If packing fails to control the bleeding, inflow occlusion is the next step. The index finger is placed through the foramen of Winslow posterior to the hepatoduodenal ligament, and a window is created in the gastrohepatic ligament. An umbilical tape is then passed through the window in the gastrohepatic ligament and out through the foramen of Winslow, thereby surrounding the portal triad, which is then occluded en masse with either a Rummel tourniquet or a vascular clamp. The occlusion time should be kept to a minimum: 15 minutes of hepatic inflow occlusion is safe in elective hepatic resection (Tralhão et al, 2009). Intermittent hepatic inflow occlusion has been used safely with a total inflow occlusion time in excess of 120 minutes (Ishizaki et al, 2006), although no level 1 data are available to define the safe duration of hepatic inflow occlusion in trauma patients.

If the bullet or knife tract is superficial, a tractotomy can expose the injured vessel for direct suture ligation (Badger et al, 2009). Tractotomy can be performed using the Endo GIA (gastrointestinal anastomosis) stapler (Covidien, Boulder, CO) with a vascular stapler load, gradually dividing the roof of the tract in a piecemeal fashion so that the deep bleeders in the tract can be individually suture ligated or doubly clipped with a hemoclip. If the injury involves the left lateral segment, a stapled segmentectomy, using either the Endo GIA or a TA (thoracoabdominal; Covidien) stapler, is an expedient solution (Schemmer et al, 2007).

More often, the problem arises from a deep tract or through-and-through injury to the main mass of the right lobe. Filling the tract with omentum, Flowseal (Baxter Healthcare, Zurich, Switzerland), or Avitene (Davol, Warwick, RI) will often achieve hemostasis. Balloon tamponade is another useful technique (Poggetti et al, 1992), wherein a balloon device is improvised from a red rubber (Robinson) catheter inserted into a 1-inch Penrose drain. The distal end of the drain is tied closed, and the proximal end is secured snugly around the catheter with a pair of heavy silk ties. The balloon device is inserted through an appropriate stab incision in the right upper quadrant abdominal wall and into the tract and is inflated with saline injected through the catheter. A closed suction drain is placed in the subhepatic space. The balloon is deflated and removed either at planned relaparotomy, 48 to 72 hours after the original operation, or percutaneously if the abdomen was closed.

Sometimes a bleeding vessel can be exposed and suture ligated at the base of a deep liver laceration, using the technique of finger-fracture hepatotomy with selective vascular ligation under inflow occlusion (Hirshberg & Mattox, 2006); however, attempts to reach a deep vessel are often ill advised, as they lead to continued blood loss and physiologic deterioration and may even aggravate the bleeding. Packing, when successful, is the best approach, and immediate postoperative angiographic embolization (see Chapters 28 and 83), if available, can be a lifesaving adjunct.

Resectional debridement of the injured tissue is an option for extensive destruction of the periphery of the liver; however, the surgeon must always keep in mind that the one and only major goal of the operation is to achieve hemostasis as rapidly as possible; other considerations are secondary and must wait. Resectional debridement, if necessary, is more frequently used to address devascularized liver tissue during a delayed reoperation rather than bleeding in the initial procedure.

Bleeding from the Hepatic Veins and Juxtahepatic Vena Cava

The large retrohepatic veins are a low-pressure system; when injured, they are often contained by the triangular ligaments of the liver. An injury to the retrohepatic cava or the major hepatic veins can therefore manifest either as bleeding *through* a hole in the liver, if the suspensory ligaments remain intact, or as bleeding *around* the liver, if they are disrupted (Buckman et al, 2000); bleeding through the liver stops with effective packing of the hole in the liver, but bleeding around the liver does not.

Juxtahepatic vena caval hemorrhage should be suspected if a large volume of dark blood gushes around or through a

high-grade liver injury. Posterior and inferior traction on the falciform ligament may compress the liver mass onto the retrohepatic vena cava and reduce the bleeding. The next step is packing, although bleeding around the liver may not stop with packing despite heroic efforts. In these situations, when packing and the Pringle maneuver fail to stop the bleeding, an *early* decision to achieve control of the hepatic outflow tract—that is, the second vascular pedicle—is critical. Delay of the decision ensures failure and patient death as a result of continued massive blood loss.

Vascular isolation of the injured liver is a formidable surgical challenge (see Chapter 91A; Yellin et al, 1971), not only because of the technical complexity involved but also because cross-clamping the suprahepatic and infrahepatic vena cavae (Krige et al, 1990) is poorly tolerated by the hypovolemic patient. Furthermore, although creating a sling to occlude the infrahepatic vena cava can usually be accomplished relatively quickly after a Kocher maneuver, dissection of the infradiaphragmatic suprahepatic cava is difficult, particularly for the emergency surgeon who operates infrequently in this area.

Several options are available for achieving outflow control, and by far the most well-known is the atriocaval shunt (Fig. 102.3; Schrock et al, 1968). After performing a median sternotomy, a No. 32 chest tube is inserted through the purse-stringed right atrial appendage and threaded through the right atrium and juxtahepatic vena cava to a position just above the renal veins. At the same time, a second team isolates the inferior vena cava (IVC) in its suprarenal infrahepatic segment, and a side hole is fashioned at the level of the right atrium. Rummel tourniquets are tightened around the vena cava and the stent within the pericardium and just above the renal veins. Using a 9.5-mm endotracheal tube with a side hole 17 cm from the tip obviates the need to isolate the suprarenal cava, because inflating the balloon of the tube occludes the caval lumen. This maneuver shunts venous return to the heart around the injured segment and controls most of the bleeding, enabling the surgeon to visualize and repair the hole in the vein by completely mobilizing the right lobe of the liver and rotating it medially. This is a difficult and uncommonly used technique, as evidenced by the popular adage that "the number of articles published about atriocaval shunt far exceeds the number of patients who survived it" (Fig. 102.3).

Another option for outflow control is complete hepatic vascular isolation (see Chapter 91A) by clamping the inferior vena cava above and below the liver, in conjunction with simultaneous aortic cross-clamping (Khaneja et al, 1997), or use of a centrifugal pump to return blood to the heart (Baumgartner et al, 1995; Horwitz et al, 1995) to reduce the risk of hypovolemic arrest after caval occlusion. Even hepatic explantation and back-bench repair of hepatic vein avulsion followed by hepatic autotransplantation has been reported (Boggi et al, 2006). Despite all of these elegant technical concepts, which are of very limited utility in the real clinical situation, the mortality rate for

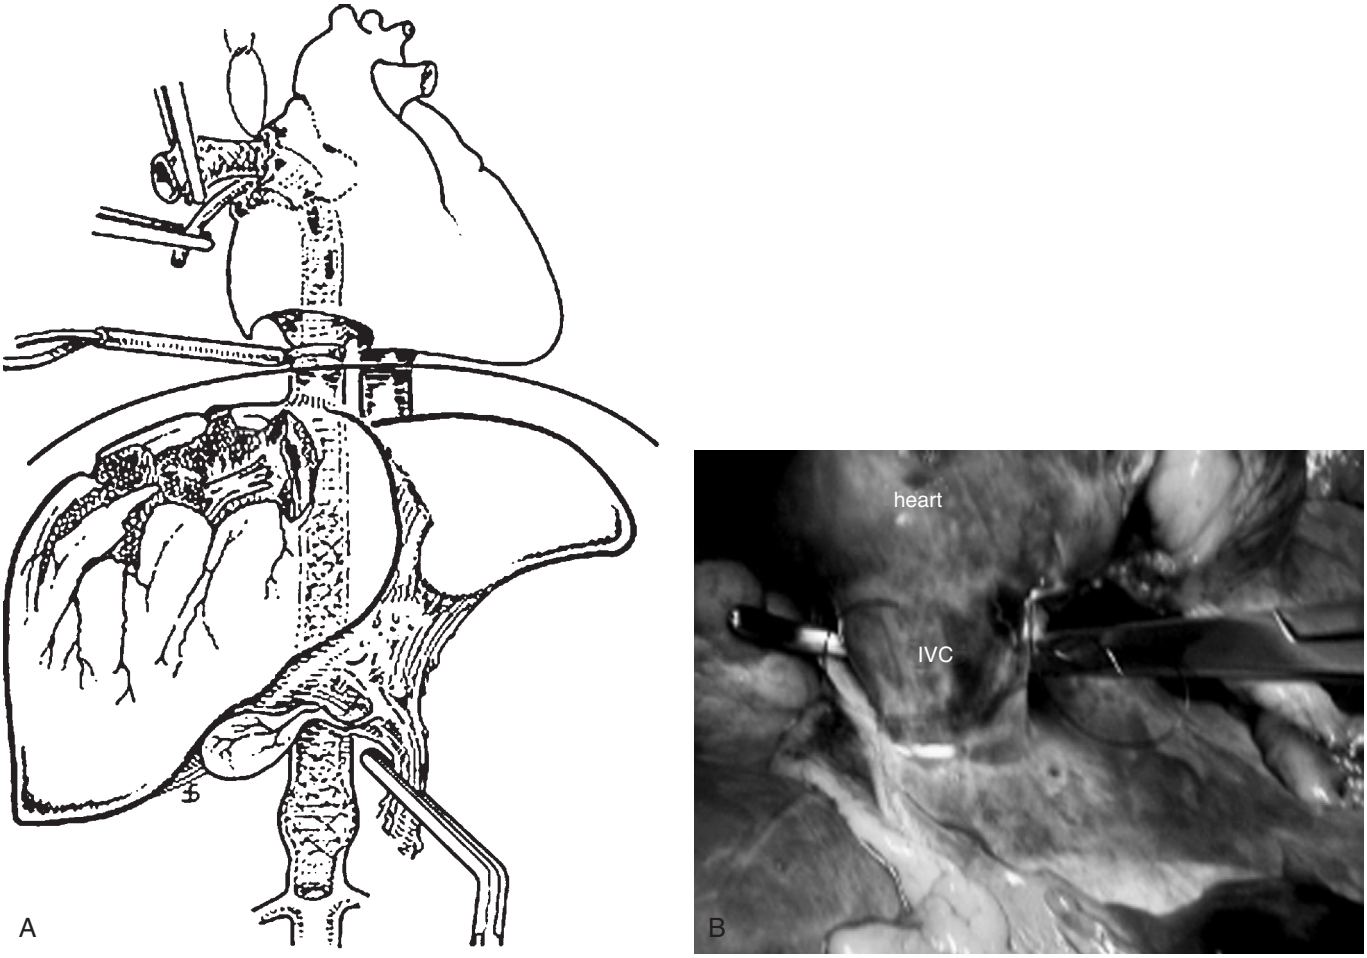

FIGURE 102.3. An atriocaval shunt. *IVC*, inferior vena cava.

unstable patients with juxtahepatic vena caval injury unresponsive to packing remains extremely high (Phelan et al, 2001).

Urgent Reoperation

The three indications for urgent reexploration of a patient with liver injury are 1) continued bleeding, 2) abdominal compartment syndrome, or 3) a missed injury. At laparotomy, the liver packs are removed, and the injury is closely inspected for hemostasis. Thorough exploration of the abdomen in search of other sources of bleeding is then carried out.

The most common causes of bleeding found at urgent relaparotomy for trauma are inadequate hemostasis of the original injury, another source of bleeding in the vicinity, iatrogenic trauma, or diffuse coagulopathy (Hirshberg et al, 1993). In cases of rebleeding, mortality is extremely high, and the prognosis is especially bleak, if no discrete source of hemorrhage is found.

The liver encountered at urgent reoperation is often "hostile" and is very different from the normal organ. It is grossly swollen to twice or more its normal size with a tense capsule that tears easily. The edematous parenchyma does not hold clips or ligatures well, and it is often impossible to properly mobilize such a swollen, friable liver without adding an iatrogenic insult to the original injury. Hemostatic liver sutures tend to tear through the capsule and lose their hemostatic effect. This hostile environment represents a very bad turn of events in an already precarious situation.

Some patients develop intraabdominal hypertension following the initial operation, as previously discussed. In most cases, an urgent decompressive laparotomy with temporary abdominal closure, leaving the abdomen "open," is the only way to save a rapidly deteriorating patient. Occasionally, this problem can be managed by catheter drainage of the peritoneum, if the patient is relatively stable.

Planned Reoperation

Planned reoperation is an integral part of the damage-control sequence for treatment of severe liver trauma. In general, the patient is reexplored 36 to 48 hours after the initial operation, once hemodynamic stability has been achieved. Although such a practice is not supported by data, trauma surgeons are reluctant to remove liver packs sooner than 36 hours after the initial operation, because earlier removal often results in rebleeding and a need to repack the liver. Packs should rarely, if ever, be left in any patient for more than 72 hours (Scott et al, 2006), because the risk of infection increases sharply. If the packed liver injury is associated with damage control of a bowel injury, intestinal reconstruction should be performed, and the packs should be removed last.

Extreme care should be taken to remove liver packing, which should be done slowly and only after flooding the right upper quadrant with saline. A Toomey syringe is used for continuous pulse irrigation and blunt atraumatic separation of the packs off the liver capsule, assisted by the jet of saline. Bleeding should prompt the surgeon to stop and address the bleeding point with the argon beam coagulator or another local hemostatic technique. Special care should be taken to avoid stripping the liver capsule. The area should be widely drained, and resectional (nonanatomic) debridement of areas of obvious necrosis should be considered, if hemostasis has been achieved and the patient is otherwise stable. Ongoing oozing from the unpacked areas should prompt consideration of repacking; it is important to admit defeat early and repack rather than continue with attempts at futile hemostasis in a hostile liver.

Extrahepatic Biliary Injury

Most extrahepatic biliary injuries result from penetrating trauma (Posner & Moore, 1985) and are discovered at exploratory laparotomy. The gallbladder is the most common structure injured, and cholecystectomy definitively solves the problem (Posner & Moore, 1985); however, it may be unwise in an unstable coagulopathic patient with an associated liver injury, because it creates another source of hemorrhage from the liver bed. A tube cholecystostomy or closure with an absorbable stitch and drainage of a small hole in the gallbladder are therefore better options in a damage-control situation.

Small stab wounds to the extrahepatic biliary ducts can be managed by primary closure with absorbable suture and external drainage (Bade et al, 1989). The use of a T-tube for a common bile duct (CBD) injury is rarely a practical option in a healthy young adult with a normal CBD. Major injuries to the extrahepatic bile ducts require Roux-en-Y choledochojejunostomy or hepaticojejunostomy for definitive repair (Degiannis et al, 2001).

Penetrating trauma to the biliary tree is often associated with injuries to vascular structures such as the portal vein, hepatic artery, and vena cava (Jurkovich et al, 1995). Injuries to adjacent structures—such as the duodenum, pancreas, stomach, and liver—are also common. The hemodynamic stability of the patient and the complexity of the other injuries will govern management of the bile duct injury.

Roux-en-Y choledochojejunostomy and hepaticojejunostomy are the definitive treatments of choice, as they are for bile duct injuries complicating cholecystectomy; however, more often than not, the patient is unstable because of associated injuries that preclude a complex biliary reconstruction. Damage-control drainage of the bile duct injury by temporary T-tube drainage of a complex laceration—or via an infant feeding tube tied into the proximal duct, if the duct has been completely transected—and continued resuscitation in the ICU with subsequent elective biliary reconstruction under controlled conditions is a much better option. Although temporary ligation of the proximal transected duct is another option in a damage-control situation, drainage is generally preferred.

Blunt injury to the gallbladder as a result of a "blowout" (Zellweger et al, 2005) or adhesive tear is uncommon, but the treatment principles are similar to those for penetrating injury. Rarely, the surgeon may encounter avulsion of the common bile duct from the duodenum. If this is an isolated injury, the duodenum can be oversewn, and a Roux-en-Y choledochojejunostomy can be constructed (Melton et al, 2003). Regardless of the type of biliary management, wide drainage is essential.

SUMMARY

Nonoperative management of hemodynamically stable patients with blunt hepatic injury has become the standard method of care; however, this conservative approach often requires the use of adjunctive measures to manage sequelae and complications. A missed hollow viscus injury is an unusual but potentially lethal complication of this conservative management strategy.

Hemodynamically unstable patients with a bleeding liver require emergency laparotomy, although most patients with

significant hemorrhage can and should be managed by packing. Rarely, a patient with a juxtahepatic hepatic vein or vena caval injury will not respond to packing. In this situation, an early decision to achieve proximal and distal vascular control of the liver is essential, if there is to be any chance of salvage. Even in the most experienced hands, the mortality rate for juxtahepatic vena caval injuries is high.

Penetrating injuries to the extrahepatic biliary tract are relatively uncommon. Hemodynamically unstable patients should be managed with damage-control techniques, and prolonged procedures to reconstruct the biliary tract should only be undertaken when the patient is stable.

CHAPTER 103

Pancreatic and duodenal injuries

William P. Schecter and Asher Hirshberg

OVERVIEW

Torrential bleeding from the region of the pancreatoduodenal complex (PDC), surging like a crimson tide, is one of the most intimidating sights in trauma surgery. This particularly lethal pancreatic injury is but one of the challenges posed by this unforgiving organ. Hidden deep in the upper recesses of the retroperitoneum, the injured pancreas exhibits a spectrum of clinical presentations, from that of occult injury to dramatic exsanguination. This chapter reviews the modern approach to the management of pancreatoduodenal trauma with emphasis on the need for a high index of suspicion, modern imaging technology, and safe operative principles.

EVOLUTION OF THE APPROACH TO PANCREATIC TRAUMA

The modern approach to pancreatic trauma reflects advances in elective foregut surgery. Better confidence in surgery of the PDC, advanced imaging, and better physiologic insight have combined to shape the current management of the injured pancreas.

A patient with blunt pancreatic injury was first reported in the Lancet as early as 1827, by Tavers. Although several survivors were subsequently reported after ligation and excision of exteriorized penetrating pancreatic wounds (Otis, 1876), the major advance in the operative treatment came in 1923, when Walton described distal pancreatectomy (see Chapter 62) as the treatment of choice for pancreatic transection. The dramatic reduction in mortality among patients with pancreatic injuries—from 56% in World War II, mostly due to associated injuries, to 22% in the Korean War—was more a result of improvements in general perioperative care than of specific technical innovations (Sako et al, 1955).

In the final decades of the last century, advances in medical imaging and in surgical technique converged to improve the care of patients with pancreatic trauma. The most important of these was computerized tomography (CT) of the abdomen (see Chapter 16), which for the first time allowed detailed visualization of the pancreas (Udekwu et al, 1996). This enabled surgeons to diagnose hitherto unrecognized pancreatic injuries and to drain peripancreatic fluid collections without the need for a laparotomy.

At approximately the same time, the introduction of endoscopic retrograde cholangiopancreatography (ERCP; see Chapter 18) provided a minimally invasive approach to diagnose leakage from the pancreatic duct after trauma (Buccimazza et al, 2006; Gupta et al, 2004; Lin et al, 2004; Wind et al, 1999; Wong et al, 2002). By contrast, the role of magnetic resonance cholangiopancreatography (MRCP; see Chapter 17) in the evaluation of the injured pancreatic duct remains to be defined (Bhasin et al, 2009; Fulcher et al, 2000).

The presumed adverse effect of pancreatic enzymes on the suture lines of duodenal repairs in patients with injuries to both organs led to the development of the Berne duodenal diverticulization, essentially a Bilroth II gastrectomy combined with biliary diversion (Berne et al, 1968, 1974), to preemptively divert gastric secretions around the repaired duodenum. Later, Jordan introduced the pyloric exclusion procedure (Vaughan et al, 1977), which achieves the same result but with a much simpler operation. Because of its conceptual elegance and technical simplicity, pyloric exclusion rapidly became the buzzword of PDC trauma in the 1990s. This led to very liberal use of the procedure in reported series (Feliciano et al, 1987); however, pyloric exclusion has never been subjected to a prospective randomized trial, and most attempts to compare it retrospectively to simple duodenal repair have demonstrated increased morbidity without benefit (DuBose et al, 2008; Seamon et al, 2007).

Resection of the entire PDC (see Chapter 62), which is routinely done in elective pancreatic surgery, is very rarely needed in the trauma situation. When complete disruption of the head of the pancreas and surrounding duodenal loop leaves the surgeon with no other choice, a so-called trauma Whipple (TW) may be necessary, but only as a last resort to save an exsanguinating patient. When necessary, the procedure is performed in a staged fashion with resection during the original operation and reconstruction 24 to 48 hours later (Subramanian et al, 2007). This is a reflection of the move toward damage control surgery, the most important paradigm shift in trauma surgery in the last two decades of the last century (Hoey & Schwab, 2002).

Distal pancreatectomy remains the mainstay of treatment of patients with major ductal disruption (Balasegaram & Lumpur, 1976; Heitsch et al, 1976); however, reports of successful stenting of the injured pancreatic duct via ERCP (Lin et al, 2006, 2007) suggest that this minimally invasive intervention may evolve into a safe management option in selected patients. Pancreatic trauma continues to tax the judgment and operative skills of experienced surgeons, even as sophisticated, minimally invasive diagnostic and therapeutic adjuncts continue to evolve.

SURGICAL ANATOMY OF THE PANCREAS AND DUODENUM: A TRAUMA SURGEON'S PERSPECTIVE (SEE CHAPTERS 1A AND 1B)

The injured pancreas is not immediately accessible during laparotomy for trauma and requires special maneuvers for exposure and access. In addition, the complex pancreatic anatomy

Table 103.1

Pancreas Injury Scale

Grade*	Type of Injury	Description of Injury	ICD-9	AIS-90
I	Hematoma	Minor contusion without duct injury	863.81–863.84	2
	Laceration	Superficial laceration without duct injury		2
II	Hematoma	Major contusion without duct injury or tissue loss	863.81–863.84	2
	Laceration	Major laceration without duct injury or tissue loss		3
III	Laceration	Distal transection or parenchymal injury with duct injury	863.92/863.94	3
IV	Laceration	Proximal† transection or parenchymal injury involving ampulla	863.91	4

dictates that the head and the body of the pancreas be managed operatively as two separate organs.

The closest anatomic relationship of the injured *body and tail* of the pancreas is with the spleen. The pancreatic body is typically approached by first mobilizing the spleen medially to enter the anatomic plane behind the spleen and pancreas. The splenic artery and vein are then easily exposed and controlled on the posterior surface of the gland; however, if necessary, control of the splenic vessels can be achieved by mobilizing the body of the gland along its superior and inferior aspects, with no need for splenic mobilization. Based on this anatomic arrangement, trauma surgeons view the body and tail of the pancreas as an organ with a single accessible vascular pedicle, similar to the kidney or spleen. When necessary, the injured pancreatic body can be easily resected by performing an en bloc distal pancreatectomy and splenectomy. The major concern in trauma is whether the main pancreatic duct is damaged, because this can cause a persistent fistula with its associated complications. In contrast, bleeding is usually not a major concern.

The head of the pancreas is densely adherent to the duodenal loop, and it is convenient to group them together as the PDC, which is approached from the right side. The PDC is supplied by multiple vascular arcades with ample collaterals that are not easily controlled. When injured, the PDC is difficult to resect and requires a high-risk reconstruction. The major concern after complex injuries to the PDC is a leaking duodenal suture line.

From the trauma surgeon's perspective, most of the major vascular structures of the upper abdomen converge on a small area, not much larger than a silver dollar, around the PDC. The superior mesenteric vessels, portal vein, inferior vena cava, and hilum of the right kidney are all in close proximity to the pancreatic head. The vascular structures around the PDC are arranged in three overlapping layers. The deepest one consists of the inferior vena cava and right renal pedicle. Above it, just behind and below the gland, are the portal vein and superior mesenteric vessels. The uppermost layer consists of the gastroduodenal artery and pancreaticoduodenal arcades.

As a result of this unique multilayered anatomic arrangement, penetrating trauma to the PDC often involves associated injuries to more than one major vascular structure, some of which—for example, the retropancreatic portal vein—are not immediately accessible from the front. It is therefore not surprising that penetrating trauma to this area presents what is widely held by trauma surgeons to be the most formidable challenge in abdominal trauma.

The organ injury scales for the pancreas and duodenum, developed by the American Association for the Surgery of Trauma (AAST) (Tables 103.1 and 103.2; Moore et al, 1990) are used for grading injuries of these two organs. Unfortunately, these scales do not acknowledge the fundamental anatomic differences between the pancreatic body and tail and the PDC, and therefore their clinical usefulness is limited.

For practical purposes, trauma to the pancreas ranges from superficial injuries that require only drainage (Feliciano, 1989) to ductal disruption that mandates a distal pancreatectomy. Low-grade injuries to the duodenum can be repaired the same as any other penetrating injury to the gut; however, high-grade duodenal injuries, and especially those that combine duodenal and pancreatic trauma, require a different approach because of the high risk and unforgiving nature of a duodenal leak. Injuries that destroy the PDC or disrupt the ampulla are rare and carry very high mortality rates because of associated trauma to adjacent major vascular structures. This perspective on pancreatic anatomy forms the basis for a detailed discussion of the management of pancreatic injuries in the forthcoming sections.

Diagnosis of Pancreatic and Duodenal Trauma

Hemodynamically stable patients with injuries to the pancreas and/or duodenum may exhibit only subtle signs because of the retroperitoneal location of these organs. Patients with a history of acceleration/deceleration injury; forceful anterior compression of the abdomen, such as from kicks or handlebar injuries; and lower thoracic and upper lumbar vertebra fractures are at increased risk. A seatbelt sign across the upper and middle abdomen should suggest the possibility of serious intraabdominal injury (Velmahos et al, 1999); however, the physical examination can be remarkably benign: abdominal pain and peritoneal signs sometimes take days to develop. For all of these reasons, a high index of suspicion is essential to avoid missing an injury (Wright & Stanski, 2000).

Routine laboratory tests are not particularly helpful. Obviously, patients with elevations in white blood cell count, amylase, or lipase require further investigation. Unfortunately, many patients are seen with normal values. In fact, as many as 35% of patients with a pancreatic transection have normal amylase

Table 103.2

Duodenum Injury Scale

Grade*	Type of Injury	Description of Injury	ICD-9	AIS-90
I	Hematoma	Involving single portion of duodenum	863.21	2
	Laceration	Partial thickness, no perforation	863.21	3
II	Hematoma	Involving more than one portion	863.21	2
	Laceration	Disruption <50% of circumference	863.31	4
III	Laceration	Disruption 50%-75% of circumference of D2	863.31	4
		Disruption 50%-100% of circumference of D1, D3, D4	863.31	4
IV	Laceration	Disruption >75% of circumference of D2	863.31	5
		Involving ampulla or distal common bile duct		5
V	Laceration	Massive disruption of duodenopancreatic complex	863.31	5
	Vascular	Devascularization of duodenum	863.31	5

*Advance one grade for multiple injuries up to grade III.

AIS, Abbreviated Injury Score; ICD, International Classification of Diseases; D1, first position of duodenum; D2, second portion of duodenum; D3, third portion of duodenum; D4, fourth portion of duodenum

levels (Adamson et al, 2003; Jones, 1985; Sriussadaporn, 1994; Takishima et al, 1997).

On abdominal CT scan, injury to the duodenum is usually obvious; however, the initial CT findings of pancreatic injury may be quite subtle (Akhrass et al, 1997; Bradley et al, 1998; Canty & Weinman, 2001; Ilahi et al, 2002) even with a study using thin slices of the pancreatic area. If a definitive diagnosis is not possible, a repeat CT scan 8 to 12 hours later allows time for retroperitoneal edema as a result of leakage of pancreatic secretions, which better delineates the injury. Fluid in the lesser sac, pancreatic hematomas, and pancreatic lacerations all suggest the diagnosis (Subramanian et al, 2007).

Unfortunately, the abdominal CT scan cannot reliably diagnose a laceration of the main pancreatic duct, unless a complete pancreatic transection is visible (Bradley et al, 1998). ERCP (see Chapter 18) is an excellent test for that purpose and can also be used to stent lacerated ducts in selected patients (Bhasin et al, 2009; Silviera et al, 2009); however, the procedure itself has the potential to cause pancreatitis (Cotton et al, 2009; Silviera et al, 2009) and is generally indicated only when diagnosis of a lacerated duct will change the management of the injury. The role of MRCP in the management of pancreatic trauma remains to be determined (Gillams et al, 2006).

OPERATIVE MANAGEMENT OF INJURIES TO THE BODY AND TAIL OF THE PANCREAS (SEE CHAPTER 62)

The operative approach to injuries to the body and tail of the pancreas is similar for both blunt and penetrating injuries. Full exposure is achieved by either dividing the gastrocolic ligament or by freeing the greater omentum from the transverse colon, reflecting the stomach up and taking down any adhesions between the posterior wall of the stomach and the retroperitoneum. The organ is then thoroughly inspected to assess the damage. Any area of injury, contusion, or hematoma is explored by opening the posterior peritoneum over the anterior aspect of the pancreas, because a superficial and seemingly innocent hematoma may hide a deep laceration. Severe bleeding almost never originates from the pancreas itself but rather from adjacent structures.

In assessing the body and tail of the pancreas, the key question that the surgeon must address is whether a pancreatic duct injury is present (Bach & Frey, 1971; Bradley et al, 1998; Tyburski et al, 2001; Voeller et al, 1991). Unless there is an obvious complete transection, it is difficult to diagnose a duct injury by simple inspection. The integrity of the duct can be interrogated by intraoperative imaging, either by amputating the tail and cannulating the distal duct or by cannulating the gallbladder and injecting contrast into the common bile duct. Both these options are cumbersome and do not have high success rates (Berni et al, 1982).

A transduodenal pancreatogram is mentioned here only to be condemned, because it converts a pancreatic injury into a pancreaticoduodenal (PD) injury. Intraoperative ERCP, first reported in 1986, is another option, if it can be organized expeditiously (Laraja et al, 1986). The more practic option in the middle of the night is to simply proceed with empiric distal pancreatectomy, whenever a deep laceration is in the vicinity of the main pancreatic duct, or a large hematoma is found in the center of the gland. An alternative option for nonbleeding pancreatic injuries, particularly in the face of multiple associated injuries, is closed suction drainage of the lesser sac. Patton and colleagues (1997) demonstrated excellent results by simple drainage, regardless of the location of the injury. A disruption of the capsule should be drained without attempting to repair it. Drainage of an injured main pancreatic duct is an effective solution, but it often results in a high output pancreatic fistula, so distal pancreatectomy may be a better option.

The trauma literature of the 1970s and 1980s is replete with descriptions of pancreas-preserving techniques for complete pancreatic transections (Frey, 1982). The most popular of these was anastomosis of the distal pancreatic stump to a Roux-en-Y loop of jejunum to create a pancreatojejunostomy. The proximal stump, which drains into the duodenum, was then oversewn. The rationale for pancreas-preserving approaches is to maintain pancreatic function and to prevent potential long-term complications of exocrine insufficiency and/or diabetes mellitus; however, this elegant technical solution involves a high-risk

jejunal anastomosis to a traumatized edematous pancreatic stump in an unstable patient who will not tolerate a leak. So in spite of the fact that it is sometimes technically feasible, preservation of the distal pancreatic stump is not in the best interests of the trauma patient; distal pancreatectomy is a much safer solution (Krige et al, 2005; Steele et al, 1973).

Distal Pancreatectomy

Distal pancreatography (see Chapter 62) is often performed in unstable patients with associated injuries, which is not the time for splenic preservation (Subramanian et al, 2007). The spleen should be rapidly mobilized to the midline and used as a handle to lift up the body and tail of the pancreas as it is dissected bluntly from the surrounding retroperitoneal fat. The most expedient technique is to use a stapler to divide the gland, followed by selective suture ligation of the splenic artery and vein. If the pancreas is found to be transected already, an effort is made to deploy the stapler immediately to the right of the injury, in healthy tissue. If the pancreatic duct is visible, it should be suture ligated. As an alternative, the free edge of the proximal stump can be oversewn with a 2-0 polypropylene running suture. Closed suction drainage of the pancreatic bed and left upper quadrant is mandatory (Farrell et al, 1996).

POSTOPERATIVE PANCREATIC FISTULA

Approximately 25% of patients develop a fistula after distal pancreatectomy for trauma (Fahy et al, 2002). In most cases, the fistula is controlled by the drains placed at the time of surgery. Neither the technique of pancreatic closure (Ferrone et al, 2008; Sheehan et al, 2002) nor the use of sealants (Fisher et al, 2008; Suc et al, 2003; Yamamoto et al, 2009) significantly affects the risk of fistula. Nutritional support, preferably via jejunal feeding, is a crucial element of fistula management; however, the presence of a pancreatic fistula does not necessarily require abstinence from oral intake; indeed, depending on the nature and extent of associated injuries, most patients will be able to eat normally during the time it takes for the fistula to close. Endoscopically placed pancreatic stents can reduce the volume and duration of fistula drainage in problem cases (Goasguen et al, 2009; Grobmyer et al, 2009). Failure to identify and drain a contained leak can result in a pancreatic pseudocyst, which may on rare occasion require surgery.

