patients with both liver and kidney involvement.

When present, symptoms relate either to an increase in the size of single cysts or, with PCLD, to an increase in the size of the whole liver. Apart from acute complications, the most frequent of which is intracystic bleeding, these symptoms have frequently evolved progressively for a prolonged period. It may therefore be difficult for clinicians to differentiate cyst-related symptoms from those of associated conditions. It may even occasionally take some time to understand the true severity of cyst-related symptoms, to which some patients have unconsciously become accustomed.

This chapter focuses on pathology, prevalence, manifestation, and diagnosis of PCLD. Differential diagnosis from other cystic lesions is addressed at the end of this chapter, and therapeutic management is addressed in Chapter 69B.

SIMPLE CYSTS OF THE LIVER

Simple cysts of the liver contain serous fluid and do not communicate with the intrahepatic biliary tree. Numerous terms have been used to designate such lesions; such terms include *biliary cyst, nonparasitic cyst of the liver, benign hepatic cyst, congenital hepatic cyst, unilocular cyst of the liver,* and *solitary cyst of the liver* (the last designation is inappropriate because simple cysts are often multiple, as described later in this chapter). Simple cysts frequently occur in the general population. Most simple cysts are less than 3 cm in diameter, are easily identified by ultrasound (US), and are asymptomatic. When present, symptoms occur in larger cysts, usually related to intracystic bleeding that changes the morphologic appearance of the cyst. In this circumstance differential diagnosis with other cysts, most notably cystadenoma or hydatid disease, may prove difficult.

Pathology and Pathogenesis

Macroscopically, a simple cyst of the liver has a spherical or ovoid shape. The diameter ranges from a few millimeters to 20 cm or more, and the cyst does not communicate with the intrahepatic bile ducts. Small cysts are surrounded by normal hepatic tissue. Large cysts produce atrophy of the adjacent hepatic tissue; a huge cyst may result in complete atrophy of a hepatic lobe with compensatory hypertrophy of the other lobe. Atrophy respects the large bile ducts and blood vessels, which appear to be abundant in the atrophic tissue in contact with the cyst. Large bile ducts and blood vessels that persist after atrophy may protrude and form folds over the inner surface of the cyst. No septation is apparent, the cysts are unilocular, and cystic fluid is usually clear; however, intracystic bleeding is relatively common, and the fluid may be brownish when this is the case. Even when a simple cyst is apparently unique, imaging studies disclose the presence of one or more small additional cysts in most patients. In a few cases, simple cysts are multiple, resembling the liver cysts of PCLD; criteria for distinguishing both conditions are given below.

Microscopically, the cysts appear to be bordered by a single layer of cuboid or columnar epithelial cells, resembling biliary epithelial cells (Fig. 69A.1). The cells are uniform, without any atypia. Stroma is absent in small cysts and is reduced to a thin layer of connective tissue in large cysts. Simple cysts of the liver are regarded as a congenital malformation, likely aberrant bile ducts that have lost communication with the biliary tree and

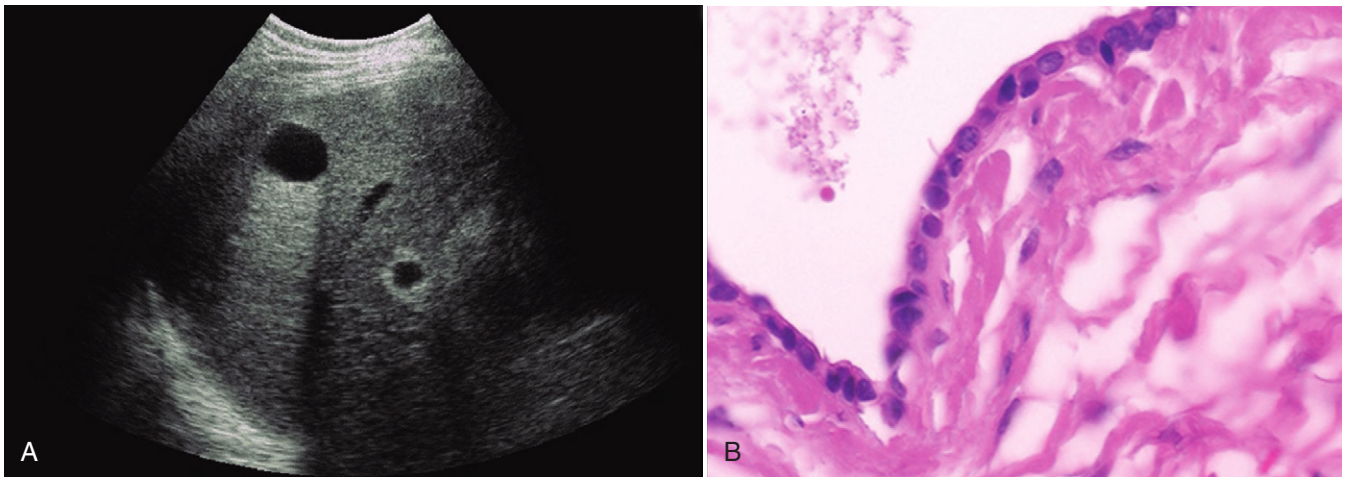

FIGURE 69A.1. A, Ultrasound of a simple cyst of the liver. **B,** Microscopic view of its epithelial lining.

dilate progressively. Liver cyst epithelial cells retain differentiated secretory function; they secrete fluid and generate a positive luminal pressure that may be greater than 30 cm H_2O, which accounts for most symptoms. The composition of the fluid, which contains water and mineral electrolytes without bile acids and bilirubin, is close to that of the normal secretion of the epithelium of the bile ducts. It is not toxic to the peritoneum, which is the rationale for cyst fenestration (see Chapter 69B).

Prevalence and Etiology

Simple cysts had been considered rare. By 1971, only 350 cases had been reported (Flagg & Robinson, 1967; Moreaux & Bloch, 1971), and early estimates from autopsy studies were less than 1% (Larsen, 1961). However, the development of imaging techniques revealed that simple cysts are much more frequent. Prevalence in ultrasound studies is 3% to 5% (Caremani et al, 1993; Gaines & Sampson, 1989); however, in a more recent spiral computed tomographic (CT) study of an adult population, prevalence was 18% (Carrim & Murchison, 2003). These discrepancies are explained by the usual small size of most cysts, which are discovered only by accurate imaging techniques. An association between simple hepatic cysts and simple renal cysts has been documented (Carrim & Murchison, 2003), but this association has not yet been explained.

The incidence of simple cysts is age and gender related. Simple cysts are uncommonly identified before age 40 years, but their incidence increases sharply thereafter. Simple cysts also are larger in adults older than 50 years (Larsen, 1961). The female/male ratio is 1.5 : 1 for all simple cysts shown at necropsy or imaging; however, this statistic jumps to 9 : 1 in symptomatic or complicated simple cysts (Moreaux & Bloch, 1971). Huge cysts affect women older than 50 years almost exclusively. Based on these observations, the diagnosis of simple cysts should be retained with caution, when a large or symptomatic cystic mass is observed in a male patient or in a young woman.

Manifestations and Diagnosis

In most cases, simple cysts—all small cysts, but also most large cysts—are asymptomatic and fortuitously shown by US or CT. Only some large cysts produce abdominal pain or discomfort. Because of the high prevalence of simple cysts in adults, the coincidence of this lesion and another hepatic or extrahepatic disease is common. The causal relationship between abdominal pain or discomfort and a simple cyst of the liver must be admitted with caution and accepted only if the cyst is large, and other possible causes of the symptoms have been excluded. At clinical examination, only large cysts can be palpated as spherical tumors. In most cases, the fluid content of the tumor can be suspected. In some cases, the cyst is so tense that it may be taken for a solid tumor. The condition of individuals with a simple cyst of the liver is generally good, and liver function tests are normal; abnormal liver function tests in a patient with a simple cyst of the liver are not related to the cyst but are caused by another liver disease, except when the cysts compress bile ducts.

US is the best imaging modality for recognizing simple cysts, which appear as a circular or oval, completely anechoic lesion with sharp, smooth borders and strong posterior wall echoes that indicate a well-defined tissue-fluid interface (Liang et al, 2005). Echoes beyond the cyst are accentuated compared with echoes at a similar depth transmitted through normal adjacent liver tissue (see Fig. 69A.1). Accentuation of the echoes beyond the cyst indicates that the lesion is filled with fluid. This so-called *acoustic posterior enhancement* is observed only when the deep tissue transmits US; it is not seen when a total reflector, such as gas or bone, lies behind the cyst or when the cyst is very posterior. Neither wall nor septation is apparent, but a false image of septation may be seen when two cysts are adjacent. In some patients, intracystic echoes or material can be detected after intracystic bleeding.

Other imaging procedures have less utility in diagnosis compared with US and are generally not required. CT confirms the presence of one or several round or oval, water-dense lesions but no septations or intracystic formations; dynamic CT shows that such lesions are avascular. In small cysts, recognition of water density may be difficult; the average density of the cyst is obscured by the density of the adjacent liver tissue, but an apparent increase in density may be observed after intravenous injection of contrast medium. On magnetic resonance imaging (MRI), the cyst is homogeneous, very hypointense on T1-weighted images, and very hyperintense on T2-weighted images, as are the gallbladder contents (Fig. 69A.2). If the

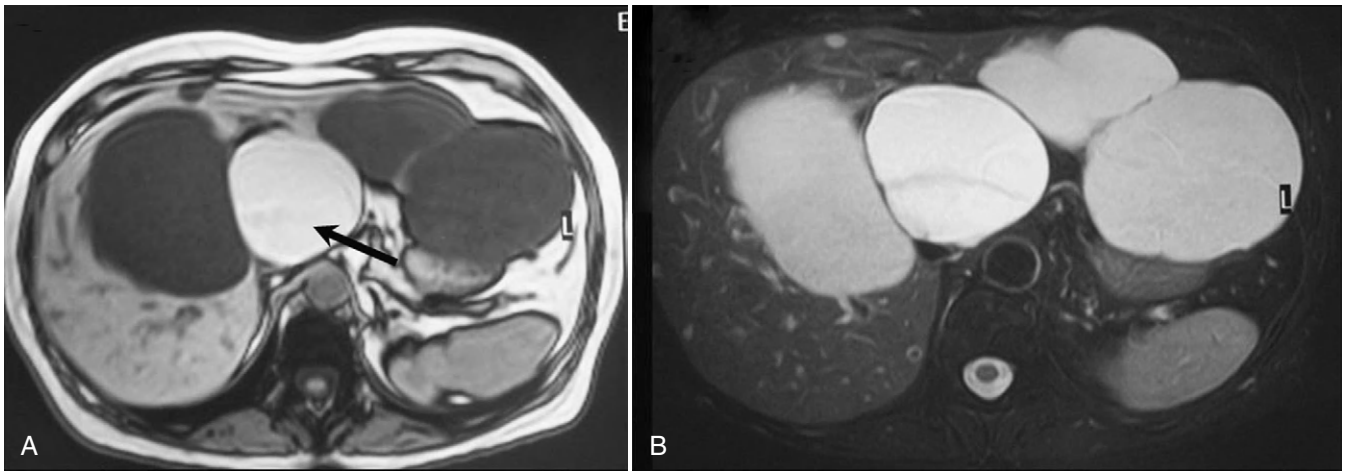

FIGURE 69A.2. Magnetic resonance image of a patient with multiple cysts. **A,** On T1-weighted images, cysts are hypointense, except for one cyst, which is hyperintense as a result of intracystic bleeding (*arrow*). **B,** All cysts are hyperintense on T2-weighted images.

patient lives or has been living in an area where hydatid disease is endemic, or when any doubt exists about a possible hydatid cyst, serologic tests for this parasitic infection should be performed, although their accuracy is fairly low. MRI should also be performed (see Chapter 68).

Course and Complications

In most cases, simple cysts are asymptomatic and remain silent; serial US studies usually show no appreciable changes over a matter of years, and surveillance is not required. In some patients, the cysts grow slowly. In a few patients, the size of the cysts increases rapidly; such a course, which may be associated with severe pain and discomfort, is observed almost exclusively in women older than 50 years.

Complications are uncommon, but intracystic bleeding is the most frequent observed (Frisell et al, 1979; Moreaux & Bloch, 1971) and is presumed to result from the erosion of an artery adjacent to the cyst. The clinical manifestations consist of sudden, severe pain and an increase in the size of the cyst. The pain resolves in a few days; in some cases, pain is mild or absent. There is no evidence of anemia, and the biologic liver tests show only a moderate elevation of γ-glutamyltransferase (GGT). On US, echoic material corresponding to clots is seen within the cyst (Fig. 69A.3); this material usually is mobile, sliding in the inferior part of the cyst. Hemorrhagic cysts also become hyperintense on T1-weighted MRI, whereas uncomplicated cysts are hypointense (see Fig. 69A.2). After gadolinium injection, an enhancement of the periphery of the cyst is frequently seen when hemorrhage is recent, which corresponds to compressed liver parenchyma (Fig. 69A.4). Contrast US may also prove useful in the future by showing that neither the cyst wall nor the intracystic material is enhanced, unlike cystadenoma (see Fig. 69A.4; Chapter 79B), but larger studies are required (Akiyama et al, 2008). Communication with the bile duct lumen may develop, presumably also by an erosive mechanism; however, bacterial infection in contrast is exceptional.

Spontaneous rupture into the peritoneal cavity (Fig. 69A.5; Akriviadis et al, 1989; Salemis et al 2007)—or, more rarely, into the pleural cavity or the duodenum (Williamson et al, 1978)—is exceptional. In contrast to hydatid cysts, peritoneal perforation of simple cysts is self-limited. Severe hemoperitoneum has been described only in patients with PCLD undergoing dialysis.

Because simple cysts are tense, they may compress the bile ducts or the inferior vena cava (Fig. 69A.6), and although anecdotal, there have been reports of pulmonary embolism after clot formation (Buyse et al, 2004). As discussed in Chapter 69B, compression of biliary branches or hepatic veins is a potential source of intraoperative or postoperative complications.

POLYCYSTIC LIVER DISEASE

PCLD—or, more precisely, *diseases*—is a term for genetic disorders responsible for the progressive development of multiple cysts in the liver. PCLD was initially considered to exclusively develop in the context of ADPKD (Moschcowitz, 1906). However, identification of families with PCLD but no ADPKD proved that PCLD may also occur alone (Berrebi et al, 1982; Tahvanainen, et al, 2003). These two forms of PCLD—those with and without ADPKD—are linked to distinct gene mutations. Both, however, have an autosomal dominant transmission and an almost identical clinical course. Of note, one third of patients with isolated PCLD may have a few kidney cysts, usually one or two (van Keimpema et al, 2010), as does the general population of adult patients (Carrim & Murchison, 2003). Distinction between the two forms of PCLD is addressed below.

Genetics

Polycystic Liver Disease and Autosomal Dominant Polycystic Kidney Disease

PCLD associated with ADPKD is linked to mutations in either the *PKD1* or *PKD2* gene. *PKD1* (Ward et al, 1996) is located on the short arm of chromosome 16 and encodes polycystin-1; its mutation accounts for 85% of mutations in ADPKD patients. Most of the rest are related to a mutation in *PKD2* (Mochizuki et al, 1996), which is located on chromosome 4 and encodes polycystin-2. *PKD1* mutation is associated with more renal cysts, larger cysts, more prevalent hypertension, and faster progression to end-stage renal disease than *PKD2* mutation.

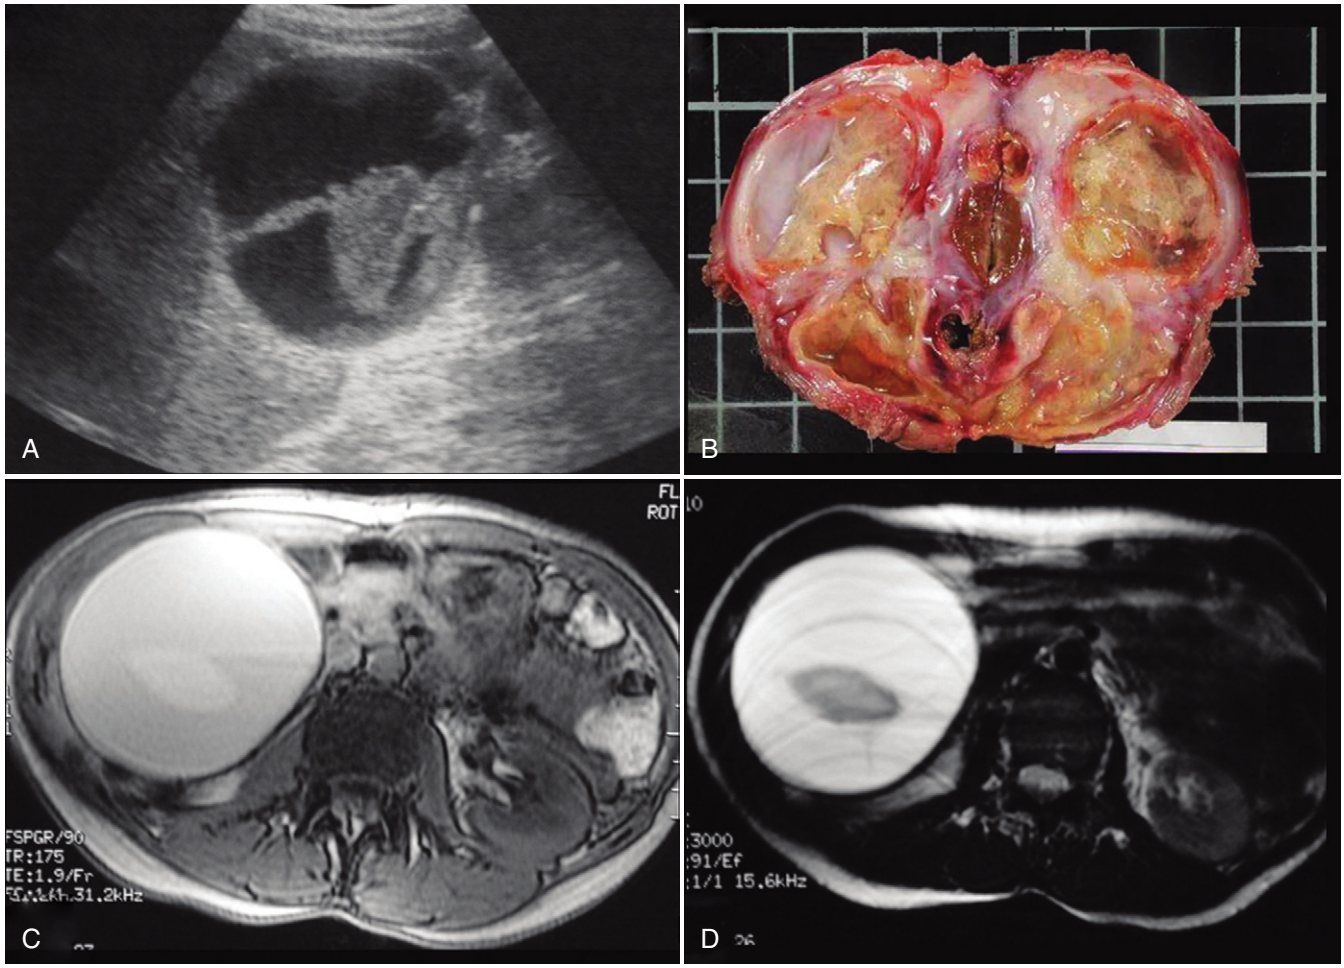

FIGURE 69A.3. Hemorrhagic simple cyst of the liver that has become atypical as a result of intracystic bleeding. **A,** Ultrasound. **B,** Macroscopic view of the resected specimen. **C** and **D,** Magnetic resonance imaging.

Isolated Polycystic Liver Disease

Isolated PCLD—that is, PCLD without ADPKD—is associated with heterozygous mutation in either the *P*rotein *K*inase *C* *S*ubstrate 80K-*H* (*PRKCSH*) or *SEC63* genes. Both genes are located in the endoplasmic reticulum and function in the early secretory route of the cell. *PRKCSH* is located on the short arm of chromosome 19, which encodes the protein hepatocystin (Drenth et al, 2004). Hepatocystin functions as the β-subunit of α-glucosidase II and is involved in the protein-folding processes and quality control of newly synthesized glycoproteins (Trombetta et al, 2001). *SEC63* is located on the long arm of chromosome 6 and encodes the *SEC63* protein involved in protein transport across the endoplasmic reticulum membrane (Brodsky et al, 1995). However, these mutations only explain 25% to 40% of cases (Davila et al, 2004; van Keimpema et al, 2010), which suggests that one or more other genes is involved.

The Two-Hit Theory

PCLDs have an autosomal dominant phenotype but are considered to be a recessive disease at the molecular level because they require a second somatic mutation. According to this theory, a germline mutation is present in either *PKD1* or *PKD2*. However, cell proliferation and cyst formation occurs in individual cells that have in addition received a second loss-of-function somatic mutation in the other gene copy (Everson et al, 2004). This second hit would explain why affected cells are few and why cysts develop from place to place; it may also account for the extreme heterogeneity of the disease. This theory has been designed for PCLD associated with ADPKD but has not been investigated for isolated PCLD. It is unclear as to why these various mutations may affect both the liver and kidney or only the liver.

Pathology and Pathogenesis

Liver cysts in PCLD are macroscopically and microscopically similar to simple cysts of the liver, and their number and distribution are highly variable. They are lined by a single-layered epithelium that has phenotypic and functional characteristics of biliary epithelium (Perrone et al, 1995) and retain in particular a secretory capacity and responsiveness to secretin (Everson et al, 1990). The cysts result from abnormal remodeling of the ductal plate and mainly arise from dilation of biliary microhamartomas, also known as *von Meyenburg complexes,* which have lost their communication with the biliary tree (Melnick, 1975). Some cysts also arise from peribiliary glands surrounding large intrahepatic bile ducts (Fig. 69A.7; Kida et al, 1992).

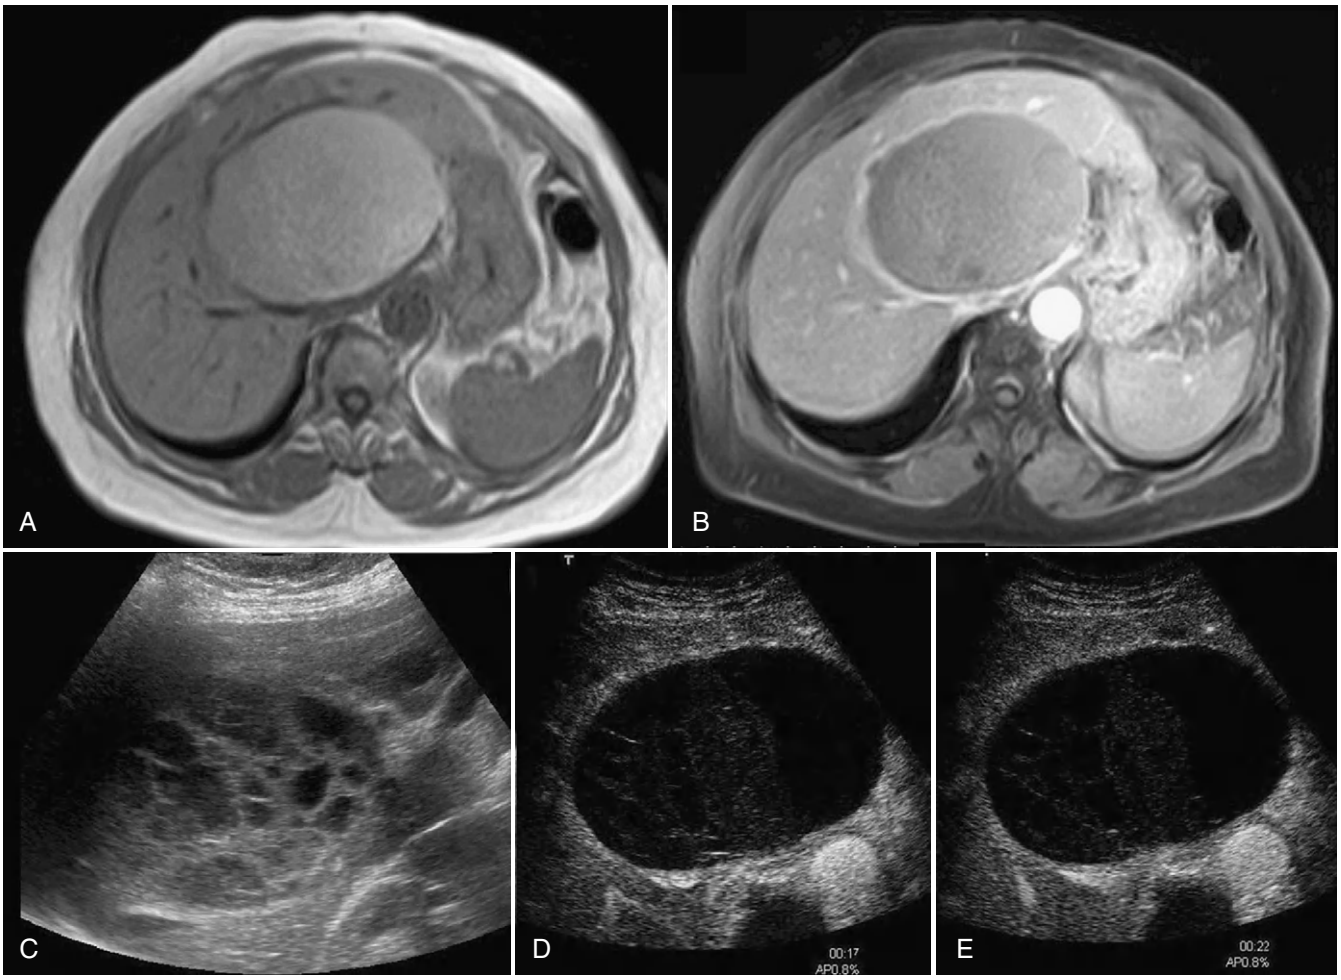

FIGURE 69A.4. Other examples of a hemorrhagic simple cyst. **A,** The cyst is hyperintense on T1-weighted images. **B,** Peripheral enhancement follows injection of gadolinium as a result of compression of the adjacent liver. **C,** On ultrasound, the cystic lesion appears with echogenic and anechogenic portions. **D** and **E,** The echogenic portions do not enhance during contrast ultrasound.

The mechanisms of cyst expansion are still not fully explained but appear similar to those involved in the development of renal cysts. Growth results from a combination of proliferation of epithelial cells, remodeling of the extracellular matrix required for the cyst to invade the surrounding liver parenchyma (Murray et al, 1996), and neovascularization that results in increased density of the vascular bed surrounding the cysts (Bello-Reuss et al, 2001; Nichols et al, 2004).

As in the kidney tubules, the microvilli and long cilia normally on cholangiocytes are believed to play a dominant role. These mechanosensory organelles may be bent by bile flow and can also react to hormonal, morphogen, or growth factor stimuli; they may even function as sensors of cell injury. These cilia and microvilli modulate concentrations of intracellular levels of cyclic adenosine monophosphate (cAMP) and Ca^{2+} that are mediators of proliferation and secretory activity of cholangiocytes. In PCLD, these cilia progressively disappear from the luminal surface of the epithelium as cysts enlarge (Alvaro et al, 2008). Their absence could impair Ca^{2+}-dependent counterregulation of cAMP, which is a key determinant of cholangiocyte proliferation. It is unclear whether the disappearance of these cilia is a primary event or a result of increased pressure. However, polycystin-1 and polycystin-2 are localized to the cilia, and their absence as a result of a *PKD1* or a *PKD2* mutation could result in ciliary dysfunction. In patients with isolated PCLD, it has been postulated that polycystins could be the target of aberrant maturation of newly synthesized glycoprotein caused by *PRKCSH* or *SEC63* mutations.

Two other targets of the cell cycle have been identified. One is the mammalian target of the rapamycin (mTOR)-mediated signaling cascade (Shillingford et al, 2006), which explains growing interest from the industry for mTOR inhibitors (see Chapter 69B). The other is through micro-RNAs, small, noncoding RNAs that inhibit target messenger RNA transcripts via sequence-specific base paring; micro-RNA-15a in particular is downregulated in cyst epithelium, resulting in an overexpression of Cdc25A, which activates cyclin-dependent kinases and progression of the cell cycle (Lee et al, 2008).

Fluid secretion by the epithelium lining the cyst may also contribute to cyst expansion. Ciliary dysfunction could also play a role because it has also been shown to result in maintenance of an immature phenotype by biliary epithelial cells with postnatal expression of developmental proteins. A variety of cytokines and growth factors present in increased

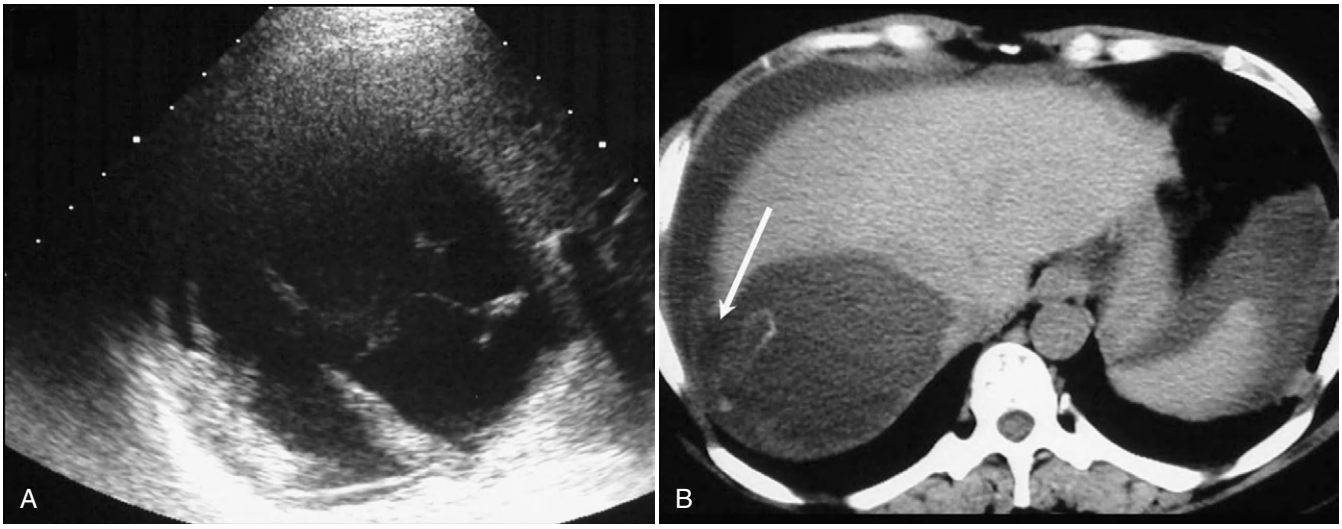

FIGURE 69A.5. Spontaneous rupture of a simple cyst. **A,** Ultrasound. **B,** Computed tomographic scan. The cystic lesion is heterogeneous and poorly limited. A communication is visible with the peritoneal cavity (*arrow*), where ascites is visible.

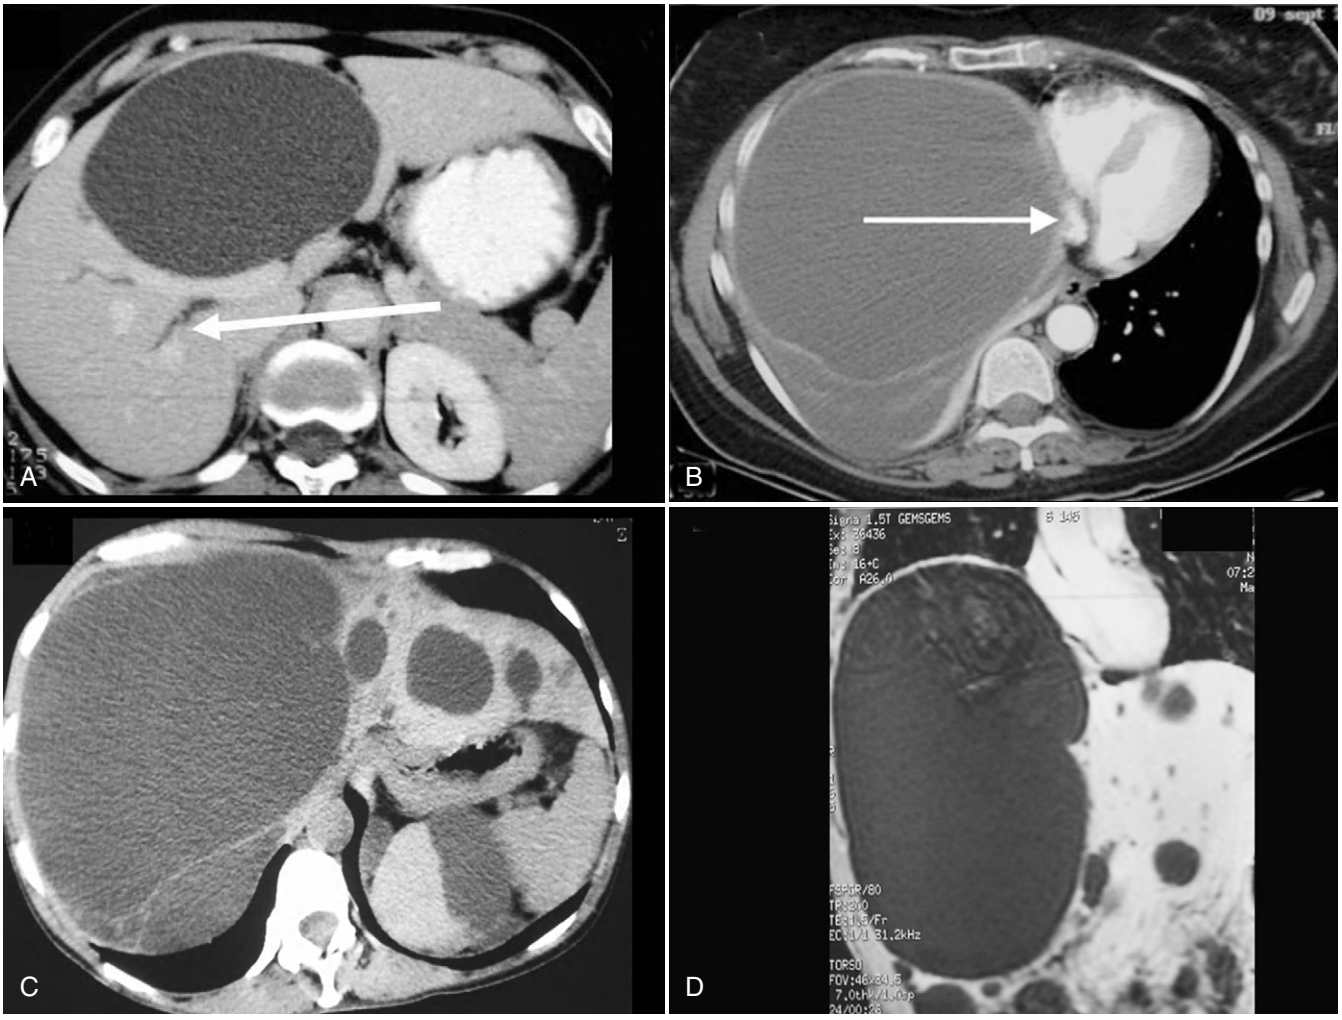

FIGURE 69A.6. Compression by hepatic cysts. **A,** Cyst of the biliary confluence with enlarged bile ducts upstream (*arrow*). **B,** The inferior vena cava with a small clot in the caval lumen (*arrow*). **C,** The stomach is compressed indirectly by a large cyst of the right liver, rotating the left lateral section. **D,** The diaphragm and right atrium are also rotated.

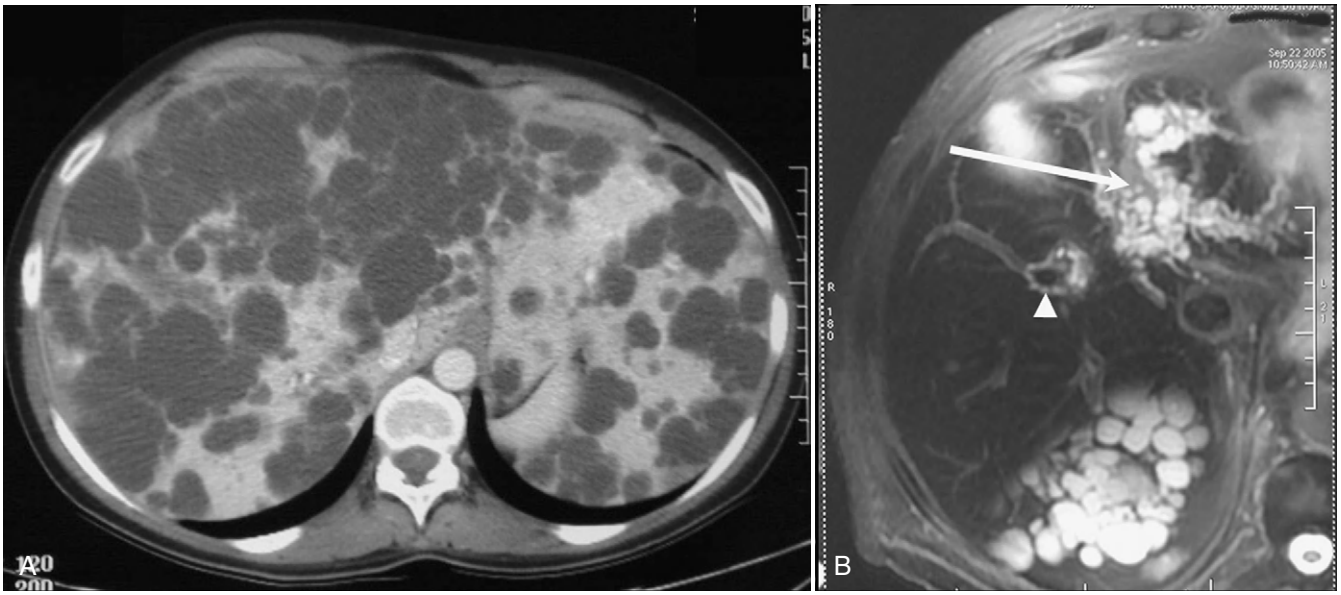

FIGURE 69A.7. Polycystic liver disease. Cysts arise peripherally (**A**) or from peribiliary glands (**B**). Note that they are prominent around the left bile duct (*arrow*) but can also be seen around the right portal pedicle (*arrowhead*).

concentration in the cysts have been implicated in cyst growth by autocrine-paracrine signaling (Alvaro et al, 2008; Fabris et al, 2006; Nichols et al, 2004). Angiogenic factors in particular could play a role by promoting vascularization of the cyst and also by directly stimulating cholangiocytes. Furthermore, the epithelium stains positive for insulin growth factor 1 (IGF-1) and its receptor, as well as for estrogen receptors (Alvaro et al, 2008), and is particularly sensitive to this signaling.

All these observations and hypotheses account for the rationale of using vasopressin antagonists or somatostatin analogues known to inhibit cAMP; sirolimus, an inhibitor of mTOR signaling; or vascular endothelial growth factor inhibitors in the treatment of PCLD (see Chapter 69B). The presence of estrogen receptors also provides a rationale for the influence of the patient's estrogen status on the clinical course of the disease. In particular, women with ADPKD are more likely to develop hepatic cysts than their male counterparts (Chapman, 2003), and nulliparous women are less likely to develop hepatic cysts than their multiparous counterparts (Gabow et al, 1990). Oral contraceptives and postmenopausal hormonal substitutive therapy increases both the number and size of liver cysts (Sherstha et al, 1997).

Epidemiology

PCLD ASSOCIATED WITH ADPKD. ADPKD occurs in approximately 1 in every 800 live births and is characterized by progressive development and enlargement of fluid-filled cysts, ultimately leading to renal failure in 50% of affected individuals. PCLD is the most frequent extrarenal associated condition, but liver cysts develop later than renal cysts. The prevalence of liver cysts also increases with age. This was recently evaluated by MRI in a young adult population with relatively preserved kidney function and was found to be 58% in patients aged 15 to 24 years, 85% in those aged 25 to 34 years, and 94% in those aged 35 to 46 years (Bae et al, 2006). Overall prevalence is the same in men and women, but as for simple cysts, women have more severe liver disease than men; multiparity and use of oral contraceptive drugs or estrogen replacement therapy also tends to worsen the condition (Bae et al, 2006; Sherstha et al, 1997; Torres et al, 2007). Prevalence of liver cysts is also correlated with kidney volume and renal cyst volume (Bae et al, 2006).

ISOLATED POLYCYSTIC LIVER DISEASE. Isolated PCLD is considered rare, with an estimated incidence of less than 0.01%. Compared with PCLD associated with ADPKD, the overall incidence of isolated PCLD is in fact only slightly lower (Karhunen & Tenhu, 1986); however, in clinical series dealing with symptomatic patients, it is two to five times less frequent (Hoevenaren et al, 2008; Schnelldorfer et al, 2009), which may reflect the milder course of isolated PCLD. As for PCLD associated with ADPKD, cysts increase with age, and although the disease is transmitted equally in men and women, 85% of symptomatic patients are women (van Keimpema et al, 2010).

Manifestations and Diagnosis

SYMPTOMS. In most patients, liver cysts are small and sparse and remain clinically silent. Even with massive organ enlargement, significant hepatic complications remain fairly uncommon, although patients or others may have noted a protuberant abdomen. Some patients develop symptoms that may include abdominal pain or discomfort, early satiety, shortness of breath, and leg edema. These result from compression of the stomach, diaphragm, and inferior vena cava by single large cysts (see Fig. 69A.6) or, much more frequently, because of enlargement of the entire liver (Fig. 69A.8C). As symptoms have progressively evolved over a prolonged period, patients have often become used to these discomforts and are either unaware of them or minimize them. At clinical examination, the liver may reach an enormous size, and its inferior border is frequently palpated in the iliac fossa. The cysts may be so tense that they can be confused with solid tumors.

Previous history of self-resolving acute abdominal pain is not unusual and probably witnesses spontaneous bleeding within one or more cysts. However, these episodes may remain

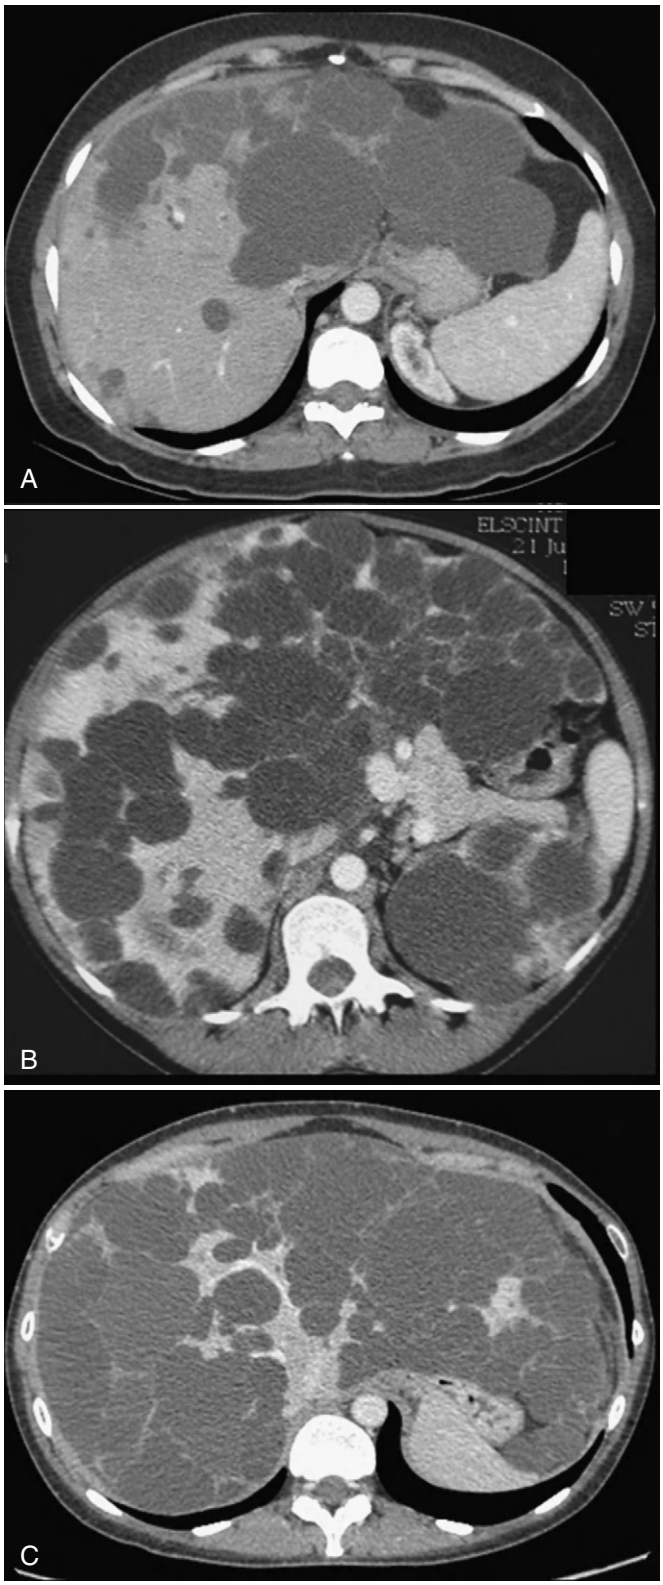

FIGURE 69A.8. Representative examples of the heterogeneity of polycystic liver diease. **A,** *Limited extension:* Several large cysts are evident, but large areas of noncystic liver remain. **B,** *Intermediate form:* Intermediate-sized cysts are scattered throughout the liver, but some areas of noncystic liver remain. **C,** *Severe form:* Almost all the liver is replaced by cysts, and there is likely vascular injury within the few remnant noncystic areas.

clinically silent. As the disease progresses, nutritional deficits may develop and be associated with ascites or pleural effusion (Fig. 69A.9). Body weight is an inaccurate marker because muscular loss correlates with the progressive increase in the weight of the liver, which may reach more than 10 kg. The clinician should instead focus on the thickness of the muscles of the abdominal wall or psoas muscle on imaging studies.

Typically, patients referred to surgeons are women between 35 and 50 years of age with liver cysts diagnosed 10 years previously whose symptoms have become incapacitating for 6 to 18 months. Clinical manifestations, as well as complications and management, are the same whether PCLD is isolated or associated with ADPKD (Hoevenaren et al, 2008; Qian et al, 2003).

BIOLOGY. The only abnormality may be an increase in GGT or alkaline phosphatase, but this is infrequent. Although the liver may be diffusely involved by liver cysts, the hepatic parenchymal volume is preserved (Everson et al, 1988). Therefore no sign of liver failure is evident; when present, a superimposed cause of chronic liver disease is likely. This lack of influence on liver function explains how polycystic livers from brain-dead donors have even been used in the context of emergency liver transplantation (Glanemann et al, 2000).

IMAGING. US shows multiple, fluid-filled, round or oval cysts with sharp margins in the liver and, when associated with ADPKD, in the kidneys. Coalescent cysts may give a false image of septation. On CT scan, the cysts have fluid attenuation values of −5 to +20 Hounsfield units (HU) and have distinct margins with the parenchyma. Calcification of the cysts has been reported but is rare (Coffin et al, 1990; Kutcher et al, 1977). Considering the high prevalence of associated ADPKD, injection of contrast agents should be used with extreme caution. Cysts do not show contrast enhancement, and it may be extremely difficult to identify vascular and biliary structures or even normal landmarks of the liver. Similar to simple cysts, uncomplicated cysts of PCLD are very hyperintense on T2-weighted MRI and very hypointense on T1-weighted images; cysts complicated by hemorrhage become hyperintense on T1-weighted images (see Fig. 69A.2). Identifying peribiliary cysts is difficult but may be suspected when tubular structures run parallel to portal branches, mimicking a biliary dilatation (see Fig. 69A.7; Gupta et al, 1999).

With respect to treatment (see Chapter 69B), attention should be paid to several factors:

1. *The severity of cystic involvement* (see Fig. 69A.8). In a small subset of patients, symptoms are not related to the size of the entire liver but to one or two large cysts. These patients should be identified because even though they may have multiple cysts, management is the same as for those with simple cysts.
2. *The distribution of the cysts.* This is frequently uneven; some areas are relatively spared, in particular segments V or VI, which is the rationale for liver resection.
3. *Peribiliary cysts or cysts located around the biliary confluence and those located in the vicinity of the termination of the hepatic veins.* These may be a common finding. Right hepatic vein compression is frequent and results in an easily identifiable collateral circulation between the right and middle hepatic vein (Fig. 69A.10), which can be a source of intraoperative bleeding.

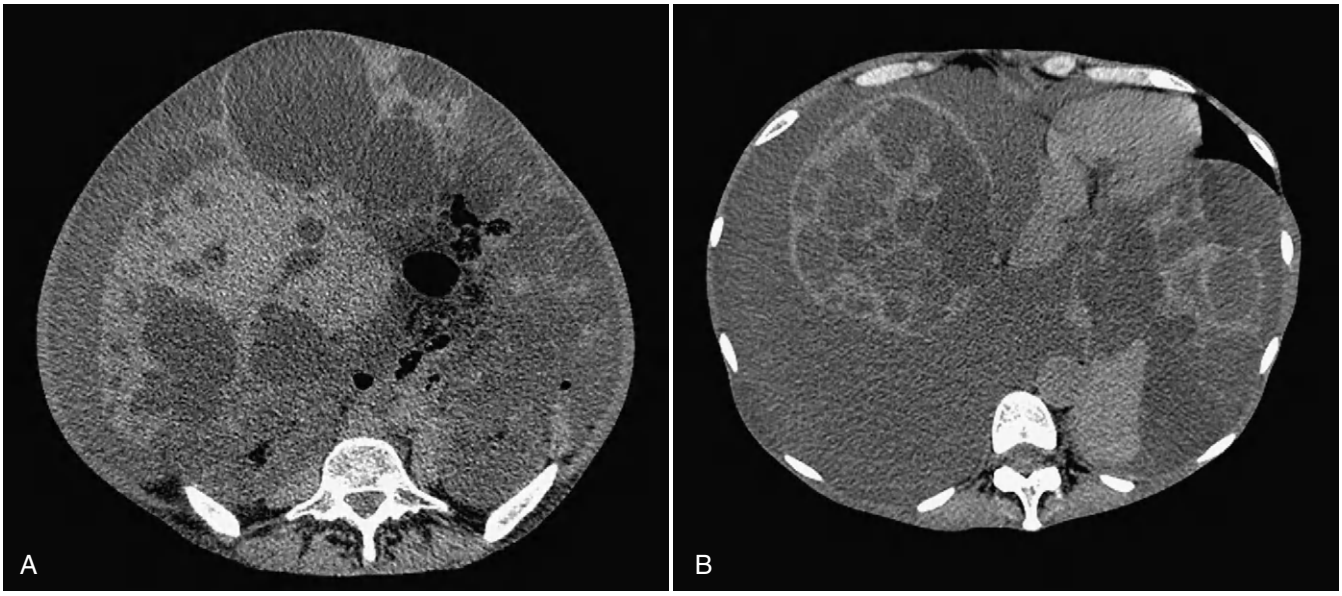

FIGURE 69A.9. Two examples of polycystic liver disease associated with poor nutrition; note that muscles of the abdominal wall are very thin. **A,** Ascites. **B,** Pleural effusion.

Natural History

In patients with ADPKD, the number and size of liver cysts are greater in women than in men, and they increase with patient age and correlate with the size of the kidney (Bae et al, 2006) and the severity of kidney dysfunction. Pregnancy, multiparity, and use of female steroid hormones further increase the risk of severe hepatic cystic disease (Sherstha et al, 1997). The natural course is highly variable from one individual to the other or within members of the same family, but the progression is fairly linear for a given patient. Hence, age at the time of diagnosis, first symptoms, incapacitating symptoms, and kidney involvement are useful markers to predict the future need for transplantation (see Chapter 69B). As the lifespan of patients with ADPKD has lengthened with dialysis and transplantation, liver-related symptoms have become more frequent.

In patients with isolated PCLD, liver involvement also correlates with female gender and number of pregnancies (Qian et al, 2003; Van Keimpema et al, 2010). Apart from kidney

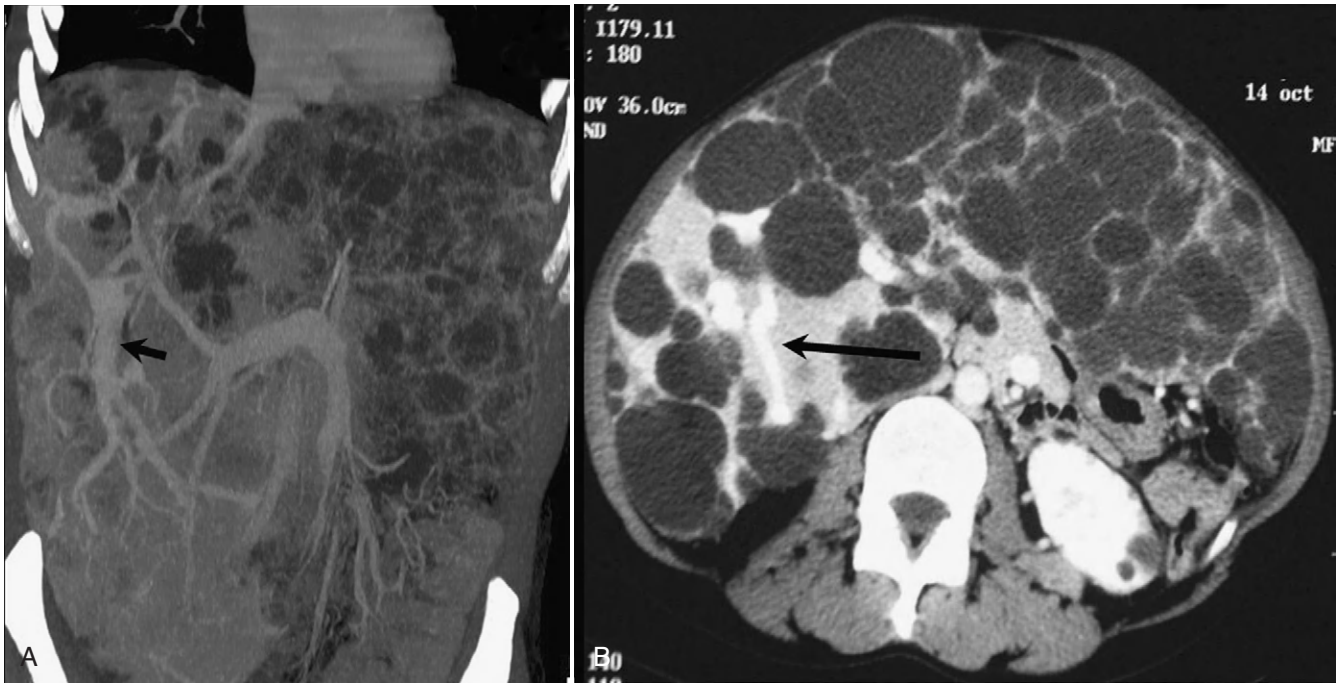

FIGURE 69A.10. A, Polycystic liver disease resulting in compression of hepatic veins (*arrow*). **B,** A collateral circulation between the right and middle hepatic vein is visible (*arrow*).

symptoms, which are absent, the course is the same as that of PCLD associated with ADPKD (Hoevenaren et al, 2008).

Complications

Within Cysts

Bacterial infection is the most severe complication and, although very rare, can be severe enough to be life threatening (Robson & Fenster, 1964; Telenti et al, 1990). Symptoms may include fever, chills, and right upper quadrant pain or less typical symptoms. Cyst infection has mainly been observed in patients with ADPKD under dialysis or in those taking immunosuppressive drugs after renal transplantation (Bourgeois et al, 1983). It is exceptional, if it exists at all, in patients with isolated PCLD (Hoevenaren et al, 2008; Qian et al, 2003; van Keimpema et al, 2010). Differentiating infection within kidney or liver cysts is difficult. The infected cysts can be recognized by US and CT, which show echoic material within the cysts, corresponding to pus (Telenti et al, 1990). Thickened, irregular cyst wall, hyperdense content, and fluid-fluid or air-fluid levels may also be seen. Positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose labeled leucocytes or ^{111}In-labeled leukocyte scintigraphy may be used to document and localize infection (Kjaer et al, 2004; Desouza et al, 2009). Treatment of an infected cyst should include aspiration and drainage in addition to antibiotics provided the infection has been documented (Telenti et al, 1990).

Intracystic bleeding is quite common and may occasionally be mistaken for cyst infection. Although it has been claimed that malignant transformation can occur, it is still unclear whether the hepatic cysts predisposes to the development of cholangiocarcinoma; our opinion is that it does not.

Complications from Cyst Compression

Cholestasis secondary to compression of the biliary bifurcation by large cysts (Ergün et al, 1980; Howard et al, 1976) or by peribiliary cysts may occur. In contrast, jaundice is rare and may result from progressive or acute enlargement of cysts, the latter in cases of intracystic bleeding. Mild dilation of the common bile duct is also not unusual (Ishikawa et al, 1996). As a result of portal or hepatic vein compression, portal hypertension with ascites and variceal bleeding have been described (McGarrity et al, 1986; Ratcliffe et al, 1984; Sato et al, 2002). Severe forms may also occur in the few patients with ADPKD who have associated congenital hepatic fibrosis or in patients with autosomal recessive PKD, in which liver cysts are rare.

Compression of adjacent organs by the enlarged liver is responsible for most symptoms, as previously discussed; less common is the compression of the right atrium, which may result in hypotentive episodes (Lasic et al, 2004), or the inferior vena cava. The parenchymal impact of hepatic or portal vein compression is frequent. In our experience with liver resection or transplantation, this is present in more than 75% of the patients and includes centrolobular fibrosis, sinusoidal congestion, peliosis, and nodular regenerative hyperplasia (Fig. 69A.11).

Complications from Associated Conditions

ADPKD is well known for other extrarenal manifestations other than those of the liver. These include, most notably, intracranial aneurysms, but dolichoectasias, thoracic aortic and cervicocephalic artery dissections, and coronary artery aneurysms are also possible. These vascular diseases have directly been linked to *PKD1* or *PKD2* mutations in experimental models (Bichet et al, 2006).

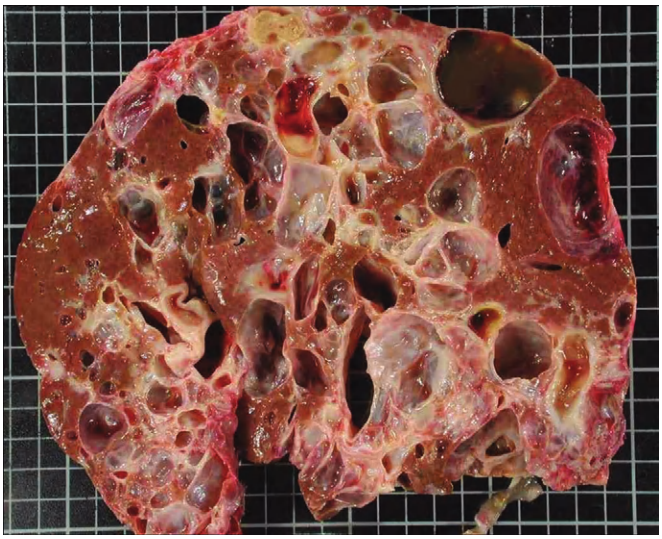

FIGURE 69A.11. Macroscopic view of a resected specimen of polycystic liver disease. Microscopic injuries are frequent because of compression by cysts or inflow/outflow obstructions.

The incidence of cerebral aneurysms is 8%, three to four times higher than in the general population (Pirson et al, 2002). It has been linked to a mutation in the 5′ region of *PKD1*, rather than the 3′ region; therefore the main risk factor is a family history of intracerebral aneurysms or subarachnoid hemorrhage (SAH) (Rossetti et al, 2003). In this context, the incidence is 16%. Most of these aneurysms are small (<6 mm in diameter) and do not seem to be at increased risk of growth or rupture compared with those of the general population (Gibbs et al, 2004). Widespread screening is not indicated and should be restricted to individuals with a family history of aneurysm or SAH, previous aneurysm rupture, preparation for major elective surgery, high-risk occupations (such as airline pilots), and patient anxiety despite adequate information (Pirson et al, 2002). The ideal method of detection is MRI.

Mitral valve prolapse and pericardial effusion are frequently also found in 25% and 35% of patients with ADPKD, respectively. These are generally well tolerated and do not require therapeutic intervention (Lumiaho et al, 2001; Qian et al, 2007). Cerebral aneurysms and mitral valve abnormalities have been reported with the same or a slightly lower incidence in patients with isolated PCLD (Hoevenaren et al, 2008; Qian, et al 2003).

Staging

Several systems have been proposed to grade the severity of PCLD, and the rationale behind their design is different.

Gigot's Classification

Gigot's classification relies on CT imaging and was designed to identify the indications and limits of fenestration in the treatment of PCLD (Gigot et al, 1997): *type I* shows a limited number (<10) of large cysts (>10 cm); *type II* shows diffuse involvement of liver parenchyma by multiple medium-sized cysts with remaining large areas of noncystic liver parenchyma on preoperative CT; *type III* shows massive, diffuse involvement

of liver parenchyma by small and medium-sized liver cysts and only a few areas of normal liver parenchyma between cysts. The drawback of this classification is that some patients may seem to have either one or the other type depending on the CT slice because the distribution of cysts is uneven.

Qian's Classification

Qian's classification has been used in the context of familial screening and relies on cyst number and the presence of symptomatic hepatomegaly (Qian et al, 2003): *grade 0* refers to 0 cysts; *grade 1*, 1 to 10 cysts; *grade 2*, 11 to 20 cysts; *grade 3*, more than 20 cysts; and *grade 4*, more than 20 cysts and symptomatic hepatomegaly.

Schnelldorfer's Classification

Schnelldorfer's classification aims at differentiating patients who could benefit from resection or transplantation. It is more complex but also more reliable (Schnelldorfer et al, 2009). It takes into account the presence of symptoms (absent, mild, or severe), the number and size of the cysts, the presence of relative normal areas of liver parenchyma (≥2 sectors, ≥1 sector, or <1 sector), and whether an isosectoral portal or hepatic vein occlusion of the preserved sector is present.

DIFFERENTIATION BETWEEN SIMPLE CYSTS, ISOLATED PCLD, AND PCLD ASSOCIATED WITH ADPKD

The distinction between isolated PCLD and PCLD associated with ADPKD relies on the number of kidney cysts and familial history. In adults with a positive family history, the diagnosis of ADPKD is established by radiologic evidence of at least two unilateral or bilateral cysts in patients younger than 30 years, at least two cysts in each kidney in those 30 to 59 years, and at least four cysts in each kidney in those 60 years or older (Ravine et al, 1994). Of note, one third of patients with isolated PCLD may have a few kidney cysts, but most usually have one or two (van Keimpema et al, 2010), as does the general population of adult patients (Carrim & Murchinson 2003). In the absence of a family history, the diagnosis of ADPKD is retained if more than five kidney cysts in either one or both kidneys are visible on CT.

Unlike ADPKD, no clinical guidelines have established what distinguishes PCLD from simple cysts that are frequently multiple. Some surgical series have used a threshold of five or six cysts, whereas others have required involvement of more than 50% of the parenchyma. These differences should be taken into account when analyzing the results of these series. More recently, in the case of family screenings, it has been proposed that sporadic cases of PCLD be defined by the presence of more than 15 to 20 cysts, but when there is a positive familial history the presence of four cysts is sufficient (Hoevenaren et al, 2008; Qian et al, 2003). Genetic testing is neither required nor useful in clinical practice for either form of PCLD because not all mutations have been identified.

DIFFERENTIAL DIAGNOSIS

Single Cysts

Hydatid cysts, liver abscesses, cystadenoma, and *cystadenocarcinoma* are the main differential diagnoses, especially when simple cysts have become atypical. These entities are addressed separately in Chapters 68, 66, 67, and 79B, respectively.

Embryonal sarcomas (see Chapter 82) are mostly observed in children between the ages of 2 and 15 years and are exceptional in adults. The tumor is usually large and poorly differentiated with abundant myxoid or necrotic content. Although the tumor may appear as cystic on CT scan and MRI because of the very high water content of the myxoid stroma, US shows that it is, in fact, solid. Late-phase contrast imaging on CT and MRI shows late enhancement, which is incompatible with a cystic tumor.

Other Primary Tumors

Hepatocellular carcinoma and *cholangiocarcinoma* may occasionally be cystic (see Chapters 50 and 80). This cystic appearance corresponds to necrosis that may be either spontaneous, particularly for rapidly growing tumors, or treatment induced. However, with few exceptions, these tumors remain mostly solid. *Giant hemangiomas* may occasionally present as partly cystic; this corresponds to noncirculating areas. Hemangiomas are hypointense on T1-weighted MRI images and hyperintense on T2-weighted images, the same as any cystic lesion, but the kinetics of contrast enhancement is typical (see Chapters 17 and 79A).

In the context of acute pancreatitis or pancreatic duct rupture, *intrahepatic pseudocysts* are exceptional, with fewer than 20 reported cases (Balzan et al, 2005). They may be located in the left liver along the lesser omentum, or in the right liver along the right portal vein. They have a subcapsular location, hemorrhagic or necrotic content, and a fibrous wall that enhances at the late phase of the injection. Pancreatic MRI is occasionally useful to document rupture of the pancreatic duct (see Chapter 54).

Liver hematomas are rarely spontaneous and usually appear in the context of trauma or liver surgery. They have also been described in association with hepatocellular carcinoma, liver adenoma, or, very rarely, metastases. When occurring at the end of a pregnancy, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) should be suspected. Clinical symptoms are usually obvious, with pain and associated symptoms from intraabdominal hemorrhage if capsular rupture has occurred. When the clots are fresh, these hematomas are spontaneously echogenic on US, hyperdense on CT scan, hyperintense on T1-weighted MRI sequences, and hypointense on T2-weighted MRI sequences. At a later phase, clots liquefy and the content appears cystic (see Chapter 17).

Bilomas are cystic lesions that contain bile as a result of spontaneous, traumatic, or iatrogenic bile duct rupture; such lesions are surrounded by a fibrous capsule. Biliary anomalies—such as dilation, stenosis, or a combination of these—are frequent.

Ciliated Hepatic Foregut Cysts

Ciliated hepatic foregut cysts have been described in all areas where the foregut extends during the embryonic period, including the sublingual area, esophagus, stomach, ileum, pancreas, and gallbladder. They also may be present within the liver.

Although extremely rare, ciliated hepatic cysts warrant special consideration. Such cysts are located within the liver parenchyma and have a characteristic four-layer border that consists of a pseudostratified, ciliated columnar epithelium covering a subepithelial connective tissue, smooth muscle bundles, and an outer fibrous capsule. The lining epithelium may secrete fluids of different composition, from watery to viscous or mucous, which explains why its echogenicity may be variable

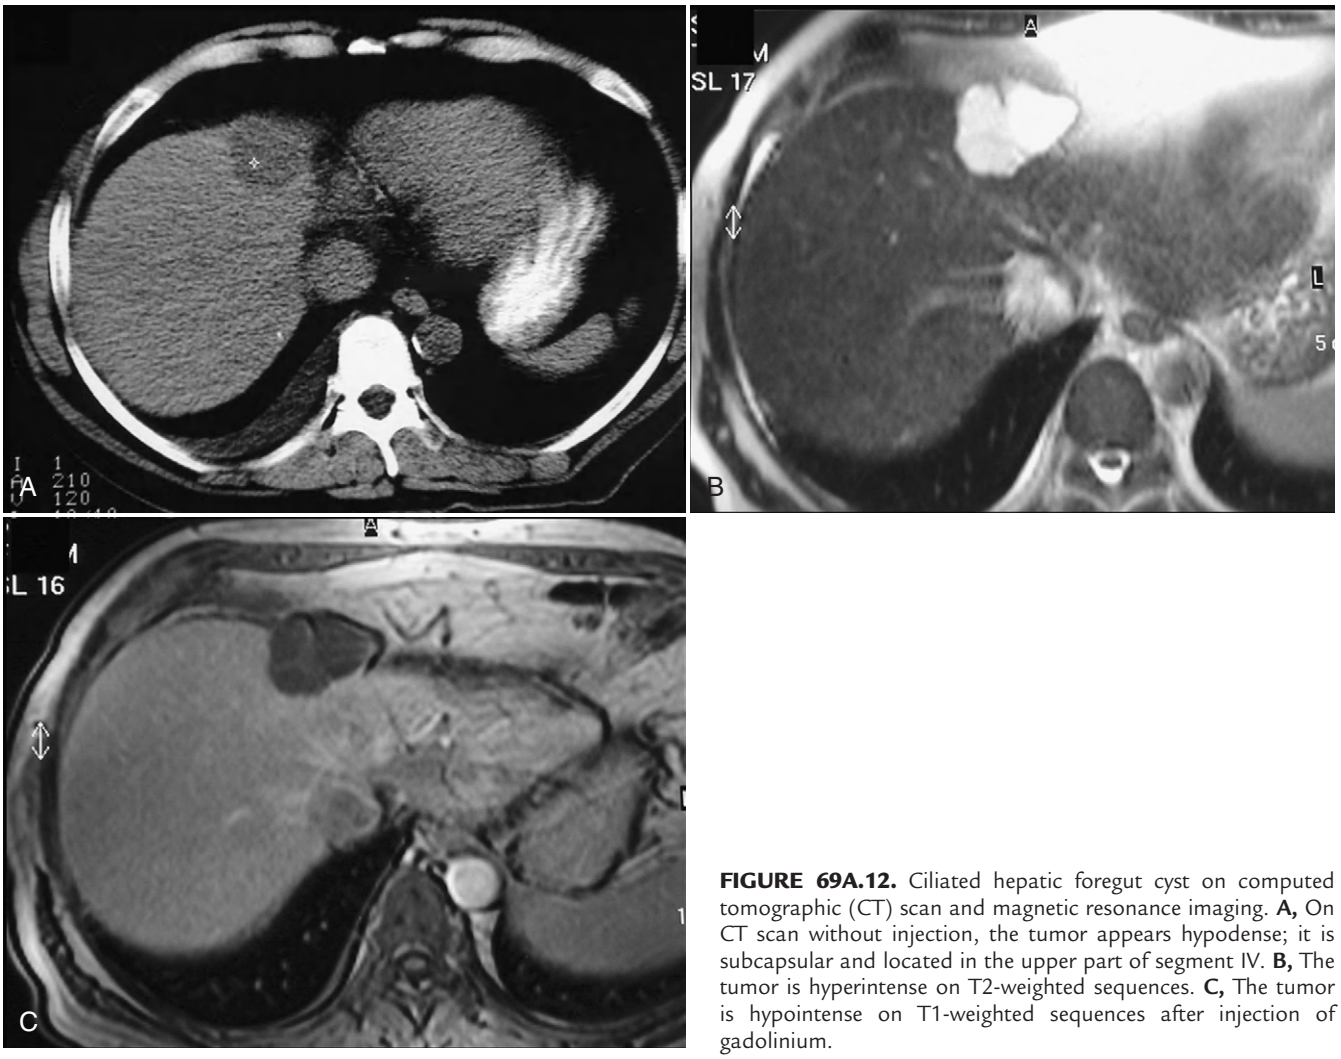

FIGURE 69A.12. Ciliated hepatic foregut cyst on computed tomographic (CT) scan and magnetic resonance imaging. **A,** On CT scan without injection, the tumor appears hypodense; it is subcapsular and located in the upper part of segment IV. **B,** The tumor is hyperintense on T2-weighted sequences. **C,** The tumor is hypointense on T1-weighted sequences after injection of gadolinium.

and why calcifications may be present, although this is exceptional. The second characteristic of these cysts is that they are subcapsular, usually located on the anterior surface of the liver close to the insertion of the falciform ligament. Two thirds are localized in the left lobe of the liver in segment IV, but right lobe cysts also have been described (Takahiro et al, 2003). The final characteristic of these cysts is that they are classically unilocular and usually less than 4 cm in diameter. Typically these cysts do not communicate with the biliary system, although this has been reported, particularly in children.

PREVALENCE AND ETIOLOGY. Although recognized since 1857, ciliated hepatic cysts are exceptional, with approximately 100 cases reported in the literature, most in the past 20 years (Sharma et al, 2008). There is no gender predominance, and patient age ranges from newborn with prenatal diagnosis (Guérin et al, 2010) to 82 years, with a mean age of 48 years.

MANIFESTATION AND DIAGNOSIS. Most ciliated hepatic foregut cysts, two thirds of reported patients, are asymptomatic and discovered incidentally during abdominal imaging studies or surgical explorations. Abdominal symptoms are rare, probably because of the small cyst size. When symptoms are present, the most frequent symptom is epigastric or right upper quadrant pain that can be observed even with small tumors because of their subcapsular location.