INJURIES IN THE STABLE PATIENT

The first step in the operative management of the injured PDC is wide exposure of the area with a Kocher maneuver. Full mobilization of the PDC from the common bile duct to the superior mesenteric vein (SMV) exposes the head of the pancreas, the second and some of the third portions of the duodenum, and the underlying vena cava. Additional exposure of adjacent structures and an improved workspace can be developed by extending the incision in the posterior peritoneum caudad along the white line of Toldt and mobilizing the right colon (Buscaglia et al, 1969), the so-called extended Kocher maneuver. Complete visualization of the entire third and fourth portions of the duodenum is achieved by carrying the peritoneal incision around the cecum and along the line of fusion of the small bowel mesentery to the posterior peritoneum, all the way up to the ligament of Treitz. This *Cattell-Braasch maneuver* is a technique for the exposure of the third and fourth portions of the duodenum (Cattell & Braasch, 1960), which allows complete reflection of the midgut onto the chest wall and provides access to the entire duodenum; however, after performing the maneuver, the entire midgut remains suspended on the superior mesenteric vascular pedicle and should be handled with care.

After complete mobilization, the entire PDC must be thoroughly explored. The trajectory of the wounding missile must be reconstructed to avoid missing an injury, and the number of holes in the gut should be even; an uneven number should prompt a renewed search for another injury. It is especially easy to miss a hole on the medial side of the duodenal loop adjacent to the pancreas. In these cases, the safest option is to enlarge the hole on the free border of the duodenum in a transverse fashion to inspect and repair the medial wall from inside.

Low-grade duodenal injuries are repaired transversely when possible, to avoid narrowing the lumen. A well-vascularized tension-free repair is essential, but the specific technique and suture material are a matter of individual preference. Decompressive tube duodenostomy is unnecessary, but any injury to the PDC, no matter how simple, should be drained. If the duodenum cannot be closed without tension, it is not a low-grade injury.

High-grade duodenal injuries require sound judgment and safe technical solutions. An extensive laceration or loss of a segment of duodenal wall should never be closed under tension. Instead, the simple and versatile solution is a Roux-en-Y jejunal loop anastomosed to the injured portion of the duodenum.

All cases of complex duodenal repair benefit from establishing a route for enteral feeding distal to the duodenal suture line. Despite being recognized as a key principle, it is often forgotten in the excitement of the moment. Either a nasojejunal tube or a feeding jejunostomy will enable early postoperative feeding and greatly facilitates postoperative management if the duodenal repair leaks.

High-grade PDC injuries are an indication for *pyloric exclusion* (Degiannis & Boffard, 2000), the goal of which is to preemptively divert the gastric effluent around the injured duodenum by temporarily occluding the pylorus. If the duodenal repair leaks, a low-output end-duodenal fistula is much easier to manage than a high-output side fistula.

Pyloric exclusion begins with a generous longitudinal gastrotomy in the anterior wall of the antrum, close to the pylorus. The pylorus is grasped with two Babcock clamps, delivered through the gastrotomy and oversewn with size 0 PDS sutures. A side-to-side gastrojejunostomy with a short afferent limb is then constructed at the gastotomy site (Fig. 103.1). Some surgeons prefer to staple across the duodenum just distal to the pylorus, instead of suturing it from the inside. In most cases, the duodenum spontaneously opens several weeks later regardless of the method of closure; we prefer to use an absorbable synthetic suture.

The gastrojejunostomy is the source of most postoperative morbidity after a pyloric exclusion. This led Ginzburg and colleagues (1997) to attempt pyloric exclusion without gastrojejunostomy, relying on the spontaneous reopening of the sutured pylorus. Pyloric exclusion is, in theory, an ulcerogenic operation, but the incidence of marginal ulcers is unknown (Buck et al, 1992; Feliciano et al, 1987; Martin et al, 1983). Routine vagotomy or delayed takedown of the gastrojejunostomy is not indicated. Routine pyloric exclusion has recently been criticized

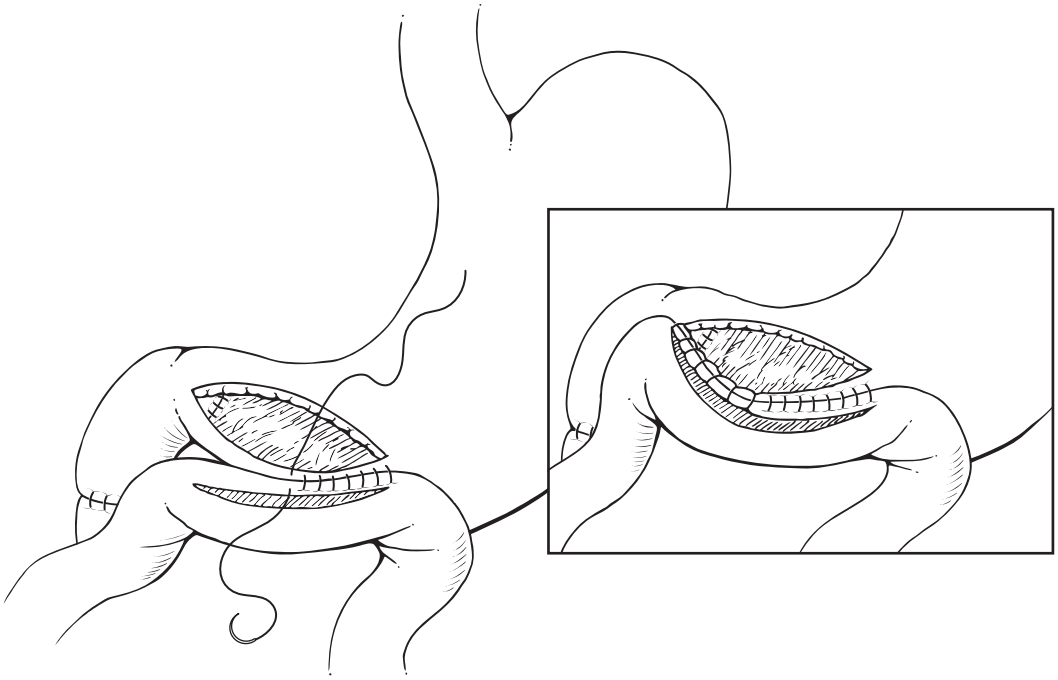

FIGURE 103.1. Pyloric exclusion showing occlusion of the duodenum just distal to the pylorus followed by a gastrojejunostomy.

because of reported increased complications and no effect on outcome (Seamon et al, 2007); however, in our practice, we continue to perform pyloric exclusion in patients with tenuous duodenal closures and in those with high-grade pancreatic injuries associated with a duodenal injury of any grade.

Occasionally, a high-grade injury to the PDC is encountered during a trauma laparotomy with massive blood loss unrelated to the PDC. In this situation, a rapid damage control solution is the only feasible alternative (see Chapter 102). The damage-control option for the injured nonbleeding pancreas is external drainage, regardless of the grade of injury. Similarly, the "bail-out" solution for duodenal injuries is either rapid closure with external drainage or placement of a large Malecot catheter through the hole affixed in place with a purse-string suture to create a controlled fistula.

MANAGEMENT OF A LEAKING DUODENAL REPAIR

A leak from the duodenal suture line after a PDC injury is unusual but can be devastating (Seamon et al, 2007). Leakage of bile from the drain in a Morison pouch, or any deviation from the patient's expected clinical trajectory, especially signs of unexplained sepsis, mean a duodenal leak until proven otherwise. A CT scan with contrast in the gastrointestinal tract will demonstrate the leak and establish whether it is controlled. If the leak is uncontrolled—that is, if free fluid is present in the peritoneal cavity—an urgent laparotomy is indicated to achieve source control and effective drainage. Such leaks can be difficult to manage, especially if the pylorus is open; the duodenum cannot be resected or exteriorized. Proximal diversion, if not done during the original procedure, is rarely an option; in addition, the inflamed duodenal wall does not hold sutures well. Inserting an appropriately sized Malecot tube into the hole, combined with wide regional drainage, is often the only feasible option. A creative variation of tube drainage is insertion of a spiral three-channel tube for continuous intraluminal irrigation (Parc et al, 1999). Although we have no personal experience with this method, it nevertheless underscores the technical difficulty of controlling a duodenal leak.

Late discovery of a duodenal leak in a septic patient is an indication for open-abdomen management with planned reoperations for peritoneal toilet to optimize drainage; this is not the time for complex duodenal reconstructions. If the leak is discovered early, pyloric exclusion may perhaps still be feasible, but in most cases, it is a hazardous undertaking in the inflamed peritoneal cavity of a septic patient.

If the CT scan demonstrates a leak but not collection or free fluid in the peritoneum, the leak is controlled. The appropriate conservative approach in this situation hinges on early and aggressive nutritional support while awaiting spontaneous closure. If a pyloric exclusion was done, fluid management of the low-output fistula is usually straightforward. Most duodenal leaks close spontaneously; if the leak does not close, it is important to rule out distal obstruction. If the leak persists, but no distal obstruction is found, the approach is to wait at least 6 weeks or more and then perform a Roux-en-Y duodenojejunostomy to the fibrotic edges of the hole in the duodenum.

A complex PDC injury in the second portion of the duodenum resulting in destruction of the ampulla of Vater and/or the ductal systems draining both the biliary tree and the pancreas requires a pancreatoduodenectomy (PD). This situation is very rare—neither of us has encountered it in a hemodynamically stable patient. The technical details of a TW are discussed in the next section.

PANCREATODUODENAL INJURIES IN THE UNSTABLE PATIENT

Severe bleeding from the area around the PDC is seen either immediately upon entering the peritoneal cavity, or it begins suddenly, when a periduodenal hematoma is explored. In either

case, the surgeon must be prepared technically and mentally to deal with a major vascular injury, often more than one.

The first step is temporary packing of the bleeding area, until the rest of the peritoneal cavity is explored; however, each time the packs are removed, the operative field is immediately immersed in blood, which precludes accurate visualization of the injuries. The complex multilayered vascular anatomy around the PDC does not allow simple proximal and distal control of the injured vessels. The solution is to encircle the injured area with a ring of tightly rolled laparotomy pads held on sponge-holding forceps and firmly pressed downward by assistants. This "compressive ring" of pads occludes the major veins around the PDC, giving the surgeon an opportunity to identify and repair the injured vessels.

Injuries to the retroduodenal inferior vena cava (IVC) are typically associated with trauma to the PDC and sometimes also to the right renal pedicle. The key to rapid exposure is a complete Kocher maneuver. Once the IVC is exposed, bleeding is controlled by compressing it above and below the bleeding site. The pararenal segment of the IVC is especially difficult to access and control. Two helpful maneuvers to improve access are application of assertive retraction to the liver in a cranial direction, using a deep Deaver retractor, and rapid mobilization of the right kidney. Simple lacerations of the IVC are repaired using a running monofilament suture. A hole in the posterior wall must occasionally be repaired from within the vessel by enlarging the hole on the anterior wall of a through-and-through injury.

It is important to remember that complex IVC injuries can be treated with ligation. Lacerations of the pararenal segment are especially difficult to repair, even if both renal veins are first isolated and controlled, because bleeding continues from lumbar veins, and ligation of the pararenal IVC means loss of at least the right kidney. Unfortunately, in the massively bleeding patient with several sources of hemorrhage, this may be the only realistic option to save the patient's life. Injuries to the renal hilum in the context of penetrating trauma to the PDC are best addressed by a rapid right nephrectomy. Rapid mobilization of the right kidney out of the Gerota fascia and medially also allows the surgeon to gain access to the lateral and posterior aspect of the pararenal IVC.

Exsanguinating hemorrhage into the lesser sac is most often due to an injury to the peripancreatic portal vein and is almost always associated with a penetrating injury to the neck of the pancreas. Effective circular compression as described above will dramatically reduce the bleeding, allowing the surgeon to perform a Kocher maneuver and widely open the lesser sac (Fig. 103.2).

One of the authors (A.H.) always performs a Cattell-Braasch maneuver in these situations to gain maximal exposure of the infrarenal retroperitoneum. Careful dissection along the inferior border of the mobilized duodenal loop is carried all the way to the point at which the SMV dives behind the pancreatic neck. The portal vein is then identified in the hepatoduodenal ligament along the upper border of the first portion of the duodenum. Bluntly developing the plane between the common bile duct and the portal vein from above allows the surgeon to pass a finger behind the pancreatic neck, divide it, and repair the portal vein directly from the front (Fig. 103.3). An early decision to transect the pancreas limits blood loss. A distal pancreatectomy is performed after the vascular repair, and the proximal stump is oversewn. In a damage-control situation, the SMV and the portal vein may be ligated (Sheldon, 1985); however, repair is preferable whenever possible, because massive bowel edema inevitably ensues that complicates fluid and wound management. The early fluid requirements during the first 24 hours after ligation of the SMV or portal vein can exceed 20 L. A second-look laparotomy is mandatory approximately 24 hours after the original operation to assess bowel viability.

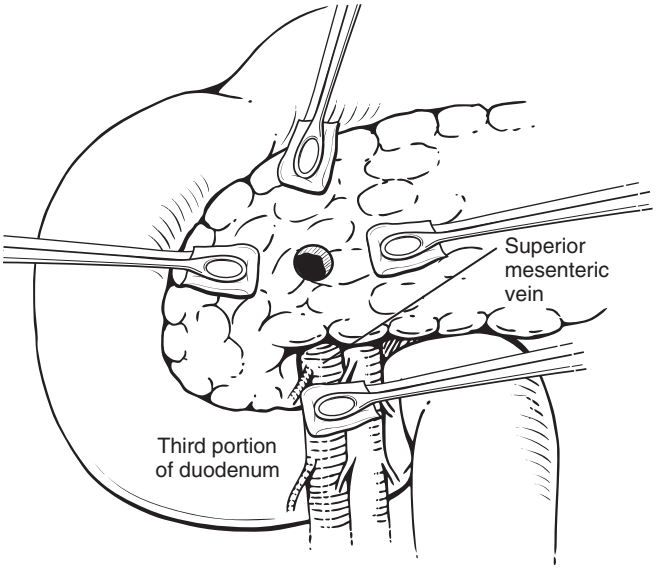

FIGURE 103.2. Sponge-stick control of bleeding from the portal vein. The white circles indicate areas of compression.

These vascular injuries usually occur in the context of multiple injuries to the PDC and adjacent structures. Damage-control solutions, rather than definitive repairs, are the rule in these situations, because the exsanguinating patient is racing toward a lethal physiologic insult. It is far better to stop the bleeding, close the holes in the bowel, and drain the entire area than to attempt a complex visceral reconstruction in an unstable, coagulopathic patient. Reconstruction of the anatomy can safely be done 36 to 48 hours after completion of resuscitation in the ICU.

Trauma Whipple

Complete disruption of the PDC, usually in association with major hemorrhage from the vena cava and/or portal vein, is the only indication for PD in trauma—the TW. A popular saying among trauma surgeons is that a PD is indicated only when the gunshot has done the dissection for you. The paradox of the TW is that the patients who need it are too unstable to tolerate it, and those who are stable enough to tolerate it probably do not need it (Hirshberg & Mattox, 2006). In the 1970s and 1980s, these operations were reported with enthusiasm and applauded as heroic achievements. Unfortunately, patients rarely survived the combined insults of the external injury and the operative trauma. In the era of damage-control surgery, the TW is viewed as a weapon of last resort that is very rarely indicated. In fact, one of the authors (W.S.), during a career in trauma surgery spanning some 30 years, has never found himself in a situation in which a TW was necessary.

On the very rare occasions when a TW seems like the only possible solution, it is important to keep in mind several key

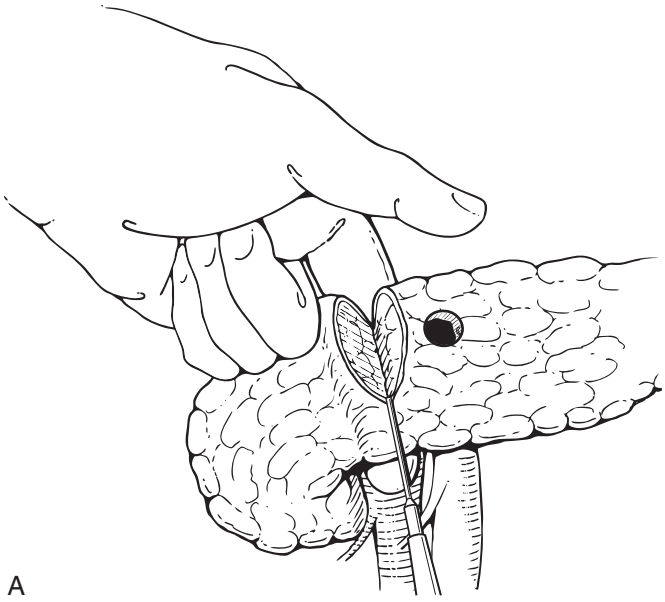

FIGURE 103.3. A, Division of pancreas to expose portal vein. **B,** Portal vein injury with distal pancreatectomy and splenic preservation.

technical differences from the elective oncologic operation. Most importantly, a TW should always be done as a staged procedure. Only resection and hemostasis are done during the original operation; reconstruction is performed 24 to 48 hours later on a stable, resuscitated patient.

During resection, early division of the stomach opens up the injured area behind it and facilitates access and exposure of the injuries. Preserving the gallbladder is important, because it is much safer to suture the bowel to the fundus of the gallbladder than to suture it to an edematous, friable, common bile duct of normal caliber; however, it is imperative to ensure that a low-entry cystic duct is not present and transected, thereby precluding decompression of the biliary tree with a cholecystoenterostomy. Time should not be wasted on meticulous dissection of the uncinate process off the SMV, because this is not an oncologic procedure. Instead, the uncinate process should be divided longitudinally parallel to the superior mesenteric vessels; its medial segment remains attached to the SMV and can be oversewn if necessary.

The staged reconstruction generally takes place in the inflamed and edematous peritoneal cavity of a patient who, albeit hemodynamically stable, is still critically ill with extensive third spacing and a massive systemic inflammatory response. If the bowel is edematous, and the peritoneal cavity is grossly inflamed, the distal pancreatic stump should be oversewn instead of creating a pancreatoenteric anastomosis. The soft, friable, edematous pancreas does not hold sutures well, and such a patient will not tolerate a leak.

CONCLUSION

Injuries to the pancreas and duodenum are uncommon. Most pancreatic injuries do not involve the pancreatic duct and can be managed by simple drainage. Ductal injuries to the body and tail of the pancreas should be treated by distal pancreatectomy. The emerging role of endoscopically placed stents in the treatment of pancreatic ductal injuries remains to be defined; however, isolated ductal injuries in the head of the pancreas are not an indication for a trauma Whipple, and these should be drained with or without ductal stenting.

Most injuries to the duodenum can be treated with simple closure. A preemptive pyloric exclusion should be considered in patients with PDC injuries at high-risk for a duodenal leak. Penetrating injuries to the medial wall of the second duodenum are best repaired from within the duodenum through an incision on the lateral duodenal wall. Complex injuries to the duodenum are best repaired with a Roux-en-Y duodenojejunostomy.

Major disruption of the PDC is very rare. Even a busy trauma surgeon can expect to see only a handful of these injuries in his or her career. In the overwhelming majority of cases, simple damage-control solutions are a much better option than heroic operations that involve long and elaborate resections; therefore, a TW should be considered only as a last, desperate resort.

CHAPTER 104

Aneurysm and arteriovenous fistula of the liver and pancreatic vasculature

Suzanne C. Schiffman and Robert C.G. Martin II

OVERVIEW

Traumatic injuries to the hepatic pedicle generally occur in conjunction with injuries to the liver or pancreas. Hemorrhage or hematoma at the porta hepatis can be indicative of injury to the hepatic artery, portal vein, or both. In blunt trauma, injury is often secondary to compression or shearing forces and disruption at the points of maximal fixation, where the porta hepatis is relatively fixed to the retroperitoneum. An isolated pedicle injury may occur with penetrating trauma, which may involve intrahepatic or extrahepatic vessels with disruption of any structure in the trajectory; see Chapters 102 and 103 for further discussion on traumatic injuries.

Vascular control can be attempted using the Pringle maneuver (1908) or by clamping the porta hepatis; this controls arterial and portal vein hemorrhage from the liver. Continuing hemorrhage is due to retrograde bleeding from the vena cava or hepatic veins. Kocherization of the duodenum and head of the pancreas by dividing the peritoneum along the lateral border of the duodenum allows for better exposure (see Chapter 63A). This maneuver is especially useful for distal pedicle injuries or those to the retropancreatic portion of the portal vein.

In cases of severe injury, hepatic arterial ligation can be used in the operating room or with the aid of angiography; this should be considered if the patient has a noticeable decrease in bleeding after the Pringle maneuver is performed. Complete selective hepatic arterial ligation is used in approximately 1% of patients (David et al, 2000). Disruption of the right or left hepatic artery may be treated by ligation, providing the ipsilateral portal vein is intact. Simple lacerations of the common hepatic artery may be repaired primarily, but blind placement of sutures should be avoided because of the proximity of the common bile duct and potential for iatrogenic injury. With vascular injuries to the pedicle, common bile duct injury should be suspected, and a cholangiogram should be performed. If right or common hepatic artery ligation is performed, or if injury to the common bile duct is evident, a cholecystectomy should be performed.

Injuries to the portal vein are difficult to manage because of profuse bleeding and the relative inaccessibility of the portal vein owing to its posterior position in the porta hepatis. These injuries are associated with a 50% to 70% mortality rate and carry a high risk of other vascular injuries (Asensio et al, 2007; Buckman et al, 2001; Coimbra et al, 2004; Fraga et al, 2009; Pearl et al, 2004). Shock or systolic blood pressure below 90 mm Hg is a significant predictor of survival, and 90% of injuries to the portal vein are caused by penetrating trauma; the most common location of injury is within the hepatoduodenal ligament. The three classifications of portal vein injuries are *type A*, less than 50% of vein circumference is disrupted; *type B*, disruption is greater than 50%; *type C*, complete transection is evident (Coimbra et al, 2004).

Patients with portal vein injuries are often hemodynamically unstable at presentation and require emergent exploration. Immediate control of portal vein bleeding is by the Pringle maneuver, and visualization is obtained by kocherization of the duodenum, followed by mobilization of the hepatic flexure and medial reflection of the right colon. Division of the gastroduodenal artery provides further exposure. In certain cases, the pancreatic neck may be divided, and the lower common bile duct and pancreas are reflected to the right to facilitate exposure of the retropancreatic portal vein. In most cases of retropancreatic portal vein injury, it is typical to find associated pancreatic injury that requires repair or resection.

Primary venorrhaphy is the preferred approach for repair of portal vein injuries in the stable patient (Fraga et al, 2009; Pearl et al, 2004). The hemodynamic status of the patient generally determines the complexity of the repair. Other alternatives are end-to-end anastomosis, portocaval shunt, graft interpostition, vein patch graft, and portal vein ligation (Coimbra et al, 2004; Fraga et al, 2009; Pearl et al, 2004; Stone et al, 1982). Portal vein ligation can be performed only if the hepatic artery is intact, and it is an appropriate damage control option in an unstable and coagulopathic patient. Portal vein ligation has been reported with a 50% to 80% survival rate and low incidences of subsequent portal hypertension (Coimbra et al, 2004; Stone et al, 1982). Following ligation of the portal vein or superior mesenteric vein (SMV), bowel will become edematous with areas of ischemia. Most surgeons would recommend temporary abdominal closure followed by a second-look laparotomy in 48 to 72 hours. Injury to both the hepatic artery and portal vein are rare and technically difficult to manage, and at least one of these structures must be repaired to avoid hepatic necrosis.

SMV injuries are uncommon but devastating; this is due to the difficulty in obtaining exposure and getting control of hemorrhage quickly. Primary venorrhaphy is the preferred repair, when such is possible; although ligation of the SMV has been performed with variable success, it should be reserved for use in the hemodynamically unstable patient (Asensio et al, 2000, 2007). It should also be noted that superior mesenteric venous injuries are often associated with portal vein and other vascular injuries (Asensio et al, 2007).

HEPATIC ARTERY ANEURYSMS AND PSEUDOANERYSMS

Visceral artery aneurysms are rare, with an average incidence of approximately 0.1% to 2% (Hossain et al, 2001; Panayiotopoulos et al, 1996). Splenic artery aneurysms account for approximately 60% of all visceral aneurysms, followed by hepatic artery aneurysms, which constitute 20% (Abbas et al, 2003). Hepatic artery aneurysms were initially described by Wilson in 1809 (O'Connor et al, 1995). The first successful surgical repair was performed by Kehr in 1903, in which he ligated the feeding vessel proximal to the hepatic artery (Carr et al, 1996; Guida & Moore, 1966). Within the past 2 decades, endovascular therapy has been utilized with increasing frequency, and O'Connor and colleagues reported successful endovascular stent exclusion of a hepatic artery aneurysm in 1995.

Hepatic artery aneurysms are more common in men, with a 2:1 prevalence (Abbas et al, 2003; Panayiotopoulos et al, 1996). The mean age of presentation is generally around 60 years of age, but hepatic artery aneurysms have been reported in all age groups (Abbas et al, 2003). The etiology of nontraumatic hepatic artery aneurysms remains unclear. True aneurysms undergo dilation and thinning of the vessel wall, although the blood is still contained within the vessel wall (Ikeda et al, 2008). A common histopathologic feature is medial degeneration of the arterial wall, which may be congenital but is further stressed by various factors (Abbas et al, 2003; Panayiotopoulos et al, 1996). Atherosclerosis is present in approximately 30% of aneurysms, but it is debatable whether it is a causative event or a secondary phenomenon (Messina & Shanley, 1997).

Several other conditions have been associated with hepatic artery aneurysms; these include arterial fibrodysplasia, vasculitis, polyarteritis nodosa, systemic lupus erythematous, tuberculosis, Marfan syndrome, Ehler-Danlos syndrome, arteritis, and hyperflow conditions (Abbas et al, 2003; Ikeda et al, 2008; Panayiotopoulos et al, 1996; Messina & Shanley, 1997). In the early twentieth century, most true hepatic artery aneurysms were mycotic, with bacterial endocarditis being the most common cause. With the advent of antibiotics, this form is generally only found in intravenous drug users (Shanley et al, 1996a).

Approximately 50% of all hepatic artery aneurysms are false aneurysms, or *pseudoaneurysms,* caused by a ruptured arterial wall with subsequent periarterial hematoma formation. These are generally the result of trauma, iatrogenic injury, inflammation, or infection (Carr et al, 1996; Guida & Moore, 1966). Pseudoaneurysms that result from iatrogenic injury to the hepatic arterial system are usually secondary to biliary, hepatic, or pancreatic interventions and to the laparoscopic or open treatment of abdominal and retroperitoneal pathologies (Bulut et al, 2002; Duce et al, 2002; Grego et al, 2003; Ikeda et al, 2008; Larson et al, 2002; Tessier et al, 2003; Tulsyan et al, 2007; see Chapters 28, 33, 34, and 54). Aneurysms resulting from laparoscopic cholecystectomy frequently affect the right hepatic artery but may be confined to the cystic artery remnant (Tessier et al, 2003). Pancreatitis and other inflammatory diseases can damage the arterial wall and lead to pseudoaneurysm formation (Mallick & Winslet, 2004). Additionally, hepatic artery pseudoaneurysm after resection of a hilar cholangiocarcinoma has been reported (Briceno et al, 2008).

Most hepatic artery aneurysms are solitary (80%), either saccular or fusiform, with a maximum diameter ranging from 1 to 14.5 cm (Abbas et al, 2003; Shanley et al, 1996). Other concomitant visceral artery aneurysms are present 31% of the time, and nonvisceral artery aneurysms are evident in 42% (Abbas et al, 2003). The majority, 66% to 80%, occur extrahepatically; however, the incidence of intrahepatic aneurysms may be increasing, compared with extrahepatic aneurysms (Abbas et al, 2003; Messina & Shanley, 1997). This change in presentation is likely the result of increasing use of percutaneous and laparoscopic interventions and also of improved imaging modalities utilized in the trauma setting (Kasirajan et al, 2001).

In one review of reported cases from 1985 to 1995, the right hepatic artery was found to be most commonly affected (47%), followed by the common hepatic artery (22%), the proper hepatic artery (16%), the left hepatic artery (13%), and rarely the cystic artery (1%) (Shanley et al, 1996). The natural history of these lesions is that of progressive growth, and it is probable that increasing size is accompanied by an increasing rate of rupture, in spite of a paucity of supporting evidence (Abbas et al, 2003). Nonatherosclerotic aneurysms carry a higher risk of rupture than atherosclerotic aneurysms (Abbas et al, 2003).

The lifetime risk of rupture for hepatic artery aneurysm ranges from 14% to 80% (Abbas et al, 2003; Carr et al, 2001; Dolapci et al, 2003; Ikeda et al, 2008; Lagana et al, 2006; Panayiotopoulos et al, 1996), and the mortality rate for ruptured hepatic artery aneurysms is 3% to 40% (Abbas et al, 2003; Ikeda et al, 2008; Panayiotopoulos et al, 1996; Shanley et al, 1996; Tessier et al, 2003). Rupture can occur into the peritoneal cavity (43%), biliary tree (41%), gastrointestinal (GI) tract (11%), or portal vein (5%) (Carr et al, 2001). Abdominal pain is often present, usually in the epigastrium with radiation to the back or right shoulder. Approximately 60% of patients with rupture come to medical attention in hypovolemic shock.

In 1871, Quincke described jaundice, hemobilia (see Chapter 105), and biliary colic in a patient with a hepatic artery aneurysm. These symptoms have become known as the *classic triad,* but in actuality, they are present in fewer than 40% of cases (Messina & Shanley, 1997). These symptoms are caused by erosion into the biliary tree, which causes intraductal clot or external compression of the bile duct (Messina & Shanley, 1997); rupture into the bile duct causes hemobilia. Occasionally, with a large hepatic artery aneurysm, a mass may be palpated in the upper abdomen, often with an associated bruit or thrill; however, pulsatile masses and bruits are uncommon in intact aneurysms. Expanding aneurysms can cause upper abdominal discomfort with pain radiating into the back, and pseudoaneurysms that result from placement of transhepatic biliary drainage catheters often manifest with a sentinel hemorrhage and blood in the collection bag.

With recent advances in cross-sectional imaging and arteriography, true hepatic artery aneurysms are being detected earlier in their course. Asymptomatic aneurysms (30% to 60%) may be discovered incidentally during radiologic investigation performed for other indications (O'Connor et al, 1995; Panayiotopoulos et al, 1996; Tulsyan et al, 2007). On plain radiographs, a hepatic artery aneurysm may appear as an eggshell-like calcification in the right upper quadrant (O'Driscoll et al, 1999). If this diagnosis is suspected, further investigation with contrast-enhanced computed tomography (CT) scan or magnetic resonance angiography is warranted to delineate the extent of the lesion and define its relationship to surrounding structures. Angiography (see Chapter 19) can be used to characterize hepatic artery blood flow

prior to operative treatment (Messina & Shanley, 1997), but ultrasound is rarely used to diagnose hepatic artery aneurysms. A hepatic artery aneurysm may be discovered during abdominal surgery for another indication and will appear as a calcified nodule on the hepatoduodenal ligament.

Improvements in the quality and availability of cross-sectional imaging (see Chapters 16 and 17) have led to an increasing number of aneurysms being detected prior to rupture. Although it is unclear whether the actual incidence of true hepatic artery aneurysms is increasing, incidental discovery during imaging performed for unrelated reasons has increased. For example, the routine use of CT scan in trauma patients has led to increased detection of false aneurysms of the intrahepatic arterial branches (Messina & Shanley, 1997). Also, the increased use of diagnostic and therapeutic biliary interventions have contributed to the increasing incidence of false aneurysms (Messina & Shanley, 1997).