Three characteristics that appear on imaging are 1) their predominant location in segment IV, 2) their small size (4 ± 2 cm), and 3) their subcapsular location. Most (>90%) are unilocular. Two thirds of the cysts are hypoechoic on US, hypodense on CT, and do not enhance after injection of contrast material (Fig. 69A.12). They are anechoic as formal biliary cysts in less than 5% (Horii et al, 2003). Some ciliated cysts may also have an atypical, solid tumor appearance on CT and a noncystic appearance on US (hyperechoic), probably as a result of mucinous material, calcium, and cholesterol crystals within the cyst. On MRI the lesion is highly hyperintense on T2-weighted images but highly variable on T1 sequences; they are hyperintense in 52%, isointense in 24%, and hypointense in 14%. When atypical on imaging, the differential diagnosis includes cystadenoma or cystadenocarcinoma and may be difficult, especially because carbohydrate antigen (CA) 19-9 may be expressed by the epithelium of the ciliated cysts, and its serum level may be slightly elevated (Wu et al, 1998). Fine needle aspiration cytology may help by showing ciliated, pseudostratified, tall columnar epithelial cells suspended in a

mucous background. The presence of these cells is virtually diagnostic of this condition, and the positive predictive value of aspiration is 76% (Sharma et al, 2008).

COURSE, COMPLICATIONS, AND TREATMENT. Ciliated hepatic foregut cysts are usually believed to follow a benign course. Compression of adjacent structures is extremely rare, with a single case report of portal compression resulting in portal hypertension (Harty et al, 1998) and another case report of jaundice (Vick et al, 1999). Malignant transformation into squamous cell carcinoma has been reported in four patients in recent years (de Lajarte-Thirouard et al, 2002; Furlanetto & Dei Tos, 2002; Vick et al, 1999; Zhang et al, 2009), and one other patient had extensive squamous metaplasia (Ben Mena et al, 2006), yielding a risk of malignancy of less than 5%. Because this transformation has occurred in patients with cysts larger than 7 cm, most authors agree that excision is indicated when the cyst is larger than 4 to 5 cm, shows abnormalities in its wall, enlarges, or is symptomatic, although other authors recommend broader indications.

Multiple Cysts

Biliary hamartomas, also known as *von Meyenburg complexes*, also correspond to an anomalous arrangement of the ductal plate; long recognized by pathologists and surgeons, they are a frequent finding during liver surgery (see Chapters 47 and 48). Biliary hamartomas may be observed within an otherwise normal liver (6% of the population) but may also be associated with Caroli disease (see Chapter 46) and congenital hepatic fibrosis; in PCLD, they are particularly prevalent—virtually constant. Identification of biliary hamartomas is important because they may be mistaken for liver metastases. These lesions are asymptomatic and are discovered incidentally. They range in size between 2 and 10 mm and may appear on US as hypoechogenic, hyperechogenic, or heterogenous depending on their size, associated biliary dilation, and fibrous stroma (Zheng et al, 2005). They are hypodense on CT and do not enhance; on MRI, they are very hypointense on T1-weighted images, very hyperintense on T2-weighted images, and are best seen on cholangio-MRI sequences (Fig. 69A.13; see Chapters 16 and 17).

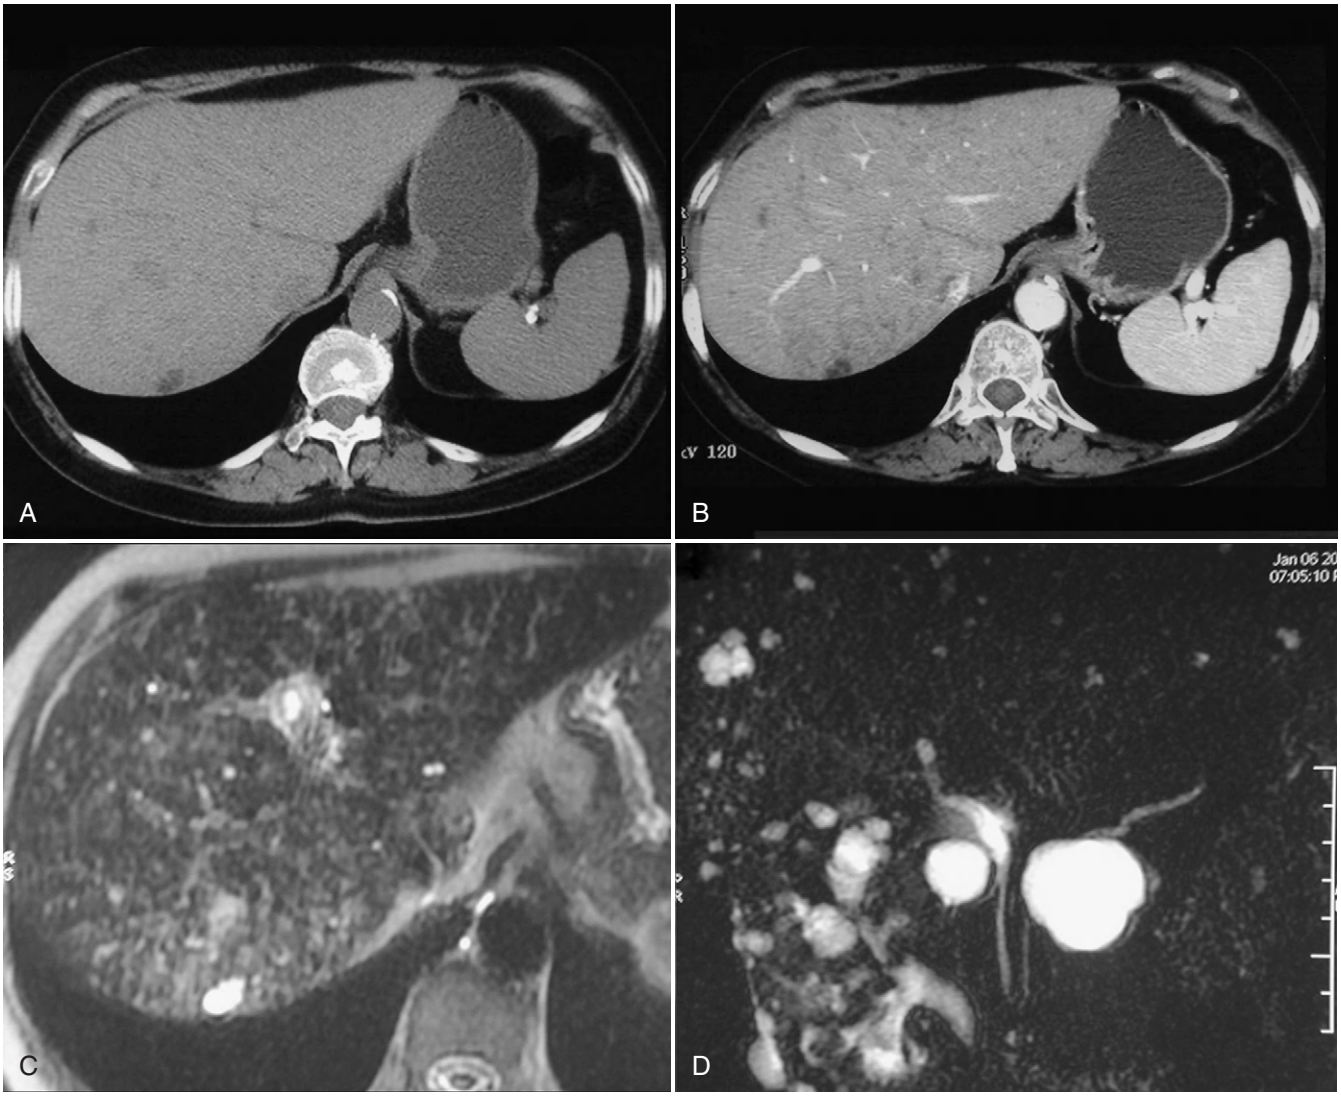

FIGURE 69A.13. Biliary hamartoma. **A,** On computed tomographic scan, hypodense lesions are visible. **B,** They do not enhance after injection but become more visible. They are better seen on T2-weighted images (**C**) and on cholangiographic magnetic resonance imaging sequences (**D**).

Peribiliary cysts arise from cystic enlargement of peribiliary glands located in and around the walls of extrahepatic and large intrahepatic bile ducts. These cysts may have a diameter up to 2 cm and are mainly observed in the context of severe chronic liver disease, including cirrhosis with portal hypertension or PCLD and after liver transplantation. They are usually asymptomatic, but obstructive jaundice has been reported. When known, imaging features are easily recognized. At US, the cysts are located along the main bile ducts or within portal tracts beside portal veins. At cholangio-MRI, they may mimic an enlarged bile duct, but smaller biliary branches upstream are not dilated. Increases in size and diameter are possible but rare (Motoo et al, 2001).

Cystic Metastases

Cystic metastases are solid tumors, and the cystic form is rare. The cystic component may be partial or total, and cystic metastases frequently arise from neuroendocrine, sarcomas or melanomas, or occasionally from bronchial or breast primary tumors. They can also result from ovarian or pancreatic cystadenocarcinomas. Finally, although very rare, metastases from anal carcinoma are frequently cystic. If the primary is unknown, the presence of peripheral hypervascularization and multiplicity of the lesions should raise the suspicion of this diagnosis. MRI diffusion sequences may also be helpful.

CHAPTER 70A

Cirrhosis and portal hypertension: pathologic aspects

Rish K. Pai and Elizabeth M. Brunt

OVERVIEW

Cirrhosis is the final stage of a variety of chronic diseases involving the liver. Histopathologically, cirrhosis is characterized by remodeling of the vascular architecture with septal formation and nodular groups of regenerating hepatocytes. Biochemically, the cirrhotic liver functions less efficiently than the normal liver. Decompensated cirrhosis manifests as portal hypertension and liver failure, both of which are associated with numerous clinically important complications (see Chapters 70 through 77). In addition, regardless of the underlying etiology, cirrhosis is a major predisposing condition to the development of hepatocellular carcinoma (HCC) (Suriawinata & Xu, 2004). Portal hypertension secondary to cirrhosis develops as a result of the alterations of the hepatic microcirculatory system. Portal hypertension may also occur in the absence of the structural alterations of cirrhosis (noncirrhotic portal hypertension). The conditions associated with this may be idiopathic; all are subdivided into *prehepatic, intrahepatic,* or *posthepatic*. This chapter focuses on the pathology of cirrhosis and noncirrhotic portal hypertension and many of the conditions that result in portal hypertension.

CIRRHOSIS

The true prevalence of cirrhosis in the United States is unknown because many patients with compensated cirrhosis do not exhibit symptoms or signs of liver failure, but cirrhosis is among the top 10 causes of death in the Western world. In autopsy series, cirrhosis is documented in 5% to 10% of cases, but autopsy subjects may not be representative of the general population (Karsan et al, 2004). Currently, the only available and definitive treatment for established cirrhosis is liver transplantation.

Pathogenesis and Reversibility

The transformation from normal hepatic architecture to cirrhosis ultimately results from progressive deposition of fibrous tissue in regions of "extinct" parenchyma and vascular remodeling, regardless of the underlying etiology. Fibrogenesis is dynamic, and it is triggered by liver injury and mediated by a complex interplay of cellular necrosis, inflammation, apoptosis, and various cytokines. The cells that contribute to the development of hepatic fibrosis are the activated hepatic stellate cells and portal myofibroblasts. Once activated, these cell types are primed to respond to a wide variety of chemokines and cytokines (Friedman, 2008). In particular, transforming growth factor (TGF)-α seems to be a major fibrogenic mediator that induces these cells to produce collagens and other types of extracellular matrix and degradatory products (Canbay et al, 2004; Friedman, 2008; Pinzani & Marra, 2001; Ramadori & Saile, 2004). Recent work has shown the fibrogenic nature of leptin, the anorectic hormone produced in adipose tissue (LeClercq et al, 2002). During pathologic fibrogenesis, prevention of matrix degradation by metalloproteinases is orchestrated by the release of potent tissue metalloproteinase inhibitors; apoptosis of fibrogenic hepatic stellate cells also is inhibited. Scar formation ultimately is the consequence of the imbalance of collagen synthesis, deposition, and degradation. Another increasingly recognized pathway of fibrogenesis in the liver is that of epithelial-mesenchymal transformation (EMT), in which "injury" results in a cascade of cytokines that lead to epithelial cells developing and expressing mesenchymal markers (Rygiel et al, 2008); the exact role EMT plays in fibrogenesis is being studied.

Established cirrhosis has traditionally been considered irreversible. Accumulating clinical and experimental evidence

suggests, however, that reversal or regression of liver fibrosis and cirrhosis may be possible (Fallowfield & Iredale, 2004). A study by Poynard and colleagues (2002) analyzed 3010 patients with chronic hepatitis C virus (HCV) included in four major clinical trials to receive randomized treatment regimens with interferon or pegylated interferon, with or without additional ribavirin. Reversal of cirrhosis was reported in 75 (49%) of 153 patients with baseline cirrhosis. Pol and associates (2004) examined 64 immunocompetent patients with HCV-related cirrhosis and found that cirrhosis disappeared in five patients (7.8%) on follow-up biopsies at a mean interval of 4.6 years. In addition, three of four patients undergoing dialysis showed reversal of cirrhosis secondary to HCV infection, and resolution of cirrhosis was shown in two patients upon examination of the whole liver explants at the time of transplantation.

More recently, Falize and colleagues (2006) analyzed 36 patients with hereditary hemochromatosis and demonstrated that regression of fibrosis was seen in 69% of those with bridging fibrosis and in 35% of patients with cirrhosis after institution of venosection therapy. Regression of cirrhosis has also been reported in patients with other diseases, such as hepatitis B virus (HBV), alcoholism, autoimmune hepatitis, and primary biliary cirrhosis (Arthur, 2002; Fallowfield & Iredale, 2004; Serpaggi, et al, 2006; Wanless et al, 2000). Spontaneous resolution of fibrosis also has been described in rats treated with carbon tetrachloride (Iredale et al, 1998; Issa et al, 2004). The proposed mechanisms for breakdown and remodeling of liver fibrosis include loss of activated stellate cells via apoptosis, decreased expression of metalloproteinase inhibitors, and increased production and activity of metalloproteinases or collagenases (Arthur, 2002; Benyon & Arthur, 2001; Fallowfield & Iredale, 2004; Gieling, et al, 2008). It is unclear, however, how these molecular and cellular events are initiated and regulated.

Currently, the extent to which cirrhosis is truly reversible is the subject of debate (Arthur, 2002; Chedid, 2000; Desmet & Roskams, 2003; Geller, 2000; Ray, 2000). Many important questions remain to be answered. Even if scar tissue is resorbed, can normal hepatic architecture be completely restored? Were there sampling differences or interpretation errors on biopsies in the studies showing reversibility? It is possibile that some of the reversed cases might have undergone a conversion of micronodular to macronodular cirrhosis, as shown in animal models (Issa et al, 2004), a condition that made the diagnosis of cirrhosis more difficult on a needle core biopsy sample (Desmet & Roskams, 2003)? Regardless, this discussion may have important clinical implications. Many liver diseases progress insidiously, and patients may seek medical attention only at the advanced stage, when treatment choices are limited. If cirrhosis is truly reversible, many patients with advanced liver disease still may benefit from medical treatment for specific etiologies, particularly with the discovery of new drug therapies.

Role of Liver Biopsy

In modern medicine, investigation of patients with chronic liver disease and cirrhosis involves multiple disciplines that include pathology, radiology, chemistry, biochemistry, virology, serology, and molecular biology. Liver biopsy evaluation remains the primary diagnostic tool, despite the drawback of invasiveness (Rockey et al, 2009). Noninvasive screening methods show promise in excluding patients with advanced fibrosis; however, in a recent study evaluating one of these tests, the positive predictive value for advanced fibrosis was still quite low, and the test fared poorly at distinguishing between intermediate stages of fibrosis (Zaman et al, 2007). For cirrhotic patients, liver biopsy can serve several important purposes, such as establishing or confirming diagnoses; assessing the possible underlying causes of disease; analyzing the grade of ongoing necroinflammatory activity; detecting dysplastic lesions or an occult HCC; and providing tissue for chemical, biochemical, molecular, or ultrastructural studies (Brunt, 2000a).

Two broad types of biopsy are used to sample liver tissue: *needle biopsy* and *wedge biopsy*. Needle biopsy has proved to be the most useful technique to obtain representative liver tissue for analysis. This procedure can be done percutaneously, transjugularly, or during open surgery or laparoscopy; a cutting needle or the Menghini aspiration needle may be used, although the former generates a better biopsy specimen. If cirrhosis is suspected clinically, a cutting needle is the preferred method of biopsy because an aspiration needle often provides a fragmented specimen that makes histologic evaluation difficult. The size of the needle biopsy specimen is important in avoiding sampling error. Traditionally, it has been recommended that an adequate biopsy specimen should be no smaller than 20 gauge and at least 1.5 cm in length, or it should contain at least five portal tracts (Afdhal & Nunes, 2004; Rockey et al, 2009). It has been suggested more recently, however, that for accurate and reliable grading and staging of chronic viral hepatitis, a biopsy specimen of 2 cm in length or longer that contains at least 11 complete portal tracts is needed (Guido & Rugge, 2004).

Usually performed during open surgery or laparoscopy, wedge biopsy is discouraged for evaluation of diffuse parenchymal liver diseases because this technique samples primarily the subcapsular liver parenchyma, which may contain misleading fibrous septa extending from the capsule that could be easily confused with cirrhosis or bridging fibrosis (Fig. 70A.1). The same issue can also occur in a subcapsular needle biopsy. In addition, nonspecific necroinflammatory change can occur quickly in the subcapsular region during surgical procedures, which may further confuse histology. A wedge biopsy is more suitable for focal lesions present on or immediately below the

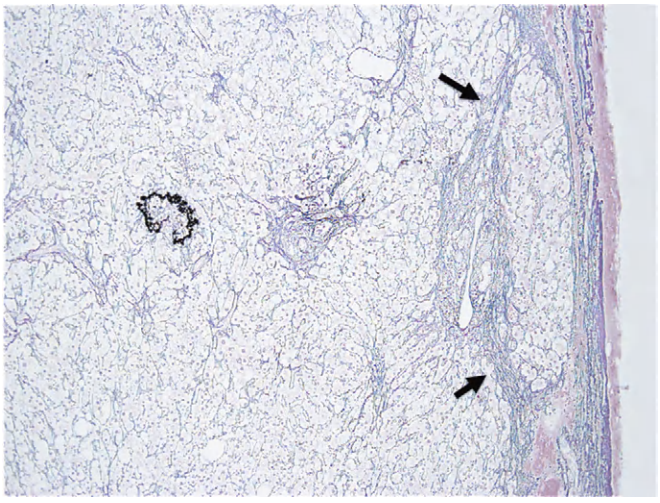

FIGURE 70A.1. Wedge biopsy showing overestimation of fibrosis just beneath the liver capsule (Gomori reticulin stain). *Arrows* indicate fibrous septa extending into the hepatic parenchyma.

capsule. Even during open surgery, a needle biopsy to sample deep liver parenchyma is preferred (Guido & Rugge, 2004).

Prompt fixation of the liver biopsy specimen in buffered formalin is vital to high-quality histology. Many special stains and analyses, such as iron or copper quantitation, can be performed on formalin-fixed, paraffin-embedded (FFPE) tissue. If a metabolic disorder is suspected, and electron microscopic examination is expected, additional tissue should be fixed in glutaraldehyde. If fresh tissue is submitted for molecular analyses, it should never be dry or immersed in saline; the appropriate fixation method is to place the tissue on a piece of saline-moistened gauze in a container. Consultation with a pathologist before the biopsy procedure is encouraged to help avoid inappropriate tissue handling.

Histopathologic interpretation of liver biopsy specimens can be challenging. The importance of communication among surgeons, hepatologists, and pathologists cannot be overemphasized. Clinicians should provide sufficient clinical information when submitting a liver biopsy specimen for pathologists to analyze histologic findings in the appropriate clinical setting.

Morphology

Grossly, the liver with established cirrhosis exhibits a nodular appearance that diffusely involves the entire liver (Fig. 70A.2). Microscopically, the liver parenchyma is divided by variable-sized fibrovascular septa, which contain profiles of ductular structures and diverse inflammatory cell types, into nodules that typically no longer retain a terminal hepatic venule or identifiable portal tracts. The normal portal-central relationship is completely effaced; the exception to this is biliary cirrhosis, in which the terminal hepatic venule may retain its central location. The hepatocytes within the nodules may appear morphologically normal, or they may show evidence of regeneration. The latter may be characterized by thickened cell plates with up to two cells across; anisonucleosis; large cell change with maintenance of nuclear/cytoplasmic (N/C) ratio; or small, crowded cells with markedly increased N/C ratios. The reticulin stain is useful to show cord thickening. The increased ductular profiles (ductular proliferation) are referred to as a *ductular reaction* (Roskams et al, 2004). Some cases may retain lymphoid aggregates in the septa, and some may have interface hepatitis.

According to the size of the nodules, cirrhosis has been classified as *micronodular* if nearly all the nodules are less than 0.3 cm in diameter, or *macronodular* if nodules are greater than 0.3 cm. Mixed micronodular and macronodular cirrhosis is defined by the presence of relatively equal numbers of small and large nodules. Although this morphologic classification may provide clues to the underlying etiology in some cases, it is not recommended for clinical practice because micronodular cirrhosis may progress to a macronodular pattern over time. Mixed micronodular and macronodular cirrhosis is common in end-stage liver disease regardless of the underlying etiology.

Biliary cirrhosis is caused by disorders such as primary biliary cirrhosis, primary or secondary sclerosing cholangitis, and biliary atresia. This type of cirrhosis exhibits unique morphologic features characterized by a highly irregular "jigsaw puzzle" or "geographic" nodular pattern (Fig. 70A.3). As noted, the terminal hepatic venule may be retained, and loss or effacement of native bile ducts by either lymphoid aggregates or scar tissue may be evident. Ductular reaction (proliferation) may be more pronounced than that seen in other types of cirrhosis. A characteristic clue to biliary cirrhosis is the constellation of findings in periseptal hepatocytes referred to as *cholate stasis*. These findings include periseptal hepatocyte ballooning, Mallory-Denk bodies (Mallory's hyaline), and copper deposition. In addition, foamy cell aggregates may be seen in the nodules. Some investigators have attributed large cell change to chronic cholestasis. Another subtle histologic clue to biliary cirrhosis is the presence of nodular regenerative hyperplasia in the regenerative nodules.

Recognition of cirrhosis is usually straightforward when an adequate biopsy specimen is examined, even on hematoxylin and eosin–stained sections. It may be helpful to use Masson trichrome stain to highlight the dense perisinusoidal fibrosis of alcoholic hepatitis and cirrhosis, particularly for fragmented needle biopsy specimens (Fig. 70A.4). Fragmentation of the specimen noted at the time of biopsy should raise the suspicion of cirrhosis. On histologic sections, a thin layer of collagen, better appreciated on trichrome and reticulin stains, tends to adhere to the surface of detached nodules. Cirrhosis also may be difficult to diagnose on needle biopsy specimens, when a

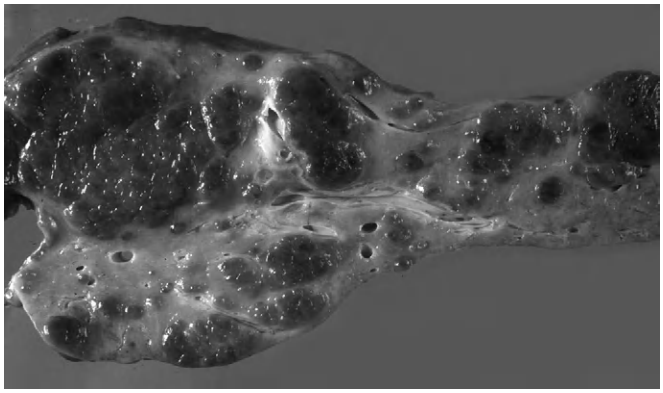

FIGURE 70A.2. Gross appearance of cirrhosis showing diffuse involvement of the entire liver by regenerative nodules and broad fibrous bands.

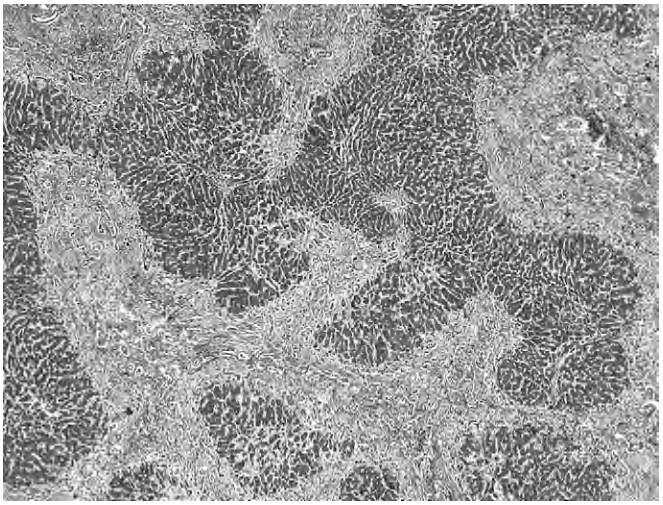

FIGURE 70A.3. Biliary cirrhosis exhibiting a "jigsaw puzzle" pattern (Masson trichrome stain).

FIGURE 70A.4. Cirrhosis visible on a needle biopsy specimen (Masson trichrome stain).

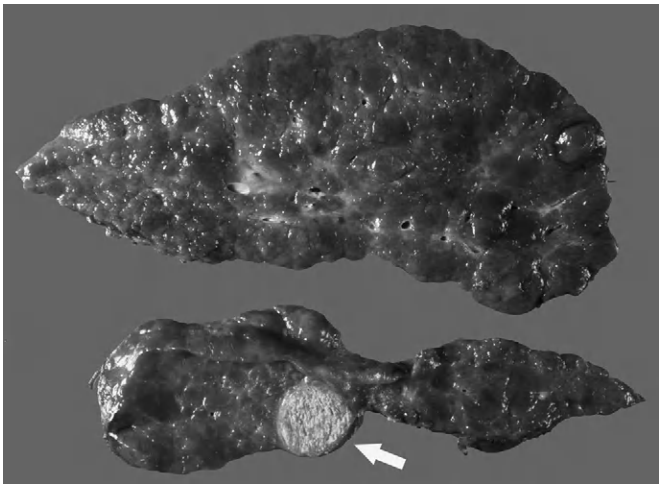

FIGURE 70A.5. Hepatocellular carcinoma (*arrow*) in a cirrhotic liver.

macronodule is sampled, or when cirrhosis is incomplete (incomplete septal cirrhosis). In the last case, the complete spectrum of morphologic features of cirrhosis are not exhibited but vascular relationships are markedly altered, and ectatic, eccentrically located portal veins may be noted. In addition, the septa are thin, and some may be seen to extend into the parenchyma and end blindly. This type of "cirrhosis" is not uncommon in HBV-related liver disease.

Additional stains considered routine by liver pathologists in evaluation of liver biopsies include the iron stain and periodic acid-Schiff stain after diastase digestion (PAS-d). The former is useful in detecting small amounts of hepatocellular or reticuloendothelial iron and highlighting intracanalicular bile plugs, and the latter is useful in detecting PAS-d "globules" characteristic of α_1-antitrypsin deficiency. PAS-d also is quite helpful in noting bile duct basement membranes, perisinusoidal basement membranes, and the PAS-d–laden Kupffer cells and septal macrophages characteristic of recent necroinflammatory activity.

Cancer Risk

The most common cancer that arises in cirrhotic livers is HCC (Fig. 70A.5; see Chapter 80), although cholangiocarcinoma is being increasingly recognized in cirrhosis (see Chapter 50A; Shaib, et al, 2007). Although these cancers may occur in cirrhosis of any etiology, particular risks include HBV and HCV infection, alcoholic liver disease (ALD), and hemochromatosis. Grossly, HCC may be multifocal, or it may grow as a well-circumscribed mass; it may show evidence of necrosis, or it may possess a different color and texture from background cirrhotic nodules. It also may bulge from the cut surface on sectioning. Most cases of HCC arising in cirrhotic livers are found in nodules larger than 1 cm (Bruix et al, 2001). Studies have shown, however, that nodules smaller than 1 cm can be malignant in the setting of cirrhosis (Caturelli et al, 2004). Premalignant lesions, or dysplastic nodules, may be indistinguishable from HCC by gross examination.

Cholangiocarcinoma (CCa) in cirrhosis may or may not be distinguishable grossly from HCC. The diagnosis rests with the microscopic appearance of atypical glandular structures, commonly in desmoplastic stroma. CCa also develops in long-standing primary sclerosing cholangitis and is seen more often than HCC in noncirrhotic livers (see Chapter 50A). The tumor may infiltrate the liver diffusely, or it may occur as a mass lesion that may be intrahepatic or extrahepatic. The cirrhotic liver is considered to be resistant to metastases from extrahepatic tumors.

Not all large nodules detected in cirrhotic livers are HCC. A macroregenerative nodule or large regenerative nodule usually measures 0.5 to 1.5 cm and is rarely 5 cm or more in diameter (International Working Party, 1995). It is seen more commonly in macronodular cirrhosis and may be distinct from surrounding cirrhotic nodules on gross examination. Histologically, a macroregenerative nodule may contain portal structures or short fibrovascular septa. The hepatocytes within the nodule are similar to the hepatocytes in smaller cirrhotic nodules but almost always exhibit hyperplastic change, evidenced by thickened plates. The clonal nature of the macroregenerative nodule has been shown, and its malignant potential is an area of ongoing discussion (Bailey & Brunt, 2002).

A dysplastic nodule is a premalignant lesion that usually measures more than 0.5 cm (International Working Party, 1995). Evolution to HCC within months or a few years has been well documented (Hytiroglou, 2004). A high-grade dysplastic nodule exhibits more clear-cut architectural or cytologic atypia, such as bulging or maplike clonal growth; pseudoglandular formation; unpaired arteries; and small cell change characterized by increased cell density, high nuclear/cytoplasmic cell ratio, and nuclear hyperchromasia. These morphologic changes are insufficient, however, for the diagnosis of HCC because a dysplastic nodule does not invade the surrounding stroma or blood vessels and it maintains cell plates no more than three cells wide (Roncalli, 2004).

Distinguishing a high-grade dysplastic nodule from well-differentiated HCC can be extremely difficult or impossible from a needle biopsy specimen, although it may be less ambiguous when an explant is examined (Kojiro, 2004). Identification of ductular reaction at the periphery aids in positive identification of cirrhosis or dysplastic nodule (Park et al, 2007; Lennerz et al, 2009). Clinical management of patients with cirrhosis and dysplasia in biopsy specimens is challenging.

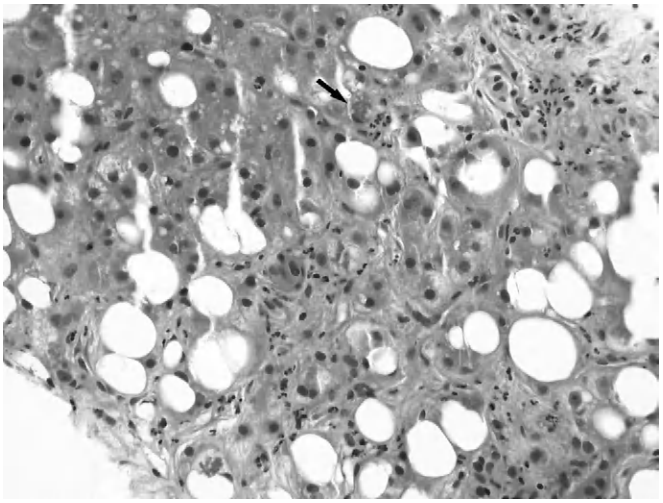

FIGURE 70A.6. Alcoholic hepatitis characterized by macrovesicular steatosis, hepatocyte ballooning, lobular neutrophilic infiltration, and presence of Mallory-Denk bodies. One of the hepatocytes containing a Mallory-Denk body is partially surrounded by neutrophils (*arrow*).

Assessment of Underlying Etiology

Cirrhosis is best classified by its underlying etiology (Box 70A.1), which can be determined by clinical history and laboratory investigation in many but not all cases. Morphologic examination may help establish the diagnosis or guide the clinical investigation. In the following discussion, the morphologic features characteristic of many chronic liver diseases that commonly cause cirrhosis are illustrated. At end-stage liver disease, however, the histopathologic findings may be nonspecific and indiscriminate even to experienced hepatopathologists. Many cases of "cryptogenic" cirrhosis represent burned-out processes, for which no identifying clinical or morphologic features remain. These cases are frequently due to ALD, autoimmune hepatitis, and nonalcoholic fatty liver disease (NAFLD). The contribution of as yet unnamed viral agents is not known but is recognized.

Alcoholic Liver Disease

Excessive alcohol consumption is the leading cause of liver disease in the Western world, which encompasses a clinicopathologic spectrum that includes fatty liver, alcoholic hepatitis, and alcoholic cirrhosis (Haber et al, 2003; Menon et al, 2001; O'Connor & Schottenfeld, 1998; Tome & Lucey, 2004). Alcoholic cirrhosis, or Laënnec cirrhosis, is classically micronodular and may retain some of the features of alcoholic hepatitis at the initial stage. The liver may appear pale or yellow, enlarged, and greasy on gross examination. Histologically, lesions predominate in the perivenular region (zone 3) of the acinus and include various combinations of steatosis (fatty change), ballooning, Mallory-Denk bodies, and satellitosis. Steatosis may be predominantly macrovesicular, defined by the presence of large fat droplets in the cytoplasm of hepatocytes displacing the nuclei. Microvesicular steatosis also can be seen, characterized by fine fat droplets surrounding the central nuclei. Alcoholic hepatitis is characterized by an inflammatory infiltrate rich in neutrophils, most frequently distributed in the lobules adjacent to hepatocytes containing Mallory-Denk bodies, and dense, perisinusoidal fibrosis (Fig. 70A.6). Lymphocytes and histiocytes also may be present, sometimes in the form of lipogranulomas, and megamitochondria also may be evident. In the portal and periportal regions, ductular reaction with numerous neutrophils may occur. Cholangiolitis and canalicular bile plugs are worrisome lesions for concomitant pancreatitis.

The patterns of fibrosis in alcoholic hepatitis are characteristic. Fibrosis usually involves the terminal hepatic venules, leading to the thickening of the wall; luminal occlusion may be seen with necrosis of adjacent hepatocytes and Mallory-Denk bodies within remaining hepatocytes, a lesion referred to as *central hyaline necrosis.* Subendothelial fibrosis is a venoocclusive lesion of alcoholism that may be noted even in end-stage cirrhotic livers. Fibrosis may extend into the lobules in perisinusoidal spaces as delicate or dense strands, giving rise to a distinctive "chicken wire" pericellular (perisinusoidal) distribution (Brunt, 2002). Trichrome stain is particularly useful in detecting this unique form of fibrosis. With time, the liver may be replaced by micronodular cirrhosis; often, the septa of ALD are quite broad as manifestations of the microvascular obliteration.

As alcoholic cirrhosis progresses, the aforementioned morphologic features may become less obvious. The liver may shrink and be nearly replaced by fibrosis, and the cirrhosis may evolve into a macronodular or mixed nodular architecture with characteristic broad septa. Steatosis, ballooning, and Mallory-Denk bodies may not be discernible, especially in patients who have stopped consuming alcohol for several months.

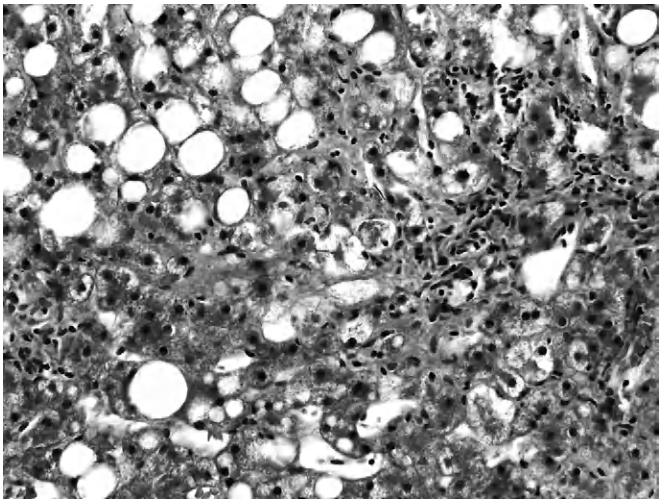

FIGURE 70A.7. Zone 3 "chicken wire" perisinusoidal fibrosis; this feature can be seen in nonalcoholic and alcoholic steatohepatitis (Masson trichrome stain).

Nonalcoholic Fatty Liver Disease

NAFLD is increasingly recognized as a significant form of potentially progressive liver disease. Prevalence studies estimate that approximately 20% to 25% of the U.S. population is affected by fatty liver; of these individuals, 15% to 20% are at risk for progression to cirrhosis (Angulo, 2002). The lesions noted in liver tissue may resemble many of the features of alcohol-induced liver damage in individuals who are not heavy drinkers (Brunt, 2004; Salt, 2004; te Sligte et al, 2004; Zafrani, 2004). The disease is etiologically attributed primarily to insulin resistance and is considered the hepatic manifestation of the metabolic syndrome, a constellation of obesity, hypertension, diabetes, and hyperlipidemia (Marchesini et al, 2001). Studies have also correlated the lesions of nonalcoholic steatohepatitis (NASH) with features of metabolic syndrome.

Most, but not all, of the histopathologic features described for alcoholic hepatitis can be found in NASH. These mainly include steatosis, which is predominantly macrovesicular and commonly of zone 3 (centrilobular) distribution; hepatocyte ballooning; lobular inflammation, which is usually mild and includes neutrophils; small lipogranulomas; and zone 3 perisinusoidal fibrosis (Fig. 70A.7). Hepatocytes also may exhibit prominent glycogenated nuclei in NASH, particularly when associated with diabetes. Portal inflammation may be present in some cases but is usually mild and less intense than lobular inflammation. The presence of heavy portal inflammation, particularly when accompanied by lymphoid aggregates or abundant plasma cells, should raise the suspicion of overlapping disease, such as chronic viral hepatitis or autoimmune hepatitis (Brunt et al, 2003). However, extensive portal chronic inflammation in the absence of an overlapping disease has been shown to correlate with progressive NASH and more severe metabolic features (Brunt et al, 2009). In addition, Mallory-Denk bodies may or may not be seen in NASH; if present, they may be poorly formed. In contrast to ALD, in which Mallory-Denk bodies may be present in apoptotic hepatocytes, in NASH they are restricted to ballooned hepatocytes. Recently, an immunohistochemical stain to detect loss of K8/18 in ballooning, as well as presence of clumped K8/18 in Mallory-Denk bodies, has been introduced (Lackner et al, 2008). If numerous Mallory-Denk bodies are present in the background of steatohepatitis, an alcoholic origin is more likely (Brunt, 2002, 2004). Likewise, marked cholestasis is highly unlikely in NASH but can occur in ALD. The broad septa of ALD are rare in NAFLD as well.

Fibrosis in NASH begins in the pericentral perisinusoidal spaces; with time, portal and periportal fibrosis develop, and eventually bridging fibrosis and cirrhosis may occur. This typically does not obliterate the terminal hepatic venules, a feature dissimilar to alcoholic hepatitis. A grading and staging system has been proposed for NASH primarily based on the extent and severity of the constellation of steatosis, ballooning change, the grade of lobular and portal inflammation, and the stage of fibrosis and remodeling (Brunt, 2004; Brunt et al, 1999). Similar to the widespread use of grading and staging in other forms of chronic liver disease, this proposal was made in recognition of the unique features of steatohepatitis to facilitate further reproducible evaluation for clinical and laboratory investigation. A revision of this system has been introduced as a method of semiquantification for use in clinical trials (Kleiner et al, 2005).

Chronic Hepatitis C

A high proportion of patients infected with HCV develop cirrhosis (Poynard et al, 2003), especially patients with a long duration of infection, concurrent alcohol consumption, coinfection with HBV or human immunodeficiency virus, nonresponse to antiviral therapy, and those of male gender (de Torres & Poynard, 2003; McCaughan & George, 2004). HCV-related cirrhosis is virtually always macronodular or mixed macronodular and micronodular. The fibrovascular septa vary in width and usually are infiltrated by mononuclear cells, predominantly lymphocytes, but also include plasma cells and eosinophils. Lymphoid aggregates, often with well-formed germinal centers, are characteristic although not pathognomonic (Fig. 70A.8). A mild degree of bile duct damage (the Poulsen lesion) also may be seen in some cases, and interface hepatitis may also be present. The lobular inflammation is typically spotty and mild, with or without acidophilic bodies. Subendothelial inflammation in portal veins, identical to endotheliitis, also may occur in

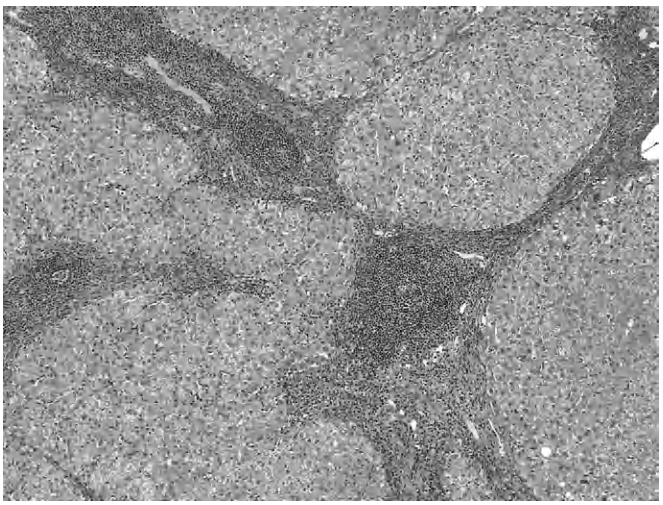

FIGURE 70A.8. Hepatitis C virus cirrhosis with characteristic septal lymphoid aggregates.

HCV infection, but no reliable antibody for immunohistochemical detection of HCV proteins has been found.

Steatosis is a common histologic finding in chronic HCV and may be a manifestation of host phenotype (increased body weight, presence of the metabolic syndrome) or viral cytopathic effect, as in genotypes 3 and 1. Although a small subset of the patients may have concurrent steatohepatitis of either nonalcoholic or alcoholic origin (Brunt et al, 2003; Ramalho, 2003), viral proteins have been shown to promote fat accumulation in hepatocytes directly (Lai, 2002; Lonardo et al, 2004; Ramalho, 2003). Accumulating evidence indicates that steatosis contributes to fibrosis progression, particularly in patients infected with genotype 3 HCV (Brunt & Tiniakos, 2002; Ramalho, 2003; Rubbia-Brandt et al, 2004a).

Liver biopsy plays a central role in assessing the grade of necroinflammation and the portal-based progression of fibrosis and in evaluating the effect of antiviral therapy. Numerous grading and staging systems for chronic hepatitis have been developed; these systems share the assessment of portal and lobular inflammation and necrosis for grade and portal-based fibrosis for stage (Brunt, 2000b).

Chronic Hepatitis B

Chronic hepatitis secondary to HBV infection is another common cause of cirrhosis (Fattovich, 2003; Ganem & Prince, 2004; Lai et al, 2003). Compared with hepatitis caused by HCV, HBV hepatitis may exhibit more severe portal and lobular necroinflammation, particularly when there is an acute exacerbation. Confluent or multiacinar bridging necrosis with collapse of the lobular framework may be seen. A relatively specific finding in chronic HBV hepatitis is the presence of "ground-glass" inclusions within hepatocytes, which are uniform, pale, or eosinophilic cytoplasmic alterations resulting from enriched smooth endoplasmic reticulum filled with hepatitis B surface antigen (Fig. 70A.9). However, changes resembling ground-glass inclusions have been observed in a variety of conditions (Wisell et al, 2006). A definitive diagnosis can be established by histochemical stains (orcein, Victoria blue) or with immunohistochemical detection of hepatitis B surface antigen in the cytoplasm and hepatitis B core antigen in the nucleus.

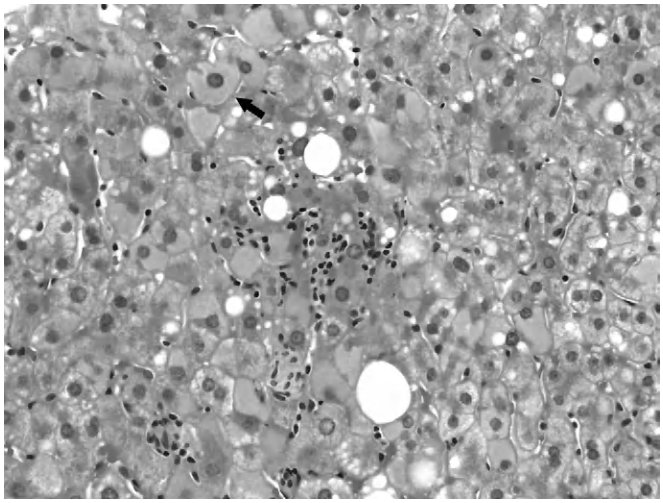

FIGURE 70A.9. Ground-glass hepatocytes (*arrow*) in chronic hepatitis B virus.

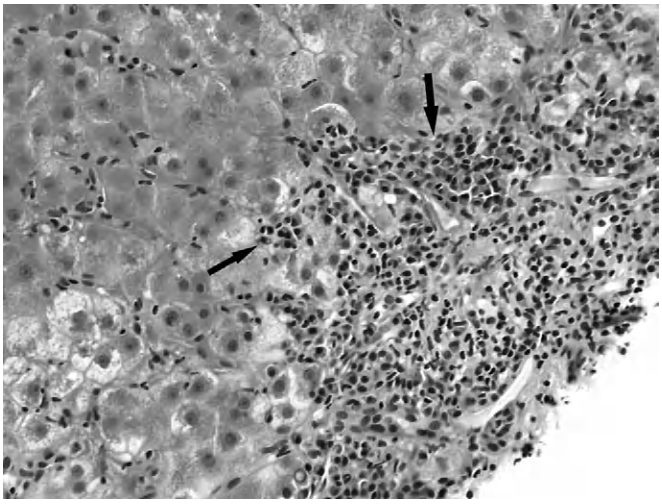

FIGURE 70A.10. Autoimmune hepatitis may be characterized by hepatitic "rosettes" and numerous plasma cells (*arrows*) in the portal tracts and lobules.

Coinfection or superinfection with hepatitis D virus (HDV) in HBV patients usually causes more severe liver damage and accelerates the development of cirrhosis (Farci, 2003). Immunohistochemical detection of HDV intranuclear antigen is helpful in establishing the diagnosis.

Autoimmune Hepatitis

The diagnosis of autoimmune hepatitis relies on a constellation of clinical, laboratory, and histopathologic findings, none of which alone is considered specific (Alvarez et al, 1999; McFarlane, 2002a, 2002b; Vergani & Mieli-Vergani, 2003). Histopathologic examination of liver tissue serves important roles in confirming the clinical concern and excluding diseases secondary to other etiologies (Carpenter & Czaja, 2002). Classic autoimmune hepatitis exhibits a dense portal, septal, and lobular mononuclear cell infiltrate, with marked periportal or periseptal interface hepatitis enriched in plasma cells. The presence of numerous plasma cells in portal inflammation and within lobular foci of necrosis and the formation of hepatitic "rosettes" are characteristic (Fig. 70A.10). In severe cases, confluent or bridging necrosis may be seen, sometimes accompanied by pseudoacinar formation. Predominantly centrilobular necrosis with relatively mild portal inflammation also has been described in autoimmune hepatitis (Misdraji et al, 2004). Fibrosis usually develops rapidly in untreated patients. At the cirrhotic stage, the liver parenchyma is divided by broad, fibrous bands into variable-sized nodules, similar to those caused by alcoholic or chronic viral hepatitis; plasma cells and rosettes may become less prominent. Burned-out autoimmune hepatitis may be a cause of "cryptogenic" cirrhosis, and morphologic features do not separate different types of autoimmune hepatitis, classified by either autoantibody profiles or immunogenetic markers (McFarlane, 2002a).

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is an autoimmune disorder that leads to progressive destruction of intrahepatic bile ducts (Leuschner, 2003; Selmi et al, 2004). In the early stage, the

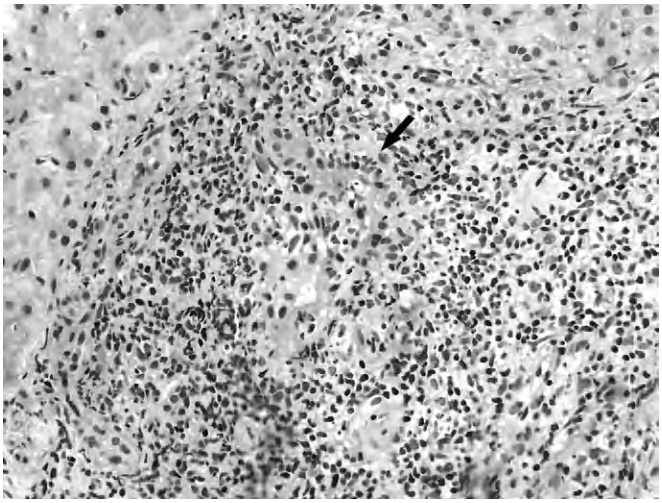

FIGURE 70A.11. Florid duct lesion with granulomatous portal inflammation and damaged bile duct (*arrow*) in early stage primary biliary cirrhosis.

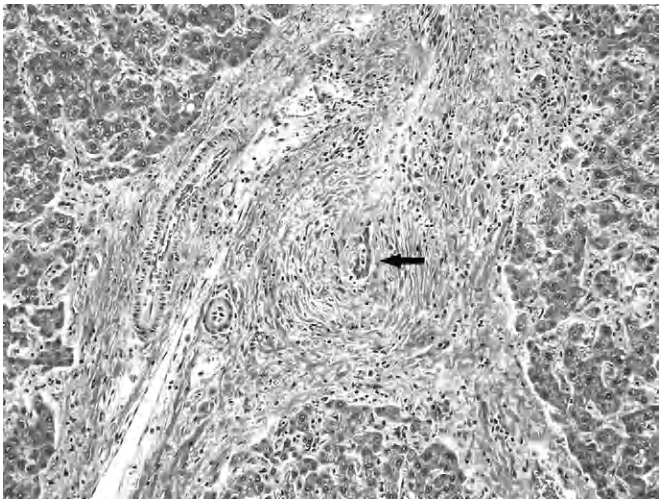

FIGURE 70A.12. Characteristic concentric onionskin periductal fibrosis in primary sclerosing cholangitis. The residual duct epithelial cells show atrophic and degenerative changes (*arrow*) (Masson trichrome stain).

disease is characterized by mixed chronic portal inflammation with lymphocytes, plasma cells, eosinophils, and the pathognomonic florid duct lesion, characterized by lymphocytic or granulomatous bile duct infiltration (Fig. 70A.11). Ductular reaction and interface hepatitis may be seen in more advanced cases. In the setting of positive serum antimitochondrial antibody (AMA), the florid duct lesion is essentially diagnostic. The affected duct may rupture, or the duct epithelium may exhibit degenerative change. With disease progression, ductopenia becomes evident. The native ducts may be absent or obscured by lymphoid aggregates or collections of foamy macrophages. Cholate stasis, as previously described, may be an initial clue to the diagnosis. Features of autoimmune hepatitis also may occur in AMA-positive primary biliary cirrhosis, referred to as *overlap syndrome* (Dienes et al, 2002; Durazzo et al, 2003); however, it must be kept in mind that significant lobular and interface activity can be seen in patients with PBC alone.

Cirrhosis is seen only at the late stage of PBC; it is commonly inhomogeneously distributed and may be micronodular. Florid duct lesions and granulomas may continue to exist where native bile ducts have not been completely destroyed. Canalicular cholestasis with bile plugs may be seen in the late stage and is regarded as a sign of poor prognosis.

The term *autoimmune cholangiopathy*—also known as *antinuclear antibody–positive, AMA-negative PBC*—has been used to describe the disease seen in a small subset of patients who present with typical clinical and histopathologic findings of PBC but are seronegative for AMA. These patients may have other autoantibodies, such as antinuclear antibody and anti–smooth muscle antibody, as seen in autoimmune hepatitis. Accumulating evidence suggests that autoimmune cholangiopathy and PBC are likely to be a single disease with variations in the type and concentration of autoantibodies (Vierling, 2004).

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is another autoimmune inflammatory and fibrosing process that segmentally affects the extrahepatic and intrahepatic biliary tree, leading to biliary stricture and cirrhosis (Cullen & Chapman, 2003; Mendes & Lindor, 2004; Rodriguez & Bass, 2003). It is strongly associated with inflammatory bowel disease, including both Crohn disease and ulcerative colitis (Broomé et al, 2006), and with the development of cholangiocarcinoma.

The definitive diagnosis of PSC rests on characteristic cholangiographic findings. Histopathologic examination of a liver biopsy specimen may or may not reveal diagnostic features because of the patchy nature of the disease. Mild portal lymphocytic infiltration and mild bile ductular reaction may be the only observations. The relatively specific finding of concentric periductal fibrosis with an "onionskin" appearance indicates chronic biliary obstruction of any cause and thus is not pathognomonic of PSC. The duct epithelium usually exhibits atrophic and degenerative changes, and a characteristic fibro-obliterative scar eventually replaces the bile duct (Fig. 70A.12). As in other forms of biliary cirrhosis, inhomogeneity of cirrhosis and histologic evidence of cholate stasis are recognized features in PSC. Careful evaluation of explant livers for occult cholangiocarcinoma with sampling of the entire hilar tissue is recommended.

Hereditary Hemochromatosis

Hereditary hemochromatosis (HH) is an autosomal recessive iron-overload disorder primarily associated with mutation of the *HFE* gene (Limdi & Crampton, 2004; Pietrangelo, 2004). Iron deposition initially occurs in zone 1 (periportal) hepatocytes with a decreasing gradient toward the centrilobular area. The iron granules are concentrated along the border of the canaliculi; this is best shown by Perls' Prussian blue stain (Fig. 70A.13). With progression, untreated HH results in iron deposition throughout the entire lobule, and iron granules are seen not only in hepatocytes but also in Kupffer cells, biliary epithelial cells, and portal macrophages. Kupffer cell clusters, or siderotic nodules, are common, and usually little to no significant portal and/or lobular inflammation is evident. This pattern of iron deposition is not restricted to HH; the diagnosis rests with genetic testing.

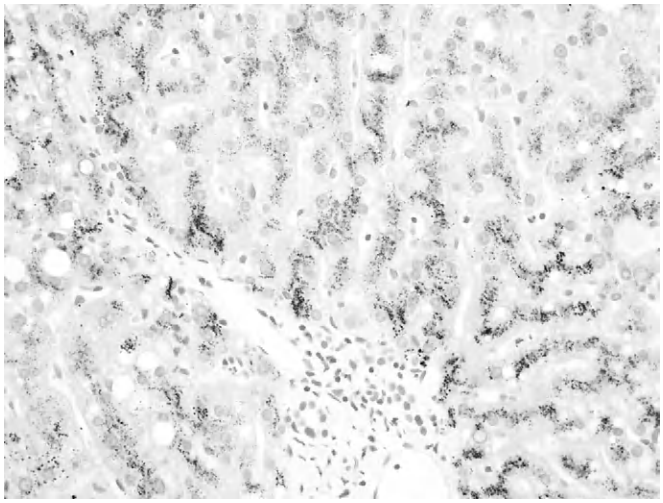

FIGURE 70A.13. Hepatocellular iron deposition in a pericanalicular location in the periportal (zone 1) hepatocytes in hereditary hemochromatosis (Perls' Prussian blue stain).

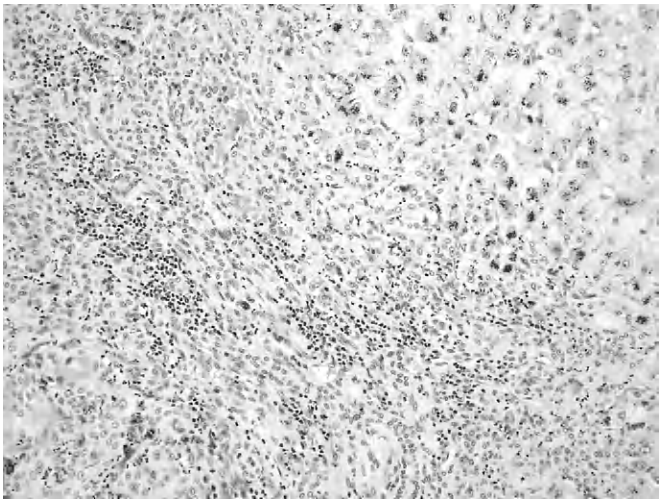

FIGURE 70A.14. Abundant copper deposition in a case of Wilson disease (Rhodanine stain).

Fibrosis in HH is portal based. When cirrhosis develops, it is typically micronodular with exquisite portal to portal bridging and retention of the terminal hepatic venules. Hepatocytes in cirrhotic nodules also are loaded with iron, which may exhibit a periseptal distribution pattern. Occurrence of iron-free nodules or foci is of concern for dysplasia or HCC, which occurs frequently in cirrhotic HH patients.

Secondary iron overload in the liver is a common finding in a variety of conditions, including cirrhosis of nonbiliary origins (Limdi & Crampton, 2004). Iron deposition secondary to transfusion can be heavy, but initially, it principally involves Kupffer cells in the sinusoids. Significant amounts of stainable iron may be detected in chronic HCV and HBV hepatitis, alcoholic steatohepatitis and NASH, and cirrhosis unrelated to HH or the above-mentioned chronic liver diseases. Iron deposition in these conditions is usually mild and rarely exceeds 2+ when a semiquantitative histologic score of 1 to 4 is used. Iron granules may be found in hepatocytes, Kupffer cells, and endothelial cells. If a higher score is appreciated in hepatocytes (e.g., 3+ or 4+, which is more commonly associated with HH), age-adjusted chemical quantitation of iron concentration in dry hepatic tissue, the hepatic iron index, or genetic testing for *HFE* mutations should be performed. An hepatic iron index greater than 2 was developed to distinguish HH from iron overload secondary to alcoholic siderosis, but this is not considered a diagnostic test for HH (Bacon, 2001). Patients with chronic viral hepatitis or steatohepatitis who also have an increased liver iron content have a higher chance of harboring *HFE* mutations. It has been suggested that these patients are less likely to respond to therapy and are more prone to develop fibrosis and cirrhosis (Bonkovsky et al, 2003). Other genetic markers have been developed to correlate with the more unusual cases of non-HFE iron overload (Pietrangelo, 2004).

Wilson Disease

Wilson disease is an autosomal recessive inherited metabolic disorder of copper metabolism. Any young patient with unexplained chronic or fulminant liver disease should be investigated for Wilson disease (Ferenci, 2004; Gitlin, 2003). Morphologic features in the liver vary widely at different stages of the disease and lack specificity. At the precirrhotic stage, lymphocytic portal inflammation with interface hepatitis that mimics chronic viral hepatitis or autoimmune hepatitis may be evident. Hepatocytes may show variable degrees of steatosis, necrosis, anisocytosis, and anisonucleosis. In later stages, atypical lipofuscin, canalicular cholestasis, and Kupffer cell iron accumulation may be noted. Periportal hepatocytes may contain glycogenated nuclei and Mallory-Denk bodies, and cirrhosis is usually micronodular.

Copper and copper binding protein accumulation may be shown on tissue sections by histochemical techniques, such as rhodanine, rubeanic acid, orcein, or Victoria blue stains (Fig. 70A.14) and is most likely present in cirrhosis. Copper deposition also may be seen in other chronic cholestatic liver diseases, such as PBC or PSC, usually in zone 1 or in periseptal hepatocytes. Alternatively, the absence of stainable copper in a noncirrhotic liver does not exclude the diagnosis of Wilson disease. Copper quantitation in hepatic tissue is the diagnostic test, which can be performed reliably on FFPE tissue. A value of greater than 250 μg/g dry hepatic tissue has been used as a cutoff value. Currently, genetic testing has not yet become practical for clinical diagnosis.

α_1-Antitrypsin Deficiency

Liver injury in α_1-antitrypsin deficiency, an autosomal recessive inherited metabolic disorder, results from retention of mutant α_1-antitrypsin molecules in hepatocytes (Carrell & Lomas, 2002; Perlmutter, 2000). The histopathologic hallmark of the disease is the presence of eosinophilic globules of varying sizes in zone 1 hepatocytes in patients older than infants. These globules are best shown by PAS-d stain (Fig. 70A.15), but immunohistochemical stain may confirm the diagnosis. The globules can be seen in homozygous (PiZZ) and heterozygous (PiMZ) phenotypes, which may be determined by serum protein electrophoresis, but homozygous patients seem to be more likely to develop liver disease and cirrhosis. Other morphologic findings in the liver are relatively nonspecific, which may or may not

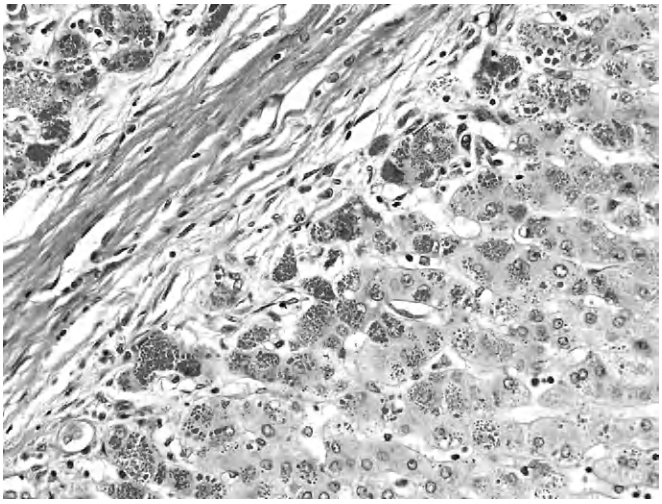

FIGURE 70A.15. Varying sizes and shapes of diastase-resistant hyaline globules in periseptal hepatocytes in α_1-antitrypsin deficiency (PAS-d).

include hepatic inflammatory infiltration. When chronic hepatitis is seen in α_1-antitrypsin deficiency, other causes, such as HCV or alcohol, should be excluded (Ishak, 2002). Cirrhosis developing from α_1-antitrypsin deficiency can be micronodular, macronodular, biliary, or mixed in pattern. Dysplasia and HCC may occur in cirrhotic livers, just as it may in other cases of chronic hepatitis.

Cryptogenic Cirrhosis

In approximately 10% to 15% of patients, no clinically or pathologically identifiable cause of cirrhosis is identified. However, accumulating evidence suggests that a large proportion of cryptogenic cirrhosis may represent burned-out NAFLD. This suggestion is based on reported biopsy series of diagnosed NASH followed by subsequent cryptogenic cirrhosis with complete loss of the features of active steatohepatitis. In addition, several authors have shown that many of these patients have type 2 diabetes, obesity, or both compared with patients with cirrhosis of other etiologies (Ayata et al, 2002; Caldwell et al, 1999; Ong et al, 2001; Poonawala et al, 2000; Sakugawa et al, 2003; Sanjeevi et al, 2003). Development of posttransplant NAFLD also is frequent in this group of patients (Ong et al, 2001; Sanjeevi et al, 2003), but whether this represents actual recurrence of NASH or de novo NASH is an area of discussion (Czaja, 1997).

An autoimmune etiology also has been proposed based on clinical and histopathologic findings (Ayata et al, 2002; Kaymakoglu et al, 1998), but autoantibodies may no longer be detectable in these cases (Carpenter & Czaja, 2002). PSC and alcoholic cirrhosis may present as cryptogenic cirrhosis, and one case report documented prior biopsy-proven Budd-Chiari syndrome presenting as cryptogenic cirrhosis 34 years later (Havlioglu et al, 2003). Finally, the possibility of an as yet unknown viral infection or metabolic condition cannot be excluded in cryptogenic cirrhosis. Evaluation of patients with unexplained cirrhosis should include careful review of all prior liver biopsy specimens, especially those from several years prior.

NONCIRRHOTIC PORTAL HYPERTENSION

An increase in the pressure of the portal venous system can be seen in a heterogeneous group of prehepatic, intrahepatic, and posthepatic conditions in the absence of cirrhosis (Box 70A.2). The etiopathogenetic mechanisms leading to portal hypertension in these conditions, the clinical presentation, and the prognoses vary widely (Molina & Reddy, 2001; Okuda, 2002). Portal hypertension in Budd-Chiari syndrome (see Chapter 77) is secondary to posthepatic vein obstruction and may have an acute or subacute clinical course with liver failure. Portal hypertension associated with infiltrative amyloid or hematologic disorders—such as leukemia, mastocytosis, and Gaucher disease—is believed to occur primarily at the intrahepatic sinusoidal level. Precirrhotic alcoholic hepatitis also may cause portal hypertension because of hepatocyte swelling, sinusoidal fibrosis, and central sclerosis, which may be more insidious clinically. Liver biopsy functions to confirm the absence of cirrhosis and helps establish or suggest the diagnosis (Roskams et al, 2003). The histopathologic features of several selected entities associated with noncirrhotic portal hypertension are discussed briefly.

Nodular Regenerative Hyperplasia

Portal hypertension has been reported in about half of patients with nodular regenerative hyperplasia (Al-Mukhaizeem et al, 2004). It is associated with a wide range of conditions, mainly including hematologic disorders, connective tissue diseases, and medications. The pathogenesis is unclear, but it may involve portal venous thrombosis leading to a microcirculatory disturbance in the liver that causes localized, nonlethal ischemia and compensatory hepatocyte hyperplasia. The liver may be normal in size or enlarged when associated with a hematologic disease. On cut surface, the liver is diffusely nodular in appearance, with nodules ranging from 0.1 to 1 cm in diameter. Microscopically, the nodular appearance is best appreciated with reticulin stain (Fig. 70A.16), which highlights regenerative hepatocytes within the nodules and atrophic hepatocytes at the edges of the nodules. Nodular regenerative hyperplasia differs

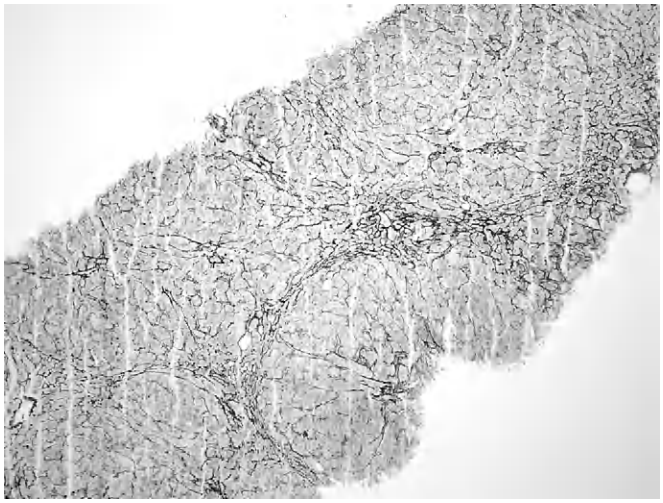

FIGURE 70A.16. Reticulin stain highlights nodularity of the parenchyma in nodular regenerative hyperplasia; no scar tissue (fibrous septum) is present (Sweet's reticulin).

from cirrhosis in that fibrosis, if present, is minimal, and the portal tract architecture is usually unaltered. These characteristic features may be shown more easily on a wedge biopsy specimen but may be difficult to appreciate on a needle biopsy specimen.

Partial nodular transformation is a rare condition with an underlying pathogenesis similar to that proposed for nodular regenerative hyperplasia. Partial nodular transformation is a localized lesion almost always seen in the perihilar region. The hyperplastic hepatocyte nodules are larger than those of nodular regenerative hyperplasia, often well defined, and surrounded by fibrous tissue.

Venous Outflow Obstruction

Obstruction of hepatic venous outflow increases sinusoidal pressure and results in subsequent portal hypertension. Etiologically, it ranges from congestive heart failure, narrowing or occlusion of large hepatic veins (Budd-Chiari syndrome; see Chapter 77), to obliteration of the terminal or sublobular hepatic veins. Liver injury caused by congestive heart failure is characterized by zone 3 sinusoidal dilation and congestion and, when severe or acute, extravasation of red blood cells under the space of Disse into the hepatic cords. Hepatocellular necrosis is usually uncommon but may become evident if accompanied by systemic hypotension and hypoperfusion. The portal tracts are typically unremarkable and devoid of significant inflammatory cell infiltration. In longstanding cases, zone 3 hepatocytes exhibit atrophic change with markedly attenuated cell plates. Lipofuscin pigment and sinusoidal lining cell iron may accrue, and perivenular fibrosis and bridging fibrosis also may develop and rarely may result in septa formation, reverse lobulation, and cardiac cirrhosis.

Budd-Chiari syndrome results from obstruction at any level of the hepatic venous system between the liver and the inferior vena cava or the right atrium. It involves a variety of thrombotic and nonthrombotic causes, among which hypercoagulable states secondary to myeloproliferative disorders are the most common (Menon et al, 2004). The histopathologic features of Budd-Chiari syndrome are similar to those of congestive heart failure, but acute onset also may give rise to a hemorrhagic appearance at zone 3 with extravasation of red blood cells under the space of Disse, to replace hepatocytes within the cords, and more significant hepatocyte necrosis. If unrelieved, Budd-Chiari syndrome results in cord atrophy, replacement by fibrosis, and eventual cirrhosis.

In contrast to Budd-Chiari syndrome, venoocclusive disease rarely results in cirrhosis and has variable clinical manifestations that range from elevation of liver function tests to life-threatening ascites and liver failure. This process affects the distal sinusoids, the intrahepatic portion of the hepatic venous system, and the terminal hepatic and sublobular veins. It has been stressed that the injury in this process is to the sinusoidal lining cells and surrounding hepatocytes. DeLeve and colleagues (2002) recommended a nomenclature change to *sinusoidal obstruction syndrome*. It is common after bone marrow or hematopoietic stem cell transplantation, is more likely to occur in HCV-infected subjects, and is associated with chemotherapeutic agents and hepatic radiation (Coppell et al, 2003; Kumar et al, 2003; Wadleigh et al, 2003).

Oxaliplatin-based chemotherapy is increasingly recognized as a cause of marked damage to the sinusoids, with the subsequent risks of nodular regenerative hyperplasia, perisinusoidal and outflow vein fibrosis, and liver failure (Rubbia-Brandt et al, 2004b). Patients usually present within 30 days after chemotherapy; however, late-onset venoocclusive disease has been reported (Carreras et al, 2007). The lesion is characterized by subendothelial edema, zone 3 sinusoidal dilation, congestion, hemorrhage, and perivenular hepatocyte necrosis, followed by collagen deposition in the subendothelial space and sinusoids. A reticulin stain is useful in highlighting the obstruction of sinusoids and terminal hepatic veins by collagen. As the lesion progresses, the terminal hepatic veins become thickened and narrowed and are eventually obliterated by fibrosis (Fig. 70A.17). Bridging fibrosis, cirrhosis, or nodular regenerative hyperplasia may ensue in more advanced cases.

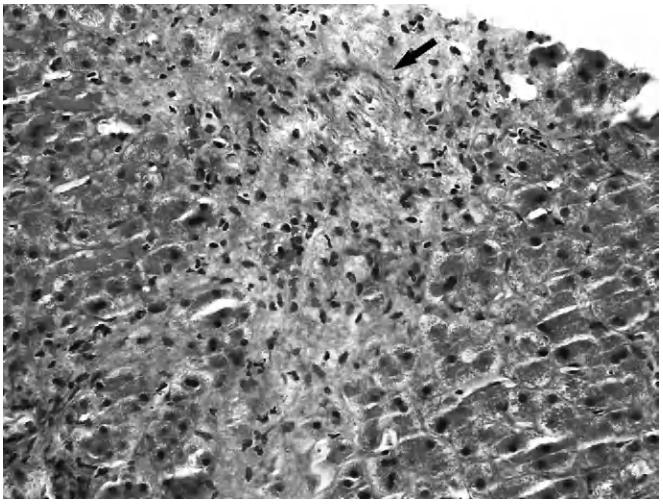

FIGURE 70A.17. This connective tissue stain highlights the lesions of venoocclusive disease (sinusoidal obstruction syndrome). The remnants of the wall of the terminal hepatic venule are seen (*arrow*); necrosis and dropout of the perivenular, zone 3 hepatocytes are demonstrated. (Masson trichrome stain).

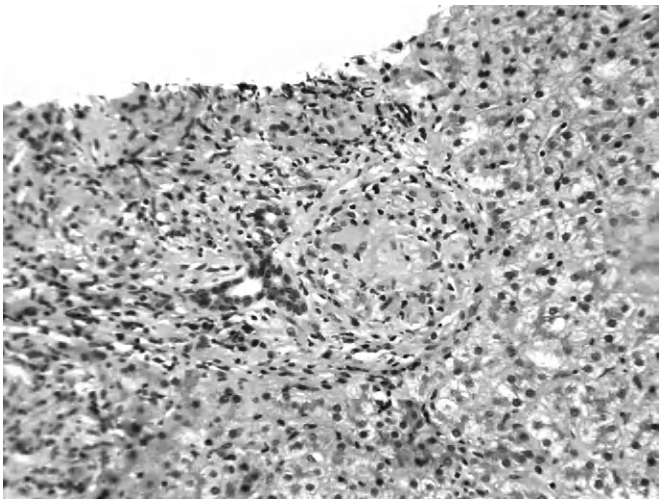

FIGURE 70A.18. Noncaseating, nonnecrotizing epithelioid granulomas in a patient with hepatic sarcoidosis.

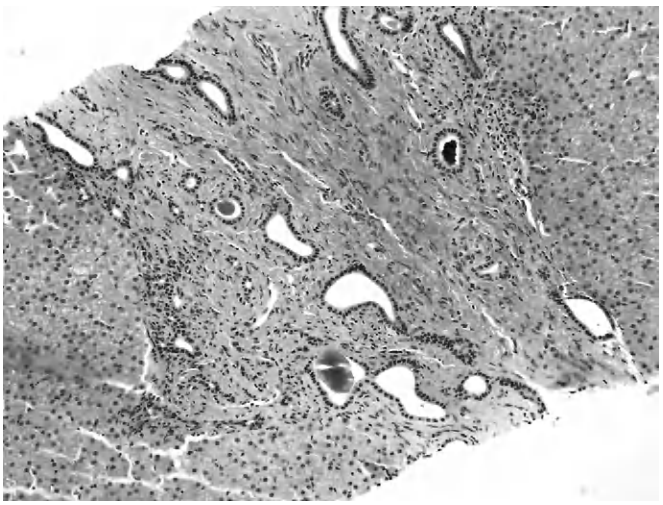

FIGURE 70A.19. Congenital hepatic fibrosis. The duct plate abnormality is manifested by remnant ductal profiles along the limiting plate; some of the duct structures contain inspissated bile.

Sarcoidosis

The histopathologic hallmark of hepatic sarcoidosis is the presence of multiple granulomas composed of well-defined, rounded collections of epithelioid histiocytes rimmed by variable amounts of lymphocytes, multinucleated giant cells, plasma cells, and eosinophils (Ishak, 1998). The giant cells sometimes contain Schaumann and asteroid bodies. Small areas of central fibrinoid necrosis may be noted, but the caseating necrosis seen in tuberculosis is never present. The granulomas typically are traversed by reticulin fibers and surrounded in a concentric fashion by collagen. They are noted scattered throughout the liver but tend to be more frequent in the portal and periportal regions (Fig. 70A.18). They may coalesce to become confluent, masslike lesions. Portal hypertension may develop in some patients as a result of extensive fibrosis or cirrhosis, which may or may not be related directly to fibrous conversion and hyalinization of the granulomas. Portal hypertension also occurs in the absence of marked fibrosis, possibly as a result of compression of portal vein branches and sinusoids by granulomatous inflammation (Blich & Edoute, 2004; Valla & Benhamou, 2000). Nodular regenerative hyperplasia and Budd-Chiari syndrome also have been proposed as potential mechanisms.

Not all granulomas in the liver are due to sarcoid. Noncaseating granulomas can be identified in the liver in a wide variety of disorders, and the pathologist may not always be able to differentiate them (Gaya et al, 2003; Valla & Benhamou, 2000). Common examples include PBC, HCV hepatitis, autoimmune hepatitis, mycobacterial or fungal infections, schistosomiasis, drug reaction, Hodgkin lymphoma, and idiopathic granulomatous hepatitis. A diagnosis of hepatic sarcoidosis requires correlation with clinical, radiologic, and laboratory findings and cannot be rendered solely based on histopathologic examination.

Schistosomiasis

In endemic areas, infestation by *Schistosoma japonicum* or *S. mansoni* is a frequent cause of portal hypertension (Bica et al, 2000; Okuda, 2002). The mechanism involves ova deposition in the portal venules, which incites a granulomatous inflammatory response and extensive, so-called *clay pipe stem fibrosis*, leading to hemodynamic disturbance. Definitive diagnosis can be made by showing the presence of schistosomal ova.

Congenital Hepatic Fibrosis

Congenital hepatic fibrosis is a developmental disorder of the ductal plate predominantly seen in children and only rarely seen in adults. It is inherited in an autosomal recessive or, less commonly, autosomal dominant fashion and may be part of the spectrum of polycystic kidney and liver disease (Kamath & Piccoli, 2003). The affected patient may initially come to medical attention with portal hypertension, and the liver is usually enlarged and of firm consistency. Microscopically, the portal tracts are expanded by fibrous tissue and may show portal-to-portal bridging fibrous bands that do not have the characteristic features of septa described above. An increased number of aberrant duct profiles are distributed at the periphery of the portal tracts, which are believed to represent remnants of incompletely remodeled ductal plates (Fig. 70A.19). Inspissated bile may be noted in the lumina, and the portal vein branches may be hypoplastic or decreased in number, but the branches of hepatic artery may be hypertrophic and abnormally numerous (Desmet, 1992), suggesting arteriovenous anastomosis.

Drugs and Toxins

Chronic liver injury attributable to drugs or toxins may cause extensive fibrosis and cirrhosis, leading to portal hypertension. Examples include methotrexate toxicity, long-term exposure to arsenic or vinyl chloride, and chronic hypervitaminosis A. Drugs and toxins also induce noncirrhotic portal hypertension via different mechanisms, such as venoocclusive disease, Budd-Chiari syndrome, and nodular regenerative hyperplasia. Herbal medicines have been increasingly recognized as hepatotoxic agents in recent years (Stedman, 2002). A classic example found in a variety of herbal medicines is pyrrolizidine

alkaloids, which can cause venoocclusive disease and portal hypertension.

Idiopathic Portal Hypertension

As the name implies, idiopathic portal hypertension is a disorder of unknown etiology, characterized by splenomegaly, anemia, and longstanding portal hypertension in the absence of cirrhosis (Nakanuma et al, 2001; Okudaira et al, 2002). It is primarily a disorder of middle-aged adults and generally has a better prognosis than cirrhotic portal hypertension because liver function is usually preserved. It is also called *hepatoportal sclerosis* and *noncirrhotic portal fibrosis* in the literature (Dhiman et al, 2002). Subtle differences may exist among these terms, however, which may reflect different underlying etiologies (Sarin & Kapoor, 2002).

Although the etiology is obscure, idiopathic portal hypertension is frequently associated with autoimmune disorders; immunologic disturbance is thought to be involved in pathogenesis. Bacterial infection leading to repeated stimulation also has been proposed as a candidate mechanism, but this remains speculative. In addition, some authors (Hillaire et al, 2002; Nakanuma et al, 2001; Sarin & Kapoor, 2002) suggest that prothrombotic disorders and thromboembolism play a role in etiopathogenesis, but this hypothesis has not been accepted by others (Okudaira et al, 2002).

Because idiopathic portal hypertension is essentially a diagnosis of exclusion, morphologic examination of liver tissue is imperative to rule out the presence of cirrhosis or other known etiology. The pathologic changes in idiopathic portal hypertension are believed to represent the effects of longstanding portal venous insufficiency, which may or may not be related to the initiating factors (Nakanuma et al, 2001). They are subtle, heterogenous, and nonpathognomonic and may be missed on a needle biopsy specimen. Macroscopically, the liver may have a reduced weight, and the surface may be irregularly undulant or finely wrinkled, owing to subcapsular parenchymal atrophy (Krasinskas et al, 2005). The cut surface may show portal and perivascular fibrosis, dilation and wall thickening of the veins, and unusual distribution and approximation of the portal and outflow vascular structures. Microscopically, the normal relationship between the portal and central areas is distorted. The portal tracts are either abnormally approximated to each other or widely separated. The terminal hepatic vein may be eccentrically located in the lobule adjacent to a portal tract, and sometimes multiple ectatic tributaries (angiomatous lesions) are seen in a single lobule. Conspicuous fibrosis usually is present in the portal tracts, which may extend into the periportal areas and the lobules in a pericellular fashion. The portal veins may show loss of the normal muscle coat or marked wall thickening, and luminal narrowing or obliteration may also be evident (Fig. 70A.20).

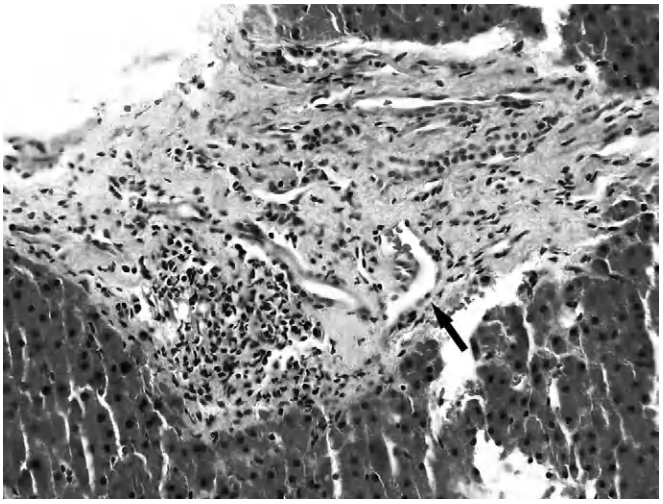

FIGURE 70A.20. Portal fibrosis in hepatoportal sclerosis (idiopathic portal hypertension). The portal vein (*arrow*) is small and has a narrowed lumen (Masson trichrome stain).

CONCLUSION

Longstanding portal hypertension causes serious extrahepatic complications. Common presentations include esophageal varices with variceal bleeding, portal hypertensive gastropathy, congestive splenomegaly with hypersplenism, and ascites with spontaneous bacterial peritonitis. Portal hypertension also contributes to the development of hepatic encephalopathy and hepatorenal syndrome. In general, portal hypertension secondary to a noncirrhotic etiology has a better prognosis than portal hypertension caused by liver cirrhosis because of maintained synthetic function. Pathologic recognition of the characteristic morphologic features of many commonly encountered disorders underlying cirrhosis and noncirrhotic portal hypertension can aid in clinical management of patients with cirrhosis and portal hypertension.

CHAPTER 71

Portal hypertension in children

Ross W. Shepherd and Yumirle P. Turmelle

SPECIAL FEATURES OF PORTAL HYPERTENSION IN CHILDREN

Portal hypertension secondary to chronic liver disease and prehepatic or posthepatic vascular events is a major cause of morbidity and death in both adults and children (see also Chapter 70A). However, children with these conditions provide a different set of challenges in the understanding and management of portal hypertension because of a predominance of congenital etiologies combined with growth and developmental considerations.

In general, portal hypertension is the result of a combination of increased portal blood flow and increased portal resistance; it occurs when portal blood pressure rises above approximately 10 mm Hg. Signs and symptoms are primarily the result of decompression of this elevated pressure through portosystemic collaterals, but special developmental vascular alterations apply in children (Fig. 71.1). The major problems seen in children are bleeding varices, ascites, and malnutrition. Encephalopathy, portopulmonary hypertension, and hepatorenal syndrome, although important when they do occur, are seen less frequently in children. Splenomegaly and hypersplenism rarely require specific intervention.

CAUSES OF PORTAL HYPERTENSION IN CHILDREN

Portal hypertension may arise as a result of an extrahepatic (portal vein), posthepatic (hepatic vein), or intrahepatic block; the block may be presinusoidal, sinusoidal, or postsinusoidal. Causes in children are shown in Box 71.1.

Extrahepatic Causes

Although possibly declining in frequency, extrahepatic portal venous obstruction, caused by a congenital thrombotic or atretic process, is an important cause of noncirrhotic portal hypertension, especially in developing countries but certainly not confined there (Sarin & Agarwal, 2002). Septic or traumatic umbilical vein injury from omphalitis and/or catherization accounts for some cases, but most cases are idiopathic or represent a congenital malformation of the portal venous system. Portal vein stenosis or thrombosis may also occur in the context of portal vein anastomoses in liver transplantation. In the congenital form, the portal vein is transformed into a cavernoma, resulting in portal hypertension and esophagogastic varices. Importantly, from a treatment standpoint, splenic vein or more extensive portal system involvement results in somewhat different hemodynamics, with an extensive collateral circulation involving a preponderance of gastric varices (Shah et al, 2003) and sometimes ectopic varices involving paracholecystic, paracholedochal, and pancreatoduodenal veins. Esophageal bleeding, or sometimes gastric variceal bleeding, is thus the most important consequence, although the presence of naturally occurring shunts may reduce the risk over time, usually by the second decade of life. Besides variceal bleeding, which is the commonest presentation, hypersplenism is common, and anemia, easy bruising from thrombocytopenia, and abdominal pain may be presenting features. Some patients may develop symptomatic portal biliary obstruction. Growth retardation from malabsorption as a result of failure of the enteropancreatic and enterohepatic circulation is not uncommon. Overt encephalopathy as a result of shunting appears uncommon, but subclinical signs may occur, including disturbed neurocognitive function, particularly attention and short-term memory problems (Mack et al, 2006). Although the liver may appear normal, reversible decompensation may be seen after an acute variceal hemorrhage, and functional compromise may develop over the long term.

Intrahepatic Causes

Portal hypertension may result from a range of presinusoidal, sinusoidal, and postsinusoidal causes of increased portal bed resistance within the liver. Presinusoidal conditions, such as congenital hepatic fibrosis, do not result in impaired liver function. *Congenital hepatic fibrosis* is a developmental disorder that belongs to the family of hepatic ductal plate malformations and is characterized histologically by a variable degree of periportal fibrosis and irregularly shaped proliferating bile ducts (Summerfield et al, 1986). Liver biopsy is highly specific for the diagnosis. In most patients, the first manifestations of the disease are signs or symptoms related to portal hypertension, especially splenomegaly and varices, often with spontaneous gastrointestinal (GI) bleeding that occurs from early childhood and sometimes even into adulthood.

Increased sinusoidal resistance and portal hypertension occur almost invariably in cirrhosis in children. In children, common causes include forms of infant cholestasis, such as biliary atresia, as well as a range of metabolic disorders, infections, toxins, and vascular and nutritional diseases. Cirrhosis is a chronic, diffuse disease characterized by irreversible widespread hepatic fibrosis with regenerative nodule formation (see Chapters 6 and 70). The prominent fibrous tissue contains vascular anastomoses, which cause hemodynamic alterations and portosystemic shunting. This diffuse pathology superimposed on the primary liver disease often obscures the nature of the original insult. The major pathophysiologic consequences are the result of impaired hepatic function and portal hypertension. Progression to cirrhosis and its complications in pediatric liver diseases is highly variable and represents an important consideration in management, particularly when considering surgical options that may compromise later outcomes. In some conditions, such as neonatal extrahepatic biliary atresia, the development of cirrhosis can be extraordinarily rapid, occurring by 12 to 16 weeks of age with liver failure as early as 24 weeks of age.

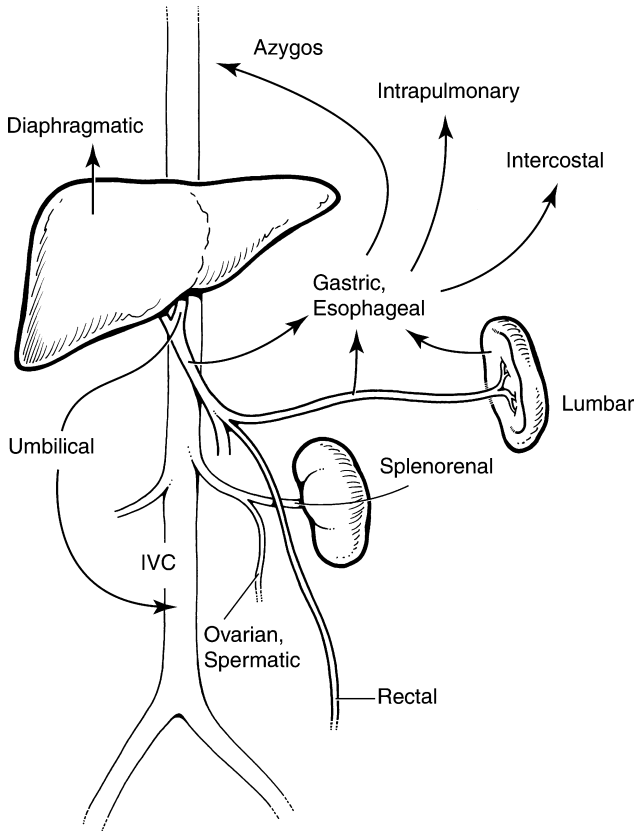

FIGURE 71.1. Sites of portosystemic shunts in children with portal hypertension. IVC, inferior vena cava.

Early diagnosis and surgical treatment by hepatoportoenterostomy improves outcome, but in most cases, liver transplant becomes the only available treatment option. Other disorders, such as cystic fibrosis–associated focal biliary cirrhosis, can be compatible with normal liver function for many years, presenting with signs of portal hypertension in the second decade of life.

Postsinusoidal intrahepatic conditions, such as venoocclusive disease, are rare in children and usually occur only in the context of chemotherapy for childhood cancers (Gharib et al, 2006) or occasionally related to toxin ingestion, such as from eating poisonous mushrooms. However, posthepatic portal hypertension is a significant condition in children (see Box 71.1). Obstruction to hepatic venous outflow, such as from hepatic vein anastomotic stenosis, can occur after liver transplantation, with Budd-Chiari syndrome, or as a result of cardiac lesions that cause an increase in right atrial pressure and/or chronic systemic venous hypertension. Acute Budd-Chiari syndrome is rare in children; although it may occur with some thrombophilic disorders, it is usually idiopathic and is not associated with the causes seen in adults, such as myeloproliferative disorders. A cavopulmonary or atriopulmonary shunt, known as a *Fontan procedure*, allows life-saving systemic-pulmonary blood flow in single-ventricle syndromes in neonates but results in chronic systemic venous hypertension (pressures may be >20 mm Hg) and eventually to portal hypertension (Narkewicz et al, 2003).

Box 71.1

Causes of Portal Hypertension in Children

Extrahepatic

Extrahepatic portal vein obstruction/thrombosis
Congenital malformations and diseases
Acquired conditions (dehydration)

Postsinusoidal: venoocclusive diseases

Posthepatic

Budd-Chiari syndrome (webs, thrombophilia, idiopathic)
Anastomotic stenosis or thrombus (after liver transplantation)
Constrictive pericarditis
After a Fontan procedure

EFFECTS OF PORTAL HYPERTENSION IN CHILDREN

An understanding of portal hypertension requires knowledge of the anatomy and physiology of the portal system in infants and children. In fetal life, the ductus venosus connects the umbilical vein and the inferior vena cava (IVC), and the umbilical vein joins the left branch of the portal vein (PV); these may persist, and in some situations they may remain patent postnatally. Portal capillaries originate in the mesentery of the intestine and spleen and in the hepatic sinusoids. Capillaries of the superior mesenteric and splenic veins supply the PV with nutrient-rich and hormone-rich blood. At the hilum of the liver, the PV divides into two major trunks that supply the right and left lobes of the liver, and these trunks undergo a series of divisions to supply various segments of the liver; these terminate in small branches that pierce the limiting plate of the portal tract and enter the sinusoids through short channels. The partly oxygenated portal venous blood supplements the oxygenated hepatic arterial blood flow to give the liver unique protection against hypoxia. Blood flow from both the hepatic artery and the PV is well regulated, allowing the liver to withstand thrombosis of either one of these major vessels.

The major pathologic effect from portal hypertension is the development of collaterals that carry blood from the portal venous system to the systemic circulation in the upper part of the stomach, esophagus, rectum, and falciform ligament. These collaterals may drain into the IVC via the umbilical vein remnant, or they may drain into the left renal vein (see Fig. 71.1). Absence or disconnection of the IVC or interruption to the azygos system, such as occurs in some cases of bilary atresia, may cause special concern. Similarly, in extrahepatic portal venous malformations, the splenic vein can be small and possibly thrombosed.

Only the submucosal collaterals, such as in the esophagus and stomach and rarely in other parts of the intestine, are associated with GI bleeding. Collaterals in other parts of the intestine are more frequent and are more likely to occur at sites of surgery along the GI tract, particularly from stoma and anastomotic sites. Portal hypertensive gastropathy, which is suggested by dilated mucosal veins and capillaries and mucosal congestion in the stomach, may occur after esophageal variceal obliteration.

Although changes in vascular resistance to flow of blood between the splanchnic bed and the right atrium appear to be the initial events in the development of portal hypertension, a number of other hemodynamic changes contribute to and amplify the increased portal blood pressure. There is a

- Malabsorption
- Protein-losing enteropathy
- Growth failure
- Anemia, thrombocytopenia

hyperdynamic circulatory state with increased cardiac and decreased splanchnic arteriolar tone, both of which increase portal inflow. Changes in intravascular volume also play an important role, as do alterations in adrenergic tone in the splanchnic system. These observations have led to new experimental and clinical studies that suggest possible pharmacologic treatments for portal hypertension (Boyer, 2001). However, because the major clinical effect is that of bleeding from esophageal varices, direct treatment of variceal hemorrhage, or shunt surgery in selected cases, remains the primary approach, except in the presence of liver decompensation, in which case the treatment of choice is liver transplantation (see Chapters 97A and 98A).

CLINICAL FEATURES

The main clinical features are splenomegaly, nutritional growth failure, and ascites, along with esophageal, gastric, and rectal varices (Box 71.2).

In extrahepatic portal hypertension, or in the presence of compensated liver disease, symptoms may be absent. The first indication of portal hypertension may be a GI hemorrhage, an incidental finding of splenomegaly alone, anemia, or thrombocytopenia as a result of hypersplenism. The liver is commonly small and impalpable; with an intrahepatic cause, however, it can be enlarged, hard, or nodular with a small right lobe and/or splenomegaly. Cutaneous features such as spider angiomata, prominent periumbilical veins (*caput medusae*), and palmar erythema may provide a clue to the presence of liver disease. Spider angiomata may also occur in healthy children younger than 5 years and thus are not pathognomonic of liver diseases in children. However, the appearance of new spider angiomata or more than five or six may be indicative. They are frequently observed in the vascular drainage of the superior vena cava and feature a central arteriole from which radiate numerous fine vessels, ranging from 2 to 5 mm in diameter. Other cutaneous features include easy bruising; fine telangiectasia on the face and upper back; white spots, most often on buttocks and arms, which when examined with a lens show the beginnings of spider angiomata; and clubbing of the fingers. On intranasal examination, prominent telangiectasia of the area of Little is common and is associated with recurrent epistaxis.

Although compensated cirrhosis in adults is mostly cryptogenic, metabolic liver diseases, such as Wilson disease, cystic fibrosis, and α_1-antitrypsin deficiency, may present with compensated cirrhosis in children. In Wilson disease, specific features include hemolytic anemia and subtle signs of encephalopathy that include personality changes, loss of memory, or school failure; Kayser-Fleischer rings may also be present, evident to an experienced examiner with a slit lamp. Children with cholestatic liver disease will have predominant signs or symptoms of persisting jaundice or pruritus. The liver is usually enlarged, and xanthelasma, malnutrition, and deficiency of fat-soluble vitamins, particularly vitamins D and K, may be prominent features.

Decompensated liver disease is characterized by clinical and laboratory findings of liver synthetic failure and by the occurrence of complications; in addition to the features mentioned above, the major features include malnutrition, ascites, peripheral edema, coagulopathy, and GI bleeding.

Signs of hepatic encephalopathy are subtle and uncommon in children with portal hypertension. Malnutrition with reduced lean tissue and fat stores as well as poor linear growth is a well-recognized and important feature resulting from malabsorption and impaired protein synthesis (Chin et al, 1992). Spontaneous bruising caused by impaired hepatic production of clotting factors and thrombocytopenia as a result of hypersplenism are signs of advanced disease. Cirrhosis with decompensation may also be associated with changes in the systemic and pulmonary circulations and with arteriolar vasodilation, increased blood volume, a hyperdynamic circulatory state, and cyanosis as a result of intrapulmonary shunting. Renal failure is a late but serious event.

DIAGNOSIS

Confirmation of the diagnosis of portal hypertension is based on the suggestive clinical findings detailed above, with or without signs of chronic liver disease, and on four investigations: ultrasonography, endoscopy, liver biopsy, and angiography.

Ultrasonography allows visualization and measurement of the size, patency, and flow of the portal vein, the occurrence of a cavernoma, and information about liver size and homogeneity. Renal cysts on ultrasound or a suggestive family history may provide a clue to the diagnosis of congenital hepatic fibrosis. Echocardiography is useful to exclude primary cardiac causes of hepatic venous outflow obstruction.

Endoscopy should be performed to evaluate the occurrence of varices, and the presence of cherry-red spots, which correlate with risk of rupture, and to visualize and perhaps treat the source of bleeding varices. Other features can be visualized, such as portal gastropathy and features that help exclude other sources of GI bleeding.

Liver biopsy either aids in the diagnosis of cirrhosis or excludes liver disease, as in the case of extrahepatic obstruction. Differentiation between cirrhosis and presinusoidal and extrahepatic causes of portal hypertension, such as congenital hepatic fibrosis and extrahepatic portal hypertension, can sometimes cause diagnostic difficulties. In both of these latter conditions, no signs of chronic liver disease are apparent, and transaminases and synthetic liver function are normal. In congenital hepatic fibrosis, the liver is enlarged and hard, and hepatocytes are normal histologically, but prominent, abnormal bile ducts appear in wide bands of fibrous tissue, although nodules are absent. In extrahepatic portal hypertension resulting from PV malformation or obstruction, the liver is small but histologically normal, although some steatosis may be evident. Mild derangement of coagulation parameters may be evident secondary to an underlying coagulation disorder, such as a protein C or S deficiency. Obstruction of hepatic venous outflow causes centrilobular hemorrhagic necrosis, with fibrosis that extends from central veins to portal tracts.

A full range of laboratory and imaging investigations should be performed before a liver biopsy. Such investigations may be diagnostic for the underlying cause and may allow appropriate

handling of the liver biopsy specimen in regard to specific histologic and biochemical analysis, particularly for metabolic disorders.

Angiography, either direct venography or computed tomography (CT) angiography, can provide important information about the site of the blockage, the size and patency of major veins in the portal system, and relationship to the coronary esophageal or other varices (see Chapters 16 and 19). Suspected obstruction to hepatic venous outflow requires venography and/or cardiac catheterization, which are the diagnostic procedures of choice in such cases. Pressure gradient measurements may be useful across venous blocks and to determine the magnitude of the portal pressure.

MANAGEMENT (SEE CHAPTERS 74 TO 76E)

Therapy for portal hypertension is primarily directed at the major complication—the prevention and management of variceal hemorrhage—except in cases for which directly treatable causes must be considered, including end-stage liver disease, for which liver transplantation is the primary therapy, hepatic venous outflow obstruction, vena caval webs, and constrictive pericarditis. Encephalopathy rarely requires specific therapy, but ascites can be a major problem and often does require specific treatment. Although common, hypersplenism rarely results in morbidity or death. The management of these and other complications of portal hypertension in children is primarily medical and is beyond the scope of this chapter.

In most cases, direct therapy of varices is indicated before considering surgery because the various options for creation of a surgical shunt are indirect treatments for varices by reduction in portal pressure. The four main factors that influence any decision for the application of shunt surgery in children are the risk of variceal bleeding, the potential evolution of spontaneous shunts over time, the presence or absence of liver disease, and the portal vascular anatomy.

Variceal hemorrhage presents clinically as a need for emergency therapy or as a need for prophylaxis of initial or subsequent rebleeding. Most of the data concerning the management of variceal hemorrhage have come from large controlled trials in adults, and the pediatric literature is generally descriptive or anecdotal, with some exceptions.

Emergency Therapy

Bleeding esophageal varices in children require emergency treatment (Fig. 71.2); no matter how small the hemorrhage, admission to the nearest hospital with blood transfusion facilities is advised. As soon as the blood transfusion available and the patient has a secure intravenous infusion line and is hemodynamically stable, referral to a tertiary center with experience in the management of variceal hemorrhage in children is recommended. Initial melena or other signs of a sentinel hemorrhage may precede sudden hematemesis and shock, which require rapid blood transfusion to prevent death. Significant bleeding with hypotension impairs hepatic perfusion, often causes deterioration of liver function, and precipitates ascites and encephalopathy. Initial fluid management in the form of crystalloids followed by red blood cell transfusion is important, and any coagulopathy should be corrected with vitamin K and fresh frozen plasma. Pharmacologic therapy with a short-acting splanchnic vasoconstrictor may be useful (Boyer, 2001).

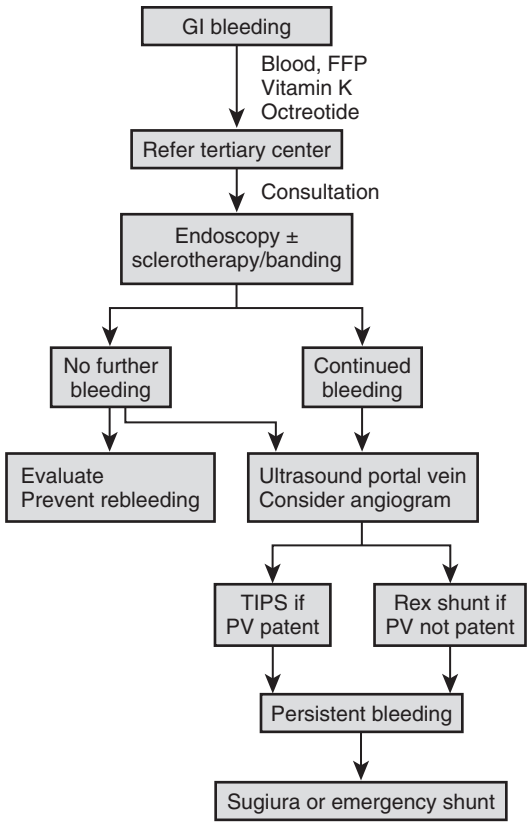

FIGURE 71.2. Management of acute variceal bleeding in children. FFP, fresh frozen plasma; GI, gastrointestinal; PV, portal vein; TIPS, transjugular intrahepatic portosystemic shunting.

Octreotide is the drug of choice in this circumstance (maximum dose 1 μg/kg/h IV or 2 to 4 μg/kg/8 h subcutaneously for 24 h, or until bleeding has ceased) because of fewer side effects (Moitinho, 2001). Alternatives are vasopressin (0.3 U/kg as a bolus over 20 minutes followed by continuous infusion of the same amount on an hourly basis) or its inactive precursor, glypressin (0.01 mg/kg bolus q4-6h or 0.05 mg/kg infusion over 6 h for 24 to 48 h). Common side effects include skin pallor, abdominal colic, and chest pain. Studies in adults have indicated that an adjunctive vasodilator, such as nitroglycerine in the form of a 10-mg patch, may reduce these hemodynamic complications. Nasogastric intubation is an essential part of management, allowing the documentation of ongoing bleeding and the removal of blood that could precipitate encephalopathy.

When the patient is hemodynamically stable, endoscopy is indicated. A significant percentage of patients with known varices have bleeding from sources other than the varices, including duodenal or gastric ulceration. In addition, meta-analysis of multiple controlled adult studies clearly shows that endoscopic treatment plus pharmacologic treatment is currently the best measure to achieve initial control of significant acute variceal bleeding (Banares et al, 2002).

Endoscopic Treatment of Acute Variceal Bleeding

Episodes of minor variceal hemorrhage may spontaneously terminate, but endoscopic treatment by sclerotherapy or band ligation is often necessary (Fig. 71.3). Both techniques are well described in children (Goenka et al, 1993; Goncalves et al,

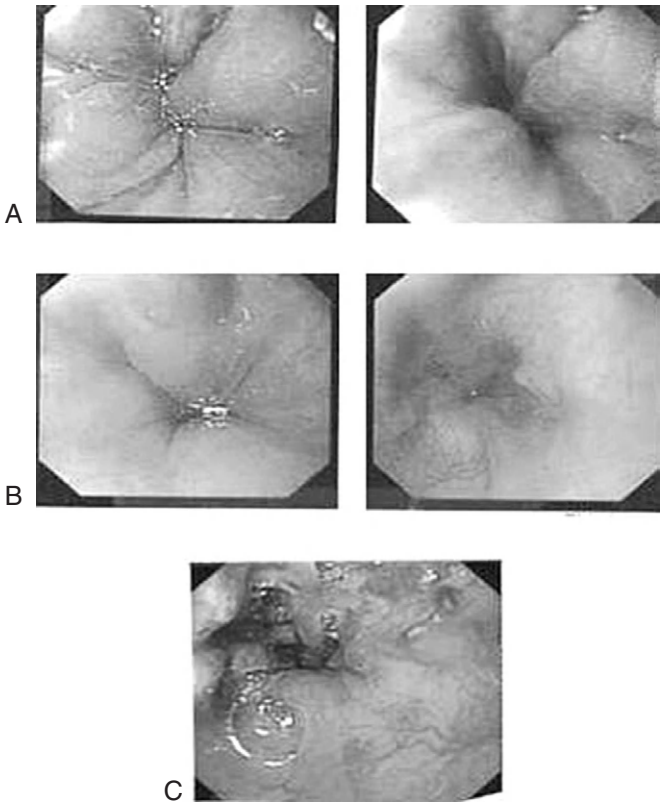

FIGURE 71.3. Ablation of esophageal varices by sclerotherapy in a 6-year-old child with portal hypertension after a Fontan procedure for congenital heart disease.

2000; Zargar et al, 2002). In adults, comparative trials of sclerotherapy and ligation indicate equal efficacy in controlling bleeding, reducing rebleeding, and ablating varices, but fewer adverse effects are reported with banding. The two procedures can be complementary, and access to both procedures may be warranted. Ligation may be technically difficult in an esophagus awash with blood or for small varices, particularly in small infants, where entrapment of part of the esophageal wall with perforation or bleeding can occur. In these circumstances, sclerotherapy is more appropriate.

Sclerotherapy involves injection of sclerosant (ethanolamine or tetradecyl sulfate) either paravariceally or intravariceally in volumes of 0.5 to 1.0 mL just above the gastroesophageal junction. Care should be taken to avoid injecting too high above the cardia, which can increase bleeding from a distal varix. This procedure is associated with bacteremia, and broad-spectrum antibiotics should be prescribed (amoxicillin, cefuroxime, metronidazole). Complications, which should be uncommon in experienced centers, include esophageal ulceration, stricture, and pain.

Sengstaken-Blakemore Tube

Should the measures described above fail to control bleeding, which is rare, temporary cessation of bleeding can be achieved using mechanical compression of esophageal and gastric varices using a pediatric Sengstaken-Blakemore tube or a Linton tube. These devices are best inserted under anesthesia at the time of attempted sclerotherapy but should not be used for longer than 24 or 48 hours because of the risk of ulceration, particularly in the esophagus. A high incidence of rebleeding is reported when the tubes are removed.

Emergency Surgical Approaches and Emergency Portosystemic Shunts (See Chapters 75A to 76E)

Emergency creation of portosystemic shunts or other surgical therapy is usually a last resort for persistent, acute, exsanguinating variceal hemorrhage. Patients with shunts who come to the emergency department often have gastric variceal bleeding. Considerations in these circumstances include potential death, and the range of techniques available include transjugular intrahepatic portosystemic shunting (TIPS), surgical shunting, esophageal transection, and esophagogastric devascularization with splenectomy. TIPS is an attractive approach because it does not require major surgery. It has been used effectively in critically ill adults to control bleeding before liver transplantation, and it has also been used in some children with bleeding stomal varices (Lagier et al, 1994). The procedure appears to decrease portal pressure acutely, although 60% occlude within 3 to 12 months; therefore it is best viewed as a bridging procedure only. Pediatric application is limited by size constraints, but in experienced hands and in selected children older than 2 to 5 years, the procedure has application and is preferable to major shunt surgery for hepatic causes of portal hypertension.

Prophylaxis Against the First Gastrointestinal Bleed

In recognized cases of portal hypertension with varices, controversy exists regarding whether any therapy reduces the risk or prevents the occurrence of GI bleeding. However, in all cases it is reasonable to be prepared for the possibility by ensuring that the child's caregivers understand the importance of seeking early medical advice by attending the nearest hospital for blood crossmatching and appropriate referral to a tertiary unit. β-Blockers, such as propranolol and the more selective atenolol, reduce hepatic arterial and portal vein blood flow and have been studied with respect to reduction in portal pressures to less than 12 mm Hg, thereby reducing the risk of an initial hemorrhage (Shasidhar et al, 1999). Under certain circumstances, prophylactic sclerotherapy may be indicated, but the potential in children for bleeding of known varices that have never bled is conjectural. Goncalves and colleagues (2000) compared sclerotherapy to no treatment in a controlled clinical trial in children and found a reduced risk of bleeding but an increase in portal gastropathy.

Prevention of Recurrent Gastrointestinal Bleeding

Intrahepatic Causes of Portal Hypertension

DIRECT OBLITERATION OF VARICES. Where bleeding has occurred from intrahepatic causes of portal vein obstruction, direct obliteration of the varices is the initial treatment of choice, although consideration of the underlying liver disease is the major determinant of long-term management. Randomized controlled trials in adults have shown a reduction in the frequency of bleeding and improved survival. Although no randomized controlled trials have been performed in children,

several large studies of sclerotherapy or banding in children with portal hypertension indicate that both procedures are safe, and both reduce the chance of rebleeding (Fox et al, 1995; Goenka et al, 1993; McKiernan et al, 2002). Neither technique reduces portal pressure, but both obliterate the dangerous varices. The procedures described above may cause some interference with the vascular hemodynamics; hypersplenism and portal gastropathy temporarily gets worse, but ultimately, with time, spontaneous portosystemic shunts will arise to reduce portal pressures.

In multiple controlled trials in adults, several vasoactive drugs have also now been documented to reduce the risk of rebleeding by reducing portal and systemic pressures (Boyer, 2001). A combination of a nonselective β-blockers and certain nitrates, such as isosorbide 5-mononitrate, are the drugs of choice, aiming at a 25% reduction in resting heart rate. Major adverse effects of β-blockers include reactive airway disease and heart block, in which cases they are contraindicated.

SURGERY. Where there is active liver disease and a significant risk of death from bleeding, surgical management of portal hypertension is a major consideration (Box 71-3). Such patients should ideally be evaluated and treated in a transplant center, where the range of surgical options can be assessed. *Surgical portosystemic shunts* may reduce the risk of GI bleeding, but they cause a decrease in portal blood flow and hepatic perfusion, and they carry the risks of hepatic decompensation and encephalopathy, which either enhances the difficulty of liver transplantation or precludes it entirely. Moreover, randomized controlled trials in adult patients have not shown any significant improvement in survival with portosystemic shunts in patients with intrahepatic causes of portal hypertension. If a shunt operation is contemplated in a critically ill patient, the use of TIPS as a bridging procedure is probably the best choice. Ultimately, the surgical procedure of choice for uncontrolled portal hypertension as a result of intrahepatic disease is liver transplantation. In nonshunt, nontransplant candidates, a Sugiura procedure (esophageal disconnection and devascularization) may be life saving, with the added advantage of a low-risk of encephalopathy.

Special consideration should be given to shunt surgery in some cases of liver disease associated with cystic fibrosis, in which there is a slow evolution of hepatic dysfunction (Debray et al, 1999), and in congenital hepatic fibrosis, a presinusoidal cause of portal hypertension not associated with the occurrence of liver synthetic dysfunction. In these cases, the choice of the type of shunt is determined by the vascular anatomy, the size of the veins, the risk of thrombosis and failure, and the risk of encephalopathy. *Selective shunts* are preferred, such as distal splenorenal or distal splenoadrenal shunts (see Chapter 76; Valayer et al, 1985; Kato et al, 2000); the latter often allows better size matching of the splenic and enlarged adrenal vein and avoids renal vein clamping.

Box 71.3

Surgical Options for Portal Hypertension in Children

- Devascularization
  - Sugiura procedure
- Nonselective shunts
  - Mesocaval (H-graft or direct)
  - Portacaval
  - Central splenorenal
  - TIPS
- Selective shunts
  - Distal splenorenal
  - Splenoadrenal
- Restorative shunt
  - Rex shunt (mesenteric left portal bypass)
- Anatomic repair
  - Hepatic or portal webs, stenosis
- Orthotopic liver transplantation

TIPS, transjugular intrahepatic portosystemic shunting

Extrahepatic Portal Venous Obstruction

Portal hypertension as a result of extrahepatic portal venous obstruction in children is associated with a better long-term prognosis and quality of life than portal hypertension associated with intrahepatic diseases, and management considerations are quite different. Acute variceal bleeding is usually well tolerated because of normal liver function, but recurrent variceal bleeds can be associated with significant morbidity (Zargar et al, 2004). Although long-term outcomes of individual center approaches have been documented (Bambini et al, 2000; Orloff et al, 2002; Zargar et al, 2004), no controlled trials have compared long-term outcomes from the two main approaches to therapy: direct variceal ablation and shunt surgery. This is compounded by the fact that some patients never bleed at all, and anecdotal and published data suggest that some patients develop spontaneous decompression of their varices over time (Goenka et al, 1993; Lykaverios et al, 2000).

DIRECT VARICEAL ABLATION. Endoscopic therapy has gained increasing acceptance in the treatment of bleeding esophageal varices in children with extrahepatic portal hypertension. Zargar and colleagues (2004) reported a 15-year follow-up of 69 children. Almost 90% had no rebleeding after eradication, which was achieved in 90% of patients. Maksoud and colleagues (1991) reported that 7% to 8% of patients did not respond to sclerotherapy and subsequently underwent shunt surgery. Stringer and Howard (1994) reported that only 4 (11%) of 36 patients required shunt surgery after variceal sclerotherapy over an 8-year follow-up. All these studies had little or no morbidity or deaths, but several repeat sessions of sclerotherapy were necessary during follow-up for complete variceal eradication. The main reason for long-term failure was the occurrence of gastric varices, but clearly this does not occur in all cases, and some studies suggest that the occurrence of spontaneous shunts after successful sclerotherapy negates the need for shunt surgery altogether (Goenka et al, 1993).

SURGERY. Surgery may be required for patients with extrahepatic portal hypertension with preserved liver function for recurrent bleeding or, rarely, for massive hypersplenism. Surgical options in the management of extrahepatic portal venous obstruction include portosystemic shunts, Rex shunts (mesenteric left portal bypass), devascularization, and transection (see Box 71.3).

Although earlier outcomes of portosystemic shunts were disappointing, some recent reports of have shown recurrence of bleeding in only 2.5% to 10%, low mortality rates, a continued shunt thrombosis rate of 7% to 13%, and an apparently low risk of encephalopathy (Botha et al, 2004; Kato et al, 2000; Orloff et al, 2002). Nonselective mesocaval shunts and the more selective distal splenorenal shunt have been the procedures of choice in the past, although a central splenorenal shunt with splenectomy is sometimes advocated if massive hypersplenism and pain from splenic infarcts are present. However, these shunts may

not be technically possible because of thrombotic involvement of splenic or mesenteric veins, and in some cases, particularly where varices are derived from the cavernoma, certain shunts may not alter variceal pressures to the coronary esophageal veins.

The *Rex shunt,* usually an internal jugular vein graft and mesenteric to left portal vein bypass, has the major theoretical advantage of restoring portal flow to the liver and reducing risk of encephalopathy, and it obviates the technical problems associated with splenic vein thrombosis (Bambini et al, 2000; de Ville de Goyet, 1999). First introduced for portal vein thrombosis after liver transplantation, this procedure may become the surgical procedure of choice for all causes of extrahepatic portal vein obstruction. Thrombosis and stenosis rates appear to be similar to those of portosystemic shunts. Patency of the intrahepatic portal system can be difficult to prove before the procedure. The use of a preprocedural portal venogram to ensure patency antegrade to the liver is important when performing any type of shunt surgery for extrahepatic venous obstruction, particularly where a cavernoma is present; selective division of the portal system (e.g., coronary branch), where there are residual collaterals, must also be considered.

SUMMARY

Therapeutic options for children with portal hypertension now include a broad range of pharmacologic, endoscopic, radiologic, and surgical procedures, the latter being mainly indicated in those at high risk for recurrent variceal bleeding. Thorough assessment of the causes, effects, venous anatomy, and consequent selective application of some or all of these options can improve quality of life, reduce the complications of portal hypertension, and decrease mortality rate.

Where there is preserved liver function, children with variceal bleeding as a result of extrahepatic portal hypertension can usually be effectively and safely managed with initial direct variceal ablation by sclerotherapy or banding, which in many cases can alter the natural history of the disease and reduce the risk of rebleeding. The development of portal hypertensive gastropathy and/or rebleeding after these palliative procedures can be definitively managed by shunt surgery, preferably with the more physiologic Rex shunt.

Patients with intrahepatic portal hypertension who are transplantation candidates are best palliated with endoscopic treatment but occasionally benefit from TIPS. Those who are not candidates for transplantation and those who have not responded to nonsurgical treatments can have good outcomes with selective portosystemic shunts. Well-planned, definitive surgical treatments will continue to be important components in the treatment of children with portal hypertensive complications or progressive liver disease.

CHAPTER 72

Management of liver failure

John G. O'Grady

LIVER FAILURE

Liver failure presents as one of two quite distinct clinical problems: the specific entity of *acute liver failure,* a term used interchangeably with *fulminant hepatic failure,* and the more frequently encountered scenario of an episode of acute decompensation of established chronic liver disease, called *acute-on-chronic liver failure*. Acute liver failure evolves after a catastrophic insult to the liver and results in the development of encephalopathy within a matter of days or weeks of the liver injury. Acute-on-chronic liver failure usually occurs in patients with cirrhosis and is often precipitated by infection or gastrointestinal hemorrhage. The principles of management are similar in some respects, such as the treatment of encephalopathy and coagulopathy, but very different in others; for example, cerebral edema is almost exclusively observed in acute liver failure. The presentation of this chapter is based mainly on acute liver failure unless specified otherwise.

Acute liver failure is a heterogeneous condition that incorporates a range of clinical syndromes. The dominant factors that give rise to this heterogeneity include the underlying etiology, which varies significantly from country to country (Table 72.1); the age of the patient; and the duration of time over which the disease evolves. Natural history studies indicate that survival rates without liver transplantation range from 10% to 90%, with the best outcomes seen in patients with pregnancy-related syndromes, acetaminophen overdose, and hepatitis A. Survival rates are also poor in older patients and possibly in very young children.

The rate of progression of the disease is used to classify patients into groups with differing clinical problems and outcomes. Universal agreement on terminology is lacking, but the main options in use, and the terms used in this chapter, are *hyperacute liver failure,* or encephalopathy within 7 days of the onset of jaundice; *acute liver failure,* encephalopathy within 8 to 28 days of the onset of jaundice; and *subacute liver failure,* encephalopathy that occurs more than 28 days after the onset of jaundice.

ETIOLOGY OF ACUTE LIVER FAILURE

Viruses and drugs account for the majority of cases of acute liver failure, although a significant number of patients have disease for which no definable cause can be found. The latter condition is referred to as *seronegative hepatitis* in this chapter, but it is also known as *non–A-E hepatitis* and *acute liver failure of indeterminate etiology.* In the United States, the overall incidence of acute liver failure as a complication of acute hepatitis is 0.9%, which equates to approximately 2000 deaths annually. Most of the drug-induced cases are rare, idiosyncratic reactions, but some cases, such as those involving acetaminophen, are at least in part dose-related toxic events.

Viral

Acute liver failure is a very uncommon complication of hepatitis A infection, occurring in 0.14% to 0.35% of hospitalized patients and in 0.4% of all cases seen in the United States. The incidence of acute liver failure following hepatitis B infection is 1% to 4% of hospitalized patients. In early studies, hepatitis D coinfection or superinfection was thought to increase the risk, as it was found in 34% to 43% of patients with acute liver failure as a result of hepatitis B infection compared with 4% to 19% of less severe cases. However, the prevalence of hepatitis D appears to have decreased dramatically in recent years. Vaccination and antiviral therapy with drugs that have a rapid onset of action (e.g., lamivudine, tenofovir) should alter the observed pattern of hepatitis B–related acute liver failure (Sjögren, 2003). The risk of developing acute liver failure after exposure to hepatitis C appears to be low, although well-documented cases have been reported. Hepatitis E is common in parts of Asia and Africa but is being increasingly recognized in Western countries. The natural history of hepatitis E in India has recently been revised to show that, although pregnant females are more likely to develop acute liver failure, the outcome is independent of sex, pregnancy status, and trimester of pregnancy (Bhatia et al, 2008).

Seronegative hepatitis accounts for 14% to 32% of acute liver failure in the Western world. In the United States, a proportion of these events are considered to be related to acetaminophen (Davern et al, 2006). There is little evidence to suggest that an unrecognized viral infection is to blame because most cases are sporadic. Unidentified toxins or autoimmune processes may be the underlying mechanisms. Middle-aged females are most frequently affected, and the risk of developing acute liver failure has been calculated at 2.3% to 4.7% of hospitalized cases.

Drugs

Acetaminophen (paracetamol) overdose is the commonest cause of acute liver failure in the United Kingdom and the United States (Bernal, 2003; Lee, 2003). In the United Kingdom, excess amounts are usually taken with suicidal or parasuicidal intent; only 8% of such events were ascribed to inadvertent overdose with therapeutic use. However, in the United States, unintentional overdoses accounted for at least 48% of cases (Larson et al, 2005). Susceptibility to developing acetaminophen hepatotoxicity is increased in people with liver enzyme induction as a consequence of antiepileptic therapy, regular alcohol consumption, or malnutrition.

Table 72.1

Geographic Variation in the Etiology of Acute Liver Failure

Cause	U.K. (%)	U.S. (%)	France (%)	India (%)	Japan (%)	Spain (%)
Acetaminophen	54	46	2	—	—	2
Drug reactions	7	12	15	5	—	17
Seronegative	17	14	18	24	45	32
Hepatitis A or B	14	10	49	33	55	37
Hepatitis E	—	—	—	38	—	—
Other causes	8	18	16	—	—	12

Drug-induced liver injury resulted in liver-related death in 3% to 4% of cases in a prospective study of 300 cases (Chalasani et al, 2008). More than 100 different agents were implicated, with 46% being associated with antimicrobials and 15% with central nervous system agents. Some of the more common offending drugs linked to acute liver failure are listed in Box 72.1. The risk of developing acute liver failure from an idiosyncratic reaction ranges from 0.001% for nonsteroidal antiinflammatory drugs (NSAIDs) to 1% for the isoniazid/rifampicin combination. Nontherapeutic drugs, such as MDMA (3,4-methylenedioxymethamphetamine; "ecstasy") and some herbal remedies, can also cause acute liver failure. The diagnosis is made on the basis of a temporal relationship between exposure to the drug or hepatotoxin and the development of acute liver failure.

Other Etiologies

Acute liver failure associated with pregnancy tends to occur during the third trimester. Three discrete entities have been described, but considerable overlap is frequently observed. *Acute fatty liver of pregnancy* usually occurs in primagravids carrying a male fetus and is characterized by severe microvesicular steatosis. The syndrome is defined as the combination of ***h***emolysis, ***e***levated ***l***iver enzymes and ***l***ow ***p***latelets (HELLP). Acute liver failure complicating preeclampsia or eclampsia typically exhibits very high serum transaminase levels and abnormal tissue perfusion patterns on CT scanning that reflect the microvascular infarction characteristic of this condition.

Wilson disease may present as acute liver failure, usually during the second decade of life. It is characterized clinically by a Coombs test negative for hemolytic anemia and demonstrable Kayser-Fleischer rings in the majority of cases. Poisoning with *Amanita phalloides* mushrooms is most commonly seen in central Europe, South Africa, and the West Coast in the United States. Severe diarrhea, often with vomiting, is a typical feature and commences 5 hours or more after ingestion of the mushrooms; liver failure develops 4 to 5 days later. Autoimmune chronic hepatitis may present as acute liver failure, but by then, it is usually beyond rescue with corticosteroid or other immunosuppressive therapy. Budd-Chiari syndrome (see Chapter 77) may present with acute liver failure, and the diagnosis is suggested by hepatomegaly and confirmed by the demonstration of hepatic vein thrombosis. Malignancy infiltration, especially with lymphoma, is another rare cause of acute liver failure that is typically associated with hepatomegaly. Ischemic hepatitis is being increasingly recognized as a cause of acute liver failure, especially in older patients. Other unusual causes of acute liver failure include heat stroke and sepsis.

Box 72.1

Examples of Drugs Causing Acute Liver Failure

Category 1: Common Causes	Category 2: Rarer Causes
Paracetamol	Benoxyprofen
Halothane	Phenytoin
Isoniazid/rifampicin	Isoflurane
Nonsteroidal antiinflammatory drugs	Enflurane
Sulfonamides	Tetracycline
Flutamide	Allopurinol
Sodium valproate	Ketoconazole
Carbamazepine nimesulide	Monoamine oxidase inhibitors
Lamotrigine	Disulphiram
Rosiglitazone	Methyldopa
Ecstasy	Amiodarone
	Tricyclic antidepressants
	Propylthiouracil
	Clozapine 2,3,-dideoxyinosine

Pediatric Causes

Children are at risk of developing some of the causes of acute liver failure discussed above, but they also are vulnerable to other unique underlying causes, especially in the category of metabolic disease. Neonatal hemochromatosis may occur within the first few weeks of life and has been treated by liver transplantation as early as 5 days of age. Acute liver failure as a result of mitochondrial disorders may be triggered by bacterial infections and are characterized by high lactate levels in blood. Other metabolic causes include tyrosinemia, galactosemia, and fructose intolerance. Young infants can develop acute liver failure with viral infections, such as adenovirus, coxsackie virus, and cytomegalovirus (see Chapter 71).

DIAGNOSIS

The diagnosis of acute liver failure is a clinical one based on the detection of encephalopathy in patients with acute liver disease. The diagnosis of encephalopathy is generally made on overt clinical criteria, but psychometric testing may be useful in patients with subacute liver failure to detect subtle changes in mental state. Commonly, hypoglycemia and, unusually, uremia may mimic hepatic encephalopathy in patients with acute liver failure; these need to be excluded before the diagnosis is confirmed.

The etiology of acute liver failure must be accurately identified; the appropriate investigations are outlined in Tables 72.2 and 72.3 and cover the key essential investigations and those

Table 72.2

Core Investigation of the Etiology of Acute Liver Failure

Etiology	Investigation
Hepatitis A virus (HAV)	IgM anti-HAV
Hepatitis B (HBV) + D (HDV)	IgM anticore, HBV DNA (NB HBsAg may be negative)
Hepatitis E virus (HEV)	Anti-HEV
Paracetamol	Drug levels in blood

IgM, immunoglobulin M; *NB HbsAg,* hepatitis B surface antigen.

that are relevant in certain circumstances, respectively. Imaging assesses the size and shape of the liver and screens for portal hypertension; however, the detection of portal hypertension does not always indicate chronic liver disease because ascites and/or splenomegaly may be seen in subacute liver failure and in the acute presentation of Wilson disease.

Histologic assessment of liver tissue may aid the diagnosis of the cause of acute liver failure (see Chapter 70A). Confluent necrosis is the most common histologic finding; it may be zonal or may involve all of the parenchyma. Necrosis that is zonal within the acinus and coagulative or eosinophilic is more likely to be secondary to a toxic insult or ischemia. The features of necrosis and parenchymal collapse may be interspersed with evidence of regeneration, either occurring in a diffuse pattern of small areas throughout the liver or in randomly occurring larger nodules that give the maplike pattern that has often been described in this condition. The latter pattern is most commonly seen in patients with subacute liver failure.

Histologic features may suggest specific diagnoses, including sodium valproate toxicity, malignant infiltration, Wilson disease, pregnancy-related syndromes, and Budd-Chiari syndrome. Sodium valproate toxicity is characterized by microvesicular steatosis. Screening for malignant infiltration as the cause of acute liver failure is one of the stronger indications for performing a liver biopsy in this condition. Patients with Wilson disease that presents as acute liver failure usually have established cirrhosis, commonly associated with interface hepatitis that resembles autoimmune disease, with hepatocyte ballooning and steatosis. Liver histology may be very useful in making a precise diagnosis within the spectrum of pregnancy-related liver diseases. The histologic features of Budd-Chiari syndrome are extreme sinusoidal dilation, congestion, and coagulative necrosis.

Liver biopsy may also be of assistance in differentiating acute liver failure from established cirrhosis and acute alcoholic hepatitis, whether or not it is associated with cirrhosis. The former scenario can usually be distinguished on clinical grounds, but acute alcoholic hepatitis can present with clinical features very similar to subacute liver failure. A history of high alcohol consumption may not be available, but the diagnosis of acute alcoholic hepatitis is suggested by the investigational findings outlined in Box 72.2.

Box 72.2

Findings Suggestive of Acute Alcoholic Hepatitis

Hepatomegaly
Marked elevation of γ-glutamyl transferase
High white cell count not responding to antibiotics
Elevated immunoglobulin A level
Appearance of fatty infiltration on ultrasound

PROGNOSIS

In acute liver failure, the grade of encephalopathy correlates strongly with outcome; this is true for both the grade of encephalopathy at the time of presentation to a specialist unit and the maximum grade attained. The prognosis deteriorates further when grade 4 encephalopathy is complicated by cerebral edema and is even worse when the latter coexists with renal failure. However, other patients with acute liver failure have a very poor prognosis despite the absence of cerebral edema and renal failure. This is especially true of patients with subacute liver failure who, in addition, often do not manifest severely abnormal coagulation parameters.

The use of transplantation has intensified the need for early indicators of prognosis, so that those in need of this intervention could be identified as quickly as possible (see Chapter 97C). The King's College criteria, with some modifications, are still widely used to identify the patients most in need of liver transplantation (Boxes 72.3 and 72.4). The acetaminophen criteria have been found to be specific but lack adequate sensitivity, and serum lactate levels (>3.5 before resuscitation and 3.0 after) have been suggested as an alternative or supplementary

Table 72.3

Extended Investigation of Etiology of Acute Liver Failure

Etiology	Investigation
Idiosyncratic drug reactions	Eosinophil count, histology
Autoimmune	Autoantibodies, immunoglobulins
Pregnancy-related syndromes	
Fatty liver	Ultrasound, uric acid, histology
HELLP syndrome	Platelet count
Toxemia	Serum transaminases
Wilson disease	Urinary copper, ceruloplasmin, alkaline phosphatase/bilirubin ratio, AST/ALT ratio, slit-lamp examination
Budd-Chiari syndrome	Ultrasound or venography
Malignancy	Imaging, histology
Ischemic hepatitis	Transaminases

HELLP, hemolysis, elevated liver enzymes and low platelets; *AST/ALT,* aspartate aminotransferase/alanine aminotransferase.

Box 72.3

Indicators of a Poor Prognosis in Paracetamol-Induced Acute Liver Failure

Arterial pH <7.25 >24 hours after drug ingestion and after adequate fluid resuscitation
Serum lactate >3.5, or >3.0 after adequate fluid resuscitation
All the following or three of the following concomitantly:
- Prothrombin time >100 sec or international normalized ratio >6.5
- Creatinine >300 μmol/L or anuria
- Grade 3 to 4 encephalopathy

INR, international normalized ratio

Box 72.4

Indicators of a Poor Prognosis in Non-Acetaminophen Acute Liver Failure

Prothrombin time >100 sec or INR >6.7
Acute presentation of Wilson disease
Any three of following:
- Unfavorable etiology (seronegative hepatitis or drug reaction)
- Age <10 years or >40 years
- Acute or subacute categories (e.g., jaundiced >7 days)
- Serum bilirubin >300 µmol/L
- Prothrombin time >50 sec or INR >3.5

INR, international normalized ratio.

assessment of prognosis in these patients (Bernal et al, 2002). Another problem with these criteria is the difficulty applying the coagulation parameters outside the United Kingdom. The scale on which prothrombin times are reported in the United States is dramatically shorter than in the United Kingdom, reflecting differences in technique; in addition, the reagents used and the implementation of the international normalized ratio (INR) have not entirely resolved this problem because of loss of accuracy at higher readings. The Model for End-Stage Liver Disease (MELD) score is being increasingly used to prognosticate in acute liver failure. In France, the factor V levels are used in preference to either the prothrombin time or INR; levels below 20% in patients younger than 30 years and below 30% in older patients are indicative of a poor prognosis once encephalopathy develops. In Germany, the BiLE score—a combination of serum ***bi***lirubin level, ***l***actate, and ***e***tiology—is used (Hadem et al, 2008). A study from India used a combination of six demographic, clinical, and laboratory variables (Dhiman et al, 2007). In reality, these different prognostic tools use a total of 10 variables (Table 72.4), and considerable commonality is found among them (O'Grady, 2007).

Assessment of the volume of viable hepatocytes by histologic examination is considered by some to be of prognostic value, but the potential for sampling error is considerable. The critical mass that suggests a good prognosis has been calculated at between 25% to 40%. A small liver on clinical or radiologic assessment or, more particularly, a liver that is found to be shrinking rapidly is another poor prognostic indicator that is especially useful in subacute liver failure.

Table 72.4

Components of Models to Assess Prognosis in Acute Liver Failure

Factor	King's College	Clichy	MELD	BiLE	India
Age	+	+			+
Etiology	+			+	
Jaundice to encephalopathy	+				+
Coagulation	+	+	+		+
Bilirubin	+		+	+	
Creatinine	+		+		+
pH	+				
Lactate				+	
Encephalopathy grade	+				+
Cerebral edema					+

MELD, Model for End-Stage Liver Disease; *BiLE,* bilirubin level, lactate, and etiology.

MANAGEMENT

Overall Strategy

In acute liver failure, the overall strategy is a combination of intensive medical care (see Chapter 73), liver transplantation in selected patients (see Chapter 97C), and, to some degree, the use of a liver support device (Chapter 73). Management starts with identification of etiology and an initial assessment of prognosis that is then progressively updated as each individual's clinical course evolves. Early referral to specialist centers that offer liver transplantation is recommended; monitoring is instituted, and a decision on the need for immediate liver transplantation is reviewed. Patients are then treated for the complications that may develop to the point of recovery, death, or transplantation. Although considerable variation is found among centers and countries, the outcomes in fully functional programs approximate 40% survival without transplantation, and 40% proceed to liver transplantation; a 20% mortality rate is reported without transplantation.

Patients with acute-on-chronic liver failure often require, and benefit from, intensive monitoring. This is especially appropriate when deterioration has been triggered by a specific, reversible complication, especially variceal bleeding (see Chapter 75). Patients with hepatorenal failure are also frequently admitted to intensive care, which is particularly appropriate in patients who are active candidates for liver transplantation. Liver support systems, particularly the Molecular Adsorbents Recirculation System (MARS; Gambro, Stockholm, Sweden), are being increasingly used in this situation.

General Measures in Liver Failure

A number of drugs have well-defined roles in specific etiologies of acute liver failure. N-acetylcysteine is established as an antedote to paracetamol hepatotoxicity when given within 16 to 24 hours of the overdose, but it has also been shown to be beneficial in reducing mortality rates and cerebral edema when begun as late as 36 hours after the overdose. In the United States, a trial of N-acetylcysteine in nonacetaminophen acute liver failure showed improved transplant-free survival of 52%, compared with 30% in patients receiving placebo, when patients were started on therapy prior to the onset of grade 3 to 4 encephalopathy (Lee et al, 2009). Penicillin, and possibly silymarin, should be added at the earliest opportunity to the standard supportive measures in patients with *Amanita phalloides* toxicity. Patients with Wilson disease complicated by encephalopathy do not respond to chelating therapy, but penicillamine should be considered for acute presentations not yet complicated by encephalopathy. Acute liver failure caused by autoimmune hepatitis rarely responds to immunosuppressive therapy. Patients with severe acute alcoholic hepatitis may benefit from corticosteroid therapy or treatment with pentoxifylline; however, neither of these medications is indicated in acute-on-chronic episodes of alcoholic cirrhosis in the absence of a component of alcoholic hepatitis.

MANAGEMENT OF SPECIFIC COMPLICATIONS

Neurologic Complications

By definition, encephalopathy is present in acute liver failure and is often present in acute-on-chronic liver failure. Encephalopathy in both settings is categorized clinically on a scale from 1 to 4. Patients with grades 1 and 2 encephalopathy exhibit degrees of drowsiness or disorientation, but they can be roused and respond appropriately to verbal stimuli. Patients with chronic liver disease usually have a hepatic flap and *fetor hepaticus*, but these classic features of encephalopathy are absent in most patients with acute liver failure and an equivalent degree of encephalopathy. In acute liver failure, progression to grade 3 encephalopathy may be heralded by a short period of extreme agitation before the patient becomes very confused and, at best, only obeys simple commands. Grade 4 encephalopathy signifies deep coma; at best, patients are responsive to painful stimuli; most patients in this situation require intubation and supported ventilation.

Cerebral edema is common in hyperacute and acute liver failure but unusual in subacute liver failure. Clinically apparent cerebral edema has only been reported on an anecdotal basis in patients with cirrhosis (excluding Wilson disease). Emerging evidence suggests that the incidence of cerebral edema is decreasing with modern management protocols, but the precise reasons for this change have yet to be determined (Stravitz & Kramer, 2009). Nevertheless, in individual patients, cerebral edema remains an important complication that may cause death or may disqualify patients from transplantation; on that basis, treatment of cerebral edema retains its prominent role in management protocols. The clinical features of cerebral edema include systemic hypertension, "decerebrate" posturing, hyperventilation, abnormal pupillary reflexes, and, ultimately, impairment of brain stem reflexes and functions. Papilledema is rarely seen. The risk to life with cerebral edema can be from classic brain stem herniation or hypoxic brain damage.

Encephalopathy with acute-on-chronic liver failure is managed with dietary protein restriction and lactulose and phosphate enemas, usually with good effect. Treatment of triggering events is also fundamental to the management of encephalopathy, and empiric antibiotics and intravenous fluids are standard components of care (Box 72.5). With the possible exception of subacute liver failure, specific management options for encephalopathy have limited impact in acute liver failure. L-ornithine L-asparate given in a dose of 30 g/day for 3 days failed to lower ammonia levels or improve survival in acute liver failure (Acharya et al, 2009). Liver support devices can reduce ammonia and lighten encephalopathy, but no single system has demonstrated improvement in patient survival (McKenzie et al, 2008; Stradlbauer et al, 2009).

Box 72.5

Common Precipitants of Acute-on-Chronic Hepatic Encephalopathy

Infection	Excessive dietary protein intake
Constipation	Narcotic drugs
Gastrointestinal bleeding	Benzodiazepines

Mannitol (0.25 to 0.5 mg/kg) is the first-line treatment for surges in intracranial pressure. This process is repeated as determined by the pattern of clinical relapses, but the serum osmolarity should not be allowed to exceed 320 mOsm. Sodium thiopentone (phenobarbitone) was shown to control cerebral edema that had become unresponsive to mannitol in an uncontrolled study, but it has not been subjected to a controlled trial, nor has it been shown to improve the survival rate. Acute, but not chronic, hyperventilation was reported to be of benefit in reducing critical surges in intracranial hypertension. Nevertheless, hyperventilation to pCO_2 levels below 25 mm Hg is routinely incorporated as a first-line treatment in protocols in the United States. Hypothermia, hypertonic saline infusions, and indomethacin have also been shown in small studies to be useful adjuncts in the management of intracranial hypertension (Auzinger & Wendon, 2008; Stravitz & Kramer, 2009).

In the later stages of the neurologic complications, the emphasis of management changes to the preservation of cerebral perfusion pressure, increased oxygen delivery to the brain, and manipulation of the neuronal microcirculation to promote cerebral oxygen extraction (Auzinger & Wendon, 2008; Stravitz & Kramer, 2009). The patient should be positioned with the trunk at an angle of 20 to 30 degrees to horizontal. The options for increasing the mean arterial pressure, and consequently improving cerebral perfusion pressure, are outlined in the section in this chapter dealing with hemodynamics. These adjustments are made to maintain a cerebral perfusion pressure greater than 50 mm Hg if possible. At this stage of the complication, spontaneous recovery is unlikely without liver transplantation, and hepatectomy is useful to secure transient improvement. Occult seizure activity may contribute to neurologic instability in patients with grade 4 encephalopathy. Phenytoin and diazepam are effective therapies despite the theoretic consideration that the latter may aggravate the underlying encephalopathy.

The use of intracranial pressure monitoring is controversial and has not been subjected to clinical trials (Stravitz & Kramer, 2009). Early detection of cerebral edema and a facility with the appropriate equipment to constantly monitor this complication help to optimize therapeutic interventions. Intracranial pressure monitoring allows earlier and more accurate detection of pressure changes—especially in the ventilated patient, in whom most of the clinical signs are masked—and it facilitates careful monitoring of the intracranial pressure during high-risk therapeutic interventions, such as hemodialysis and tracheal suctioning. It is also considered valuable during orthotopic liver transplantation because increases in intracranial pressure often occur during the dissection and reperfusion phases of the transplant operation. The most commonly used system places transducers on or through a small nick in the dura. The risk of intracranial hemorrhage is a deterrent, although the studies that have systematically addressed safety have favored the use of intracranial pressure monitoring, especially using fiberoptic extradural or subdural devices. Proponents argue that this has been shown to be effective and relatively safe, despite the attendant coagulopathy. Epidural transducers were associated with a low complication rate of 3.8%, but subdural and parenchymal devices had higher complication rates of 20% and 22%, respectively. Noninvasive monitoring using transcranial Doppler ultrasonography may provide an alternative way of assessing intracranial pressure and cerebral perfusion pressure in this setting (Aggarwal et al, 2008).

Infection

Immunoparesis is a feature of acute liver failure (Antonides et al, 2008); it is therefore no surprise that bacterial and fungal infections are prominent complications in all varieties of this condition (see Chapters 9 though 11). Considerable overlap is seen between the clinical features of infection and the systemic immune response syndrome (SIRS), but microbial infection can also be seen in the absence of these typical markers of sepsis. Infection is one of the most common causes of death and plays an integral role in the evolving cycle of hemodynamic instability and multisystem failure (Rolando et al, 2000). It also frequently delays or disqualifies potential candidates from emergency liver transplantation. Bacterial infection occurs in up to 80% of patients, and fungal infection occurs in 30%. Systemic fungal infection is notoriously difficult to diagnose in the setting of acute liver failure, and a high index of suspicion is required, especially in high-risk patients and in those with a very high white cell count or an arrest in the normalization of the parameters of coagulation activity during an apparent recovery phase. Risk factors for both bacterial and fungal sepsis include coexisting renal failure, cholestasis, treatment with thiopentone, and liver transplantation. Surveillance cultures are required on a regular basis (Auzinger & Wendon, 2008; Stravitz & Kramer, 2009).

Clinical trials of prophylactic antibiotics have demonstrated that systemic antibiotics reduced the incidence of culture-positive bacterial infection by half, but this strategy was associated with the emergence of highly resistant organisms in up to 10% of cases. However, this reduction in infection rates was not accompanied by a significant impact on major clinical outcomes (death, progression to transplantation) or economic considerations (length of intensive care unit and hospital stay, overall cost of antimicrobials). Small bowel decontamination was not effective in altering the pattern of infection; however, systemic antibiotics are recommended when infection is suspected, and the precise regimens used are determined by local antibiotic policy.

In chronic liver disease, infection of an apparent trivial nature is common and can be the trigger for an episode of acute-on-chronic liver failure; as a result, antibiotic therapy is a standard component of the management of this condition. Spontaneous bacterial peritonitis is a particularly important infection to consider in this setting, and the diagnosis can only be excluded with confidence if the white cell count in ascites is less than 250/mm^3. Patients with a history of spontaneous bacterial peritonitis should be maintained on low-dose antibiotic prophylaxis, such as with norfloxacin 400 mg daily.

Hemodynamic Instability and Oxygen Debt

The hemodynamic changes in liver failure are very similar to those observed in SIRS. The early hemodynamic profile reflects a hyperdynamic circulation with increased cardiac output and reduced systemic peripheral vascular resistance. Profound vasodilation may cause relative hypovolemia, and invasive monitoring is used to determine appropriate fluid regimens and adequate intravascular volumes. Progressive disease leads to circulatory failure, either as a result of a falling cardiac output or an inability to maintain an adequate mean arterial pressure. Patients with acute liver failure and sepsis exhibit a different hemodynamic profile than patients in septic shock in the absence of liver disease (Tsai et al, 2008). The patients with acute liver failure had higher cardiac indexes and oxygen delivery but lower systemic vascular indexes and oxygen extraction/consumption. Circulatory failure is another important contraindication to liver transplantation and is a common mode of death in liver failure.

Hemodynamic monitoring using volumetric indices of preload is preferred over pressure-derived variables (Auzinger & Wendon, 2008). Circulatory failure is initially managed with appropriate fluid replacement in combinations of colloids, crystalline fluids, and blood products as clinically appropriate. Persistent hypotension after volume repletion indicates vasopressor agents, with a clear preference for norepinephrine as first-line therapy (Auzinger & Wendon, 2008; Stravitz & Kramer, 2009). Dopamine and vasopressin may also be used, although vasopressors may cause or aggravate an oxygen debt, but prostacyclin and N-acetylcysteine have been shown to improve these parameters in patients receiving vasopressors. Some patients with acute liver failure who develop resistance to inotropes may have a hypoadrenal profile that responds to hydrocortisone (Harry et al, 2002).