Recent studies demonstrate that a selective approach can be used to manage asymptomatic hepatic artery aneurysms. Currently, no consensus exists regarding size criteria for intervention, but many advocate that small (<2 cm) lesions can be safely observed (Abbas et al, 2003; Ikeda et al, 2008); however, surgical repair, ligation, or embolization should be considered for aneurysms larger than 2 cm in a patient who is a reasonable operative risk with a life expectancy greater than 2 years. In patients with marginal or poor health and aneurysms that measure 2 to 5 cm, careful observation may be warranted (Abbas et al, 2003). The presence of multiple aneurysms is a risk factor for rupture and warrants intervention. Likewise, it is generally recommended that all pseudoaneurysms should be treated, given the high risk of rupture that they pose.

Although some centers allow for a degree of permissive hypotension, the management of ruptured hepatic artery aneurysms consists of volume resuscitation and correction of coagulopathy followed by definitive treatment involving surgical repair, embolization, occlusion, or endovascular stenting (Carr et al, 2001). Occasionally, angiographic intervention may be used as an adjunct prior to repair. In the elective setting, the choice of open surgical repair versus endovascular treatment depends on many factors, including the size and anatomy of the aneurysm, the shape of the sac and its accessibility to endovascular device placement or embolization, the need to restore arterial continuity, and the general health of the patient. A past failure of endovascular intervention does not necessarily preclude further attempts.

Open repair of hepatic artery aneurysms depends on the anatomy and location of the aneurysm, collateral blood flow, operative risk, and clinical status. In the elective setting, the anatomy of the aneurysm, delineation of arterial circulation, and identification of collateral vessels in the port hepatic are ideally determined preoperatively by angiography. In general, aneurysms of the common hepatic artery may be ligated, with or without resection of the aneurysm sac, as long as the portal vein is patent. Reconstruction is usually unnecessary secondary to collateral circulation via the gastroduodenal and right gastric arteries. Failure to confirm adequate collateral vessel circulation can lead to hepatic necrosis (Rokke et al, 1997).

If the patient has underlying hepatic parenchymal disease or is in a state of hemorrhagic shock, reconstruction is recommended, because the liver will be more sensitive to ischemia (Messina & Shanley, 1997; Shanley et al, 1996). Arterial reconstruction is recommended for aneurysms of the proper hepatic artery and its extrahepatic branches, because ligation may interfere with collateral circulation and may induce ischemic necrosis. Autogenous vein grafts, synthetic grafts, aneurysmorraphy with vein patch closure, and aortohepatic bypass have been utilized to restore blood flow. Aortohepatic bypass with saphenous vein or polytetrafluoroethylene (PTFE) graft that originates at the supraceliac aorta is generally preferred when bypass is required.

Intrahepatic aneurysms usually require ligation of the branch hepatic arteries and may require liver resection. Simple ligation of proximal vessels can help control bleeding intrahepatic aneurysms and may be a safer alternative to resection in critically ill patients, despite the risk of necrosis. In all hepatic aneurysms, vascular control can be gained from within the aneurysm, if surrounding inflammation prevents adequate exposure and dissection of adjacent arteries (Messina & Shanley, 1997). Complications after surgical repair are generally related to ischemic necrosis of the liver, abscess formation, and sepsis (Abbas et al, 2003).

Endovascular management of hepatic artery aneurysms has become increasingly popular over the past decade and is particularly useful for treating pseudoaneurysms that arise from iatrogenic injuries (Figs. 104.1 and 104.2). These procedures offer an alternative to conventional open surgical intervention with the benefit of lower morbidity and mortality (Ikeda et al, 2008; Larson et al, 2002; Saltzberg et al, 2005; Tulsyan et al, 2007). Recent studies found rates of technical success from 75% to 98% (Kasirajan et al, 2001; Mallick & Winslet, 2004; Sachdev et al, 2006).

Various minimally invasive techniques are available to treat aneurysms and pseudoaneurysms. Selective catheterization of the involved vessel and embolization with coils or polymerizing agents has been used for ablation of hepatic artery aneurysms, and percutaneous embolization is being used with increasing frequency in cases of emergent aneurysm rupture (Tulsyan et al, 2007). Endovascular stent grafts allow for preservation of end-organ flow and exclusion of the aneurysm. The arterial anatomy and the location of the aneurysm have a significant impact on the technical ability to place a stent graft (Larson et al, 2002); sufficient normal caliber artery must be available on either side of the aneurysm to allow for a proper stent graft seal and aneurysm exclusion, although further studies are needed to elucidate the long-term durability of stents.

The tortuosity and redundancy of the visceral vessels can increase the difficulty of endovascular interventions. Migration of embolic material and stent graft occlusion are recognized complications of transcatheter treatment. Additional complications include endoleak, failure to completely occlude the aneurysm, hepatic ischemia, and recanalization (Abbas et al, 2003; Kasirajan et al, 2001).

HEPATIC ARTERIOVENOUS FISTULAE AND SHUNTS

Congenital Hepatic Vascular Shunts

The vascular system begins to form during the third week of gestation as a network of interlacing blood spaces in primitive mesenchyme. The system gradually develops by processes of vascular coalescence and cellular differentiation that culminates in separate arterial and venous conduits. Congenital intrahepatic shunts are very rare anomalies characterized by abnormal

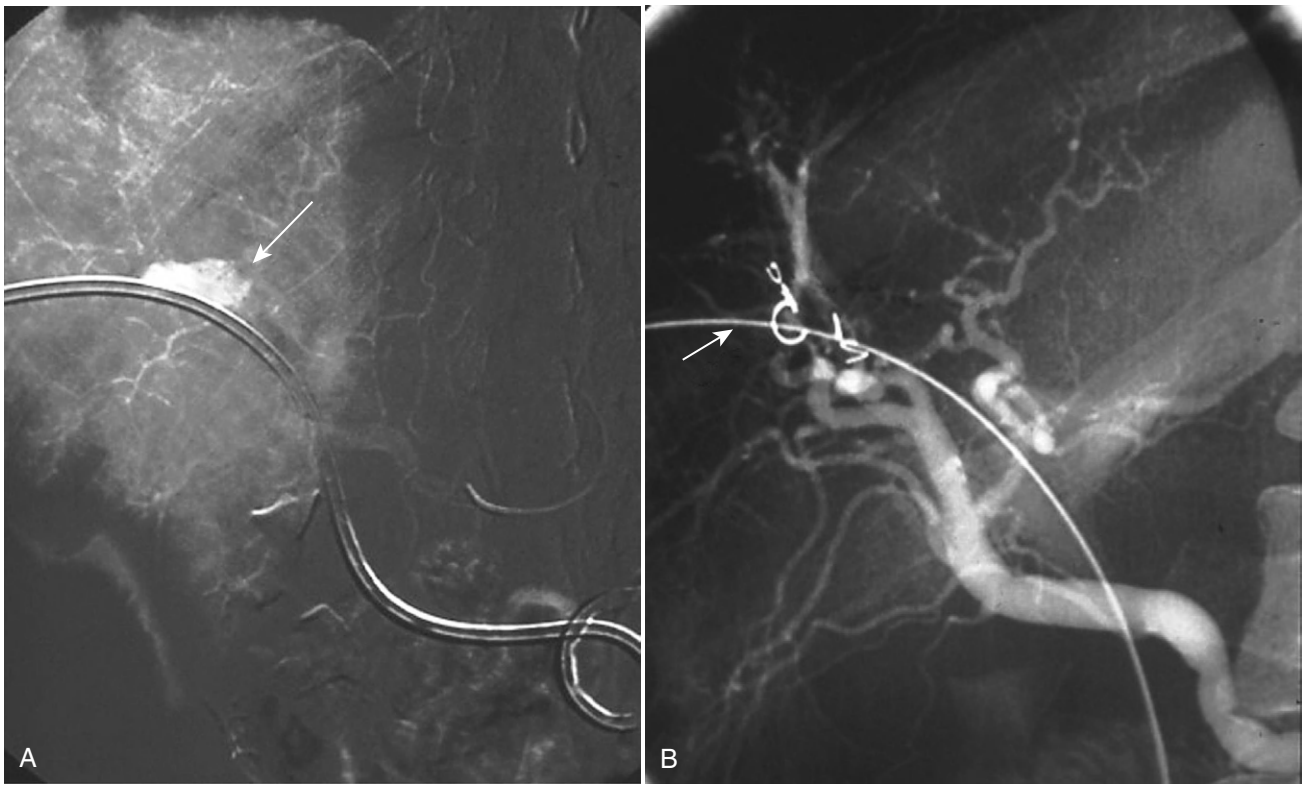

FIGURE 104.1. Hepatic pseudoaneurysm. **A,** After percutaneous biliary stent insertion (*arrow*). **B,** Managed by embolization (*arrow*).

communication between the hepatic arterial system, portal veins, hepatic veins, or systemic veins as a result of disordered embryologic development around the fifth gestational week. Normal development of the hepatic vascular system commences with anastomosis of the paired vitelline veins, as they enter the *septum transversum* and intersperse with rapidly proliferating hepatocytes. The left vitelline vein involutes, and the blood is redistributed to the right vitelline vein, which enlarges and forms the terminal inferior vena cava, hepatic veins, and portal vein.

The paired umbilical veins bring oxygenated blood to the embryo and course on either side of the liver. When they contact the hepatic sinusoids, the right umbilical vein and portions of the left umbilical vein become obliterated; the persistent left umbilical vein carries blood from the placenta to the fetus. A large channel, the *ductus venosus,* connects the left umbilical

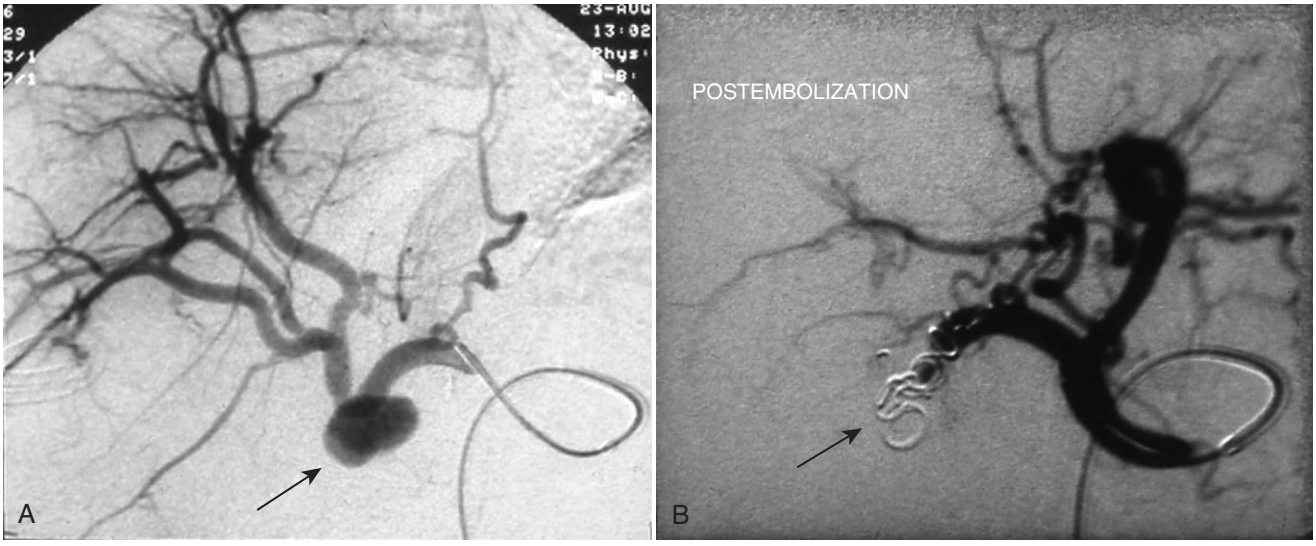

FIGURE 104.2. Pseudoaneurysm of hepatic pseudoaneurysm. **A,** Artery after laproscopic cholecystectomy (*arrow*). **B,** Managed by embolization (*arrow*).

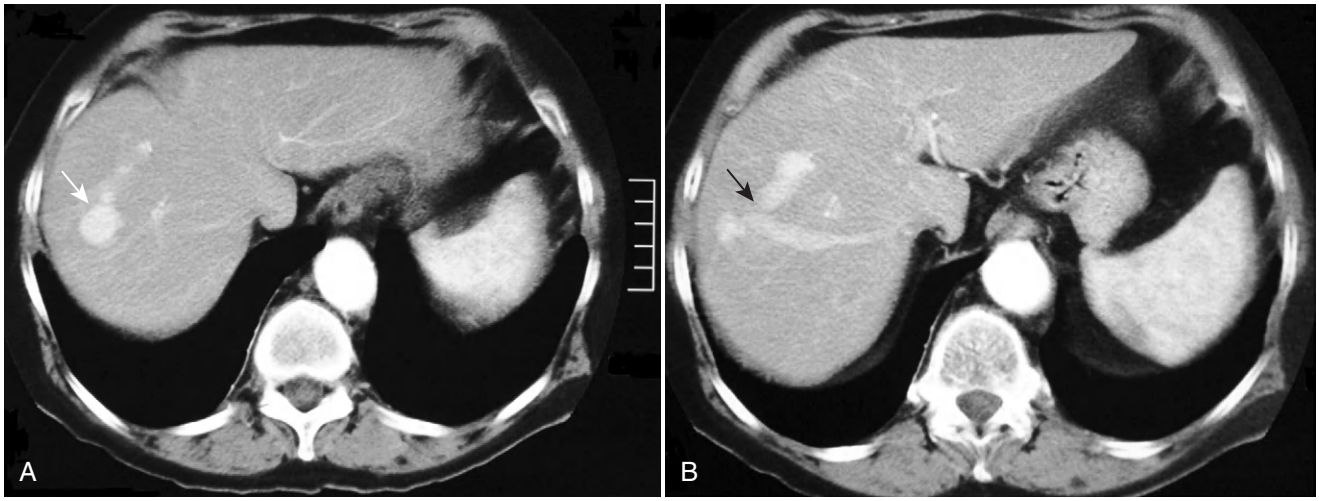

FIGURE 104.3. **A,** Contrast-enhanced computed tomography scan shows an aneurysmal fistula (*arrow*). **B,** Fistula between the right portal vein and right hepatic vein (*arrow*).

vein to the inferior vena cava to allow oxygenated blood to bypass sinusoid circulation (Gallego et al, 2004). Any deviation from the normal vascular system's embryologic development can lead to abnormal fistulae and shunting (Fig. 104.3).

HEMANGIOMAS

Some congenital hepatic neoplasms can cause vascular shunting; these include hemangiomas, hepatoblastomas, angiosarcomas, hamartomas, and metastatic neuroblastomas (Burrows et al, 2001; Gallego et al, 2004; Ingram et al, 2000). Infantile hemangiomas are a group of benign vascular tumors with a high rate of endothelial cell proliferation that results in a large mass and dilation of vascular channels, which are often accompanied by arteriovenous (AV) shunting. Following rapid growth, these tumors typically undergo a period of involution and increasing fibrosis (Boon et al, 1996). They are more common in females and may be solitary or multiple. Many small, asymptomatic hemangiomas remain undetected or are discovered on imaging indicated for another reason. Symptomatic presentation may include high-output congestive heart failure, hepatomegaly, anemia, thrombocytopenia, respiratory distress, hemorrhage, jaundice, and hypothyroidism secondary to overproduction of type III iodothyronine deiodinase (Boon et al, 1996; Burrows et al, 2001; Christison-Lagay et al, 2007; Ho et al, 2005; Huang et al, 2000; Konrad et al, 2003; Prokurat et al, 2002; see also Kasabach-Merritt syndromein Chapter 80A). Association with cutaneous hemangiomas and hemangiomatosis of the central nervous system, GI tract, and respiratory tract have been observed (Christison-Lagay et al, 2007). All patients with significant multifocal or diffuse disease should be screened with thyroid function tests and echocardiogram (Dickie et al, 2009).

Magnetic resonance imaging (MRI) is the diagnostic modality of choice for hemangiomas; lesions appear as hypointense relative to liver on T1-weighted images and hyperintense on T2-weighted images (Christison-Lagay et al, 2007; Gallego et al, 2004; see Chapters 17 and 79A). A gadolinium sequence typically demonstrates centripetal enhancement, and multiple flow voids can be present adjacent to or within the lesions (Gallego et al, 2004; Fig. 104.4). Selective arteriography can be used to determine the extent of the lesion and to evaluate the large vessels feeding the tumor, but this is rarely necessary (Stocker, 2001).

Hepatic hemangiomas should be individually assessed based on initial presentation, size, and disease progression (Dickie et al, 2009). Asymptomatic patients without evidence of cardiac failure or significant shunting can be monitored with ultrasonography to assess for change (Christison-Lagay et al, 2007; Isaacs, 2007), and solitary tumors can often be successfully treated by resection (von Schweinitz, 2003). Large, multiple, and diffuse lesions are associated with significant morbidity and mortality; for these, treatment options include medical management, surgery, embolization, radiation, or transplantation (Dickie et al, 2009).

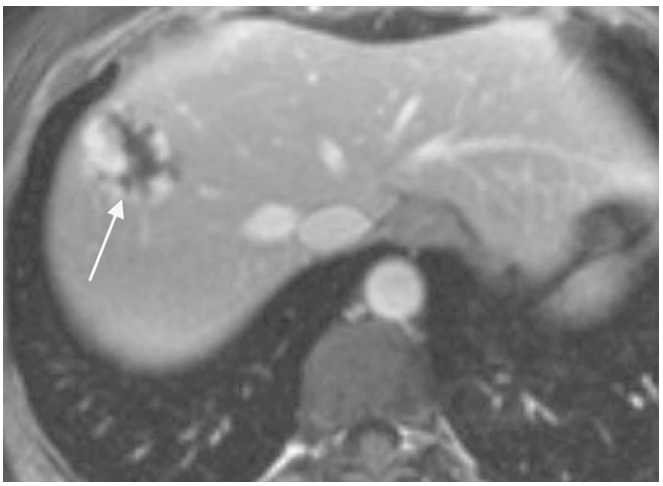

FIGURE 104.4. Axial portal venous phase of contrast-enhanced T1-weighted magnetic resonance imaging shows a hepatic hemangioma with the typical findings of early peripheral nodular enhancement and progressive centripetal filling. *(From Elsayes KM, et al, 2005: Focal hepatic lesions: diagnostic value of enhancement pattern approach with contrast-enhanced 3D gradient-echo MR imaging. Radiographics 25:1299-1320.)*

The mortality of large multiple hemangiomas treated with supportive observation has been reported to range from 30% to 80% (Boon et al, 1996; Gallego et al, 2004;). Patients with significant shunting are initially treated with corticosteroids or interferon (IFN)-α with close observation by ultrasonography for spontaneous regression (Deb et al, 2002; von Schweinitz, 2003). Pharmacotherapy failure is an indication for angiographic embolization, but the presence of multiple collaterals can make embolization difficult. When embolizing tumors with a large portal venous component, the portal vein should be done prior to the hepatic arterial component to prevent hepatic necrosis (Burrows et al, 2001). In patients with large hemodynamically significant shunts and cardiac failure, consider early angiographic intervention or ligation. Embolization can be used for interim control of congestive heart failure during pharmacotherapy or prior to operative intervention. Patients with diffuse intrahepatic hemangiomas often respond poorly to pharmacotherapy or other interventions and may require transplantation (see Chapter 97A; Christison-Lagay et al, 2007).

HEPATIC ARTERIOVENOUS MALFORMATIONS

True congenital arteriovenous malformations (AVMs) are malformations of the vascular channels and are classified by the predominant endothelium lining the channel and also by flow characteristics (Lima et al, 2005). Blood is shunted through direct arteriovenous connections that have no growth potential and that do not regress spontaneously. They are generally localized to one lobe of the liver (Boon et al, 1996; Gallego et al, 2004; Prokurat et al, 2002) and are usually present in neonates with congestive heart failure, portal hypertension, hepatomegaly, and anemia (Boon et al, 1996). Cardiac failure is noted in 50% to 60% of affected newborns with an associated 50% to 90% mortality rate (Boon et al, 1996; Luks et al, 1991). AVMs can also come to medical attention in late childhood in the clinical setting of hereditary telangiectasia with heart failure, portal hypertension, and hepatic ischemia (Boon et al, 1996; Burrows et al, 2001).

Duplex ultrasound (see Chapter 13) may show a nest of tortuous, dilated vessels with increased venous pulsatility and high peak Doppler shifts in both arteries and veins (Gallego et al, 2004). Contrast-enhanced CT scan shows homogeneous enhancement in the arterial or early portal venous phase with rapid washout of contrast material. MRI shows intrahepatic AVMs as large flow voids and localized masses that are hyperintense on T1-weighted images (Boon et al, 1996). MRI is a useful tool for differentiating AVMs from infantile hemangiomas, because AVMs will show an absence of delayed uptake of contrast material around the hypertrophic vessels (Gallego et al, 2004). Arteriography shows anomalous blood supply and arteriovenous shunting within the vasculature and can help delineate anatomy and resectability criteria.

Many different therapies have been used in the treatment of hemangiomas, including corticosteroids, radiotherapy, embolization, hepatic artery ligation, and hepatic lobectomy (Boon et al, 1996; Gallego et al, 2004; Lima et al, 2005). Superselective catheterization and embolization (see Chapter 28) with total occlusion of the feeding arteries close to the AVM must be achieved for effective treatment (Lima et al, 2005). Some studies advocate embolization with subsequent hepatic resection (Boon et al, 1996), but complications include incomplete occlusion, rapid development of collateral vessels, and necrosis. Liver transplantation is indicated for very large or diffuse lesions.

CONGENITAL ARTERIOPORTAL FISTULAE

Arterioportal fistulae are characterized by anomalous communication between the arteries and the portal venous system. Congenital arterioportal fistulae are discovered during infancy by portal hypertension, as compared with congestive heart failure with AVMs. Rarely, these fistulae are associated with hereditary telangiectasia, Ehler-Danlos syndrome, and biliary atresia (Burrows et al, 2001; Gallego et al, 2004). Age of presentation varies, but infants with congenital arterioportal fistulae generally come to medical attention within the first year of life. Hepatofugal flow in the portal vein causes arterialization of the portal vein and resultant portal hypertension, which can cause subsequent splenomegaly, gastroesophageal varices, ascites, diarrhea, and intestinal malabsorption (Gallego et al, 2004).

Doppler ultrasound shows arterialization of the portal vein, turbulent flow at the site of the fistula, increased peak velocities, and heterogeneous hepatic parenchyma secondary to vibration artifact (Gallego et al, 2004; Marrone et al, 2006). An enlarged hepatic artery and dilated portal vein segment at the fistula site may also be visible (Gallego et al, 2004). Contrast enhancement of the portal vein on arterial phase images and perfusion anomalies of adjacent hepatic parenchyma are demonstrated by CT scan and MRI (Fig. 104.5; Gallego et al, 2002).

Arteriography with embolization is the preferred therapeutic option, and it should be performed soon after diagnosis to minimize hepatoportal sclerosis and portal radicle fibrosis secondary to progressive portal hypertension (Altuntas et al, 1998). If angiography is unsuccessful, surgical ligation of the arterial feeding vessels may be performed with or without liver resection. Resection of the fistula proper is not necessarily required, although fistulae may recur through arterial collateralization, and patients must be followed closely after intervention. In infants with biliary atresia, liver viability usually depends on arterial inflow, and embolization may precipitate liver ischemia. Liver transplantation is preferred in this subset of patients (Choi et al, 2002).

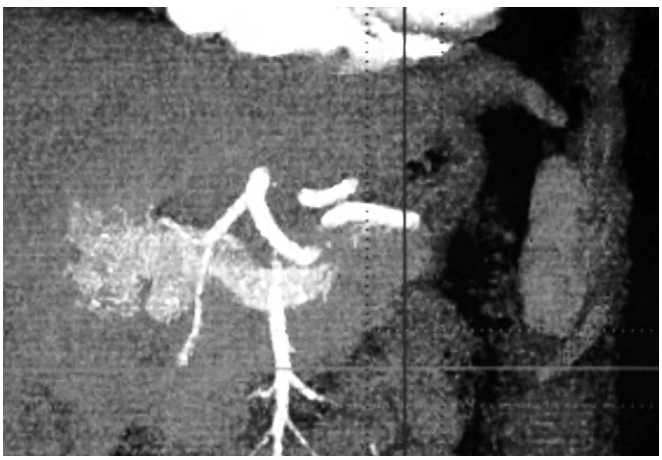

FIGURE 104.5. Multislice computed tomographic scan with intravenous contrast administration shows arterioportal fistula with retrograde filling of the portal vein.

ACQUIRED ARTERIOPORTAL FISTULAE

The most common causes of acquired arterioportal fistulae are cirrhosis, trauma, iatrogenic trauma stemming from hepatic or biliary intervention, hepatic neoplasms, inflammation, and gastrectomy (Gallego et al, 2004; Marrone et al, 2006; Tomczak et al, 1997). Acquired arterioportal fistulae often present with bleeding from an upper GI source secondary to mucosal congestion, and upper endoscopy shows friable and edematous mucosa. The diagnosis is often missed because patients generally enter a quiescent phase, as collateral circulation forms over the next 6 months to 5 years. As with congenital fistulae, portal hypertension develops and causes GI bleeding and varix formation, splenomegaly, ascites, and intestinal dysfunction (see Chapters 70A and 71; Blumgart & Fong, 2000).

When blood flow through the portal vein is decreased, the hepatic arterial flow increases, causing an arterioportal shunt through multiple anatomic routes (Choi et al, 2002; Park et al, 1990). In localized portal vein obstruction—such as from tumor thrombus or external compression—blood flows from the hepatic artery through the communicating *vaso vasorum* into distal unobstructed portal vein. In hypervascular tumors, arterial blood may flow directly through the tumor into the portal vein. In patients with increased hepatic vein resistance secondary to Budd-Chiari syndrome or cirrhosis, arterial blood fills the portal vein by retrograde flow through the sinusoids (see Fig. 104.5). In cases of complete obstruction of the portal vein, a peribiliary vascular plexus develops along the intrahepatic and extrahepatic biliary tree.

Contrast enhancement of the portal vein on arterial phase images and perfusion anomalies of adjacent hepatic parenchyma are demonstrated by CT scan and MRI (Gallego et al, 2002). As with congenital arterioportal shunts, treatment options include embolization, surgical correction, and transplantation. Fistulae may recur through arterial collateralization, and patients need to be followed closely after intervention.

PORTOSYSTEMIC VENOUS SHUNTS

Portosystemic shunts can be intrahepatic or extrahepatic; congenital shunts are the apparent result of disruption of the complex embryologic process of vitelline, umbilical, and hepatoportal venous involution. In 1793, Abernethy first reported an extrahepatic portosystemic shunt. Two types of extrahepatic portosystemic shunts are found: in *type I,* the portal vein is congenitally absent, and portal blood flow is completely diverted into the vena cava; in *type II,* a side-to-side extrahepatic communication exists between the vena cava and portal vein, through which some of the portal flow is diverted to the vena cava (Gallego et al, 2004). These shunts have been observed alone or in combination with other congenital malformations, including biliary atresia (see Chapter 40), genitourinary malformations, mental retardation, and as a part of Goldenhar syndrome (Gallego et al, 2004). Hepatic tumors may also be associated with systemic diversion of portal blood flow.

Congenital intrahepatic portosystemic shunts are abnormal connections between branches of the portal vein and hepatic veins thought to be due to persistent communication between the vitelline veins of the omphalomesenteric system and the *sinus venosus* (Lane et al, 2000). Infantile hepatic hemangiomas and cutaneous hemangiomas have been associated with these shunts (Gitzelmann et al, 1997). Intrahepatic shunts are classified into four types: 1) a single, large tube that connects the right portal vein to the inferior vena cava, 2) one or more communications present in a single hepatic segment, 3) portosystemic shunt through an aneurysm, and 4) multiple communications between portal and hepatic veins (Park et al, 1990).

Doppler ultrasound may demonstrate abnormal communicating structures between the portal venous branches and hepatic veins and may also reveal an absence of portal vein at the liver hilum. A pulsatile triphasic or biphasic spectral pattern in the portal or splenic veins suggests the presence of a portosystemic shunt (Gallego et al, 2004), the ratio of which can be determined by portal scintigraphy using iodine 123 iodoamphetamine. The isotope is administered rectally, is absorbed into the inferior mesenteric vein, and travels to the liver. When a shunt is present, the isotope can be detected in the liver and lungs simultaneously, and the ratio is determined by dividing the lung counts by the liver counts (Gallego et al, 2004).

Portosystemic venous shunting causes elevated levels of galactose, bile acid, glucose, and ammonia (Gallego et al, 2004). The clinical manifestations may include cataract formation (hypergalactosemia), encephalopathy, liver dysfunction secondary to lack of hepatocyte nutrition, and GI dysfunction. Adults are more susceptible to hepatic encephalopathy than young children. Reduced portal inflow causes liver dysfunction, fatty degeneration, and atrophy as a result of lack of nutrition, but liver function can be improved with restoration of portal blood flow.

Intrahepatic shunts generally close within the first 2 years of life, thus observation is sufficient in asymptomatic infants. With mild metabolic abnormalities, a protein-free diet supplemented with branched-chain amino acids, and lactulose is recommended. In all patients, shunt ratios greater than 60% require correction by embolization or surgical interruption (Gallego et al, 2004). If these interventions fail, hepatic transplantation is often necessary.

AQUIRED HEPATIC VASCULAR FISTULAE

Hepatic neoplasms, cirrhosis, and trauma are the most common causes of acquired fistulae of the hepatic vasculature. Additionally, iatrogenic injury from procedures such as endoscopic retrograde cholangiopancreatography (ERCP), liver biopsy, and chemoembolization and hepatic, biliary, or gastric surgery can precipitate fistula formation.

GASTRODUODENAL AND PANCREATODUODENAL ARTERY ANEURYSMS

Since 1895, when Ferguson first described a superior pancreatoduodenal artery (PDA) aneurysm, few studies have addressed the management and natural history of these lesions (Moore et al, 2004). True aneurysms of the PDA and the gastroduodenal artery (GDA) are rare and account for 2% and 1.5% of all splanchnic artery aneurysms, respectively (Shanley et al, 1996). Pseudoaneurysms are more common and are generally seen in the setting of inflammation, specifically pancreatitis (see Chapter 54). It is important to distinguish between true and false aneurysms, because the implications for diagnosis and management will be different.

A review of all reported PDA and GDA aneurysms between the years 1946 and 2001 identified approximately 146 cases

(Moore et al, 2004). The mean age at presentation was 58 years (range, 20 to 72 years), with an equal distribution across ethnic groups and an equal male/female gender distribution; however, past studies have demonstrated a male predominance, which might be explained by a lack of distinction between true and false aneurysms (Moore et al, 2004; Shanley et al, 1996).

Approximately 50% of true PDA aneurysms are associated with celiac stenosis or occlusion (Moore et al, 2004), and aneurysms have also been described with common hepatic artery stenosis or occlusion (Bracale et al, 1996). Sutton first described the association of PDA aneurysms with celiac artery occlusion or stenosis in 1973 (Sutton & Lawton, 1973). Celiac artery entrapment by the median arcuate ligament can cause increased blood flow through collateral vessels and may be an etiologic factor (de Perrot et al, 1999b). Hyperdynamic flow and retrograde flow through the pancreatic collateral vessels leads to arterial hypertension and subsequent weakening of the arterial wall (Kalva et al, 2007). Other possible etiologies include degenerative disease of the arterial wall, fibromuscular dysplasia, Takayasu disease, and polyarteritis nodosa. In addition, the presence of a second aneurysm in a remote location—such as in the cerebral vasculature, found in 18% of GDA aneurysms and 24% of PDA aneurysms—suggests a systemic factor contributes to aneurysm formation (Moore et al, 2004). Medial arterial wall degeneration and atherosclerosis are present on pathologic examination.

The majority of patients with GDA or PDA aneurysms are symptomatic at the time of presentation. Epigastric pain with radiation to the back is common in the majority of symptomatic patients, and about 6% are seen initially for a palpable abdominal mass (Moore et al, 2004). Nonruptured aneurysms may also manifest with GI bleeding, occasional jaundice, and nonspecific GI symptoms (Shanley et al, 1996). Approximately 38% to 62% of PDA aneurysms and 35% to 56% of GDA aneurysms are brought to medical attention by rupture, which is associated with a mortality rate that ranges from 21% to 50% (Chiesa et al, 2005; Ikeda et al, 2008; Moore et al, 2004; Saltzberg et al, 2005; Sessa et al, 2004). About 20% of PDA aneurysms have the potential to rupture into the bowel and cause hematemesis, melena, and other signs of GI hemorrhage. Approximately 50% of GDA aneurysms will erode into the duodenum and cause GI bleeding. Aneurysms may also erode into adjacent vessels, organs, the bile duct (*hemobilia;* see Chapter 105), and the pancreatic duct (Ikeda et al, 2008). Aneurysms rupture into the intestinal tract and peritoneal cavity with equal frequency.