Renal Failure

Urea synthesis is impaired in acute liver failure. Consequently, serum creatinine levels are preferred for the purposes of monitoring renal function. Renal failure developed in 75% of patients with acetaminophen-related acute liver failure and in 30% of acute liver failure from other causes. Renal failure after an acetaminophen overdose is a consequence of direct renal toxicity and develops early in the course of the illness. Early renal dysfunction is also seen in Wilson disease, *Amanita* poisoning, and pregnancy-related syndromes. In the other etiologies, renal impairment develops relatively late and progresses from a stage of "functional" or prerenal failure (urinary sodium <10 mmol/L; urine/plasma osmolarity ratio >1.1) to acute tubular necrosis. The presence of SIRS correlated with the development of renal dysfunction in nonacetaminophen etiologies of acute liver failure but not in acetaminophen-induced disease (Leithead et al, 2009).

Hepatorenal failure is a serious complication of acute-on-chronic liver failure. Two types are recognized: *type 1* is hepatorenal syndrome with a rapidly progressive decline in renal function, leading to a doubling of the initial serum creatinine to a level greater than 2.5 mg/dL, or a 50% reduction of creatinine clearance to less than 20 mL/min over a period of no longer than 2 weeks. *Type 2* is hepatorenal syndrome with renal failure not fulfilling the parameters outlined above.

Hepatorenal syndrome can improve dramatically after liver transplantation, which reflects the role of vasospasm in the pathogenesis of the condition. However, true hepatorenal syndrome can progress imperceptibly to acute tubular injury that does not recover as quickly.

Optimization of intravascular filling is essential in patients with deteriorating renal function. The prophylactic use of dopamine has been common practice, but its benefits have been challenged, especially in the setting of profound vasodilation that is typical of acute liver failure. The metabolic complexity of combined liver and renal failure suggests that early intervention with hemodialysis, preempting standard indications, is prudent in the setting of acute liver failure. Continuous filtration systems are associated with less hemodynamic instability and run a lower risk of aggravating latent or established cerebral edema than does intermittent hemodialysis. Some evidence suggests

that high-volume, continuous venovenous hemofiltration may reduce vasopressor requirements through modulation of proinflammatory mediators (Auzinger & Wendon, 2008). The role for renal support therapy is less well defined in acute-on-chronic liver failure, but MARS therapy may be especially useful in deeply jaundiced patients with renal dysfunction.

Metabolic Abnormalities

Hypoglycemia is common in acute liver failure and can induce reversible impairment of consciousness prior to the onset of classic encephalopathy. The signs and symptoms of hypoglycemia are often masked, and regular blood glucose monitoring is required. Metabolic acidosis is present in 30% of patients who develop acute liver failure after an acetaminophen overdose, and it is associated with a particularly high mortality rate (>90%) if the pH of arterial blood is lower than 7.30 on the second or subsequent days after the overdose. This acidosis precedes the onset of encephalopathy and is independent of renal function. In contrast, metabolic acidosis is found in 5% of patients with other etiologies of acute liver failure; it occurs later in the disease process and is also associated with a poor outcome. Increased serum lactate levels have been documented in patients with metabolic acidosis, and these correlate inversely with mean arterial pressure, systemic vascular resistance, and oxygen extraction ratios. The hyperlactatemia possibly reflects tissue hypoxia resulting from impaired oxygen extraction as a result of microvascular shunting of blood away from actively respiring tissues. In most etiologies of acute liver failure, alkalosis is the dominant acid-base abnormality and may be associated with hypokalemia. Hyponatremia may reflect sodium depletion in patients with vomiting, or it may be dilutional, resulting from excessive antidiuretic hormone secretion or intracellular sodium shifts. Hypophosphatemia is most frequently encountered in acetaminophen-induced acute liver failure when renal function is preserved.

Hyponatremia is the dominant abnormality seen in acute-on-chronic liver failure. This does not reflect sodium depletion because total body sodium levels are almost always above normal in these patients. Diuretic-induced hyponatremia may be seen in patients with ascites, and withdrawal of diuretic therapy is advised if the serum sodium level falls below 130 mEq/L. Refractory hyponatremia is managed by fluid restrictions of 800 to 1500 mL per day depending on severity. Hemofiltration may be used to correct hyponatremia in severe cases or when the serum sodium is less than 120 mEq/L immediately prior to liver transplantation This is to reduce the risk of central pontine myelinolysis associated with the rapid increase in serum sodium levels that inevitably occur.

Coagulopathy

The liver is responsible for the synthesis of most of the coagulation factors (except Factor VIII, which is produced by endothelial cells) and some of the inhibitors of coagulation and fibrinolysis. In acute liver failure, circulating levels of fibrinogen, prothrombin, and Factors V, VII, IX, and X are reduced, and the prothrombin time is widely used as an indicator of the severity of liver damage. In addition to decreased synthesis of coagulation factors by the liver, increased peripheral consumption is evident. Overt disseminated intravascular coagulation (DIC) is occasionally observed, especially in the pregnancy-related syndromes, but sensitive investigative techniques point to the presence of a low-grade process in most patients. Both quantitative and qualitative defects in platelet function are well described in acute liver failure, and platelet counts of less than 100×10^9/L are seen in up to 70% of patients. Platelet aggregation is impaired, but there is an increase in platelet adhesiveness, a pattern that may be due to increased levels of circulating von Willebrand factor.

Poor correlation is reported between the laboratory and clinical manifestations of the coagulopathy of acute liver failure. This has been attributed to the fact that the decrease in the procoagulant and anticoagulant proteins is proportional (Stravitz & Kramer, 2009). The use of prophylactic repletion of coagulation has never been practiced in the United Kingdom except before significant invasive procedures. Recent data from the United States show that 92% of patients were given fresh frozen plasma at a mean of 14 units during the first week of hospitalization, even though it was acknowledged that only a minority of patients had gastrointestinal bleeding or intracranial pressure monitoring (Munoz et al, 2008). The practice of prophylactic repletion of clotting factors is also controversial because it may interfere with assessment of prognosis, especially in patients being considered for liver transplantation. The highest risk of bleeding is seen in those with an associated thrombocytopenia or a frank DIC syndrome rather than in the patients with isolated severe prolongations of prothrombin time. It has been proposed that the lack of coagulation factors does not result in a bleeding diathesis unless accompanied by an inadequate platelet scaffold on which to propagate a clot (Stravitz & Kramer, 2009). Clinical bleeding is managed by infusions of fresh frozen plasma, cryoprecipitate, and platelets as required. Limited data are available on the utility of recombinant activated Factor VII in this setting (Caldwell et al, 2004).

The severity of the abnormality of coagulation is usually less in acute-on-chronic liver failure, and thrombocytopenia in this setting is usually due to hypersplenism. Patients with protracted cholestasis may have a component to the coagulopathy that responds to parenteral vitamin K. The management of the coagulopathy follows the same principles as in acute liver failure.

Nutrition

Although the standard patient with acute liver failure is well nourished at the onset of the illness, it is important to institute nutrition support as soon as possible (see Chapter 24). The catabolic rate increases in patients with acute liver failure, and this is most apparent in those with complicating sepsis and those undergoing liver transplantation. The theoretical problems that limit nutrition options are legion: gastrointestinal ileus, desire to minimize gastrointestinal protein, difficulty maintaining isoglycemia, fluid restrictions secondary to renal failure, amino acid ratios possibly mediating encephalopathy, difficulty handling lipids, aggravation of sepsis by intravenous feeding, and so on. Despite all these considerations, adequate nutrition support can be obtained in the majority of patients. An element of enteral nutrition is desirable to help maintain the integrity of the small intestinal mucosa, which is titrated against the volume of gastric aspirates and the development of diarrhea.

Nutritional support in acute-on-chronic liver failure is equally important but subject to more constraints. Unlike acute

liver failure, these patients are frequently undernourished prior to the onset of the episode of acute-on-chronic liver failure. Protein intake should not exceed 60 g/day in patients with encephalopathy. There may also be restrictions on fluid volume and the sodium content of feeds. A substantial proportion of patients will have some degree of insulin resistance that may lead to hyperglycemia with high carbohydrate intake. There is little evidence that patients with problematic esophageal varices do not tolerate the presence of nasogastric tubes for feeding purposes.

CHAPTER 73

Support of the failing liver

Geir Nedredal, James E. Fisher, Joseph B. Lillegard, Achilles A. Demetriou, and Scott L. Nyberg

THE FAILING LIVER

A failing liver is a serious condition that warrants a multimodal approach. The best option for a failing liver from either acute liver failure (ALF) or decompensated liver failure, is liver transplantation (Burroughs et al, 2006). However, the rapidity of progression and variable course of ALF, which includes progression to hepatic coma and the possibility of cerebral herniation, limit the effectiveness of transplantation. Furthermore, the downside of orthotopic liver transplantation is lifelong immunosuppression, and the side effects of these drugs include nephrotoxicity, diabetes mellitus, and infections.

The incidence of ALF in the United States is 2000 to 3000 persons per year (Ostapowicz et al, 2002), but the number is much higher for patients with acute decompensation of chronic liver failure (>200,000). The outcome of ALF varies by etiology: those with favorable prognoses are acetaminophen overdose, hepatitis A, and ischemia, with approximately 60% spontaneous survival (Lee et al, 2008). Etiologies with poor prognoses are drug-induced ALF, hepatitis B, and idiopathic cases, with approximately 25% spontaneous survival.

Several promising approaches are being evaluated, including cell transplantation and the application of extracorporeal liver support. These approaches are promising in the setting of ALF because a complete recovery will not impose sequelae such as lifelong immunosuppression with liver transplantation. The aim of extracorporeal support in the setting of decompensated cirrhosis, on the other hand, is to return the patient to the compensated state, but it does not offer the possibility of cure. Extracorporeal liver support serves as a treatment of choice for both ALF and decompensated cirrhosis or as a bridge to transplantation, whereas orthotopic liver transplantation is the definitive treatment. A failing liver may not regenerate or recover completely; buying time to bridge to liver transplantation can be lifesaving. Because of high mortality rates, increasing wait lists, and an expansion of indications for transplantation, interest in liver-assist devices is great.

This chapter emphasizes novel and promising techniques, such as extracorporeal liver support and cell transplantation. A historic summary of the different attempts to support the failing liver is also reviewed. Extracorporeal liver support isdivided into *biologic* and *nonbiologic* systems.

MEDICAL THERAPY

Once a patient is diagnosed with ALF, medical management must be initiated in a coordinated, systematic fashion (see Chapter 72). The goals of medical management are to 1) facilitate recovery, 2) reduce ongoing liver injury with N-acetyl cysteine, 3) prevent systemic manifestations such as cerebral edema, 4) correct hemodynamic instability, and 5) start preparing for liver transplantation if necessary. Treatment measures are initiated according to the severity of hepatic encephalopathy (HE).

For patients in stage I HE, evidenced by behavior changes with no changes in consciousness, baseline laboratory values are obtained for serum electrolytes, Mg^{2+}, Ca^{2+}, lactate, arterial blood gases, liver function tests, lactate dehydrogenase (LDH), ammonia, complete blood count (CBC), albumin, and coagulopathy panel. Twice-daily glucose checks are also recommended. Vitamin K is administered to help prevent or correct coagulopathy (Pereira et al, 2005), and lactulose is given orally for at least two loose stools per day because elevated blood ammonia can be detrimental. Ulcer prophylaxis is also started (Macdougall et al, 1977). Therapeutic measures are initiated when indicated, such as N-acetyl cysteine for acetaminophen overdose (Smilkstein et al, 1988).

If a patient progresses to stage II HE—with disorientation, delayed mentation, and asterixis—the measures for stage I HE are continued, and the patient is transferred to the intensive care unit (ICU) for a multidisciplinary evaluation from a critical care intensivist or hepatologist in consultation with a neurologic intensivist and a liver transplant surgeon. The patient's level of consciousness is scored using both the Glasgow Coma Scale and the Mayo Clinic FOUR (Full Outline of UnResponsiveness) score (Wijdicks et al, 2005). Laboratory work obtained for stage I HE patients is continued on a routine schedule.

A head computed tomographic (CT) scan or a magnetic resonance image (MRI) scan is obtained to evaluate brain edema and rule out other causes for mental status change, such as hematoma. Depending on the clinical picture, either enteral or parenteral nutrition is begun, with a protein load not to exceed 0.5 g/kg/day and with caloric intake based on Harris-Benedict guidelines: ideal body weight plus 20%. Branched-chain amino acids (HepatAmine) are used at the discretion of dietetics, and antifungal and antiviral prophylaxes are considered because of the high incidence of opportunistic infections in the setting of ALF (Rolando et al, 1996). If these patients require sedation, we advocate the use of the short-acting agent propofol (Wijdicks et al, 2002).

As patients progress to stage III HE, endotracheal intubation is performed to protect the airway and initiate mechanical ventilation. Goals of ventilatory support are to maintain a

PaO_2 greater than 70 mm Hg, preferably using an FiO_2 less than 40%. Mannitol is used to control intracranial pressure, with a goal serum osmolality of 310 to 320 mEq/L (Canalese et al, 1982); it is discontinued if oliguria develops. Simple maneuvers are initiated to lower intracranial pressure (ICP), such as keeping the head of the bed elevated between 30 and 45 degrees, limiting endotracheal suctioning, decreasing stimuli from lighting, and controlling agitation with propofol. IV fluids are adjusted to maintain serum Na^+ between 140 and 150 mEq/L. Vasopressors are used to increase the mean arterial pressure (MAP) if the cerebral perfusion pressure (CPP) falls below 60 mm Hg. Vasodilators are used to decrease MAP if the CPP is above 100 mm Hg. More invasive monitoring systems are also instituted, including an arterial line and an ICP monitor (Vaquero et al, 2005). Prior to ICP monitor placement, a coagulation profile is obtained and INR is corrected to 1.5 or less with fresh frozen plasma. If correction requires large volumes of fresh frozen plasma, we consider the addition of recombinant Factor VII (Shami et al, 2003). The cerebral perfusion pressure (CPP = MAP – ICP) is maintained between 60 and 100 mm Hg. If the CPP falls below 60 mm Hg or the ICP rises above 20 mm Hg for more than 5 minutes, the patient is hyperventilated to a $PaCO_2$ of 25 to 30 mm Hg (Strauss et al, 1998). Hyperventilation is only maintained short term.

Intracranial hemorrhage must be excluded if ICP remains high. Ultrasounds to assess hepatic mass and vasculature are obtained every 2 days. Hemodynamic instability often occurs secondary to a systemic inflammatory response (Rolando et al, 2000) or intravascular depletion. Intravascular volume is monitored with a Foley catheter for continuous urine output assessment and either a central venous or pulmonary artery catheter and is maintained for adequate end-organ perfusion. Human 5% albumin is the volume expander. Continuous venovenous hemodialysis is preferred in renal failure and ALF because of the risk of hypothermia and reduced CPP during intermittent hemodialysis (Davenport et al, 1993).

Hypothermia (33° to 35° C) is considered if cerebral edema is refractory to other therapies (Jalan et al, 2004). The duration has not been standardized, although some centers discontinue hypothermia before transplantation because of the risk of bleeding. Other centers continue hypothermia for 24 hours after transplantation because of late risks of cerebral edema.

If patients proceed to stage IV HE (coma, unresponsive to stimuli), the same measures started for the previous three stages are continued. If seizures occur in these patients, metabolic causes, such as hypoglycemia and electrolyte imbalances, must be ruled out. Electroencephalographic monitoring is initiated in the case of status epilepticus, which is treated with benzodiazepines. Stage IV HE patients are also evaluated for evidence of irreversible brain damage or brain death because both are contraindications to liver transplantation.

NONBIOLOGIC LIVER SUPPORT

Plasma Exchange and Hemodiafiltration

Plasma exchange was a natural outgrowth of the less effective blood-exchange transfusion technique. The goals of plasma exchange in ALF are to reduce the level of circulating toxins and to replace deficient essential factors, such as clotting factors produced by the liver. Plasma exchange is achieved by apheresis, with removal of the patient's jaundiced plasma and replacement with normal plasma. The results of early clinical trials were discouraging; encephalopathy often improved temporarily, but patient survival was not affected. Therapeutic gains, such as reduction in serum bilirubin and partial recovery from coma, were short lived and seen predominantly in patients with drug-induced ALF (Freeman et al, 1986; Lepore et al, 1972; Sabin et al, 1968). The overall survival rate of ALF patients treated by plasma exchange remained less than 50% (Takahashi et al, 1991). In addition, a significant complication rate was reported with plasma exchange, including chemical toxicity, viral infections, and death from lung and brain complications (Brunner et al, 1987). However, the effects of repeated, high-volume plasma exchange in patients with ALF have been studied under nonrandomized conditions (Kondrup et al, 1992).

In 1999, Clemmesen and colleagues investigated the effect of repeated, high-volume (15% of body weight) plasma exchange in 23 patients: 14 patients with ALF and 9 with decompensated cirrhosis (Table 73.1). The etiologies of ALF were acetaminophen in 8, hepatitis in 3, and nonhepatitis (A, B, C) in 3. Of the patients with acetaminophen intoxication, 25% died, and 21% were bridged to transplantation.

In Japan, where the option of liver transplantation is limited by the low rate of cadaveric organ donation, a dual approach that combines hemofiltration with plasma exchange has become popularized as a treatment of ALF (Inoue et al, 2009). In this Japanese study, all patients regained consciousness, and no patient developed brain edema or hepatorenal syndrome during plasma exchange and hemodiafiltration treatment. The median number of treatment sessions was 21 (range, 4 to 30), and 4 of 7 patients (57%) with indeterminate etiology and 1 of 5 patients (20%) with acute hepatitis B infection survived.

Despite its limitations and unproven efficacy, plasma exchange continues to be a frequently used method of liver support in patients with ALF. It is used for the correction of coagulopathy and for nonspecific removal of accumulated toxins.

Historic Blood Purification Options

Throughout the 1960s and 1970s, it was believed that small (<5 kD) dialyzable molecules caused coma in ALF (Kiley et al, 1956; Opolon, 1979). As a result, numerous attempts were made to treat ALF patients with hemodialysis (Kiley et al, 1958; Merrill et al, 1950) and charcoal hemofiltration (O'Grady et al, 1988) for removal of these small toxins. Although case reports and controlled studies of both therapies have shown reversal of hepatic encephalopathy and improved survival (Gimson et al, 1982; O'Grady et al, 1988), neither therapy has been proven successful in prospective randomized trials of either ALF or decompensated cirrhosis.

Albumin Dialysis

The MARS and Prometheus (Fresenius Medical Care, Waltham, MA) liver dialysis systems are two extracorporeal therapies that facilitate removal of nonpolar toxins by albumin in patients with ALF and decompensated cirrhosis.

MARS

MARS was developed by Stange and collegues (1993) in the early 1990s. Briefly, MARS is a two-circuit system composed of a blood circuit and a secondary albumin circuit; these are

Table 73-1

Overview of Important Biologic and Nonbiologic Extracorporeal Liver Support Device Trials

Device	Type of Trial	First Author (Year)	No. Patients	Indication	Survival (%)
Biologic					
Latvian trial	CT	Margulis (1989)	126	ALF, DC, sepsis	BAL + SMT: 63 (37/59) SMT: 40 (27/67)
ELAD	CT	Ellis (1996)	24	ALF, PNF	78 (7/9)
TECA	UCT phase I	Xue (2001)	6	ALF, DC, PHF	33 (2/6)
BLSS	UCT phase I	Mazariegos (2001)	4	ALF, DC	25* (1/4)
AMC-BAL	UCT phase I	Van de Kerkhove (2002)	12	ALF	100* (12/12)
RFB	UCT phase I	Morsiani (2002)	7	ALF, PNF	14* (1/7)
MELS	UCT phase I	Sauer (2003)	8	ALF, DC	100* (8/8)
Hybrid-BAL	UCT phase I	Ding (2003)	12	ALF	25 (3/12)
HepatAssist	RCT	Demetriou (2004)	171	ALF, PNF	BAL + SMT: 71* (60/85) SMT: 62* (53/86)
Nonbiologic					
Charcoal hemoperfusion	RCT	O'Grady (1988)	62	ALF	Device + SMT: 35 (10/29) SMT: 39 (13/33)
BioLogic-DT	CT	Ellis (1999)	10	ALF	0 (0/5)

	RCT	Saliba (2008)	102	ALF	Device + SMT: 85 (45/53) SMT: 76 (37/49)
Prometheus	UCT	Rifai (2003)	11	DC, HRS, PNF	73 (8/11)
	UCT	Grodzicki (2009)	52	ALF, PHF, PNF	54* (28/52)

*Survivors include patients bridged to liver transplantation.

RCT, randomized controlled trial; ALF, acute liver failure; BAL, bioartificial liver; CT, controlled trial; DC, decompensated cirrhosis; HRS, hepatorenal syndrome; phase I, safety assessment trial, PHF, postoperative hepatic failure; PNF, primary nonfunction; SMT, standard medical therapy; UCT, uncontrolled trial

separated by a high-flux dialyzer membrane with a pore size and nominal molecular weight cutoff (MWCO) of approximately 50 to 60 kD. The pore size of this membrane makes it impermeable to albumin but permeable to smaller water and nonpolar waste substances. On the opposing side of this membrane is an albumin circuit that consists of supraphysiologic levels (>10%) of human albumin dialysate. Waste removal occurs by the concentration gradient between the patient's blood and the albumin dialysate in the secondary circuit. The high concentration of albumin is believed to facilitate removal of nonpolar molecules known to bind to albumin. Detoxification of these nonpolar waste molecules occurs when the albumin passes over adsorbent columns, including an anion exchange resin column and an activated charcoal column (Steiner et al, 2004). The secondary circuit also provides conventional low-flux dialysis for detoxification of water-soluble molecules.

One of the earlier MARS trials was an uncontrolled trial of 13 patients who had not responded to standard medical treatment of decompensated liver failure (Stange et al, 1999). The etiologies of liver cirrhosis were hepatitis C in one patient and alcohol abuse in the rest; the precipitating events were unknown in 10 cases. This early uncontrolled study showed an overall survival of 69% (9 of 13). A prospective, controlled trial of the MARS system (n = 12) versus standard medical therapy (n = 11) was performed by Heemann and colleagues (2002) in patients with decompensated cirrhosis. The authors concluded that albumin dialysis was associated with a significant improvement in 30-day survival (11 of 12 survived with MARS, 6 of 11 survived in the control group). An editorial to this study raised concerns regarding stratification, standard medical care before randomization, and the inclusion criteria (Kamath, 2002). A larger randomized controlled trial of the MARS system plus standard medical therapy (n = 39) versus standard medical therapy alone (n = 31) in the treatment of hepatic encephalopathy in advanced cirrhosis was reported by Hassanein and colleagues (2007). In contrast to previous reports on MARS, mostly from European centers, this trial was conducted mostly at centers in the United States. This trial demonstrated that the use of MARS therapy was associated with an earlier and more frequent improvement of grades 3 and 4 hepatic encephalopathy compared with standard medical therapy alone. This 5-day trial did not attempt to assess the role of MARS therapy on survival or cirrhotic patients. A trial that did evaluate survival was reported by Saliba and colleagues (2008). This randomized prospective trial of MARS in the treatment of ALF included 102 patients randomized to MARS therapy (n = 53) or standard medical treatment alone (n = 49). Survival at 6 months was greater after MARS treatment (84.9% vs. 75.5%); however, this difference did not reach a significant level by log rank test.

Along with hepatic encephalopathy, MARS has been shown to improve other secondary end points associated with a failing liver, including renal dysfunction, jaundice, and hemodynamic parameters such as systemic vascular resistance and

mean arterial pressure (Schmidt et al, 2003). One prospective randomized controlled trial showed significant improvement in survival in patients with hepatorenal syndrome (Mitzner et al, 2000). MARS therapy has been associated with prolonged relief of intractable pruritus in patients with cholestatic liver disease (Pares et al, 2004). In addition, in a study by Novelli and colleagues (2007), MARS therapy was associated with an improvement in Model of End-Stage Liver Disease (MELD) scores at 1 and 3 months after treatment.

A meta-analysis of MARS use evaluated patients with ALF or decompensated cirrhosis in four randomized clinical trials involving 67 patients and two nonrandomized trials involving 61 patients. This meta-analysis failed to show a significant survival benefit with MARS treatment (Khuroo et al, 2004). As a result, many clinicians are still hesitant to use MARS therapy on their patients with liver failure because a reproducible survival benefit has not been shown.

Prometheus

Prometheus is another form of albumin dialysis for supporting a failing liver. Prometheus functions by fractionating the plasma component of blood, in which the fractionated plasma is detoxified as it passes through two adsorption columns. Prometheus and MARS differ in the MWCO of their blood-separation membranes. MARS uses a 50- to 60-kD MWCO membrane that does not allow passage of albumin from the blood, whereas Prometheus uses a membrane with a 250-kD MWCO that allows the passage of albumin. Therefore greater potential removal of albumin-bound toxins from the patient's blood is possible with the Prometheus system (Rifai et al, 2003). There have been concerns of dropping the patient's albumin levels using Prometheus (Krisper et al, 2007) and concerns of losing clotting factors, presumably because of reduction in protein C and protein S concentrations after the fractionation and adsorption process (Meijers et al, 2007). As with MARS, a survival advantage of Prometheus over standard medical therapy has not yet been shown in a prospective randomized trial.

BIOLOGIC LIVER SUPPORT

Standard medical care alone has been associated with less than 50% recovery from ALF; therefore an effective liver support device to reduce the need for liver transplantation and increase the possibility of spontaneous recovery is needed. Many investigators believe that liver support at this level of complexity requires the use of a biologic component that comprises a mammalian liver tissue preparation, such as isolated hepatocytes and liver slices, rather than blood detoxification techniques. Accordingly, numerous investigators have used whole livers for cross-perfusion, hepatocyte transplantation, and isolated primary hepatocytes and hepatocyte-based cell lines kept in various configurations to support a failing liver. However, limiting factors that include complexity of the systems, limited availability of high-quality liver tissue, and immunologic barriers have prevented the widespread use of BAL support systems.

Ex Vivo Liver Perfusion

In 1965, Eiseman and colleagues reported the use of xenoliver (porcine) cross-perfusion to treat eight comatose patients. None of these patients survived, but transient clinical improvement, such as awakening from the comatose state, was reported. Later, in 1967, Burnell and colleagues reported the use of human-human cross-circulation in the treatment of three patients with fulminant hepatic failure. Moreover, livers from a variety of species—porcine, dog, and bovine—have been used (Abouna et al, 1970; Chari et al, 1994; Eiseman et al, 1965). Evident after the treatments were symptoms of hyperacute rejection—gastrointestinal bleeding, hemolysis, and thrombocytopenia—and less specific symptoms such as fever and nausea that would subside after each session. Human organs found not to be suitable for transplantation were used in a cross-perfusion setting reported in 1993; in this study, two of three patients were successfully bridged to transplantation, but the last patient did not improve clinically (Fox et al, 1993).

Hepatocyte Transplantation

Transplantation of liver cells, specifically hepatocytes, is promising for patients with inherited liver disorders such as tyrosinemia (Grompe et al, 1994) and hyperbilirubinemia Crigler-Najjar syndrome (Fox et al, 1998), which eventually lead to liver failure.

The possibility of treating liver insufficiencies with hepatocyte transplantation has been investigated over the years. The infusion of purified glucocerebridase in patients with enzyme disorders such as Gaucher disease have been attempted (Brady et al, 1974). Allogeneic hepatocyte transplantation to animals with enzyme deficiencies is a promising option. Studies in 1976 and 1977 showed conjugation of bilirubin in Gunn rats with deficiency in the enzyme uridine diphosphate glucoronyltransferase after alloinfusion of functional hepatocytes in the portal vein (Matas et al, 1976) and both the portal vein and intramuscularly (Groth et al, 1977). Later, a group at University of Minnesota (Sutherland et al, 1977) transplanted hepatocytes both intraportally and intraperitoneally in rats to support the recovery of hepatic necrosis (i.e., acute liver failure induced by dimethylnitrosamine).

Experimental models of liver failure and genetic defects of liver metabolism indicate that transplanted hepatocytes can assume the full range of functions of intact whole livers (Arkadopoulos et al, 1998). Intraportal infusions of hepatocytes in humans succeeded the intraportal infusion of purified enzymes. A limiting factor of enzyme therapy has been only short-term efficacy; the indications for hepatocyte transplantation with functionally intact hepatocytes have been liver failure (Habibullah et al, 1994), as a bridge to liver transplantation because of a failing liver (Strom et al, 1997), treatment of ornithine transcarbamylase deficiency (Horslen et al, 2003), and allogeneic hepatocyte transplantation in humans via the portal vein for Crigler-Najjar syndrome type 1 (Fox et al, 1998). These disorders have been partially corrected by hepatocyte transplantation, and these attempts have shown a proof of principle for cell transplantation therapy despite the effects being only short term (Strom et al, 2006).

Extracorporeal Hepatocyte Systems

Because of the scarcity of donor livers, it is valid to search for artificial means of liver replacement and/or assistance. The aim is to support patients with borderline functional liver cell mass until an appropriate organ becomes available for transplantation, or until their livers recover from injury as a result of a regeneration process. An artificial liver could also support patients during periods of functional recovery after transplantation with marginal livers and after extended liver resections for

trauma or cancer. The development of a bioartificial liver (BAL) is a formidable task that must take into account the vast functions of the liver; this organ is not like the kidneys or lungs, which in a supportive context have one or two functions that need to be supported.

A BAL device can be assessed at different levels, such as relative to short-term and long-term outcomes. Secondary, short-term end points often include improvements in blood levels of bilirubin, ammonia, and alanine aminotransferase (ALT). Other secondary clinical end points often include renal function, pulmonary function, and hepatic encephalopathy. However, the primary and long-term end point is increased survival with or without liver transplantation.

To achieve these effects, an artificial liver should be able to lower blood levels of substances toxic to the brain, liver, and other organs, and it should provide whole liver functions that are impaired or lost. The concept of an artificial liver was developed by Sorrentino (1956), who demonstrated more than 50 years ago that fresh liver tissue homogenate converts urea from ammonium chloride and metabolizes ketone bodies, barbiturates, and salicylic acid. However, it was not until the mid-1970s that Wolf and Munkelt (1975) placed hepatoma cells in the extrafiber space of the hollow-fiber cartridge and showed that an extracorporeal device was capable of performing liver-specific functions, such as conjugating bilirubin.

The first clinically applied BAL support was by Matsumura and colleagues (1987) in California, and the first BAL recipient was a 45-year-old patient in hepatic failure because of an inoperable bile duct carcinoma. The device contained isolated rabbit hepatocytes separated from the patient's blood by a dialysis membrane. Figure 73.1 depicts a schematic overview of a generic BAL.

Clinical Trials of Bioartificial Liver Devices

Nine BAL devices have been evaluated in clinic trials (see Table 73.1). The different systems differ in perfusion rate, cell source, and duration of treatment (continuous vs. intermittent).

Latvian Hybrid Bioreactor Trial

A controlled study with 126 patients from Latvia in the former Soviet Union compared two groups: one group received standard medical treatment (n = 67), and a second group received standard medical treatment and BAL therapy (n = 59) (Margulis et al, 1989). The indications were liver failure caused by viral and toxic etiologies and decompensated alcoholic cirrhosis and sepsis. The device contained pig hepatocytes in liquid suspension along with activated charcoal granules. The 20-mL device was perfused through an external Scribner atrioventricular shunt (i.e., no external pump was applied). The results from this trial are admirable: 63% survival in the BAL-treated group as opposed to 41% in the control group. Of note, there was a selection bias, with 44% comatose patients in the control group as opposed to 33% in the BAL-treated group.

HepatAssist System

The first BAL device to be evaluated in a randomized prospective trial was the HepatAssist System (Circe Biomedical, Lexington, MA) (Demetriou et al, 2004). This was the first biologically based liver-assist device to be tested in an FDA-approved phase II/III trial. This trial enrolled a total of 171 patients, 86 controls and 85 BAL treated. The 30-day survival was 71% for the BAL group and 62% for the control group that received standard medical treatment. A trend was seen toward a better survival in the BAL group, although this difference did not reach statistical significance. Significant improved survival was found in a subgroup of patients with known etiology of ALF treated with BAL. Side effects of ALF included thrombocytopenia, renal failure, and increased intracranial pressure. These were higher in the controls, but the difference did not reach statistical significance. The authors of this proof-of-concept xenogeneic study concluded that the HepatAssist System was safe with regard to zoonosis; all the patients tested negative for porcine endogenous retrovirus after treatment. The HepatAssist System used a hollow-fiber–based configuration with membrane pore size of approximately

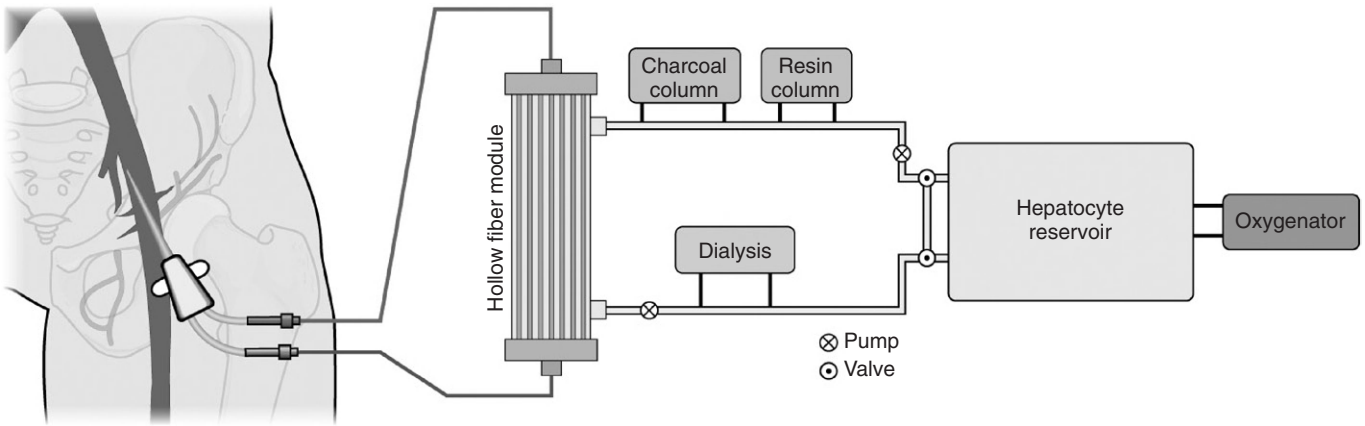

FIGURE 73.1. A schematic overview of a generic bioartificial liver (BAL), which consists of two extracorporeal circuits, a blood circuit, and an albumin circuit in direct contact with the biologic component, liver cells. The two compartments are separated by a semipermeable membrane, consisting of a hollow-fiber module in this example. The molecular weight cutoff of the semipermeable membrane may range from 70 kD to 0.2 μm, and the albumin circuit consists of supraphysiologic levels of albumin (>10%). The patient's blood is detoxified by removal of waste molecules across the membrane into the albumin solution. The waste molecules are eliminated from the albumin solution, when it is perfused through the charcoal and resin columns, or when it is exposed to hepatocytes within the hepatocyte reservoir. Depending on the hydration status and kidney function of the patient, water can be removed from the albumin solution as ultrafiltrate from a high-flux dialysis module. This cycle is repeated continuously during extracorporeal BAL therapy.

0.15 μm to separate the patient's plasma from 7 billion primary porcine hepatocytes in the device. The plasma circuit of the BAL also included a charcoal column and an oxygenator. The future of this system may include a scaled-up version of the device loaded with 14 billion cryopreserved hepatocytes (approximately 140 g) under the new name HepaLife (www.hepalife.com).

Extracorporeal Liver-Assist Device

After several early case reports, the extracorporeal liver-assist device (ELAD) was evaluated by Ellis and colleagues (1996) in a controlled trial of patients with ALF. Two groups of patients were studied: those judged to still have a potentially recoverable lesion (group 1, 17 patients) and patients who already fulfilled criteria for transplantation (group 2, 7 patients). Patients were randomly allocated to BAL treatment or control. The etiologies of ALF were acetaminophen overdose in 17 cases, non-A non-B fulminant viral hepatitis in 5 cases, and hepatotoxicity from antituberculous chemotherapy in 2 cases. Of those who received BAL treatment, 7 (78%) of 9 survived compared with 6 (75%) of 8 in the control group (group 1). Only 1 (33%) of 3 patients from group 2 who received BAL treatment survived compared with one 1 (25%) of 4 in the control group. Biologic activity in the ELAD device was provided by a human hepatoblastoma cell line (C3A) loaded in a hollow-fiber cartridge. Later, Millis and colleagues (2002) reported a study of five ALF patients whose etiologies of liver failure were idiopathic, adverse drug reactions to leukemia treatment, and autoimmune hepatitis. This ELAD device differed from the device used by Ellis and colleagues in 1996 in that four cartridges loaded with hepatoma cells were used by Millis, whereas Ellis only used one cartridge. All patients in the Millis study were successfully bridged to transplantation, and the 30-day mortality rate was 20% (1 patient died). Each ELAD cartridge contained approximately 100 g of C3A cells within the extracapillary space of the hollow-fiber cartridges (a total of 400 g). The membrane used to generate the ultrafiltrate from the patient's blood had a MWCO of 120 kD.

The most recent trial of ELAD (Vital Therapies, San Diego, CA) was reported as an abstract in 2007 (Duan et al, 2007). In that study, 54 patients with decompensated cirrhosis participated in a randomized controlled trial in which ELAD was tested at two different centers in China. The end point was 30-day survival. A significant difference was reached between the control group, with 47% (9 of 19) survival, and the ELAD-treated group, with 86% (30 of 35) survival. A third generation of ELAD will be evaluated in upcoming trials and will include a total of 440 g of C3A cells and increased fiber porosity, from 120 kD to 0.2 μm (www.vitaltherapies.com).

TECA-Hybrid Artificial Liver Support System

The TECA-Hybrid Artificial Liver Support System was tested in a clinical trial (a phase I safety trial) that included six comatose patients with liver failure; isolated primary porcine hepatocytes were used (Xue et al, 2001). The indications were variable and included ALF, decompensated cirrhosis, and postoperative hepatic failure after resection for biliary cancer. The survival rate was at least 33% (2 of 6), and none of the patients was listed for transplantation. The authors applied a hollow-fiber configuration in which plasma circulated inside the hollow fibers with the primary porcine hepatocytes on the outside of the hollow fibers.

Bioartificial Liver Support System

The Excorp Medical (Minneapolis, MN) Bioartificial Liver Support System (BLSS) was evaluated in four patients, two with ALF and two with decompensated cirrhosis (Mazariegos et al, 2001). The etiologies behind ALF were acetaminophen toxicity and adverse effects of chemotherapy, but the etiologies behind the decompensated cirrhosis were Wilson disease and alcoholic hepatitis. One patient was bridged to auxilliary liver transplantation, but the other three did not survive (25% survival). The device contained approximately 120 g primary porcine hepatocytes in a hollow-fiber cartridge perfused with the patient's whole blood.

Radial Flow Bioreactor

A radial flow bioreactor was evaluated in a phase I clinical trial with seven grade III and IV comatose patients (Morsiani et al, 2002). The etiologies included primary biliary cirrhosis, viral hepatitis, primary nonfunction, and liver trauma. Six of seven patients were bridged to transplantation (86% survival rate). Two of seven died, including the patient with liver trauma and subsequent liver transplantation. The trial applied isolated primary porcine hepatocytes (up to 230 g) contained in a radial flow bioreactor.

Modular Extracorporeal Liver Support System

The modular extracorporeal liver support (MELS) system was evaluated in a phase I trial in 2003 that included eight patients with liver failure as a result of etiologies such as hepatitis B (two patients), drug toxicity (two patients), and unknown causes (three patients) (Sauer et al, 2003). The trial demonstrated safety; all 8 patients were successfully bridged to transplantation, and all were alive at the 3-year follow-up. The MELS device is a complex system of four independently functioning hollow-fiber capillary compartments that contain approximately 500 g of primary porcine hepatocytes. The MELS system is the only device clinically tested that has included human hepatocytes (Sauer et al, 2002).

Amsterdam Medical Center Bioartificial Liver

The Amsterdam Medical Center Bioartificial Liver (AMC-BAL) was evaluated in a phase I safety trial conducted in Italy (van de Kerkhove et al, 2002, 2004). The trial enrolled 12 patients; 11 successfully bridged to orthotopic liver transplantation (OLT). One patient survived after BAL treatments without OLT, and four patients died within 1 month after OLT of disease and transplant-related problems. The configuration of AMC-BAL is a three-dimensional, nonwoven, hydrophilic polyester matrix rolled like a mat with oxygen-carrying fibers in between. The patient's plasma is in direct contact with the primary isolated porcine hepatocytes, a configuration that differs from devices that separate the patient's blood and plasma from the cells by a semipermeable hollow-fiber membrane. The AMC-BAL cartridge houses 10 billion hepatocytes.

Hybrid Bioartificial Liver

Ding and colleagues (2003) evaluated their hybrid BAL in a phase I safety trial (Ding et al, 2003). The device was evaluated in 12 patients with ALF. The main etiology was hepatitis B infection after acute decompensation of underlying liver disease. Nine of 12 patients showed clinical and biochemical

improvement. The reported mortality rate was 25%, but the length of the follow-up period was not mentioned. The principle of the BAL was detoxification of plasma with an apheresis unit and a hollow-fiber bioreactor loaded with 10 billion primary porcine hepatocytes.

FUTURE DIRECTIONS

As of today, the BAL devices that have reached clinical testing have been inoculated with hepatocytes from either primary or transformed sources. The trials performed so far have shown safety and proof of concept; however, efficacy data to convincingly demonstrate support of a patient with a failing liver are still missing. Limitations of the first-generation BAL systems have included excess device complexity (Uchino et al, 1988), insufficient hepatocytes to support a failing liver (Margulis et al, 1989), or loss of differentiated function (Matsushita et al, 2003). To address these limitations, a number of research efforts are currently underway. Various novel configurations have been undertaken to improve hepatocyte viability and functional activity in the quest to improve device efficacy. For example, promising reports have shown that combining different cell types of the liver in cocultivation with hepatocytes is a promising option because it more closely mimics the liver environment in vivo (Auth et al, 1998; Bhatia et al, 1999; Nedredal et al, 2007). As another example, Nyberg and colleagues (2005) have developed a novel method of forming hepatic spheroids through gentle oscillation in a rocked bioreactor. Compared with traditional monolayer systems, spheroids show superior function in albumin production, phase I and phase II metabolism, and ureagenesis. In addition, the spheroidal reservoir grown in a bioreactor is capable of supporting 250 to 500 g of primary hepatocytes. This cell mass is increased several times over most first-generation devices. A calculated value of greater than 150 g viable hepatocytes is needed in a BAL to effectively detoxify ammonia, assuming a clinical production rate of 400 μmol/h of ammonia (Nedredal et al, 2009).

Improved detoxification through enhanced mass transfer is another important aspect of future BAL designs. Optimal mass transfer is achieved with the use of semipermeable membranes with an MWCO that provides efficient waste removal and an effective immunologic barrier to protect the nonautologous cells in the BAL. A recent study showed optimal mass transfer with a 400-kD cutoff membrane compared with a 70-kD membrane (Nedredal et al, 2009). Membranes with cutoffs greater than 400 kD, including membranes used for apheresis, may allow immune-mediated damage of xenogeneic hepatocytes in the BAL (Nyberg et al, 2003, 2004).

An abundant source of metabolically active hepatocytes is essential to any successful BAL system. Porcine hepatocytes have been used with limited acceptance because of immunologic concerns and theoretical risks of zoonosis (Cascio et al, 2001; Patience et al, 1997). Meanwhile, immortalized human hepatocytes have yet to be shown to express a full battery of hepatocyte functions that includes ammonia detoxification and normal phase I and phase II activities, along with theoretical risks of malignant spread to an immunocompromised transplant recipient (Mavri-Damelin et al, 2007). These risks of transformed cells have led researchers to explore alternative options for expansion and for hepatocyte-like cells in vitro (Kulig et al, 2004) and hepatocytes in vivo, because efforts to proliferate primary hepatocytes in vitro have been of limited success.

One alternative system for expansion of human hepatocytes in vivo uses u-plasminogen activator–transgenic severe combined immunodeficiency mice (uPA/SCID mice) (Okamura et al, 2006; Sandgren et al, 1991, 1995; Tateno et al, 2004). These transgenic mice express u-plasminogen activator (uPA) under the transcriptional control of a hepatotoxic albumin promoter (Sandgren et al, 1991). Taking advantage of their immunodeficient state, human hepatocytes can be successfully transplanted into these mice without rejection. As the recipient murine hepatocytes die, healthy, unaffected human hepatocytes expand unopposed within the mouse liver, yielding chimeric human/mouse livers (Rhim et al, 1995). This system has led to engraftment levels exceeding 50%. Critics of the SCID-mouse system point to difficulties in animal husbandry, renal disease in the transgenic mice, and difficulties in controlling the mutant phenotype, leading to a narrow window for human hepatocyte transfer (Tateno et al, 2004).

In response to concerns over the SCID-mouse system, an alternative approach has been used to expand human hepatocytes with other transgenic mice. Using immunodeficient $Rag2^{-/-}/Il2rg^{-/-}$ mice, researchers sought to generate an essential hepatocyte deficit and a selective pressure for the stable engraftment of human hepatocytes (Azuma et al, 2007). Fumarylacetoacetate hydrolase (Fah) is an essential enzyme in tyrosine catabolism. Mice deficient for Fah develop tyrosinemia and liver disease in the absence of the protective drug 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione, better known as *NTBC* (Grompe et al, 1995). $Fah^{-1-}/Rag2^{-/-}Il2rg^{-/-}$ triple-knockout mice were shown to be a successful model of stable engraftment and proliferation of human hepatocytes for the treatment of Fah deficiency (Overturf et al, 1998). Animals in this system are easily bred, devoid of renal disease, and are transplantable at a range of ages.

Interesting and promising approaches to hepatocyte production have been made with stem cells (Campard et al, 2008; Basma et al, 2009). Embryonic stem cells are pluripotent, meaning they have the potential to differentiate into most cell types and therefore could be a source of human hepatocytes. This would also increase the possibility of obtaining unlimited numbers of human hepatocytes and thus further the development of cell-based therapies for liver diseases. The potential uses for stem cells are numerous (Fausto, 2004; Karp, 2009). Drawbacks to stem cell–produced hepatocytes are the limited number of approved human cell lines; the lack of recognition of how to control the development of immature stem cells to mature, phenotypic, liver-specific cell types; and the possibility of teratoma formation.

Novel systems for in vivo (Azuma et al, 2007; Sandgren et al, 1991) and in vitro expansion of human hepatocytes are still early in development (Dalgetty et al, 2009; Yu et al, 2007). Critical to any system used to expand human hepatocytes is the ability to produce a large quantity of stable, healthy cells with normal hepatocyte phenotypes. In this regard, in vivo systems appear to be more advanced than in vitro systems; however, in vivo systems are currently limited by the number of hepatocytes that can be expanded from a mouse—approximately 5 g. Therefore cloning studies are underway to extend in vivo systems of human hepatocyte expansion to larger animal models with the prospect of overcoming scale-up limitations. Large animals with humanized livers may someday be a practical source of hepatocytes for cell-based BAL devices.

CHAPTER 74

Management of ascites in cirrhosis and portal hypertension

Kevin Korenblat

HISTORIC OVERVIEW

One of the most visible manifestations of liver disease is that of *ascites,* broadly defined as the pathologic accumulation of fluid within the peritoneal cavity (Runyon, 2009). The almost reflexive association of ascites with liver disease notwithstanding, ascitic fluid volume and composition demonstrate a variability that reflects the range of disease processes, from benign to sinister, from whence it originates.

Descriptions of ascites exist in both human history and prehistory. Indian medical treatises from 1500 BCE, Mayan figurines with protuberant abdomens and everted umbilici, and the writings of Hippocrates all testify to the experience of varied cultures with this problem. Even the term *ascites*—derived from the Greek *askos*, a bag made of leather or sheepskin used to contain liquids—reflects its ancient origins (Reuben, 2004).

High-volume ascites is readily evident on physical examination; however, smaller volumes may evade detection, particularly in the obese. Ultrasound is the best imaging modality for detection of ascites. It is inexpensive, avoids ionizing radiation, and has the added benefit of providing information on liver architecture and portal vein patency (see Chapter 13).

All clinicians should maintain a low threshold for performing paracentesis. The procedure is necessary in the diagnostic evaluation of newly developed ascites, or when there is a change in the clinical condition in an individual with cirrhosis and ascites. A percutaneous approach that avoids the epigastric vessels offers an avascular plane that is safe even in coagulopathic and thrombocytopenic patients (Wong et al, 2008).

The available fluid can be analyzed for concentrations of proteins (albumin), enzymes (lactate dehydrogenase, amylase), and other molecules (glucose, creatinine, bilirubin, and triglycerides) and for a cell count and differential. Peritoneal fluid can also be cultured and submitted for cytologic evaluation.

PORTAL HYPERTENSION AND MECHANISMS OF ASCITES FORMATION

Ascites is the most common complication of portal hypertension arising from cirrhosis, occurring at an annual incidence of 1% (see Chapter 70; Ginès et al, 1987). Its development heralds a significant change in clinical condition, with a median survival of 50% over 2 years (D'Amico et al, 1986). Portal hypertension can arise from cirrhotic and noncirrhotic causes, although as a manifestation of portal hypertension, ascites is most common in disorders that increase pressures within the hepatic sinusoids, either from sinusoidal processes (cirrhosis) or postsinusoidal processes (heart failure, hepatic venous obstruction). By comparison, ascites is uncommon in presinusoidal portal hypertension.

The normal liver architecture consists of sinusoids that convey blood from the portal vein to the central vein. The sinusoids are separated from cords of hepatocytes by a fenestrated endothelium through which oxygen, cells, and plasma components are permitted to diffuse. The principal collagen-producing cells of the liver, the stellate cells, reside within the space of Disse, and activation of these cells leads to collagen deposition (Friedman et al, 1992). Other cells that contribute to the extracellular matrix within the liver are bone marrow–derived myofibroblasts and fibroblasts derived from epithelial-mesenchymal transition (Forbes et al, 2004; Kalluri & Neilson, 2003).

In cirrhosis, extracellular basement membrane deposition of collagen fibers within the space of Disse results in capillarization of the hepatic sinusoids (Huet et al, 1982). The resulting architectural changes cause a static increase in pressure within the splanchnic circulation (see Chapter 6).

The endothelial cells of the liver also play an important role in controlling dynamic changes to the hepatic microcirculation through the elaboration of nitric oxide (Mittal et al, 1994; Shah et al, 1997) and expression of endothelin-1 receptors (Bauer et al, 2000). Decreased endothelial nitric oxide synthase (eNOS) activity (Gupta et al, 1998; Shah et al, 1999), increased eNOS inactivator activity (Liu et al, 2005), and endothelin-1 overexpression in cirrhosis (Pinzani et al, 1996) have all been proposed as mechanisms that promote endothelial cell dysfunction in cirrhosis (see Chapter 6).

In the splanchnic circulation outside of the hepatic environment, different but equally important changes occur that contribute to portal hypertension. The most prominent of these is splanchnic arterial vasodilation. In experimental models of cirrhosis, vasodilation is mediated by NO-dependent (Sieber & Groszmann, 1992; Sieber et al, 1993) and NO-independent processes. The NO-independent processes include those related to endogenous vasodilatory cannabanoids (Garcia et al, 2001) and overexpression of vascular endothelial growth factor (VEGF) and VEGF receptor-2 to promote splanchnic angiogenesis, thereby augmenting blood flow in the splanchnic circulation (Fernandez et al, 2007). Vasodilation in the splanchnic circulation would decrease the effective arterial circulation if not for compensatory increases in cardiac output (Iwakiri & Groszmann, 2006).

With progression of portal hypertension, other compensatory mechanisms are activated to maintain the arterial circulation in the face of even greater increases in vasodilation and declines in cardiac output. These mechanisms include activation of the renin-angiotensin system and sympathetic nervous

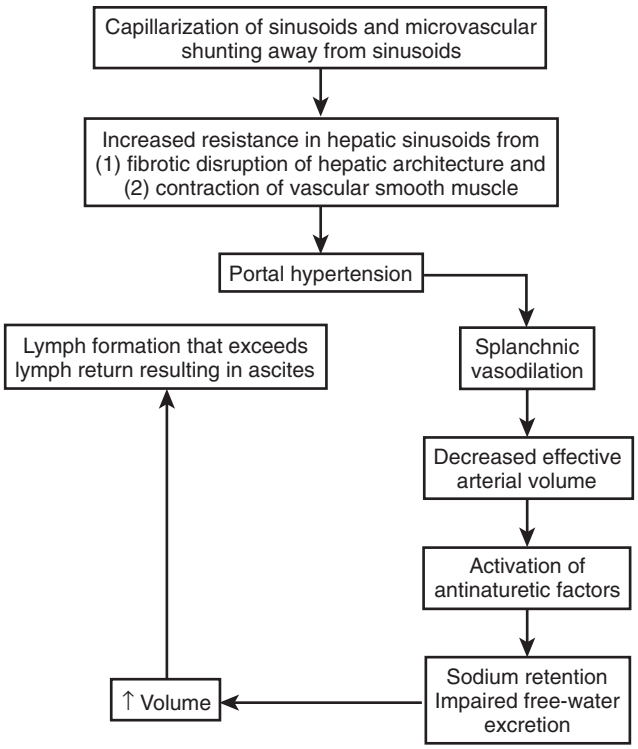

FIGURE 74.1. Mechanisms that lead to the development of portal hypertension and ascites in cirrhosis.

system to stimulate sodium retention by the kidneys (Arroyo et al, 1983). The nonosmotic release of arginine vasopressors is an additional compensatory mechanism to increase the effective arterial volume, even at the expense of tonicity; this is reflected in the development of hyponatremia (Arroyo et al, 1994). The cumulative effect of increased hydrostatic pressure in the hepatic microcirculation in the setting of increased splanchnic volume is that of hepatic lymph formation in excess of its removal; the resulting excess fluid weeps into the peritoneal cavity and is recognized as ascites (Fig. 74.1).

CHARACTERISTICS AND EVALUATION OF ASCITES

Ascitic fluid in cirrhotics is transparent but will generally take on a yellow or amber color. The fluid generally has a low leukocyte (<100 μL/mm) and red blood cell content. The fluid protein is typically less than 2.5 mg/dL, and the protein content varies inversely with the severity of the portal hypertension (Hoefs, 1983). Measurement of the serum albumin ascites gradient (SAAG) is both a highly accurate and clinically facile technique for assessing the origins of ascites. The SAAG is calculated by subtracting the concentration of albumin in the ascites from that in the plasma (Pare et al, 1983). With an approximately 97% accuracy, a gradient greater than 1.1 g/dL indicates the presence of portal or sinusoidal hypertension (Runyon et al, 1992).

Opacification of ascitic fluid can arise from a number of disparate processes. Bloody ascites (hematocrit >0.5) can be seen in traumatic paracentesis or in the spontaneous rupture of hepatocellular cancer. Chylous ascites is milky in appearance from increased concentration of chylomicron-rich triglyceride (Aalami et al, 2000). It arises from processes that disrupt lymphatic flow, most commonly lymphangiectasia and lymphoma, but it can also occur with abdominal trauma and surgical disruption of the cysterna chyli. Cirrhotic ascites can also take on a chylous appearance, owing to rupture of abdominal lymphatics from portal hypertension (Rector, 1984). In these cases, known as *pseudochylous ascites,* the triglyceride concentration is generally less than the threshold value of 110 mg/dL found in pure cases of chylous ascites.

Both malignancy and tuberculosis peritonitis can result in ascites, and in both circumstances the SAAG is less than 1.1 g/dL; however, confusion may arise when liver disease coexists, as in the case of tuberculosis and alcohol-related liver disease (Aguado et al, 1990; Shakil et al, 1996). The diagnosis of malignant ascites is established by the finding of cancer cells within the peritoneal cavity. This can be done by conventional cytology with a diagnostic sensitivity of 40% to 60% (Siddiqui et al, 1992). The accuracy of cytology can be improved when combined with immunohistologic staining (Aslam & Marino, 2001).

The peritoneum is a common site of involvement of tuberculosis (TB), and in the United States, the peritoneum is the sixth most common extrapulmonary site. Peritoneal cell counts typically vary between 500 and 1500 cells/mm^3 with a lymphocyte predominance in 68% (Sanai & Bzeizi, 2005), although the absence of a lymphocyte predominance does not exclude TB, particularly in patients with underlying renal failure, in whom the cells are mostly neutrophils (Lui et al, 2001). Mycobacterial culture of the fluid has a diagnostic sensitivity of 34% and requires several weeks of intubation. Measurement of adenosine deaminase activity in the peritoneal fluid has been proposed as another diagnostic test with high sensitivity and specificity, although the positive predictive value has been reported to be low in the setting of concomitant cirrhosis (Hillebrand et al, 1996). Of all diagnostic strategies, laparoscopy with peritoneal biopsy affords the highest sensitivity and specificity and permits exclusion of other granulomatous and nongranulomatous processes that can produce a low-SAAG ascites. The ascites concentration of lactate dehydrogenase (LDH) tends to be higher than that of serum LDH in malignant ascites and less than half that of serum in tuberculous peritonitis.

MANAGEMENT

Choosing the appropriate treatment for ascites must take into account a number of factors, including the volume of ascites, the severity of liver disease, and the presence of renal dysfunction or electrolyte disorders.

Dietary Sodium Restriction

Avid renal sodium retention is the initial response to splanchnic arterial vasodilation; thus initial treatment strategies involve tipping the balance in favor of a net loss of sodium; this is most simply accomplished with dietary sodium restriction. The estimated mean sodium consumption among nonhypertensive adults in the United States is 3600 mg/day (Ajani et al, 2005). Those with ascites are commonly advised to restrict dietary salt intake to 1.5 to 2 g per day (67 to 87 mmoL/day), the lower value of which is considered adequate for daily needs. In patients with mild degrees of ascites, sodium restriction may be singularly effective. This group usually has baseline rates of sodium excretion of at least 40 mEq/L per day and normal plasma sodium

Table 74.1

Diuretics and Dosages Commonly Used in the Management of Ascites

Medication	Dose	Comments
Aldosterone Antagonists		
Spironolactone	50-400 mg daily	
Amiloride	5-10 mg daily	Suitable substitute when spironolactone use is associated with painful gynecomastia
Loop Diuretics		
Furosemide	20-160 mg daily	Avoid intravenous use

concentrations (Arroyo et al, 1981). Although seemingly a simple intervention, success with dietary salt restriction requires counseling and vigilance. Most of the sodium present is added during food processing, and the patient's actual consumption may not be apparent to them unless food labeling is read and understood (Cook, 2008).

Medical Management

Diuretics

Most patients will at some point require diuretics. Between 500 and 750 mL per day of ascites can be mobilized without intravascular depletion, and greater amounts of ascitic fluid losses may be tolerable in the presence of edema, which tends to act as a buffer (Pockros & Reynolds, 1986). The avoidance of rapid fluid loss is critical because precipitous and excessive volume contraction can give rise to hepatorenal syndrome.

Aldosterone Antagonists

The aldosterone antagonists spironolactone and amiloride (Table 74.1) can be used as either monotherapy or in combination with loop diuretics. These agents prevent sodium reabsorption in the distal tubule and cortical collecting duct. Although aldosterone antagonists are weak natriuretics, they are effective in patients with cirrhosis (Perez-Ayuso et al, 1983).

Urine sodium excretion and plasma aldosterone concentration are hyperbolically and inversely related in patients with cirrhosis, and a greater sensitivity to the dose-response curve is observed in those with ascites (Bernardi et al, 1983). One explanation for the effectiveness of these agents in cirrhotic ascites may be that they target the functional hyperaldosteronism that would otherwise permit sodium reabsorption in the cortical collecting tube of fluid filtered in the loop of Henle. In addition, unlike other diuretics that require access to the tubular lumen, spironolactone enters the principal cell of the collecting duct from the plasma compartment and thereby circumvents decreases in renal blood flow and hypoalbuminemia, commonly encountered in patients with cirrhosis, that might otherwise impair its activity (Horisberger & Giebisch, 1987).

Spironolactone is commonly started at 50 to 100 mg daily. Its dose can be doubled every 3 days to a maximum of 400 mg per day. Its long half-life makes daily dosing permissible even at maximal dosages. Both hyperkalemia and hyponatremia may occur and are best addressed with dose reduction or discontinuation. In men who have tender gynecomastia from spironolactone, amiloride can be substituted at doses of 5 to 10 mg per day.

Loop Diuretics

As monotherapy for ascites, loop diuretics are often unsuccessful. The reasons for this are unclear but may relate to a decreased rate of drug entry into the tubular lumen or to a compensatory increase in distal tubular sodium resorption mediated by aldosterone. By comparison, the combination of loop diuretics and aldosterone antagonists is the most commonly used combination for moderate to severe ascites and can achieve reductions in ascites beyond that of aldosterone antagonists alone. The most commonly used loop diuretic is furosemide (see Table 74.1), beginning at doses of 20 to 40 mg daily. The dose is doubled in a coordinated fashion with increases in spironolactone, until therapeutic effect is achieved. Like spironolactone, a fourfold doubling of the dose (160 mg daily) is considered a maximal dose. An added benefit of loop diuretics is that they counteract the hyperkalemia associated with aldosterone antagonists, and they may also benefit those who develop dependent edema in addition to ascites.

Alhough the parenteral administration of loop diuretics is a common therapy for edema as a result of heart and renal failure, this route should be avoided for the management of ascites because it may precipitate the hepatorenal syndrome. Successful use of diuretics requires diligent monitoring for electrolyte disturbances and azotemia. Advanced cirrhosis is often associated with a catabolic state and lean muscle mass loss; thus even modest increases in serum creatinine may reflect significant impairment in glomerular filtration rate.

The development of azotemia should prompt dose reduction or cessation of diuretics. Renal dysfunction may also be a sign of a complication of liver disease, including spontaneous bacterial peritonitis or portal hypertensive gastrointestinal (GI) bleeding. In these situations, diuretics should be discontinued until the condition resolves.

Albumin

Hypoalbuminemia is a frequent finding in patients with cirrhosis, and it may influence the development of edema and ascites through alterations in plasma oncotic pressure and the activity of loop diuretics in the lumen of the collecting tubule. Limited evidence supports a role for albumin administration as an adjunct to diuretic therapy in ascites that is difficult to control (Gentilini et al, 1999). However, this strategy may not be broadly applicable with the diuretics currently available or when there is recourse to other treatments (Blendis & Wong, 1999). Intravenous albumin administration does have a secure role in the prevention of renal dysfunction, which occurs in the one third of patients who develop spontaneous bacterial peritonitis (Sort et al, 1999). In addition, vasoconstrictor agents used in the treatment of hepatorenal syndrome are more effective when coadministered with albumin than when administered with saline or other crystalloids (Ortega et al, 2002). Thus albumin appears to achieve a successful volume expansion in patients with cirrhosis, greater than that that of crystalloid, which is translatable into improvement in solid clinical end points.

Arginine Vasopression Receptor Antagonists

The nonosmotic release of antidiuretic hormone (ADH) is commonly observed in patients with cirrhosis as a compensatory mechanism for the decrease in effective arterial volume that occurs with splanchnic vasodilation. ADH exerts its effects through arginine vasopressin receptor-2 (AVPR2), which is predominantly expressed in the distal convoluted tubule and

collecting ducts of the kidney (van den Ouweland et al, 1992). Satavaptan is a selective AVPR2 receptor antagonist that has been tested in clinical studies of both the syndrome of inappropriate ADH release (Soupart et al, 2006) and hyponatremia occurring with cirrhosis (Ginès et al, 2008). The study in patients with cirrhosis was a multicenter, double-blind, randomized controlled study of 110 subjects with ascites and hyponatremia. Treatment with satavaptan and spironolactone was associated with improvement in ascites volume concomitant with improvements in hyponatremia more often than the placebo. The use of satavaptan and other aquaretic agents represents a promising area for pharmacologic management of ascites if these early successes are confirmed in other clinical trials.

Refractory Ascites

Ascites that persists despite dietary sodium restriction and high-dose diuretics (spironolactone 400 mg/day and furosemide 160 mg/day) is referred to as *refractory ascites* (Arroyo et al, 1996). *Diuretic-intolerant ascites* describes diuretic failure because of intolerant side effects—such as azotemia, hyponatremia, and encephalopathy—that prevent the attainment of a dose sufficient to effect an adequate ascites loss. The clinical significance of refractory ascites should not be overlooked; the survival curves of individuals with refractory ascites approximate those with type II hepatorenal syndrome (Ginès et al, 2004).

Before labeling a patient as having refractory ascites, it is important to exclude excessive sodium intake and other medications that may influence the diuretic response. In particular, nonsteroidal antiinflammatory agents, including aspirin (Planas et al, 1983), may both decrease the response of diuretics and contribute to azotemia.

Treatment options for refractory ascites includes therapeutic paracentesis, transjugular intrahepatic portosystemic shunting (TIPS) (see Chapter 76E), peritoneal shunting, and liver transplantation (see Chapter 97A).

Paracentesis

High-volume paracentesis, also known as *therapeutic paracentesis,* was a technique known to and practiced by physicians as far back as ancient Greece. It was also the most effective treatment in practice before the development of modern diuretics, after which the practice fell out of favor until it was reintroduced in 1987 as safe and effective (Ginès et al, 1987).

A number of large-bore needles (15 gauge or smaller) of various configurations and features have been manufactured for paracentesis. The procedure can be done with or without ultrasound guidance; commonly chosen sites for needle placement are over the right or left lower quadrant. A variety of techniques have been described for fluid removal, includng drainage by gravity, peristaltic pumps, and vacuum suction, but no single technique is superior to the others (Fig. 74.2).

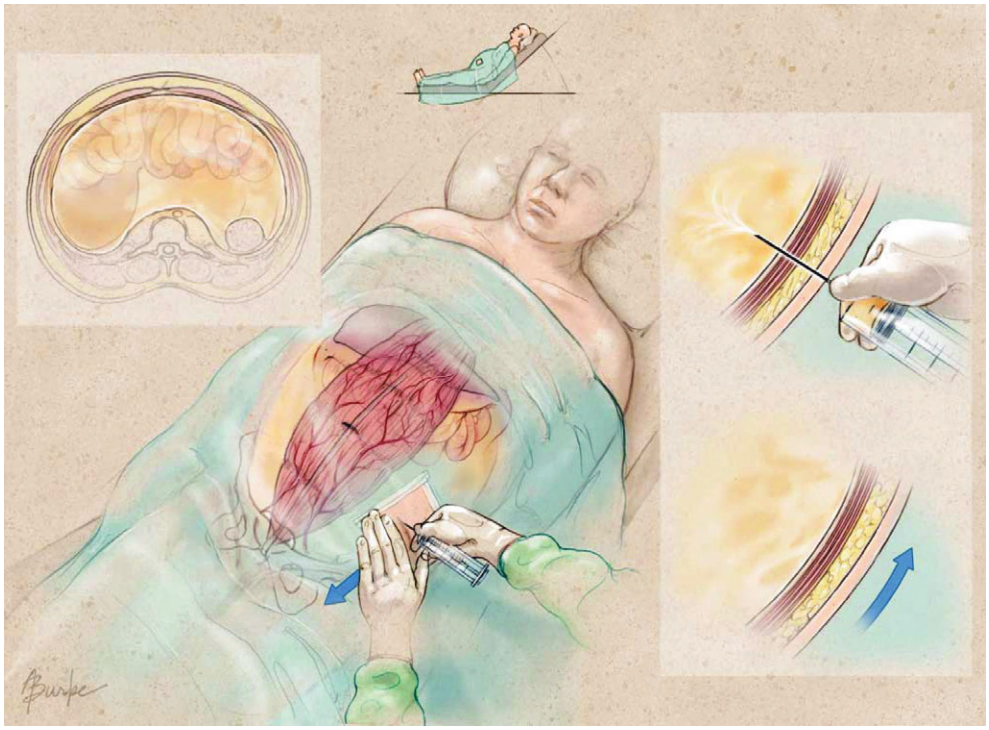

FIGURE 74.2. Patient positioning and performance of diagnostic paracentesis using the Z-tract technique. Diagnostic paracentesis is done with the patient in the supine position with the head of the bed elevated 30 to 45 degrees. Percussion can be used to identify sites of dullness. Commonly chosen sites are the left lower quadrant or 2 cm below the umbilicus, with care taken to avoid the epigastric vessels. The site of needle insertion should be cleaned and draped with sterile technique. With the nondominant hand, stretch the skin 1 to 2 cm caudad to the insertion site. Slowly advance a needle attached to a syringe while gently aspirating. After the ascites is collected, remove the needle, relax tension on the skin, and bandage the insertion site.

There are two central debates in paracentesis. The first centers on the maximal volume of fluid that can be removed at one time, and the second centers on whether circulatory volume expanders are required. Because ascites is extravascular fluid, paracentesis can be safely done until fluid withdrawal is complete. Immediately after paracentesis, cardiac stroke volume and output increase, and the renin-angiotensin-aldosterone (RAA) axis is suppressed. More than 12 hours after paracentesis, a rebound increase in the RAA and increased arterial vasodilation are seen. These changes are reflected in a reduction in systemic vascular resistance and form the basis of *postparacentesis circulatory dysfunction* (Ruiz-del-Arbol et al, 1997), a condition associated with renal dysfunction, a higher incidence of hyponatremia, and decreased survival rate.

The administration of volume expanders at the time of paracentesis is principally done to ameliorate these changes. Studies comparing albumin to other colloidal agents have shown it to be more effective in preventing circulatory dysfunction in paracentesis when the volume removed is greater than 5 L (Ginès et al, 1996). Similar findings have also been described in studies that have compared albumin to saline after total paracentesis (Sola-Vera et al, 2003). In practice, 12.5 g of 25% albumin can be infused for every 2 L of ascites removed. Other groups recommend an infusion of 8 g of 20% albumin for every 1 L of ascites removed (Cardenas et al, 2009). The timing of administration has not been rigorously studied, but because of the long half-life of albumin in the circulation, its administration after completion of paracentesis is likely to be sufficient. The benefits of albumin notwithstanding, no compelling data are available to suggest that albumin administered with paracentesis improves patient survival; however, the sample size of the studies to date may make detecting any survival advantage difficult (Cardenas et al, 2009).

Potential immediate adverse events resulting from paracentesis include hematoma and hemorrhage into the peritoneal cavity. Leakage of ascites can be reduced by using the Z-tract technique (see Fig. 74.2); modest leaks are best controlled by covering the site with an ostomy appliance, but larger volume leaks may require suture closure of the site. No compelling data are available to suggest that repeated high-volume paracentesis predisposes to bacterial peritonitis. There is also no evidence to suggest that the typical patient with high-volume cirrhotic ascites is at risk for abdominal compartment syndrome; thus high-volume paracentesis should not be expected to improve renal function simply by decreased peritoneal ascites volume (Lott, 2010).

Transjugular Intrahepatic Portosystemic Shunts

TIPS (see Chapter 76E) was first introduced experimentally in 1971 (Rosch et al, 1971); its purpose is to create a pathway to bypass sinusoidal hypertension and thereby relieve portal hypertension. To date, four randomized controlled trials have compared TIPS with repeated high-volume paracentesis in the management of ascites. Three of the trials are from sites in Europe (Italy, Salerno et al, 2004; Spain, Ginès et al, 2002; and Germany, Rössle et al, 2000); the fourth is from North America (Sanyal et al, 2003). In all the studies, TIPS was associated with a greater sustained relief of ascites compared with paracentesis; between 49% and 79% of those who received TIPS for refractory ascites were able to achieve sustained relief. The effectiveness of TIPS comes at the cost of an increased risk for episodes of severe encephalopathy. Some studies have shown a survival benefit, but others have not. In one of the multicenter trials, quality of life changes were similar in the two groups (Campbell et al, 2005). A comparison between TIPS and the paracentesis groups for the outcomes of survival, relief of ascites, and incidence of encephalopathy is summarized in Table 74.2.

The magnitude of portal decompression necessary to affect ascites formation is not known. The most common indirect measure of portal hypertension is the hepatic venous pressure gradient (HVPG), which is measured by hepatic vein catheterization with a balloon-tipped, pressure-transducing catheter. However, the HVPG necessary for control of refractory cirrhotic ascites is unknown (Boyer & Haskal, 2009).

A critical ingredient to the success of TIPS is proper patient selection. TIPS is absolutely contraindicated in those with severe pulmonary hypertension and biventricular heart failure. There may also be situations in which TIPS placement would be unfeasible, with extensive portal and mesenteric vein thrombosis, for example, or a large or infiltrative hepatic tumor.

The risk of dying after TIPS is based both on the mortality immediately related to the procedure and mortality after 1 to 3 months, likely reflecting a deterioration of hepatic function from the shunt. The procedure-related risk of death ranges between 1.7% and 3% and may show a dependence on the volume of TIPS done at any particular center (Haskal et al, 2003).