Ruptured aneurysms are treated with volume resuscitation, CT scan and angiography, and endovascular treatment or laparotomy, depending on the hemodynamic status of the patient. Nonruptured aneurysms should be treated aggressively, because they pose a high risk of subsequent rupture, and the risk is not necessarily related to the size of the aneurysm (Bageacu et al, 2006; Carr et al, 2001; Messina & Shanley, 1997; Moore et al, 2004; Takao et al, 2010).

In general, PDA aneurysms are more difficult to manage operatively than GDA aneurysms, because they are located deep within the parenchyma of the pancreas, and exposure may be difficult. Intraoperative duplex scanning or arteriography may aid in diagnosis and delineation of these aneurysms (Moore et al, 2004). Hemostasis may be difficult to obtain secondary to the extensive collateralization of the peripancreatic vessels and anatomic distortion from a retroperitoneal hematoma, and pancreatoduodenectomy has occasionally been required (de Perrot et al, 1999). Suture ligation of afferent and efferent vessels from within the aneurysm sac may be useful for aneurysms embedded in the pancreas. GDA aneurysms are slightly more accessible after duodenal mobilization, although adherence to bowel and surrounding structures can increase the difficulty of the operation.

Endovascular treatment has been increasingly utilized in the management of visceral aneurysms over the past decade. Peripancreatic aneurysms are often difficult to identify and isolate operatively, and catheter-based techniques are emerging as the treatment of choice. Various methods have been employed for embolization: coils, gelatin, foam, cyanoacrylate glue, ethanol sclerosant, and balloons (Coll et al, 1998). Recently, more selective embolization has become possible with the advent of smaller catheters and wire-based techniques that decrease risk of visceral ischemia (Moore et al, 2004). Selective embolization uses selective catheterization of the superior mesenteric artery followed by subselective catheterization of the branches feeding the aneurysm sac. Ideally, both the inflow and outflow of the aneurysm should be embolized to prevent reperfusion. If the aneurysm sac cannot be occluded for technical reasons, the parent artery can be occluded with coils (Kalva et al, 2007). Percutaneous embolization under CT guidance has recently been described (Williams et al, 2006).

Most studies advocate celiac revascularization, in addition to aneurysm ligation or embolization, when the celiac axis is stenotic or occluded (Bageacu et al, 2006; Moore et al, 2004). Celiac revascularization can be accomplished with either an open bypass or transluminal endovascular intervention. Revascularization may be performed through angioplasty and stenting in cases of atherosclerotic narrowing or by surgically dividing the median arcuate ligament in patients with median arcuate ligament syndrome (Tien et al, 2004). In addition, a bypass graft between the celiac axis or hepatic artery and superior

FIGURE 104.6. Contrast-enhanced computed tomographic arteriogram demonstrates gastroduodenal artery aneurysm in a patient with chronic pancreatitis. *(From Nosher JL, et al, 2006: Visceral and renal artery aneurysms: a pictorial essay on endovascular therapy. Radiographics 26:1687-1704.)*

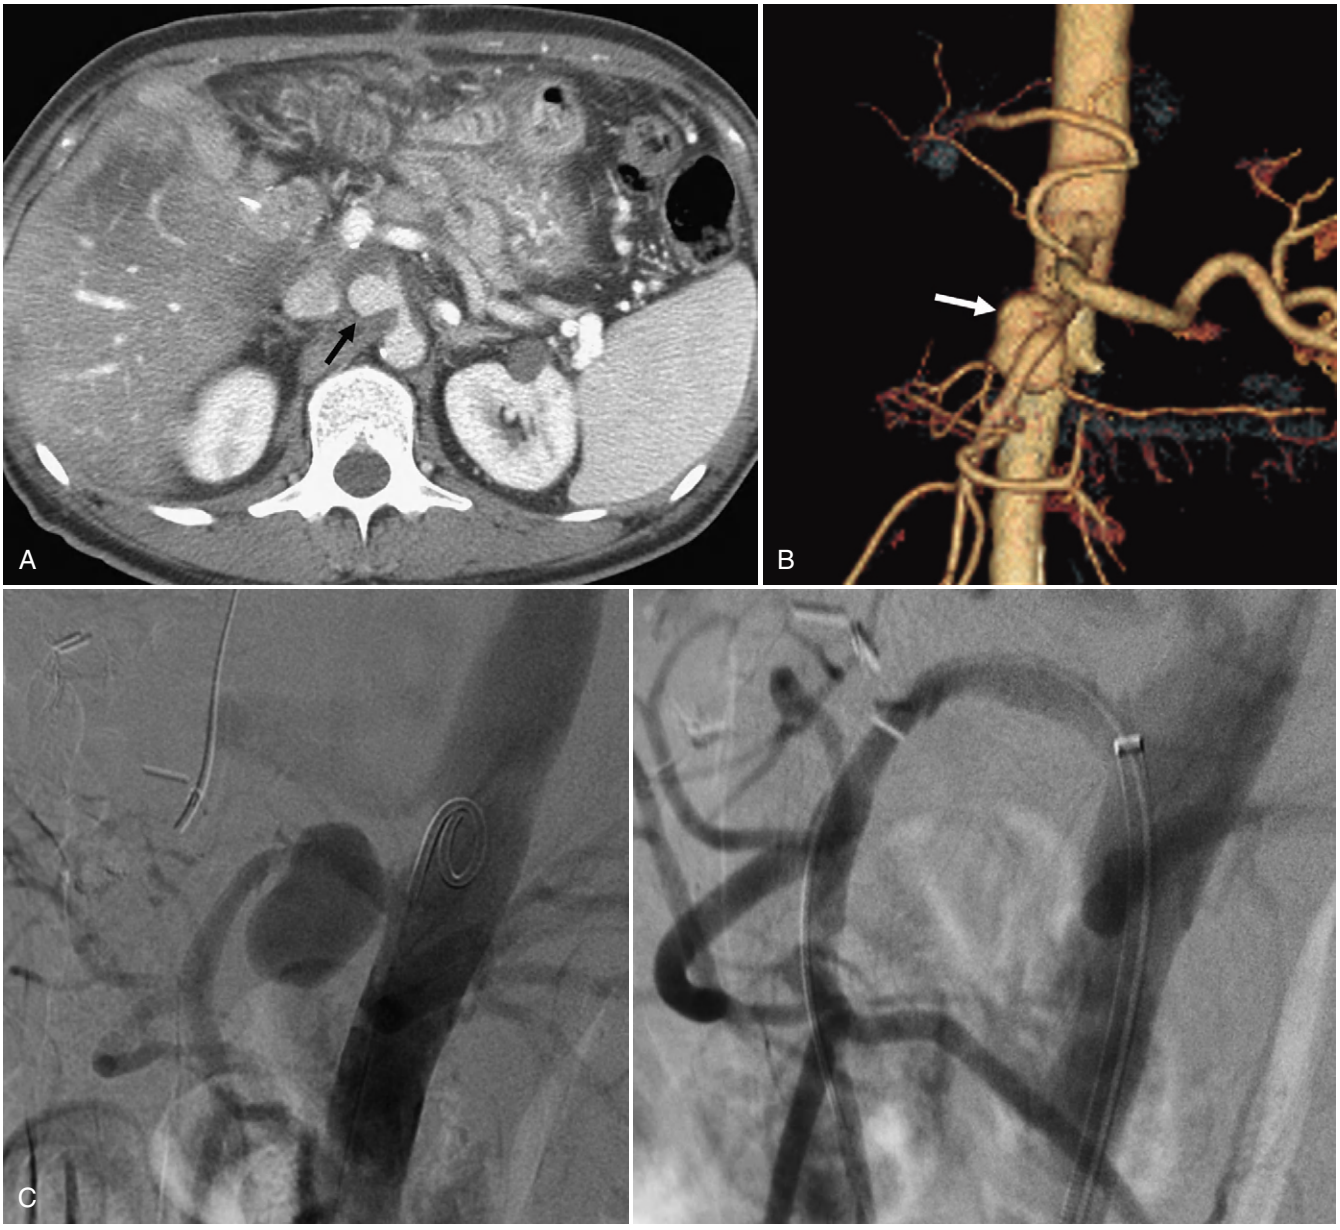

FIGURE 104.7. Pseudoaneurysm of the superior mesenteric artery in a patient with pancreatic cancer treated with chemoradiation therapy. **A,** Axial, contrast-enhanced computed tomographic angiogram. **B,** Three-dimensional reconstruction. **C,** Transfemoral visceral angiogram shows the pseudoaneurysm before (*left*) and after (*right*) placement of an endovascular stent. *(Courtesy Dr. Karen Brown, Department of Radiology, Memorial Sloan-Kettering Cancer Center.)*

mesenteric artery can be performed (Kalva et al, 2007). In nonruptured true aneurysms, it may be safer to restore celiac axis patency prior to aneurysm occlusion (de Perrot et al, 1999; Moore et al, 2004). Mesenteric ischemia and death following aneurysm occlusion in the absence of a patent celiac axis has been reported.

PSEUDOANEURYSMS

Most pseudoaneurysms that affect the peripancreatic and pancreatic vasculature are complications of pancreatitis (Fig. 104.6; see Chapter 54), but these may also result from treatment of pancreatic tumors (see Chapters 62 and 63). Pseudoaneurysms complicate 3% to 10% of acute pancreatitis cases and affect 10% to 17% of patients with chronic pancreatitis (de Perrot et al, 1999; Mallick & Winslet, 2004; Woods et al, 1995). The temporal relationship of pseudoaneurysm formation to pancreatitis is highly variable, and it is complicated by the fact that the presenting features of abdominal pain—tachycardia and hypotension—are also features of pancreatitis. A pseudoaneursym associated with chronic pancreatitis is often identified at the time of an acute exacerbation, and it remains unclear whether the pseudoaneurysm caused the exacerbation or was the result of a new episode of inflammation.

The likelihood of pancreatic pseudocyst appears to increase with the severity of the inflammation in acute pancreatitis (Flati et al, 2003). An expanding pseudocyst may erode into an adjacent vessel and form a pseudoaneurysmal pseudocyst as a result

of constant compression, ischemia, and elastolytic action (Flati et al, 2003; Shanley et al, 1996). Additionally, severe inflammation, infection, release of pancreatic enzymes, and necrosis may cause pseudoaneurysm formation and vessel erosion, which can precipitate subsequent rupture with resultant massive bleeding into the GI tract, retroperitoneum, and peritoneal cavity (Flati et al, 2003; Mallick & Winslet, 2004; Woods et al, 1995). Manipulation of friable tissue during necrosectomy may precipitate vascular damage as well. Periarterial inflammation, vascular necrosis, trauma, infection, vascular intervention, biliary intervention, and autoimmune disorders have also been identified as causative agents of pseudoaneurysms.

The splenic artery is the most frequently involved (40%), followed by the GDA (30%) (Mallick & Winslet, 2004). The size of the pseudoaneurysm is not predictive of rupture, which may occur into the abdomen, retroperitoneum, adjacent hollow organ, or blood vessel. The mortality associated with a ruptured pseudoaneurysm ranges from 7.5% to 80% (Burli et al, 2008; Flati et al, 2003), and symptoms include exacerbation of abdominal pain, hypotension, tachycardia, hematemesis, melena, or bleeding from surgical drains in patients who have recently undergone a pancreatic procedure.

The management of ruptured pseudoaneurysms of the peripancreatic vasculature and GDA is similar to that described for true aneurysms with resuscitation, CT scan, angiography, endovascular therapy, or open surgical therapy (Fig. 104.7). Immediate surgery is indicated if the patient is hemodynamically unstable. Conservative management is associated with a higher overall mortality rate (21% to 54%) than intervention (18% to 34%), therefore definitive treatment is recommended (Flati et al, 2003; Moore et al, 2004). Patients with angiographic evidence of bleeding can be treated with endovascular embolization or percutaneous thrombin injection into the aneurysm sac. Because of the extensive collateral circulation, it is imperative to occlude the artery proximal and distal to the lesion and to interrupt any collateral supply (Burli et al, 2008).

Timing of surgical intervention is critical, because open surgery during an acute episode of pancreatitis is potentially dangerous. Delaying surgery until after resolution of acute pancreatitis has fewer bleeding complications but increases the chance of rupture of a pseudoaneurysm. The optimal time for intervention is determined on a case-by-case basis.

PANCREATIC ARTERIOVENOUS MALFORMATIONS

AVM of the pancreas is a rare anomaly, first reported by Halpern in 1968 and described as a vascular mass lesion that arises via an aberrant bypass anastomosis of the arterial and venous systems in the pancreas (Halpern et al, 1968a, 1968b). Congenital pancreatic AVMs are more common (approximately 90%) and are likely a remnant of the fetal vascular network. One third of these cases are associated with Osler-Weber-Rendu syndrome (Chang et al, 2004), and acquired malformations are generally the result of trauma, tumor, infection, or inflammation, especially pancreatitis. Pancreatic AVMs have been reported in pancreatic allografts following transplantation (Barth et al, 2008).

AVMs typically come to medical attention in the fifth decade of life, but ages at presentation range from infancy to the seventh decade. Some studies note a male predominance (Takemoto et al, 2007). The most commonly involved vessels are the splenic artery (42%), GDA (22%), and small pancreatic arteries (22%; Rezende et al, 2003). Most patients are diagnosed based on presentation with complicating symptoms such as GI bleeding, portal hypertension, or pancreatitis. GI bleeding is present in 50% of patients and may be caused by rupture into the pancreatic duct, rupture of superficial vessels into the duodenum, duodenal erosion, hemobilia as a result of erosion into the bile duct (see Chapter 105), or bleeding AVMs at other sites within the GI tract (Aida et al, 2002). Pancreatic AVMs can cause portal hypertension, leading to esophageal varices, GI bleeding, and other related sequelae. Early diagnosis and intervention is warranted to prevent complications.

Angiography demonstrates an abnormal communication between the arterial and venous system with dilated feeding vessels, transient pancreatic staining, and early filling of the portal vein. Doppler ultrasound shows a mosaic pattern and abnormal blood flow and a pulsatile waveform in the portal vein (Koito et al, 2001). CT scan features include conglomeration of strong nodular stains and early enhancement of portal venous system in the arterial phase (Ogawa et al, 2009). MRI shows a circular lesion with signal void in T1- and T2-weighted images, consistent with rapid blood flow (Ogawa et al, 2009).

Angiographic embolization is the first-line treatment for pancreatic AVMs. The recurrence rate is 30% to 40% secondary to the development of multiple collateral vessels (Rezende et al, 2003). For large lesions confined to the head of the pancreas, surgical resection by pancreatoduodenectomy and total pancreatectomy has been performed. Some studies advocate embolization prior to operative intervention to potentially decrease intraoperative bleeding and postoperative morbidity and mortality (Iwashita et al, 2002; Rezende et al, 2003). Lesions localized to the tail of the pancreas can be treated by distal pancreatectomy.

CHAPTER 105

Hemobilia and bilhemia

Adam Yopp

OVERVIEW

Hemorrhage into the biliary tract occurs when disease or trauma produces an abnormal communication between blood vessels and bile ducts, termed *hemobilia* (Sandblom, 1948), from the Greek *haima* ("blood") and the Latin *bilis* ("bile"); the term *bilhemia* describes the rare condition of bile in the bloodstream. Causes of hemobilia include iatrogenic and accidental trauma, gallstones, inflammation, vascular disorders, and neoplasms. With the increasing use of invasive diagnostic and therapeutic procedures that involve the biliary tract, iatrogenic trauma has become the predominant etiology of hemobilia (see Chapters 28, 50D, 102, and 104).

Major, profuse hemobilia is a rare and sometimes life-threatening complication of liver or biliary tract disease or trauma. Minor hemobilia occurs more frequently but is rarely of long-lasting clinical significance. Although often difficult to recognize, hemobilia should be in the differential diagnosis of upper gastrointestinal (UGI) bleeding, especially in patients with a recent or remote history of liver trauma or biliary tree instrumentation (see Chapters 19, 28, 50D, and 102).

With the advent of interventional radiologic approaches, treatment of symptomatic hemobilia has shifted from surgical therapy to selective transcatheter hepatic arterial embolization (see Chapter 104). Surgical therapy via partial hepatectomy, hepatic artery ligation, or a combination of both procedures is rarely necessary and is reserved for hepatic arterial branches that cannot be safely or adequately embolized, for anatomic or technical reasons, or in patients who have large intrahepatic hematomas or sepsis.

HISTORY

Because of its obscure appearance and apparent rarity, hemorrhage into the biliary tract, although first described in the seventeenth century, was not called *hemobilia* until more recently. In the first detailed description of hepatic anatomy from 1654, Francis Glisson (Fig. 105.1) discussed the possibility of hemorrhage into the biliary tract when describing the case of a man who died from presumed GI hemorrhage following a stab wound to the liver suffered in a duel: "I believe that if the liver is injured by a contusion, it may lead to blood leaving the body by way of vomit or the stool for there is no doubt that the biliary tract takes unto itself (to the great good of the patient) some of the blood issuing into the liver and leads it down to the intestines. From there it is either impelled upwards through reverse peristalsis or downwards the normal way" (Glisson, 1654).

Over a century elapsed before the subject of hemorrhage into the biliary tract was brought up again. In Morgagni's Epistles (1765), the founder of clinical pathology noted, in the section on the causes of dilation of the biliary tract, that abscesses in the liver and the voiding of sharp gallstones could lead to bleeding through the biliary ducts (Morgagni, 1765). In 1777, Antoine Portal presented a case in which he made the diagnosis before the death of the patient and confirmed it at autopsy. In this early treatise, Portal drew attention to the difficulty of finding the source of hemorrhage in the biliary tract, "when they are slight in quantity and occur but seldom," and to the risk of mistakenly tracing them to a healthy organ, a mistake that has been made repeatedly in the history of hemobilia (Portal, 1813).

The first published case in North America was by a Boston surgeon who reported on the clinical and pathologic consequences of an "aneurysm of the hepatic artery bursting into the hepatic duct," the first direct observation of an abnormal communication between the blood vessels and biliary ducts (Jackson, 1834; see Chapter 104). In 1871, the German surgeon Quincke further characterized biliary tract hemorrhage by establishing three cardinal symptoms—GI hemorrhage, biliary colic, and jaundice—commonly referred to as *Quincke's triad* (Quincke, 1871). Hemobilia formerly was regarded as a medical curiosity, but it is now being diagnosed with increasing frequency, owing to more widespread knowledge of the syndrome and to improved diagnostic means (Sandblom, 1972).

ETIOLOGY

Common causes of abnormal vascular and biliary communication giving rise to hemobilia include trauma (accidental and iatrogenic), gallstones, neoplasms, inflammatory processes, and vascular disorders. Other less common causes include nematodes, blood coagulation defects, choledochal cysts, pancreatitis, and portal hypertension. Figure 105.2 illustrates the three largest reported case series of hemobilia and demonstrates a shift in etiology over the course of time from accidental to iatrogenic trauma. In one of the first publications devoted solely to hemobilia, Sandblom reported on 355 cases reported prior to 1972, with the largest number secondary to accidental trauma (Sandblom, 1972). Over the ensuing 30 years, iatrogenic trauma surpassed all other causes of hemobilia, and today it is responsible for the majority of cases (Green et al, 2001; Yoshida et al, 1987). The increase in hemobilia caused by iatrogenic trauma parallels the advent and increasing use of both diagnostic and therapeutic instrumentation of the biliary tract.

Iatrogenic Trauma

To an increasing extent, biliary hemorrhage is reported as a complication of diagnostic and therapeutic procedures on the liver or the bile ducts and is now responsible for the majority of reported cases of hemobilia (Fig. 105.3). The incidence of clinically significant hemobilia following percutaneous liver

FIGURE 105.1. Francis Glisson (1957–1677) gave the first account (1654) of hemorrhage into the biliary tract in his treatise *Anatomica Hepatis.*

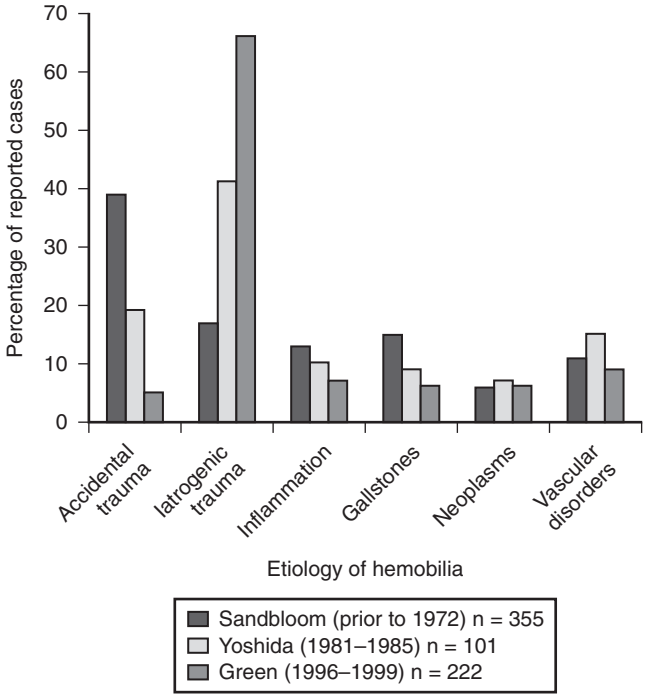

FIGURE 105.2. The distribution of 678 reported cases of hemobilia in the three largest case series. Over the course of 30 years, the predominant etiology of hemobilia changed from accidental trauma to iatrogenic trauma, presumably in parallel to the advent and increasing use of diagnostic and therapeutic manipulation of the biliary tree.

biopsy is between 0.01% and 0.2% (Piccinino et al, 1986; Seeff et al, 2010; see Chapter 20). Hemobilia arises secondary to unintentional laceration of a hepatic artery during the procedure and results in subsequent communication with the biliary tree (Fig. 105.4). Previous studies demonstrated that the risk of hemobilia following percutaneous liver biopsy may be greater in patients with chronic liver disease because of the presence of ascites, coagulopathy, and platelet dysfunction; the risk may also be higher following liver transplantation (Jabbour et al, 1995; Piccinino et al, 1986). In a recent study 2740 percutaneous liver biopsies were performed on patients with advanced chronic liver disease (cirrhosis), and it was determined that only an elevated international normalized ratio (INR) above 1.3 and a platelet count below 60,000 was associated with an increased risk of periprocedural hemobilia (Seeff et al, 2010).

Percutaneous transhepatic biliary drainage (PTBD) and percutaneous transhepatic cholangiography (PTC) are associated with a significantly higher rate of hemobilia than percutaneous liver biopsy because of the proximity of the hepatic vasculature to the biliary tree (Fig. 105.5; see Chapters 28 and 50D). In a series of 1397 patients undergoing PTBD or PTC, the incidence of clinically significant hemobilia was 1.9% (Fidelman et al, 2008). Patients undergoing PTBD had a 3.7-fold higher incidence of hemobilia compared with patients undergoing PTC, and they had a delayed presentation of hemobilia; presumably this was due to multiple catheter exchanges and a tamponade effect in PTBD patients. In this series, only large-bore needles were associated with hemobilia.

Other studies have demonstrated that use of a 21-gauge needle to access the biliary tree during PTC or PTBD, rather than an 18-gauge needle, is associated with a reduced incidence of hemobilia (Burke et al, 2003; Dousset et al, 1997; Harbin

FIGURE 105.3. Iatrogenic trauma. Percutaneous transhepatic stent placement produced a large, subcapsular hepatic hematoma and hemobilia. *(Courtesy William R. Jarnagin.)*

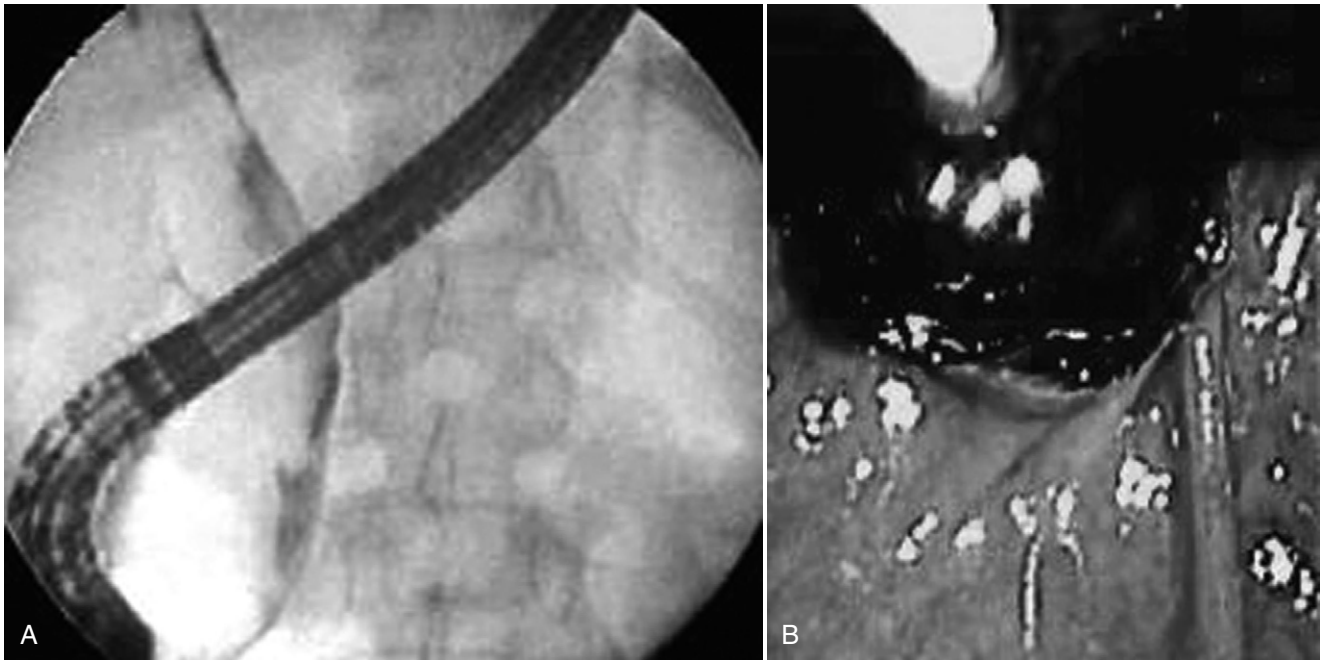

FIGURE 105.4. Iatrogenic trauma causing hemobilia. **A,** Endoscopic retrograde cholangiopancreatography (ERCP) findings of hemobilia that resulted from a percutaneous liver biopsy. Note the filling defect within the common bile duct consisting of blood clots. **B,** Removal of blood clots of the same patient during ERCP. *(From Martins FP, et al, 2008: Obstructive jaundice caused by hemobilia after liver biopsy. Endoscopy 40:E265-E266.)*

et al, 1980). In addition, correction of coagulopathy should reduce the development of clinically significant hemobilia (Hines et al, 1972). Another study concluded that neither a left-sided or right-sided hepatic approach to either PTBD or PTC is specifically associated with a higher incidence of hemobilia (Rivera-Sanfeliz et al, 2004). Other potential risk factors include cirrhosis, ascites, and absence of biliary dilation; extensive hepatic metastases do not appear to be predictive of hemobilia.

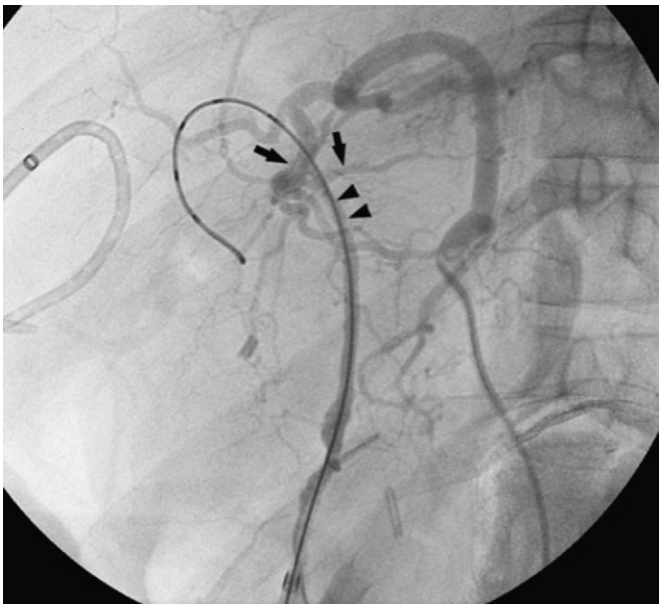

FIGURE 105.5. Hemobilia secondary to percutaneous transhepatic biliary drainage (PTBD). Angiogram obtained following placement of PTBD demonstrates a connection between the left hepatic artery (*arrows*) and biliary tree (*arrowheads*). *(From Fidelman N, et al, 2008: Hepatic arterial injuries after percutaneous biliary interventions in the era of laparoscopic surgery and liver transplantation: experience with 930 patients. Radiology 247: 880-886.)*

Surgery of the biliary tree may also lead to hemobilia as a result of injury of the hepatic artery by suture, dissection, diathermy, clip migration, erosion and subsequent arteriobiliary fistula, or pseudoaneurysm eroding into the extrahepatic bile duct (Fig. 105.6). The development of a hepatic artery pseudoaneurysm may precede the clinical manifestations of hemobilia by several weeks because of a delayed presentation; therefore, a high clinical suspicion and accurate history taking is often needed to accurately diagnose hemobilia (see Chapter 19). The advent of laparoscopic cholecystectomy for treatment of cholelithiasis and cholecystitis was originally feared to have produced an increased incidence of hemobilia secondary to vascular injury within the porta hepatis, specifically to the right hepatic artery (see Chapter 34). Stewart and colleagues (1995) reported five cases of hemobilia following laparoscopic cholecystectomy, and four of these were the result of traumatic aneurysm of the right hepatic artery; however, a large registry of 77,604 cases of patients undergoing laparoscopic cholecystectomy demonstrated that significant vascular injury was seen in only 0.16% (Deziel et al, 1993). It appears that fears of increased incidence of hemobilia following laparoscopic cholecystectomy were unfounded, overstated, and most likely secondary to the learning curve of laparoscopic surgery; however, the presentation of UGI bleeding from an unknown source weeks after laparoscopic cholecystectomy should heighten the suspicion of a potential injury to the right hepatic artery and resultant hemobilia.