Unlike procedure-related mortality, which cannot be predicted, a number of systems have been offered to predict the

Table 74.2

Comparison of Outcomes for TIPS vs. LVP in Four Randomized Trials

	NO. OF PATIENTS		ESTIMATED 1-YEAR SURVIVAL*		RELIEF OF ASCITES		INCIDENCE OF HEPATIC ENCEPHALOPATHY	
First Author (Year)	TIPS	LVP	TIPS	LVP	TIPS	LVP	TIPS	LVP
Rössle (2000)	29	31	69%	52%	79%‡	24%‡	58%	48%
Salerno (2004)	33	33	77%‡	52%‡	79%‡	43%‡	61%†	39%†
Ginès (2002)	35	35	41%	35%	49%‡	83%‡	77%†	66%†
Sanyal (2003)	52	57	65%	66%	58%‡	16%‡	38%‡	21%‡

TIPS, transjugular portosystemic shunt; *LPV,* large-volume paracentesis

*Survival is defined as 1-year survival without liver transplantation in the studies of Rössle, Salerno, and Ginès. The data for Sanyal are given as overall survival.

†The total number of severe episodes of encephalopathy was greater in the TIPS group compared with the paracentesis group.

‡Identifies comparison with statistically significant *P* values.

short-term mortality. Scoring systems that have been studied include serum bilirubin alone (Rajan et al, 2002), the Acute Physiology and Chronic Health Evaluation II (APACHE II) (Rubin et al, 1995), Child-Turcotte-Pugh (CTP) class, and the Model for End-Stage Liver Disease (MELD) (Malinchoc et al, 2000). The simplest of these is serum bilirubin as a predictor of 30-day mortality, with a 40% increased risk of death for each 1 mg/dL increase greater than 3 mg/dL (Rajan et al, 2002). Although MELD is now most commonly used for organ allocation for transplantation in the United States, it was originally developed to predict the 3-month mortality after TIPS (see Chapter 70B). The MELD score is calculated from the serum bilirubin (Tbil), international normalized ratio (INR), and serum creatinine (Scr) from the equation below, given a maximum value for any variable of 1, a serum creatinine value of 4 or less, and a MELD score no higher than 40.

$$\text{MELD score} = 10\,[0.957\,\text{Ln(Scr)} + 0.378\,\text{Ln(Tbil)} + 1.12\,\text{Ln(INR)} + 0.643]$$

Decreased survival after TIPS has been reported with MELD scores of 15 and greater (Ferral et al, 2004; Pan et al, 2008). In patients with high MELD scores, the risks and benefits of TIPS should be carefully considered, as should the patient's candidacy for liver transplantation as an alternative to TIPS or as a backup if TIPS results in deterioration of liver function.

Peritoneovenous Shunt

Peritoneovenous shunting (PVS) was introduced by Leveen in 1974 for the management of refractory ascites. The shunt is a plastic cannula subcutaneously tunneled with one end in the peritoneal cavity and the other in the central venous circulation. One-way flow is established by a pressure-sensitive valve positioned between the two ends. These surgically placed shunts go by a variety of names—including *Leveen, Minnesota,* and *Denver shunts*—that reflect proprietary differences in their technical details. The placement of shunts results in increases in plasma volume, glomerular filtration rate, and urinary sodium excretion. All these effects reflect favorable physiologic changes to decrease ascites formation; in fact, shunts have been effective in improving ascites.

One of the largest trials to investigate PVS for cirrhotic ascites was the Veterans Administration Cooperative Study on Patients with Alcoholic Cirrhosis with Ascites (Stanley et al, 1989). In this trial, PVS was compared with medical therapy in 299 men with alcoholic cirrhosis. Because the trial predated the discovery of hepatitis C, it is impossible to know how many of the men had cirrhosis from this condition. Regardless, PVS resulted in a slightly faster time to resolution of ascites and a greater time free of ascites. No difference in survival was reported among medically treated subjects and those undergoing PVS. Despite these and other positive clinical trials, PVS is uncommon in current practice. One reason for this is that 40% of shunts stop working within 1 year of placement. This most commonly reflects obstruction, either of the shunt, its valve, or the central vein to which it drains. Adverse events also reported with PVS include pulmonary edema, variceal bleeding, disseminated intravascular coagulation (DIC), and peritonitis (Moskovitz, 1990; Scholz et al, 1989). PVS has also been overshadowed by the widespread availability of both TIPS and liver transplantation; in their own way, each is effective for refractory ascites. Nonetheless, PVS continues to have a role in the management of ascites in children, in the management of chylous ascites, and in patients for whom neither TIPS nor liver transplantation is feasible, such as those with extensive hepatic metastasis.

Liver Transplantation

Liver transplantation is effective in both relieving ascites and improving survival (see Chapter 97A). Although cases of persistent ascites have been reported after liver transplantation (Urbani et al, 2003), these cases are the exception. In all patients with refractory cirrhotic ascites, consideration should be given to liver transplantation as a treatment option.

COMPLICATIONS

Hepatic Hydrothorax. *Hepatic hydrothorax* is defined as a recurrent pleural effusion in patients with end-stage liver disease and portal hypertension in the absence of comorbid cardiac or pulmonary disease (Strauss & Boyer, 1997). Theories proposed to explain the development of hydrothorax include transdiaphragmatic leakage of fluid from lymphatic channels and azygos vein hypertension (Roussos et al, 2007). However, since 1955, it has been known that those who have a hydrothorax develop frequently have defects in the diaphragm that permit egress of ascites into the negative-pressure space of the pleural cavity (Emerson & Davies, 1955). It has been proposed that intrabdominal pressure from ascites leads to herniation of the peritoneum through gaps in the diaphragmatic muscle that eventually rupture into the pleural space. This communication has been further shown by following the passage of various tracers—air, dyes, and radiolabeled substances—from the peritoneal to pleural compartments and by direct thoracoscopic visualization of the defects (Benet et al, 1992; Datta et al, 1984; Huang et al, 2005). Hydrothorax is uncommon; its reported incidence is 5% to 12%, which is remarkably similar to the incidence of hydrothorax with continuous ambulatory peritoneal dialysis (Gur et al, 2004; Lew, 2010). The effusions are mostly right sided, but they can be left sided or bilateral and can be found in patients with minimal or no abdominal ascites (Rubinstein et al, 1985).

Typical respiratory symptoms encountered with a hydrothorax include dyspnea, fatigue, and nonproductive cough. The relationship between hypoxemia and hydrothorax is more complex. Hypoxemia requires ventilation-perfusion mismatching, and the mere presence of a hydrothorax alone, even one large enough to opacify a hemithorax, does not always result in resting hypoxemia. When deoxygenation is documented, the possibility of underlying acute or chronic parenchymal lung disease or the hepatopulmonary syndrome must be considered as a cause of the hypoxemia before attributing it to the hydrothorax.

Hepatic hydrothorax should be suspected in any patient with cirrhosis and portal hypertension with a pleural effusion. Diagnostic thoracentesis should be performed as a starting point in the evaluation. The hepatic hydrothorax is transudative by traditional criteria of Light and colleagues (1972). Tracking the migration of technetium-99m–labeled albumin or sulfur colloid has been proposed and used to establish the diagnosis of hydrothorax (Holt et al, 1999), although in practice, such tests are rarely used. Rather, diagnosis is reasonable in the setting of a rapidly recurring transudative effusion in a patient with cirrhosis in whom other diseases that would predispose to transudative effusion have been excluded. If doubt persists, measurement

of the hepatic venous pressure gradient can help support the diagnosis and exclude right-sided heart failure.

Therapeutic thoracentesis is safe and can provide immediate relief from dyspnea (Castellote et al, 2001; Xiol et al, 2001). By comparison, tube thoracostomy, also known as *chest tube placement,* should be avoided if at all possible. Prominent complications associated with chest tube placement for hydrothorax include infection and acute renal failure, the latter likely reflecting large volume losses. Chest tube placement is also associated with poor outcomes in small, retrospective studies (Orman & Lok, 2009).

The principles of management of a hydrothorax are similar to those of ascites. Dietary salt restriction followed by diuretics is the first line of treatment. Even if these treatments are modestly successful, they may still be inadequate to relieve symptoms given the small capacitance of the pleural space. In these situations, TIPS should be considered early. Although the data supporting a role for TIPS in hepatic hydrothorax are not as certain as those for ascites, in one study of 73 patients undergoing TIPS for hepatic hydrothorax, a favorable clinical response was found in 79% and 75% at 1 and 6 months, respectively (Dhanasekaran et al, 2009). Not surprisingly, liver transplantation is also an effective treatment of hydrothorax.

Surgical repair of the diaphragmatic defects has been described in small series of patients (Mouroux et al, 1996). Obvious limitations to the procedure are the operative morbidity and mortality in patients with end-stage liver disease. Management of hydrothorax is particularly challenging in individuals for whom TIPS is contraindicated and in those whose hydrothorax is refractory to TIPS. One therapy used for refractory hydrothorax is tunneled pleural catheters (Park et al, 1997), which are used for the management of refractory malignant effusions. The risk of infection is theoretically reduced because the catheters are tunneled and it is a closed system. Furthermore, because they are designed for periodic use, the rate of fluid loss can be controlled. Catheters have also been proposed as useful in the palliative care of patients with end-stage liver disease (Sanchez & Talwalkar, 2006), but further studies are needed to determine whether catheters have any role beyond that of palliation.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial infection of cirrhotic ascites in the absence of suppurative infection or bowel perforation was first described by Conn and Fessel in 1971. Since then, this condition, termed *spontaneous bacterial peritonitis* (SBP), has emerged as one of the most common and feared complications of cirrhotic ascites. The prevalence and consequences of SBP are substantial: between 10% and 27% of patients with cirrhosis who have ascites will have SBP at the time of hospitalization (Guevara et al, 1998). It is also both a potentially lethal complication of cirrhosis and a marker of decreased survival. Twenty years ago, studies of patients presenting with their first episode of SBP reported a mortality rate of 47% (Tito et al, 1988). Those who survived the immediate infection still faced a high risk of dying, and in a majority of these late deaths, renal failure was judged to have played a significant role.

The forces that promote infection of ascites remain incompletely understood. The most common organisms to cause SBP are enteric gram-negative aerobic bacteria, and studies of cirrhosis in animal models show increased bacterial translocation (Casafont et al, 1997). The cirrhotic host may also be uniquely susceptible to infection as a combined effect of decreased reticuloendothelial and leukocyte function (Rimola et al, 1984) and diminished opsonic activity of ascites fluid (Runyon, 1988). The opsonic activity correlates with ascites protein levels, and patients with ascites protein less than 10 g/L have a greater probability of developing peritonitis than do those with higher ascites protein levels (Runyon, 1986).

Symptoms of SBP are varied and protean. Obvious symptoms include fever and abdominal pain, but more subtle symptoms are those of decompensation of liver disease, including acute renal dysfunction, encephalopathy, and jaundice. Gastrointestinal (GI) bleeding as a manifestation of SBP illustrates the interrelatedness of these functions in cirrhosis. GI bleeding can both promote bacterial translocation, and therefore increase the risk of SBP, and bacterial infection can result in further mesenteric vasodilation, which increases the risk of portal hypertensive bleeding. Most importantly, patients with bacterial peritonitis can be asymptomatic.

Paracentesis to exclude SBP should be performed in all subjects with new-onset ascites and in those with a change in clinical condition. The diagnosis of SBP rests on the demonstration of an abnormally high neutrophil count in the ascites fluid or culture of an organism from the fluid. The combination of the two is properly termed *spontaneous bacterial peritonitis.* By comparison, *culture-negative neutrascites* (CNNA) is the appropriate term when neutrascites alone is present. These terms notwithstanding, the natural history of SBP and CNNA are indistinguishable and should be treated in a similar fashion (Runyon, 1990). *Bacterascites* is the term applied to a positive ascites culture in the absence of neutrascites. Limited information on this subset of patients suggests that the infection may be transient (Pelletier et al, 1991).

No fewer than 747 citations have been reported to test the diagnostic accuracy of neutrophil counts in the diagnosis of SBP (Wong et al, 2008). The threshold that is commonly accepted is a neutrophil count greater than 250 polymorphonuclear cells (PMNs)/μL. If the ascites is bloody or the paracentesis traumatic, the neutrophil counts in the fluid should be adjusted for the number of red blood cells present. Inoculating ascites directly into blood culture media at the bedside increases the likelihood that organism will be recovered (Runyon et al, 1990). It has been estimated that for every five patients whose ascites is immediately inoculated into culture media rather than delayed by inoculation in the microbiology lab, one additional bacterial infection will be detected (Wong et al, 2008).

Particularly high neutrophil counts or the recovery of multiple microbiologic organisms should raise concern for secondary peritonitis that would reflect either a suppurative abdominal infection or bowel perforation. Measurement of ascites fluid protein, LDH, and glucose can help distinguish between spontaneous and secondary peritonitis. Secondary peritonitis should be strongly suspected when any two of the three following conditions are met: 1) glucose levels are less than 50 mg/dL, 2) ascites protein concentration is greater than 1 g/dL, and 3) LDH is greater than the upper limit of the reference range of serum LDH (Akriviadis & Runyon, 1990).

Antimicrobial therapy should be promptly started after SBP is diagnosed. The initial treatment should be parenteral and cover the typical organisms associated with SBP. In common practice, the antibiotics of choice are third-generation cephalosporins, particularly cefotaxime (2 g/12 h) (Rimola et al, 1995)

and ceftriaxone (1 to 2 g/24 h). Other antibiotic choices may be appropriate when chosen because of local microbial resistance patterns, medication allergies, or the patient's prior pattern of infection. Five days of therapy are as efficacious as 10 days of therapy (Runyon et al, 1991). Antifungal therapy is generally not required as empiric, first-line therapy. This treatment may, however, have a role in surgical patients who develop SBP while receiving antibacterial therapy, patients with peritonitis despite adequate antibacterial therapy, or in patients with secondary peritonitis.

The administration of intravenous albumin has emerged as a critical adjunct to antibiotics for the treatment of SBP. The major benefit of albumin is in the prevention of renal dysfunction, which occurs in as many as 30% of those with SBP despite effective antibiotic therapy. In a trial comparing a control group that received antibiotics alone to a group that received albumin and antibiotics, the rates of renal impairment were reduced from 33% to 10%, and the hospital mortality rate was reduced from 29% to 10%, respectively (Sort et al, 1999). The dose of albumin used was 1.5 g/kg body weight at diagnosis and 1 g/kg body weight on day 3. Subgroup analysis suggests that patients with preexisting renal impairment or serum bilirubin level greater than 4 mg/dL are most likely to benefit from this intervention.

Antibiotic prophylaxis has also been proposed for subjects with prior episodes of SBP or in those with an ascites protein content less than 10 g/L. A Cochrane review of the subject, limited to those without GI bleeding, found that antibiotic prophylaxis was associated with reductions in both episodes of SBP and death, with very few reported adverse events; however, the study also raised concern about the methodology of many of the studies used to reach the conclusion (Cohen et al, 2009).

CHAPTER 75A

Medical management of bleeding varices: primary and secondary prophylaxis

Hector E. Nazario and James F. Trotter

OVERVIEW

Variceal bleeding is the most serious complication of cirrhosis, with an up to 50% mortality rate within 30 days of presentation. However, as management has improved, so have patient outcomes (Carbonell et al, 2004; El-Serag & Everhart, 2000; Jamal et al, 2008a; Stokkeland et al, 2006). Specifically, the 30-day mortality rate has decreased from 30% to 43% in earlier eras to only 15% to 21% currently. These lower mortality rates may be attributed to the combined effects of aggressive clinical treatment protocols and the development of more effective therapies such as endoscopic band ligation; intravenous vasoactive medications, such as octreotide and terlipressin; and antibiotic prophylaxis. For example, Carbonell and colleagues (2004) reported that nearly all patients currently admitted for variceal bleeding receive antibiotic prophylaxis (94%) and endoscopic therapy (90%) within 24 hours compared with only 2% and 6%, respectively, 20 years ago. In addition, evidence suggests that prophylactic therapy is reducing the overall rate of bleeding; currently 15% fewer patients are hospitalized than a decade ago (Jamal et al, 2008b). This finding underscores the clinical utility of the early diagnosis of esophageal varices through aggressive screening strategies, careful surveillance for small varices, and prophylatic therapy with either β-blockers or endoscopic band ligation before or after variceal bleeding occurs.

DIAGNOSIS OF ESOPHAGEAL VARICES

Screening for esophageal varices is an important component in the long-term management of patients with portal hypertension because effective therapy may be applied once varices are identified. The gold standard test is upper endoscopy (de Franchis, 2005; Garcia-Tsao, 2007, 2008), during which the variceal size and presence of red wale markings should be noted. Varices are classified in three sizes: *small* varices show minimal elevation of veins above the mucosa; *medium* describes varices with tortuous veins that occupy less than one third of the lumen; and *large* varices occupy more than one third of the lumen. However, as recognized by all experienced endoscopists, the interobserver agreement in size estimation of esophageal varices varies (Bendtsen et al, 1990).

The diagnosis of esophageal varices should be considered in any patient with cirrhosis. (Garcia-Tsao et al, 2007; Garcia-Pagan et al, 2008). Because the risk of variceal progression and bleeding depend on both the severity of the underlying liver disease and appearance of the varices at endoscopy, patients with decompensated liver disease and high-risk endoscopic features (large varices, red wale markings) require more aggressive screening protocols. In addition, screening may also be appropriate in selected patients with bridging fibrosis because 16% may have esophageal varices (Sanyal et al, 2006). The likelihood of finding varices in a particular patient largely depends on the severity of the underlying liver disease, with a prevalence of 60% and 30% in decompensated and compensated patients, respectively (D'Amico et al, 1995; Sanyal et al, 2006). Once endoscopy has been performed, the presence or absence of varices has been established, and the varices have been graded according to severity, the requirement for further screening, surveillance, and therapy may be determined. In general, treatment recommendations for medium varices are the same as for large varices. The general protocol for screening and treatment is outlined in Table 75A.1.

In cirrhotic patients without varices, the risk of varices subsequently developing is approximately 8% per year (Groszmann et al, 2005; Merli et al, 2003). The recommended screening interval to detect varices in such patients is within 3 years. With a yearly risk of new varices of 8%, the cumulative risk of developing new varices over 3 years would only be about 25%, and during this interval the risk of bleeding is quite small (1% per year) (Groszmann et al, 2005; Merli et al, 2003). Because the risk of developing varices is higher in patients with decompensation, the screening interval may be shortened in this instance (North Italian Endoscopic Club, 1988). Prophylactic therapy with β-blockers to prevent the development of varices or bleeding in cirrhotics without varices is not effective, as was determined by two randomized studies, one with propranolol (Cales et al, 1999) and one with timolol (Groszmann et al, 2005). Because both studies failed to show a benefit with nonselective β-blockers in these populations, the pharmacologic prevention of varices, or "preprimary prophylaxis," is not possible at present.

In the patient with small varices identified at initial endoscopy, the yearly risk of developing large varices is 7% to 12% (Cales et al 1999; Merkel et al, 2004) and the risk of hemorrhage is only 5%. Repeat endoscopy should be performed at 2 years or yearly in the case of decompensation. Prophylactic treatment with β-blockers in patients with small varices has led to mixed results. In these studies, one trial reported a higher 2-year rate of developing large varices (31%) with treatment compared with placebo (14%), but the dropout rate in the

Table 75A.1

Screening and Surveillance Recommendation for Esophageal Varices

Patient Characteristics	Screening Interval
Cirrhosis, no prior varices on screening	At diagnosis of cirrhosis
Compensated cirrhosis, no varices on screening	Every 2 to 3 years
Decompensated cirrhosis, no varices on screening	Yearly
Compensated cirrhosis, small varices on screening	Every 1 to 2 years
Decompensated cirrhosis, small varices on screening	Yearly
Medium or large varices on screening	No further endoscopy
Received band ligation	

Table 75A.2

Diagnosis of Esophageal Varices

Technique	Comments
Recommended Diagnostic Strategy	
Upper endoscopy	Gold standard of treatment
Alternative Diagnostic Strategies	
Blood chemistries	Not recommended
Cross-sectional imaging	Not recommended
Transient elastography	Not recommended
Potential for Risk Stratification	
Ultrathin endoscopy	May be useful, rarely applied
Capsule endoscopy	For patients who cannot or will not undergo conventional endoscopy

study was very high. The other trial reported a lower rate of progression to large varices with β-blockers (11%) versus placebo (37%) after 3 years. The risk of bleeding was lower (12%) at 5 years with treatment compared with placebo (22%). However, the benefit of β-blockers was mitigated by the fact that the rate of bleeding in the placebo group, which was started on β-blockers once large varices were discovered, was the same as treatment once β-blocker therapy was initiated. In addition, the rate of withdrawal because of side effects was higher with β-blockers (10%) compared with placebo (1%). Because of these mixed results, patients with small varices should receive prophylactic β-blocker therapy only if they have risk factors for bleeding, such as advanced liver disease or red wale markings. In patients not receiving β-blockers, repeat endoscopy is recommended every other year or annually for decompensation, and repeat endoscopy is not required for patients taking β-blockers.

In patients with medium or large varices identified at screening endoscopy, prophylactic therapy is clearly recommended, as described below. This group of patients clearly derives the greatest benefit from therapy. The primary treatment options are obliteration with esophageal variceal band ligation (EVL) or reduction of portal pressure with oral pharmacologic agents. There is currently no role for decompressive therapy, transjugular intrahepatic portosystemic shunt (TIPS), or surgical shunting for prophylaxis of variceal bleeding. In addition, endoscopic sclerotherapy has no role in prophylaxis (see Chapter 70B).

NONINVASIVE MEANS OF DIAGNOSING ESOPHAGEAL VARICES

Although upper endoscopy is the most effective screening tool for esophageal varices, the invasive nature of this procedure has led investigators to find alternative noninvasive imaging techniques, as well as methodologies for risk stratifying patients for screening, as shown in Table 75A.2. Noninvasive screening techniques have several potential advantages over endoscopy. They are generally better accepted by patients, which could potentially increase adherence to screening protocols. In addition, these methods are typically less expensive than endoscopy. Finally, varices are absent in most patients (60%) with compensensated cirrhosis. Because the diagnostic yield in this cohort of patients is low, alternative noninvasive screening could risk stratify patients eligible for invasive screening. The four general types of alternative screening modalities are 1) blood chemistries, 2) cross-sectional imaging, 3) transient elastography, and 4) alternative endoscopic techniques, such as ultrathin endoscopy and capsule endoscopy.

The least invasive means of screening for varices is through analysis of blood chemistries. Numerous biochemical parameters have been considered to evaluate the presence of esophageal varices, including platelet count, prothrombin time, serum albumin, and Child-Turcotte-Pugh (CTP) class. However, none of these surrogate markers used alone or in combination is sufficiently reliable for use in clinical practice (D'Amico & Morabito, 2004; de Franchis, 2008; Qamar et al, 2008).

In recent years, cross-sectional imaging, including multidetector computer tomography (CT) and gadolinium-enhanced magnetic resonance (MRI), have been evaluated for esophageal variceal screening. However, compared with CT, there is relatively little experience with MRI (Annet et al, 2006; Goshima et al, 2009; Matsuo et al, 2003). Multidetector CT provides better images than conventional CT, thereby increasing the yield in identifying varices (Kim et al, 2009). In a direct comparison of multidetector CT and conventional endoscopy, both modalities identified varices, and radiologists accurately predicted the presence of large varices 93% of the time (Perri et al, 2008). However, the information from CT imaging was much less detailed compared with endoscopy. The absence of varices was accurately predicted by CT in only about 50% of patients; in more than one third of cases, it inaccurately identified small varices when large varices were seen endoscopically. Aside from limited sensitivity and specificity in variceal screening, CT has several other drawbacks . It cannot provide information about the red wale markings or other stigmata associated with increased risk for bleeding. In addition, exposure to ionizing radiation is significant, especially with repeated CT imaging (de Franchis, 2008; Thabut et al, 2008). However, one potential advantage of CT over endoscopy is its ability to identify other relevant abdominal pathology, namely hepatocellular carcinoma. Currently, cross-sectional imaging is not sufficiently reliable for use in routine clinical screening protocols for esophageal varices.

Transient elastography is an ultrasound technique that noninvasively measures tissue elasticity. This technique is studied primarily for measuring liver stiffness as a means to determine the presence and severity of hepatic fibrosis (Abenavoli et al, 2007; Del Poggio & Columbo, 2009). The test can easily be performed by nonphysicians with a dedicated device by generating a low-amplitude shear wave that propagates through the liver parenchyma. The velocity of propagation is directly proportional to liver stiffness and is automatically calculated by the device and expressed in units of pressure (kPa): the higher the value, the stiffer and more fibrotic the tissue and, by correlation, the more pressure required to deform the tissue. Although universally accepted ranges have not been developed, the general ranges for cutoff values for normal are up to 8 kPa and more than 13 to 18 kPa for cirrhosis.

Aside from being noninvasive and easily performed, the advantages of elastography include assessment of a larger hepatic area than liver biopsy and general correlation with the extent of histologic fibrosis. The disadvantages regarding variceal screening are that it is not a direct assessment of varices, and the test may be inaccurate or unreliable in patients with ascites and in obese patients. In fact, up to 10% of cases may not return any reading (Foucher et al, 2006; Sandrin et al, 2003).

Several studies have evaluated transient elastography in the noninvasive diagnosis and staging of esophageal varices. Theoretically, as liver stiffness and hepatic fibrosis progress, the likelihood of developing esophageal varices should increase. However, this methodology is subject to the same problems as other noninvasive techniques. Using a cutoff value of 12.5 kPa, Castera and colleagues (2009) studied 298 patients with hepatitis C virus (HCV) infection and reported only 76% sensitivity and 78% specificity in the diagnosis of esophageal varices. In another study, investigators compared two cutoff values for liver stiffness in predicting the presence of esophageal varices in 61 patients with advanced fibrosis from HCV (Vizzutti et al, 2007). At a lower cutoff of 17.6 kPa, the sensitivity was 90% and specificity was 43%. At the higher cutoff of 27.4 kPa, more patients with varices were missed (sensitivity of 70%), but specificity improved to 78%. Similar results were reported by Kazemi and colleagues (2006), who examined the correlation between liver stiffness and presence of large esophageal varices.

Although more studies are needed, current data suggest that the diagnostic accuracy of transient elastography is sufficiently limited that it cannot supplant upper endoscopy as a recommended screening technique for esophageal varices (de Franchis, 2008; Del Poggio, 2009). In fact, it seems unlikely that it would ever replace endoscopy as the primary screening tool. However, because it is a less invasive technique, elastography could possibly be used as an adjunct screening methodology. Patients could be monitored for changes in their transient elastography profile between recommended endoscopic screening intervals to potentially identify specific patients at higher risk for variceal progression. However, such screening and surveillance recommendations are only speculative at this point.

During the past decade, the utility of alternative video endoscopic devices has been studied in screening for esophageal varices. One of these modalities is the ultrathin endoscope inserted without sedation via a transnasal and transoral approach. The primary advantage of this procedure compared with conventional endoscopy is the avoidance of conscious sedation with its attendant risks, cost, and inconvenience. Unlike cross-sectional imaging or transient elastography, video endoscopy (ultrathin and capsule endoscopy) provides direct visualization of the esophageal mucosa that may improve estimation of variceal size and red wale markings, which is not possible with cross-sectional imaging. The primary disadvantage of alternative endoscopy is that compared with conventional endoscopy, these devices have a limited field of view and cannot perform interventions such as biopsy or banding.

Limited data are available on ultrathin endoscopy in variceal screening, and most studies, but not all, show that this technique is more easily performed, has greater patient acceptance, and provides an acceptable diagnostic yield compared with conventional endoscopy (Catanzaro et al, 2002; Madhotra et al, 2003; Saeian et al, 2002). However, these results are based on a very small number of patients. Despite some initially promising findings, ultrathin endoscopy has largely fallen out of favor; at most centers, ultrathin unsedated endoscopy is not used for screening or surveillance of esophageal varices.

Esophageal capsule endoscopy is perhaps the most promising option for minimally invasive screening of esophageal varices. This technique involves the ingestion of a capsule videoscope that transmits images as it traverses the esophagus. The patient is supine after ingestion of the device and is gradually placed in the upright position, which increases the transit time in the esophagus to provide better imaging. Compared with conventional endoscopy, capsule endoscopy offers the advantages of direct visualization of the esophagus, the absence of sedation, and less procedural discomfort and time.

Several drawbacks are associated with capsule endoscopy. Interventions obviously cannot be performed, the device cannot be manipulated to change its field of view, and it cannot insufflate the esophagus, which most physicians have found to be a critical step in the proper diagnosis and staging of varices. Finally, capsule endoscopy does not properly visualize gastric varices, which could therefore be missed.

Capsule endoscopy has been studied in the detection and grading of esophageal varices, and de Franchis and colleagues (2008) reported a study comparing capsule endoscopy with conventional endoscopy in 288 patients. The capsule and esophageogastroduodenoscopy (EGD) findings were concordant in 86% of cases. However, capsule endoscopy failed to identify varices in 28 cases, of which 24 (13%) were small and 4 (2.2%) were large varices, although the capsule was significantly more preferred by patients over EGD. Lapalus and colleagues (2009) reported similar results in a cohort of 120 cirrhosis patients, with 77% sensitivity and 88% specificity in the detection of grade 2 and higher esophageal varices and/or red signs compared with upper endoscopy. Smaller studies comparing capsule endoscopy and EGD have yielded similar results (Eisen et al, 2006; Frenette et al, 2008; Lu et al, 2009; Pena et al, 2008). Models comparing cost effectiveness of esophageal capsule endoscopy and EGD imply that they are equivalent strategies (White & Kilgore, 2009).

In summary, upper endoscopy remains the gold standard in screening for the presence and staging of esophageal varices. None of the imaging modalities mentioned above has proven sufficiently reliable to supplant the role of endoscopy in evaluation. However, capsule endoscopy may be used as an alternative, albeit a less effective, screening technique in the small number of patients who either cannot or will not undergo conventional endoscopic screening.

Table 75A.3

Primary Prophylactic Therapy for Esophageal Varices: Prevention of Initial Bleeding

Variceal Grade	Recommended Therapy
No varices	No treatment
Small, CTP class A and no red wale markings	No treatment
Small, CTP class B or C or red wale markings	β-Blocker
Medium or large, CTP class A and no red wale markings	β-Blocker preferred, endoscopic variceal ligation for patients who cannot take β-blockers
Medium or large, CTP class B or C or red wale markings	β-Blocker or endoscopic variceal ligation

CTP, Child-Turcotte-Pugh classification

PRIMARY PROPHYLACTIC THERAPY FOR ESOPHAGEAL VARICES: PREVENTION OF INITIAL BLEEDING

Once identified, all medium and large varices should be treated. In addition, small varices associated with high-risk features for bleeding, such as decompensated liver disease and red wale markings, should also be treated (Table 75A.3). The primary treatment options are obliteration with EVL or reduction of portal pressure with oral pharmacologic agents. Portal pressure can be pharmacologically reduced in three ways: 1) diminishing the portal inflow with vasoconstrictors, 2) reducing the intrahepatic vascular resistance, or 3) reducing the resistance in the collateral circulation with vasodilators. The most commonly used pharmacologic agents are nonselective β-adrenergic blockers, namely propranolol or nadolol, which act as antagonists for both the β_1 and β_2 receptors; β_1 blockade reduces portal inflow by decreasing cardiac output, and β_2 blockade reduces portal inflow through vasoconstriction of the sphlanchnic circulation. In addition, venodilators such as isosorbide reduce portal pressure by decreasing intrahepatic and/or portocollateral resistance. Isosorbide also has a systemic hypotensive effect and reduces portal pressure by reducing inflow as much as it does by reducing resistance (Blei et al, 1987).

The goal of pharmacologic therapy is to reduce portal pressure and thereby reduce variceal bleeding. A decrease in hepatic venous pressure gradient (HVPG) to less than 12 mm Hg essentially eliminates the risk of hemorrhage, and reductions less than 20% from baseline significantly reduce the risk of a first variceal bleed (Casado et al, 1998; Groszmann et al, 1990). Some patients are nonresponders to β-blockers, however, in terms of portal pressure reduction. Bendtsen and colleagues (1991) defined *nonresponse* as a less than 10% reduction in portal pressure after an oral dose of 80 mg of propranolol. Because their withdrawal returns the risk for bleeding to that of the untreated population, β-blockers should be continued for life (Abraczinskas et al, 2001).

Numerous published primary prophylaxis trials with nonselective β-blockers have been performed that include hundreds of patients. The pooled odds ratio (OR) of bleeding with β-blockers is almost half that of placebo: 0.54 (95% confidence interval [CI], 0.39 to 0.74; $P < .001$). The number of patients who need to be treated to prevent one adverse bleeding event is 10 (95% CI, 8 to 18). A study of the early trials reported a nonsignificant trend toward a lower mortality rate (OR, 0.75; 95% CI, 0.57 to 1.06) (D'Amico et al, 1999). Another recent meta-analysis similarly found no difference in mortality rate (Tripathi, 2007). Finally, propranolol has been shown to prevent acute and chronic bleeding from portal hypertensive gastropathy in a single-blind, randomized study (Pérez-Ayuso et al, 1991). β-Blockers are typically started at a low dose (propranolol 20 mg bid or nadolol 40 mg qd) and titrated either as maximally tolerated or for a reduction in pulse rate of 25%. However, side effects of β-blockers prevent their use in approximately 15% of patients, and another 15% are intolerant (Garcia-Pagan et al, 2001). In addition, without directly monitoring the effects of β-blockers with HVPG measurements, their clinical effect is difficult to determine because changes in portal pressure correlate poorly with pulse rate (Garcia-Tsao et al, 1986).

In addition to β-blockers, other pharmacologic agents have been evaluated in the prevention of a first variceal bleed, but the results have largely been disappointing. Merkel and colleagues (2000) performed an unblinded study to evaluate the combination of isosorbide mononitrate and nadolol and found the combination to be more effective in reducing bleeding, with only a small increase in side effects. However, a recent larger controlled trial reported no effect with treatment. A double-blind, placebo-controlled trial by Garcia-Pagan and colleagues (2003) composed of 349 patients found no difference in 2-year actuarial probability of variceal bleeding or survival, with adverse effects being more frequent in the combination group. Studies assessing nitrates used alone have failed to demonstrate efficacy (Angelico et al, 1997; Garcia-Pagan et al, 2001). Currently, clinical evidence is insufficient to support the use of nitrates alone or in combination with β-blockers for prophylactic therapy.

Numerous trials have compared endoscopic therapy with β-blockers in primary prophylaxis for variceal hemorrhage (De et al, 1999; Jutabha et al, 2005; Lo et al, 2004; Lui et al, 2002; Psilopoulos et al, 2005; Sarin et al, 1999; Schepke et al, 2004). Meta-analysis showed that variceal ligation significantly reduced the risk of a first bleed compared with propranolol (relative risk [RR], 0.57; 95% CI, 0.38 to 0.85), but there was no difference in terms of mortality rate (RR, 1.03; 95% CI, 0.79 to 1.36) (Khuroo et al, 2005). These data have led to an intense debate as to whether band ligation therapy should replace β-blockers as the first-line therapy for primary prophylaxis.

Proponents of β-blocker therapy point out that band ligation therapy is associated with an inherent risk of bleeding, which can result in death. In addition, there may be a bias toward positive results relative to endoscopic therapy in studies with shorter follow-up and fewer patients. In the analysis of studies that were larger or had longer follow-up—that is, more than 100 patients or follow-up longer than 20 months—no difference in outcomes was reported between the two therapies (Bosch & Garcia-Tsao, 2009). β-Blockers also have a track record of long-term safety, which cannot be said for band ligation therapy. Finally, endoscopic therapy requires ongoing procedures that may be more costly and have lower patient preference compared with pharmacologic therapy (Longacre et al, 2008).

The statements regarding prophylactic therapy from two separate organizations highlight this debate. The recommendations from the 2005 Baveno consensus conference are that β-blockers should be the first-choice treatment to prevent first variceal bleeding in patients with high-risk varices, and EVL

should be offered to patients with contraindications or intolerance to β-blockers (de Franchis, 2005). The American Association for the Study of Liver Diseases (AASLD) practice guidelines indicate that nonselective β-blockers and EVL are safe and effective in patients with medium or large varices that have a high risk of hemorrhage (CTP classes B and C or variceal red wale markings on endoscopy). The choice of therapies may be left to physician preference, although β-blockers are the preferred therapy in patients with medium or large varices that have not bled and that are not at the highest risk of hemorrhage (CTP class A patients, no red signs). EVL should be considered in patients with contraindications, intolerance, or noncompliance to β-blockers. Finally, the addition of β-blockers administered with EVL has been evaluated in one study, which failed to demonstrate a reduction in the risk of first bleed or death (Sarin et al, 2005).

SECONDARY PROPHYLACTIC THERAPY FOR ESOPHAGEAL VARICES (PREVENTION OF REBLEEDING)

Patients who survive a first episode of variceal bleeding are at very high risk of recurrent bleeding (70%) and death (30% to 50%), with the highest risk period occurring within 6 weeks of the index bleed (D'Amico & de Franchis, 2003; Grace et al, 1998). There is consensus that all patients who have previously bled from varices should have secondary therapy to prevent further variceal bleeding (Box 75A.1; Garcia-Tsao et al, 2007). Severity of liver disease (Pagliaro et al, 1994), continued alcohol abuse (Vorobioff et al, 1996), and variceal size have all been associated with variceal rebleeding. In addition, the inability to reduce HVPG to less than 12 mm Hg or achieve a less than 20% reduction from baseline significantly increases the risk of rebleeding. The treatment of acute variceal bleeding is covered in Chapter 75B.

After control of acute bleeding, prevention of recurrent hemorrhage is considered mandatory and should be initiated as soon as the patient is stable. Numerous trials have been performed on β-blockers compared with placebo or no treatment, and nonselective β-blockers have been found to reduce the risk of subsequent bleeding from 63% to 42% and to lower overall mortality rates from 27% to 20% (Bernard et al, 1997; D'Amico et al, 1999; Garcia-Pagan et al, 2008).

The addition of isosorbide to β-blocker therapy has also been evaluated for the prevention of rebleeding. These studies had their impetus from an article that stated approximately one third of hemodynamic nonresponders to β-blockers become responders after the addition of isosorbide (Garcia-Pagan et al, 1991). One of the two trials showed reduced rates of bleeding (Gournay et al, 2000), and one did not show reduced bleeding (Pasta et al, 2001, abstract). Data gathered from other trials compared this regimen with endoscopic therapy and showed that the combination of β-blockers with isosorbide is approximately 33% more effective than β-blockers alone in the prevention of rebleeding (Bosch & Garcia-Pagan, 2003; D'Amico et al, 1999). Therefore the best possible pharmacologic regimen is the combination of β-blockers and nitrates, although in clinical practice this regimen is associated with increased side effects; thus usually only β-blockers are used (Garcia-Tsao et al, 2007). This is especially true for patients with decompensated cirrhosis who are awaiting liver transplantation.

Trials have been conducted comparing pharmacologic therapy with endoscopic treatment in the prevention of rebleeding. The only modern endoscopic therapy for bleeding esophageal varices is band ligation. Sclerotherapy no longer plays a role in treatment because band ligation has clearly been demonstrated as the more efficacious therapy (Laine & Cook, 1995; Garcia-Pagan & Bosch, 2005; Garcia-Pagan et al, 2008) Therefore, although numerous studies have evaluated sclerotherapy in the prevention of rebleeding, these are largely of historic interest only. In general, after an acute variceal bleed, the patient is treated emergently with band ligation therapy and then subsequently receives recurrent EVL until the varices are completely obliterated, which usually requires three to four treatment sessions. Optimal pharmacologic therapy (β-blockers plus nitrates) has been compared with EVL in four published randomized studies with variable results (Lo et al, 2002; Patch et al, 2002; Romero et al, 2006; Villanueva et al, 2001). One study showed a benefit of pharmacologic therapy, another showed a benefit of EVL, and two showed no difference between the two therapies. A meta-analysis (Ding et al, 2009) of these four studies, which included 476 patients, found no significant difference in the rate of rebleeding, overall mortality rate, or complications between β-blocker plus isosorbide and EVL. Therefore both therapies appear to be effective in the prevention of esophageal variceal rebleeding. A more practical approach may be the combination of β-blocker and EVL because endoscopic therapy would obliterate the varices and recurrence would be prevented by β-blockers. Two studies have compared EVL and EVL plus β-blockers, both of which showed that the addition of β-blockers to EVL reduces the risk of rebleeding and variceal recurrence (de la Peña et al, 2005; Lo et al, 2000). Finally, a recent study by Garcia-Pagan and colleagues (2009) compared nadolol plus isosorbide alone or in combination with EVL. These investigators found that both therapies were equally effective in the prevention of rebleeding, but the patients who received EVL and combination drug therapy were more likely to require rehospitalization. They concluded that the addition of EVL to drug therapy was therefore was less efficacious than drug therapy alone.

Four randomized trials have compared TIPS (see Chapter 76E) with EVL, drug therapy, or the combination for the prevention of variceal rebleeding (Escorsell et al, 2002; Gülberg et al, 2002; Pomier-Layrargues & Villenueve, 2001;Sauer et al, 2002). In general, the side-effect profile was worse with TIPS—two studies found significantly more encephalopathy with TIPS, and two found no difference—but generally better control of

Box 75A.1

Secondary Prophylactic Therapy for Esophageal Varices: Prevention of Rebleeding

1. All patients should receive prophylactic therapy to prevent recurrent variceal hemorrhage.
2. The recommended therapy is β-blockers and endoscopic variceal ligation.
3. An alternative strategy is either β-blocker plus nitrates or endoscopic variceal ligation.
4. TIPS is recommended only in patients with recurrent variceal bleeding refractory to pharmacologic and endoscopic therapy.

TIPS, transjugular intrahepatic portosystemic shunt

bleeding was reported with TIPS, with significantly less rebleeding in two studies and no difference in two others. Most importantly, both these studies found no difference in survival rates. Therefore, because TIPS offers no survival advantage and has a worse side-effect profile, it is relegated to salvage therapy for patients with refractory variceal bleeding that is unresponsive to pharmacologic and EVL treatment.

In summary, the current recommendations for the prevention of variceal rebleeding suggest that all patients receive prophylactic therapy to prevent recurrent variceal hemorrhage. The recommended therapy is β-blockers and EVL (Garcia-Tsao et al, 2007; Gonzalez, 2008), although another consensus statement recommends β-blockers plus nitrates or EVL (de Franchis, 2005). TIPS is recommended only in patients with recurrent variceal bleeding refractory to pharmacologic and endoscopic therapy.

Finally, portal hypertensive gastropathy is a recognized cause of upper intestinal bleeding in patients with cirrhosis. The natural history of portal hypertensive gastropathy is that it worsens with increasing severity of liver disease and portal hypertension; acute bleeding is infrequent. Chronic anemia is more common with mild portal hypertensive gastropathy (Merli et al, 2004; Primignani et al, 2000). Propranolol has been shown to prevent acute and chronic bleeding in a single-blind, randomized study (Pérez-Ayuso et al, 1991). The actuarial percentages of patients free of rebleeding from portal hypertensive gastropathy at 12 months were 65% versus 38% ($P < .05$); at 30 months, the figures were 52% versus 7% ($P < .05$). In addition, fewer episodes of acute rebleeding were reported (mean episodes per patient per month were 0.01 vs. 0.12).

HEMODYNAMIC MONITORING WITH HEPATIC VENOUS PRESSURE GRADIENT

HVPG is equal to the wedge hepatic venous pressure minus free hepatic venous pressure. Some centers have advocated monitoring of HVPG to assess target reductions of portal pressure because HVPG measurement is the most reproducible and reliable method of assessing the portal pressure in cirrhosis (Groszmann & Wongcharatrawee, 2004). Wedge hepatic venous pressure is equivalent to portal venous pressure in cirrhosis when the major site of resistance is sinusoidal or presinusoidal (alcoholic and viral hepatitis B and C) or both. A decrease in HVPG of 20% or more from baseline or to 12 mm Hg or less has been shown to correlate with a significant reduction in bleeding. Therefore HVPG measurement offers the opportunity to tailor a patient's reponse to pharmacologic therapy based on changes in portal pressure. Ideally, HVPG could be measured before the initiation of pharmacologic therapy.

After the maximal tolerated dosage is achieved, HVPG could be remeasured. For patients responsive to pharmacologic therapy, no further treatment or adjustment in dosing would be required. However, nonresponders—that is, patients with portal pressure higher than 12 mm Hg or with a less than 20% decrease from baseline—could receive additional pharmacologic therapy. Some data suggest that this approach is efficacious (Bureau et al, 2002; Feu et al, 1995; McCormick et al, 1998; Patch et al, 2002; Villanueva et al, 1996, 2001). However, titration of medication requires multiple invasive procedures to measure HVPG, and some investigators have suggested that patients with early rebleeding are not available for repeated studies; therefore these high-risk patients are excluded from analysis (Thalheimer et al, 2004). Undoubtedly a valuable tool, the applicability of HVPG needs further prospective evaluation in future studies (Bosch et al, 2009; Garcia-Pagan et al, 2008).

CHAPTER 76A

Location of portosystemic shunting

Stuart J. Knechtle and John R. Galloway

OVERVIEW

Esophageal varices develop in patients with portal hypertension, most commonly secondary to hepatic cirrhosis (see Chapter 70). They occur most frequently in the distal esophagus, although they may be accompanied by gastric varices. Rupture of varices is associated with massive upper gastrointestinal (GI) bleeding with an attendant high mortality rate. Therapy aimed at the prevention and treatment of bleeding varices has included pharmacologic, endoscopic, radiologic, and surgical strategies. All these therapies have evolved technically, and increasing clinical experience has resulted in more accurate definition of the role of each treatment modality. This chapter discusses the appropriate role of surgical shunts for the management of bleeding esophageal varices. An understanding of the role of surgical therapy also requires an understanding of the context in which it is applied, however. The natural history of bleeding esophageal varices is discussed first, followed by a description of the roles of alternative therapies. In current medical practice, it is most appropriate to apply surgical shunts within the context of medical (see Chapter 75A) and endoscopic management (see Chapter 75B), transjugular intrahepatic portosystemic shunts (TIPS; see Chapter 76E), and liver transplantation (see Chapter 97). Many patients are treated sequentially with more than one modality, and algorithms are presented to help establish the appropriate clinical context for surgical shunt therapy.

NATURAL HISTORY OF ESOPHAGEAL VARICES

Esophageal varices may produce massive upper GI bleeding that is difficult to control. Not all varices bleed, and not all patients with cirrhosis or portal hypertension will have esophageal varices develop. Clinical studies have sometimes included control groups without medical intervention, and analysis of these trials has helped define the natural history of esophageal varices. In one series, 46% of 819 patients with biopsy or clinical evidence of cirrhosis and no history of bleeding had esophageal varices by endoscopy (PROVA Study Group, 1991).

Over time, varices may appear, disappear, or change in size depending on alterations in patient physiology. A study of 84 patients with cirrhosis without previous bleeding who were monitored by serial endoscopy over 2 years showed that 31% of patients without varices progressed to large varices over 2 years, whereas in 70% of patients with small varices, the varices enlarged after 2 years (Cales et al, 1990). Dagradi (1972) studied the influence of alcohol on varices in patients with cirrhosis and found that variceal length increased in 65% of patients with cirrhosis who continued to consume alcohol, but it decreased in 80% of patients with cirrhosis who abstained from alcohol. Baker and colleagues (1959) reported that varices regress in 25%, disappear in 32%, and progress in 21% of patients with cirrhosis whose varices are monitored by endoscopy.

Most bleeding episodes in long-term studies occur during the first 1 to 2 years after identification of varices (Baker et al, 1959; Groszmann et al, 1990; Siringo et al, 1994; Triger et al, 1991). Average mortality rates after bleeding from esophageal varices are 23% at 1 year, 34% at 2 years, and 58% at 3 years. Approximately one third of deaths in patients with known esophageal varices are attributable to upper GI bleeding; a larger proportion die as a result of liver failure. The mortality rate directly attributable to variceal hemorrhage is 10% to 17% for cirrhotic patients (Baker et al, 1959; Sauerbruch et al, 1988; Triger et al, 1991). In patients with varices, upper GI bleeding is attributable to variceal hemorrhage in roughly two thirds of patients (Gebhard, 1998). Clinical parameters associated with increased risk of hemorrhage and death from esophageal varices include large varices, those with cherry-red spots (Dagradi, 1972), concurrent gastric varices (Kleber et al, 1991), Child-Turcotte-Pugh (CTP) classification, continued alcohol use (Dagradi, 1972), and infection (Goulis et al, 1999). Death correlates more closely with CTP classification (Merkel et al, 1989) than with any other parameter studied.

Rebleeding and mortality rates markedly increase after varices bleed. Studies have reported rebleeding rates to be 30% within 6 weeks of an initial variceal hemorrhage (Copenhagen Esophageal Varices Sclerotherapy Project [CVESP], 1984; Graham & Smith, 1981) and 60% to 75% within 1 year (Baker et al, 1959; Graham & Smith, 1981). Esophageal varices are the cause of bleeding in approximately 16% of hospital admissions for upper GI bleeding (de Franchis et al, 1991). Mortality rates from all causes within 1 year of initial hemorrhage have been estimated at 40% to 66% (Burroughs et al, 1989; CEVSP, 1984; Graham & Smith, 1981; Le Moine et al, 1992). The risk of dying increases as the interval between initial and second hemorrhage decreases (Gebhard, 1998). If patients survive for more than 12 weeks after a variceal hemorrhage, the risk of rebleeding or dying returns to that of patients who have never bled (Gebhard, 1998).

PHARMACOLOGIC MANAGEMENT OF PORTAL HYPERTENSION (SEE CHAPTER 75)

Prophylaxis

β-Blocker therapy has been studied to test its efficacy in preventing primary variceal hemorrhage in patients with known varices. Nadolol is a *nonselective β-blocker,* meaning it blocks both β_1 and β_2 receptors; patients given nadolol were compared with untreated control subjects. Nadolol reduced the incidence of bleeding from 35% ± 3% to 12% ± 3%, and the incidence of fatal bleeds was reduced from 18% ± 3% to 10% ± 2%. There

was no difference in overall mortality rate (Poynard et al, 1991). This study is used to support the use of prophylactic β-blockade to prevent a first variceal hemorrhage.

Nitrates are vasodilators whose action is mediated by nitric oxide on vascular smooth muscle. Nitroglycerin decreases portal pressure in patients with cirrhosis when high doses are used (Moreau et al, 1989). In animal studies, nitroglycerin lowered portal pressure 13%, and systemic blood pressure decreased 25%. This drug lowers portal pressure less than systemic pressure. Nitrates in combination with β-blockade may offer prophylaxis against an initial variceal bleed.

Randomized, controlled clinical trials comparing nonselective β-blockers (propranolol or nadolol) with no therapy in cirrhotic patients showed that drug treatment effectively reduced the risk of a first variceal hemorrhage (Poynard et al, 1991). The combination of isosorbide mononitrate and β-blockade further reduces portal pressure and has been shown in three studies to effectively reduce the risk of a first variceal bleed compared with β-blockade alone (Garcia-Pagan et al, 1990; Villanueva et al, 1996; Vorobioff et al, 1993). These investigations have noted, however, the difficult problem of compliance, particularly in patients with alcoholism. In addition, fatigue may be a side effect of therapy with β-blockade, and even more seriously, if patients do bleed, their ability to compensate for blood loss by tachycardia is compromised.

Acute Variceal Hemorrhage

The posterior pituitary hormone vasopressin causes splanchnic arteriolar vasoconstriction, reducing portal blood pressure by approximately 15% when given intra-arterially or intravenously (Chojkier et al, 1979; Huet et al, 1987). Intravenous use is preferred for safety and convenience, and the optimal dose of the drug is 0.3 to 0.4 U/min intravenously. As a result of simultaneous vasoconstrictive effects on the cardiac, mesenteric, and cerebral circulations, the complications increase when doses of 0.5 to 0.7 U/min are administered. It is not necessary to taper the dose; the infusion can be stopped when the therapeutic end point is reached. In a controlled study comparing vasopressin with no therapy, approximately half of the patients on vasopressin stopped bleeding, but this result did not differ from control subjects (Chojkier et al, 1979; Fogel et al, 1982).

Nitrogen is often administered concurrently with vasopressin to reduce the systemic vasoconstrictive effects of vasopressin, and it may further reduce portal pressure. Nitroglycerin infusion begins at 40 μg/min and is titrated to a mean arterial blood pressure of 65 to 75 mm Hg (Gimson et al, 1986).

Octreotide reduces bleeding (D'Amico et al, 1995) and enhances the results of sclerotherapy (Besson et al, 1995). Somatostatin and octreotide are endogenous peptides that act by reducing splanchnic, hepatic, and azygos blood flow (Bosch et al, 1981). Their principal advantage over vasopressin is that they do not cause vasoconstriction of the myocardial and cerebral circulations. Somatostatin and octreotide should be administered continuously at 250 μg/h and increased to 500 μg/h if bleeding continues. Preliminary studies showed that octreotide helped arrest acute variceal bleeding in six of six patients (Thulin et al, 1979; Tyden et al, 1978). Randomized, controlled trials comparing somatostatin or octreotide with vasopressin versus no infusion have shown equivocal results, which suggests that vasopressin and somatostatin have similar efficacy (Burroughs, 1996; Burroughs et al, 1990; Imperiale et al, 1995). Neither vasopressin nor somatostatin has been approved by the U.S. Food and Drug Administration (FDA) for treatment of variceal bleeding, although both agents are commonly used for this purpose (Korula, 1998). A prospective, randomized trial showed equivalence of somatostatin and sclerotherapy in the treatment of acute variceal bleeding (Planas et al, 1994).

Prevention of Rebleeding After Initial Control

Propranolol was shown by Lebrec and colleagues (1980, 1981) to reduce rebleeding significantly after acute variceal hemorrhage. This effect may be mediated by a decrease in cardiac output (β_1-blockade), increased splanchnic arteriolar resistance (β_2-blockade), and consequent decrease in portal blood flow (Lebrec et al, 1982) and collateral blood flow via the azygos venous system (Feu et al, 1993). β-Blockade is not widely used in the United States to prevent rebleeding after an episode of variceal hemorrhage because endoscopic sclerotherapy and ligation are preferred, and β-blockade after acute bleeding has not been shown to reduce mortality rate (Pagliaro et al, 1989). Meta-analysis comparing β-blockade with endoscopic sclerotherapy showed a non–statistically significant decrease in pooled relative risk for bleeding in the sclerotherapy group and no difference in mortality rate between the two groups (D'Amico et al, 1995). A randomized, controlled study showed, however, that isosorbide mononitrate (80 mg/day) in combination with nadolol (80 mg/day) was more effective than sclerotherapy in reducing rebleeding (Villanueva et al, 1996), and complications were less frequent in the group treated with drugs (16% vs. 37%). If this study is confirmed by other investigators, pharmacologic therapy may play a larger role than it currently does in the United States in the prevention of rebleeding.

ENDOSCOPIC THERAPY OF VARICEAL HEMORRHAGE

Prophylaxis

The use of prophylactic sclerotherapy to prevent a first hemorrhage was studied in three meta-analyses (see Chapter 75; Fardy & Laupacis, 1994; Pagliaro et al, 1989; Van Ruiswyk & Byrd, 1992). One study concluded that paravariceal injection with polidocanol decreased mortality rates (Fardy & Laupacis, 1994). The other two reports found that prophylactic sclerotherapy did not reduce bleeding or mortality rate and concluded that sclerotherapy was not indicated in this setting (D'Amico et al, 1995; Pagliaro et al, 1989; Van Ruiswyk & Byrd, 1992). The largest trial of prophylactic sclerotherapy was the Veterans Affairs (VA) cooperative trial. This trial included 281 patients but was prematurely closed because of excess mortality rate in the sclerotherapy group (VA Cooperative Variceal Sclerotherapy Group [CVSG], 1991). Sclerotherapy prevented variceal hemorrhage but substituted bleeding from sclerotherapy-induced ulceration. This study effectively ended the use of prophylactic sclerotherapy in the United States.

Acute Variceal Hemorrhage

When it became apparent that the once predominant therapy for variceal hemorrhage, emergency surgical shunts, were not improving survival but rather substituting death from liver

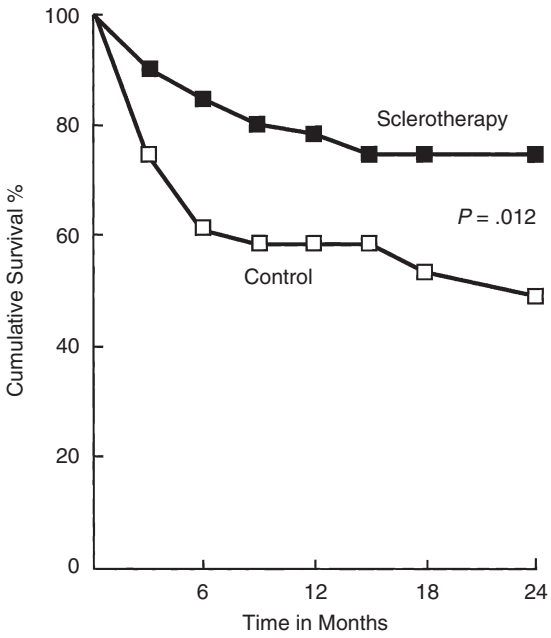

FIGURE 76A.1. Effect of sclerotherapy on survival in patients with cirrhosis: the King's College Hospital and Medical School Trial. Cumulative survivals in sclerotherapy patients (n = 51) and controls (n = 56) are shown. Control group patients received standard medical treatment, including blood transfusions, vasopressin, and Sengstaken-Blakemore tubes when necessary. *(From MacDougall BR, et al, 1982: Increased long-term survival in variceal haemorrhage using injection sclerotherapy: results of a controlled trial. Lancet 1:124-127.)*

failure for death from bleeding, endoscopic variceal injection was evaluated as a less invasive therapy. In 1980, a prospective randomized trial with 107 patients from King's College Hospital showed control of bleeding by sclerotherapy in 57% of 51 treated patients compared with 25% of 56 patients treated medically (MacDougall et al, 1982). Two years later, a follow-up study showed improved patient survival with sclerotherapy compared with controls who received blood transfusions, vasopressin, and a Sengstaken-Blakemore tube when necessary (Fig. 76A.1).

When interpreting this and subsequent trials, it is important to understand that the King's College trial had more nonalcoholic patients than alcoholic patients (60 vs. 47) and had patients with relatively mild liver failure (74 were CTP class A or B, 33 were class C). The more patients in any study of variceal hemorrhage who are alcoholic or who have CTP class C liver disease, the more difficult it is to show a survival advantage of therapy. Death from bleeding in such patients tends to be replaced by death from liver failure (Block & Reichelderfer, 1998). The VA cooperative study showed no reduction of long-term survival when acute hemorrhage was treated with sclerotherapy (CVSG, 1994).

Sclerotherapy has been shown to stop acute variceal hemorrhage effectively (Gregory, 1990; Westaby et al, 1989). Meta-analysis of 20 trials of emergency sclerotherapy versus a variety of alternative therapies supported the superiority of sclerotherapy with its success rate of 71% to 100%; however, the complication rate was high (18%), and 2.7% patients died as a direct result of sclerotherapy (D'Amico et al, 1995).

Endoscopic variceal ligation (EVL) has been developed as an endoscopic alternative to sclerotherapy, potentially lowering the risk of ulceration and perforation of the esophagus. Seven prospective, randomized, controlled trials compared EVL with endoscopic sclerotherapy (Gimson et al, 1993; Hashizume et al, 1993; Hou et al, 1995; Laine et al, 1993; Lo et al, 1995, 1997; Stiegmann et al, 1992). In all studies, EVL and sclerotherapy were equally effective in controlling active bleeding. Complications were significantly lower with EVL in all studies. No esophageal strictures were seen in patients treated with EVL compared with 5% to 33% of patients treated with sclerotherapy. The development of the multiple-band ligating device, which allows banding without repeatedly reinserting the endoscope, has made this modality of endoscopic control of varices much more attractive, such that it has now become the endoscopic therapy of choice (Laine, 1997).

Prevention of Rebleeding

Although sclerotherapy effectively stops acute variceal bleeding, rebleeding remains a problem, and intermediate (2- to 5-year) survival is not improved in many trials. A confounding variable confusing interpretation of the results in many of these trials is continued alcoholism. Alcohol abstinence for 6 months, CTP class, and aspartate aminotransferase level all were independent predictors of survival in the VA trial (CVSG, 1994). Meta-analyses of trials comparing sclerotherapy with pharmacologic management have shown sclerotherapy to prevent rebleeding more effectively and sometimes improve survival (D'Amico et al, 1995; Infante-Rivard et al, 1989). When EVL was compared with sclerotherapy, rebleeding rates were significantly decreased with EVL in three studies (Gimson et al, 1993; Hou et al, 1995; Lo et al, 1995), and mortality rates were significantly lower in three studies (Hou et al, 1995; Lo et al, 1995; Stiegmann et al, 1992). EVL seems to be at least as effective as sclerotherapy in preventing rebleeding.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (SEE CHAPTER 76E)

The development and clinical use of TIPS in the treatment of portal hypertension first occurred in the 1990s, and its use for the treatment of variceal hemorrhage has expanded (LaBerge et al, 1992; McCormick et al, 1994). TIPS is used electively far more often than in the emergency setting. Despite the effectiveness of TIPS in abruptly stopping variceal hemorrhage, overall patient mortality rates remain high (Smith & Graham, 1982). Death often is related to multisystem organ failure, progressive liver failure or sepsis, or disseminated intravascular coagulation, reflecting the use of TIPS in patients with end-stage disease. Complications are usually related to the underlying cirrhosis and associated comorbidities. In addition to relieving variceal hemorrhage, TIPS effectively relieves ascites in these patients (Crenshaw et al, 1996; Martin et al, 1993b) because TIPS is functionally a nonselective, side-to-side portacaval shunt. In contrast to all surgical shunts, TIPS creates a shunt to the suprahepatic inferior vena cava (Fig. 76A.2).

TIPS was developed as a minimally invasive procedure performed by radiologists using fluoroscopic imaging to place a noncompressible stent between the portal vein and hepatic vein. Successful TIPS lowers portal pressure, and the procedure is typically well tolerated even in very ill patients. Complications

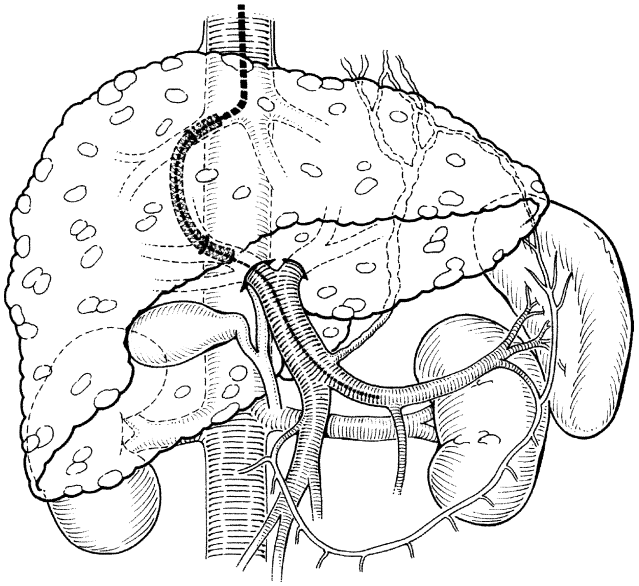

FIGURE 76A.2. Transjugular intrahepatic portosystemic shunting creates an intrahepatic portosystemic shunt from the portal vein to the hepatic vein, held open by a titanium stent.

include encephalopathy secondary to portosystemic shunting, shunt stenosis and occlusion, inability to place a TIPS, and intraperitoneal bleeding if the liver capsule is punctured. Mortality rate at 30 days has been reported at 20%, but half of these deaths were unrelated to the procedure itself (Darcy et al, 1993). In patients with CTP class C cirrhosis, a 30-day mortality rate of 67% has been reported (Martin et al, 1993a, 1993b); in a lower risk population of 100 patients, a 30-day mortality rate of 5.3% was reported (Richter et al, 1994).

Primary patency—that is, patency without radiologic intervention to revise the TIPS—has been reported to be 46% to 85% in the first 3 to 6 months (Richter et al, 1994; Saxon et al, 1993; Sterling & Darcy, 1995) and 27% to 57% at 1 year (Haskal et al, 1994; Malisch et al, 1993; Saxon et al, 1993; Sterling & Darcy, 1995). *Primary assisted patency,* meaning patency after revision, has been reported to be 85% (Haskal et al, 1994). LaBerge and colleagues (1995) reported shunt stenosis or occlusion in 47% of 90 TIPS patients over a 2-year period.

The newer polytetrafluoroethylene (PTFE)-covered stents are associated with less need for intervention, less shunt dysfunction, and better outcomes (Bureau et al, 2007). If post-TIPS ultrasound shows narrowing or thrombosis of the shunt, patency can be restored by repeat balloon dilation and stenting or by thrombectomy. Color Doppler ultrasound of TIPS is routinely performed at 1- and 6-month intervals after the procedure to evaluate luminal narrowing or increased flow velocity, which would suggest impending thrombosis of the TIPS. The rate of TIPS restenosis or occlusion is higher than the rate of recurrent symptoms because in some patients, occlusion does not produce symptoms. Nevertheless, recurrent variceal hemorrhage occurs in approximately 50% of patients with TIPS stenosis or occlusion. A multicenter trial of TIPS involving 100 patients reported that 16% of patients had rebleeding by 6 months, and five of these were from nonvariceal sources (Coldwell et al, 1995). Similarly, LaBerge and colleagues (1995) reported variceal rebleeding in 32% of 90 patients at 2 years.

Prophylaxis of Bleeding with Transjugular Intrahepatic Portosystemic Shunting

The ability of TIPS to prevent an initial variceal hemorrhage has not been studied. Patients awaiting liver transplantation who have intractable ascites are often treated with TIPS as a means of bridging to liver transplantation. Although not a true study of prophylaxis, these patients seem to be at low risk of bleeding.

Acute Variceal Bleeding and Transjugular Intrahepatic Portosystemic Shunting

TIPS may be used effectively in the control of acute variceal hemorrhage when medical management or endoscopic variceal ligation or both are ineffective. Barton and colleagues (1995) found that TIPS controlled acute variceal bleeding in 91% of patients, whereas Helton and associates (1993) reported control in 17 (74%) of 23 patients. A report by Encarnacíon and colleagues (1995) reported on 65 patients with acute variceal bleeding unresponsive to sclerotherapy or not treated with sclerotherapy because of recurrent massive hemorrhage. Acute bleeding stopped before the TIPS procedure in 26 patients, but not in the other 39 patients. Of the 65 patients with acute bleeding, 64 had successful placement of TIPS, and all these patients stopped bleeding within 3 days. The 30-day survival rate of patients who stopped bleeding before TIPS was 96%, but it was only 69% for patients actively bleeding at the time of TIPS. Survival was also linked to CTP class, with a 30-day survival rate of 91% for class A (n = 2) and class B (n = 32) patients, but survival rate was 71% for class C (n = 31) patients.

When used as primary therapy for acute variceal bleeding, TIPS may reduce treatment failure and mortality rate in high-risk patients. Monescillo and colleagues (2004) reported that in patients defined as high risk by a hepatic venous pressure gradient (HVPG) greater than 20 mm Hg randomized to treatment with TIPS (n = 26) versus no TIPS (n = 26), the no-TIPS group required more transfusions ($P = .002$), needed more intensive care unit care, had more treatment failures, and had poorer survival ($P < .05$). The no-TIPS group was treated with β-blockers, variceal banding, or sclerotherapy.

Prevention of Rebleeding by Transjugular Intrahepatic Portosystemic Shunting

TIPS has been used most frequently to prevent recurrent variceal hemorrhage. The results of four large series are shown in Table 76A.1 (Henderson et al, 1998). Rebleeding rates are similar in these series and are approximately 25% at 1 year. Thirty-day mortality rates were 14% to 16% except for the Rössle series (Rössle et al, 1994). Most deaths within 30 days were due to multisystem organ failure, whereas most later deaths were attributable to progressive liver failure. Because TIPS is a nonselective shunt, encephalopathy rates were relatively high at 25%, although in most patients this was not debilitating because it is usually controllable with lactulose, neomycin or rifaximin, and a low-protein, low-ammonia diet.

Most episodes of rebleeding after TIPS were related to stenosis or thrombosis of the shunt. In addition, many asymptomatic patients had shunt stenosis or thrombosis detected by ultrasound. Primary patency was 40% to 67% at 1 year, which improved to 79% to 88% with revision of stenotic stents

(assisted primary patency). *Secondary patency,* which is patency after TIPS thrombectomy or revision, was 95% to 100% at 1 year (Coldwell et al, 1995; Fillmore et al, 1996; LaBerge et al, 1995; Rössle et al, 1994).

In the short time since its introduction, TIPS has had a dramatic impact on the treatment of variceal hemorrhage. In addition to its use in preventing variceal hemorrhage, TIPS has the added benefit of often improving overall liver function, as measured by CTP status, and of effectively bridging patients to liver transplantation (Abouljoud et al, 1995; Menegaux et al, 1994; Millis et al, 1995; Odorico, 1998; Suc et al, 1995). Despite the suggestion that TIPS may reduce operative time and blood loss during liver transplantation, data are not yet available to support this contention. Nevertheless, it has been shown that the TIPS procedure effectively prevents rebleeding (D'Amico et al, 1995; Ring et al, 1992).

TIPS has been compared with endoscopic therapy for the long-term prevention of recurrent bleeding. In a meta-analysis of 11 randomized trials, fewer patients rebled after TIPS (19%) than after endoscopic therapy (47%), encephalopathy was more common after TIPS (34%), and TIPS dysfunction developed in 50% of patients overall (Papatheodoridis et al, 1999).

A major recent change in therapy recommendations is that in creating a TIPS, use of expanded PTFE (ePTFE)-covered stents is now preferred. The basis for this recommendation is the decreased need for shunt intervention and a suggestion of better outcomes with covered stents rather than bare ones (Angermayr, et al, 2003). Although TIPS increases the risk of hepatic encephalopathy, prophylactic use of nonabsorbable disaccharides or antibiotics does not reduce this risk and is not recommended (Riggio et al, 2005).

TIPS also has been compared with shunt surgery. The distal splenorenal shunt showed lower rates of rebleeding, encephalopathy, and shunt thrombosis than TIPS, but ascites was less common after TIPS (Khaitiyar et al, 2000). A multiinstitutional, randomized trial compared TIPS with the distal splenorenal shunt in CTP class A and B cirrhotic patients (Henderson et al, 2004). Initial analysis of the results showed no significant differences between TIPS and the distal splenorenal shunt in variceal rebleeding, shunt occlusion, and survival. However, of the TIPS patients, 80% required reintervention to maintain shunt patency, and close surveillance was required.

TIPS also has been compared with the small-diameter interposition shunt. In a controlled trial, shunt occlusion, death from hepatic failure, and the need for liver transplantation all were significantly more common after TIPS (Rosemurgy et al, 2000). At the 10-year follow-up report, the small-diameter interposition shunts continued to perform better in terms of shunt occlusion, and survival was also superior in CTP class A and B patients and in those with Model for End-Stage Liver Disease (MELD) scores less than 13 (Rosemurgy et al, 2000). Indications for TIPS supported by current data include 1) continued variceal hemorrhage after sclerotherapy or banding, 2) prevention of rebleeding or treatment of ascites in patients awaiting liver transplantation, and 3) prevention of rebleeding in patients who are not candidates for a surgical shunt or liver transplantation because of expected short survival.

Treatment of Budd-Chiari Syndrome with Transjugular Intrahepatic Portosystemic Shunting

Given the advantages of the PTFE-covered stents with regard to patency, this matter was studied in a large series of 221 patients with Budd-Chiari syndrome who were treated with

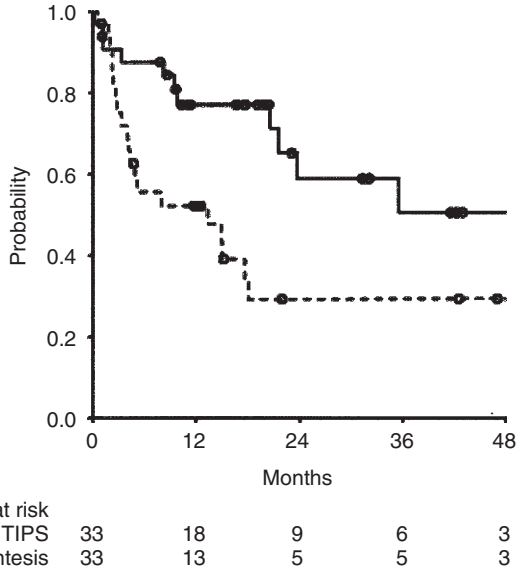

FIGURE 76A.3. Probability of survival without transplantation in patients assigned to transjugular intrahepatic portosystemic shunt (*TIPS*) treatment (*continuous line*) and patients assigned to paracentesis plus albumin (*dotted line*). The probability was superior in patients treated with TIPS (P = .021). *(From Salerno F, et al, 2004: Randomized controlled study of TIPS versus paracentesis plus albumin in cirrhosis with severe ascites. Hepatology 40:629-635.)*

TIPS (133 patients) if they had not responded to anticoagulation treatment (Garcia-Pagan et al, 2008). TIPS is now recommended for patients with Budd-Chiari syndrome who do not improve with anticoagulation therapy.

Treatment of Ascites with Transjugular Intrahepatic Portosystemic Shunting

TIPS has been used effectively to relieve ascites in patients refractory to pharmacologic therapy with diuretics. Salerno and associates (2004) reported a multicenter, randomized, controlled trial comparing TIPS (n = 33) with paracentesis plus albumin (n = 33) in patients with CTP class B and C cirrhosis. Survival without liver transplantation was superior in patients treated with TIPS (P = .021; Fig. 76A.3). By multivariate analysis, a higher MELD score and paracentesis independently predicted death. Treatment failure was more common in patients treated with paracentesis, although encephalopathy occurred more commonly in patients receiving TIPS (Salerno et al, 2004).

SURGICAL SHUNTS FOR BLEEDING ESOPHAGEAL VARICES (SEE CHAPTERS 76C AND 76D)

Prophylactic Surgery

Early trials of prophylaxis for variceal bleeding compared portacaval shunts with medical therapy. Although bleeding was effectively prevented, survival was not significantly enhanced with surgery because of a marked increase in deaths from accelerated hepatic failure (Grace, 1992). Because only one third of patients with varices eventually bleed, surgery cannot be justified as prophylaxis and is not recommended in this setting.

In a prospective, controlled study to evaluate prophylactic surgery in 112 patients with portal hypertension and esophageal varices, Inokuchi (1984) found the bleeding rates were 19.2% in the medical group and 0% in the surgical group. No difference was reported in the survival rate between the two groups at 2-year follow-up, and prophylactic surgery led to a prevention of esophageal bleeding without any increase in the mortality rates. This is the only study to support a role for prophylactic surgery, but it should be noted that the majority of these patients had posthepatic cirrhosis with reasonably well-preserved liver function.

Acute Variceal Hemorrhage

At most American centers, endoscopic therapy is the first option used to treat bleeding esophageal varices. An exception is the series reported by Orloff and coworkers (1994), who used portacaval shunts as a first-line therapy with excellent results. At most other centers, patients who do not respond to endoscopic variceal ligation are referred for consideration for TIPS or a surgical shunt. Emergency surgical shunts prevent bleeding more effectively than sclerotherapy, but overall mortality rate is equivalent (Cello et al, 1987; D'Amico et al, 1995).

Although nonoperative therapies are useful for initial management of bleeding esophageal varices, if these measures fail to control bleeding, emergency surgery should be promptly considered (Rikkers & Jin, 1994). Emergency surgical shunts normalize portal pressure immediately and effectively control variceal hemorrhage, but emergency surgery has been associated with a mortality rate of 20% to 55% (Cello et al, 1987; D'Amico et al, 1995). The high risk of dying after placement of an emergency shunt is presumably related to the frequent decompensation of liver function and associated comorbidity at the time of an acute bleed. Outcomes correlate with CTP classification rather than with the type of shunt performed. Liver failure and encephalopathy often ensue and are the proximate causes of death associated with emergency surgery in most series.

In choosing which surgical shunt to use for emergency control of bleeding, the portacaval shunt (see Chapter 76B) is an acceptable choice because it effectively decompresses the portal venous system and can usually be rapidly constructed. An end-to-side portacaval shunt is adequate, although patients with ascites should have a side-to-side portacaval shunt to relieve their ascites as well. A series by Orloff and colleagues (1994) showed the usefulness of the portacaval shunt in the emergency setting. Other functional side-to-side shunts, such as the mesocaval shunt (see Chapter 76D) and proximal splenorenal shunt (see Chapter 76C), also effectively decompress the portal vein and relieve esophageal variceal bleeding, and they should be effective for relief of ascites. In contrast to portacaval shunts, these shunts do not require dissection in the porta hepatis and do not complicate future liver transplantation. In appropriately selected patients, a distal splenorenal shunt also may be used in the emergency setting to relieve variceal hemorrhage in patients with a large, patent splenic vein and absent or medically controlled ascites (Rikkers & Jin, 1995).

Prevention of Rebleeding After Initial Control

In view of the disadvantages of emergency shunts, the more attractive role of surgical shunts is in the elective setting to prevent recurrent variceal hemorrhage. Because the

natural history of variceal hemorrhage places patients who have bled once at high risk for rebleeding, definitive therapy ought to be considered after control of the acute hemorrhage. In an appropriately selected patient, surgical shunts substantially reduce the risk of recurrent bleeding, maintain stable liver function, and obviate the need for repeated endoscopic procedures.

The role of TIPS versus a surgical shunt for prevention of rebleeding has been recently clarified by a randomized clinical trial comparing the two treatments in patients who did not respond to medical therapy (Henderson et al, 2006). No difference was found in rebleeding rates (5.5% for distal splenorenal shunt [DSRS] vs. 10.5% for TIPS, *P* value not significant), encephalopathy, or survival. TIPS patients required more interventions, although the study used noncovered stents. TIPS was slightly more cost effective than DSRS at 1 year (Boyer et al, 2008), and the study concluded that the two treatments were of equal efficacy in preventing recurrent variceal hemorrhage.

Depending on whether shunts completely divert, partially divert, or compartmentalize the portal venous circulation, they are characterized as *nonselective*, *partial*, or *selective*. Relative to nonselective shunts, the goal of partial and selective shunts is to preserve hepatic portal perfusion and minimize the risk of progressive liver failure and encephalopathy while preventing variceal bleeding.

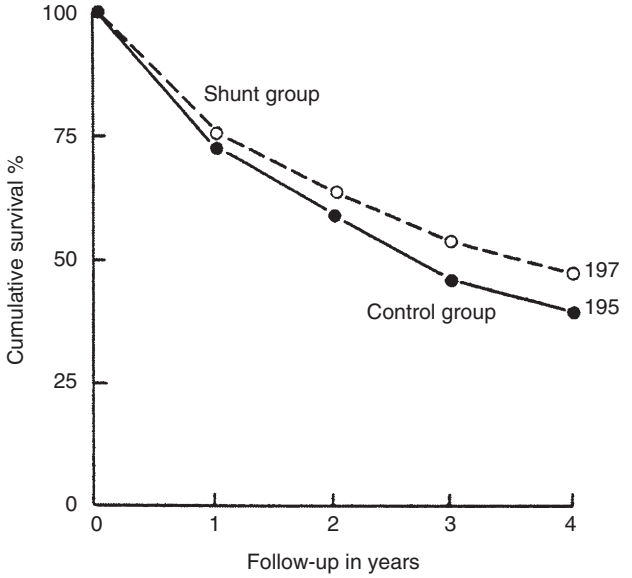

FIGURE 76A.4. Cumulative survival data from four controlled trials of portacaval shunt versus conventional medical management. *(Courtesy HO Conn; from Boyer TD, 1982: Portal hypertension and its complications: bleeding esophageal varices, ascites, and spontaneous bacterial peritonitis. In Zakim D, Boyer TD [eds]: Hepatology: A Textbook of Liver Disease. Philadelphia, Saunders, pp 464-499.)*

General Aspects of Nonselective Shunts

The end-to-side portacaval shunt was the first experimental shunt performed in dogs (Konstantinov, 1997). This shunt is the prototype of the nonselective shunt and has been compared in randomized, controlled trials with conventional medical management for the treatment of portal hypertension and its complications (Rikkers et al, 1992). Figure 76A.4 shows combined data of four controlled studies of the portacaval shunt, comparing shunted patients with medically managed patients according to survival. No survival advantage could be shown for shunt patients, although the four studies were all biased in favor of medical management because failures of medical management were crossed over to surgical therapy. Bleeding was effectively stopped in shunt patients, whereas more than 70% of medically treated patients rebled. Encephalopathy occurred in 20% to 40% of shunted patients.

When the end-to-side portacaval shunt was compared with the side-to-side shunt in a controlled trial, no significant clinical differences were noted between these two shunts (Resnick et al, 1974). The interposition mesocaval shunt (see Chapter 76D), also a nonselective shunt, was studied in a randomized trial comparing it with the direct side-to-side portacaval shunt, and no clinical or hemodynamic differences were evident (Stipa et al, 1981). The same series documented a high graft thrombosis rate after the mesocaval shunt. Nevertheless, the mesocaval shunt avoids dissection in the porta hepatis, which is an advantage for future liver transplant candidates. An additional option is a central or proximal splenorenal shunt with splenectomy. In the current era, indications for a nonselective shunt include an emergency shunt for variceal hemorrhage, an elective shunt in the presence of significant ascites, and treatment of Budd-Chiari syndrome. In some patients not suited for a selective shunt, a nonselective shunt might serve as a long-term bridge to hepatic transplantation, when bleeding is not controlled endoscopically or by TIPS.

Budd-Chiari syndrome (see Chapter 77) with ascites, abdominal pain, and portal hypertension is an indication for a side-to-side portacaval shunt. A side-to-side shunt is necessary because the portal vein (PV) serves as the major efferent conduit in this syndrome. If the disease is fulminant, or if cirrhosis has developed secondary to longstanding hepatic venous occlusion, liver transplantation is a preferable option. If liver transplantation is not anticipated, a side-to-side portacaval shunt may be the ideal procedure. Often the caudate lobe enlarges after occlusion of the major hepatic veins because the caudate lobe communicates directly with the vena cava and may become the major route of venous outflow from the liver. Massive hypertrophy of the caudate lobe may prevent a side-to-side portacaval shunt from being technically possible because of caudal expansion of the caudate lobe, which is interposed between the PV and the inferior vena cava (IVC) and prevents their side-to-side anastomosis. A mesocaval shunt may be technically more feasible in this setting.

When Budd-Chiari syndrome involves occlusion of the hepatic portion of the IVC, the infrahepatic vena cava develops collaterals to the azygos venous system. These collaterals permit the portal circulation to be decompressed into the IVC via a mesocaval shunt, and a mesoatrial shunt is generally not required in such patients. Although a mesoatrial shunt circumvents an occluded IVC, it is a long shunt with a poor patency rate and has been associated with poor outcomes. Successful management of Budd-Chiari syndrome requires accurate diagnosis and treatment of the underlying hypercoagulable state. In experienced centers, TIPS can also sometimes be used in patients with Budd-Chiari syndrome. Anticoagulation is usually necessary to prevent shunt thrombosis in both surgically treated and TIPS-treated patients.

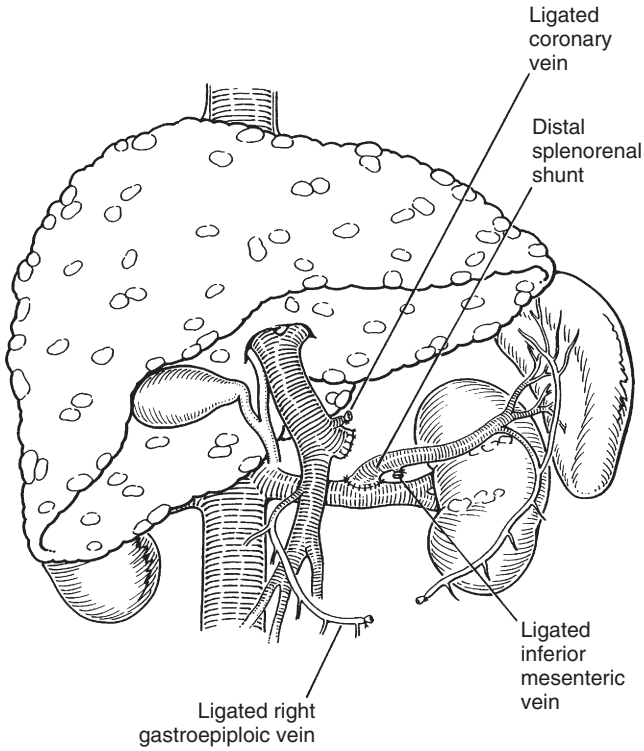

FIGURE 76A.5. Distal splenorenal shunt requires ligation of the coronary vein. Drainage of the splenic vein is into the left renal vein. The right gastroepiploic vein also is ligated and divided. *(From Knechtle SJ, 1998: Surgical shunts for portal hypertension. In Knechtle SJ [ed]: Portal Hypertension: A Multidisciplinary Approach to Current Clinical Management. Armonk, NY, Futura, pp 175-202.)*

General Aspects of Distal Splenorenal Shunt

Warren and colleagues (1967) introduced the distal splenorenal shunt (see Chapter 76C) with the goal of preserving hepatopetal blood flow in the PV while decompressing esophageal varices. The distal splenic vein is anastomosed to the left renal vein, and collateral vessels are ligated, such as the coronary and gastroepiploic veins connecting the superior mesenteric and gastrosplenic components of the splanchnic venous circulation (Fig. 76A.5). This procedure compartmentalizes the portal venous circulation into a high-pressure superior mesenteric venous system to perfuse the liver and a decompressed gastrosplenic venous system to avoid variceal bleeding (Knechtle, 1998).

In patients with advanced ascites, the distal splenorenal shunt is contraindicated because lymphatics are transected during the dissection of the left renal vein and the liver continues to have elevated sinusoidal pressures. In such patients, the distal splenorenal shunt may worsen ascites rather than relieve it. Warren's claim that the operation effectively accomplishes its goal of preserving hepatic function better than nonselective shunts remains controversial. Controlled trials have shown decreased portosystemic encephalopathy after the distal splenorenal shunt. Henderson and colleagues (1983) showed that portal flow is maintained in most patients with nonalcoholic cirrhosis and noncirrhotic portal hypertension, but portal flow rapidly collateralizes to the shunt in patients with alcoholic cirrhosis, particularly if alcohol consumption continues. Failure to ligate the coronary vein (CV) results in early loss of hepatopetal portal flow.

Despite surgical interruption of collaterals that connect the superior mesenteric venous system to the gastrosplenic system, collaterals gradually develop through a pancreatic network termed the *pancreatic siphon.* Surgical splenopancreatic disconnection improves selectivity of the distal splenorenal shunt, especially in alcoholic cirrhotics; however, the complete dissection and ligation of multiple splenopancreatic venous tributaries to disconnect the splenic vein from what is often a very fibrotic pancreas is technically demanding and frequently bloody, and the clinical benefits of this extension of the procedure have not been clearly shown.

Visceral or computed tomography (CT) angiography should be done in any patient considered for a surgical shunt and especially before a distal splenorenal shunt. A distal splenorenal shunt requires a patent splenic vein, preferably at least 7 mm in diameter. Patients who have undergone splenectomy and those who have a thrombosed splenic vein are not candidates for this shunt procedure.

Six of seven controlled trials comparing the distal splenorenal shunt with nonselective shunts have evaluated alcoholic cirrhotic patients and were summarized by Jin and Rikkers (1991). None of these trials showed a survival advantage of either procedure. Four of the seven trials showed less encephalopathy after a selective shunt, whereas the other trials showed no difference in encephalopathy rates. Rebleeding rates did not differ between the two shunt groups, although one trial noted a higher rate of rebleeding after distal splenorenal shunt.

When the distal splenorenal shunt was compared with repeated endoscopic therapy, rebleeding was less frequent with selective shunts, but hepatic portal perfusion was better maintained by sclerotherapy. Encephalopathy rates were similar in both groups (Henderson et al, 1990; Rikkers et al, 1993). These two studies suggest that sclerotherapy effectively controls initial bleeding, but patients who do not respond to sclerotherapy should promptly undergo surgery. Another indication for surgery, rather than sclerotherapy, is poor access to advanced medical care. Such patients benefit from an initial selective shunt, rather than long-term sclerotherapy, because the latter requires multiple visits to a medical center.

Partial Shunt

The partial shunt proposed by Sarfeh and colleagues (1986) is a means of decompressing varices while preserving hepatic portal perfusion. An 8- or 10-mm PTFE graft is interposed between the PV and IVC. A prospective randomized trial of partial (8-mm diameter) and nonselective (16-mm diameter) interposition portacaval shunts showed a lower frequency of encephalopathy after the partial shunt, but similar survival was reported after both types of shunts (Sarfeh & Rypins, 1994). The largest series of partial shunts was reported by Rosemurgy and colleagues (2007) and includes 170 patients older than 18 years. Small-diameter H-graft shunts were performed in patients who did not respond to endoscopic variceal ablative therapy (56% alcoholic, 44% nonalcoholic); 38% were CTP class A or B and 62% were CTP class C. Variceal bleeding after shunt placement was very uncommon (2%). Actual survival was superior to that predicted by MELD scores but did parallel

the degree of hepatic reserve. Small-diameter H-graft shunting was encouraged in those patients who were neither eligible nor suitable for liver transplantation (Rosemurgy et al, 2007).

TYPES OF SHUNTS: TECHNICAL ASPECTS

Portacaval Shunt (See Chapter 76B)

Nonselective portacaval shunts can be performed by using a side-to-side method, an end-to-side method, or with an interposition graft to create a functional side-to-side shunt. Side-to-side shunts have the advantage of relieving ascites by reducing intrahepatic sinusoidal pressure in addition to decreasing the portal venous pressure gradient. They also are effective in decompressing varices and preventing recurrent variceal bleeding. The current recommended indication for a portacaval shunt would be for a patient with significant ascites and bleeding varices unresponsive to nonsurgical treatment who would not be a future candidate for liver transplantation. Patients who may eventually receive a liver transplant ideally should not be treated with such a shunt; rather, they should have a shunt in which the dissection is performed outside the porta hepatis. Portacaval shunts involving dissection in the hilum of the liver inevitably result in postoperative scarring in the hilum and make subsequent liver transplantation more difficult, with the added potential morbidity and mortality. Nevertheless, liver transplantation in patients with previous portacaval shunts can be done safely. If liver transplantation is not anticipated as a future option, a portacaval shunt is technically more straightforward than a distal splenorenal shunt and is a shorter operation in an unstable, actively bleeding patient.

A side-to-side portacaval shunt is performed through a transverse upper abdominal incision. The common bile duct is encircled and retracted to the patient's left. If a replaced right hepatic artery arises from the superior mesenteric artery, this also needs to be encircled and retracted to the left, which makes the exposure of the PV more difficult. The PV is dissected and encircled with a vessel loop, and the IVC is dissected and encircled with a vessel loop between the lower edge of the liver and the right renal vein. Partially occluding vascular clamps are placed on the IVC and PV, and the two are approximated. A venotomy is made longitudinally in each vein approximately 2 cm in length, and stay sutures of 6-0 polypropylene are placed at the corners. These stay sutures are tied down, and the anastomosis is performed with a running technique. Vascular clamps are removed and the wound is checked for hemostasis. The completed anastomosis is shown in Fig. 76A.6.

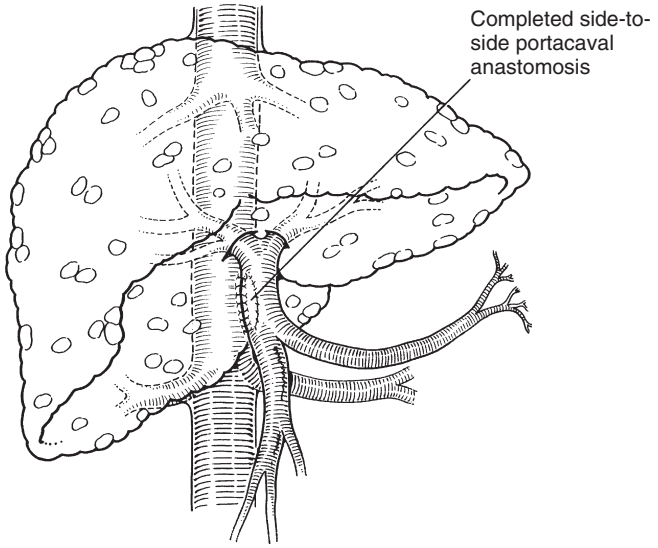

FIGURE 76A.6. The completed anastomosis normalizes portal pressures and results in hepatofugal blood flow through the shunt. *(From Knechtle SJ, 1998: Surgical shunts for portal hypertension. In Knechtle SJ [ed]: Portal Hypertension: A Multidisciplinary Approach to Current Clinical Management. Armonk, NY, Futura, pp 175-202.)*

Mesocaval Shunt (See Chapter 76D)

A mesocaval shunt may be indicated as a long-term bridge to liver transplantation or as definitive therapy in patients whose bleeding is not controlled by endoscopic methods or who have not responded to TIPS placement. Although a PTFE or Dacron graft is commonly used as a conduit between the superior mesenteric vein (SMV) and IVC, we have used an internal jugular vein autograft for this purpose. The better long-term patency rate for a vein graft favors the use of autologous vein over prosthetic material. We have had no complications from removal of one internal jugular vein and have had no shunt thromboses. Such shunts are not difficult technically and have the advantage of keeping the area of dissection away from the porta hepatis, which is an advantage if liver transplantation is a future consideration.

The mesocaval shunt is performed through a transverse upper abdominal incision. By elevating the transverse colon, the middle colic vein can be identified as it courses toward its junction with the SMV. The SMV is anterior and to the right of the superior mesenteric artery. After dividing overlying peritoneum and fat, there is generally a segment about 2 or 3 cm in length that is free of other venous tributaries. This segment of the SMV is dissected free and encircled, and the IVC can be dissected through the right colon mesentery; it is optimal to dissect a segment of IVC that is caudal to the duodenum so that the duodenum does not interfere with shunt placement. Next, the IVC is encircled with a vessel loop. The mesocaval shunt should take a straight path from the SMV to the vena cava rather than coursing around the duodenum.

When using a jugular vein conduit, the left neck is generally preferred because the left jugular vein is often slightly longer than the right jugular vein (Fig. 76A.7). An incision similar to a carotid endarterectomy incision is made along the anterior border of the sternocleidomastoid muscle. The platysma muscle is divided, and the jugular vein is identified. Branches are doubly ligated and divided, and the jugular vein is dissected free from the clavicle to the mastoid. It is ligated with silk ties proximally and distally, and the graft segment is excised and placed in sterile saline until it is used. Next, the neck wound is closed, and the proximal end of the jugular vein graft is anastomosed end-to-side to the SMV with running 6-0 polypropylene (see Fig. 76A.7). The distal end of the graft is anastomosed end-to-side to the IVC also with running 6-0 polypropylene. Partial occlusion clamps are placed on the SMV and IVC during construction of the anastomoses; after completion, the clamps are removed and shunt flow is assessed with an electromagnetic or ultrasonic flowmeter. Flow should be 1 to 2 L/min, and significantly lower flow rates should prompt inspection of the graft for technical problems.

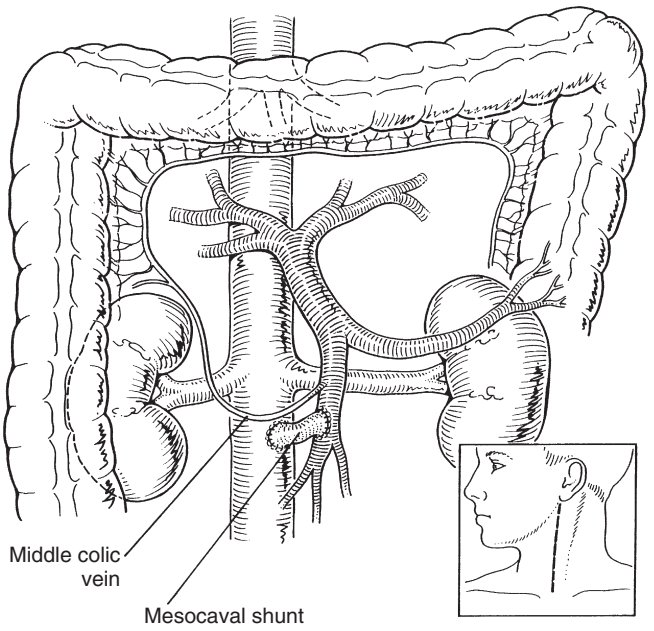

FIGURE 76A.7. The left jugular vein provides an ideal autologous endothelialized vein graft for a mesocaval shunt and is approached through the incision shown (*inset*). The vein can be excised from the clavicle to the angle of the mandible. The proximal end of the vein should be anastomosed to the superior mesenteric vein (SMV). The completed mesocaval shunt uses an 8- to 10-cm graft to decompress the SMV into the vena cava. *(From Knechtle SJ, 1998: Surgical shunts for portal hypertension. In Knechtle SJ [ed]: Portal Hypertension: A Multidisciplinary Approach to Current Clinical Management. Armonk, NY, Futura, pp 175-202.)*

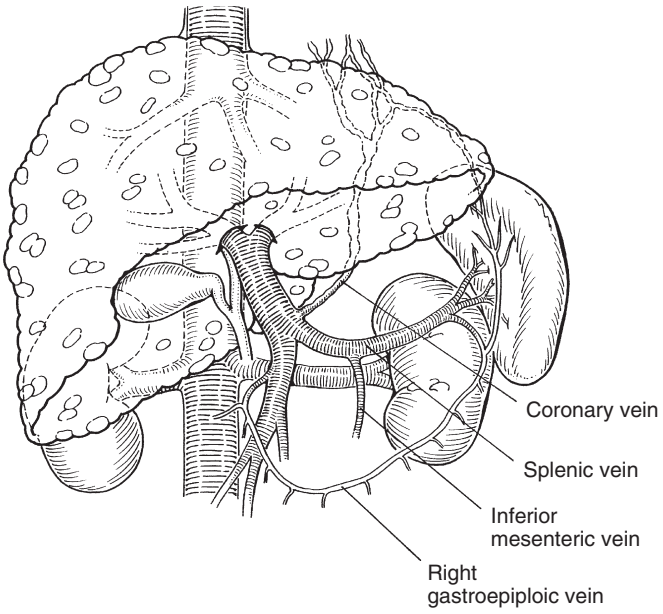

FIGURE 76A.8. The relevant anatomy exposed for a distal splenorenal shunt. The short gastric veins are left intact. The coronary vein and right gastroepiploic veins are ligated. *(From Knechtle SJ, 1998: Surgical shunts for portal hypertension. In Knechtle SJ [ed]: Portal Hypertension: A Multidisciplinary Approach to Current Clinical Management. Armonk, NY, Futura, pp 175-202.)*

Distal Splenorenal Shunt (See Chapter 76C)

A distal splenorenal shunt is performed through a transverse upper abdominal incision. The gastrocolic omentum is taken down such that the right gastroepiploic vein is divided, but the short gastric veins are left intact. The splenic flexure of the colon is mobilized and retracted caudally. The inferior border of the pancreas is retracted anteriorly and cranially to expose the posterior aspect of the pancreas and the splenic vein, which is dissected free from the pancreas, and all tributaries are ligated and divided. The CV may be one of its branches, or it may enter the PV.

The splenic vein dissection is generally the most challenging aspect of the procedure and may be particularly difficult in patients with pancreatic fibrosis from chronic pancreatitis. The splenic vein is dissected medially to its confluence with the SMV and laterally to a point that allows the vein to be brought down to the renal vein without kinking or tension. If splenopancreatic dissection is a goal of the procedure, the dissection continues all the way to the spleen such that all pancreatic tributaries are ligated and divided (Fig. 76A.8).

The left renal vein is dissected next, and adjacent lymphatics are ligated to avoid the complication of chylous ascites. The left adrenal vein is ligated and divided to assist in mobilization of the left renal vein. The gonadal vein and descending lumbrical veins are left intact to give additional venous outflow to the shunt. If a circumaortic left renal vein is present with a small anterior branch, decompression may be compromised. In this case, anastomosis directly to the IVC should be considered (i.e., a distal splenocaval shunt) (Atta, 1992). A vessel loop is placed around the left renal vein, and an adequate length of splenic vein should be dissected such that when it is divided at the PV, it can reach the left renal vein easily without tension.

Identification and ligation of the CV is an essential component of the operation. It is preferable to ligate the CV at its junction with the PV or splenic vein. The CV also can be ligated at the superior border of the pancreas, just before it extends along the lesser curvature of the stomach. The CV is generally large and attenuated and must be ligated if the shunt is to be selective. Blood flow through the completed shunt (see Fig. 76A.5) can be measured with a flowmeter and is generally 300 to 1000 mL/min.

DEVASCULARIZATION PROCEDURES FOR BLEEDING ESOPHAGEAL VARICES

Surgical devascularization procedures were developed with the intent of disconnecting varices from the hypertensive portal venous system, decreasing the risk of variceal hemorrhage (see Chapter 75C). In contrast to most shunts, these procedures avoid encephalopathy by preserving hepatic portal perfusion. The gold standard of devascularization procedures has become the Sugiura procedure, which consists of thoracic esophageal transection and devascularization followed weeks later by laparotomy to control bleeding from esophageal varices (Sugiura & Futagawa, 1973). The Sugiura procedure differs from other devascularization procedures in that extensive esophageal and gastric devascularization is performed in a manner that preserves the venous collaterals connecting the CV to the azygos system, which discourages varices from reforming. The initial report by Sugiura and Futagawa (1973) included 276 patients

and described an operative mortality rate of 4.3% and reoccurrence of varices in 2.3% after follow-up of 1 to 10 years. Actuarial survival was 83%. Survival according to CTP classification was 95% for class A, 87% for class B, and 57% for class C. Survival was better after an elective procedure than after an emergency operation.

The outstanding results achieved in the Japanese series have not been duplicated elsewhere. Many surgeons outside Japan have used modifications of the Sugiura procedure to control bleeding esophageal varices, particularly in patients with extensive mesenteric venous thrombosis or in those with a previous failed surgical shunt. Orozco and colleagues (1992) reported a 10-year experience with the elective Sugiura procedure using a one-stage transabdominal approach. Mortality rate correlated with CTP class. The Toronto experience with the modified Sugiura procedure was reported by Dagenais and colleagues in 1994 and included a 22% operative mortality rate when the procedure was used in the emergency setting; the 5-year survival rates were 100% for CTP class A, 43% for class B, and 25% for class C patients. In a series of 32 patients undergoing transabdominal esophagogastric devascularization for variceal bleeding, 11 of the 12 patients without liver disease survived more than 10 years. The other 20 patients with cirrhosis had a 5-year survival rate of 51% (Jin & Rikkers, 1996). This experience suggests that esophagogastric devascularization is an effective alternative to shunt surgery, particularly in patients whose underlying condition is diffuse splanchnic venous thrombosis in the absence of liver disease. The only prospective, randomized clinical trial comparing the Sugiura procedure with selective or total shunts was performed in patients with bilharzial cirrhosis and bleeding varices (da Silva et al, 1986). This trial concluded that patients treated with devascularization were more likely to survive longer without encephalopathy compared with patients treated with a shunt (da Silva et al, 1986; Raia et al, 1991).

Patients with portal venous anatomy unsuitable for surgical shunts, those who have had shunt failures, and those who do not respond to medical management may be considered for devascularization procedures. Patients who progress to CTP class C liver failure should be considered for liver transplantation. Devascularization procedures should be reserved for those rare patients with bleeding varices refractory to medical management and who also are ineligible for TIPS, a surgical shunt, or liver transplantation.

LIVER TRANSPLANTATION FOR BLEEDING ESOPHAGEAL VARICES

Definitive therapy for patients with advanced liver failure (CTP class B or C) is liver transplantation (see Chapter 97). Variceal hemorrhage is the most common clinical manifestation of portal hypertension to prompt liver transplant evaluation. The acute management of variceal hemorrhage in liver transplant candidates begins with endoscopic diagnosis and endoscopic variceal ligation where feasible, in combination with pharmacologic therapy, TIPS, or both for failures of endoscopic management. In view of the strong correlation between CTP class and long-term outcome, seen with virtually every form of therapy for bleeding varices, compelling evidence suggests that liver transplantation should be the treatment of choice for such patients with advanced liver disease. In the current era, each of the treatments discussed so far, including surgical shunts, should be used in a complementary fashion, and many patients require sequential application of the various modalities. Naturally, liver transplantation is the ultimate solution to cirrhosis and end-stage liver failure, when this is the underlying cause of portal hypertension and variceal hemorrhage.

Because of the disparity between the number of patients awaiting liver transplantation and the supply of donor livers, transplantation is generally accompanied by an unpredictable waiting period that varies depending on the supply of donor livers. Average waiting times for liver transplantation in the United States vary from 6 months to more than 2 years, depending on blood type (U.S. Department of Health and Human Services, 2003). Operative morbidity and mortality associated with liver transplantation correlate with the preoperative condition of the recipient. For this reason, it is advisable to use alternative measures to arrest variceal hemorrhage and to optimize the medical condition of the patient before proceeding to liver transplantation. Liver transplant programs in the United States preclude active alcoholics from liver transplantation and require at least a 6-month period of abstinence. This therapy generally is unavailable to active alcoholics with variceal hemorrhage, and such patients may need to be considered for surgical shunts. Because of immediate normalization of portal pressure, liver transplantation is effective therapy for bleeding esophageal varices resulting from underlying portal hypertension (Ewaga et al, 1994).

A portacaval shunt or surgical shunt involving dissection in the porta hepatis makes subsequent liver transplantation more technically difficult. If liver transplantation is anticipated after a surgical shunt, a shunt should be performed outside the porta hepatis whenever possible. Distal splenorenal and mesocaval shunts are preferred shunts for such patients (Knechtle et al, 1994; Shaked & Busuttil, 1991). A surgical shunt is an attractive means of controlling variceal hemorrhage in a patient who may not need liver transplantation for several years. Most patients eligible for liver transplantation with CTP class C cirrhosis require transplantation in the short term and are managed more appropriately with TIPS as a bridge to liver transplantation. TIPS may significantly improve the CTP class and may reduce morbidity for patients awaiting liver transplantation (Fig. 76A.9; Odorico, 1998).

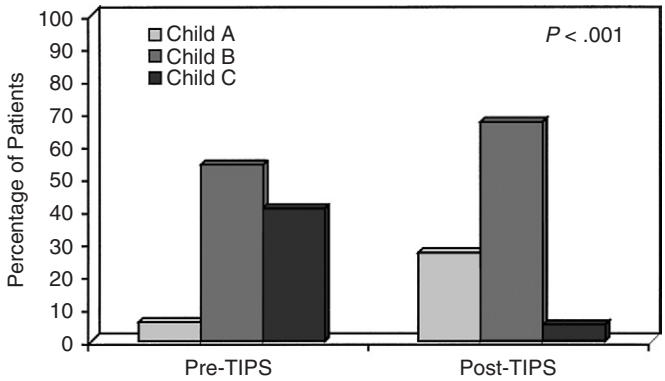

FIGURE 76A.9. Effect of transjugular intrahepatic portosystemic shunting (*TIPS*) on modified Child-Turcotte-Pugh (CTP) score. TIPS resulted in a significant shift toward improved recipient CTP score and pretransplant status ($P = .001$). *(From Odorico JS, 1998: Impact of transjugular intrahepatic portosystemic shunt on liver transplantation. In Knechtle SJ [ed]: Portal Hypertension: A Multidisciplinary Approach to Current Clinical Management. Armonk, NY, Futura, pp 253-263.)*

Meso-Rex Shunt for Portal Vein Stenosis after Liver Transplantation

Especially in children, extrahepatic PV stenosis may occur after liver transplantation, and it is generally seen many months or years after surgery. Often it manifests as portal hypertension, with GI bleeding from the Roux-en-Y, worsening splenomegaly, or even encephalopathy (Chiu & Superina, 2006; Superina et al, 2006). This problem, limiting PV blood flow to the liver and creating portal hypertension, can be addressed with a PV or SMV to left PV shunt graft, termed the *Meso-Rex shunt*. Autologous vein is generally used to create such a shunt, which relieves portal hypertension and restores physiologic blood flow to the liver (Bambini et al, 2000).

Extrahepatic Portal Vein Thrombosis

Extrahepatic PV thrombosis is a relatively uncommon cause of portal hypertension and variceal bleeding. Management of this entity is distinctly different from that of patients with cirrhosis because these patients usually have a normal liver, and survival is not limited by progression of the underlying liver disease. The etiology of PV thrombosis includes direct causes—neonatal peritonitis, trauma, and tumors of the porta hepatis—as well as congenital abnormalities of the PV, and indirect causes such as neonatal systemic sepsis, dehydration, and hypercoagulable states. PV thrombosis results in presinusoidal portal hypertension and the development of hepatopedal collaterals, which often maintain excellent portal perfusion.

Experience in the treatment of variceal bleeding as a result of PV thrombosis indicates three possible treatment options. Expectant medical management of each acute bleeding episode is tempting because the bleeding is generally well tolerated when the liver is normal. This approach may be appropriate in infants because bleeding tends to be self-limited, and half of these patients outgrow their variceal bleeding without therapy. Endoscopic variceal ablation and surgery should certainly be considered in the adult population, in whom the mortality rate for variceal hemorrhage approaches 20% over time with recurrent bleeding. It must be remembered that the same normal liver that allows patients to tolerate conservative management of bleeding also makes them excellent candidates for more aggressive treatment. Typically, the acute episode of variceal bleeding can be managed by resuscitation, vasopressin or octreotide infusion, and then endoscopic variceal ablation (Howard et al, 1988; Warren et al, 1988).

If bleeding becomes recurrent, evaluation of the portal, mesenteric, and splenic veins is performed with visceral angiography to include venous phases and/or magnetic resonance angiography. If the spleen is in situ and the splenic vein is patent, the patient is an excellent candidate for the distal splenorenal shunt, although central splenorenal shunts and mesocaval shunts can also be used if the SMV is also open. If the splenic vein is also occluded or if the spleen is absent, further endoscopic variceal ablation should be attempted. If this fails, exploration is performed. In rare cases, a shuntable vein can be found, such as the CV (a coronary caval shunt). Most often, if the spleen has not already been removed at a previous operation, usually for thrombocytopenia, a gastric devascularization with splenectomy is required. Recurrent variceal hemorrhage after devascularization can occur in 20% to 30% of patients, which requires further endoscopic variceal ablation but rarely esophagogastrectomy (Galloway & Henderson, 1990).

PRESENT ROLE OF SURGICAL SHUNTS

A shunt may often serve as a long-term bridge to liver transplantation in patients who are deemed to be acceptable candidates for liver transplantation. In a report comparing liver transplantation, shunts (82% distal splenorenal) in future candidates for liver transplantation, and shunts in patients without the future prospect of liver transplantation, the operative mortality rate was best in the two shunt groups (5% and 7% vs. 19% in liver transplant recipients). This finding was attributed to more advanced disease in the liver transplant cohort. The patients not considered for liver transplantation were excluded because of active alcoholism or advanced age. Kaplan-Meier survival analysis showed better survival in shunt patients who were transplant candidates—seven of 44 patients had progressed to liver transplantation—than either the liver transplant group or the shunt group without prospective liver transplantation during the first 5 years of follow-up. However, by 10 years no difference was reported between the groups (Fig. 76A.10). These results suggest that patients with CTP class A or early B cirrhosis, who are not actively drinking and are not too elderly or medically unfit, benefit from shunt surgery most. Because it is complicated less frequently by encephalopathy and because it has an excellent long-term patency rate, a distal splenorenal shunt is a good choice for such patients. If they progress to end-stage liver failure, they can be salvaged with transplantation (Rikkers et al, 1997). During the period studied, distal splenorenal shunts and nonselective shunts were more protective against rebleeding than was esophagogastric devascularization (Rikkers et al, 1997).

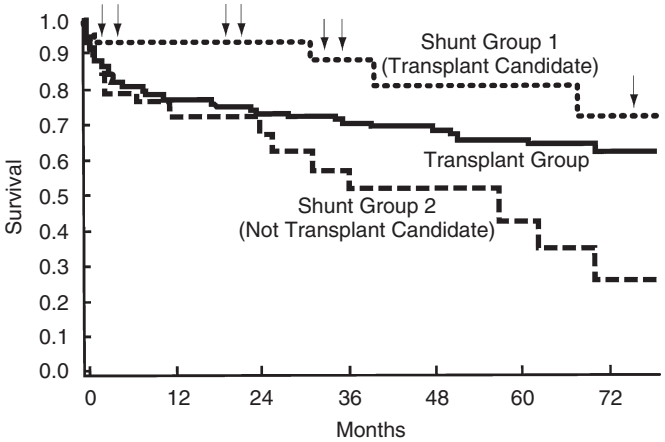

FIGURE 76A.10. Kaplan-Meier survival analysis of shunt group 1 (*dotted line*), transplant group (*solid line*), and shunt group 2 (*dashed line*). The *arrows* on the shunt group 1 curve indicate when patients from that group underwent liver transplantation. Survival of shunt group 1 is significantly different from survival of the transplant group ($P = .003$) and shunt group 2 ($P = .018$) at 1 year (log-rank test). At 5 years, the shunt group 1 and transplant group curves are no longer different, but both are significantly different from the shunt group 2 curve ($P = .006$ and $P = .029$). *(From Rikkers LF, et al, 1997: Shunt surgery during the era of liver transplantation. Ann Surg 226:51-57.)*

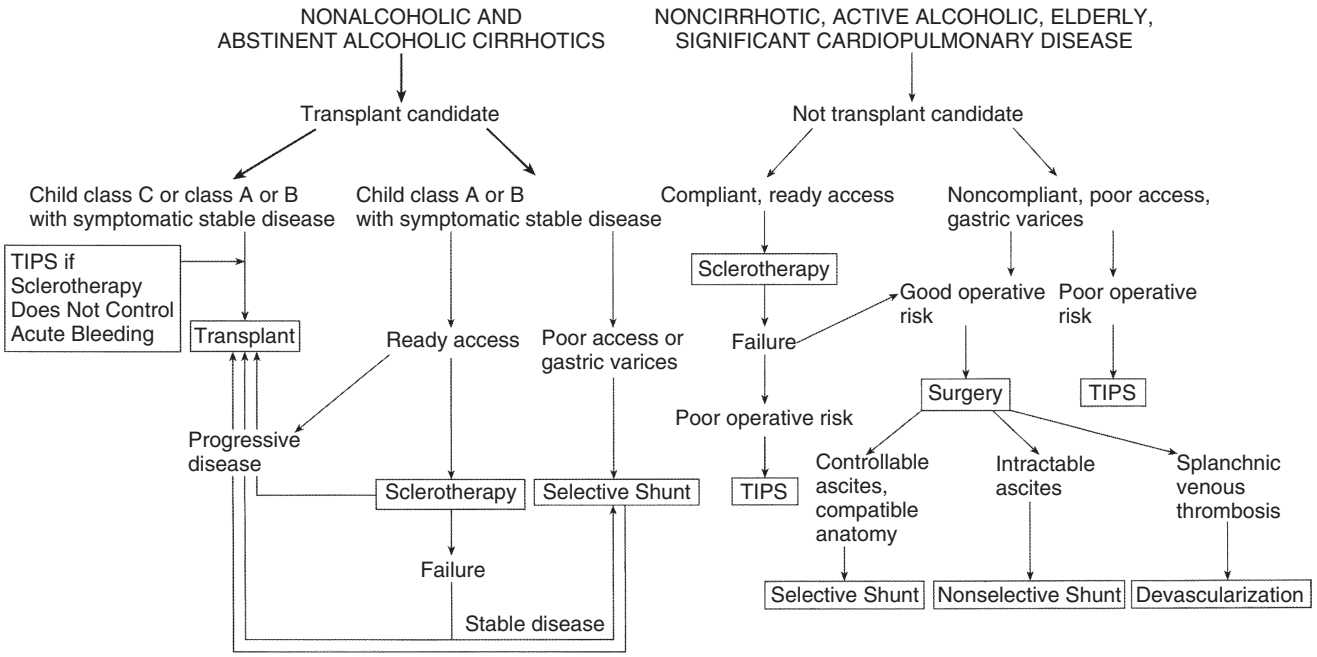

FIGURE 76A.11. Algorithm for definitive therapy of variceal hemorrhage. TIPS, transjugular intrahepatic portosystemic shunt. *(From Rikkers LF, 1995: Portal hypertension. In Levine BA, et al [eds]: Current Practice of Surgery, vol 3. New York, Churchill Livingstone, pp 1-22.)*

Consistent with the aforementioned observations, surgical shunts generally are reserved for patients with good hepatic reserve and variceal bleeding. Excellent results are achieved in this setting (Knechtle et al, 1999).

An algorithm summarizing current decision making in the management of variceal hemorrhage is shown in Figure 76A.11. Patients are divided into those potentially eligible for a liver transplant versus ineligible patients. The sequential use of various modalities is illustrated. The current use of procedures performed for variceal hemorrhage suggests that although banding continues to be used frequently, the use of TIPS has dramatically increased, as has liver transplantation. Nonselective shunts are rarely used today, and selective shunts are performed in a highly select group of patients.

During the past 25 years, liver transplantation and TIPS have evolved into effective therapies and have substantially affected management of this problem and indirectly changed the risk status (CTP class) of patients undergoing shunts. Analysis of this group of patients showed that in recent years the CTP class has progressively improved, and the need for emergency surgery has declined. The use of nonselective shunts declined because of the development of effective alternatives, such as EVL and TIPS, and because advanced liver failure with ascites was managed by liver transplantation, sometimes preceded by TIPS. Consequently, less risky patients were selected to undergo elective shunts for treatment of variceal bleeding. The incidence of postoperative encephalopathy decreased, and long-term (10-year) survival improved, especially because shunt patients could be salvaged if they developed liver failure postoperatively (Rikkers, 1998).

Another role for portosystemic surgical shunts is in children with variceal hemorrhage after endoscopic therapy. Excellent results have been achieved in children with distal splenorenal shunts and mesocaval shunts to prevent bleeding (Botha et al, 2004).

SUMMARY

The clinical management of bleeding esophageal varices has changed radically over the past 25 years. Recent changes include replacement of endoscopic variceal sclerotherapy by endoscopic variceal ligation. The excellent efficacy of EVL and its lower complication rate favor its increased use. Similarly, the minimally invasive nature of the TIPS procedure and its successful implementation by invasive radiologists has reduced further the need for surgical shunts. TIPS is being increasingly used when endoscopic intervention has failed. Another recent change is the use of ePTFE-covered stents, rather than bare stents, which allows better patency rates over time for TIPS. Liver transplantation is routinely recommended for patients with advanced liver failure. Surgical shunts are used more selectively, but with better results than in an earlier era when they were more commonly performed. A multidisciplinary approach to evaluation and treatment of variceal hemorrhage has improved the outcomes of these patients. Selective use of each of the therapies, alone or in combination with other modalities, results in improved outcomes.

We consider the current role of surgical shunts to be 1) less frequent than in the previous era; 2) of benefit in the emergency setting when other modalities—including medical therapy, endoscopic control, or TIPS—have failed; 3) useful in the elective setting as a long-term bridge to liver transplantation; 4) useful in the elective setting as definitive therapy for patients with noncirrhotic portal hypertension or CTP class A cirrhosis; and 5) a beneficial treatment for Budd-Chiari syndrome. We prefer the selective distal splenorenal shunt in patients without ascites because of its lower risk of portosystemic encephalopathy and its potential for preserving portal blood flow.

CHAPTER 77

Budd-Chiari syndrome and venoocclusive disease

Marshall J. Orloff, Mark S. Orloff, and Susan L. Orloff

OVERVIEW

Budd-Chiari syndrome (BCS) is a group of disorders caused by occlusion of the major hepatic veins or the inferior vena cava (IVC) or both at or near the level of the hepatic vein ostia. Although a brief discussion of these disorders first appeared in a book by Budd in 1845, Lambron in 1842 is said to have reported the first case. In 1899, Chiari collected 10 cases and reported three personal cases and presented the first thorough clinical and pathologic description of the syndrome, including the hypothesis that the underlying mechanism is endophlebitis of the hepatic veins. The weight of evidence favors the current opinion, however, that the primary process is usually thrombotic rather than inflammatory. Since publication of the initial description, more than 8000 cases of BCS have been described in the medical literature. In recent years, the incidence has increased substantially, most likely as a result of increased awareness of BCS, improvements in diagnostic methods, and widespread use of thrombogenic agents, such as oral contraceptives (Maddrey, 1987; Valla et al, 1986). Nevertheless, BCS remains a relatively uncommon condition.

Obstruction of hepatic venous outflow produces intense congestion of the liver and the clinical manifestations of ascites, hepatomegaly, and abdominal pain. Depending on the rapidity and extent of obstruction of hepatic venous outflow, the course of BCS may be rapid or chronic, progressing to death in a matter of weeks, or leading to death from liver failure or bleeding esophageal varices after an illness of months or occasionally years. In Western countries, a rapid course is more common, and the outcome has been fatal in many reported cases.

Venoocclusive disease (VOD), more recently called *sinusoidal obstruction syndrome,* is a group of disorders that mimic BCS, but it involves distinctly different populations of patients and is precipitated by distinctly different circumstances. In contrast to BCS, VOD occurs in the sublobular branches of the hepatic veins, the terminal hepatic venules, and the sinusoids within the liver, and the pathologic process involves obliteration of these small vessels by subendothelial sclerosis owing to endothelial injury, with thrombosis occurring secondarily. VOD is caused by a variety of toxic agents, such as pyrrolizidine alkaloids, antineoplastic drugs, and irradiation of the liver. In the Western hemisphere, the most frequent cause of VOD is bone marrow (hematopoietic stem cell) transplantation.

In recent years, effective surgical therapy has been developed that is designed to decompress the obstructed hepatic vascular bed. As a result, the previously dismal outlook for patients with BCS has improved considerably.

PREDISPOSING CONDITIONS FOR BUDD-CHIARI SYNDROME

Box 77.1 lists the specific conditions that are known to predispose to the development of BCS and VOD. Over the past 50 years, a marked change has been observed in the frequency with which a known cause or predisposing condition has been identified in cases of BCS. In the classic collective review of 164 cases of BCS reported by Parker in 1959, a predisposing condition or etiology could not be identified in 70% of the patients. In recent years, the incidence of idiopathic cases of BCS has plummeted to less than 30% (Mahmoud et al, 1996; Menon et al, 2004; Mitchell et al, 1982; Murad et al, 2009; Valla, 2003; Plessier & Valla, 2008), an improvement attributed to two factors: 1) a greater awareness of BCS and 2) improved diagnostic tools for identifying the anatomic lesions and for diagnosing thrombogenic hematologic disorders.

The distinct difference has been recognized for some time between the East and West in the conditions that predispose to the development of BCS and in the anatomic pattern of BCS. Table 77.1 displays these differences. *Membranous obstruction of the vena cava* (MOVC) is rare in the West, but it is a frequent cause of BCS in Eastern countries such as Japan, China, and India and in South Africa. In the West, thrombosis of the major hepatic veins alone is substantially more common than thrombosis or occlusion of the IVC; whereas in India, China, and Japan, IVC occlusion is far more common than hepatic vein occlusion alone. In North America, the acute or subacute forms of BCS predominate, and chronic BCS is observed less frequently, whereas in the East, the reverse is observed. In the West, BCS is seldom found during pregnancy or the postpartum period, whereas in India, pregnancy is a major predisposing condition for BCS. The same difference is seen in the incidence of infections such as hepatic amebiasis (see Chapter 67), which are rare in the West but are reported frequently in series of BCS from India. Finally, oral contraceptives are frequently associated with BCS in the United States, where use of these agents is widespread, whereas use of birth control pills is seldom associated with BCS in Eastern countries, where women use oral contraceptives much less.

Hematologic Disorders

Hematologic diseases that cause vascular thrombosis are the most common conditions that predispose to BCS in North America and Western Europe. Of disorders with thrombotic tendencies, polycythemia rubra vera is the most frequent,

Box 77.1

Conditions Predisposing to Budd-Chiari Syndrome and Venoocclusive Disease

Budd-Chiari Syndrome

- Hematologic disorders
  - Polycythemia rubra vera
  - Paroxysmal nocturnal hemoglobinuria
  - Essential thrombocythemia
  - Primary erythrocytosis
  - Myelofibrosis
  - Acute leukemias and lymphomas
  - Hemolytic anemias
  - Protein-C deficiency
  - Protein-S deficiency
  - Antithrombin-III deficiency
  - Lupus anticoagulant (antiphospholipid syndrome)
  - Factor V Leiden mutation
  - *JAK2* V617F mutation
  - Prothrombin (factor II) mutation
  - Antiphospholipid syndrome
  - Hyperhomocysteinemia
- Oral contraceptives
- Pregnancy and postpartum
- Malignant neoplasms
  - Hepatocellular carcinoma
  - Renal cell carcinoma
  - Adrenal carcinoma
  - Leiomyosarcoma of the inferior vena cava
  - Others (carcinomas of the lung, pancreas, and stomach; melanoma; reticulum cell sarcoma; adrenal sarcoma; tumor of the right atrium)
- Infections
  - Amebic liver abscess
  - Aspergillosis
  - Hydatid disease
  - Schistosomiasis
  - Syphilitic gumma
  - Filariasis
- Trauma
- Connective tissue disorders
  - Behçet syndrome
  - Sjögren syndrome
  - Mixed connective tissue disease
  - Sarcoidosis
  - Rheumatoid arthritis
  - α_1-Antitrypsin deficiency
  - Idiopathic hypereosinophilia syndrome
  - Systemic lupus erythematosus
- Membranous obstruction of the inferior vena cava
- Miscellaneous rare conditions (inflammatory bowel disease, hepatic torsion, lipoid nephrosis, protein-losing enteropathy)

Venoocclusive Disease

- Pyrrolizidine alkaloids
- Antineoplastic chemotherapy
- Irradiation of the liver
- Bone marrow transplantation
- Azathioprine
- Systemic lupus erythematosus
- Familial immunodeficiency
- Oral contraceptives

constituting 8.5% of the cases of BCS in the collected series of Parker (1959) and 10.4% of the cases in the collected series of Mitchell and colleagues (1982). In our series of 77 cases of BCS, 31% had polycythemia rubra vera, which is associated with BCS in some distinctly different ways compared with the classic disease. For one thing, it is found in young adults, rather than in middle-aged and elderly patients, and it is responsive to treatment with hydroxyurea or anagrelide, which should be started as soon as the disease is discovered and should be continued for life. In our experience, the disease runs a benign course if treated. Finally, polycythemia rubra vera associated with BCS is compatible with a long life, if it is treated with hydroxyurea.

Table 77.1

Differences Between West and East in Predisposing Conditions and Anatomic Patterns of Budd-Chiari Syndrome

Feature	West	East
Membranous obstruction of the IVC	Rare	Frequent
Hepatic vein occlusion predominates	+	–
IVC occlusion predominates	–	+
Acute or subacute BCS predominates	+	–
Chronic BCS predominates	–	+
Pregnancy/postpartum	Uncommon	Frequent
Infection	Rare	Common
Oral contraceptives	Frequent	Uncommon

BCS, Budd-Chiari syndrome; IVC, inferior vena cava

Paroxysmal nocturnal hemoglobinuria is another hematologic disorder associated with BCS (Hartmann et al, 1980; Hoekstra et al, 2009; Liebowitz & Hartmann, 1981; Valla et al, 1987). It was responsible for 6.7% of the cases in the collected series of Mitchell and colleagues (1982) and 12% of the cases in the series of Valla and colleagues (1987). In all of the hematologic disorders associated with hepatic vein thrombosis, but particularly in paroxysmal nocturnal hemoglobinuria, thrombosis of other blood vessels outside of the liver has sometimes been observed. These cases of multiple sites of thrombosis have involved the portal, splenic, and superior mesenteric veins; pelvic veins; deep calf veins; splanchnic arteries; pulmonary artery; coronary arteries; and cerebral arteries (Peytremann et al, 1972).

As hematologic diagnosis has become progressively more sophisticated, many other thrombogenic conditions have been identified in BCS, including other myeloproliferative states—such as essential thrombocythemia, primary erythrocytosis, and myelofibrosis—and thrombophilic states, such as protein C deficiency, protein S deficiency, antithrombin III deficiency, and antiphospholipid syndrome with lupus anticoagulant or anticardiolipin antibodies or both (Bertina et al, 1994; Boughton, 1991; Dahlback, 1995; Dahlback et al, 1993; Espinosa et al, 2001; Koster et al, 1993; Mahmoud et al, 1995; Menon et al, 2004; Pelletier et al, 1994; Svensson & Dahlback, 1994; Valla, 2003; Vandenbroucke et al, 1994). Subjects with the factor V Leiden mutation, which leads to activated protein C resistance, have a 5-fold to 10-fold increase in the risk of thrombosis if they are heterozygotic and a 50-fold to 100-fold increase if they are homozygotic (Dahlback, 1995; Deltenre et al, 2001; Janssen et al, 2000). More recent evidence indicates that multiple prothrombotic factors acting concurrently are involved in a substantial percentage of patients with BCS (Denninger et al, 2000; Janssen et al, 2000). Rarely, hematologic malignancies, such as acute leukemia and lymphoma, have been associated with BCS.

In 2005, identification of the underlying cause of BCS was enhanced by the discovery of a very reliable and noninvasive marker for chronic myeloproliferative disorders. The marker is the gain-of-function mutation V617F of the *JAK2* gene (Baxter et al, 2005; James et al, 2005; Jelinek et al, 2005; Jones et al, 2005; Kralovics et al, 2005; Levine et al, 2005; Steensma et al, 2005; Zhao et al, 2005). By combining identification of this marker with results of bone marrow histology and clonality assay, over 50% of the cases of BCS have been found to be due to an underlying chronic myeloproliferative disorder (Primignani et al, 2006).

It cannot be overemphasized that every patient found to have BCS should undergo a thorough hematologic evaluation. The workup that we perform is an expansion of the workup proposed by Mahmoud and Elias (1996) and others (Hirschberg et al, 2000; Valla, 2009) and is shown in Box 77.2. With these studies, it should be possible to diagnose all of the predisposing thrombogenic hematologic disorders known to be associated with BCS. If an evaluation such as this is done uniformly, it is highly likely that the incidence of idiopathic BCS will continue to decline.

Oral Contraceptives

An increased incidence of thromboembolic phenomena involving various blood vessels and organs in women taking oral contraceptives has been well established. The first case of BCS associated with use of oral contraceptives was reported by Ecker and McKittrick (1966), 5 years after these drugs became available commercially. Since then, more than 200 cases of BCS in patients taking oral contraceptive have been described (Janssen et al, 2000; Lewis et al, 1983; Maddrey, 1987; Valla et al, 1986; Zafrani et al, 1983), and the increasing overall incidence of BCS in recent years has been attributed partly to the widespread use of these agents. In the collective review reported by Mitchell and colleagues (1982), use of oral contraceptives was believed to be responsible for 9.4% of the cases of BCS during the period 1960 to 1980. Valla and associates (1986) reported that the relative risk of hepatic vein thrombosis among oral contraceptive users was close to that of stroke, myocardial infarction, and venous thromboembolism. In our series of 77 cases of BCS, 23% of patients gave a history of oral contraceptive use. The incidence is even higher if the denominator consists only of the number of women in each series. In our series, 49% of the 37 women with BCS used oral contraceptives.

Some authors have proposed that oral contraceptives are not a primary cause of BCS but contribute to thrombosis only if there is an underlying hematologic disorder (Valla et al, 1986). In our series, no hematologic disease was identified in users of oral contraceptives, but until relatively recently, our patients did not undergo the extensive hematologic workup shown in Box 77.2. The duration of usage of oral contraceptives before the diagnosis of BCS has ranged from 2 weeks to 10 years. In addition to causing BCS, oral contraceptives have been linked to other liver disorders, including VOD, portal vein thrombosis, cholestasis, hepatocellular adenoma, focal nodular hyperplasia, and possibly hepatocellular carcinoma and angiosarcoma (Zafrani et al, 1983).

Pregnancy and Postpartum

BCS has been observed in women during pregnancy and, more commonly, during the postpartum period. The first case of BCS reported by Chiari (1899) occurred in a woman who developed the disorder after childbirth. In the collective review by Mitchell and colleagues (1982), 9.9% of the cases of BCS occurred during pregnancy or postpartum, and in a series of 105 patients with BCS observed from 1963 through 1978, Khuroo and Datta (1980) reported 16 cases (15.2%) of BCS after pregnancy; 8 of the patients died, and 7 were lost to follow-up after discharge from the hospital. The hypercoagulable state that is known to occur during pregnancy is presumed to be responsible for the association of BCS with this condition, although only 1 of our 77 cases of BCS occurred during pregnancy or postpartum.

Box 77.2

Screening for Hematologic Disorders in Budd-Chiari Syndrome

Complete blood count, prothrombin time, partial thromboplastin time, fibrinogen
Red blood cell mass, plasma volume
Bone marrow biopsy, cell culture, karyotype
JAK2 gene, V617F mutation in peripheral blood granulocytes
Antithrombin-III assay
Protein-C assay
Free protein-S antigen assay
Lupus anticoagulant
Anticardiolipin antibodies
Ham's acid hemolysis test
Activated protein C resistance or Factor V Leiden mutation or both
Endogenous erythroid colony assay
Flow cytometry for blood cells deficient in CD55 and CD59 (PNH)
Molecular test for G20210A prothrombin gene mutation
Anti-β_2 glycoprotein-1 antibodies
Plasma homocysteine level

PNH, paroxysmal nocturnal hemoglobinurea.

Malignant Neoplasms

Malignant neoplasms were responsible for 13.4% of the collected cases of BCS reported by Parker (1959), 8.8% of the collected cases reported by Mitchell and colleagues (1982), and 12% of the cases reported by Powell-Jackson and colleagues (1982). Because we do not operate on patients with BCS caused by cancer, none of our 77 patients had malignant neoplasms. Occlusion of the suprahepatic IVC by invasive tumors has been the cause of BCS in many cases. The most common cancers associated with BCS are hepatocellular carcinoma, renal cell carcinoma, adrenal carcinoma, and leiomyosarcoma of the IVC. Other malignancies that rarely have caused BCS include carcinomas of the lung, pancreas, and stomach; melanoma; reticulum cell sarcoma; adrenal sarcoma; and sarcoma of the right atrium.

Infections

Infections involving the liver were believed responsible for 3% of the collected cases of BCS reviewed by Parker (1959), 9.9% of the collected cases reported by Mitchell and colleagues (1982), and none of the cases in sizable series reported in more recent years, including our own series. The most common infections associated with BCS are those caused by parasites, particularly amebic liver abscess, hydatid disease, and schistosomiasis (see Chapters 67 and 68). Syphilitic gumma of the liver accounted for 1.8% of the cases in Parker's review but has not been reported as a cause of BCS in recent years. Aspergillosis involving the hepatic veins and IVC has been a rare cause of BCS. In India, Victor and colleagues (1994) provided evidence that filariasis can cause BCS.

Trauma

Abdominal trauma has uncommonly predisposed to the development of BCS. Trauma was responsible for 1.2% of the collected cases of BCS reported by Parker (1959) and 2.4% of the collected cases reviewed by Mitchell and colleagues (1982). Blunt and penetrating trauma have been implicated in occasional cases of BCS.

Connective Tissue Disorders

Occasional cases of BCS have been reported in association with various connective tissue and autoimmune diseases, most of which are known to have thrombotic tendencies. Included among these are Behçet disease, Sjögren syndrome, mixed connective tissue disease, sarcoidosis, and rheumatoid arthritis. Numerous cases of BCS in patients with Behçet disease,

including five of our own, have been described (Bazraktar et al, 1997; Orloff & Orloff, 1999).

Membranous Obstruction of the Vena Cava

More than 600 cases of BCS resulting from MOVC have been reported from Japan (Hirooka & Kimura, 1970; Kimura et al, 1972; Okuda, 2002; Ono et al, 1983; Taneja et al, 1979; Yamamoto et al, 1968), China (Wang, 1989; Wang et al, 1989; Wu et al, 1990) and other parts of Asia, India (Khuroo & Datta, 1980), and South Africa (Semson, 1982). In the United States and Europe, MOVC is rare. A congenital cause of this condition has been proposed, but evidence strongly suggests it represents the end result of acquired thrombosis (Kage et al, 1992; Okuda 2002; Okuda et al, 1995).

MOVC usually runs a chronic course over many years, and most patients will have developed extensive hepatic fibrosis and cirrhosis and portal hypertension by the time they come to medical attention. An increased incidence of hepatocellular carcinoma has been observed in association with MOVC (Okuda, 2002; Semson, 1982). The therapeutic implications of this condition and other forms of IVC occlusion are distinctly different from those of occlusion confined to the major hepatic veins.

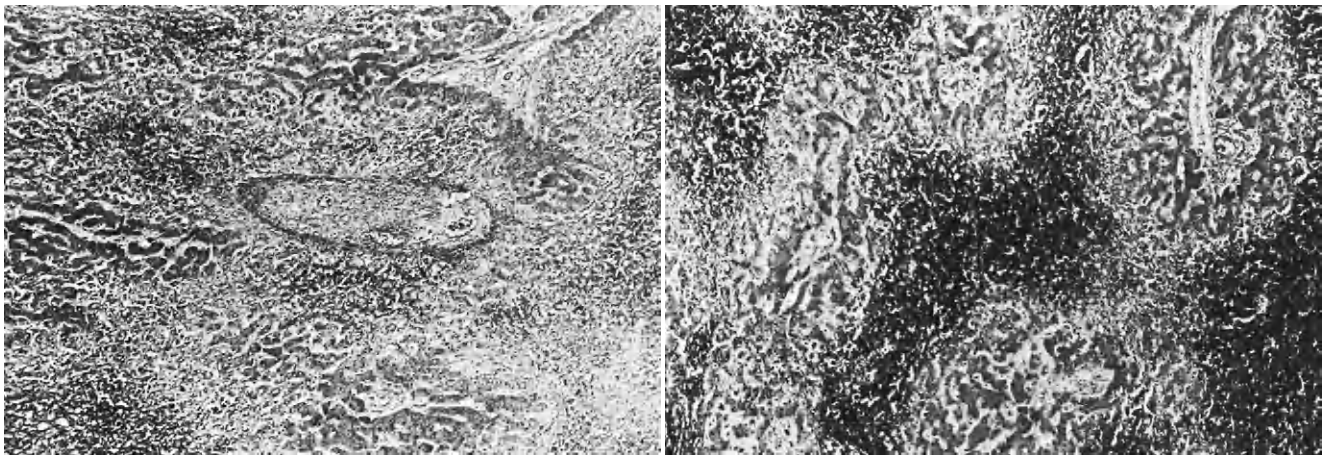
Miscellaneous Rare Conditions

Other conditions that have been rarely associated with BCS include inflammatory bowel disease, hepatic torsion after partial resection of the liver, lipoid nephrosis, and protein-losing enteropathy.

CAUSES OF VENOOCCLUSIVE DISEASE

In 1954, Bras and colleagues proposed the term *venoocclusive disease* to describe a serious and common liver disease in Jamaican children in which there was occlusion of the central and sublobular hepatic veins and surrounding centrilobular necrosis of the liver parenchyma. More recently, the condition has been called the *sinusoidal obstruction syndrome*. Shortly after his initial description, Bras and others (Bras & McLean, 1963; Brooks et al, 1970; Gore et al, 1961; Stuart & Bras, 1957) showed that VOD was due to ingestion of "bush teas" made from plants of the *Crotolaria* and *Senecio* genera, which contain well-known hepatotoxic pyrrolizidine alkaloids. It has long been known that these plants and plants of the *Heliotropium* genus produce liver failure in herbivorous animals and are common causes of poisoning of grazing cows and horses. Since the initial descriptions by Bras and others, VOD caused by ingestion of toxic pyrrolizidines has been observed in Israel (Ghanem & Hershko, 1981), Egypt (Safouh & Shehata, 1965), Iraq (Al-Hasany & Mohamed, 1970), Afghanistan (Mohabbat et al, 1976), India (Aikat et al, 1978; Tandon et al, 1976), Venezuela (Grases & Beker, 1972), Ecuador (Lyford et al, 1976), South Africa (Steenkamp et al, 2000; Zuckerman et al, 2002), and the United States (Abbott, 1988; Bach et al, 1989; Ridker & McDermott, 1989; Ridker et al, 1985; Stillman et al, 1977). In addition to poisoning by drinking bush teas, humans have been poisoned by eating flour milled from grain contaminated by the seeds of these plants and by taking herbal remedies.

Antineoplastic drugs have been identified as another cause of VOD. Included among these are cytosine arabinoside, thioguanine, and gemtuzumab ozogamicin (Mylotarg) used in the treatment of acute myelocytic leukemia (Cruz et al, 1983; Giles et al, 2001; Gill et al, 1982; Griner et al, 1976); carmustine used in the treatment of diffuse histiocytic lymphoma (McIntyre et al, 1981); dacarbazine used in the treatment of melanoma (Asbury et al, 1980); oxaliplatin used in treatment of metastatic colorectal adenocarcinoma to the liver (Cleary et al, 2009; Pawlik et al, 2007; Mehta et al, 2008; Kandutsch et al, 2008; Rubbia-Brandt et al, 2004); and gemtuzumab ozogamicin and mitomycin C combined with bone marrow transplantation (Kumar et al, 2003; Lazarus et al, 1982; McDonald et al, 1993; Wadleigh et al, 2003). Fatal VOD in renal transplant recipients has been attributed to azathioprine (Liano et al, 1989; Marubbio & Danielson, 1975).



Hepatic injury caused by therapeutic irradiation of malignant neoplasms in and near the liver is an important cause of VOD (Fajardo & Colby, 1980; Reed & Cox, 1966). Although radiation-induced VOD usually does not produce clinical manifestations with doses less than 3000 rad, the condition has been observed after smaller amounts of radiotherapy (Fajardo & Colby, 1980).

Currently, the most common cause of VOD in the Western Hemisphere is bone marrow transplantation (Ayash et al, 1990; Berk et al, 1979; Jones et al, 1987; Kriegshauser et al, 1988; Kumar et al, 2003; McDonald et al, 1984, 1993; Wadleigh et al, 2003; Senzolo et al, 2007; Helmz, 2006; Cacchione et al, 2008). It has been estimated that approximately one fourth of recipients of bone marrow transplants develop the disorder. It is uncertain whether VOD in these patients is caused by the marrow transplant, or if it is a result of the radiation and chemotherapy used in the pretransplant conditioning regimen. Berk and colleagues (1979) proposed that graft-versus-host disease might be responsible for VOD after marrow transplantation, but the studies of McDonald and colleagues (1984) cast doubt on this hypothesis. Finally, there have been rare reports of VOD in association with systemic lupus erythematosus (Pappas et al, 1984), familial immunodeficiency (Mellis & Bale, 1976), and the use of oral contraceptives (Alpert, 1976).

PATHOLOGY

Budd-Chiari Syndrome

The liver receives about one fourth of the cardiac output via its dual afferent blood supply, the portal vein and hepatic artery. After perfusing the sinusoids, the blood is returned to the heart through the hepatic veins and IVC. Obstruction to the egress of blood from the liver at any point along the outflow route results in numerous serious hemodynamic and morphologic alterations. There is a marked increase in intrahepatic pressure, which is reflected by a similar increase in portal pressure. The increased intrahepatic pressure causes extravasation of plasma from the liver sinusoids and lymphatics with formation of ascites. Obstruction to the egress of blood from the liver also results in dilation of the sinusoids and intense centrilobular congestion of the hepatic parenchyma, which is greatest around the terminal hepatic venules (central veins; Fig. 77.1). Ischemia, pressure necrosis, and atrophy of the parenchymal cells in the center of the liver lobule are apparent. With persistence of the obstruction, the necrotic parenchyma is replaced by fibrous tissue and regenerating nodules of liver tissue. The end result is cirrhosis of the type associated with chronic congestive heart failure. The rapidity with which cirrhosis develops is related to

A B

FIGURE 77.1. Photomicrographs of preoperative liver biopsy specimens obtained from Budd-Chiari syndrome (BCS) patients 4 **(A)** and 5 **(B)** in our series, showing a typical picture of BCS consisting of intense centrilobular congestion and necrosis with widespread loss of hepatocytes. A thrombosed hepatic vein is seen in the center in **A** (×50). *(From Orloff MJ, Johansen KH, 1978: Treatment of Budd-Chiari syndrome by side-to-side portacaval shunt: experimental and clinical results. Ann Surg 188:494-512.)*

the severity of outflow obstruction, but it is not unusual for cirrhosis to occur within a matter of months (Parker, 1959).

The reversibility of liver damage in BCS is a direct function of the extent and duration of hepatic venous outflow obstruction. Early in the course of the disease, relief of the obstruction can be expected to result in reversal of the parenchymal and hemodynamic abnormalities. Late in the course, the damage to the hepatic parenchyma becomes irreversible; hence the timing of therapy has profound implications with regard to prognosis.

Three major hepatic veins—the right, left, and middle—conduct blood into the IVC from the bulk of the hepatic parenchyma. The left and middle hepatic veins usually form a common trunk just before joining the IVC, and several small hepatic veins enter directly into the retrohepatic IVC and drain the caudate lobe and small central regions of the right and left lobes of the liver. Our BCS experience indicates that all three major hepatic veins usually are occluded, although occasionally the occlusion is limited to one or two of the major veins. The small hepatic veins that join the retrohepatic IVC, particularly the veins draining the caudate lobe, often are spared.

In most cases of BCS, occlusion of the hepatic veins is caused by thrombosis (Parker, 1959). The thrombus undergoes organization and ultimately is converted to fibrous tissue that permanently occludes the veins. Although recanalization of the occluded veins sometimes occurs, it rarely results in effective new outflow channels. Retrograde propagation of the thrombus into smaller hepatic veins is commonly found. Prograde propagation of the thrombus from the hepatic veins into the IVC, with partial or complete occlusion of the IVC, sometimes occurs and markedly changes the therapeutic approach and prognosis. It is important to determine by imaging studies that include angiography and pressure measurements whether the IVC has become involved in the occlusive process.