Surgical procedures and exploratory instrumentation of the intrahepatic ducts may damage their walls, and the risk of hemorrhage is great. Minor bleeding constantly accompanies such procedures, but the bleeding generally ceases spontaneously, and the resulting clots promptly dissolve. Forceful

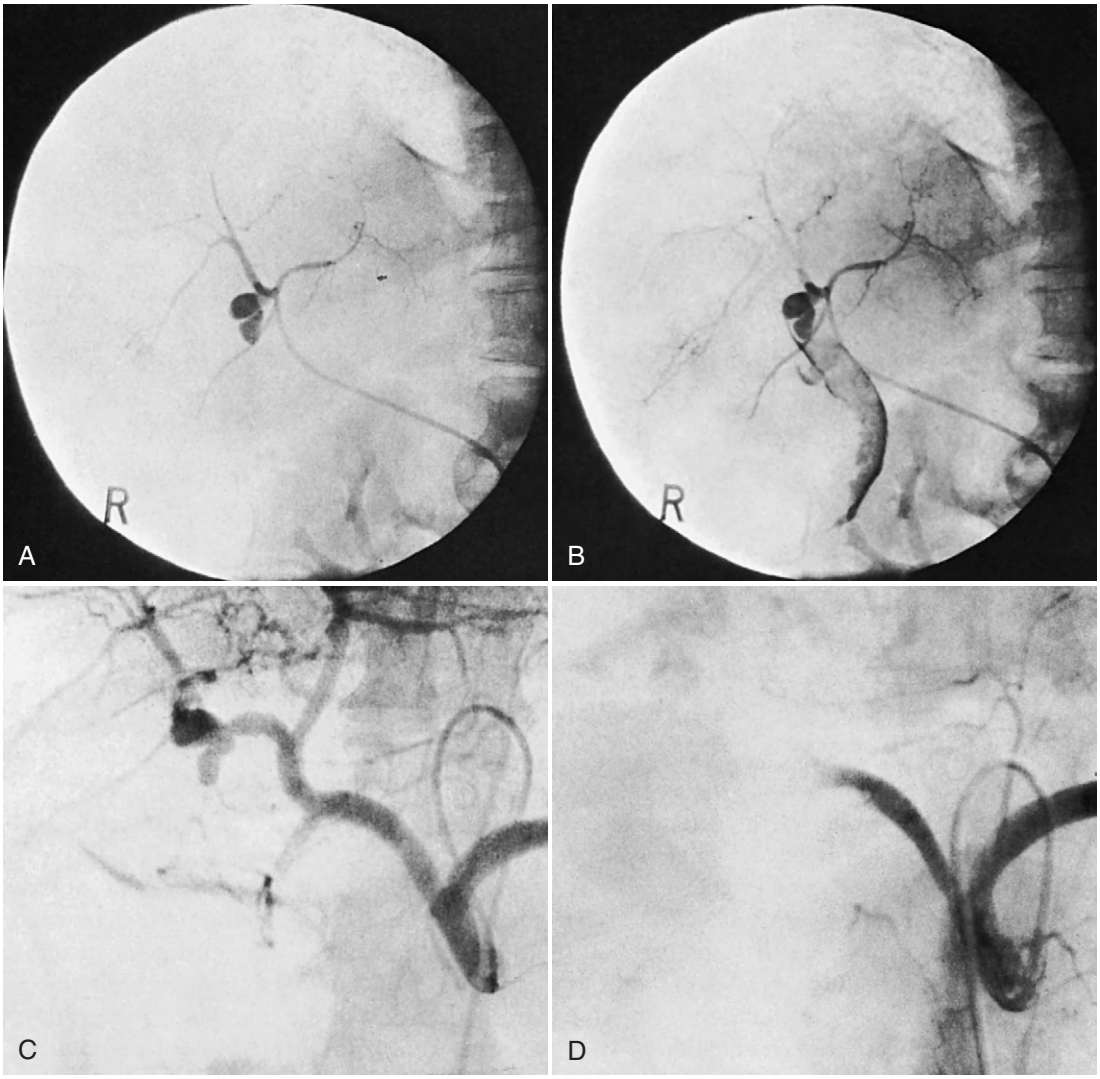

FIGURE 105.6. After complicated cholecystectomy, an iatrogenic pseudoaneurysm developed. It ruptured into the biliary tract and caused exsanguinating hemobilia, diagnosed through duodenal endoscopy and treated successfully with embolization. **A,** Selective arteriogram shows a pseudoaneurysm of the hepatic artery located at the liver hilum. **B,** A few seconds later, the contrast material is seen flowing down the hepatic duct, displaying the arteriobiliary fistula. **C** and **D,** The same aneurysm before and after obliteration of the feeding artery with artificial embolus. *(From Kelley CJ, et al, 1983: Non-surgical management of post-cholecystectomy hemobilia. Br J Surg 70:502.)*

instrumentation during exploration of the biliary tree and extraction of stones can result significant hemorrhage (Fig. 105.7). Bleeding from a T-tube occasionally can be caused by local erosion of the mucosa from tube, but if an arteriogram is done, it frequently exposes another source: a pseudoaneurysm that originates from an intraductal lesion, caused by instrumentation (see Fig. 105.7). As in other kinds of traumatic hemobilia, sometimes a considerable interval passes between the trauma and the bleeding episode.

Profuse biliary bleeding rarely complicates elective hepatic resections, although minor intraductal bleeding can result in confusing temporary postoperative jaundice. Although uncommon, hemobilia following liver transplantation may be a clinically challenging management issue; it typically occurs secondary to a percutaneous liver biopsy, and only selective embolization, which will be described later, should be used out of concern for periprocedural hepatic necrosis, ischemic biliary stricture, and sepsis.

Accidental Trauma

The liver is one of the organs most commonly injured by blunt trauma, with injuries detected in almost 25% of patients on routine computed tomography (CT) scan (Matthes et al, 2003; see Chapter 102). Nonsurgical management of blunt liver trauma in hemodynamically stable patients has become the standard treatment and is successful in 50% to 80% of patients (Carrillo et al, 1998; Forlee et al, 2004). The incidence of hemobilia following major liver injury has been reported to be as high as 3% in one series (Merrell & Schneider, 1991), but in other reports, the overall incidence is less than 0.2% (Parks et al, 1999). Other accidental traumas that result in hemobilia include injuries to the gallbladder, which is the organ injured in up to 2% of blunt abdominal trauma cases (Erb et al, 1994).

The clinical manifestations of blunt trauma to the liver are dependent on the anatomic site of damage. Tearing or injury to the liver capsule without deep parenchymal injury typically

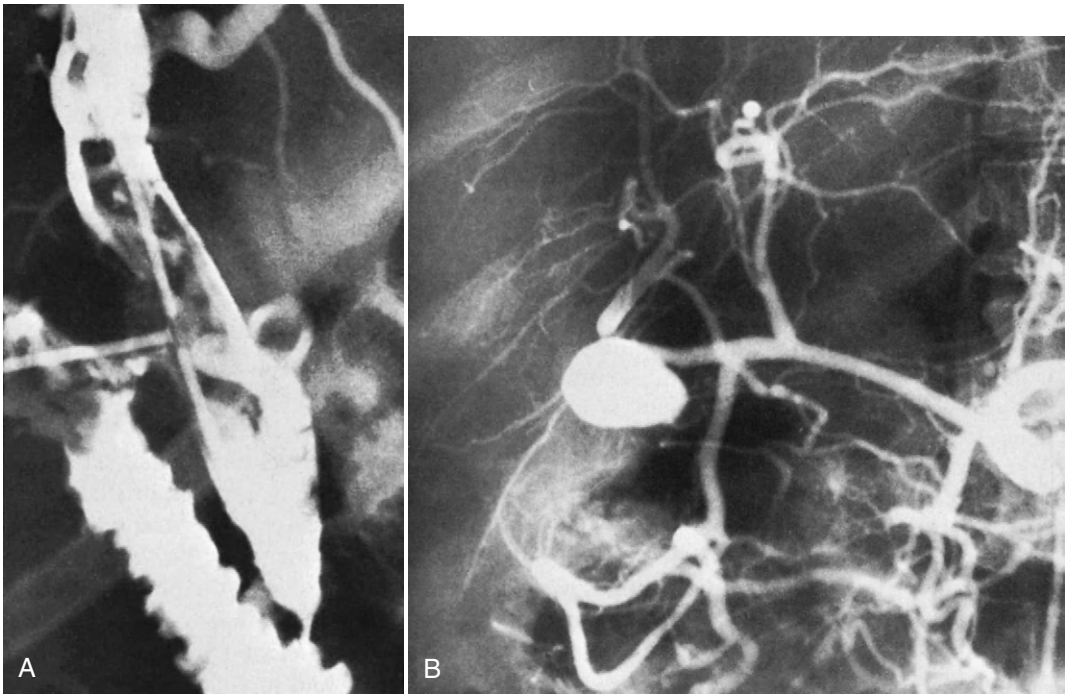

FIGURE 105.7. Iatrogenic hemobilia. Operative lesion from instrumentation during common bile duct exploration. **A,** Postoperative cholangiogram after occurrence of profuse hemobilia through the T-tube; the large filling defects represent blood clots. **B,** Hepatic arteriogram reveals the source of bleeding: a false aneurysm in the right hepatic artery.

results in intraperitoneal hemorrhage that is most often managed with emergent operative exploration. Deep parenchymal injury or a central rupture may leave a large cavity, into which damaged bile ducts and blood vessels drain; the resulting biloma or hematoma may continue to expand, liver healing is impaired, and subsequent necrosis of the cavity wall may cause erosion of adjacent structures or formation of an intrahepatic artery pseudoaneurysm (Fig. 105.8).

If operation for blunt liver trauma is necessary, careful exploration of central injuries should be performed to ensure adequate hemostasis and ligation of biliary radicles before using packs to control bleeding. Indiscriminate use of deep parenchymal sutures should be avoided to prevent further injury to biliary radicles and vessels, potentially creating a central cavity that predisposes to the development of postoperative hemobilia. The conservative management of liver injuries has not resulted in an increase in the incidence of hemobilia following accidental trauma (Carrillo et al, 1998). In a series of 135 patients with severe liver injuries managed nonoperatively, only two developed hemobilia (Carrillo et al, 1999).

Vascular Disorders

Vascular disorders account for only about 10% of cases of clinically significant hemobilia (see Chapter 19; Green et al, 2001; Yoshida et al, 1987). Hepatic artery aneurysms are the most common primary vascular disorder to produce hemobilia. Other less common causes include angiodysplasia, arteriovenous malformations, and hemangiomas (Vishnevsky et al, 1991). The frequency of true aneurysms (Ryan et al, 2002) of the hepatic artery or its branches (Maralcan et al, 2003; Morioka et al, 2004) rupturing into the biliary tract is diminishing with the disappearance of mycotic aneurysms, leaving only aneurysms of atherosclerotic origin or those associated with polyarteritis nodosa (Dutta et al, 2004;Yazici et al, 1997), fibromuscular dysplasia (Shussman et al, 2008), or trauma. When an aneurysm only leaks, it might give rise to inconspicuous hemobilia; when it ruptures into the biliary tract, the symptoms are generally clinically significant, with exsanguinating hemorrhage and intense biliary colic. Sometimes, vascular lesions associated with arterial hypertension can result in hemobilia; the structure usually affected is the gallbladder, and the disorder is known as *apoplexy of the gallbladder* (Parekh & Corvera, 2010; Fig. 105.9).

Neoplasms

Neoplasms account for only about 5% of all cases of major hemobilia (Green et al, 2001; Sandblom, 1972; Yoshida et al, 1987). Primary and secondary malignant neoplasms of the liver, bile ducts, gallbladder, and pancreas can all lead to hemobilia when the tumors invade the biliary system. The rate of blood loss is rarely rapid and in most instances produces the slow onset of microcytic anemia. Malignant tumors are three times more likely to cause hemobilia than benign tumors, and liver metastases hardly ever cause hemobilia; similarly, hemobilia is not a frequent sequela of primary cancers in the liver (Kitagawa et al, 1999), although it has been described from metastases in such rare locations as the gallbladder wall (Kubota et al, 2000) or from melanoma in the ductal mucosa. In cases of hemobilia caused by malignant tumors in the gallbladder (Hernandez-Castillo et al, 2002), the bleeding is most marked if the tumor grows in a polypoid fashion (Strauss, 1929). In the bile ducts, benign adenoma (Teter, 1954), polyps, and polyposis have a protracted course of hemobilia. Treatment of hepatic tumors, both primary and metastatic, with either chemotherapy

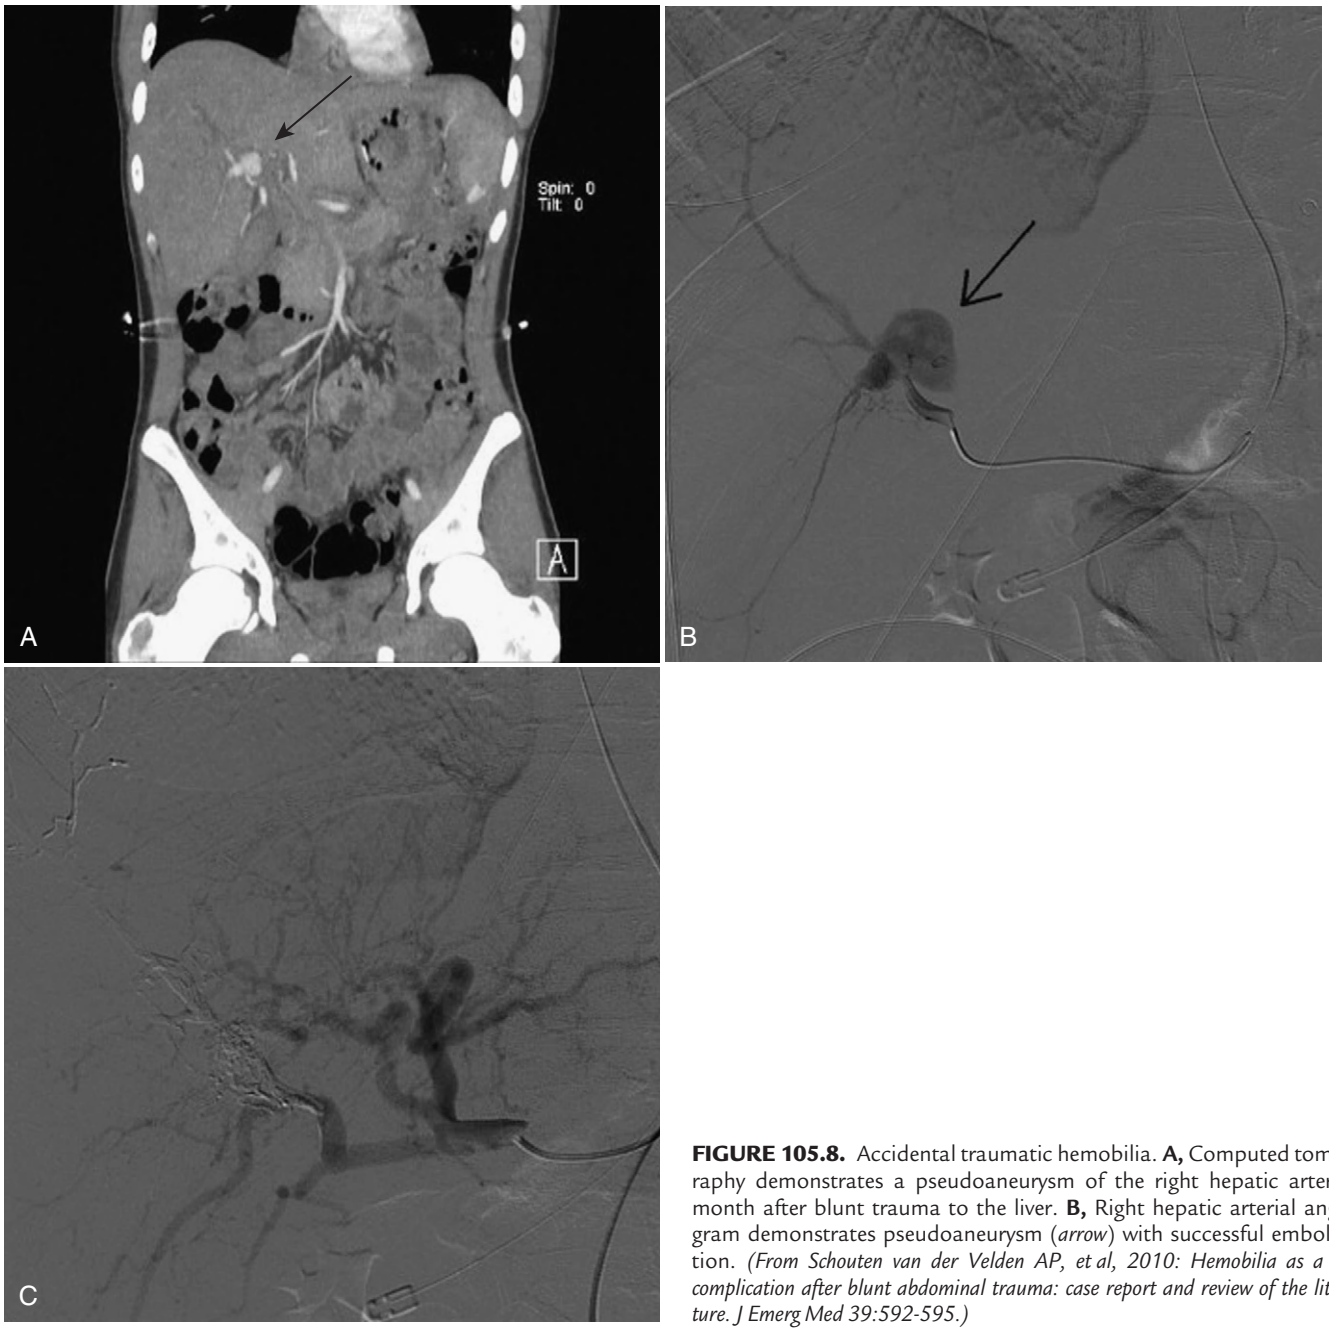

FIGURE 105.8. Accidental traumatic hemobilia. **A,** Computed tomography demonstrates a pseudoaneurysm of the right hepatic artery a month after blunt trauma to the liver. **B,** Right hepatic arterial angiogram demonstrates pseudoaneurysm (*arrow*) with successful embolization. *(From Schouten van der Velden AP, et al, 2010: Hemobilia as a late complication after blunt abdominal trauma: case report and review of the literature. J Emerg Med 39:592-595.)*

(Verset et al, 2010) or locoregional therapy (Goto et al, 2010) has also been reported to result in major hemobilia.

Gallstones

In gallstone disease, microscopic hemorrhage can be demonstrated in one of four cases with stones in the gallbladder and in one of three with stones in the common duct (Gad, 1962). Macroscopic hemobilia is rare, constituting less than 10% of all major hemobilia cases reported (Green et al, 2001; Sandblom, 1972; Yoshida et al, 1987). It generally occurs when large stones erode the cystic artery or penetrate into an adjacent viscus or vessel (Ben-Ishay et al, 2010; Contini et al, 2009; Fig. 105.10). The stones may cause profuse, exsanguinating hemobilia, and 11 out of 20 patients in one report bled to death. Hemobilia should be regarded just as seriously but is a much less frequent complication of neglected gallstones (Joo et al, 2003) compared with obstructive jaundice, cholecystitis, and pancreatitis.

Infections and Inflammation

Parasitic infection by various organisms has been reported in association with hemobilia, and it should be considered in patients with a history of travel to endemic regions, including Africa and the Asian Rim (see Chapter 45). *Ascaris lumbrocoides,* a nematode with a tendency to invade the bile ducts, frequently produces bleeding (Fig. 105.11). In India, 500 cases of biliary ascariasis have been reported (Khurro et al, 1990).

FIGURE 105.9. Sawyer, Vanderbilt University; **B,** courtesy G.B. Ong, University of Hong Kong; **C,** Courtesy R. Cavin, Lausanne, Switzerland.)*

Suppuration, but no bleeding, is mentioned. Because blood iron levels were low, and no examination for hematochezia was performed, it may be that many cases were overlooked. In addition, ruptured liver abscess has caused hemobilia in a few cases (Liou et al, 1996).

CLINICAL MANIFESTATIONS

The bleeding in hemobilia may originate in the liver parenchyma, intrahepatic biliary tract, or extrahepatic biliary tract, including the gallbladder. Most episodes of significant hemobilia are the result of an abnormal fistulous communication between a hepatic arterial branch and the biliary tree. The clinical manifestations of hemobilia are due to blood loss and formation of clots within the biliary tree. Major hemobilia causes shock and possible death from exsanguination, unless an emergency intervention is performed. Occult or minor hemobilia, if continued, may result in chronic secondary anemia as can be seen with biliary tract neoplasms (Ahmad et al, 2010).

GI bleeding in connection with biliary symptoms should arouse the suspicion of biliary tract hemorrhage. Quincke described a triad of signs and symptoms associated with hemobilia: upper abdominal pain, UGI hemorrhage, and jaundice (Quincke, 1871). The GI bleeding manifests as melena in 90% of cases and as hematemesis in 60%. Biliary colic symptoms are seen in 70% of cases, and jaundice is identified in up to 60% of patients. All three findings are seen in approximately a quarter of patients with hemobilia (Green et al, 2001). In addition to retained blood clots within the biliary tree, which produce the signs and symptoms of obstructive jaundice, patients may be seen initially with ascending cholangitis and accompanying high fevers and rigors (Kurisu et al, 2005).

The fate of blood in the biliary tree depends on a variety of factors, including the *rate*, the *source* (arterial or venous), the *timing* (continuous or intermittent), and the *frequency* (solitary or recurrent) of the bleeding. A sudden onset of massive bleeding, as in a ruptured hepatic artery aneurysm, may produce such a rapid volume of blood that the initial clinical presentation is hematemesis or melena. The formation of clots depends on the quality and quantity of the bleeding, and their fate depends on whether they are dissolved, expelled into the intestine, or retained in the biliary tract (Sandblom & Mirkovich, 1979). When clots are retained, they act like calculi and cause symptoms of biliary colic when passed (Clancy & Warren, 1997), jaundice when retained (Prata Martins et al, 2008), cholecystitis if lodged in the gallbladder (Parekh & Corvera, 2010), and pancreatitis if they obstruct a common channel above the sphincter (Alis et al, 2010). Only rarely do clots remain in the biliary tree long enough to be encrusted and form stones (Luzuy et al, 1987; Olsen, 1982).

DIAGNOSIS

A high index of suspicion is necessary to accurately diagnose and treat hemobilia. The actual workup of a patient with suspected hemobilia is ultimately dependent on the presentation and suspected etiology. It is important to remember that hemobilia may have a delayed presentation and may recur repeatedly over months, even years (Ahmad et al, 2010). For patients who come to medical attention with UGI bleeding, esophagogastroduodenoscopy (EGD) is the initial diagnostic test of choice. Although blood or clot at the ampulla ofVater is the *sine qua non* of hemobilia (Fig. 105.12), about 10% of upper endoscopies will be nondiagnostic and will necessitate additional diagnostic tests to confirm the diagnosis (Yoshida et al, 1987).

Other imaging modalities employed include endoscopic retrograde cholangiopancreatography (ERCP), which sometimes reveals clots in the bile ducts (Guitron-Cantu et al, 2002; Hendriks et al, 2009; Jornod et al, 1999; see Chapter 18 and Fig. 105.12). A lesion often first appears on ultrasonography (Trakarnsanga, et al, 2010) or CT (Burns & Slakey, 2009); these imaging modalities may show even small traumatic lesions, if a hematoma is produced, but not if there is only an arteriobiliary fistula. The ultrasound appearance of intracholecystic blood produces less distinctive shadows (or defects) than stones, and the shadows often are interpreted as being due to gravel or inspissated bile (Fig. 105.13). Magnetic resonance imaging (MRI) also can show active bleeding to the biliary tract, and

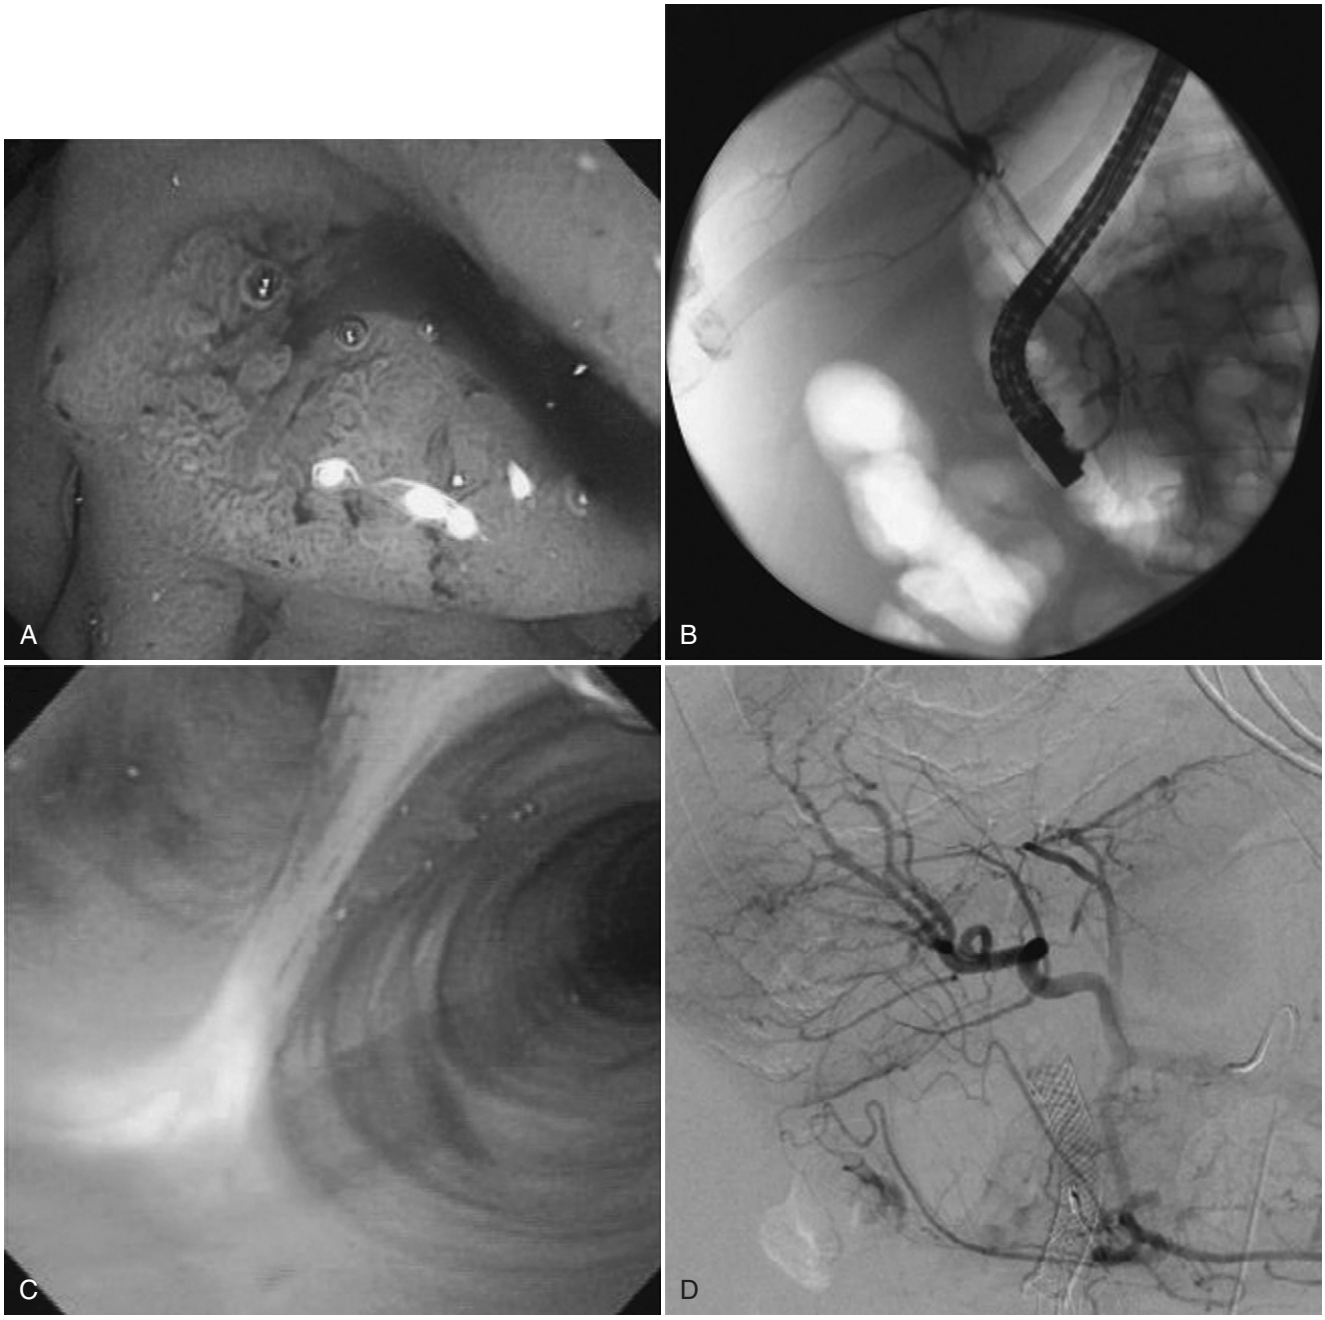

FIGURE 105.12. A case of hemobilia secondary to a transjugular liver biopsy. **A,** Upper endoscopy demonstrates blood emanating from the ampulla of Vater. **B,** Cholangiography from endoscopic retrograde cholangiopancreatography demonstrates an extensive filling defect within the extrahepatic biliary tree. **C,** Endoscopic finding of blood emanates from left hepatic duct. **D,** Subsequent angiography demonstrates no evidence of overt bleeding. *(From Parsi M, 2010: Hemobilia: endoscopic, fluoroscopic, and cholangioscopic diagnosis. Hepatology 52:2237-2238.)*

MR cholangiopancreatography (MRCP) can improve visualization of the biliary tract and gallbladder (Tseng et al, 2001; see Chapter 17).

The best way to verify a suspected diagnosis of hemobilia is by selective arteriography of the hepatic artery (see Chapter 19), which reveals the source of major bleeding in most cases (Xu et al, 2005; Yao & Arnell, 2010); hemobilia may also be demonstrated by extravasation; by displacement of the vessels around a liver mass; or by filling of a true aneurysm (see Fig. 105.7). When caught at the right moment, contrast material may be seen traveling down the hepatic duct, proving the existence of a communication with the biliary tract (see Fig. 105.6; Kelley et al, 1983), and in some cases, the artery also opens into the portal system (Gurakuqi et al, 2008). The arteriographic catheter should not be withdrawn until it has been decided whether embolization of the feeding artery should be considered as treatment. Arteriography is of special value in discovering central liver lesions, which may be difficult or impossible to localize during exploratory laparotomy. Although selective angiography is considered the gold standard for diagnosis in

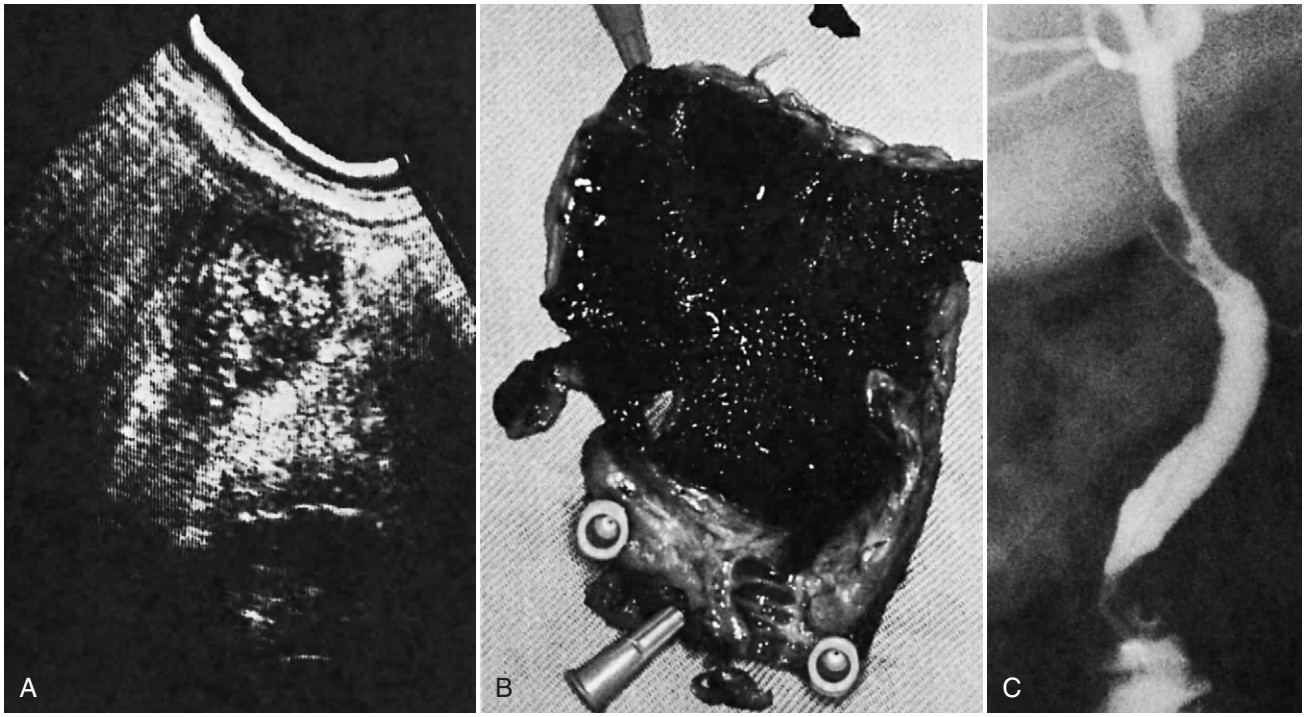

FIGURE 105.13. Hemobilia caused by clotting defect during anticoagulation therapy. **A,** Sonogram indicating dense material in the gallbladder, interpreted as *microcalculi* or *inspissated bile*. **B,** In the gallbladder, clotted blood was firmly attached to the wall. **C,** Defects in the perioperative cholangiogram caused by blood clots, the large proximal one attached to the wall and the distal one bandlike.

hemobilia, care must be taken in interpreting arteriograms; they may appear normal if the study is performed when there is no active bleeding.

Cholangiography done postoperatively through a T-tube by means of ERCP or through diagnostic percutaneous liver puncture (Fig. 105.14) may reveal a lesion by contrast filling of a cavity or by demonstration of clots, which appear as defects in the contrast filling (Millbourn, 1951).

TREATMENT

The treatment of hemobilia is predicated on resuscitation, stopping potentially life-threatening hemorrhage, and relieving biliary tract obstruction. Depending on the underlying etiology of hemobilia and briskness of hemorrhage, treatment modalities include surgical resection, arterial ligation, transcatheter arterial embolization, and conservative management.

Surgical Intervention

In 1903, Kehr first demonstrated that ligation of the proper hepatic artery could be successfully used in hemobilia in a case of communication between a hepatic artery aneurysm and the cystic duct. The predominant initial treatment method for hemobilia, surgical intervention in the form of surgical resection or arterial ligation, has declined in popularity with the advent of nonoperative approaches (see Chapters 19, 28, and 102; Green et al, 2001; Sandblom, 1972; Yoshida et al, 1987); however, surgical intervention still has a role in cases where transarterial embolization (TAE) has failed, or where the etiology demands an operative approach. Cholecystectomy done for gallstones and surgical resection for intrahepatic or extrahepatic neoplasms are suitable approaches in patients who are hemodynamically stable with signs and symptoms of hemobilia. The surgical approach involves ligation of the bleeding vessel and/or excision of the pseudoaneurysm. If the bleeding vessel is not appropriately identified intraoperatively, ligation of the right or left hepatic artery can be done with little concern for perioperative necrosis, provided free flow of the respective portal vein is demonstrated to ensure adequate oxygenation of liver parenchyma.

Arterial Embolization (See Chapters 19 and 28)

Since the description of the first successful TAE of a hemobilia-producing right hepatic pseudoaneurysm in 1976 by Walter and colleagues, nonoperative embolization has become the preferred approach for the management of hemobilia (Fig. 105.15). The goal of TAE is to decrease blood flow to the abnormal communication between the vessel and biliary tree by placement of the catheter at the periphery of the bleeding vessel and embolization with occluding materials, such as absorbable gelatin sponge, coils, polyvinyl alcohol particles, cyanoacrylate, or microballoons. As a result of the selective embolization of the bleeding vessel, oftentimes a segmental branch of the hepatic artery, the risk of hepatic necrosis is minimal, especially if the portal vein is patent. It is important to perform selective embolization, because occlusion of a major hepatic arterial branch not only allows the possibility of rebleeding, owing to revascularization, it also makes impossible repeat embolization, which may be necessary. TAE successfully manages hemobilia in 75% to 100% of cases with little to no periprocedural morbidity (Lygidakis et al, 1991; Srivastava et al, 2006; Vaughan et al, 1984).

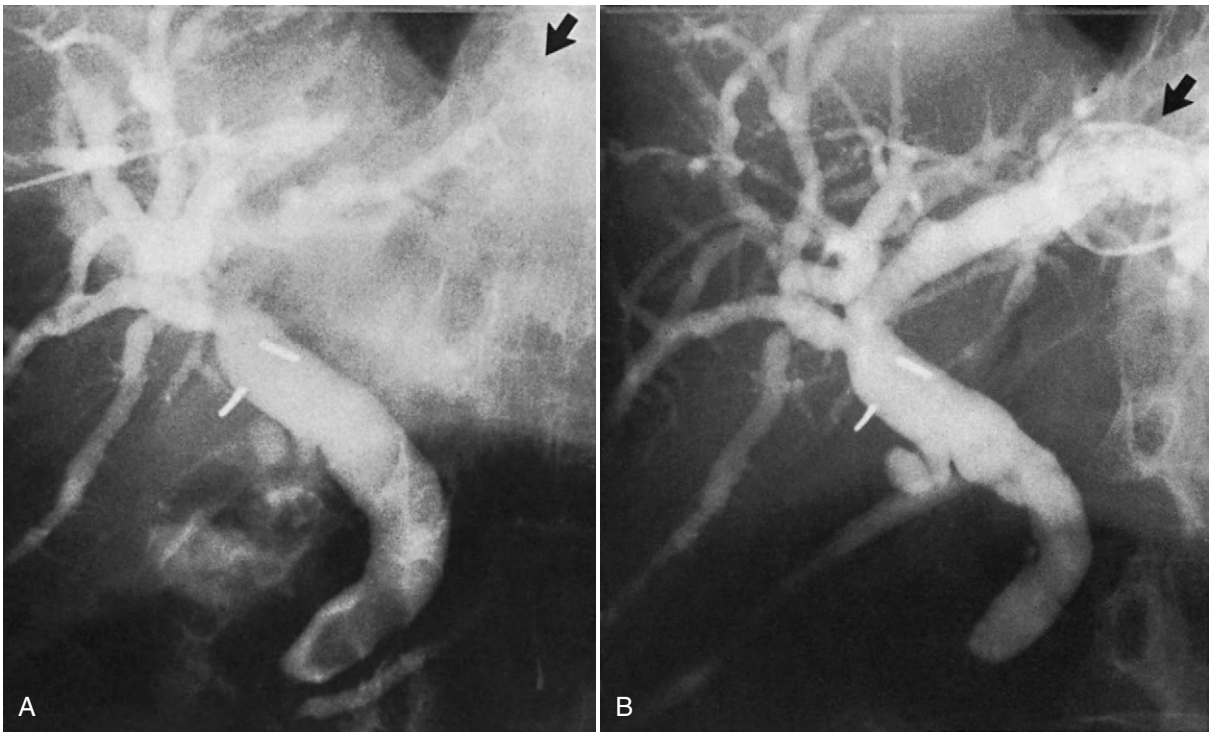

FIGURE 105.14. Lesion from transhepatic cholangiography, producing a blood clot in the common duct. **A,** The *arrow* points toward a lesion in the left hepatic duct. Filling defect in the common duct is caused by a gelatinous bile plug, probably a blood clot that disappeared through the sucker. **B,** Postoperative cholangiogram shows the extravasation from the ductal lesion responsible for the hemobilia.

First successful documented report of embolization for treatment of hemobilia secondary to a pseuduoaneurysm from a liver biopsy. **A,** Selective common hepatic arteriogram demonstrates pseudoaneurysm of the right hepatic artery (*arrows*). **B,** Follow-up arteriogram after Gelfoam embolization demonstrates complete occlusion of the right hepatic artery (*arrow*). *(From Walter JF, 1976: Successful transcatheter embolic control of massive hemobilia secondary to liver biopsy. AJR Am J Roentgenol 127:847-849.)*

Biliary Tract Management

Patients who present with hemobilia after transhepatic biliary drainage often require emergent cholangiography and arteriography to identify the cause and treat the bleeding. These patients will come to medical attention with a sudden output of blood into their biliary drainage bags. After resuscitation, the biliary drainage tube must be examined to ensure its proper position. If the tube has become partially dislodged, a side hole may have migrated into the hepatic parenchyma, in which case simple repositioning of the side holes may stop the bleeding.

To address the issue, the initial procedure should be cholangiography, which may identify a biliary-venous fistula or a biliary-arterial fistula. Portal venous fistulas are easily treated by upsizing the biliary stent; that usually will be sufficient to tamponade the fistula tract (see Chapter 50D). If arterial hemorrhage is suspected, the patient should proceed to diagnostic angiography and TAE. If a bleeding site is not identified with the biliary drainage catheter in place, it may be necessary to remove the catheter prior to performing the arteriogram.

The management of obstructive jaundice that results from clotting within the biliary tree is usually accomplished with ERCP and removal of the clot. If an external biliary drainage tube is in place, simple irrigation of the tube may be all that is required to successfully relieve the obstruction.

BILHEMIA

Bilhemia denotes the reverse of hemobilia, with bile entering the bloodstream through a communication with the hepatic veins (Sandblom, 2000; Turk et al, 2010) or with branches of the portal vein (Lagagne et al, 1988). The reversed flow is due to inversion of the pressure gradient (François et al, 1994) caused by high intraductal biliary pressure, generally resulting from a peripheral obstruction or low venous pressure. In a large series of cases of obstructive jaundice, the pressure in the bile ducts was invariably higher than in the hepatic veins (Wiechel, 1964). In five instances, gallstones eroded into the portal vein. The first case was reported in 1559, preceding the description of hemobilia by more than a century, at the necropsy of Saint Ignatius of Loyola, with three gallstones found in the portal vein.

Portal vein bilhemia was recognized relatively recently. The first recent case to be reported was caused by liver biopsy, described by Brown and Walsh in 1952; a second description was provided 15 years later by Mehta and Rubenstone (1967). The condition, which was named by Clemens and Wittrin in 1975, is rare but dangerous. Of the 50 cases reported in the literature, half were fatal. The cause of the pathologic passage was often accidental: blunt trauma in 25 cases and iatrogenic injury or manipulation during operation in 3 cases (Koehler et al, 1978). The symptoms are a rapidly increasing jaundice with elevated direct bilirubin without increase of liver enzymes. Septicemia has occurred through bilhemia with infected bile (Morettin & Dodd, 1972). Selective arteriography is nondiagnostic in bilhemia, whereas scintigraphy has been useful (François et al, 1994). ERCP, in which the contrast material follows the direction of the biliary flow, is the best means to show the fistula (Singh et al, 2007; Sugiyama et al, 2000; Fig. 105.16).

Treatment aims at release of the ductal obstruction, sometimes through endoscopic sphincterotomy or, with a higher location, through a percutaneous transhepatic drain. This procedure sometimes causes the fistula to close or at least gives temporary relief (Sears et al, 1997); more lasting effect can be obtained with endostenting (Gable et al, 1997; Weintraub et al, 2006). For definitive cure, the affected liver may have to be resected (Clemens & Wittrin, 1975), or the fistula can be occluded via angiography or ERCP (Struyven et al, 1982).

HEMOSUCCUS PANCREATICUS

Hemosuccus pancreaticus, defined as hemorrhage into the pancreatic duct and through the ampulla of Vater into the GI tract, is a rare cause of intermittent UGI bleeding. First described by Lower and Farrell in 1931, the term was not popularized until 1970 by Sandblom. It is typically caused by the rupture of a pseudoaneurysm from the celiac trunk vasculature into the pancreatic duct (Fig. 105.17) secondary to acute and/or chronic pancreatitis (Sakorafas et al, 2000), although rupture of primary celiac trunk aneurysms (Massani et al, 2009) and rupture of vessels secondary to cystic neoplasms of the pancreas have also been described (Shinzeki et al, 2010; see Chapter 104).

Similar to the diagnosis of hemobilia, a high degree of clinical suspicion is needed to diagnose hemosuccus pancreaticus. Although there is no named triad, the combination of abdominal pain, hyperamylasemia, acute upper GI bleeding, and a history of acute and/or chronic pancreatitis should raise clinical suspicion of the diagnosis. The clinical sign of abdominal pain is present in most cases secondary to raised intraductal pressure from hemorrhage into the pancreatic duct, and it is accompanied by elevated serum amylase (Sakorafas et al, 2000).

Upper endoscopy is the preferred first diagnostic test, as the diagnosis of hemosuccus pancreaticus is so rare that other sources of UGI bleeding need to be ruled out. If the hemorrhage is active, blood can be seen emanating from the ampullary papilla at the time of upper endoscopy; however, because the bleeding can be intermittent in nature, a negative upper endoscopy does not preclude the diagnosis. Axial imaging with CT can often aid in the diagnosis of a pseudoaneurysm of the celiac trunk artery. ERCP can also be of a diagnostic help in unclear cases, as cholangiography can demonstrate the filling of the pancreatic duct with clots (Toyoki et al, 2008). Similar to hemobilia, selective angiography is the optimal imaging modality for suspected hemosuccus pancreaticus. The angiogram can demonstrate findings of a pseudoaneurysm of the celiac trunk vessels, and in rare instances, it can demonstrate a connection between the vessel and the pancreatic duct (Arnaud et al, 1994).

Two treatment options are available for hemosuccus pancreaticus: surgery and angiographic embolization. Following resuscitation and hemodynamic stabilization, the initial treatment should be angiographic embolization of the aneurysm with particles, as mentioned previously (see Chapters 19 and 104). Definite treatment of the bleeding using this technique is successful in 67% to 100% of cases (Lermite et al, 2007). Surgical treatment is generally reserved for uncontrolled hemorrhage or failure of angiographic embolization.

Hepatobiliary and pancreatic surgery: historical perspective

Leslie H. Blumgart

A cursory examination of the Table of Contents of this book reveals how some of the extraordinary achievements of modern medical science and clinical practice have been applied to the management of liver, biliary, and pancreatic disease. The near-miraculous developments in our understanding of the molecular nature of disease combined with the wonders of modern imaging technology, advances in anesthesiology, and refinements in surgical technique can be so absorbing as to blind a contemporary physician to the rich history that lies behind today's practice. This introductory essay, with an appended list of references, examines the achievements of the past, on which the modern practice of liver, biliary, and pancreatic surgery depends.

ANCIENT HISTORY UNTIL THE EIGHTEENTH CENTURY

> *"For the King of Babylon stood at the parting of the way, at the head of the two ways, to use divination: he made his arrows bright, he consulted with images, he looked in the liver."*
>
> *Ezekiel 21:21*

In ancient societies, the priest had the simultaneous duties of divination, protection, and treatment of the ill. For individuals with the responsibility of divining the future, the liver was of central importance. As exposed by wounds sustained in combat, at sacrificial offerings, and at incisions after death, the liver is the most obvious organ in the abdomen and was observed to contain the most blood; because life and blood were perceived to be synonymous, the liver was considered the seat of the soul.

A tablet believed to be from the time of Hammurabi (about 2000 BCE), now in the British Museum, names the various parts of the liver and indicates the prognostic significance of each (Jastrow, 1908). The liver was divided into about 50 portions for individual inspection in an effort to overlook as little as possible. Such hepatoscopy was widely in vogue over the following centuries and was practiced by the Etruscans, as evidenced by a bronze tablet in a museum at Piacenza depicting the liver, this being strikingly similar to the Babylonian clay tablet in the British Museum.

The Roman Celsus in his text *De Medicina,* translated by W.G. Spencer in 1935, mentioned the liver and described its anatomic location: "[T]he liver, which starts from the actual partition under the praecordia on the right side, is concave within (that is on the inferior surface) and convex without; its projecting part rests lightly on the stomach and it is divided into four lobes. Outside its lower part, the gallbladder adheres to it." Celsus lived in the first century and described symptoms attributable to liver disease. Gallstones were recognized in the embalming of mummies in ancient Egypt. In 1909, a mummy with a preserved liver and a gallbladder containing 30 gallstones was presented to the Museum of the Royal College of Surgeons in London. This mummy came from Deir-el-Bahn at Thebes and was that of a priestess of the twenty-first dynasty around 1500 BCE. Elliot-Smith, an outstanding English anatomist and Egyptologist, described the gallbladder as being large and containing "many spherical calculi." The specimen was destroyed by German bombs during World War II, but the description of it was accepted as evidence that the gallstones contained therein were the earliest specimen of such calculi to have survived from antiquity (Glenn, 1971). Gordon-Taylor, a noted surgical historian in England, had likewise called attention to the terminal illness of Alexander the Great at the age of 34 (323 BCE) as an example of fatal biliary tract disease. The description of Alexander's illness as recounted by Weigall (1933) suggests that he died of complications culminating in peritonitis.

Rhazes (850-923) and Avicenna (980-1037), two Persians, wrote on general surgical topics and the nature of disease and appreciated the gallbladder but lacked knowledge of the common bile duct. Biliary fistulae were known to have formed after the drainage of an abdominal wall abscess, and it was known that individuals with fistulae had a better prognosis than those who had an external communication with the intestines (Glenn, 1971).

Greek academic achievements surpassed that of all other civilizations until the fifth century BCE. Hippocrates, widely acclaimed in medicine then and since that time, recognized the seriousness of biliary tract disease as evident in the following passage from *The Genuine Works of Hippocrates* (translated by Adams in 1939): "[I]n a bilious fever, jaundice coming on with rigor before the seventh day carries off the fever, but if it occurs without the fever, and not at the proper time, it is a fatal symptom." He also noted that in the case of jaundice, "[I]f the liver hardens it is a bad sign."

A few centuries after Aristotle recognized jaundice as an element of disease, Galen viewed biliary tract disease as a recognized clinical entity to be treated successfully in part by diet. Although Celsus had drawn attention to the gallbladder and liver in the first century CE, in the second century, Galen was the most noted author of the Greco–Roman age. Galen named three main organs that govern the body: the *heart,* the source of heat and the principal organ; the *brain,* the source of sensitivity for all parts; and the *liver,* as a principal part of the nutritive facility (Green, 1951). Galen considered jaundice to be due to yellow bile flowing into the skin and recognized that although jaundice could be the result of hepatic disease, it also could

arise when the liver was not involved at all. Galen's teaching persisted for centuries, and until the middle of the seventeenth century, many disorders were described as alterations in the balance of the main humors of the body brought about by hepatic dysfunction. As recorded by Rosner (1992), ancient Hebrew physicians used pigeons to treat jaundice by placing the pigeon on the patients umbilicus. "The pigeon will draw all yellowness out."

Many subsequent advances came from Italy about the time of the Renaissance. Benivieni (1506) in Florence described a series of autopsies in his patients, which was the first record of special reference to biliary tract disease and its clinical manifestations. Two examples are cited in the translation by Singer and Long (1954) of Benivieni's book, *The Hidden Causes of Disease:*

> *"A case of stones found in the coat of the liver—a woman of noble birth had been for long tormented by pain in the region of the liver. She had consulted many physicians but could not drive out the evil by any remedy … a few days afterward, the disease took stronger hold and she departed this life. … I then had her dead body cut open. There were found in the lower part of the membrane around the liver a collection of small stones varying in shape and color. Some were round, some pointed, some square, according as position and chance had determined, and they were also marked with reddish, blue and white spots. These stones by their weight had caused the membrane to hang down in a bag a palm's length and two-fingers wide. This we judge the cause of her death."*

The second quotation also suggests death from gallstones:

> *"Stone in the middle of the gallbladder–there died recently a noble lady, Diamantes, laid low by the pain due to stones. As she had felt no harm from it before, the physicians decided to cut open her body. A great many stones were found but none in the urinary bladder as they had expected, but save for one, which was in the gallbladder, was black and as big as a dried chestnut. [A]ll were in the covering of the liver and made its coat hang down in a little bag. This we decided was the cause of her death and declared that a wise man would be well advised to make no definite pronouncements on obscure and uncertain diseases."*

Much of the next phase of development of knowledge was centered around northeast Italy, particularly Padua, and many of the eponyms that we now use in surgery evolved from that period. The publication of Vesalius's *De Humani Corporis Fabrica* in 1543 (Fig. 1) and Harvey's *De Mortu Cordis* 100 years later marked the emergence of a new scientific spirit in anatomy and physiology. As was the custom of the times, Vesalius often recorded descriptions of findings of dissections on individuals who had recently died and expressed an opinion on the cause of death. Rains (1964), in his treatise *Gallstones—Causes and Treatment,* stated "Vesalius found [that he had] a hemoperitoneum coming from an abscess, which had eroded the portal vein. The gallbladder was yellow and contained 18 calculi. Very light, of a triangular shape with even edges and surfaces everywhere, green by color somewhat blackish. The spleen was very large." Similarly, Rains recounted that Falloppio described stones in the gallbladder and common bile duct in 1543, and that Fernell in his *De Morbis Universilibus et Particularibus* (1588) proposed that the predisposing cause of gallstone formation was stasis and observed that in jaundice, the feces become white and the urine dark, and that stones may be passed per anum. Falloppio, Vesalius, and Fernell all were active in the first half of the sixteenth century and probably discussed their theories of the cause of gallstones and the changes in the liver with which they were associated.

FIGURE 1. Andreas Vesalius, anatomist. *From* De Humani Corporis Fabrica*, 1543.*

William Harvey (1578-1657), who also worked in Padua, is held by many to be the greatest of the contributors to the study of anatomy and physiology, and he established a clear understanding of the circulation. There is little doubt that Harvey also gave thought to the liver and its relation to the circulation and to the heart in particular. Harvey's student and younger contemporary, Francis Glisson, investigated the structure and function of the liver extensively. His book *Anatomia Hepatis* was published in 1654 and is the first major modern work on hepatology. Glisson gave a clear description of hepatic anatomy, especially of the hepatic capsule and of the investment of the hepatic artery, portal vein, and bile duct. He described the fibrous framework of the liver and illustrated hepatic vascular and biliary anatomy on the basis of cast and injection studies (Fig. 2). Glisson was the first to mention a sphincteric mechanism around the orifice of the common bile duct (Boyden, 1936). He also deduced the flow of blood through the portal veins traversing the capillaries into the vena cava at a time when no microscopic studies of the liver had been done (Walker, 1966). Some of his illustrations are remarkably similar to those of Couinaud (1954, 1957, 1981) and to the images displayed

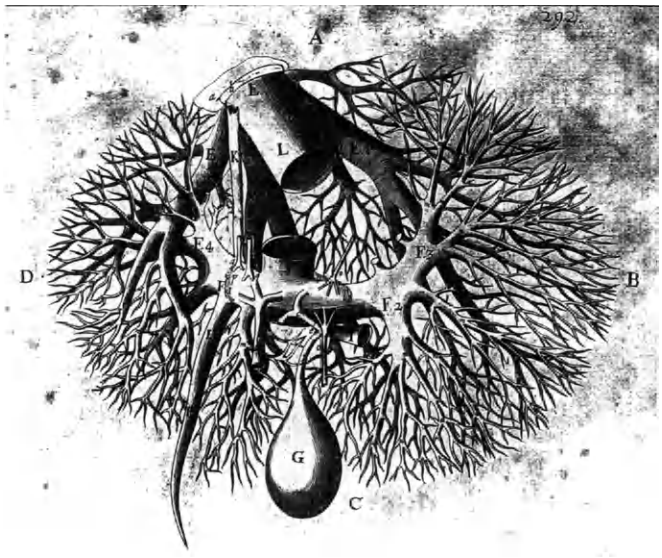

FIGURE 2. Illustration of the vasculature of the liver. *From Glisson F, 1654:* Anatomia Hepatis.

today in three-dimensionally constructed computed tomography (CT) scans. Glisson was one of the great clinical physicians of all time, yet his name is related to an anatomic structure of limited importance.

In the century that followed the time of Harvey, great activity in publication among individuals engaged in medicine occurred. As today, senior professors often held opposing opinions and expressed their feelings based on fact or fancy with equal fervor. In an attempt to select the factual, Morgagni, senior professor of anatomy and president of the University of Padua, published in 1761 an analysis of disease (translated by Benjamin Alexander in 1960) under the title *Seats and Causes of Disease,* among which are those of the liver and biliary tract. In referring to gallstones, this text analyzed the distribution of stones in male and female patients, including the age, incidence, and treatment:

> *"[A]s to the lithotomy, which has also lately been thought of, in the gallbladder, do not be surprised that I made no mention of it above. For in the first place, the pains which were excited by gallstones, that were endeavoring to discharge themselves, are not only brought on by those which come from the cysts but also by those that come from the hepatic duct. In the second place, those cystic stones which are the largest, and on account of which lithotomy seems, to some persons, to be chiefly desirable, neither endeavor to disengage themselves nor create any great uneasiness; or at least for the most part."*

This is a remarkable analysis recognizing the presence of stones in the common bile duct and the relatively innocuous nature of the large stone. A further quotation is as follows:

> *"Last of all, although there were no danger in cutting, can you suppose there would be of no great difficulty in healing the wound? We have, before our eyes, examples of three women, one of Bologna, of Frankfurt, and of Göttingen, in whom a tumor, having arisen in the epigastrium, and being opened, either by art or spontaneously discharged cystic calculi at its aperture… the first was cured; the second had a fistula left, by which a thin and chylous kind of liquor, but of a yellow color, distilled; and the third had an ulcer remain, which with its sanies discharged bilious calculi at times."*

Morgagni, as is evident in his text, presented the matter of biliary tract disease in logical sequence. He considered the incidence and the population affected in the different decades of the life span. His descriptions of the possible mechanisms by which calculi might be formed remind one of much of the writings today. Finally, he considered therapy under conservative medical management and warned about attempting to deal with the condition by operation.

As outlined by Wood (1979), numerous eponyms currently used pertain to the names of these early physicians. Johann Georg Wirsung (1600-1643) also studied in Padua and was the first to dissect the human pancreatic duct and to describe it in a letter to Riola, professor of anatomy and botany at the University of Paris in 1642. Wirsung was subsequently murdered by a Dalmatian physician, the dispute probably related to who had described the duct first (Major, 1954; Morgenstern, 1965). Abraham Vater (1684-1751) was the first to describe the papilla of the duodenum. In 1720, he wrote that "those double ducts (bile and pancreatic ducts) … come together in single combination" (Boyden, 1936). He described not an ampulla but an elevation of the mucosa of the duodenum and described the first case of an ampulla with two orifices. Likewise, the duct of Santorini takes its name from the Venetian Giovanni Domenico Santorini (1681-1737), a brilliant anatomist and one of the most exact and careful dissectors of his day. While Vater was describing the tubercle at the confluence of the pancreatic and bile ducts, Santorini was relating the first detailed observation of the orifice of the two ducts (Boyden, 1936). In observations printed posthumously, Santorini noted a second pancreatic duct of normal occurrence and named the upper one the superior pancreatic duct and the lower one the main pancreatic duct. It was not until Oddi in 1864, working in Bologna, rediscovered "Glisson's sphincter" and did studies in dogs that the holding quality of the sphincter of the outlet of the choledochus was recognized (Boyden, 1936).

The work of Morgagni was seminal in the understanding of liver and biliary disease. It started the movement toward anatomic and pathologic appreciation. Belief in the humoral causation of disease became untenable, and scientific medicine was launched. The end of the seventeenth century and the beginning of the eighteenth could be said to mark the initiation of modern medical science.

EIGHTEENTH CENTURY TO MODERN TIMES

The period from 1700 to the present day can be considered in two phases: the era before the discovery of general anesthesia, antisepsis, and x-rays in the middle of the nineteenth century and the period that followed, bringing important discoveries in blood transfusion, antibiotics, and immunology. These major developments have been followed by the birth of the electronic age, the flowering of radiologic imaging, and the increasing power of genetics and gene manipulation. The passage of surgery through these milestones is fascinating to observe, and the enormous strides in the maturation of hepatobiliary and pancreatic surgery to a recognized specialty is an important part of this story.

IMAGING IN HEPATOBILIARY AND PANCREATIC SURGERY

"Where there is no vision, the people perish. …"
PROVERBS 29:18

Following the discovery of x-rays by Roentgen (Fig. 3) in 1895, there have been continual important and extraordinary developments in radiology. A contemporary surgeon who examines images to determine the cause of disease, sometimes before taking a history or examining the patient, can hardly contemplate a time when precise imaging was not available. A landmark development in hepatobiliary imaging occurred when, after experimenting with various iodine compounds, Graham, a North American surgeon, developed oral cholecystography (Graham & Cole, 1924). Although biliary calculi had been observed by plain x-rays since 1898 (Buxbaum, 1898), the problem of detecting radiotransparent calculi was evident, and the development of oral cholecystography marked an important turning point. Postoperative cholangiography was soon developed by Mirizzi (1932) in Argentina. Intraoperative cholangiography (Mirizzi, 1937) and choledochoscopy (Bakes, 1923; McIver, 1941) also were developed.

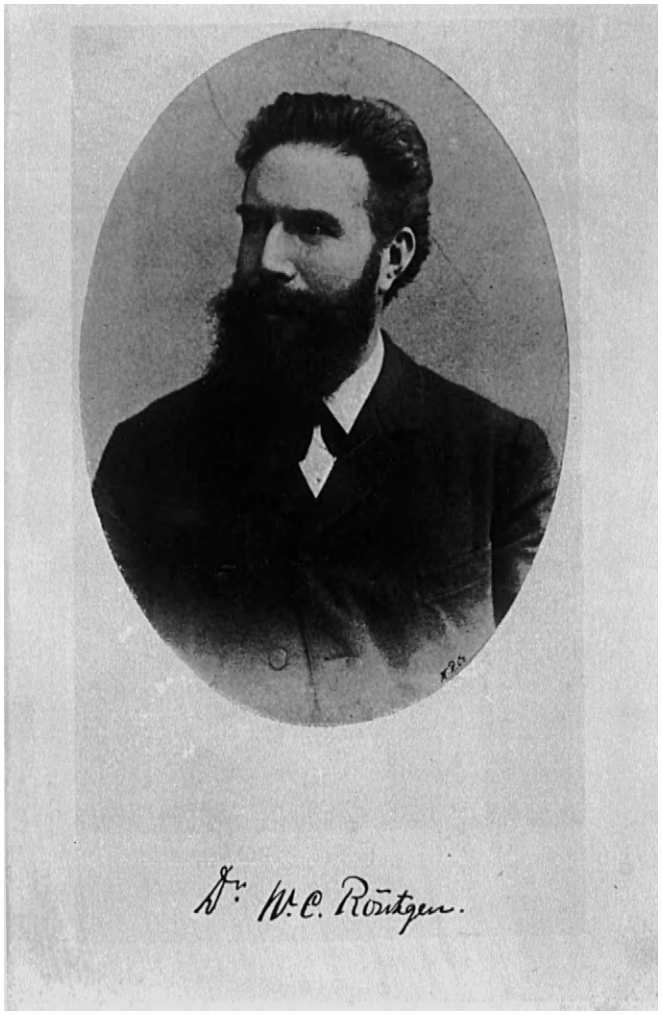

FIGURE 3. W.K. Roentgen (1845–1923). He discovered x-rays on November 8, 1895.

In the 1970s, endoscopic cholangiopancreatography (McCune et al, 1968; Demling & Classen, 1970; Oi et al, 1970; Blumgart et al, 1972; Cotton et al, 1972a, 1972b) and endoscopic papillotomy (Classen & Demling, 1974) revolutionized biliary and pancreatic radiology and approaches to common bile duct stones. The 1970s saw not only the introduction of endoscopic approaches to the biliary tract but also the development of good methods for percutaneous transhepatic cholangiography (Ohto & Tsuchiya, 1969; Okuda et al, 1974), CT of the liver (Grossman et al, 1977), and the use of ultrasound (Bryan et al, 1977) in liver and biliary surgery. Magnetic resonance (MR) axial imaging (Damadian, 1971; Lauterbur, 1973) was conceived and has led to the development of magnetic resonance imaging cholangiopancreatography (MRCP).

Not only were endoscopic and transhepatic approaches to stones now possible, endoscopic and percutaneous transhepatic intubation of the biliary tree for the relief of jaundice and for dilation of strictures became a reality. Arteriography developed to a fine degree, so that good hepatic arteriography and portography were developed (Hemingway & Allison, 1988), which inevitably led to the development of techniques for hepatic artery embolization in the management of liver tumors and of hemobilia (Allison et al, 1977).

Surgeons today have seen their world transformed by imaging; it may be said that the rapid developments in the radiology of the liver, biliary tract, and pancreas have enabled the extraordinary progress in the management of the diseases of these organs. Reference to almost any chapter in this book will attest to this fact. The extraordinary advances in technology using image guidance, rather than open operation, continue to evolve so that CT, ultrasound, and angiography now allow percutaneous image-guided methods for tumor ablation, arterial embolization, alcohol injection, and injection of other substances directly into tumors, along with the continuing development of a host of other techniques.

SURGERY OF THE BILIARY TRACT AND PANCREAS

Biliary Tract

The early part of the eighteenth century saw rapid development in the understanding of biliary disease. The ideas of Morgagni rapidly spread and were a firm basis for the changes to come. Studies regarding the structure, origin, and functions of bile were initiated in the latter half of the eighteenth century and culminated in Wieland's clarification of the structure of the various bile acids and Windaus's demonstration of the relationship of bile acids to steroids, which earned him a Nobel prize in 1927 and 1928. Boerhaave (1668-1738) established a wide surgical reputation at the University of Leiden in Holland and worked extensively on diseases of the liver and biliary tract. In 1743, Jean Louis Petit presented to the Paris Academy of Surgery a paper entitled "Considerations Concerning Tumors Produced by Retained Bile in the Gallbladder of the Liver, Sometimes Taken for Liver Abscesses." He introduced the term "biliary colic" and established the clinical treatment of it and of obstructive cholecystitis. In cases in which the gallbladder adhered firmly to the abdominal wall, Petit advised that it be punctured and opened to remove calculi, and he applied this procedure successfully in the case of one patient; this preceded Morgagni's publication of 1769

referred to earlier. Petit also coined the term "biliary colic" ("colique hepatique").