MOVC has been reported to be the most common cause of BCS in Japan (Hirooka & Kimura, 1970; Kimura et al, 1972; Okuda et al, 1995; Ono et al, 1983; Taneja et al, 1979; Yamamoto et al, 1968), India (Khuroo & Datta, 1980), China (Wang, 1989; Wang et al, 1989, 2005; Wu et al, 1990), and in the Bantu population of South Africa (Semson, 1982). The "membrane" varies from very thin to several centimeters thick and usually contains fibrous tissue, smooth muscle, and elastic tissue. The location and extent of the membrane vary considerably, and in some cases a long segment of IVC has been replaced by fibrous tissue. Occlusion of one or more of the major hepatic veins often has been associated with membranous obstruction of the IVC. Although some experienced authors have proposed a congenital cause (Hirooka & Kimura, 1970; Kimura et al, 1972; Ono et al, 1983; Semson, 1982; Taneja et al, 1979), a strong argument has been made that suggests MOVC is the end result of thrombosis of the IVC, often occurring early in life (Okuda et al, 2002). Most of the cases have run a chronic course before discovery, and when first seen by a physician, patients have had extensive hepatic fibrosis or cirrhosis with portal hypertension and all of its manifestations. The therapeutic considerations in patients with MOVC differ from those in patients with BCS caused by obstruction of the hepatic veins.

Venoocclusive Disease

VOD of the liver, more recently called *sinusoidal obstruction syndrome*, may mimic BCS clinically, because both conditions involve hepatic venous outflow obstruction. VOD involves the sinusoids and the central and sublobular hepatic veins within the liver, however, rather than the hepatic veins (Kumar et al, 2003; Shulman et al, 1987, 1994). The underlying process in VOD is subendothelial sclerosis of the hepatic veins and sinusoids secondary to endothelial injury caused by a toxic agent, such as a pyrrolizidine alkaloid, antineoplastic drug, radiation, or a stem cell transplant. Thrombosis of the small hepatic veins may occur after damage to the venous intima. Electron microscopic studies of liver biopsy specimens obtained from children with VOD caused by pyrrolizidine poisoning showed marked endothelial damage in the sinusoids and subterminal and terminal hepatic veins in all zones of the liver, with extravasation of erythrocytes into the space of Disse and narrowing of the lumen where the sinusoid entered the central vein (Brooks et al, 1970).

Similar to BCS, hemorrhagic necrosis of the liver parenchyma around the centrilobular veins occurs early in the course of VOD. Extensive occlusion of the small hepatic veins

ultimately leads to diffuse fibrosis and cirrhosis. Patients with VOD caused by chronic pyrrolizidine poisoning often have well-established cirrhosis when first seen by a physician. VOD that develops as a complication of therapy for another condition—such as occurs during cancer chemotherapy, radiation therapy, or bone marrow transplantation—usually is detected early in the course of the disease.

CLINICAL MANIFESTATIONS OF BUDD-CHIARI SYNDROME

The clinical manifestations and course of BCS are determined by the extent of occlusion of the hepatic venous outflow system and the rapidity with which the venous occlusion becomes complete. More often than not, patients in the West have an acute or subacute course, with rapid progression of liver disease and its consequences over periods of a few weeks to a few months. In some patients, however, BCS develops insidiously, with clinical manifestations appearing gradually over months or years. Patients with MOVC observed in Japan, China, India, and South Africa often come to the physician for the first time with manifestations of well-established cirrhosis after tolerating symptoms for many years.

In our series of 77 patients with BCS, 12 were referred with advanced cirrhosis as a result of prolonged hepatic outflow obstruction and were not candidates for portal decompression surgery. The other 65 patients were referred at a mean 14 weeks after onset of BCS (range 4 to 78 weeks). Fifty-nine of the 65 patients (91%) were referred less than 18 weeks after onset of symptoms, relatively early in the course of BCS. The remaining 6 patients were operated on 19, 21, 23, 25, 26, and 78 weeks after onset of symptoms. In the collected series of Mitchell and colleagues (1982), which excluded cases of MOVC, two thirds had had symptoms for less than 3 months, and 83% had had symptoms for 6 months or less at the time of diagnosis. In Parker's (1959) collected series of 133 cases, he observed that 57% had had symptoms for 3 months or less, and 71% had been symptomatic for 6 months or less.

Table 77.2 presents the frequency of symptoms and signs in our series of 77 patients with BCS, 51 of whom had hepatic vein occlusion alone, and 26 of whom had IVC occlusion and hepatic vein occlusion. The only difference between the two groups—and it is an important one—was the absence of lower extremity edema in the group without IVC thrombosis and the high incidence of edema from feet to thighs (81%) that resulted from IVC occlusion.

Symptoms

Abdominal Distension

The initial symptom in all of our patients was abdominal distension secondary to ascites, which increased progressively over a few weeks. Abdominal distension caused by ascites occurs at some time in almost every patient with BCS. In the large collected series (Mitchell et al, 1982; Parker, 1959), abdominal distension was among the first symptoms experienced by most patients.

Abdominal Pain

All of our patients had abdominal pain that was dull, nagging, and chronic. The pain was localized in the right hypochondrium in some patients, diffuse in the upper abdomen in other patients, and diffuse throughout the abdomen in several patients. The pain was probably due to distension of the liver capsule from intense hepatic congestion or to abdominal distension from rapid accumulation of ascites. Abdominal pain has been a prominent symptom in all reported series of BCS.

Weakness

All patients in our series had striking and progressive weakness as a manifestation of their severe acute illness. Weakness has not been as prominent in the chronic forms of BCS.

Anorexia

Anorexia was reported by all patients in our series and has been experienced by many patients in the reports of others (Mitchell et al, 1982).

Jaundice

Clinical jaundice was observed in 52% of the patients in our series but in only 28% of the patients in Parker's collective review (1959) and in only 17% of the patients collected by Mitchell and colleagues (1982). Usually, jaundice has been mild.

Symptoms of Chronic Liver Disease

Patients with the chronic forms of BCS, such as MOVC, often have the usual symptoms of cirrhosis and portal hypertension, including upper gastrointestinal (GI) bleeding secondary to ruptured esophagogastric varices (see Chapter 75), hepatic encephalopathy, hepatorenal syndrome, and edema of the lower

Table 77.2

Symptoms and Signs in 77 Patients with Budd-Chiari Syndrome Treated by the Authors

	% OF GROUP			% OF GROUP	
Symptom	Hepatic Vein Occlusion (n = 51)	IVC Occlusion (n = 26)	Sign	Hepatic Vein Occlusion (n = 51)	IVC Occlusion (n = 26)

Jaundice	53	50	Splenomegaly	100	100
Jaundice	53	50	Edema of thighs, legs, feet	0	81

IVC, inferior vena cava

extremities (see Chapters 72 and 73). Peripheral edema is particularly prominent in patients with MOVC, and some develop varicose veins of the legs (Parker, 1959; Semson, 1982). In our series of patients who underwent surgical portal decompression for acute BCS secondary to occlusion of the hepatic veins, one patient had these symptoms.

Findings on Physical Examination (Signs)

Ascites

All 77 patients in our series had the abdominal signs of massive ascites on physical examination at the time of diagnosis. The incidence of ascites was 93% in the collective review of Parker (1959) and 83% in the series of Mitchell and colleagues (1982).

Hepatomegaly

All patients in our series and in the series of Mitchell and colleagues (1982) had marked hepatomegaly resulting from severe congestion of the liver. In chronic forms of BCS, hepatomegaly may not be as striking, but it is usually present.

Wasting

All patients in our series had substantial wasting as a result of loss of lean body mass over a relatively short time. All of our patients appeared chronically and seriously ill.

Distension of Abdominal Veins

Forty-three of the 77 patients in our series (56%) and 55% of the patients in the collected series of Parker (1959) had distension of the superficial veins of the anterior abdominal wall. Abdominal venous distension is a manifestation of portal hypertension and the formation of portosystemic collaterals early in the course of BCS.

Splenomegaly

Splenomegaly, another manifestation of portal hypertension, was observed in all of the patients in our series, in 50% of those in the collected series of Mitchell and colleagues (1982), and in 30% in the collected series of Parker (1959). Enlargement and congestion of the spleen was sometimes accompanied by the hematologic manifestations of secondary hypersplenism.

Jaundice

Clinical jaundice was observed in 52% of the patients in our series but in only 28% of the patients in the collected series of Parker (1959) and in only 17% of the patients in the collected series of Mitchell and colleagues (1982). The jaundice in our patients who underwent surgical portal decompression was invariably mild; the highest serum bilirubin level was only 6.8 mg/dL.

Edema of the Lower Extremities

Edema of the lower extremities or lower trunk indicates involvement of the IVC in the occlusive process and was observed in 81% of the 26 patients in our series who had IVC occlusion. In our series, none of the 51 patients with thrombosis confined to the hepatic veins had substantial lower extremity edema.

Signs of Chronic Liver Disease

Patients with the chronic forms of BCS, such as patients with MOVC, often have the usual manifestations of chronic liver disease: spider angiomata, palmar erythema, asterixis, breast hypertrophy, testicular atrophy, and fetor hepaticus. In our series, these signs were seen only in patients who were placed in the liver transplantation group because of advanced cirrhosis.

SYMPTOMS AND SIGNS OF VENOOCCLUSIVE DISEASE

VOD has been observed in individuals of all ages, including infants and adults in their sixth decade; however, VOD caused by pyrrolizidine alkaloids has been seen most commonly in infants and children. The clinical manifestations depend on the disease stage at which the patient seeks medical treatment (Brooks et al, 1970; Ghanem & Hershko, 1981; Gore et al, 1961; Safouh & Shehata, 1965; Stuart & Bras, 1957). The acute stage is often preceded for 1 or 2 weeks by a febrile illness with upper respiratory symptoms, vomiting and diarrhea, or both. The patient then experiences abrupt onset of abdominal pain, weakness, anorexia, fever, and abdominal distension secondary to ascites (Kumar et al, 2003; Wadleigh et al, 2003; Senzolo et al, 2007). Jaundice is the rule, and splenomegaly with thrombocytopenia is common. Some patients develop edema of the feet and occasionally of the hands and face, and physical examination in the acute phase invariably shows hepatomegaly and ascites. Many patients have splenomegaly, some have distension of the superficial veins of the abdominal wall, and some have peripheral edema and a pleural effusion. Bone marrow transplant recipients usually develop the clinical features of VOD within 3 weeks after transplantation. Many patients have died during the acute stage from liver failure, bleeding esophageal varices, or intercurrent infection.

Patients other than bone marrow transplant recipients may be initially seen in the chronic stage of VOD with the usual clinical manifestations of cirrhosis of the liver: ascites, hepatomegaly, splenomegaly, wasting, abdominal venous distension, spider angiomata, palmar erythema, asterixis, and peripheral edema. Bleeding from esophageal varices is a major cause of death in the chronic stage, and cirrhosis of the liver has been observed 3 months after acute onset of VOD (Gore et al, 1961).

DIAGNOSTIC STUDIES IN BUDD-CHIARI SYNDROME

Hepatic Angiography and Pressures

The diagnostic study of greatest value in BCS, particularly if surgical therapy is contemplated and venous pressure measurements are required, is angiographic examination of the IVC and hepatic veins with pressure measurements (Clain et al, 1967; Kreel et al, 1967; Redman, 1975; Tavill et al, 1975). This study usually is combined with hepatic and superior mesenteric arteriography and indirect portography. In BCS confined to the hepatic veins, the IVC is patent, and IVC pressure is relatively normal for subjects with ascites (Fig. 77.2). Patency of the IVC is a prerequisite for portacaval shunt (PCS) and is a crucial finding (see Chapter 76). In some patients, the IVC is moderately compressed in its retrohepatic course by the enlarged liver and, in particular, by a hypertrophied caudate lobe (Fig. 77.3). This finding usually is not clinically significant (Clain et al, 1967; Kreel et al, 1967; Redman, 1975; Tavill et al, 1975).

The most important angiographic finding is the demonstration by hepatic venography of occlusion or marked narrowing of the major hepatic veins. Sometimes it is not possible to find

FIGURE 77.2. Inferior venacavogram in Budd-Chiari syndrome patient 3 in our series, showing a widely patent inferior vena cava; pressure was 62 mm saline. *(From Orloff MJ, Johansen KH, 1978: Treatment of Budd-Chiari syndrome by side-to-side portacaval shunt: experimental and clinical results. Ann Surg 188:494-512.)*

FIGURE 77.3. Inferior venacavogram in Budd-Chiari syndrome patient 6 in our series, showing a patent inferior vena cava with side-to-side compression in its retrohepatic course by the enlarged liver. IVC pressure at this time was 102 mm saline. *(From Orloff MJ, Johansen KH, 1978: Treatment of Budd-Chiari syndrome by side-to-side portacaval shunt: experimental and clinical results. Ann Surg 188:494-512.)*

patent orifices of any of the hepatic veins, which is indirect evidence that all of the major hepatic veins are occluded. Usually it is possible, however, to enter at least one major hepatic vein and to show the presence of a thrombus or of narrowing and distortion of the vein (Fig. 77.4A). Injection of dye in the wedged position often shows a characteristic spiderweb pattern of small hepatic venous collaterals connecting to portal or systemic veins (see Fig. 77.4B). Wedged hepatic vein pressure (WHVP) usually is markedly elevated, which reflects the obstruction to hepatic venous outflow. In patients with hepatic vein occlusion alone, IVC pressure is substantially lower than WHVP.

In our series of 77 patients, angiographic studies showed occlusion of the hepatic veins alone in 51 patients and occlusion of both the hepatic veins and IVC in 26 patients. In all of our patients with hepatic vein occlusion alone, all three major hepatic veins were occluded.

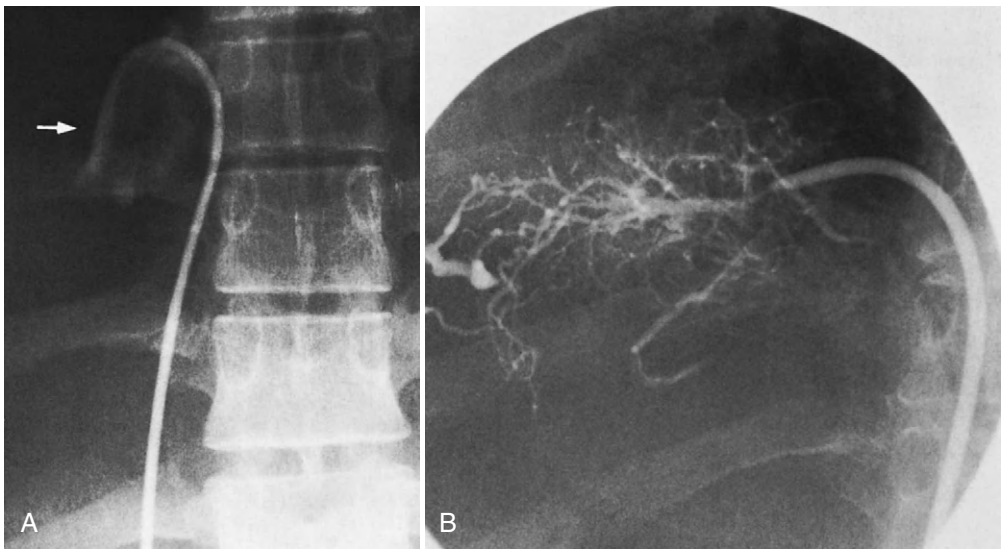

FIGURE 77.4. Hepatic venogram in Budd-Chiari syndrome patient 2 in our series. **A,** Filling defects (thrombi) in the right hepatic vein occupy much of the lumen. **B,** Typical spiderweb pattern of small venous collaterals shown by injection of dye with the catheter in the wedged position. *(From Orloff MJ, Johansen KH, 1978: Treatment of Budd-Chiari syndrome by side-to-side portacaval shunt: experimental and clinical results. Ann Surg 188:494-512.)*

Table 77.3

Results of Diagnostic Studies in 77 Patients with Budd-Chiari Syndrome Treated by the Authors

	% OF GROUP	
	Hepatic Vein Occlusion (n = 51)	**IVC Occlusion (n = 26)**
Angiography and Pressures		
Occluded hepatic veins	100	100
Occluded IVC near hepatic veins	0	100
Spiderweb pattern of hepatic veins	69	50
Patent portal and splenic veins	100	100
Stretched hepatic arteries	100	100
IVC pressure much lower than WHVP	100	0
High WHVP	100	100
Percutaneous Needle Liver Biopsy (73 Patients)		
Centrilobular congestion	100	100
Centrilobular hepatocyte loss and necrosis	100	100
Fibrosis	76	58
Cirrhosis (included also under fibrosis)	34	8
Hepatic Scintiscan		
Decreased hepatic uptake	100	100
Nonhomogeneous hepatic uptake	100	100
Excessive extrahepatic uptake	74	77
Central hot spot in liver	31	12
Computed Tomography (64 Patients)		
Absence of hepatic veins	100	100
Abnormal hepatic uptake of contrast	100	100
Occlusion of IVC	0	100
Ascites	100	100
Real-Time and Doppler Duplex Ultrasound (61/76 Patients)		
Absence of hepatic veins with flat or reversed flow	100	100
Abnormal venous structures in liver	100	100
IVC thrombosis with flat or reversed flow	0	100
Ascites	100	100
Abnormal Liver Function Tests		
Bromosulfophthalein or indocyanine green retention (23% to 90%; 24 patients)	100	100
Serum alkaline phosphatase (138 to 458 IU)	100	100
Prothrombin time (12.4 to 16.5 seconds)	98	92
Partial thromboplastin time (31 to 59 seconds)	98	92
Serum albumin (2.1 to 2.8 g/dL)	96	95
Aspartate aminotransferase (76 to 540 IU)	90	88
Serum bilirubin (3.8 to 6.8 mg/dL)	54	42
Upper Gastrointestinal Radiographs (53 Patients)		
Normal	60	0
Esophageal varices	40	100
Esophagogastroscopy (28 Patients)		
Esophageal varices	44	100

IVC, inferior vena cava; WHVP, wedged hepatic venous pressure

A spiderweb pattern was observed in 48 patients (62%). WHVP was markedly elevated in all patients in whom it was measured. In the 51 patients with thrombosis confined to the hepatic veins, the IVC was patent, with relatively normal pressures for patients with ascites, ranging from 62 to 160 mm saline (Table 77.3). Many patients had moderate compression of the retrohepatic IVC by the enlarged liver, but invariably WHVP was substantially higher than IVC pressure—a crucial finding. In contrast, in the 26 patients with IVC occlusion, IVC pressure and WHVP were similar. All patients had stretched and attenuated hepatic artery branches within the liver and a patent portal vein (PV).

An additional advantage of hepatic venography is that it facilitates performing a transjugular liver biopsy. Some investigators have stated that "at present, there is almost no place for direct or retrograde venography for the sole purpose of making a diagnosis of BCS" (Valla, 2009; Janssen et al, 2003). We hasten to point out that our use of hepatic venography was an essential guide to surgical therapy, not simply a means of making the diagnosis of BCS, as others have agreed (Kamath, 2006; Erdon, 2007).

Liver Biopsy

Percutaneous or transjugular needle liver biopsy yields histologic findings characteristic of BCS early in the course of the disease; along with hepatic angiography, it provides conclusive diagnostic information (Tang et al, 2001). The diagnostic features are quite spectacular and include intense centrilobular congestion combined with centrilobular loss of parenchyma and necrosis (see Fig. 77.1). Mild to moderate fibrosis of the liver parenchyma is found in many patients. As the disease evolves and becomes chronic, cirrhosis of the cardiac type develops. Cirrhosis has been observed within months of the onset of symptoms. Only two other conditions, constrictive pericarditis and congestive heart failure, produce a histologic picture similar to that seen in the acute stage of BCS. Both of these cardiac disorders can be eliminated easily from consideration by appropriate studies.

In our series, percutaneous or transjugular needle liver biopsy was done preoperatively in 73 of 77 patients, and open wedge liver biopsy was done at operation in all 77 patients (see Table 77.3). All patients had intense centrilobular congestion along with centrilobular hepatocellular loss and necrosis. Of the 65 patients in our series who were referred sufficiently early to undergo surgical portal decompression, 39 (60%) had fibrosis of the liver at an early point in the illness. In three patients, the fibrosis had progressed to cirrhosis. All 12 patients who were considered candidates for liver transplantation had advanced cirrhosis (see Chapter 97A).

Hepatic Scintiscanning

Scintiscans of the liver (see Chapter 15) with technetium 99m-sulfur colloid or other colloidal radionuclides show the nonspecific abnormalities of decreased and nonhomogeneous hepatic uptake of radiocolloid, increased uptake of radiocolloid by the spleen and bone marrow, and hepatosplenomegaly. Central localization of radiocolloid in the liver, the so-called central hot spot, has been reported to be of diagnostic importance (Fig. 77.5; Meindok & Langer, 1976; Tavill et al, 1975). It is seen when the thrombotic process spares the small hepatic veins that drain the caudate lobe and central areas of the right and left lobes directly into the IVC, so that these areas of the liver remain healthy and even hypertrophy. The central hot spot was observed in only 19 (25%) of the 77 patients with BCS in our series.

Computed Tomography

Computed tomography (CT; see Chapter 16) of the liver after injection of contrast agents has been shown to be of diagnostic value in BCS (Baert et al, 1983; Mathieu et al, 1987; Lupescu, 2008; Erdon, 2007; Kamath, 2006; Vogelzang et al, 1987). The findings include 1) absence of opacification of the hepatic veins, which in normal subjects usually can be shown clearly; 2) nonhomogeneous and delayed uptake of contrast material in the liver; 3) delayed emptying of contrast material from venous structures at the periphery of the liver; and 4) occlusion of the IVC in patients with IVC thrombosis. CT also shows ascites and hepatomegaly. We performed CT in 64 of our 77 patients and observed these abnormalities in all of them.

Ultrasonography

Real-time and Doppler duplex ultrasonography (US) of the liver have been shown to be of diagnostic value in BCS (Baert et al, 1983; Becker et al, 1986; Bolondi et al, 1991; Chaubal et al, 2006; Grant et al, 1989; Gupta et al, 1987; Hosoki et al, 1989; Powell-Jackson et al, 1986; Rossi et al, 1981; see Chapter 13). Findings include 1) absence of normal hepatic veins draining into the IVC with flat or reversed flow, 2) an abnormal intrahepatic network of comma-shaped venous structures, 3) thrombus in IVC and flat or reversed flow in patients with IVC thrombosis, and 4) enlargement of the caudate lobe. Ascites has been shown regularly. We observed these abnormalities in all 61 patients in whom US was performed in our series. We regularly used Doppler US as an initial screening tool, but we depended on angiography for a definitive diagnosis and guide to treatment.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI; see Chapter 17) is capable of showing patency or obstruction of the hepatic veins and is particularly effective in visualizing the entire length of the IVC. It has been reported to be useful in differentiating the acute form of BCS from the subacute and chronic forms (Noone et al, 2000; Kamath, 2006; Erdon, 2007; Lupescu et al, 2008). Because of the high cost of MRI, it is not a first-line diagnostic procedure in our program; none of our 66 patients underwent MRI.

Abnormal Liver Function Tests

Results of liver function tests are usually abnormal in BCS, although the type of abnormality varies and is nondiagnostic (see Table 77.3). All 24 patients in our series who had studies of injected bromosulfophthalein or indocyanine green dye clearance had marked retention of dye, ranging from 23% to 90% (normal <6%). All 77 patients had elevation of serum alkaline phosphatase, ranging from 138 to 458 IU (normal 25 to 85 IU). Of 77 patients, 74 had prolonged prothrombin time and partial thromboplastin time, and 96% had a marked decrease in serum albumin concentration (range, 2.1 to 2.8 g/dL); 69 patients (90%) had elevations of aspartate aminotransferase (range, 76 to 540 IU), and 39 (51%) had mild to moderate elevations of serum bilirubin (range, 3.8 to 6.8 mg/dL). These biochemical abnormalities are not specific to BCS, but they indicate significant hepatic dysfunction and are an important part of the diagnostic workup.

Ascitic Fluid Analysis

Analysis of ascitic fluid in patients with BCS is of little diagnostic value, because the results vary considerably (Mitchell et al, 1982; Tavill et al, 1975). Protein concentration has been reported to range from 0.5 to 4.9 g/dL.

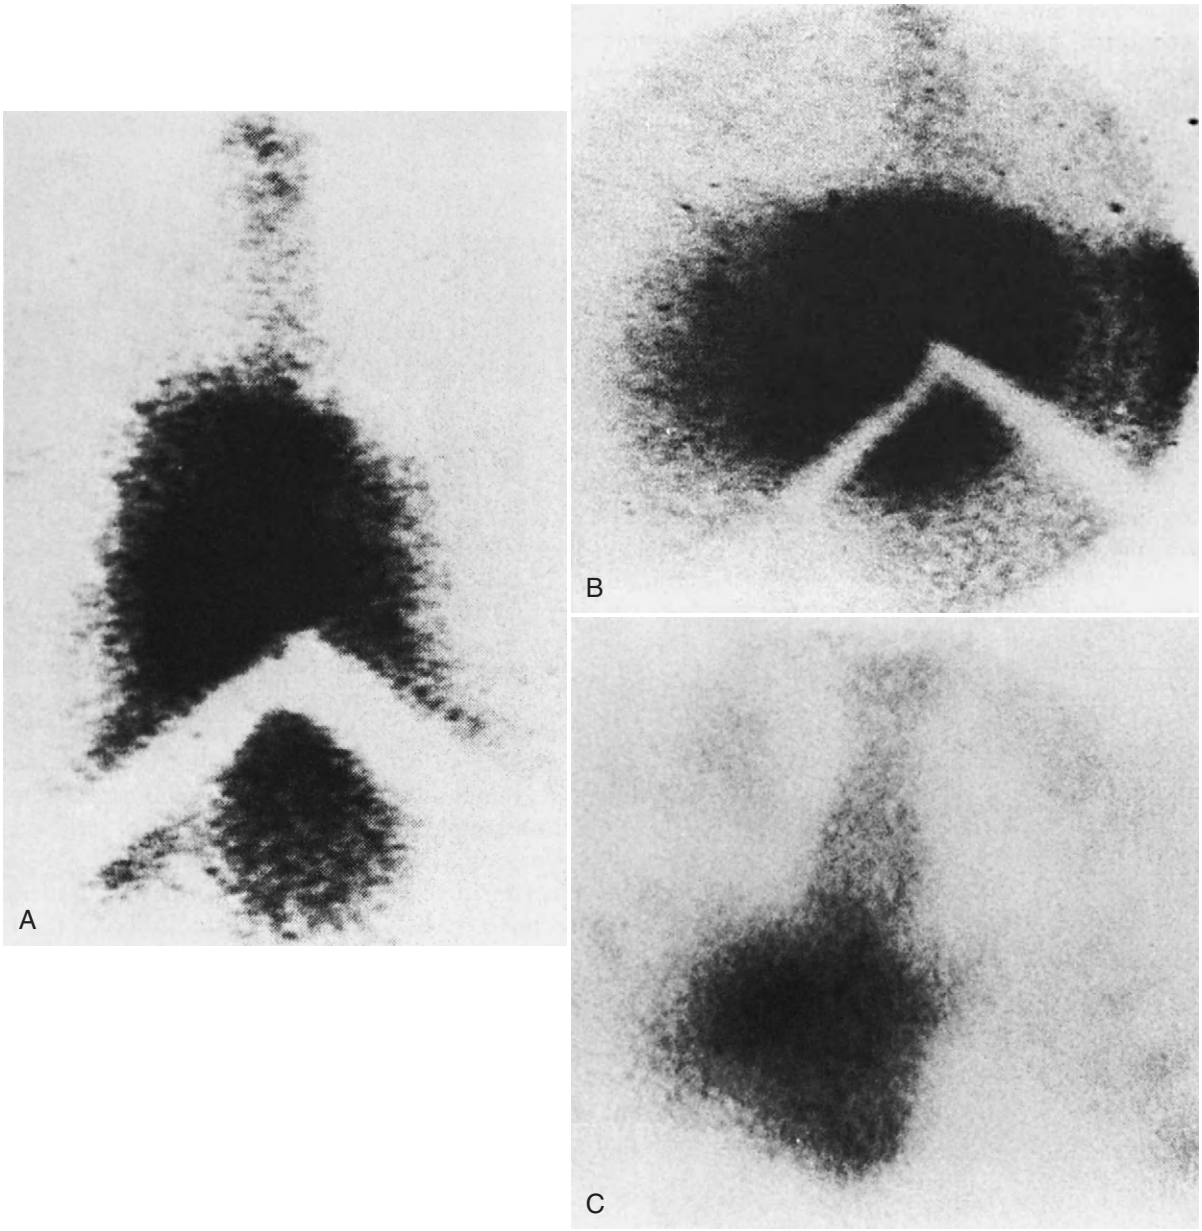

FIGURE 77.5. A-C, Scintiscan of liver in three cases of Budd-Chiari syndrome, showing central accumulation of radionuclide, the so-called central hot spot. *(From Mitchell MC, et al, 1982: Budd-Chiari syndrome: etiology, diagnosis and management. Medicine [Baltimore] 61:199-218.)*

Upper Gastrointestinal Radiographs

Barium contrast upper GI radiographs were obtained in 53 patients with BCS in our series. The results were normal in 31 patients but showed esophageal varices in 22 patients (42%); 13 of the 22 patients with varices had cirrhosis. In the chronic forms of BCS, esophageal varices can be shown regularly by radiography and confirmed by esophagogastroscopy. Currently, we infrequently perform contrast upper GI radiographs.

Esophagogastroscopy

Esophagogastroscopy (EG) was performed in 28 patients, 18 of whom (64%) were found to have esophageal varices (see Chapter 75).

DIAGNOSTIC STUDIES IN VENOOCCLUSIVE DISEASE

The diagnosis of VOD is strongly suspected when, in the proper setting—such as following bone marrow transplantation—patients develop ascites, jaundice, hepatomegaly, and right upper quadrant abdominal pain (Senzolo et al, 2007). The most important diagnostic study in VOD is needle liver biopsy, which shows the specific abnormality of extensive occlusion of the small hepatic veins within the liver (Brooks et al, 1970; Gore et al, 1961; Shulman et al, 1995; Stuart & Bras, 1957). In the acute stage of VOD, an additional biopsy finding is centrilobular hemorrhagic necrosis of the hepatic parenchyma. In the chronic stage of VOD, the biopsy specimen shows diffuse fibrosis or cirrhosis of the liver.

Angiographic studies are not as helpful in VOD as they are in BCS (see Chapter 19). The major hepatic veins and IVC are

normal on venography, but WHVP is invariably elevated, a finding that supports the diagnosis of VOD. Findings on hepatic arteriography and indirect portography are similar to the findings in BCS. Because of the significant risk of bleeding after bone marrow transplantation, it is safest in such patients to perform liver biopsy by the percutaneous transjugular route. WHVP can be measured at the same time.

The abnormalities shown by hepatic scintiscanning in VOD are similar to those in BCS, except that the central hot spot has rarely been reported. Real-time and Doppler duplex US and, to a lesser extent, CT may provide useful diagnostic information in VOD.

Liver function test results are invariably abnormal in VOD and do not differ from the results seen in BCS; in other words, the abnormalities reflect serious hepatic dysfunction but are not specific for VOD. After bone marrow transplantation, elevated plasma levels of plasminogen activator inhibitor (PAI)-1 have been reported to be a useful marker in distinguishing VOD from several other causes of posttransplant hepatic dysfunction, such as graft-versus-host disease, drug-induced hepatotoxicity, sepsis, and viral hepatitis (Salat et al, 1997a). PAI-1 has been implicated in the pathology of VOD.

Because so many patients with VOD caused by pyrrolizidine alkaloids have been seen for the first time when the disease was far advanced, they often have had many or all of the manifestations of cirrhosis and portal hypertension. Esophagogastric varices have been shown in many patients by esophagogastroscopy and barium contrast upper GI radiographs.

FINDINGS AT OPERATION

The findings at operation in the 65 patients who underwent surgical portal decompression in our series are summarized in Tables 77.4 and 77.5, and they typify what can be expected in patients with BCS. All patients had marked ascites ranging in volume from 2.6 to 15.9 L, congestive hepatomegaly, splenomegaly, and extensive portosystemic collateral veins. All of the patients had portal hypertension. In the group of 39 patients with thrombosis confined to the hepatic veins, the mean PV-IVC pressure gradient was 244 mm saline. In all 39 of these patients, portal pressure was substantially higher than IVC pressure so that a direct side-to-side portacaval shunt (SSPCS) was feasible. In contrast, in the group of 26 patients with IVC occlusion and hepatic vein occlusion, the mean PV-IVC pressure gradient was only 11 mm saline, because the high pressure in the obstructed IVC was similar to the high portal pressure. All 26 patients had a large pressure gradient between the PV and right atrium that averaged 202 mm saline. A wedge liver biopsy specimen obtained at operation showed intense centrilobular congestion and marked centrilobular cell loss and necrosis in all but one patient (see Fig. 77.1), and 35 (54%) of the 65 patients had hepatic fibrosis; this was mild or moderate in 30 patients and severe in 5 patients, 4 of whom had cirrhosis. In patients with the chronic forms of BCS, and in most patients with VOD, the operative findings are typical of cirrhosis of the liver by the time the patient receives treatment.

NONOPERATIVE THERAPY

The objectives of nonoperative therapy of BCS are to 1) remove the cause of the venous thrombosis, 2) relieve the high pressure and congestion within the liver, 3) prevent extension of the venous thrombosis, and 4) reverse the massive ascites. It is often impossible to accomplish these objectives.

In many cases of BCS, the cause of the venous thrombosis is unknown or, if known, it cannot be removed. In some cases, however, it is possible to remove or modify the predisposing condition. Examples are cases of BCS caused by oral contraceptive ingestion; hematologic disorders, such as polycythemia rubra vera and paroxysmal nocturnal hemoglobinuria; and pregnancy.

Decompression of the liver by nonoperative measures is often not possible. Thrombolytic therapy with urokinase or streptokinase has been used in many patients in an attempt to dissolve the thrombi and restore hepatic venous outflow (Cassel & Morely, 1974; Gooneratne et al, 1979; Greenwood et al, 1983; Hodkinson et al, 1978; Hoestra et al, 2008; Malt et al, 1978; Mitchell et al, 1982; Powell-Jackson et al, 1982; Thijs et al, 1978; Warren et al, 1972; Plessier & Valla, 2008; DeLeve et al, 2009; Barrault et al, 2004; Sharma et al, 2004; Murad et al, 2009; Zimmerman et al, 2006; Menon et al, 2004). The experience with thrombolytic therapy has been recorded in sketchy anecdotal reports involving short periods of follow-up. Approximately one third of patients were believed to have had a clinical response to treatment for periods of 2 months to 1 year. Half of the patients died as a result of BCS during the brief periods of observation. In the experience of Powell-Jackson and colleagues (1982), all four patients who received thrombolytic treatment in the acute phase of BCS died without evidence of a response.

Urokinase and streptokinase have been administered by systemic intravenous (IV) infusion and by infusion directly into the IVC. In the use of thrombolytic drugs to treat deep venous thrombosis (DVT) of the lower extremities, peripheral IV infusion has been as effective as perfusing the agents directly into the clot. The recommended regimen (Greenwood et al, 1983) involves an IV loading dose (urokinase, 4400 IU/kg; streptokinase, 250,000 IU) followed by a constant IV infusion of urokinase at 4400 IU/kg/h or streptokinase at 100,000 IU/h for 2 to 7 days. Pulmonary embolization developed in two patients during thrombolytic therapy and is a potentially serious complication of this type of treatment.

Anticoagulant therapy has been used widely in BCS to prevent propagation of the thrombi (Ecker & McKittrick, 1966; Hartmann et al, 1980; Khuroo & Datta, 1980; Langer et al, 1975; Lewis et al, 1983; Liebowitz & Hartmann, 1981; Mitchell et al, 1982; Peytremann et al, 1972; Powell-Jackson et al, 1982; Thijs et al, 1978; Plessier et al, 2008; DeLeve et al, 2009; Zimmerman et al, 2006; Valla, 2009). Most reports of the effectiveness of this form of treatment have been anecdotal and lack long-term follow-up. There is no evidence that the use of either heparin or warfarin (Coumadin) brings about dissolution of established thrombosis.

In BCS caused by hematologic disorders, such as polycythemia rubra vera and paroxysmal nocturnal hemoglobinuria, some dramatic responses to IV heparin therapy have been reported, although relapses have been common (Hartmann et al, 1980; Liebowitz & Hartmann, 1981; Peytremann et al, 1972). Long-term anticoagulation with oral warfarin has been recommended to follow the initial IV use of heparin during the acute phase of BCS, although initiation or enhancement of bleeding is a potential complication of anticoagulant therapy, particularly in patients who develop cirrhosis and esophageal varices.

Control of ascites is feasible in some patients with BCS by use of the usual diuretic regimens, although ascites is resistant to therapy in many patients (see Chapter 74). Therapeutic measures include stringent sodium restriction, administration of diuretic drugs, and repeated IV infusion of salt-poor albumin or ascitic fluid. Renal function should be monitored closely during diuretic therapy to avoid precipitating the hepatorenal syndrome. There is no evidence that control of ascites influences the long-term outcome.

The prognosis of BCS with nonoperative therapy is poor (Mitchell et al, 1982; Parker, 1959; Powell-Jackson et al, 1982; Tavill et al, 1975). In his large collective review in 1959, Parker wrote, "The majority of cases have proved fatal, and there is little evidence to suggest that recovery from occlusion of the major hepatic veins occurs once symptoms have been produced." Similarly, in 1975, Tavill and associates wrote, "The prognosis of the Budd-Chiari syndrome is almost uniformly bad…." In 1982, Mitchell and colleagues stated in their collective review, "Spontaneous resolution of hepatic vein occlusion rarely, if ever, occurs. Conventional medical therapy does little to reverse the pathophysiology in patients with hepatic vein occlusion." Many patients with BCS that is treated nonoperatively die within a few months of the onset of symptoms. Patients who survive the acute phase usually go on to develop cirrhosis of the liver and die within a few years from hepatic failure, bleeding esophageal varices, or other complications of chronic liver disease. In the 5 years since preparation of the previous edition of this book, despite publication of numerous reviews, expert panels, and case summaries, no data have emerged to indicate that nonoperative therapy of BCS is effective.

TREATMENT OF HEPATIC VEIN OCCLUSION BY SIDE-TO-SIDE PORTACAVAL SHUNT

Experimental Studies

The theoretical basis for the use of SSPCS to relieve BCS resulting from occlusion of the hepatic veins is provided by substantial evidence indicating that the valveless PV can be converted into an outflow tract by an in-continuity anastomosis with the systemic venous system to decompress the obstructed hepatic vascular bed (Britton & Shirey, 1962; Britton et al, 1967; Burchell et al, 1976; Long et al, 1960; Longmire et al,

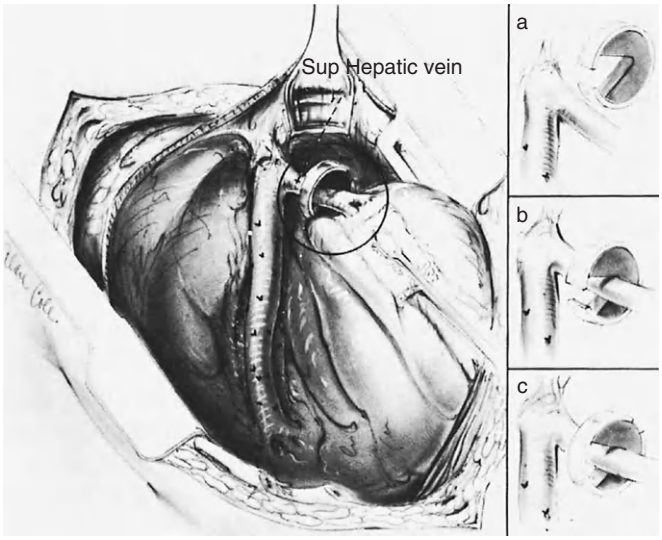

FIGURE 77.6. Our technique of induction of Budd-Chiari syndrome in dogs by ligation and division of all hepatic veins except the large left hepatic vein, which was surrounded by a hygroscopic, casein-plastic ameroid constrictor that gradually swelled centrally and occluded the vein. *(From Orloff MJ, Johansen KH, 1978: Treatment of Budd-Chiari syndrome by side-to-side portacaval shunt: experimental and clinical results. Ann Surg 188:494-512.)*

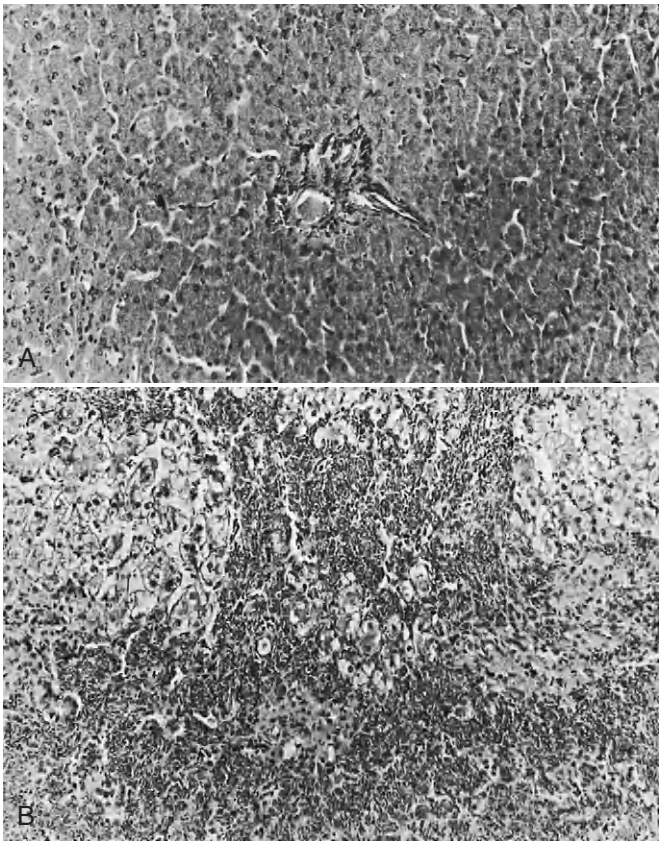

FIGURE 77.7. Photomicrographs of liver biopsy specimens obtained from a dog. **A,** Before hepatic vein ligation, when the liver was normal. **B,** Just before portacaval shunt, when Budd-Chiari syndrome was well established, and ascites was massive. Intense congestion and necrosis of the hepatic parenchyma is evident in the biopsy specimen (×140). *(From Orloff MJ, Johansen KH, 1978: Treatment of Budd-Chiari syndrome by side-to-side portacaval shunt: experimental and clinical results. Ann Surg 188:494-512.)*

1958; Moreno et al, 1967; Mulder & Murray, 1960; Murray & Mulder, 1961; Orloff et al, 1997; Orloff & Snyder, 1961; Tamaki et al, 1968; Warren & Muller, 1959). To test this hypothesis, we conducted an experimental evaluation of SSPCS in dogs with BCS (Orloff & Johansen, 1978). Our method of producing BCS in dogs consisted of ligation and division of all hepatic veins except the large left hepatic vein, which was loosely surrounded by an ameroid constrictor (Fig. 77.6; Orloff et al, 1963, 1965; Sweat et al, 1966). The lumen in the ameroid constrictor gradually narrowed as the hygroscopic casein plastic swelled centrally so that the remaining left hepatic vein was completely occluded within several weeks, and severe hepatic outflow block, portal hypertension, and massive, intractable ascites resulted. BCS was produced in 64 dogs, which were put into three treatment groups when ascites was massive: group I underwent sham laparotomy, group II underwent end-to-side PCS, and group III underwent SSPCS.

Table 77.6 summarizes the results of our experimental study. All dogs rapidly re-formed ascites after either sham laparotomy or end-to-side PCS and died with massive ascites within 6 months. In striking contrast, only 1 of the 24 dogs in group III reaccumulated ascites after SSPCS, and 67% of these dogs survived in good health without ascites until the time of sacrifice 1 year postoperatively. Before hepatic vein ligation, the liver was normal in all dogs on gross and microscopic examinations. At the time of sham laparotomy or shunt, when BCS was well established, all livers were enlarged two to four times normal size and appeared congested and friable. Liver biopsy specimens at this time showed intense centrilobular congestion, necrosis of cells around the central veins, dilated lymphatics, and subcapsular edema (Fig. 77.7). In the dogs in group I, these gross and microscopic abnormalities were unchanged at the

time of death, and substantial fibrosis was found in many of the liver biopsy specimens. Similarly, all of the dogs in group II had hepatomegaly at the time of death, and severe congestion, necrosis, and fibrosis were found in all liver biopsy specimens; although, in 38% of the animals, the microscopic picture was less severe than at the time of the end-to-side shunt operation. Only one dog with SSPCS in group III, the single animal with ascites, had an enlarged liver and microscopic findings of congestion and necrosis at the time of death. The other 23 dogs in group III had a liver that was normal in size and gross appearance at autopsy; liver biopsy specimens were normal in 35% of these dogs and showed minimal fibrosis in the remaining 65%.

Clinical Results of the Authors

On the basis of the results of our experimental studies, which showed SSPCS was effective in relieving BCS and reversing liver damage, we performed SSPCS in 39 patients with BCS caused by thrombosis of the hepatic veins without involvement of the IVC (Orloff & Girard, 1989; Orloff & Johansen, 1978; Orloff et al, 1992b, 2000); subjects were 21 women and 18 men, and ages ranged from 19 to 45 years. Of the 39 patients, 14 had polycythemia rubra vera, 11 had been taking oral contraceptives, 5 had Behçet disease, and 1 had protein C deficiency. In the remaining 8 patients, no condition predisposing to hepatic vein thrombosis was identified. Patients operated on before 1996 did not undergo the extensive hematologic workup shown in Box 77.2 that is currently performed. The symptoms, signs, results of diagnostic studies, and findings at operation are shown in Tables 77.2 to 77.5.

Tables 77.5 and 77.8 summarize the long-term results of SSPCS in our series. One patient underwent emergency operation, when the thrombosis of his hepatic veins suddenly extended into and occluded his previously patent IVC. An attempt to reverse a rapid downhill course by IVC thrombectomy and PCS was unsuccessful, and the patient died 6 days postoperatively with multiorgan failure and recurrence of IVC thrombosis. The remaining 38 patients (97%) recovered from the shunt operation and were long-term survivors. A striking feature of the early recovery period was a rapid gain in lean body weight that averaged 28 pounds in 3 months.

The 38 survivors of the shunt operation have been followed up for 5 to 37 years (mean follow-up 15 years). All survivors have been followed up for 5 years or more. One long-term death occurred in a patient with Behçet disease, who was relieved of BCS and ascites but died of diffuse vasculitis that caused hemorrhagic infarction of the colon 2 years postoperatively. The other 37 patients are currently alive, for an overall survival rate of 95%. All of the survivors have remained free of ascites without requiring diuretic therapy. Results of periodic liver function tests have been consistently normal except in the three patients who already had cirrhosis when they were referred to us. None of the patients has portosystemic encephalopathy, undoubtedly because they have good hepatic function. Hepatosplenomegaly has disappeared in all patients. Of the 38 survivors of SSPCS, 36 are employed or work full time at home. Of the 37 current survivors, 36 (97%) are leading productive lives of good quality.

One patient had recurrence of ascites 5 years after the shunt operation and was found to have developed marked narrowing of the IVC at the level of the previously occluded hepatic vein orifices. He was treated surgically with a bypass graft extending from below the area of obstruction in the IVC to the right atrium. Twenty-seven years after the bypass operation, the patient is free of ascites, and angiographic studies show a patent bypass graft with normal pressures in the IVC and PV.

Liver biopsies and angiographic or US studies were performed periodically for 37 years after shunt in the 38 survivors, and the results are summarized in Table 77.8. Cirrhosis persisted in the three patients who already had cirrhosis by the time of the shunt operation, including the patient with Behçet disease. In 97% of the survivors, there was no longer any evidence of hepatic congestion or necrosis in the follow-up biopsy specimens, as shown in Figure 77.8. Mild to moderate fibrosis was found in 42% of the patients, but 50% had normal liver biopsy specimens. Angiography or US showed patency of the PCS and IVC, and pressure measurements showed a wide-open anastomosis with a gradient that ranged from 0 to 44 mm saline and averaged only 4 mm across the shunt. Two patients with polycythemia rubra vera developed thrombosis of the PCS 1 week and 3 months postoperatively. Both patients were operated on immediately, the shunt was taken down, fresh thrombus was removed from the PV, and the portacaval anastomosis was reconstructed with an H-graft of autologous internal jugular vein. Subsequently, both patients were maintained on anticoagulant therapy with warfarin. One patient has remained well for 28 years since revision of the shunt. The other patient developed recurrent shunt thrombosis and required liver transplantation (LT), but he is well 19 years after transplantation. It is now our policy to maintain all patients with a known coagulopathy on permanent anticoagulant therapy.

Our experience with the surgical treatment of BCS differs from almost every other report of surgery for BCS in the following respects: 1) it involved unselected, consecutive patients with BCS who were referred to us and were treated at a single institution; 2) the patients were treated and studied prospectively, and our report is based on prospectively collected data, not on retrospective reviews of medical records with all the known shortcomings; 3) SSPCS was performed by a single senior faculty surgeon, whose experience included performance of more than 2500 SSPCS procedures; 4) follow-up was 100% and was performed regularly for more than 3 decades.

Our series is the single largest clinical experience reported to date involving the use of SSPCS in BCS confined to the hepatic veins. Our clinical experience confirmed our experimental observations regarding the efficacy of SSPCS in relieving hepatic venous outflow obstruction. All 39 of our patients in whom thrombosis remained localized to the hepatic veins survived the operation and remained free of ascites for years without requiring diuretic therapy, and the shunt remained permanently patent in all but one patient. All but three of the survivors were operated on early in the course of the disease, before liver damage was irreversible; in these patients hepatosplenomegaly disappeared, and liver function rapidly returned to normal. The results of serial liver biopsies performed for 5 to 37 years postoperatively are particularly encouraging, because they showed that the shunt had brought about substantial and long-term reversal of the striking pathologic lesions of BCS (see Fig. 77.8). SSPCS seems to be the most effective treatment of BCS confined to the hepatic veins. The long-term survival rate of the patients in our series has not been equaled by any other form of therapy, medical or surgical.

The single postoperative death in our series taught us a valuable lesson. When this 28-year-old man with polycythemia rubra vera was admitted to our hospital, clear clinical and angiographic evidence showed the occlusive process confined to the hepatic veins. During the 8-day course of his diagnostic workup, however, the thrombosis extended into the IVC, and

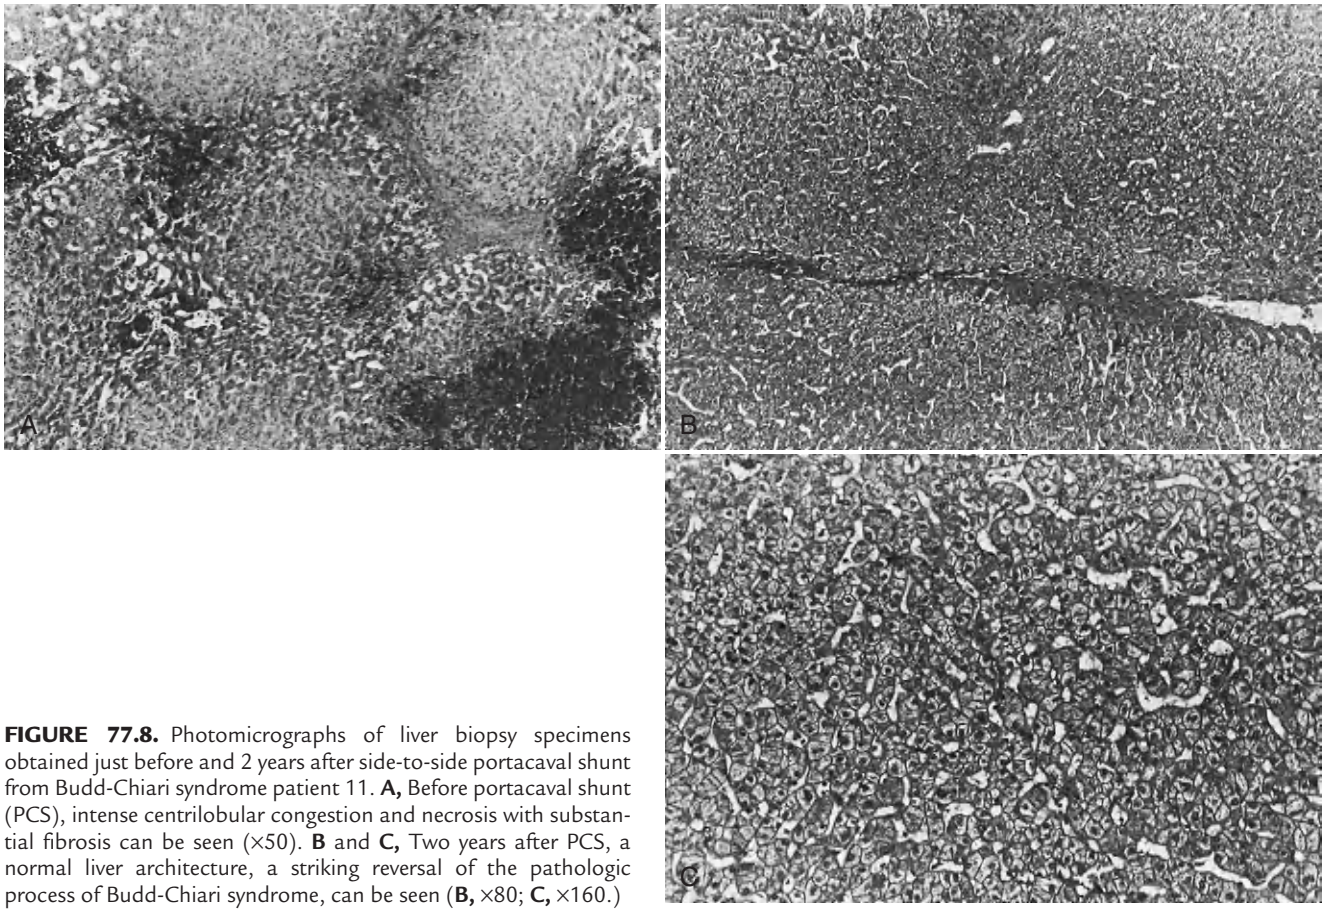

FIGURE 77.8. Photomicrographs of liver biopsy specimens obtained just before and 2 years after side-to-side portacaval shunt from Budd-Chiari syndrome patient 11. **A,** Before portacaval shunt (PCS), intense centrilobular congestion and necrosis with substantial fibrosis can be seen (×50). **B** and **C,** Two years after PCS, a normal liver architecture, a striking reversal of the pathologic process of Budd-Chiari syndrome, can be seen (**B,** ×80; **C,** ×160.)

his condition deteriorated dramatically. An emergency attempt at IVC thrombectomy and PCS failed. Extension of the thrombotic process from the hepatic veins into the IVC is a well-known event in BCS (Parker, 1959), and the potential for this devastating complication exists in every patient; therefore when the diagnosis of hepatic vein occlusion has been made, it seems unwise to delay operation.

SSPCS is indicated only in patients with BCS who have a patent IVC and an IVC pressure that is substantially lower than WHVP or portal pressure. Obstruction or occlusion of the IVC, manifested clinically by edema of the lower extremities and lower trunk and shown by angiography and IVC pressure measurements, is a contraindication to PCS. It is not unusual for patients with BCS caused by hepatic vein occlusion to have an elevated pressure in the IVC as a result of caval compression by an enlarged, congested liver or massive ascites or both. The absolute level of IVC pressure is not crucial to the effectiveness of SSPCS, as long as the portal pressure is substantially higher than caval pressure, and the IVC is shown to be patent. Others have reported relief of BCS by an in-continuity mesocaval shunt in patients with high IVC pressure but substantially higher portal pressure, showing that it is possible to decompress the liver as long as the differential is substantial between pressures in the PV and IVC (Vons et al, 1986). In our long-term follow-up studies after SSPCS, we have observed that compression of the IVC disappears with relief of hepatic congestion, and caval pressure returns to normal.

After SSPCS, the occlusive process in the hepatic veins extended into the adjacent IVC in only one of the 38 long-term survivors in our series. This untoward development occurred 5 years after the shunt operation and was treated successfully by a bypass graft from the IVC to the right atrium. It is possible that the infrequency of this complication is attributable to the PCS, which might inhibit propagation of the thrombus by increasing blood flow in the IVC and relieving stasis of blood in the liver.

The importance of performing SSPCS early in the course of BCS cannot be overemphasized. Hepatic venous outflow obstruction produces widespread destruction of the hepatic parenchyma by pressure necrosis and ischemia, and the liver damage becomes irreversible in a surprisingly short time: some patients have developed cirrhosis within 3 or 4 months of the onset of symptoms. Relieving ascites is far less important than decompressing the liver. Recently, groups of physicians that did not include surgeons have recommended a stepwise approach to treatment of BCS, beginning with a trial of anticoagulants, then angioplasty or thrombolysis and stenting, then transjugular intrahepatic portosystemic shunt (TIPS), and finally liver transplantation (Plessier & Valla, 2009; Janssen et al, 2003; de Franchis, 2005; Hoekstra & Janssen, 2008; DeLeve et al, 2009). The stepwise plan carries with it the danger of permitting liver damage to become advanced and irreversible.

Although a few patients have recovered spontaneously from BCS, most have not. The literature is replete with descriptions of patients who would have been suitable candidates for PCS but were treated nonoperatively and died. Our experience shows that it is imperative to perform SSPCS as soon as possible after the diagnosis of BCS has been made.

Clinical Results of Other Surgeons

Treatment by direct SSPCS or its hemodynamic equivalents—the portacaval interposition graft, mesocaval interposition graft, or splenorenal shunt—of BCS caused by occlusion of the hepatic veins has been reported in more than 300 patients by other surgeons (Ahn et al, 1987; Auvert & Farge, 1963; Bachet et al, 2007; Bismuth & Sherlock, 1991; Cameron et al, 1983; Dong et al, 2005; Eisenmenger & Nickel, 1960; Erlik et al, 1962; Fisher et al, 1999; Gentil-Kocher et al, 1988; Gibson, 1960; Hemming et al, 1996; Henderson et al, 1990; Hoyumpa et al, 1971; Huguet et al, 1979; Klein et al, 1990; Langer et al, 1975; Ludwick et al, 1967; Malt et al, 1978; McCarthy et al, 1985; Millikan et al, 1985; Montano-Loza et al, 2009; Murad et al, 2004; Noble, 1976; Panis et al, 1994; Pezzuoli et al, 1985; Powell-Jackson et al, 1982; Prandi et al, 1975; Schramek et al, 1974; Singhal et al, 2006; Slakey et al, 2001; Vons et al, 1986; Wang, 1989; Wu et al, 1990; Zeitoun et al, 1999). Many of the reports have involved descriptions of single cases. Some more recent retrospective multiinstitutional studies involving reviews of medical records have been based on analyses, as a single entity, of patients with widely different characteristics, such as the stage and type of BCS, time lapsed from diagnosis to treatment, site of hepatic venous outflow occlusion, and type of portosystemic shunt. Portacaval, mesocaval, splenorenal, mesoatrial, mesoinnominate, cavoatrial, portoatrial, and TIPS have been considered as a single entity termed a *portosystemic shunt* (Murad et al, 2004; Zeitoun et al, 1999). It is not possible to compare the results of these studies with our results, which were based on a prospective study of patients with BCS caused by hepatic vein thrombosis alone, all of whom underwent a direct SSPCS early in the course of their disease by a single surgeon at a single institution.

At institutions that have reported series of cases, success rates of portal decompression in BCS have been approximately 85% after direct SSPCS (Ahn et al, 1987; Bismuth & Sherlock, 1991; Hemming et al, 1996; McCarthy et al, 1985; Panis et al, 1994; Pezzuoli et al, 1985) and 67% after splenorenal shunt (Ahn et al, 1987; McCarthy et al, 1985; Millikan et al, 1985; Wang, 1989). Mesocaval or portacaval interposition grafts with autologous internal jugular vein have been reported in about 50 patients with BCS, most of them in France, with a success rate of 89% (Bismuth & Sherlock, 1991; Gentil-Kocher et al, 1988; McCarthy et al, 1985; Panis et al, 1994; Pezzuoli et al, 1985; Vons et al, 1986). Mesocaval or portacaval interposition grafts using synthetic materials, such as Dacron or polytetrafluoroethylene (Gore-Tex), have been successful in approximately 52% of 39 patients with BCS, which is the lowest success rate of the various in-continuity portal decompressive procedures (Ahn et al, 1987; Hemming et al, 1996; Henderson et al, 1990; Klein et al, 1990; McCarthy et al, 1985; Millikan et al, 1985; Pezzuoli et al, 1985; Wang, 1989). In our opinion, use of synthetic interposition portacaval or mesocaval grafts and the splenorenal shunt are inferior to direct SSPCS in the treatment of BCS, although all three shunts are hemodynamically similar. Occlusion of the shunt is a serious complication that may result in death: the splenorenal shunt and the synthetic interposition grafts have a substantial incidence of thrombosis, not only in BCS but also in other diseases that cause portal hypertension (Dowling, 1979; Hemming et al, 1996; Orloff, 1977, 1998; Orloff & Orloff, 1992); in contrast, the incidence of shunt occlusion in our series of more than 2500 direct SSPCS procedures—most of which have been followed up repeatedly by catheterization, angiography, or US—is 0.5%.

Four patients underwent end-to-side PCS for treatment of BCS. One patient had a favorable response during 1 year of follow-up (Marchal et al, 1974), but the other three died (Alpert, 1976; Brink & Botha, 1955; Langer et al, 1975). Because the hepatic side of the transected PV is ligated in an end-to-side PCS, the PV cannot function as an outflow tract to decompress the liver. It has been well established that in the presence of hepatic outflow block, the side-to-side anastomosis is substantially more effective than the end-to-side shunt in overcoming intrahepatic hypertension (Reynolds et al, 1962; Taylor & Myers, 1956; Warren & Muller, 1959).

Since our chapter on BCS was being prepared for the previous edition of this book 6 years ago, a number of reviews by nonsurgeons have been published (Janssen et al, 2003; Bachet et al, 2007; Plessier & Valla, 2008; Hoekstra & Janssen, 2008; Amarapurkar et al, 2008; DeLeve et al, 2009). These reviews, authored by physicians who had no personal experience with surgical treatment of BCS, were based on retrospective data collected from the literature, and they contained negative evaluations of the portosystemic shunt that were contrary to the results of our prospective studies. Examples of these negative evaluations that we believe are erroneous are: 1) "Overall perioperative mortality has been high, averaging 25%" (our perioperative mortality rate is 0%); 2) "The rate of shunt dysfunction due to early or late thrombosis or to late stenosis has reached 30% in series with long-term follow-up" (only 2 [5%] of our 38 patients developed thrombosis of the PCS 1 week and 3 months postoperatively, and this was permanently corrected by reoperation); 3) "Surgical portosystemic shunting … failed to show any impact on survival after adjustment for independent prognostic factors" (the survival rate in our series 5 years to 38 years postoperatively is 95%).

It is noteworthy that recent reviews, authored mainly by surgeons who have had personal experience with portosystemic shunts, have been supportive of the use and effectiveness of this important modality of the treatment in BCS (Menon et al, 2004; Klein, 2006; Zimmerman et al, 2006; Singhal et al, 2006; Montano-Loza et al, 2009).

Authors' Technique of Side-to-Side Portacaval Shunt

We have performed more than 2500 SSPCS operations over 50 years. From this experience, we have concluded that it is possible, with the proper technique, to perform a satisfactory SSPCS in almost every patient who has a patent PV. Contrary to some statements in the literature, we have been able to perform SSPCS without difficulty in every patient with BCS on whom we have operated. We have performed shunt catheterization and angiography or US every 1 to 2 years in almost all of our patients since the 1970s, and we have observed a 99.5% long-term shunt patency rate. Our technique of SSPCS (Orloff, 1983; Orloff & Orloff 1992, 1994; Orloff et al, 2007) is illustrated in Figures 77.9 to 77.18. Important technical features of the operation are as follows:

1. The position of the patient on the operating table is crucial and can make the difference between an easy and a difficult operation.

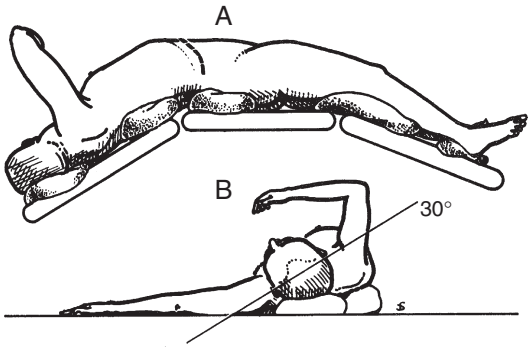

FIGURE 77.9. Position of patient for side-to-side portacaval shunt.

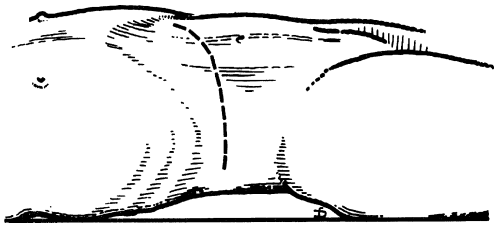

FIGURE 77.10. Long right subcostal incision used for side-to-side portacaval shunt.

FIGURE 77.11. Exposure of the operative field for side-to-side portacaval shunt.

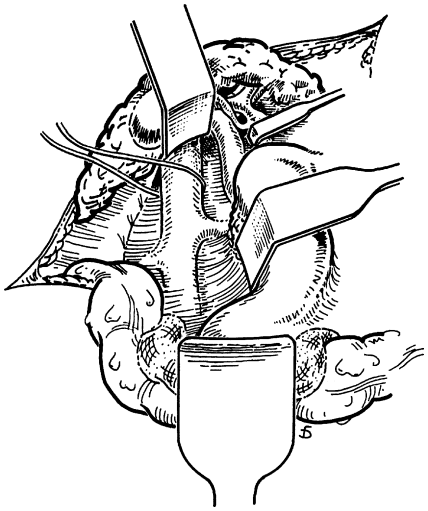

FIGURE 77.12. Circumferential isolation of the inferior vena cava between renal veins and liver in preparation for side-to-side portacaval anastomosis.

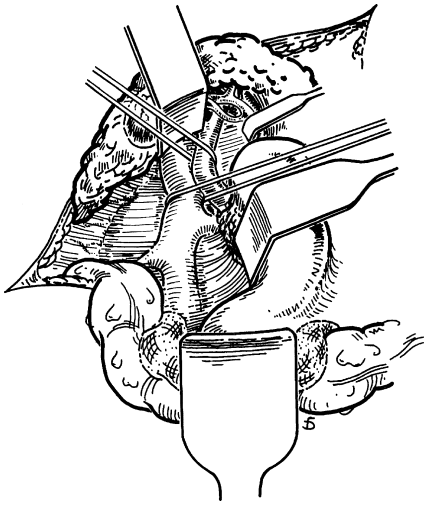

FIGURE 77.13. Exposure of portal vein in preparation for side-to-side portacaval anastomosis.

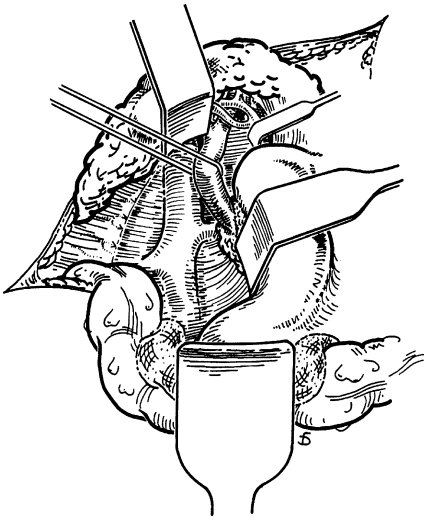

FIGURE 77.14. Mobilization of a long length of portal vein, including the segment behind the pancreas, in preparation for side-to-side portacaval anastomosis.

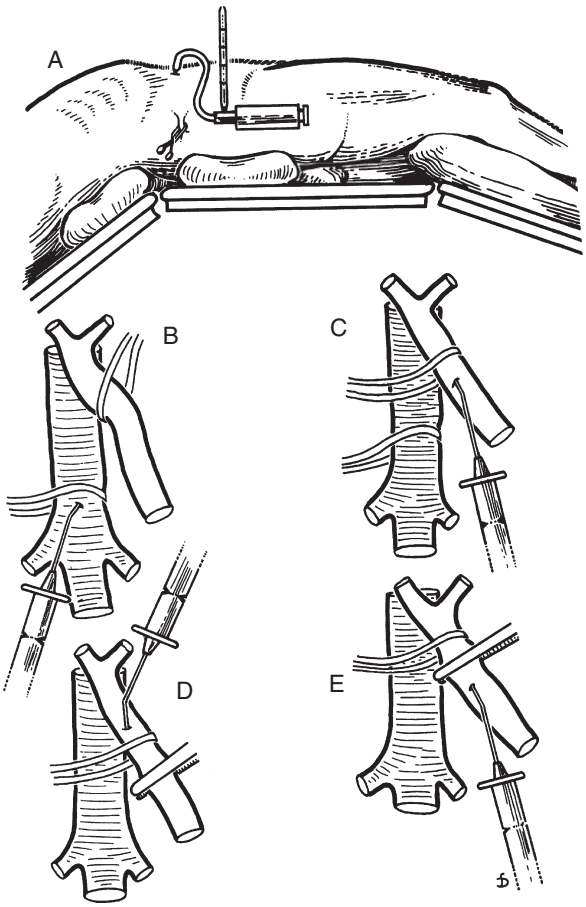

FIGURE 77.15. Measurement of pressures in the inferior vena cava (IVC) and portal vein (PV) with a saline (spinal) manometer by direct needle puncture before performance of portacaval anastomosis. All portal pressures are corrected by subtracting the IVC pressure from the portal pressure. Pressures in the IVC and PV are measured again after completion of the shunt. **A,** For all pressure measurements, the bottom of the manometer is positioned at the level of the IVC, which is marked on the skin surface of the body with a towel clip. **B,** IVC pressure. **C,** Free portal pressure. **D,** Hepatic occluded portal pressure, obtained on the hepatic side of a clamp occluding the portal vein. **E,** Splanchnic occluded portal pressure, obtained on the intestinal side of a clamp occluding the portal vein.

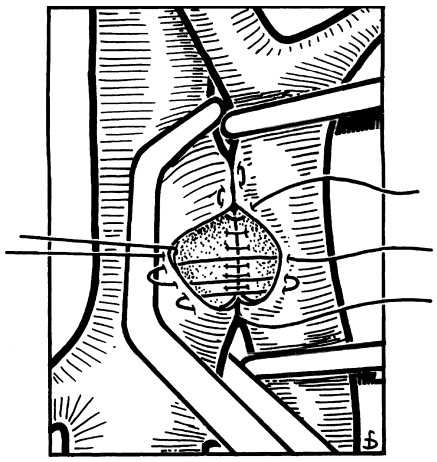

FIGURE 77.17. Side-to-side portacaval anastomosis. Placement of anterior row of two continuous everting sutures of 5-0 vascular material.

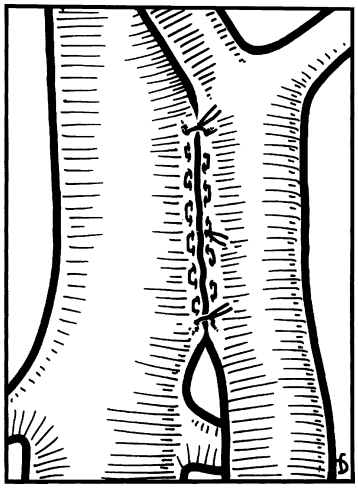

FIGURE 77.18. Completed side-to-side portacaval anastomosis.

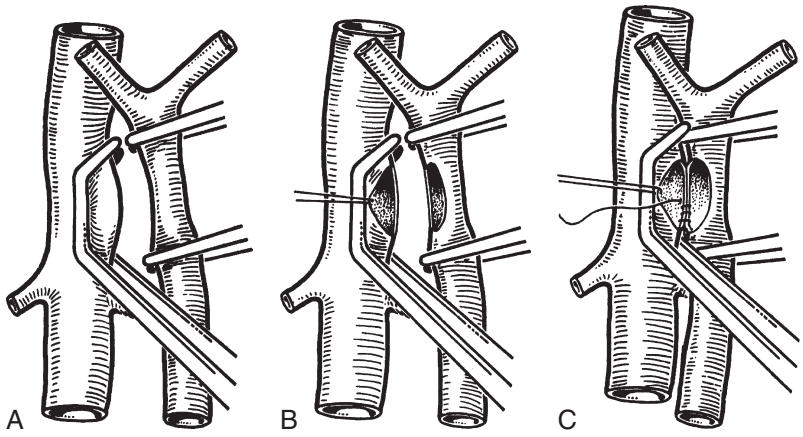

FIGURE 77.16. Side-to-side portacaval anastomosis. **A,** Placement of clamps on the inferior vena cava (IVC) and portal vein (PV). **B,** Strips of IVC and PV 2.5 cm in length have been excised. **C,** Placement of a posterior row of continuous 5-0 vascular suture from inside the lumina of IVC and PV.