Biliary surgery began in Indiana on July 15, 1867, when John Bobbs operated on a woman who had a large tumor that he believed to be an ovarian cyst. To his amazement, when the abdomen was opened, he found an enormous gallbladder filled with stones. He opened it and extracted the calculi, sutured it carefully, and replaced it back in the abdomen (Bobbs, 1868). It was nearly a decade before a similar cholecystostomy was performed almost simultaneously by a Swiss, Theodore Kocher (Fig. 4), a North American, Sims, and an Englishman, Lawson Tait. All three surgeons planned operations in which the gallbladder was affixed to the abdominal wall to allow extraction of stones and pus and to leave it open to the exterior, so that peritonitis as a result of maneuvers within the abdomen could be avoided.

Sims worked on both sides of the Atlantic, and in Paris he operated on a patient with long-standing jaundice and a tumor in the right hypochondrium. With antiseptic technique, he opened the gallbladder and extracted 60 calculi then sutured the gallbladder to the abdominal wall; this was perhaps the first elective surgical procedure for obstructive jaundice (Sims, 1878). In the same year, in Bern, Switzerland, Kocher performed a cholecystostomy in two stages (Glenn, 1971). In the first stage, he packed the wound with gauze to the bottom of the gallbladder, and 8 days later, he emptied the residual stones from the gallbladder. Incidentally, Kocher, who won the Nobel prize in medicine in 1909 for his work on the physiology and surgery of the thyroid gland, also described sphincterotomy, or internal choledochoduodenostomy. His name is remembered by every biliary surgeon who performs mobilization of the duodenum as described by the great master (Kocher, 1903). Kocher originally described the maneuver for use in gastric surgery, but similar to so many other firsts in surgery at that time, the maneuver was first described by Jourdan (1895) and was first performed in biliary surgery by Vautrin (1896). Perhaps the maneuver should be referred to as "Vautrin's maneuver" rather than Kocher's. Tait, the great British surgeon, is given credit for performing the first cholecystostomy for gallbladder lithiasis in one stage. The patient, a 40-year-old woman, survived, and by 1884, he had performed the procedure in 14 cases with only 1 death (Tait, 1885).

The first elective cholecystectomy was done by Langenbuch (Fig. 5). While others were pursuing the construction of biliary fistulae and direct removal of gallstones, Langenbuch observed

FIGURE 4. Theodore Kocher (1841–1917), surgeon.

FIGURE 5. Karl Langenbuch (1846–1901), surgeon.

that because stones were known to recur, others had "busied themselves with the product of the disease, not the disease itself" (Langenbuch, 1882). As he was later to recount, two thoughts kept occurring to him: first, that in animal experiments, Zambeccari in 1630 and Teckoff in 1667 had performed cholecystostomy and cholecystectomy in dogs and had shown that the gallbladder was not essential to life (Langenbuch, 1896); second, that his medical colleagues believed that the gallbladder itself gave rise to stones. He developed the technique for cholecystectomy over several years of cadaver dissection and performed the operation at the Lazarus hospital in Berlin on July 15, 1882. The patient had had biliary colic for 16 years and was addicted to morphine. He was afebrile the day after the operation, had little pain, and was smoking a cigar; the patient was walking at 12 days and left the hospital 6 weeks later, pain free and gaining weight (Traverso, 1976). Report of this case (Langenbuch, 1882) led to a controversy over cholecystostomy as championed by Tait. Langenbuch's operation was the new cholecystectomy.

In 1886, Gaston had tabulated 33 cholecystostomy operations with a mortality of 27% compared with 8 cholecystectomies (5 by Langenbuch) with 1 death recorded, a mortality of 12%. By 1890, 47 cholecystectomies had been done by 27 surgeons, and in 1897, the number had increased to nearly 100 operations with a mortality of less than 20% (Gaston, 1897).

The most important recent advance in surgery of the gallbladder came 100 years after Langenbuch's first cholecystectomy. Laparoscopic cholecystectomy was conceived and first performed in Germany by Muhe in 1985. Between 1985 and 1987, he performed 94 laparoscopic cholecystectomies (Muhe, 1986, 1991). Mouret in Lyon, France, performed the first video laparoscopic cholecystectomy. He did not publish his experience, but the news spread rapidly, and Dubois in Paris published the first series of laparoscopic cholecystectomies (Dubois et al, 1989, 1990). Perissat, working in Bordeaux, further developed the laparoscopic approach and introduced it to the United States in 1989 (Perissat et al, 1990). The procedure has since been extended, so that laparoscopic exploration of the common bile duct is now possible and is routinely carried out. Today, most cholecystectomies are done using laparoscopic techniques, such that the modern surgical trainee often has little or no experience in open cholecystectomy. More recently, cholecystectomy has been done via minimally invasive techniques using robotics (Marescaux et al, 1998; Satava, 1999) to manipulate the instruments.

Not long after the performance of the first cholecystectomy, attempts were made to remove stones from the bile ducts. In 1898, Thornton performed the first removal of a stone from the common bile duct. A year later, Courvoisier operated successfully on another case of choledocholithiasis and published his well-known monograph on the pathology and surgery of the biliary ducts. He also enunciated the law that was to bear his name, which established that in cases of jaundice, if the gallbladder is not distended, the case is more likely to be one of stones. The operative procedure for exploration of the common bile duct for choledocholithiasis was not popularized, however, because of the risk of peritoneal infiltration of bile.

In 1897, Kehr (Fig. 6) performed the procedure and placed a rubber tube in the common bile duct through the cystic duct; this was the first systematic use of biliary intubation. Kehr's name is properly associated with the development of biliary intubation; Kehr (1912) and Quenu and Duval (1908) were

FIGURE 6. Hans Kehr (1862–1916), surgeon.

able to extract stones along the tunnels created by the drainage tubes. These were the precursors for techniques later developed by Mondet (1962) and Mazzariello (1966, 1974). Kehr had developed numerous combinations of drainage in patients with biliary stones, and many other surgeons rapidly developed choledochotomy without suture and using tube drainage.

Surgery of the bile ducts rapidly disseminated across Europe, England, and the United States, and in 1912, Kehr developed what came to be known as the *T-tube*. Not only was choledochotomy simplified, but biliary tract repair was done over these tubes. Kehr became justly famous for his introduction of biliary intubation and was probably the most outstanding biliary surgeon of his day. In 1913, he published a treatise entitled *Surgery of the Biliary Tract,* which for more than 40 years was the most respected text on the subject. Kehr (1908a, 1908b) described the resection of cancerous gallbladders, including hepatic resection, and he resected hepatic tumors and aneurysms of the hepatic artery. He also performed the first hepaticoenteric anastomosis.

Before the development of Kehr's tubes, choledochotomies often became biliary fistulae, either because of residual supraampullary stones, or because the surgeon had inadvertently opened the bile duct proximal to a cancer. German and Austrian surgeons were the first to perform supraduodenal choledochoduodenostomy (Riedel, 1892; Sprengel, 1891). Sprengel's operation described a side-to-side choledochoduodenostomy, and it subsequently became popular in Europe

and the United States (Madden et al, 1965). Cholecystenterostomy also was developed initially by von Winiwarter (1882) and was used later by many surgeons, including Oddi (1888).

Transduodenal surgery was not long in developing. In 1895, Kocher wrote an article on internal choledochoduodenostomy to remove supraampullary choledochal calculi; by 1899 he had performed the operation 20 times. MacBurney (1898) published his experience with duodenostomy and papillotomy in patients with impacted periampullary calculi. These early procedures of a choledochotomy and choledochoenteric anastomosis for the treatment of jaundice and of stones in the biliary tract are still used today, with frequent application of the same principles but with the use of the endoscope.

At about the same time, surgeons began to operate on cancer of the papilla. In Baltimore in 1900, Halsted resected a portion of the duodenum that included a tumor and reimplanted the common duct, at the same time performing a cholecystostomy. He then reoperated to remove the gallbladder. Mayo (1901) reported an operation on a 49-year-old man with papillary cancer. Mayo opened the duodenum, removed the tumor, and carried out a choledochoduodenostomy. This was the first transduodenal ampullectomy. Kausch (1912) in Germany and Harmann (1923) in France gave accounts of resections of ampullary tumors. In Lausanne, Switzerland, Roux, a disciple of Kocher, had described preparation of a "jejunal loop" for use in gastric surgery, and it soon became an adjunct in biliary surgery (Roux, 1897). This Roux-en-Y procedure was soon used by Monprofit (1904) in the performance of cholecystojejunostomy, and he proposed it for hepaticojejunostomy at the French Congress of Surgery in 1908. Dahl (1909), in what he called "a new operation on the bile ducts," was the first to advocate the Roux anastomosis in biliary surgery.

With the advent of cholecystectomy and choledochostomy came the inevitable sequelae of residual bile duct stones and iatrogenic lesions. Initially, these were treated by various forms of intubation, similar to the techniques advocated by Kehr, but many leading surgeons, such as Moynihan and Mayo, used hepaticoduodenal anastomoses (Estefan et al, 1977). Dahl (1909) used the Roux-en-Y loop, but more recently, other authors (Madden et al, 1965; Schein & Gliedman, 1981) have preferred choledochoduodenostomy as described previously.

Operative biliary drainage in upper biliary tract cancer and in patients with severe scarring in the porta hepatis is always difficult. Kehr (1913) successfully performed three operations in which he fixed a jejunal loop to a cut section of a hepatostomy wound; similar procedures were done by others, as cited by Praderi (1982). Longmire and Sanford (1948) performed a similar operation, resecting the end of the left lobe of the liver and anastomosing it to a jejunal loop. This technique, although popular for a short time, was complicated by stenosis and has fallen out of favor.

Goetze (1951) developed a procedure of transanastomotic drainage with a catheter that went through the hepatic parenchyma, the anastomosis, and the jejunal loop. Goetze's contribution was apparently forgotten but was reinvented and popularized by others, including Praderi in 1962 (Praderi, 1982). Praderi argued strongly that Goetze's procedure was the answer to difficult procedures in the high biliary tract but conceded that the development of transhepatic percutaneous cholangiography (Okuda et al, 1974) allowed for the development of transhepatic percutaneous methods for intubation and dilation of the biliary tract, which are now common procedures throughout the world.

The greatest advances in techniques for repair of biliary injuries came from two sources. At the Lahey clinic in the United States, three generations of famous surgeons headed by Lahey, Cattell, and Warren perfected the reconstruction of the common bile duct as an immediate or delayed procedure and splinted their anastomoses with a variety of tubes (Estefan et al, 1977). The results of these techniques were unsatisfactory, with numerous recurrent strictures. However, following the detailed study of the anatomy by Couinaud in France (1954), Hepp and Couinaud (1956) and Soupault and Couinaud (1957) developed techniques for direct biliary–enteric anastomosis, either to the left hepatic duct or to the segment III duct of the left liver. These surgical techniques have become widely accepted and are used throughout the world (Bismuth & Corlette, 1956; Bismuth et al, 1978; Voyles & Blumgart, 1982; Warren & Jefferson, 1973).

Pancreas

Like liver surgery, pancreatic surgery developed largely as a result of responding to wounds inflicted in wars. Claessen (1842), Ancelet (1866), Da Costa (1858), and Nimier (1893) documented the early development of pancreatic surgery. In 1923, Harmann wrote an extensive review of the French, German, and English literature. Early efforts at elective pancreatic surgery largely revolved around drainage of cysts (Thiersch, 1881). In 1883, Gussenbauer marsupialized a pancreatic pseudocyst, and the patient survived. Other surgeons, including Senn (1886), soon performed similar procedures.

Direct anastomosis of the pancreas to the gastrointestinal tract followed in the early part of the twentieth century, when Coffey (1909) performed an anastomosis of the tail of the pancreas to the small bowel. Ombredanne (1911) anastomosed a pancreatic cyst to the duodenum, and Jedlicka (1923) anastomosed a cyst to the posterior wall of the stomach. Chesterman (1943) performed a cystojejunostomy, and König (1946) carried out the same operation to a Roux-en-Y loop of jejunum.

Operations for pancreatic tumors were being done at about the same time. Ruggi (1890) reported a resection of a large lesion of the tail of the pancreas, and Briggs (1890) performed a similar operation. Biondi (1897) reported resection of a tumor arising from the inferior part of the head of the pancreas, and the patient was still alive 18 months later.

Whipple (Fig. 7) and associates (1935) published a technique for cephalic duodenopancreatectomy, done in two stages, for cancer of the ampulla of Vater. In the first operation, they performed a cholecystogastrostomy and gastroenterostomy. In the second and subsequent procedure, they resected the head of the pancreas with a portion of the duodenum without anastomosis to the stump of the pancreas, which they sutured. Whipple (1941) subsequently performed this operation in one stage and reported 41 cases with a mortality of 27%. Eventually, the technique of this operation was perfected. Although English-speaking surgeons throughout the world continue to call this operation "Whipple's operation," the procedure had been done many years before.

Sauve (1908) reviewed the literature on pancreatectomy and reported that several surgeons had resected small tumors from the head of the pancreas, and larger ones from the body of the organ, without touching the duodenum. Codivilla of Italy is

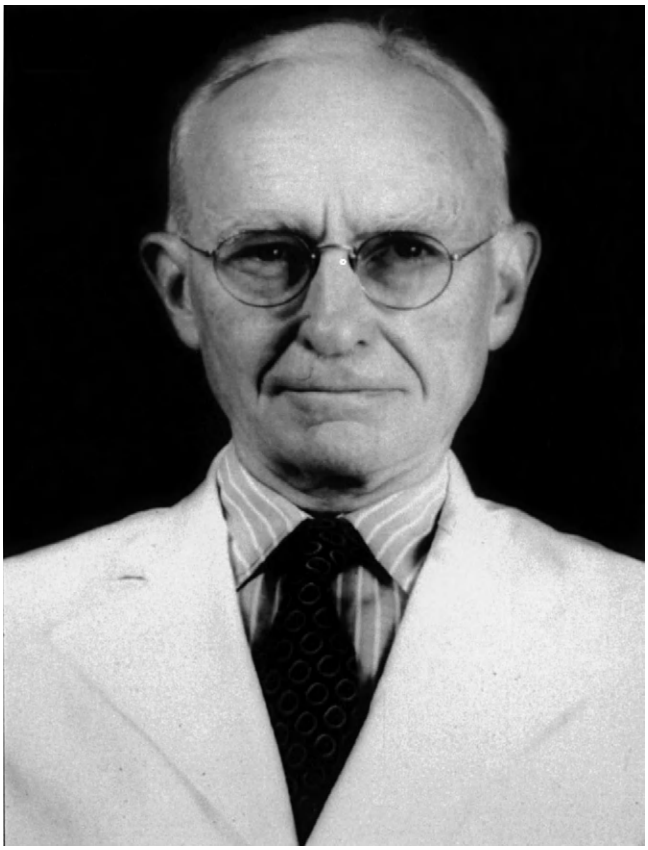

FIGURE 7. Allen O. Whipple (1881–1963), surgeon.

reported to have resected the duodenum and head of the pancreas and performed a cholecystojejunostomy in 1898, but the patient died in the postoperative period. The first surgeon to perform cephalic pancreaticoduodenectomy successfully was Kausch, a professor of surgery in Breslau and later in Berlin. On June 15, 1909, he performed a cholecystojejunostomy on a jaundiced 49-year-old man; on August 21, 1909, Kausch reoperated, performing a posterolateral gastroenterostomy and resection of the head of the pancreas with the tumor, the pylorus, and the first and second part of the duodenum. He anastomosed the third portion of the duodenum to the pancreatic stump. Kausch (1912) published a report entitled "Cancer of the Duodenal Papilla and Its Radical Treatment." He gathered in that publication all reports that included excisions of the papilla. Tenani (1922) reproduced this operation with success, also in two stages but with one difference: Tenani performed a choledochojejunostomy, and the patient survived 3 years. Kausch and Tenani, although cited by Whipple (1941), are generally ignored in the English and American literature.

Resection later was extended to deal with cancers of the common bile duct and of the duodenum (cancers of the proximal bile duct are described subsequently in the section on liver surgery). Recognition of endocrine tumors of the pancreas later led to operations for these conditions. Wilder and colleagues (1927) reported the first case of resection of an insulinoma arising from the islet cells of the pancreas. Mayo operated on a patient in whom he found a tumor of the pancreas with metastases to the liver, and an extract from one of the metastases produced an insulin-type reaction when injected into a rabbit. Graham and Hartman (1934) reported subtotal pancreatectomy for hypoglycemia, and total pancreatectomy was performed by Priestley and colleagues (1944) for a patient in whom there was proven hyperinsulinism, but no tumor of the pancreas was to be found. The patient was cured by the operation, and the small tumor causing the syndrome was discovered during the pathologic examination.

Later, Fallis and Szilagyi (1948) performed total pancreatectomy for cancer, and this procedure was developed further in the hope that total removal of the gland would reduce morbidity and mortality and perhaps lead to better results. ReMine and colleagues (1970) and Brooks and Culebras (1976) adopted this approach, but early suggestions regarding efficacy were not fulfilled, and total pancreatectomy for pancreatic cancer has largely been abandoned. Fortner (1973) described the even more extensive procedure of regional pancreatectomy. The operation included an extensive total pancreatectomy and resection of the pancreatic segment of the portal vein—and sometimes the hepatic and superior mesenteric arteries, if these vessels were invaded by tumor—together with subtotal gastrectomy and regional lymph node dissection. Fortner's results have not been reproduced by others.

Surgery for pancreatitis also developed over the same period, and the severity of acute pancreatitis was recognized. Ockinczyc (1933) revealed the frustration of the times when he advocated "the use of drainage of the pancreas and hope." Because the mortality of emergency surgery reached 78%, the conservative approach to acute pancreatitis was advocated. Nevertheless, some patients with acute pancreatitis still came to operation because of the necessity to treat gallstones and pancreatitis or to deal with complications, such as abscess and pseudocyst (Cattell & Warren, 1953).

The development of intensive care, antibiotics, and better metabolic management of patients with acute pancreatitis led to improvements in outcome, although the death rates remained unacceptably high. Ranson and colleagues (1976) and Imrie (1978) made important contributions in that they defined the evaluation of the severity of an attack. The surgical treatments of abscess and peritonitis were made systematic. The role of gallstones in acute pancreatitis was defined, particularly by Acosta and Ledesma (1974), and endoscopic papillotomy to extract calculi impacted at the papilla of Vater was also described.

Surgical procedures aimed at the treatment of chronic pancreatitis had been developing since the beginning of the twentieth century. As mentioned previously, Coffey (1909) had anastomosed the tail of the pancreas to a loop of jejunum, and in 1953, Link reported external drainage of a pancreatic duct in a patient who lived for a prolonged period but expelled calculi periodically from the fistula tract. Roget (1958) described 50 cases treated this way, but only a few patients were cured by drainage. Doubilet and Mulholland (1948) attempted sphincterotomy in the treatment of pancreatitis. As a result of the success of cystojejunostomy in the treatment of pancreatic pseudocyst mentioned earlier, Cattell in 1947 used a side-to-side anastomosis between a loop of jejunum and the pancreatic duct in an attempt to relieve pain in a patient with cancer of the head of the pancreas. Subsequently, Longmire and associates (1956) carried out end-to-end pancreaticojejunostomy to a Roux-en-Y loop of jejunum; however, this procedure proved unsuccessful. Du Val (1957) performed a similar operation in an attempt to drain the pancreatic duct, but this too was unsuccessful.

Leger and Brehand (1956) and von Puestow and Gillespy (1958) performed pancreatic ductal drainage in chronic pancreatitis patients for the relief of pain. Longitudinal opening of the pancreactic duct allowed better decompression after anastomosis to a jejunal loop. Mercadier (1964) performed a similar operation without the need for splenectomy, and further technical variations were introduced more recently by Prinz and Greenlee in 1981 and by Frey and Smith in 1987. Mallet-Guy (1952) and Mercadier (1964) performed resection of the left pancreas for chronic pancreatitis. This approach subsequently was extended, so that only a small portion of the head of the pancreas remained. A more modern approach aimed at conserving pancreatic parenchyma has since been developed (Beger et al, 1985) and was further promoted by Buchler and collegues (Di Sebastiano et al, 2007).

LIVER SURGERY

Liver surgery has evolved from being almost nonexistent to comprising a repertoire of operations that can safely remove nearly any amount of liver tissue (Chakravorty & Wanebo, 1987; Fortner & Blumgart, 2001). These operations are now performed at numerous hospitals and medical centers throughout the world. Courageous surgeons were enabled by extraordinary developments in anesthesiology, blood transfusion, infectious disease, and radiologic imaging.

Features of the anatomy and physiology of the liver that allow major resection were known in ancient times. The structural arrangement of the liver into lobes was apparent to individuals preparing animals for food or for ceremony or to those preparing humans for mummification. Two other properties of the liver, functional reserve and rapid regeneration, were suggested by the early Greek mythology of Prometheus, in which Prometheus's liver grew back nightly after the eagle's daily and apparently bloodless "resections." This oft-cited myth does not necessarily mean that the ancient Greeks knew about liver regeneration; however, more recent evidence provides dramatic proof of the liver's power to grow back rapidly (Blumgart et al, 1971).

Knowledge of the liver's lobar and segmental structures, functional reserves, and capacity to regenerate and the prevention of hemorrhage are essential for major surgical resection. This knowledge also is relevant to transplantation, particularly of split-liver homograft transplantation and in the use of living, related donors.

Early descriptions of operations on the liver usually concerned complete or partial avulsion of some portion that was protruding externally as a result of abdominal trauma. Berta in 1716 amputated a portion of liver protruding from the abdomen after a wound, and Von Bruns in 1870 (Beck, 1902) removed a lacerated part of the liver of a soldier wounded in battle. Despite these anecdotal descriptions, true hepatobiliary operations were not possible until the advent of anesthesia (Fig. 8) and antisepsis (Lister, 1867a, 1867b; Fig. 9). Although Warvi (1945) recounted that Couzins performed a liver resection in 1874, Langenbuch (1888) recorded the first planned hepatic resection in Germany. In the United States, Tiffany (1890) resected a liver tumor, and Lucke (1891) reported a liver resection for cancer. Keen (1899) in the United States reported 76 liver resections, of which 37 were for benign or malignant tumors.

About the time of these surgical developments, Rex (1888) and later Cantlie (1897a, 1897b) did detailed anatomic studies of the liver and its intrahepatic architecture. These studies established the lobar and segmental structure of the liver and of the Glissonian sheath enclosing structures that enter or leave the organ at the porta hepatis. They delineated the planes within the parenchyma of the organ that were relatively devoid of major blood vessels and bile ducts. These descriptions would make possible controlled hepatic resection.

FIGURE 8. Ether anesthesia. The first public demonstration of surgical anesthesia was given in Boston by Professor J.C. Warren and W.T.G. Morton on October 16, 1846. This photograph depicts a second procedure carried out on October 17th.

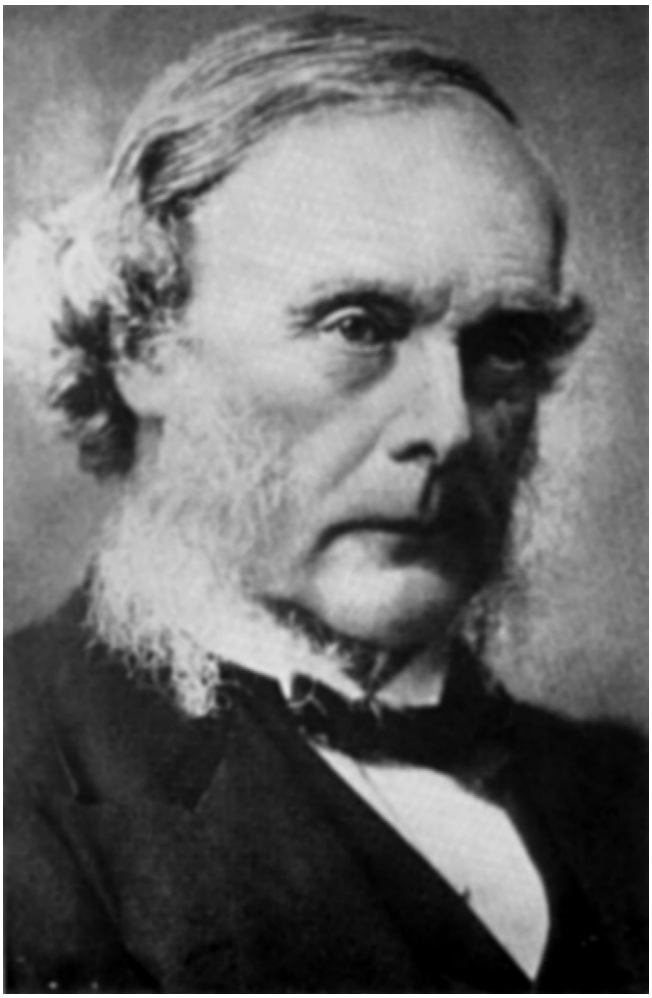

FIGURE 9. Joseph Lister (1827–1927), surgeon.

Surgeons quickly learned to fear the liver's friability and capacity for bleeding and its propensity for biliary leakage after operation. Elliot (1897) wrote that the liver is "so friable, so full of gaping vessels and so evidently incapable of being sutured that it seemed impossible to successfully manage large wounds of its substance." Kousnetzoff and Pensky (1896) reported, however, passing ligatures in the liver substance at a sufficient distance from the margins of the wound to ensure that they would not slip, and reported that, by pulling these up tightly, it was possible to allow them to cut into the liver parenchyma and compress the blood vessels. In writing about surgical approaches for parenchymal transection of the liver and the arrest of bleeding during operations on the liver, Garre (1907) paid respect to Kousnetzoff and Pensky's work, in which they had essentially shown that the vessels in human liver are no less resistant than arteries and veins of similar caliber in other parts of the body, and that they were suitable for ligature. These basic techniques for suture of the liver substance and ligation of vessels as a means of controlling hemorrhage have persisted to modern times and find recent application in the control of the pedicles of the liver within its parenchyma, as described by Ton (1979), and more recently in approaches to the control of the pedicles of the liver described by Couinaud (1954), Patel and Couinaud (1952a, 1952b), Takasaki and others (1986), and as developed and practiced by Launois and Jamieson (1992). Although ligatures and suture ligation remain the basic mainstays for the control of intrahepatic vessels, stapling techniques are now used for the same purpose (Fong & Blumgart, 1997).

Garre (1907) described the use of Doyen's elastic stomach clamp to provide compression of the liver before it is transected, and he referred to the work of Masnata and Lollini in Bologna, who used a similar clamp. This method also has been used more recently by Storm and Longmire (1971) and Balasegaram (1972a, 1972b). Although almost totally abandoned in recent times, such clamps still are occasionally employed. Garre (1907) mentioned attempts to provide perforated plates to be used on either side of a wound of the liver, through which sutures could be passed to allow compression of liver tissue and bleeding vessels. This technique also was conceived more recently for the management of bleeding after elective liver resection (Wood et al, 1976) and for the control of bleeding from liver injury (Berne & Donovan, 2000).

Garre (1907) also emphasized the use of packing bleeding hepatic wounds, and he advocated that packing ought to be considered more frequently in cases of injury; this, too, was prophetic. Having passed through the phases of vascular ligation and hepatic resection for wounds of the liver, modern surgeons now rely much more frequently on packing to control oozing and hemorrhage for ragged and exposed liver lacerations (Berne & Donovan, 2000). The use of such packing recognizes, but does not specifically state, that major hemorrhage in the liver does not usually occur from the cut surface of the parenchyma but rather occurs from the main hepatic veins or lacerations to the vena cava.

In a seminal contribution in 1908, Pringle described a method of temporarily compressing the portal inflow vessels so as to reduce liver bleeding, but all eight patients he described died during surgery or shortly thereafter. Later, Pringle described the method as being uniformly successful in animals and used the technique successfully on a patient. This technique has been used ever since to control hepatic inflow, and although initially used to occlude the inflow for periods of 1 hour or more, it is now employed in an intermittent fashion.

The early understanding of liver structure and function and of the first operations on the liver in the latter half of the nineteenth century set the scene for the rapid advances of the twentieth century. Not only did anatomic description reach a high level of accuracy relevant to the operating surgeon, advances in operative technique and extraordinary developments in diagnostic imaging as outlined previously allowed the flowering of hepatobiliary surgery as a specialty.

Major Hepatic Resection

Wendell (1911) was the first to perform a successful right hepatic lobar resection using hilar ligation. Nevertheless, his achievement was lost to his colleagues for many years, and it was not until the detailed anatomic studies of Hjortsjo in 1951, Healey and Schroy in 1953, and Couinaud in 1954 that the concept of segmental anatomy as originally described by Rex and Cantlie was finally accepted. Couinaud's (Fig. 10) seminal work in 1954 simplified the understanding of segmental liver anatomy and made it easily applicable by numbering the liver segments I through VIII. Goldsmith and Woodburne (1957) used a different nomenclature but subdivided the liver similarly. Subsequent refinements in the description of the liver were

FIGURE 10. Claude Couinaud (1922–2008), surgical anatomist.

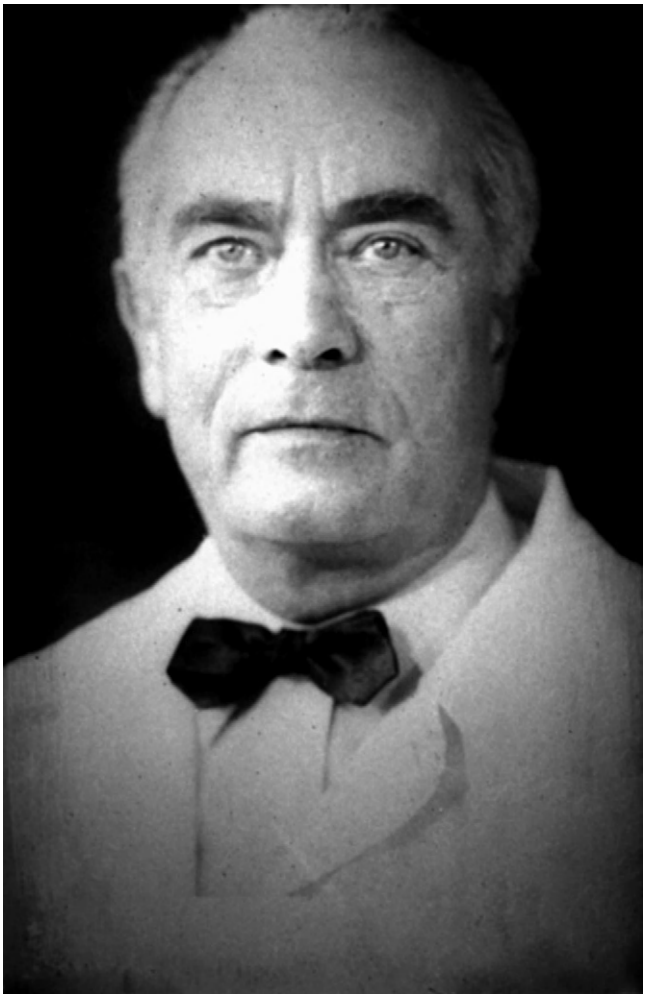

FIGURE 11. Jean Louis Lortat-Jacob (1908–1992), surgeon.

offered by Couinaud (1981) in a monograph, which contributed greatly to the understanding of practical surgical anatomy.

In 1950, Honjo published a case of anatomic right hepatectomy; the operation was performed in Kyoto, Japan, on March 7, 1949, and was later reported by Honjo and Araki (1955) in English. In 1952, Lortat-Jacob (Fig. 11) and Robert performed a true anatomic liver resection with preliminary vascular control. These reports opened the way for the development of liver surgery. Lortat-Jacob's operation captured much attention, and many further case reports followed. As recounted by Fortner and Blumgart (2001), at the Southern Surgical Association's meeting in the United States on December 10, 1952, Quattlebaum (1953) described a right hepatic lobectomy for hepatoma. The operation had been done about 4 months after that of Lortat-Jacob and Robert. Apparently unaware of Quattlebaum's achievement, and thinking he would be the first to do a so-called right hepatic lobectomy in the United States, Pack at Memorial Sloan–Kettering Cancer Center in New York performed the operation on a 40-year-old woman on December 14, 1952 (Pack et al, 1955).

Pack and colleagues (1962) recognized quickly the opportunity to study liver regeneration. Their studies were the first to describe and document regeneration of the human liver after major resection and suggested that complete regeneration occurs over 3 to 6 months. Later, Lin and Chen (1965) studied metabolic function and regeneration of the cirrhotic liver and found no discernible regeneration after resection. Blumgart and colleagues (1971) described the speed of liver regeneration as recovery of liver size within 10 to 11 days after major hepatic resection for trauma.