2. A long right subcostal incision is associated with fewer postoperative complications than a thoracoabdominal incision and is much preferred.
3. Use of electrocautery throughout the operation substantially reduces both operating time and blood loss.
4. Bleeding from the many portosystemic collateral vessels is best managed by pressure with gauze sponge packs, particularly because most of the bleeding stops as soon as the portacaval anastomosis is completed, and the portal hypertension is relieved. Attempts to control each of the bleeding collaterals with ligatures and sutures prolong the operation and increase blood loss: the objective is to decompress the portal system as rapidly as possible.
5. Circumferential mobilization of the IVC between the entrance of the renal veins and the liver is essential for the side-to-side anastomosis and is neither hazardous nor difficult to perform. Apposition of the two vessels is greatly facilitated by elevation of the IVC toward the PV.
6. Essential for the side-to-side anastomosis is mobilization of a long segment of PV, which includes division of the tough fibrofatty tissue that binds the PV to the pancreas and sometimes includes division of a bit of the head of the pancreas.
7. Beware of the replaced hepatic artery crossing the PV behind the head of the pancreas! Ligation of the hepatic artery may be lethal. Palpate it with the index finger in the tunnel between the head of the pancreas and PV.
8. Resection of an enlarged caudate lobe of the liver to facilitate apposition of the two vessels is hazardous and unnecessary.
9. Pressures in the IVC and PV always should be measured after completion of the PCS. A pressure gradient greater than 50 mm saline is unacceptable and requires revision of the anastomosis.

Figure 77.9 shows the position of the patient on the operating table, viewed from the patient's right side. The patient is positioned with the right side elevated at an angle of 30 degrees to the table, and the table is "broken" at the level of the costal margin and at the knees to widen the space between the right costal margin and right iliac crest.

Figure 77.10 shows the incision. A long right subcostal incision extending from the xiphoid to well into the flank is made two fingerbreadths below the costal margin; we have used this incision in every operation over the course of 50 years. The skin is incised superficially with the scalpel, and the other layers are incised with electrocautery, which greatly reduces blood loss and shortens the operating time. When electrocautery is used, it is usually unnecessary to clamp any blood vessels with hemostats. The right rectus abdominis, external oblique, and transverses abdominis muscles are completely divided, and the medial 3 to 4 cm of the latissimus dorsi muscle is often incised. The peritoneum often contains many collateral blood vessels and is incised with the electrocautery to obtain immediate hemostasis.

Figure 77.11 shows the exposure of the operative field. The viscera are retracted by three Deaver retractors positioned at right angles to each other: the inferior retractor retracts the hepatic flexure of the colon toward the feet, the medial retractor displaces the duodenum medially, and the superior retractor retracts the liver and gallbladder toward the head. The posterior peritoneum overlying the IVC is incised with electrocautery by an extended Kocher maneuver just lateral to the descending duodenum, and the retractors are repositioned to retract the head of the pancreas medially and the right kidney caudally. Alternatively, a self-retaining retractor may be used in place of the three handheld Deaver retractors.

Figure 77.12 shows the isolation of the IVC: the anterior surface is cleared of fibroareolar tissue, and the IVC is isolated around its entire circumference, from the entrance of the right and left renal veins below to the point where it disappears behind the liver above. The IVC is surrounded with an umbilical tape. To accomplish the isolation, several tributaries may have to be ligated in continuity with fine silk ligatures and then divided. These include the right adrenal vein, one or two pairs of lumbar veins that enter on the posterior surface, and the caudal pair of small hepatic veins that enter on the anterior surface of the IVC directly from the liver. When the IVC has been mobilized completely, it can be lifted up toward the PV. Failure to isolate the IVC circumferentially is one major reason for the erroneous claim that SSPCS often cannot be performed, because the PV and IVC are too widely separated.

Figure 77.13 shows the exposure of the PV. The superior retractor is repositioned medially so that it retracts the liver and gallbladder at the point of entrance of the portal triad. The PV is located in the posterolateral aspect of the portal triad and is approached from behind. The fibrofatty tissue on the posterolateral aspect of the portal triad contains nerves, lymphatics, and lymph nodes and is divided by blunt and sharp dissection; this is a safe maneuver, because there are no portal venous tributaries on this aspect of the portal triad.

As soon as the surface of the PV is exposed, a vein retractor is inserted to retract the common bile duct and hepatic artery medially. The PV is mobilized circumferentially at its midportion and is surrounded with an umbilical tape. It is isolated up to its bifurcation in the liver hilum, and several tributaries on the medial aspect are ligated in continuity with fine silk and divided.

Figure 77.14 shows the mobilization of the PV behind the pancreas. Using the umbilical tape to pull the PV out of its bed, it is cleared to the point where it disappears behind the pancreas. The tough fibrofatty tissue that binds the PV to the pancreas must be divided. Several tributaries that enter the medial aspect of the PV and one tributary that enters the posterolateral aspect are divided, but it is usually unnecessary to divide the splenic vein. Wide mobilization of the PV is essential for performance of a side-to-side portacaval anastomosis. Failure to mobilize the PV behind the pancreas is a second major reason for difficulty in accomplishing an SSPCS. In some patients, it is necessary to divide a bit of the head of the pancreas to obtain adequate mobilization of the PV. Bleeding from the edges of the divided pancreas is controlled with suture ligatures. Division of a small amount of the pancreas is a helpful maneuver, and we have never observed postoperative complications, such as pancreatitis, from its performance.

Figure 77.15 shows the measurement of pressures in the IVC and PV before performing the portacaval anastomosis. The performance of an SSPCS is illustrated in Figures 77.16 to 77.18. After it is determined that the IVC and PV can be brought together without excessive tension, a Satinsky clamp is placed obliquely across a 5-cm segment of the anteromedial wall of the IVC in a direction that is parallel to the course of the overlying PV, and the IVC is elevated toward the PV. One 5-cm segment of the PV is isolated between two angled vascular clamps, and the PV is depressed toward the IVC, bringing the two vessels into apposition (see Fig. 77.16). One 2.5-cm long,

thin strip of the IVC and one 2.5-cm strip of the PV are excised with the scissors (see Fig. 77.16B). It is important to excise a thin longitudinal segment of the wall of each vessel rather than simply to make an incision in each vessel. A retraction suture of 5-0 vascular suture material is placed in the lateral wall of the vena caval opening and is weighted by attachment to a hemostat to keep the vena caval orifice open. The clamps on the PV are momentarily released to flush out any clots, then the openings in both vessels are irrigated with heparinized saline.

The anastomosis is started with a posterior, continuous, over-and-over suture of 5-0 vascular suture material (see Fig. 77.16C). The posterior continuous suture is tied at each end of the anastomosis. The anterior row of sutures consists of an everting, continuous, horizontal mattress stitch of 5-0 vascular material started at each end of the anastomosis (see Fig. 77.17). The suture started at the superior end of the anastomosis is discontinued after three or four throws and is deliberately left loose so that the interior surface of the vessels can be visualized as the anastomosis is completed. In this way, inadvertent inclusion of the posterior wall in the anterior row of sutures is avoided. The suture started at the inferior end of the anastomosis is inserted with continuous tension until it meets the superior suture, at which point the superior suture is drawn tight, and the two sutures are tied to each other. Before drawing the superior suture tight, the clamps on the PV are momentarily released to flush out any clots, and the anastomosis is thoroughly irrigated with heparinized saline.

Figure 77.18 shows the finished anastomosis, upon completion of which a single interrupted tension suture is placed just beyond each end of the anastomosis to take tension off the anastomotic suture line. The clamp on the IVC is removed first, the clamp on the hepatic side of the PV is removed next, and finally the clamp on the intestinal side of the PV is removed. Bleeding from the anastomosis occurs infrequently, but it can be controlled by one or two well-placed interrupted sutures of 5-0 vascular suture material.

Pressures in the PV and IVC must be measured after the anastomosis is completed. Usually the pressures in the PV and IVC are similar after the shunt is in place. A pressure gradient of greater than 50 mm saline between the two vessels indicates that there is an obstruction in the anastomosis, even when no obstruction can be palpated. In such circumstances, the anastomosis should be opened to remove any clots, and if necessary, the entire anastomosis should be taken down and done again. It is essential that there be no more than a 50-mm saline gradient between the PV and IVC to achieve permanently adequate portal decompression and to avoid ultimate thrombosis of the shunt.

TREATMENT OF INFERIOR VENA CAVA OCCLUSION BY PORTAL DECOMPRESSION

Mesoatrial Shunt

When BCS is caused by thrombosis of the IVC and of the hepatic veins, SSPCS and equivalent decompressive procedures are ineffective, because the high pressure in the infrahepatic IVC does not permit adequate decompression of the portal system and liver. Under such circumstances, a mesoatrial shunt has been advocated. Synthetic Dacron or Gore-Tex grafts ranging from 14 to 20 mm in diameter have been used in most cases and have been connected end-to-side to the superior mesenteric vein in the abdomen and the right atrium in the thorax.

We performed mesoatrial shunting in eight patients with BCS caused by thrombosis of the IVC and the hepatic veins. A 16-mm ring-reinforced Gore-Tex prosthesis was used. The operation was performed through a midline laparotomy and a median sternotomy. The superior mesenteric vein was isolated circumferentially for a distance of about 3 cm in the root of the small bowel mesentery, and the pericardium was opened to expose the lateral wall of the right atrium. The graft was anastomosed to the side of the superior mesenteric vein with continuous 5-0 vascular suture, tunneled through the root of the transverse mesocolon and greater omentum, then passed anterior to the stomach and left lobe of the liver into the mediastinum through an opening made in the anterior diaphragm. Finally, the prosthesis was anastomosed to the side of the right atrium with a continuous 5-0 vascular suture. To ensure wide-open anastomoses, an ellipse of the wall of the superior mesenteric vein and of the right atrium was excised before connecting the prosthesis.

Our results of mesoatrial shunting are shown in Tables 77.5, 77.7, and 77.8. A mesoatrial shunt reduced the mean gradient between the PV and right atrium from 211 to 78 mm saline. All eight patients survived the operation and left the hospital alive, although five (63%) of the eight patients subsequently developed thrombosis of the graft and died from liver failure. Three of the deaths occurred during the first postoperative year, one occurred in the second year, and one occurred in the fifth year. All five patients developed recurrence of ascites, and three developed portosystemic encephalopathy as their hepatic function deteriorated. The causes of BCS in the five patients whose mesoatrial shunt failed were oral contraceptives in one, polycythemia rubra vera in one, antithrombin III deficiency in one, and a postpartum state in one; the cause of the other one was unknown. These causes were no different from those found in the long-term survivors of portal decompression in our series. The patients whose mesoatrial shunt failed were not a higher risk group; they died because their mesoatrial shunt thrombosed 1 to 5 years after insertion, not because they were poorer risk patients to start with.

The three long-term survivors of the mesoatrial shunt (38%) have been followed up for 23 years, 21 years, and 21 years, respectively. Angiography and US have shown patency of their grafts. They are free of ascites, have normal liver function, and do not require diuretics; two of the three are gainfully employed. Serial liver biopsy specimens show residual congestion in one patient and moderate fibrosis in two. In one patient, the liver appears normal.

Several series of mesoatrial shunting that involve 5 or more patients have been reported in the literature, although the length of follow-up generally has been relatively short. Stringer and colleagues (1989) of London reported excellent results in 5 patients, but the follow-up period of 9 to 16 months was too short to warrant conclusions. Wang and colleagues (1989, 2005) of Beijing reported a survival rate of 61% and 50% at 5 and 10 years, respectively, in 70 patients, but his reports contain insufficient details to determine how many of the patients had patent and functioning grafts, how well the patients were followed, or the exact nature of the BCS that was being treated. Emre and colleagues (2000) of Istanbul reported an 85% survival rate of 13 patients during follow-up of 1 to 76 months, with one known thrombosed shunt. Behera and associates (2002) of Chandigarh, India, described 100% graft patency during 6 to 71 months of follow-up of 10 patients,

with a survival rate of 90%. Khanna and colleagues (1991) of Chandigarh, India, reported a 62% survival rate of 13 patients during follow-up of 2 months to 7.5 years.

The results of Henderson and colleagues' (1990) study of nine patients, of Klein and colleagues (Klein et al, 1990; Slakey et al, 2001) study of 15 patients, and of our own investigations of eight patients are representative of the experience with mesoatrial shunting in the United States. Survival rates ranged from 38% to 67%, and the percentage of patients with grafts that were patent and decompressing was only 33% to 60% during relatively short follow-up periods. Cameron and colleagues (1984; Klein et al, 1990) reported improved results with the use of an 8-cm external silicone rubber sleeve around a 16-mm ring-reinforced Gore-Tex prosthesis to prevent compression of the graft by the sternum. This innovation may reduce the frequency of graft thrombosis, but the results of mesoatrial shunting generally have been disappointing.

The high thrombosis rate of the mesoatrial shunt may be due to the fact that it is a relatively low-flow synthetic graft placed within the venous system. It does not decompress the obstructed IVC. To overcome these shortcomings, we worked in the experimental laboratory to devise a new operation for this form of BCS consisting of a combined SSPCS and cavoatrial shunt (CAS) through a Gore-Tex graft (Orloff et al, 1992a). This combined shunt was aimed at decompressing the hypertensive IVC and shunting the entire systemic venous flow from the lower two thirds of the body and the entire portal venous flow through the graft.

Experimental Studies

BCS was produced in rats by gradual occlusion of the suprahepatic IVC with an ameroid constrictor. As the hygroscopic casein plastic took up fluid and swelled centrally, the lumen in the ameroid gradually narrowed until, after 25 to 30 days, it completely occluded the IVC and produced severe hepatic outflow block, portal hypertension, and massive intractable ascites typical of BCS. One month after insertion of the ameroid constrictor around the IVC, when all rats had massive ascites, hepatomegaly, and portal hypertension, they were randomly divided into three groups (Fig. 77.19). Group I was composed of 16 control rats that underwent a sham thoracolaparotomy when BCS was well established. Group II consisted of 22 rats subjected to a mesoatrial shunt from the superior mesenteric vein to the right atrium with a 3-mm Gore-Tex graft inserted by microsurgical technique. Group III comprised 22 rats that underwent SSPCS combined with CAS from the IVC to the right atrium with a 3-mm Gore-Tex graft. Forty-four rats survived the operations and were studied.

Table 77.9 summarizes the results in the three groups of rats. All control rats that underwent sham thoracolaparotomy in group I rapidly reaccumulated ascites and died within 2 months. Nine of 16 rats with mesoatrial shunts in group II re-formed ascites and died within 2 months. All of these animals were found at autopsy to have thrombosis of the mesoatrial graft. In contrast, only 2 of 16 rats treated by combined SSPCS and CAS in group III developed CAS-graft thrombosis, re-formed ascites, and died. The remaining 14 rats in group III were found to have patent grafts and shunts when they were sacrificed after 3 months. Liver biopsy specimens in all rats were normal before IVC constriction, and after BCS was well established, they showed intense centrilobular congestion and moderate central necrosis. Severe pathologic changes persisted until death or sacrifice in all control rats in group I and in 11 of 16 rats with mesoatrial shunts in group II; however, combined SSPCS and CAS in group III reversed the liver pathology in 14 of 16 rats.

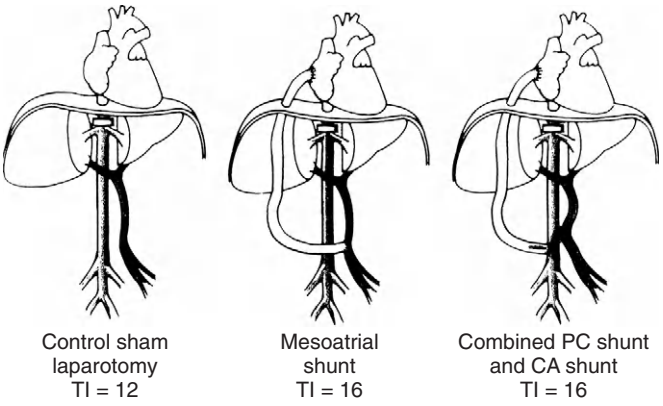

FIGURE 77.19. Experimental groups of rats with Budd-Chiari syndrome produced by constriction of the inferior vena cava by an ameroid constrictor. Control sham laparotomy, mesoatrial shunt, and combined side-to-side portacaval (*PC*) shunt and cavoatrial (*CA*) shunt were compared. *(From Orloff MJ, et al, 1992: Treatment of Budd-Chiari syndrome due to inferior vena cava occlusion by combined portal and vena caval decompression. Am J Surg 163:137-143.)*

Our Clinical Results with Combined Side-to-Side Portacaval Shunt and Cavoatrial Shunt

On the basis of the encouraging results of our experimental studies, we have treated 18 seriously ill patients with BCS caused by IVC thrombosis with combined SSPCS and CAS using a 20-mm ring-reinforced Gore-Tex graft. The characteristics of the patients are summarized in Tables 77.4 and 77.5. The study included 12 men and 6 women, ranging in age from 25 to 37 years. All 18 patients were in good health before the onset of symptoms and signs, which consisted of marked ascites, edema of the lower extremities, hepatosplenomegaly, abdominal pain,

Table 77.9

Results of Treatment in Rats with Experimental Budd-Chiari Syndrome Produced by Inferior Vena Cava Occlusion

Group	N	Graft or Shunt Thrombosis	Re-formed Ascites	Survived 3 Months	Reversal of Liver Pathology
I: Sham thoracolaparotomy	12	—	12	0	0
II: Mesoatrial shunt	16	9	9	7	5
III: Combined portacaval shunt and cavoatrial shunt	16	2	2	14	14

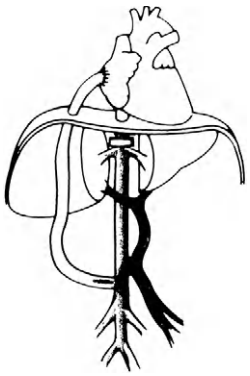

FIGURE 77.20. Combined side-to-side portacaval (*PC*) shunt and cavoatrial (*CA*) shunt using a 20-mm ring-reinforced Gore-Tex graft. The operation was done in 18 patients with Budd-Chiari syndrome secondary to inferior vena cava occlusion. *(From Orloff MJ, et al, 1992: Treatment of Budd-Chiari syndrome due to inferior vena cava occlusion by combined portal and vena caval decompression. Am J Surg 163:137-143.)*

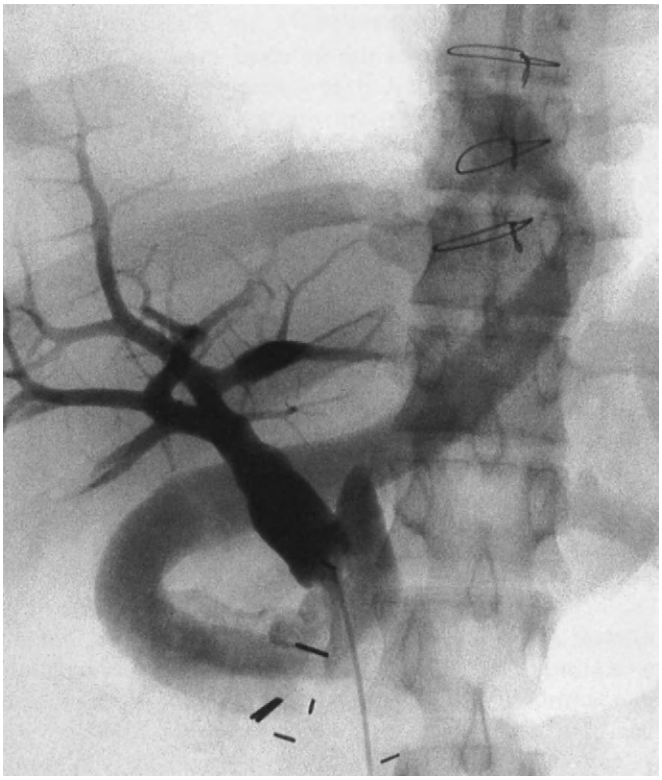

FIGURE 77.21. Shunt catheterization and venogram showing patency of the portacaval shunt (PCS) and cavoatrial shunt (CAS) 1 year after performance of combined PCS and CAS in a patient with Budd-Chiari syndrome secondary to inferior vena cava occlusion. Serial angiographic studies showed patency and excellent function of the PCS and CAS in all patients. *(From Orloff MJ, et al, 1992: Treatment of Budd-Chiari syndrome due to inferior vena cava occlusion by combined portal and vena caval decompression. Am J Surg 163:137-143)*

weakness, and muscle wasting. The combined operation is depicted in Figure 77.20.

The procedure was performed through a long right subcostal incision for the PCS and then a medium sternotomy for the CAS. After completion of the SSPCS, a 20-mm diameter, ring-reinforced Gore-Tex graft was anastomosed to the side of the IVC at the level of the PCS. The graft was channeled anterior to the liver through an opening made in the right leaf of the diaphragm and was anastomosed to the side of the right atrium. Combined SSPCS and CAS reduced the mean gradient between the PV and right atrium from 196 mm saline to 23 mm saline. All 18 patients survived the combined shunt operation and are alive 5 to 25 years postoperatively (see Tables 77.7 and 77.8). Mean follow-up is 12 years. All patients are free of ascites, and none requires diuretics; hepatomegaly and splenomegaly are gone; and liver function tests results are normal in all survivors, with no instance of portosystemic encephalopathy. All survivors are gainfully employed or keeping house and leading productive lives of good quality.

Serial percutaneous liver biopsy specimens have shown normal architecture in 14 patients and mild fibrosis in four. Serial angiographic studies with pressure measurements and Doppler duplex US have shown patency and good function of SSPCS and CAS in all patients (Fig. 77.21). Recanalization of the IVC or hepatic veins has not occurred. Permanent anticoagulation with warfarin and low-dose acetylsalicylic acid (aspirin) has been maintained in all patients. In our program, combined SSPCS and CAS has replaced mesoatrial shunt as the preferred treatment for BCS caused by IVC obstruction.

OTHER TYPES OF SURGICAL AND RADIOLOGIC THERAPY

Transjugular Intrahepatic Portosystemic Shunt

TIPS (see Chapter 76E) is SSPCS inserted percutaneously under radiographic control. As such, it is based on the same rationale for relieving hepatic venous outflow obstruction and intrahepatic portal hypertension as the surgical SSPCS. The attractiveness of TIPS lies in the fact that it can be done without a major surgical abdominal operation in patients who have liver disease, who are often quite ill. Its major disadvantage is a substantial incidence of occlusion of the TIPS that may require repeated revisions and hospitalizations and often involves recurrence of symptoms. In some patients who have complete occlusion of the hepatic veins or complete occlusion of the IVC, an additional disadvantage is technical inability to insert the TIPS. Insertion of the TIPS by direct puncture of the retrohepatic IVC, which sometimes is the only way that the shunt can be created, may be associated with a substantial incidence of complications (Rössle et al, 2004).

Between 1995 and 2004, there were many reports of TIPS treatment of BCS, each involving a few patients (Blum et al, 1995; Cejna et al, 2002; Ganger et al, 1999; Huber et al, 1997; Mancuso et al, 2003; Michl et al, 1999; Perello et al, 2002; Rogopoulos et al, 1995; Rössle et al, 1998; Uhl et al, 1996). The largest and longest reported experience with TIPS in BCS during that period was that of Rössle and colleagues (2004) at the University Hospital of Freiburg, Germany, who described their experience with 35 patients—11 acute, 13 subacute, and 11 chronic—who were followed up for a mean of 37 (± 29) months. Shunt failure occurred in 7 patients (20%): 2 were

technical failures, 2 required LT (1 died), and 3 died after TIPS. Excluding the 2 patients who required LT but including the 2 who could not have TIPS for technical reasons, the 5-year survival rate was 74%. TIPS occlusion requiring revision occurred in 19 (58%) of 33 patients. One patient required 10 revisions during a follow-up period of 53 months.

Results reported by others were not as good as those of the Freiburg group. Mancuso and associates (2003) described a series of 15 patients, with 5 deaths and 1 technical failure—a 40% negative outcome. Cejna and colleagues (2002) reported a series of 8 patients; 2 (25%) died 2 weeks after TIPS, 1 developed TIPS occlusion requiring LT, and 3 others required two to seven revisions for TIPS stenosis. Only 2 (25%) of 8 of the initial series of patients had revision-free TIPS patency. Perello and colleagues (2002) reported a series of 13 patients in which there were three shunt failures (23%). The failures included 1 death, 1 TIPS thrombosis that necessitated a surgical shunt, and 1 patient that required LT. Of the remaining 10 patients, 7 (70%) developed TIPS occlusion. In 5 of these, TIPS dysfunction had not been corrected.

Since 2004, use of TIPS in BCS has increased substantially, mainly in Europe, in part as a result of the availability of polytetrafluoroethylene (PTFE)-covered stents. Most of the reports have involved retrospective reviews of small numbers of cases followed up for short periods of time. In 2006, Rössle and colleagues reported results of TIPS with PTFE-covered stents in 112 patients, 17 of whom had BCS. Of these, 12 patients were lost to follow-up, and 16 developed TIPS failure. The 1-year TIPS failure rate was 10%, 22 patients died, and 3 underwent LT. The mortality rate without and with the patients lost to follow-up was 20% and 30%, respectively. The authors concluded that the TIPS procedure was improved by the PTFE-covered stent.

Other recent reports of TIPS treatment of BCS include a 124 patients (Murad et al, 2008 [16 patients]; Garcia-Pagan et al, 2008; Eapen et al, 2006 [30 patients]; Plessier et al, 2006 [20 patients]; Gandini et al, 2006 [13 patients]; Hernandez-Guera et al, 2004 [25 patients]; Attwell et al, 2004 [17 patients]). Garcia-Pagan and colleagues (2008) conducted a retrospective review of 124 BCS patients treated with TIPS in six European centers between 1993 and 2006. It is noteworthy that 147 of 221 patients with BCS were eligible for TIPS, but 14 were excluded for technical contraindications, and attempts at TIPS failed in an additional nine patients. Thus, in a population of patients with BCS, only 60% actually underwent TIPS. Twenty-two patients had complications associated with the TIPS procedure, and 2 died as a result. Sixty-one (41%) of the 124 patients had TIPS dysfunction during follow-up that required restenting in 35, angioplasty in 20, and thrombolysis in 6. Portosystemic encephalopathy developed in 21% of patients within 1 year. During follow-up, 16 patients died (13%), and 8 required LT (6.5%). Actuarial LT-free survival rates at 1, 5, and 10 years were 88%, 78%, and 69%, respectively.

Surprisingly, Garcia-Pagan and colleagues drew the following conclusions: 1) "Our results show that overall TIPS is an extremely effective therapy for patients with severe BCS in whom medical treatment has failed." 2) "However, treatment with TIPS resulted in excellent long-term survival." 3) "In conclusion, in experienced hands, TIPS is an extremely useful therapy for most BCS patients in whom medical treatment or recanalization fails. It may improve survival and should therefore be considered the treatment of choice."

The survival rate of surgical portosystemic shunt in our series is shown in Table 77.7. In patients with acute and subacute BCS resulting from occlusion of the hepatic veins, operative mortality after SSPCS has been 3%, and 5-year survival has been 97%. In patients with BCS secondary to IVC occlusion treated by combined SSPCS and CAS, the 5-year survival has been 100%. All of the patients have been relieved of the symptoms of BCS, and readmission to the hospital has been infrequently necessary. These results are superior to the best reported results of TIPS in comparable patients. Without doubt, the long-term health care costs of TIPS are substantially higher than the costs of surgical therapy.

Liver Transplantation

LT (see Chapter 97) is a radical, drastic treatment for BCS, but it is effective when a patient's life is at stake, and no other form of therapy would work. LT is not in competition with SSPCS or any other type of treatment. It is useful in far advanced, decompensated liver disease, when it is too late to accomplish survival with portal decompression procedures.

It is imperative that the indications for the use of LT in BCS be established and clearly understood. The indications that we adhere to are as follows:

1. Cirrhosis with progressive liver failure that has reached the point of permitting a reasonable prediction that the patient will die within 1 year—the most common indication for LT and, incidentally, it is the same one used widely in other liver diseases (Scharschmidt, 1984; Schenker, 1984)
2. Failure of a portosystemic shunt or TIPS, usually because of thrombosis, with persistence or recurrence of symptoms and signs of BCS
3. BCS with unshuntable portal hypertension secondary to thrombosis of the PV, splenic vein, and much of the superior mesenteric vein—a rare indication that applies if patent blood vessels are available to vascularize the liver allograft
4. Acute fulminant hepatic failure—a rare indication and one that we have not encountered

Using these indications, 12 of our patients have been approved and listed for LT. Their characteristics are shown in Table 77.10. In 10 of the 12 patients, an underlying thrombogenic hematologic disorder was identified. The time lapse from clinical onset of BCS to LT was much longer than in our patients who were treated by SSPCS, ranging from 11 to 21 months and averaging 15.9 months. These patients had a chronic form of BCS. The indication for LT was cirrhosis with progressive liver failure in 11 patients whose severe hepatic decompensation precluded consideration of SSPCS, and thrombosis of a PCS with recurrence of clinical manifestations of BCS was the indication in one patient. In 11 of our patients, thrombosis was confined to the hepatic veins, and in one patient, the hepatic veins and suprahepatic IVC were occluded. All but one patient, the one with an occluded PCS, had a patent PV.

Table 77.11 shows the clinical findings in our 12 patients. All patients had massive ascites, jaundice, severe muscle wasting, hepatomegaly, splenomegaly, and dilated collateral veins on the abdominal wall. Encephalopathy had occurred in 50%, and one or more episodes of bleeding varices had occurred in 58%. All patients had cirrhosis on preoperative liver biopsy and in the recipient liver removed at LT. This was a group with advanced,

decompensated liver disease. All of them were Child-Turcotte-Pugh (CTP) class C (Child & Turcotte, 1964) determined by the quantitative scoring method of Campbell and colleagues (1973).

Table 77.12 shows the results of preoperative liver function tests. Serum bilirubin was substantially elevated, and serum albumin was markedly depressed in every patient. Prothrombin activity was invariably low, resulting in a mean international normalized ratio of 2.0. Aspartate aminotransferase and serum alkaline phosphatase were significantly elevated. Liver function test results were highly abnormal and reflected serious hepatic failure.

Table 77.11

Preoperative Clinical Findings in 12 Patients Approved and Listed for Liver Transplantation for Budd-Chiari Syndrome

Finding	%
Ascites (3.8 to 7.2 L)	100
Jaundice	100
Severe wasting	100
Encephalopathy	50
Bleeding varices	58
Hepatomegaly	100
Splenomegaly	100

Serum alkaline phosphatase (IU)	233	198-282

Table 77.13 shows the survival rate of the 12 patients who were approved and listed for LT. Three patients died of liver failure while awaiting LT during periods of 4 to 10 months. Two patients died during the immediate period after LT, one from relentless graft rejection and one from sepsis with multisystem organ failure. A third patient died 9 months postoperatively of liver failure, but no patients were lost after the first year. The 1- and 5-year survival rates were 50%. If the three patients who died before LT could be accomplished are excluded, the actual 1-year and 5-year survival rates of the patients who underwent LT are 67%. The 5-year survival rate is comparable to the reported survival rate of LT in CTP class C patients who do not have BCS.

The six long-term survivors of LT have been followed up for more than 5 years and have had a life of good quality (see Table 77.13). Five are working full time, and BCS has not recurred in any. All survivors were placed on anticoagulant therapy postoperatively and are receiving lifelong maintenance warfarin and aspirin treatment.

Table 77.13

Long-Term Results of Liver Transplantation for Budd-Chiari Syndrome in 12 Patients Approved and Listed for Orthotopic Liver Transplantation

Survival	%
Operative mortality rate (n = 2/9)	22
One-year mortality rate (n = 6/12)	50
Five-year survival (n = 6/12)	50
Five-year survival of patients transplanted (n = 6/9)	67
Causes of Six Deaths	
Rejection (25 days; n = 1)	
Sepsis (30 days; n = 1)	
Liver failure (9 months; n = 1)	
Liver failure awaiting OLT (4 to 10 mo, n = 3)	
Quality of Life in Six Survivors of OLT	
Ascites (n = 2)	33

Normal liver function tests (n = 5)	83
Encephalopathy (n = 2)	33
Working full time (n = 5)	83
Recurrent BCS	0
Receiving anticoagulants (n = 6)	100

BCS, Budd-Chiari syndrome; OLT, orthotopic liver transplantation

Experience with Liver Transplantation in Budd-Chiari Syndrome Reported in the Literature

To date, the English literature contains reports of more than 1000 patients with BCS who have undergone LT, and Table 77.14 summarizes these reports. The largest number of case reports have come from reviews of 248 patients registered in the European Liver Transplantation Registry and 510 patients registered in the United Network for Organ Sharing (UNOS) Liver Standard Transplant Analysis and Research files. All of the reports were based on retrospective reviews of medical records. No prospective studies of LT in BCS have been done.

As shown in Table 77.14, the indications for LT varied greatly, and it cannot be said that LT was done in patients who had 1 year or less to live because of cirrhosis with progressive liver failure. In several series (Jamieson et al, 1991; Melear et al, 2002; Ringe et al, 1995; Segev et al, 2007), the indications were not clearly stated. Ulrich and colleagues (2008) reported 12% of the 39 patients were CTP class A, and 57% were class B, obviously not in liver failure. The report of Halff and colleagues (1990) stated, "The decrease in synthetic function was not as severe as in many other causes of end-stage liver disease." Every series had some patients who underwent LT because of a failed portosystemic shunt. In the registry review of Mentha and associates (2006), 49 of the 248 patients had failure of a portosystemic shunt (Campbell et al, 1988; Krom et al, 1984).

Table 77.15 shows the survival statistics in the reported series. All of the studies suffer from the fact that follow-up of many of the patients was short, sometimes less than 1 year. A substantial variation in patient selection was apparent from one series to the next, particularly with regard to severity of liver disease, so that they cannot be compared with each other. The early mortality rate in series that had 10 or more patients ranged from 5% to 36% and averaged 15%. The 5-year survival rate, when it was reported, ranged from 45% to 95% and averaged 71%. Segev and colleagues (2007) in their UNOS registry review reported that since introduction in 2002 of the Model for End-Stage Liver Disease (MELD) scoring system for organ allocation by disease severity, 3-year patient survival has increased from 72.6% to 84.9%, and 3-year graft survival has increased from 64.5% to 80.6%.

Most of the series did not report the results of pathologic examination of the liver removed from the patient with BCS. The reports of Ringe and colleagues (1995) on 43 patients, Halff and colleagues (1990) on 32 patients, Sakai and Wall (1991, 1994) on 11 patients, and Srinivasan and associates (2002) on 19 patients described the findings in the host liver, however, and confirmed the clinical impression that many patients underwent LT without having decompensated liver disease. Only 17 of the 43 patients of Ringe and colleagues (1995) had cirrhosis; the others had congestion alone (14 patients) and fibrosis alone, lesions that are found in the early stages of BCS. Similarly, in the report of Halff and colleagues (1990), none of the 32 patients had cirrhosis, and Sakai and Wall (1994) reported that 3 of 11 of their patients had central congestion and necrosis but no fibrosis or cirrhosis.

An important concern about LT in BCS is recurrence of BCS in the transplanted liver (Bahr et al, 2003; Goldstein et al, 1991). Table 77.16 shows the incidence of recurrent BCS in the liver allograft. Some investigators reported no recurrence of BCS, whereas others (Knoop et al, 1994a, 1994b; Halff et al, 1990; Cruz et al, 2005) reported substantial recurrence rates of

13% to 27% despite treatment with anticoagulants. Most series have shown a substantial incidence of posttransplant thrombosis in other splanchnic blood vessels, particularly in the PV (range, 9% to 40%), often with disastrous consequences. The frequent development of thrombosis makes it mandatory that patients receive early and lifelong anticoagulation therapy after LT. At the same time, it should be recognized that anticoagulation sometimes fails to prevent thrombosis.

One of the potential benefits of LT in certain thrombogenic disorders, such as antithrombin III deficiency and protein-C deficiency, is correction of the underlying defect by transplantation of a liver from a normal donor. It has been suggested that LT is preferable to SSPCS in the treatment of BCS, because if SSPCS fails, the risk of performing subsequent LT is increased. It has been proposed that mesocaval shunt is preferable to SSPCS, because it is advantageous to avoid dissection of the hepatic hilum, should subsequent LT be required (McMaster, 1994; Bismuth & Sherlock, 1991; Slakey et al, 2001). In our experience, patients with BCS treated by SSPCS infrequently require LT. Of 57 patients with BCS whom we treated by SSPCS, only 1 (2%) subsequently required LT during long-term follow-up. In our experience with more than 2500 PCS procedures in patients with cirrhosis, the long-term shunt patency rate has been 99.5%.

Additionally, at least 10 more recent studies have shown that previous portosystemic shunt, regardless of type, had no influence on the outcome of LT (Aboujaoude et al, 1991; Bismuth et al, 1990; Boillot et al, 1991; Iwatsuki et al, 1988; Langnas et al, 1992; Mazzaferro et al, 1990; Minegaux et al, 1994; Turrion et al, 1991). Aboujaoude and colleagues (1991) emphasized that thrombosis of a portosystemic shunt may seriously compromise performance of LT; long-term shunt patency should therefore be the main factor that determines the type of shunt selected for the potential LT candidate, a point that is all the more true in patients with BCS. Direct PCS has had a thrombosis rate of 0.5% or less in all of our studies, compared with occlusion rates of 24% to 53% reported in the literature for mesocaval interposition shunts using synthetic grafts (Fletcher et al, 1981; Hemming et al, 1996; Smith et al, 1980; Terpstra et al, 1987). Mesocaval interposition shunts using autologous internal jugular vein grafts, which have been used widely in France, have shown patency rates comparable to direct SSPCS (Bismuth & Sherlock, 1991; Gentil-Kocher et al, 1988; Vons et al, 1986).

A second important indication for LT is failure of a portosystemic shunt, usually because of thrombosis, with persistence or recurrence of clinical manifestations of BCS. In experienced hands, and with the routine, long-term use of anticoagulation therapy after portosystemic shunt, this should be a rare indication—but the literature indicates that such is not the case.

The third and fourth indications for orthotopic liver transplantation (OLT) in BCS are rare, and we have not encountered such cases, although they have been reported without many details in the literature. These are unshuntable patients with portal hypertension resulting from thrombosis of the portal venous system, provided that there are patent blood vessels available to vascularize the liver allograft, and acute fulminant hepatic failure (Sakai & Wall, 1994).

It is important to emphasize that SSPCS and LT are not competing forms of treatment. SSPCS is the appropriate treatment in the early and middle stages of BCS, when portal decompression would sustain life by reversing or stabilizing the liver disease. OLT is the appropriate treatment in the late stages of BCS, when the liver disease is no longer reversible, and when stabilization of progressive hepatic decompensation is impossible. Most patients who are candidates for LT should be in CTP class C.

In considering treatment of BCS by LT, it is important to take into account the downside of such therapy, namely 1) insufficient donor livers to treat the many patients who need LT; 2) long periods on the waiting list during which, as was true in our patients, more than one third of the patients die; 3) the unpredictable availability of donor organs; 4) the need for and consequences of lifelong immunosuppression; and 5) the high cost of LT, which our data show is almost five times the cost of portosystemic shunt.

Surgical Removal of Venous Obstruction

Senning (1981, 1983) reported a direct method of removing obstruction of the IVC and hepatic veins in patients with chronic BCS. The operation is performed with cardiopulmonary bypass and involves opening the suprahepatic IVC and right atrium, removing any vena caval thrombus, resecting the dorsocranial part of the liver containing the confluence of the occluded major hepatic veins, and reconstructing the hepatic outflow tract by suturing the right atrium to the liver capsule. Since his initial description, Senning (1987) and others (Pasic et al, 1993) have reported the results of the operation in 17 patients, 2 of whom (12%) died within 2 weeks of operation and 4 of whom died later. Actuarial 1-year and 3-year survival rates were 76% and 57%, LT was required for 2 patients, and 3 developed recurrent thrombosis. During follow-up of 7 months to 11 years, 10 (67%) of the 15 early survivors had prolonged relief of BCS.

Kawashima and colleagues (1991) reported success of the Senning operation in 5 of 7 patients during follow-up of 2 months to 5 years, and Nakao and colleagues (1988) described success in 2 patients followed up for 1 to 2 months. In a modification of the operation, Koja and associates (Koja et al, 1996; Kuniyoshi et al, 1998) described direct removal of the IVC obstruction under partial cardiopulmonary bypass in 32 patients with chronic BCS resulting from IVC obstruction of 1 to 42 years' duration. Koja and associates (Koja et al, 1996; Kuniyoshi et al, 1998) reopened the IVC and occluded hepatic veins under direct vision without resecting the liver and reconstructed the hepatic outflow tract with a patch graft of autologous pericardium. Many of the patients had cirrhosis or severe fibrosis of the liver, and 29 of the 32 had esophageal varices. No operative deaths were reported. During 1.5 to 17 years of follow-up, there were four late deaths, and seven patients developed hepatocellular carcinoma. Survival rates at 5 and 10 years were 93.6% and 81%. In a follow-up to their earlier report, in 2009 Kuniyoshi and colleagues (Inafuku et al, 2009) reported their results from 1979 to 2008 in 53 patients. Overall mortality rate was 32%, and 14% of survivors developed total obstruction or severe stenosis of the reconstructed IVC, therefore it does not appear that radical open-end venectomy is the first-choice operation for IVC occlusion.

Percutaneous Transluminal Angioplasty

Use of percutaneous transluminal angioplasty has been reported in more than 300 patients with BCS (Anonymous, 1982; Baijal et al, 1996; Furui et al, 1990; Griffith et al, 1996; Jeans et al,

1983; Martin et al, 1990; Sato et al, 1990; Tyagi et al, 1996; Wu et al, 2002; Xu et al, 1996; Yamada et al, 1983, 1991; Yang et al, 1996; Li et al, 2009). Most of the patients had chronic liver disease of long duration, and many of them had obstruction of the IVC of the membranous or segmental types. The obstructed vein was dilated with one or more balloon catheters. In all cases, the pressure gradient that existed before balloon dilation was substantially reduced or eliminated at the time of dilation. Stenosis often recurred, however, and required repeated balloon dilations. Most of the patients have not had long-term follow-up, so it is difficult to evaluate the ultimate effectiveness of percutaneous transluminal angioplasty. Of the few patients who have been observed for several years, the long-term success rate is less than 50% (Griffith et al, 1996; Martin et al, 1990; Sato et al, 1990; Yamada et al, 1991), although Wu and associates (2002) reported restenosis in only one of 41 patients during follow-up of 32 (± 12) months.

The use of expandable metallic stents has been added to balloon angioplasty in an attempt to maintain prolonged patency of the IVC (Baijal et al, 1996; Furui et al, 1990; Sawada et al, 1991; Xu et al, 1996, 1999; Li et al, 2009). The follow-up period of the patients who have IVC stents is too short to evaluate the efficacy of this procedure. In our opinion, based on the available evidence, percutaneous transluminal angioplasty and placement of expandable metallic stents warrant consideration only in patients with chronic BCS resulting from stenosis of the IVC. Patients treated by transluminal angioplasty should have careful follow-up that includes venography and pressure measurements every few months to detect recurrent stenosis of the IVC.

Thoracic Transposition of the Spleen

Transposition of the spleen into the left pleural cavity to create collateral venous connections between portal and pulmonary systems has been used sporadically in the treatment of portal hypertension and, in addition, has been advocated for treatment of BCS secondary to occlusion of the IVC (Akita & Sakoda, 1980; Khuroo & Datta, 1980; Schrieber & Gonzalez, 1967; Strauch, 1970). The procedure involves displacing the spleen into an opening in the left diaphragm and suturing the left lower lobe of the lung to the spleen after removing the splenic capsule and abrading the surface of the lung. It is impossible to evaluate the effectiveness of this procedure because of the paucity of information in the few case reports. Akita and Sakoda (1980) of Japan reported the use of "splenopneumopexy" in 15 patients who had diseases that they called BCS. Although few details were given, it seems that most or all of the Japanese patients had a chronic disorder that consisted of cirrhosis and esophageal varices in addition to IVC obstruction. It is possible that many of the patients had the typical MOVC that accounts for most of the cases of BCS in Japan. Portal hypertension, determined by splenic pulp pressure measurements, persisted after splenopneumopexy in all patients. It is doubtful that thoracic transposition of the spleen can decompress the liver and portal system sufficiently to prevent or reverse liver damage in the crucial early stages of BCS caused by occlusion of the IVC.

Peritoneovenous Shunt

Peritoneovenous shunt is a device that relieves ascites by transferring fluid through a one-way valve from the peritoneal cavity into the superior vena cava. It has been advocated as primary treatment for BCS by LeVeen and colleagues (LeVeen et al, 1976). The peritoneovenous shunt may be useful as a palliative measure in patients in whom portal decompression is not feasible or has been tried and failed. The peritoneovenous shunt is not indicated as the primary treatment of most patients with BCS, however, because it does not decompress the obstructed hepatic vascular bed, and it has no effect on the ongoing liver damage. Use of this device early in the course of BCS may squander the opportunity to reverse the liver damage by therapy that effectively decompresses the liver. Long-term studies of peritoneovenous shunting in patients with BCS have not been reported, probably because most patients in whom this device has been used have died from their underlying disease. There is predictable evidence, however, that the liver disease progresses to cirrhosis in the face of a functioning peritoneovenous shunt (Cameron et al, 1983).

SURGICAL TREATMENT OF MEMBRANOUS OBSTRUCTION OF THE VENA CAVA

Patients with MOVC described in the literature by and large have had a chronic disorder that has progressed to cirrhosis and portal hypertension by the time they came to medical attention. The lesion causing IVC obstruction has varied from a thin membrane located in the suprahepatic IVC to an extensive area of stenosis involving the retrohepatic IVC. Japanese surgeons have reported the largest experience with the treatment of MOVC.

When the area of IVC obstruction is short and is located at or above the level of the hepatic vein orifices, two treatment options are available: *percutaneous transluminal angioplasty* and *transcardiac membranotomy*. Reported experience with percutaneous transluminal angioplasty in MOVC has been small, and the recurrence rate of IVC stenosis or thrombosis has been high (Eguchi, 1974; Griffith et al, 1996; Hirooka & Kimura, 1970; Iwahashi, 1981; Sato et al, 1990; Sharma et al, 1992; Tyagi et al, 1996; Yamada et al, 1991; Yang et al, 1996). Long-term IVC patency has been less than 0%. Transcardiac membranotomy has been the most frequently used treatment of MOVC when the membrane is thin. The technique involves fracture of the membrane by the finger or a dilator inserted through the right atrial appendage (Fig. 77.22). More than 125 cases have been described in the literature, with a successful outcome in 70% to 90% during periods of follow-up that ranged from 2 months to 7 years but generally were brief (Espana et al, 1980; Hirooka & Kimura, 1970; Iwahashi, 1981; Kimura et al, 1972; Okamoto et al, 1983; Semson, 1982; Suchato et al, 1976; Takeuchi et al, 1971; Taneja et al, 1979; Wang, 1989; Wu et al, 1990; Yamamoto et al, 1968).

When more than a thin membrane causes obstruction of the IVC, and particularly when a long area of stenosis involves the retrohepatic IVC, the treatment options are different and consist mainly of direct excision and repair of the involved area of IVC (endovenotomy) or a cavoatrial bypass graft. A direct attack on the lesion generally has involved excising the obstructing tissue in the lumen of the IVC and repairing the vein with a synthetic or pericardial patch graft. Twelve such attempts have been described in the literature, with success in five patients and failure in seven, four of whom died (Hirooka & Kimura, 1970; Iwahashi, 1981; Kimura et al, 1972). Koja and colleagues (Koja et al, 1996; Kuniyoshi et al, 1998) reported

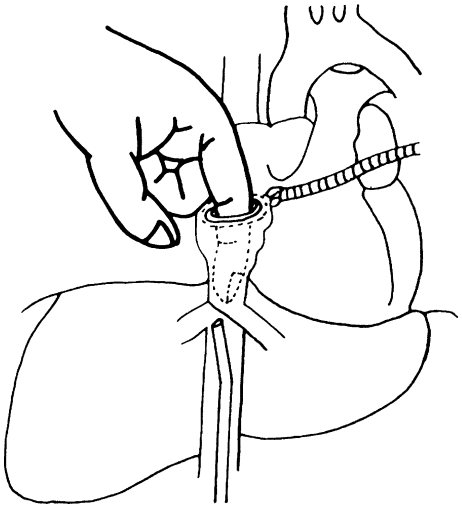

FIGURE 77.22. Technique of transcardiac membranotomy. *(From Iwahashi K, 1981: Surgical correction of the inferior vena cava obstruction with Budd-Chiari syndrome. Arch Jpn Chir 50:559-570.)*

direct removal of the IVC obstruction under partial cardiopulmonary bypass in 32 patients with impressive results, although the reported periods of follow-up were short.

Use of a cavoatrial bypass graft has been reported in 11 patients who had a long segment of IVC stenosis. The procedure succeeded during short periods of follow-up in three patients and failed in eight, four of whom died (Eguchi et al, 1974; Hirooka & Kimura, 1970; Ohara et al, 1963; Reichart et al, 1981; Yamamoto et al, 1968). When the IVC obstruction involves or extends below the orifices of the hepatic veins, cavoatrial bypass does not decompress the liver. Under such circumstances, consideration should be given to adding SSPCS to the cavoatrial bypass. The combined procedure of IVC and portal decompression has not been reported in MOVC.

Finally, patients with MOVC have undergone a variety of operations designed to create portosystemic or portopulmonary collateral venous connections. Included among these are omentosternopexy, hepatopneumopexy, splenopneumopexy, omentonephropexy, ileal stripping, and the Talma operation (Hirooka & Kimura, 1970; Ono et al, 1983; Yamamoto et al, 1968). It is difficult to evaluate the efficacy of these procedures, because insufficient information has been presented in the case reports. We doubt that these procedures are capable of relieving the high pressures in the IVC and portal venous system or of influencing the course of MOVC.

TREATMENT OF VENOOCCLUSIVE DISEASE

Substantial experience has been reported with treatment of patients with VOD caused by pyrrolizidine alkaloids (Bras & McLean, 1963; Ghanem & Hershko, 1981; Gore et al, 1961; Stuart & Bras, 1957). If such patients are seen during the acute stage of VOD, the initial treatment consists of withdrawal of the causative agent and measures to support the damaged liver. About one fourth of patients recover from the acute phase with supportive medical therapy, approximately one fifth die of liver failure or bleeding esophageal varices, and the remainder develop a chronic condition that waxes and wanes as cirrhosis of the liver evolves. SSPCS is indicated during the acute phase in patients who bleed from esophageal varices and in patients who, within 4 to 8 weeks of onset, show no signs of recovery, such as disappearance of ascites, improvement in liver function, and improvement in the lesions seen on percutaneous needle biopsy of the liver. Serial liver biopsy specimens are helpful in assessing the course of the disease.

Patients who are seen during the chronic phase of VOD have the usual manifestations of cirrhosis. The mortality rate of these patients is high, and the major cause of death is bleeding esophageal varices. Gore and colleagues (1961), who accumulated an extensive experience with VOD in Jamaica, recommended PCS when varices develop in the chronic phase, even if no bleeding has occurred. The added advantage of PCS is that it decompresses the obstructed hepatic vascular bed, which might facilitate regeneration of the liver. No sizable series of patients with VOD who were treated by PCS has been reported.

During the past decade there has been a marked increase in the use of bone marrow transplantation and a corresponding increase in the frequency of VOD. This increase has given rise to numerous trials of various interventions aimed at preventing and at treating VOD. In mild forms of VOD, spontaneous recovery is reported in 70% to 85% of patients (Senzolo et al, 2007). However, severe forms do not resolve without treatment (Schlegel et al, 1998).

Agents studied in prophylaxis of VOD include defibrotide, ursodeoxycholic acid (UDCA), tissue plasminogen activator (tPA), antithrombin III (ATIII), prostaglandin E_1 (PGE1), and anticoagulation with low-dose heparin (Senzolo et al, 2007; Ho et al, 2008). Of these, the most promising is defibrotide. In five retrospectively controlled studies of VOD prophylaxis, the incidence and severity of VOD was reduced by defibrotide (Versluys et al, 2004; Chalandon et al, 2004; Dignan et al, 2007; Corbacioglu et al, 2006; Qureshi et al, 2008).

Prophylactic administration of ursodeoxycholic acid (UDCA), an antioxidant and antioptatic agent, has been evaluated in six randomized trials. In five of the trials, UDCA showed a significant benefit, with reductions in both the incidence of VOD and mortality (Tay et al, 2007; Essell et al, 1998; Ohashi et al, 2000; Park et al, 2002; Giles et al, 2002; Ruutu et al, 2002).

Because microthromboses and fibrin deposition in hepatic central veins are hallmark features of VOD, investigational efforts have focused on the use of systemic anticoagulants and potent thrombolytics. Several reports have described series of patients in which tPA was used to prevent VOD (Bearman et al, 1997; Leahey et al, 1996; Hagglund et al, 1995; Yu et al, 1994; Schriber et al, 1999; Kulkarni et al, 1999; Kumar et al, 2003; Wadleigh et al, 2003). In the largest of these studies involving 42 patients treated with tPA and unfractionated heparin (Bearman et al, 1997), 12 (29%) had clinical improvement with at least a 50% reduction in pretreatment bilirubin. However, overall survival was poor, and no patients with multiorgan failure (MOF) responded. Furthermore, 10 patients (24%) developed severe bleeding attributable to tPA, and this proved fatal in a significant number. Based on these results, investigators have concluded that tPA with or without heparin should not be administered in VOD patients.

A number of trials and case studies have evaluated the use of ATIII in prophylaxis of VOD, based on findings that ATIII confers a protective effect on vascular endothelium, and ATIII levels are decreased in patients with VOD (Morris et al, 1997; Mertens et al, 1999; Ibrahim et al, 2004). However, a recent pediatric trial in which 91 children received preemptive ATIII replacement demonstrated that ATIII did not reduce the

incidence of VOD compared with a control group of 71 children (Haussmann et al, 2006).

PGE1 is a vasodilator with a cytoprotective effect on endothelium. It is also an inhibitor of platelet aggregation with prothrombolytic activity. Unfortunately, a large prophylactic trial of PGE1 was complicated by excessive toxicity and no benefit (Bearman et al, 1993).

Anticoagulation with low-dose heparin by continuous infusion, alone or in combination with other agents, has been evaluated as VOD prophylaxis in at least 12 studies. In a review of these studies, Imran and colleagues (2006) found no statistically significant benefit of anticoagulation. Moreover, an increased risk of hemorrhage was reported with low-dose heparin (Attal et al, 1992; Bearman et al, 1990; Marsa-Vila et al, 1991). Low molecular weight heparins seem to be relatively safe and may have some effect in the prevention of VOD, but well-designed, multicenter randomized studies are needed to confirm these preliminary results (Or et al, 1996; Simon et al, 2001; Park et al, 2002; Forrest et al, 2003).

Agents studied in the treatment of established VOD include defibrotide, tPA, ATIII, and methylprednisolone. Of these, defibrotide has been subject to the most extensive investigation. In six studies of defibrotide treatment of patients with established VOD, all or most of them high risk with multiorgan failure, 36% to 76% had complete remission of VOD (Richardson et al, 1998, 2002; Bulley et al, 2007; Chopra et al, 2000; Richardson et al, 2006; Corbacioglu et al, 2004). Encouraging responses to defibrotide have been found in children as well as in adults (Corbacioglu et al, 2004). Additionally, defibrotide was found to be effective in VOD following liver transplantation (Mor et al, 2001), although extensive studies of this serious problem have not been done.

Use of tPA in treatment of VOD has been evaluated in about 130 patients (Senzolo et al, 2007; Vaughan et al, 1989). The response rate has been about 30% in the largest series (Bearman et al, 1997); however, no response was seen in patients with renal, respiratory, or multiorgan failure. Moreover, 24% developed severe bleeding. Thus administration of profibrinolytics and anticoagulants should be avoided in these patients but conversely should be given early in the course of VOD.

Several studies of ATIII in treatment of VOD have been reported. In a retrospective review of the largest series, which involved 48 patients, Peres and colleagues (2008) observed that ATIII failed to reduce the incidence rate of VOD but seemed to be beneficial in mild to moderate VOD and especially in severe VOD. These results were similar to those of Haussman and colleagues (2006) in pediatric patients.

A single study of methylprednisolone treatment of VOD was reported recently (Al Beihany et al, 2008) with results suggesting a therapeutic benefit. However, prospective comparative studies are needed to warrant use of this agent.

Transjugular intrahepatic portosystemic shunting (TIPS) has been used in a small number of patients with VOD. Senzolo and colleagues (2007) summarized the results of TIPS in 27 patients with generally severe VOD, 24 of them following bone marrow transplantation. All but three of the bone marrow transplant patients died. Available data suggest that although portal hypertension and ascites improve after TIPS, long-term efficacy and overall survival remain poor (Senzolo et al, 2005, 2006; Smith et al, 1996; Alvarez et al, 2000; Fried et al, 1996; Azoulay et al, 2000; de la Robia et al, 1996).

Because of the high mortality rate of severe VOD after bone marrow transplantation, LT warrants consideration. Experience with LT in severe VOD is limited, with case reports in the literature on 12 patients (Membreno et al, 2008; Bunin et al, 1996; Hagglund et al, 1996; Nimer et al, 1990; Rapoport et al, 1991; Salat et al, 1997b; Schlitt et al, 1995), and 5 of the 12 were long-term survivors. The problems associated with use of LT, not unique to VOD, include predicting which patients will not survive despite other forms of treatment; the timing of the LT operation, before multiorgan failure is so severe that survival is not possible; and obtaining a suitable liver graft. One fourth of patients with VOD develop the severe form of the disease. The causes of death in severe VOD are hepatic failure, renal failure secondary to hepatorenal syndrome, respiratory failure owing to pulmonary VOD or infection, GI bleeding, sepsis, and congestive heart failure. In the Seattle study of a cohort of 355 patients, the mortality rate of severe VOD was 98% (McDonald et al, 1993).

SSPCS has been used effectively in severe VOD after bone marrow transplantation, but the experience has been limited because of a general reluctance to subject these very ill patients to a major operation despite their almost certain death without effective nonoperative treatment (Murray et al, 1987). Experience is similarly small with the use of TIPS in severe VOD secondary to bone marrow transplantation, and its role remains to be defined. It seems that hematologists have considered TIPS more attractive than a surgical shunt, because it does not involve a major surgical operation.

SUMMARY

More than 8000 cases of BCS caused by occlusion of the major hepatic veins or the IVC or both have been reported, and the condition is being recognized with increasing frequency. Although in many cases of BCS, no etiologic or predisposing condition can be identified, in recent years an underlying disorder has been found in more than 70% of cases. The most common conditions that predispose to BCS are hematologic disorders with thrombotic tendencies, such as polycythemia rubra vera and paroxysmal nocturnal hemoglobinuria (~18% to 30% of cases); use of oral contraceptives (~9% to 28% of cases); pregnancy and the postpartum period (~2% to 10% of cases); malignant neoplasms that invade the IVC and hepatic veins from adjacent organs (~5% to 12% of cases); and infections of the liver, such as amebic abscess, hydatid cyst, and schistosomiasis (~0% to 10% of cases), which are common in the East but rare in the West. Evidence indicates that multiple prothrombotic hematologic factors acting concurrently are involved in many patients with BCS. In Japan, China, India, and South Africa, a common chronic form of BCS is MOVC, an idiopathic condition that probably results from acquired thrombosis and recanalization of the IVC. The membrane has been found to vary from very thin to several centimeters thick and sometimes has occluded a long segment of retrohepatic IVC.

The pathologic lesion of BCS is thrombosis of the major hepatic veins or the IVC or both, which results in hepatic venous outflow obstruction; intrahepatic and portal hypertension; dilation of the liver sinusoids; intense centrilobular congestion of the hepatic parenchyma; and ischemia, pressure necrosis, and atrophy of the parenchymal cells in the center of the liver lobule. Early in the course of BCS, these lesions are reversible, if the obstruction is relieved. Persistence of the high pressure

and congestion within the liver results in irreversible damage, hepatic fibrosis, and progression to cirrhosis, often within a matter of months. The two paramount dangers in BCS are development of irreversible liver damage and extension of thrombosis from the hepatic veins into the IVC. The most striking difference between the East and West in the pathology of BCS is the site of the venous occlusion causing hepatic outflow obstruction: in the East, it is usually in the IVC; in the West, it is most often in the major hepatic veins.

The clinical course of BCS in Western countries is most commonly acute or subacute, with rapid progression of liver disease and its consequences over periods ranging from a few weeks to a few months. In some patients, however, BCS develops insidiously and progresses over months or years. The usual clinical manifestations are abdominal distension secondary to ascites, hepatomegaly, splenomegaly, abdominal pain, weakness, wasting, and anorexia. Some patients additionally have mild jaundice and distension of the superficial veins of the anterior abdominal wall. When the IVC is obstructed, an important additional sign is edema of the lower extremities and lower trunk. In the chronic forms of BCS, all of the manifestations of cirrhosis of the liver are found.

The diagnosis of BCS in the initial weeks and months is based on finding the typical symptoms and signs combined with abnormal results of several diagnostic studies, the most important of which are angiographic examination of the IVC and hepatic veins with pressure measurements and percutaneous transjugular needle liver biopsy. In BCS confined to the hepatic veins, angiographic studies show a patent IVC and relatively normal IVC pressure for patients with ascites, whereas in BCS involving the IVC, cavography shows an area of IVC obstruction, and IVC pressure is markedly elevated. Hepatic venography shows occlusion of the major hepatic veins, and wedge injection shows a distinctive spiderweb pattern of venous collaterals. WHVP is markedly elevated. In BCS confined to the hepatic veins, WHVP is substantially higher than IVC pressure, but in BCS involving IVC obstruction, WHVP is similar to IVC pressure.

Liver biopsy reveals the typical lesions of obstruction to hepatic venous outflow: intense centrilobular congestion and centrilobular loss of parenchyma and necrosis. Other diagnostic studies that may be helpful as screening procedures are 1) CT, which shows absence of opacification of the major hepatic veins; 2) US, which shows absence of normal hepatic veins; and 3) hepatic scintiscanning, which shows decreased and nonhomogeneous hepatic uptake of radiocolloid and sometimes shows central localization of radiocolloid, the so-called central hot spot. Liver function tests invariably show significant hepatic dysfunction. In patients who are operated on for BCS confined to the hepatic veins, the clinical manifestations and results of diagnostic studies are confirmed by the findings of marked ascites; an enlarged, congested liver; splenomegaly; extensive portosystemic collateral veins; IVC pressure that is substantially lower than PV pressure; portal hypertension; and a markedly elevated hepatic occluded portal pressure, which sometimes is higher than the free portal pressure.

Nonsurgical therapy of BCS includes medical treatment with thrombolytic agents, anticoagulants, and diuretics and radiologic therapy consisting of transluminal angioplasty, venous stenting, and TIPS. Infusion of thrombolytic agents, such as streptokinase and urokinase, in hopes of dissolving thrombi in the hepatic veins or IVC or both has had limited short-term success but a high rate of ultimate failure. Anticoagulant therapy to prevent propagation of the thrombi has produced a limited, short-term response when used alone. None of these measures have been effective, and nonoperative medical therapy has been associated with an almost uniformly poor prognosis: most patients in Western countries have died within a few months of onset of symptoms, and the few patients who have survived the acute phase have almost all died from the complications of cirrhosis within a few years. Control of ascites is feasible in some patients with BCS by use of the usual diuretic regimens, although the ascites is resistant to therapy in many patients, and no evidence suggests that control of ascites influences the long-term outcome.

Radiologic therapy consisting of percutaneous transluminal angioplasty with and without the use of metallic stents has had some short-term success in patients with chronic BCS resulting from stenosis of the IVC, but recurrent stenosis has been the rule; the long-term success rate has been less than 50%, although one report from China claimed a high success rate. The TIPS procedure has been used in recent years with increasing frequency for all forms of BCS. The advantage of TIPS is that it does not require a major surgical operation; disadvantages are a high rate of TIPS stenosis and occlusion requiring repeated revisions, frequent recurrence of symptoms, and the need for numerous radiologic procedures and hospitalizations. The incidence of TIPS occlusion has decreased markedly with the introduction of polytetrafluoroethylene-covered stents, but it is still substantial. In the most experienced hands, the 5-year survival rate after TIPS has been well below the 5-year survival rate of surgical shunt therapy in our series (Orloff, 2010).

SSPCS has proved to be the most effective therapy of BCS caused by thrombosis of the hepatic veins. Its use is based on substantial evidence that shows it converts the valveless PV into an outflow tract, decompressing the obstructed hepatic vascular bed. In an experimental evaluation of PCS in dogs with BCS, we found that SSPCS decompressed the liver and cured ascites in 96% of the dogs; reduced the liver to a normal size; reversed the pathologic lesions in the liver, often to normal; and resulted in long-term survival of many of the dogs.

On the basis of these experimental findings, we have performed SSPCS early in the course of disease in 39 unselected patients with acute or subacute BCS confined to the hepatic veins with one operative death and one long-term death. The 37 survivors of operation have lived free of ascites without diuretic therapy for 5 to 38 years (mean follow-up, 15 years). The shunt has remained patent in all but 1 patient. Liver function has returned to normal in the 34 patients who did not already have cirrhosis preoperatively, hepatosplenomegaly has disappeared, and no encephalopathy was reported. Serial liver biopsy specimens obtained for 37 years postoperatively showed substantial reversal of the pathologic lesions of BCS. Our experience shows the importance of performing SSPCS early in the course of BCS to reverse the liver damage and prevent extension of thrombosis from the hepatic veins into the IVC.

Splenorenal shunt, interposition mesocaval shunt, and PCS using synthetic grafts are hemodynamically similar to SSPCS but are inferior operations in BCS because of a high incidence of thrombosis and occlusion. Interposition shunt using an autogenous internal jugular vein H-graft has produced results similar to those of direct SSPCS. Important technical features of SSPCS are proper positioning of the patient, use of a long right subcostal incision, and extensive mobilization of the IVC

and PV so that the two vessels can be brought together. Resection of the caudate lobe of the liver has not been necessary in any of the BCS patients, nor has it been needed in any of the more than 2500 patients in whom we have performed the SSPCS.

SSPCS is contraindicated when BCS is caused by thrombosis or occlusion of the IVC. Under such circumstances, a mesoatrial shunt has been used with some short-term success, although there has been a high incidence of thrombosis of the bypass graft. In our series of eight patients, thrombosis of the mesoatrial shunt developed in five, and the 5-year survival rate was only 38%. Similarly, others have reported thrombosis of the mesoatrial shunt in 40% to 70% of patients, an event that is often followed by death. Because of dissatisfaction with the results of mesoatrial shunt, we worked in the experimental laboratory to devise a shunting procedure aimed at decompressing the hypertensive IVC and shunting the portal venous flow and the entire IVC flow to the right atrium. The new operation, which consists of a combined SSPCS and CAS through a Gore-Tex prosthesis, was found to be effective in relieving BCS in rats and has been successful in each of 18 patients with BCS secondary to IVC occlusion during follow-up of 5 to 25 years. In our program, the combined shunt operation has replaced the mesoatrial shunt as the preferred treatment for BCS caused by IVC occlusion.

LT is indicated in patients with chronic BCS who have cirrhosis with progressive hepatic failure and in patients who have had an unsuccessful portosystemic shunt. In approximately 1043 patients with advanced liver disease secondary to BCS, LT has resulted in a mean actuarial 5-year survival rate of 71%. BCS recurred in 13% to 27% of the liver grafts, and thrombosis of other blood vessels, particularly the PV, occurred in 9% to 40% of patients. In our experience with 12 patients who were approved for LT, 3 died on the waiting list, and the 5-year survival rate of patients who underwent LT was 67%. It is important to note that LT and SSPCS are not competing forms of treatment: LT is appropriate therapy in the late stages of BCS, when the liver disease no longer can be reversed by SSPCS.

Other surgical procedures of uncertain value in BCS are direct surgical removal of the venous obstruction, percutaneous transluminal angioplasty, thoracic transposition of the spleen, and peritoneovenous shunt. The latter two procedures are rarely if ever used today. Direct surgical resection of the occluded hepatic veins and IVC with the aid of cardiopulmonary bypass has produced good short-term results in about 100 patients with chronic BCS involving the IVC, but prolonged and detailed follow-up revealed an overall mortality rate of 32%, obstruction of the IVC in 14%, and development of hepatocellular carcinoma in some patients. The success rate of percutaneous balloon angioplasty has been less than 50%. Peritoneovenous shunt is a palliative procedure that should not be used as primary treatment of BCS, because it does not decompress the liver or influence the ongoing hepatic damage.

Several surgical procedures have been used by Japanese surgeons to treat the chronic form of BCS caused by MOVC. When the area of IVC obstruction has been short, fracture of the membrane by transcardiac membranotomy has been the principal treatment and has had a short-term success rate of 70% to 90% during follow-up periods ranging from 2 months to 7 years. Percutaneous transluminal angioplasty also has had some short-term success, but recurrence of IVC stenosis has been frequent. When the area of IVC obstruction has been long, treatment has consisted of direct excision and repair of the involved area of IVC or cavoatrial bypass graft. Both of these procedures have had some success but have been associated with a substantial incidence of failure and a substantial mortality rate. Finally, patients with MOVC have undergone a variety of operations of uncertain value, all designed to create portosystemic or portopulmonary collateral venous connections.

It is a fact that no treatment has accomplished a survival rate comparable to SSPCS in BCS resulting from thrombosis of the hepatic veins or of combined SSPCS and CAS in BCS resulting from occlusion of the IVC.

VOD, otherwise known as *sinusoidal obstruction syndrome,* is a group of disorders in which hepatic venous outflow obstruction is due to subendothelial sclerosis of the sublobular hepatic veins, terminal hepatic venules, and sinusoids within the liver. VOD is caused by antineoplastic drugs, ingestion of plants containing pyrrolizidine alkaloids, and irradiation of the liver. In the Western Hemisphere, the most frequent cause is bone marrow transplantation. Approximately one fourth of bone marrow transplant recipients develop VOD. Extensive occlusion of the small hepatic veins results in centrilobular hemorrhagic necrosis of the liver parenchyma, which progresses to diffuse fibrosis and cirrhosis. Although it can occur at any age, VOD caused by pyrrolizidine alkaloids has been observed most often in children: after a prodromal febrile illness, acute-onset abdominal distension owing to ascites ensues, along with abdominal pain, hepatosplenomegaly, weakness, and sometimes jaundice and peripheral edema.

The most important symptoms and signs of VOD after bone marrow transplantation are ascites, jaundice, and abdominal pain. Some patients recover from the acute stage of VOD, but approximately one fifth of patients with pyrrolizidine poisoning die; the remainder go on to develop cirrhosis rapidly, with all of its clinical manifestations. The mortality rate of severe VOD after bone marrow transplantation has been reported to be 98%. The most important diagnostic study in VOD is percutaneous needle liver biopsy, which shows the specific abnormality of extensive occlusion of the small hepatic veins within the liver and centrilobular hemorrhagic necrosis. The results of hepatic scintiscanning, liver function tests, and WHVP measurements are similar to results found in BCS, but angiographic studies are not helpful, because the major hepatic veins and IVC are normal in VOD. Elevated WHVP supports the diagnosis of VOD.

Substantial experience with treatment of VOD has been reported in patients who have the disorder as a result of ingestion of pyrrolizidine alkaloids. When such patients are seen in the acute stage, supportive medical therapy is used. SSPCS is indicated during the acute stage if bleeding esophageal varices develop, or if the clinical and liver biopsy signs of hepatic venous outflow obstruction do not subside after 4 to 8 weeks. In the chronic phase of VOD, when the usual manifestations of cirrhosis have developed, SSPCS is recommended even before varix hemorrhage has occurred.

The mortality rate of chronic VOD is high, and the major cause of death is bleeding esophageal varices. Medical therapy of the many patients who have developed VOD after bone marrow transplantation has included defibrotide, tissue plasminogen activator, ursodeoxycholic acid, antithrombin III, prostaglandin E_1, anticoagulation with low-dose heparin, and

high-dose corticosteroids. None of these agents has been uniformly effective, but the most promising agent in prophylaxis and treatment of VOD is defibrotide, which has been reported to produce a complete response rate of 36% and a 100-day survival rate of 35% in severe VOD. In addition, SSPCS, TIPS, and LT have been used in a few patients with severe VOD. These procedures have had some success and deserve further evaluation, particularly because one fourth of patients with VOD develop the severe form of the disease, and the mortality rate of severe VOD has been reported to be 98%.