Contrary to the trends toward anatomic precision, Lin (1958) advocated a finger-fracture technique for liver resection, removing a hepatic lobe in 10 minutes with an average of 2000 mL of blood replacement. The surgical bluntness of this approach and the absence of the customary surgical principles and techniques precluded widespread acceptance of the technique. Similarly, a prominent figure in the early development of liver surgery, Brunschwig (1953; Serrea & Brunschwig, 1955) advocated nonanatomic resection, but his results—with a very high operative mortality for so-called simple right lobectomy, mostly from uncontrolled hemorrhage—led him to accept the approach of Lortat-Jacob. Brunschwig's report of long-term survivors after hepatic resection for advanced cancer challenged the prevailing skepticism about resecting liver tumors.

The laparothoracotomy approach of Lortat-Jacob and Robert in 1952 quickly became the standard for major hepatic resection. Opening the chest added operating time and increased morbidity but gave needed exposure to the liver. Later, the introduction of costal arch retractors made thoracotomy

extension obsolete for most hepatic resections. Steps generally considered unnecessary, such as T-tube drainage of the common bile duct, were eliminated in the 1970s. Opinions were divided in the 1970s and 1980s about the superiority of either intrahepatic or extrahepatic management of the major hepatic veins. Closed drainage was substituted for multiple Penrose drains and packing, although these were still advocated by some in the 1980s. Many hepatic resections have been done without drainage, as described by Franco and associates (1989) and subsequently at Memorial Sloan–Kettering Cancer Center (Fong et al, 1996).

Methods for anatomically based segmental liver resection that conserves parenchyma were developed and have proved valuable in hepatic resection for tumor. Numerous methods to transect the liver parenchyma had been advocated, including the knife handle (Quattlebaum, 1953), nitrogen knife (Serrea & Brunschwig, 1955), electrocautery (Fortner et al, 1978), microwave tissue coagulator (Tabuse, 1979), waterjet (Papachristou & Barters, 1982), ultrasonic aspiration dissector (Hodgson & DelGuercio, 1984), and harmonic scalpel; other techniques are described on an almost daily basis, and simple crushing of the liver tissue remains in use by many.

Bleeding has remained a problem in many cases, and preliminary vascular control is difficult or impossible in some clinical settings. Inflow occlusion using the Pringle maneuver for longer than 15 to 20 minutes was considered hazardous. Local and general hypothermia was used in an effort to increase the liver's tolerance of the presumed ischemic anoxia associated with the procedure (Longmire & Marable, 1961). More complete vascular control was obtained by Heaney and colleagues (1966), without hypothermia, by employing aortic cross clamping and temporary occlusion of the porta hepatis and vena cava for 24 minutes without ill effect. Fortner and colleagues (1971) described isolation-hypothermic perfusion of the liver, making prolonged vascular isolation for complicated resections possible. Huguet and associates (1978) challenged the long-held belief that the liver could tolerate only 15 to 20 minutes of normothermic perfusion by extending the period to 65 minutes. This observation was subsequently confirmed (Bismuth et al, 1989; Huguet et al, 1992, 1994). As described previously, however, major bleeding during liver resection usually arises from the major hepatic veins or vena cava, and development of techniques of low central venous pressure anesthesia during liver resection, as first described by Blumgart and colleagues (Cunningham et al, 1994, Melendez et al, 1998), have proved simple and efficacious and have rendered vascular isolation techniques rarely necessary (Jarnagin et al, 2002).

Apart from hepatic resection, many other techniques for the enucleation of tumors and of hydatid cysts have been developed. Garre (1907) had first noted that if he kept close to the line of the dense membrane around hydatid cysts—so as not to enter the tissues of the liver too deeply, where large vessels may be encountered—it was possible to resect such lesions with minimal blood loss. Enucleative techniques are now used by contemporary surgeons, not only for the removal of hydatid cysts but also for the enucleation of giant hemangiomata (Baer et al, 1992; Blumgart et al, 2000; Hochwald & Blumgart, 2000). As described in this book, enucleation also may be used for resection of certain neoplasms of the liver, such as fibronodular hyperplasia.

The widespread use of laparoscopic cholecystectomy led to the development of techniques for laparoscopic resection of the liver. First used by Gagner and colleagues (1992), laparoscopic partial hepatectomy has been used by many surgeons. Ferzli and colleagues (1995) and Azagra and colleagues (1996) developed the operation for anatomic resection of the left lateral segment, and most operations have involved this procedure. More recently, major hepatectomy has been performed using laparoscopic techniques. Experience is limited, however, and the indications and place of laparoscopic liver resection are under active investigation.

Liver Tumors

The management of liver tumors has a relatively short history. After the initial reports of hepatic resection for tumors performed by Langenbuch (1888), Tiffany (1890), Lucke (1891), and Keen (1899), no significant reports were published until Foster's review in 1970 of a multiinstitutional survey conducted on 296 adults who had liver resection for primary cancer and were followed for at least 5 years or until death. The operative mortality rate was 24%. Foster also studied the records of 115 patients who had had hepatic resection for metastatic colorectal cancer. Operative mortality was 17.3%, and 21% survived for at least 5 years. Hemorrhage during operation was still a problem, and the operative mortality rate was essentially the same or higher than the cure rate so that skeptics remained unconvinced.

In the 1970s, major hepatic resection for tumors became more frequent, and this coincided with improvements in anesthesia, surgical technique, postoperative support, and significantly with the development of better imaging modalities. In the United States, Wilson and Adson (1976), Fortner and colleagues (1974), and Thompson and colleagues (1983) were major figures in this area of endeavor. In Asia, Ong (1977) and others were early explorers in the field, and other major centers made significant technical improvements with encouraging results (Attiyeh et al, 1978; Cady et al, 1979; Starzl et al, 1975).

Morbidity and mortality rates decreased dramatically, and major centers began to provide encouraging preliminary long-term survival figures. As described by Fortner and Blumgart (2001), by the 1980s, the early reluctance by many surgeons to accept the therapeutic benefit of hepatic resection for tumors faded before the onslaught of encouraging reports from a variety of institutions in the United States, Europe, and Southeast Asia.

Methods for limiting the extent of the parenchymal transection developed along with the emergence of surgical resection for tumors in cirrhotic and noncirrhotic livers. Although suggested originally by Pack and Miller (1961) and by McBride and Wallace (1972), Asian and European surgeons soon assumed a leadership role in developing isolated segmental resection and described various operations (Bismuth et al, 1982; Hasegawa et al, 1989; Scheele, 1989; Ton, 1979). The development of reliable intraoperative ultrasound allowed further developments in liver resection (Bismuth et al, 1982; Makuuchi et al, 1985), and subsegmental resection was developed. More recently, the segmental approach was reported and popularized in the United States, particularly by Blumgart and others (Billingsley et al, 1998; DeMatteo et al, 2000). The difficulty of the approach to the caudate lobe was addressed, and the surgical anatomy and technique for caudate resection, either as an isolated segment (Lerut et al, 1990) or in combination with major resections, was described by Blumgart and colleagues (Bartlett et al, 1996).

Probes to perform cryosurgical ablation were developed (Ravikumar & Kaleya, 2000), and cryosurgery-assisted segmental resection has been described (Polk et al, 1995). Radiofrequency ablation for liver tumors also has been evaluated (Curley et al, 1999; Wood et al, 2000). In the future, surgeons may perform controlled tumor ablation or hepatic resection for tumors using robotic techniques and refinements in the development of virtual reality techniques (Marescaux et al, 1998; Satava, 1999). Image-guided surgery opens great possibilities for developments in hepatic surgery in the future.

The evolution of liver surgery for cancer was influenced profoundly by the geographic distribution of the disease. Surgeons in the United States and Europe were confronted much more often with metastatic cancer or hepatocellular carcinoma (HCC) in otherwise normal livers. In the 1980s and early 1990s, surgeons in the United States had no great drive to conserve normal liver tissue. By contrast, surgeons in Asia were confronted frequently with HCC in patients with hepatitis B and cirrhosis of the liver. Estimating the functional reserve of the cirrhotic liver became a major concern, and methods for limiting the resection of nontumorous liver were developed. Screening programs for the detection of HCC at an early stage were a natural corollary.

Primary liver cancer (HCC) occurs mainly in areas where viral hepatitis is endemic. Because of the prevalence of hepatitis B infection in Southeast Asia, most of the initial, significant, published experiences examining the treatment of primary HCC are from Southeast Asia. Improved diagnostic and surgical approaches in Japan permitted the Liver Cancer Study Group of Japan (1990) to report a 5-year survival rate of 57.5% for HCC; a high proportion of the cases were small, encapsulated tumors. From China, Tang (1993) reported a 5-year survival rate of 40.2%.

In the West, experience with HCC differed from that reported in the East in material ways: tumors were generally large at presentation, the incidence of viral hepatitis was much lower, and many patients did not have underlying cirrhosis. There were several reports of surgical mortality rates for hepatic resection in cirrhotic patients, ranging from 15% to 100%. In recent years, spread of hepatitis B and hepatitis C has changed the demographics of the disease in the United States and in Western Europe. This change has allowed a much greater surgical experience, and better techniques and improved patient selection have led to vastly improved results. Blumgart's group (Fong et al, 1999) reported a mortality rate of 5% in 100 resections, 57 being major resections, in patients with HCC and cirrhosis, and a 5-year survival of 37% was reported among patients operated on since 1990.

Today the surgical mortality rate in noncirrhotic patients, even for the most extensive resections, is uniformly less than 5% in major centers. The overall 5-year survival is approximately 35% in patients with HCC reported from Western series, in which small HCC is relatively rare (Bismuth et al, 1986; Ringe et al, 1991). In a study reported by Blumgart and others (Fong et al, 1999), patients who had HCC with a median tumor size of 10 cm but no cirrhosis had hepatic resection with a surgical mortality of 3.7% and a 5-year survival of 42%. Although survival rates have not changed substantially, a great improvement has been seen in morbidity and mortality.

In recent years, a move toward hepatic transplantation has been seen in selected patients with small HCCs within a cirrhotic liver. Patients with small HCCs and compromised liver function seem to be ideal candidates for total hepatectomy and allotransplantation.

The treatment of metastatic liver tumors by hepatic resection was viewed initially as highly dubious. Many regarded the removal of tumor from the liver by hepatic resection as an irrational approach. The natural history of colorectal cancer offered the opportunity for resection of liver metastases more often than any other cancer in Western countries. The multiinstitutional report from Foster (1970) in the United States suggested a 5-year survival rate of 25%, and multiple other reports supported that view. However, the question remained: How long could patients have lived without surgical operations?

A landmark article from Glasgow (Wood et al, 1976) described the natural history of colorectal hepatic metastases. It was shown that survival depended on the extent of the disease, and that multiple bilobar metastases indicated a much more serious prognosis than single or multiple nodules on one side of the liver. In Wood's study, only one patient survived for 5 years (1%). It was clear that if the operative mortality declined, as it had in many reported series, the issue was closed. A major study from Memorial Sloan–Kettering Cancer Center (Fong et al, 1999) described the results in 1,001 consecutive patients with a 5-year overall survival of 37% and an operative mortality rate of 3.4%. Five-year survival reached more than 50% in patients with favorable prognostic factors. Tumor recurrence with the liver being the only site of recurrence is common, and such hepatic recurrences are often amenable to repeated resections, with risks and results similar to those of the initial operation (Elias et al, 1992; Fong et al, 1994; Scheele & Stangl, 2000).

More recently the Memorial Sloan-Kettering Cancer Group reported 1,600 patients with metastatic colorectal cancer treated since 1985 (House et al, 2010) and showed an improvement of results over time with results between 1999 and 2004 showing a 5-year survival of 51% in 563 patients, who had an operative mortality of only 1%.

Pichlmayr and colleagues (1990) did the first ex situ tumor resection on the liver, removing the liver for bench surgery, then autotransplanting it back into the patient. The liver was preserved by hypothermic perfusion, as had been described earlier for the in situ procedure (Fortner et al, 1974). This approach may prove to have merit in highly selected cases, but it has not been accepted generally.

Although initially completely ineffective, systemic chemotherapy improved dramatically with the development of new agents, and its use as a neoadjuvant agent and as adjuvant chemotherapy after resection has been extensively explored. The use of neoadjuvant chemotherapy to convert unresectable tumors to resectable ones was reported by Bismuth and colleagues (1996), and extensive studies were reported regarding the possible benefits of chemotherapy after hepatic resection using hepatic arterial infusion of chemotherapy (Kemeny et al, 1999). Kemeny's study followed the demonstration in 1982 by Ensminger and colleagues of an implantable pump for hepatic arterial infusion therapy. Others have studied regression of advanced refractory cancer in the liver using isolated hepatic perfusion chemotherapy (Alexander et al, 2000).

As described in this book, hepatic resection also has been shown to yield satisfactory results in terms of relief of symptoms and prolonging of life in the management of hepatic metastases from neuroendocrine cancer and sarcoma. Hepatic resection for biliary and gallbladder cancer also has developed in a

remarkable fashion. Launois and associates in France (1979) reported the first major series of patients in whom hepatic resection was performed to ensure clearance of hilar cholangiocarcinoma. Working contemporaneously, Fortner and colleagues (1976) and Blumgart and Beazley and associates (Beazley et al, 1984; Blumgart et al, 1984) reported similar results, and in some patients, hepatic resection was accompanied by resection of the portal vein and portal venous reconstruction (Blumgart et al, 1984). Multiple other reports have confirmed that hepatic resection offers advantages in the management of hilar cholangiocarcinoma and helps achieve negative tumor margins and that this is associated with long-term survival (Hadjis et al, 1990; Jarnagin et al, 2001; Klempnauer et al, 1997; Nimura et al, 1990). Surgeons in Southeast Asia and Japan have contributed considerably in this area and in particular have contributed to the development of caudate lobe resection and vascular reconstruction (Mizumoto & Suzuki, 1988; Nimura et al, 1990).

Pack and colleagues (1955) advocated a similar radical approach for gallbladder cancer. They believed that an extended right hepatic lobectomy had its greatest applicability for gallbladder cancer, and they recommended an en bloc lymph node resection of the porta hepatis to be included with the operation. Brasfield (1956) reported a microscopic focus of metastatic cancer in a patient without gross liver involvement and helped establish the need for hepatic resection for gallbladder cancer. More recent reports indicate that for more invasive lesions and for patients seen after initial cholecystectomy, at which cancer was inadvertently found, an extensive resection seems to be effective (Fong et al, 2000). Fortner and colleagues (1970) performed total hepatectomy and orthotopic liver transplantation in two such patients with short-term survival.

Tumor ablation has been a major feature of the recent history of liver surgery for tumors. Cryosurgery (Adam et al, 1997; Crews et al, 1997; Zhou et al, 1988) has been used for treatment of small tumors and for the management of recurrent disease after resection or for the management of unresectable tumors in combination with chemotherapy. More recently, radiofrequency ablation of tumors has been developed, and its use in primary and metastatic cancer has been reported (Curley et al, 1999; Wood et al, 2000). This technology is still being explored, but it seems to have limitations similar to those of cryosurgery in that tumor cell necrosis is inadequate, particularly when the tumor is located close to large blood vessels. The technique can be used percutaneously, but as with cryosurgery, local recurrence remains a problem.

Ethanol injection has been used in the management of small HCCs (Ebara et al, 1990; Tanikawa, 1991). It is of particular interest because it is inexpensive, widely available, and easily used with a low complication rate even in poor-risk patients, and it can be repeated frequently. Hepatic arterial embolization can also be used to ablate tumors and may be particularly effective in primary HCCs and in metastatic tumors arising from primary neuroendocrine sources (Allison et al, 1977; Allison, 1978).

Liver Transplantation

Starzl (2001) has provided a fascinating overview of the origins of clinical organ transplantation. A historical consensus development conference was convened in March 1999 at the University of California, Los Angeles, to identify the principal milestones leading to the clinical use of various transplantation procedures; the conclusions were published in the July 2000 issue of the *World Journal of Surgery* (Groth & Longmire, 2000). The early history of the evolution of organ transplantation followed the first convincing evidence that organ rejection is a host-versus-graft immune response (Gibson & Medawar, 1943; Medawar, 1944). For further details, the reader is referred to the publications of Starzl (2001) and of Murray and Hills (2005). This portion of the review of the history of liver surgery is concerned with the history of liver transplantation.

In a magnificent leap forward, Starzl (Fig. 12) and associates (1968) in the United States did the first successful total hepatectomy with orthotopic liver transplantation. Calne and Williams (1968) in the United Kingdom reported similar studies. The contributions of both groups to the development of liver transplantation and immunosuppressive therapy have been monumental. Fortner and colleagues (1970) reported the first successful heterotopic (auxillary) liver homograft. This contribution was the forerunner of the further development of heterotopic liver transplantation and of split-liver and living related-donor transplants. Liver transplantation underwent continued evolution despite the only modestly effective immunosuppressive therapy initially available. One-year survival

FIGURE 12. Thomas Starzl (1926–), surgeon.

rates slowly reached 50% by 1979 (Calne & Williams, 1979; Starzl et al, 1979). Chronic infection, rejection, and surgical infections diminished the small group to only a few long-term survivors. The report in 1979 of immunosuppression with cyclosporine by Calne and associates (1979) transformed the field rapidly. A consensus conference held in 1983 declared that liver transplantation was now an acceptable therapy and no longer an experimental procedure. Zeevi and colleagues (1987) reported on another powerful immunosuppressive agent, tacrolimus.

Serious complications of immunosuppressive therapy for liver and other organ transplants have been described, including de novo malignancy (Penn, 1988; Penn & Brunson, 1988; Penn & Starzl, 1972). In 1988, Iwatsuki and associates reported an overall 54% survival of patients at 5 years. Development was rapid, and by 1992, more than 3,000 orthotopic liver transplantations were done annually in the United States (United Network for Organ Sharing).

Total hepatectomy and liver transplantation were initially disappointing for liver cancer. Iwatsuki and colleagues (1988) reported that three of every four patients who lived at least 2 months after transplantation for cancer had recurrence, and adjuvant chemotherapy had no demonstrable benefit. Ringe and associates (1989) reported a 5-year survival of 15.2% for such patients, and Calne and colleagues (1986) had similar results. The best results and apparent cure were obtained when a cancer was an incidental finding in a liver removed for noncancerous disease (e.g., alcoholic cirrhosis). Geevarghese and associates (1998) reported an 1-year survival of 85% and a 5-year survival of 78% for such cases.

Current adjuvant chemotherapy may improve the results. Olthoff and colleagues (1995) reported a 3-year survival of 45% using fluorouracil, doxorubicin, and cisplatin, but only three survivors had cancers larger than 5 cm. Laine and associates (1999) reported five children with advanced hepatoma who were alive at a mean of 4.6 years after transplantation preceded by induction chemotherapy.

Improved immunosuppression has allowed surgical techniques to blossom. Bismuth and Houssin (1984) reported reduced-size orthotopic liver grafts in children, and Pichlmayr and colleagues (1988) reported the use of one donor liver for two recipients (split-liver transplantation). Raia and associates (1989), in a letter to the *Lancet,* and Strong and colleagues (1990) were the first to report living-donor liver transplantation using segments II and III of the liver; Yamaoka and colleagues (1994) reported using the right lobe of the liver. Use of split-liver grafts and living, related donors for grafts of both the right and left lobes has been driven by cultural restrictions and by a shortage of donor organs. This has been a major development, and the potential for mortality and morbidity not only of recipients but also of the live donors has remained a major ethical concern.

Liver transplantation for tumors has evolved considerably in the field of primary HCC. Although liver resection remains the treatment of choice for HCC in patients with good liver function, similar patients with compromised liver function and patients with hepatitis C and a small tumor in a portion of the liver geographically unfavorable for resection are now considered best treated by liver transplantation. Liver transplantation has come to be a recognized therapy for many patients with small HCCs (Bismuth et al, 1999), a wide range of benign disease, and in particular for patients with compromised liver function as a result of cirrhosis of the liver, Budd–Chiari syndrome, polycystic liver and kidney disease, sclerosing cholangitis, and for patients with a wide variety of other parenchymal and metabolic liver diseases. Liver transplantation for patients with hilar cholangiocarcinoma is under investigation and is occasionally indicated for patients with widespread neuroendocrine metastatic disease of the liver. Patients with metastatic disease from adenocarcinoma have had poor results, and transplantation is no longer used for this indication.

In writing this historical account, I have drawn freely on the work of the following excellent publications: Chakravorty and Wanebo (1987), Glenn (1971), Praderi (1982), and Starzl (2001). I have no doubt that there will be some inaccuracies and disputed claims as to "firsts," but I have attempted to relate a fascinating surgical story. I apologize for any disagreement I may ignite.

CHAPTER 1B

Surgical and radiologic anatomy of the liver, biliary tract, and pancreas

Leslie H. Blumgart and Lucy E. Hann

ANATOMY OVERVIEW

Precise knowledge of the internal architecture of the liver, biliary tract, and pancreas and specific and detailed knowledge of related blood vessels and lymphatic drainage is essential for the successful performance of surgical operations on these organs.

LIVER

The liver lies protected under the lower ribs, closely applied to the undersurface of the diaphragm and astride the vena cava posteriorly. Most of the liver bulk lies to the right of the midline, where the lower border coincides with the right costal margin, but it extends as a wedge to the left of the midline, between the anterior surface of the stomach and the left dome of the diaphragm. The upper surface is boldly convex and molded to the diaphragm, and the surface projection on the anterior body wall extends up to the fourth intercostal space on the right and to the fifth intercostal space on the left. The convexity of the upper surface slopes down to a posterior surface that is triangular in outline. The liver is invested with peritoneum except on the posterior surface, where the peritoneum reflects onto the diaphragm, forming the right and left triangular ligaments. The undersurface of the liver is concave and extends down to a sharp anterior border. The posterior surface of the liver is triangular in outline with its base to the right, and here the liver lying between the upper and lower "leaves" of the triangular ligaments is bare and devoid of peritoneum. The anterior border lies under cover of the right costal margin, lateral to the right rectus abdominis muscle, but it slopes upward to the left across the epigastrium. Anteriorly, the convex surface of the liver lies against the concavity of the diaphragm and is attached to it by the falciform ligament, left triangular ligament, and upper layer of the right triangular ligament.

Retrohepatic Inferior Vena Cava

The inferior vena cava (IVC) runs on the right of the aorta on the bodies of the lumbar vertebrae, diverging from the aorta as it passes upward. Below the liver, the IVC lies behind the duodenum and head of the pancreas as a retroperitoneal structure passing upward behind the foramen of Winslow posterior to the right hilar structures of the liver. The renal veins lie in front of the arteries and join the IVC at almost a right angle on the left and obliquely on the right. Behind the liver, the IVC is embraced in a groove on its posterior surface (Figs. 1B.1 and 1B.2). The IVC comes to lie on the right crus of the diaphragm, behind the bare area of the liver; it extends to the central tendon of the diaphragm, which it pierces on a level with the body of T8, behind and higher than the beginning of the abdominal aorta. As the IVC courses upward, it is separated from the right crus of the diaphragm by the right celiac ganglion and, higher up, by the right phrenic artery. The right adrenal vein is a short vessel that enters the IVC behind the bare area (see Fig. 1B.1). There may be a small accessory right adrenal vein on the right that enters into the confluence of the right renal vein and the IVC. The lumbar veins drain posterolaterally into the IVC below the level of the renal veins, but above this level, there are usually no vena caval tributaries posteriorly.

Hepatic Veins

The hepatic veins (Figs. 1B.3 to 1B.5) drain directly from the upper part of the posterior surface of the liver at an oblique angle directly into the vena cava. The right hepatic vein, which is larger than the left and middle hepatic veins, has a short extrahepatic course of approximately 1 cm. The left and middle hepatic veins may drain separately into the IVC but are usually joined, after a short extrahepatic course, to form a common venous channel approximately 2 cm in length that traverses to the left part of the anterior surface of the IVC below the diaphragm (see Figs. 1B.3 and 1B.5). In addition to the three major hepatic veins, there is the umbilical vein, which is single in most cases and runs beneath the falciform ligament between the middle and left hepatic veins; it empties into the terminal portion of the left hepatic vein, although rarely it drains into the middle hepatic vein or directly into the confluence of the middle and left hepatic veins. Additional posteriorly and inferiorly draining hepatic veins, with a short course into the anterior surface of the IVC, are frequent and may be large (see Fig. 1B.4). Hepatic venous drainage of the caudate lobe is directly into the IVC, as described below.

This classic description of the anatomy of the liver is sufficient for gross appreciation and for mobilization of the liver to allow access for repair of injuries, liver transplantation, or the placement of probes onto or into the liver substance. Hidden within this external gross appearance is a detailed internal anatomy; however, an understanding of which is essential to the performance of precise hepatectomy. This internal anatomy has been called the *functional* anatomy of the liver.

Functional Surgical Anatomy

The internal architecture of the liver is composed of a series of segments that combine to form sectors separated by scissurae

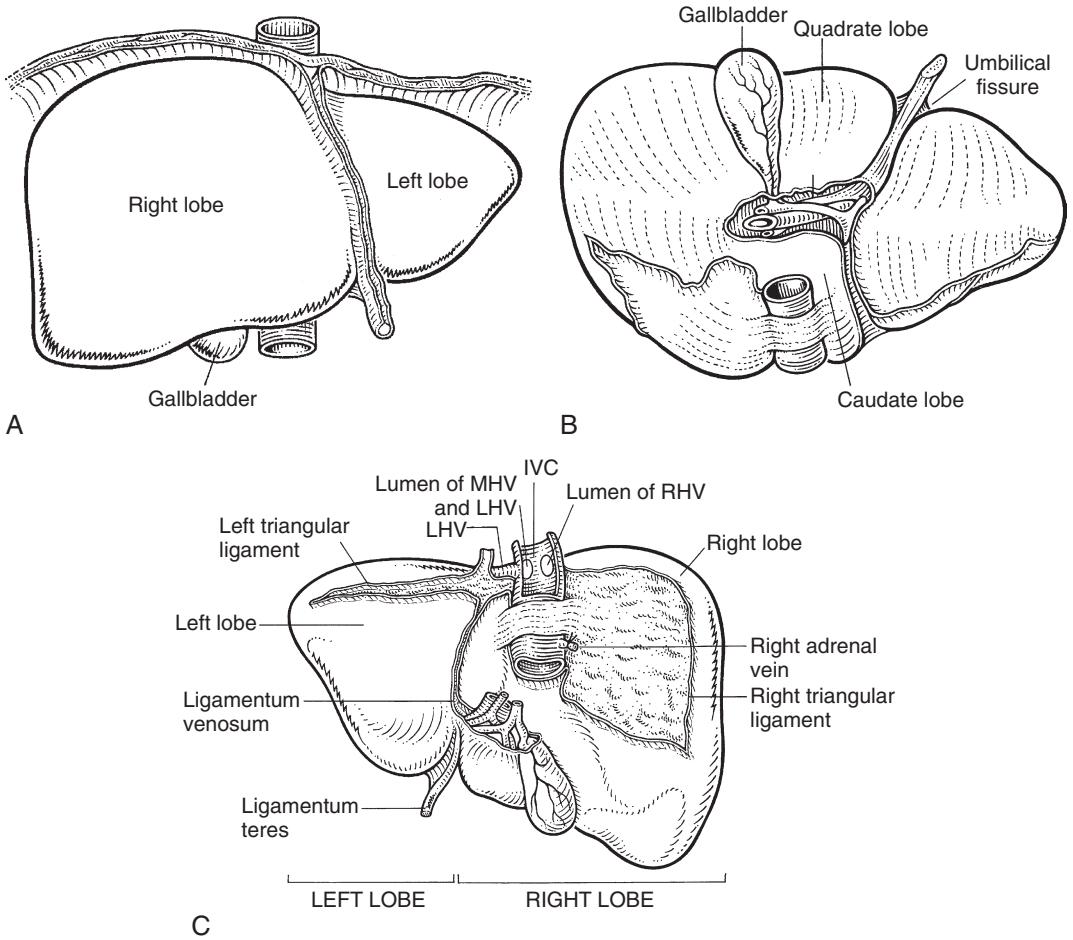

FIGURE 1B.1. **A,** The liver has two main lobes, a large right and a smaller left, and conventional description places their line of fusion on the upper surface of the liver along the attachment of the falciform ligament at the inferior extent of which the ligamentum teres enters the umbilical fissure. **B,** On the inferior surface of the right lobe is the transverse hilar fissure, which constitutes the posterior limit of this lobe. The portion of the right lobe located anterior to the fissure is called the *quadrate lobe*, limited on the left by the *umbilical fissure*, on the right by the gallbladder fossa. Posterior to the hilar transverse fissure is a fourth lobe, the *caudate lobe*, which hugs the inferior vena cava (IVC) and extends upward on its left side. The liver comprises two main lobes and two smaller lobes, separated by visible, well-defined fissures on the liver surface. **C,** The IVC lies snugly in a deep groove within the bare area; the hepatic veins open directly into it. Within this bare area, the right suprarenal gland lies adjacent to the IVC, and the adrenal vein drains into the right of the IVC. The remainder of the bare area of liver is directly in contact with the diaphragm. To the left of the IVC, the caudate lobe slopes upward from the inferior to the posterior surface of the liver and is demarcated on the left by a fissure, within which lies the ligamentum venosum. The gastrohepatic omentum is attached to the ligamentum venosum, placing the caudate lobe within the lesser sac of the peritoneum; but the left lobe of the liver is situated anteriorly in the supracolic compartment of the peritoneal cavity. The posterior surface of the left lobe is narrow; there is a very fine bare area on this side. As the vena cava traverses upward in the groove on the posterior surface of the liver, it is shielded on the right side by a layer of fibrous tissue that passes from the posterior edge of the liver backward toward the lumbar vertebrae and fans out posteriorly, especially in the upper part. Behind the IVC, a prolongation of this fibrous layer joins a less marked fibrous extension from the lateral edge of the caudate lobe. This layer of fibrous tissue, sometimes called the *ligament of the vena cava*, must be divided on the right, to allow surgical exposure of the IVC and the hepatic veins, and on the left, to allow mobilization of the caudate lobe. Occasionally, the liver tissue embraces the vena cava completely, so that it runs within a tunnel of parenchyma. LHV, left hepatic vein; MHV, middle hepatic vein; RHV, right hepatic vein.

that contain the hepatic veins (Fig. 1B.6). Together or separately, these constitute the visible lobes described previously. The internal structure has been clarified by the publications of McIndoe and Counseller (1927), Ton That Tung (1939, 1979), Hjörtsjö (1931), Healey and Schroy (1953), Goldsmith and Woodburne (1957), Couinaud (1957), and Bismuth and colleagues (1982); however, the description by Couinaud is the most complete, exact, and useful for the operating surgeon, so it is generally used here. An alternative terminology suggested by a committee of the International Hepato-Pancreatico-Biliary Association (Strasberg et al, 2000) adds little to the understanding or practicality of Couinaud's description. The main difference is that in the alternative terminology, Couinaud's sectors are referred to as *sections*, particularly in describing the anatomy of the left liver (see Chapters 90A to 90F for differences in the terminology of the various hepatic resections).

Essentially, the three main hepatic veins within the scissurae divide the liver into four sectors, each of which receives a portal

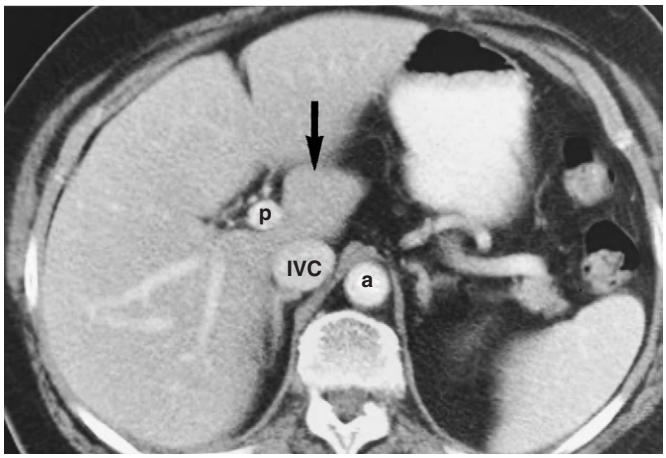

FIGURE 1B.2. Contrast-enhanced computed tomographic scan of the liver shows the intimate relationship of the caudate lobe (*arrow*), inferior vena cava (*IVC*), portal vein (*p*), and aorta (*a*).

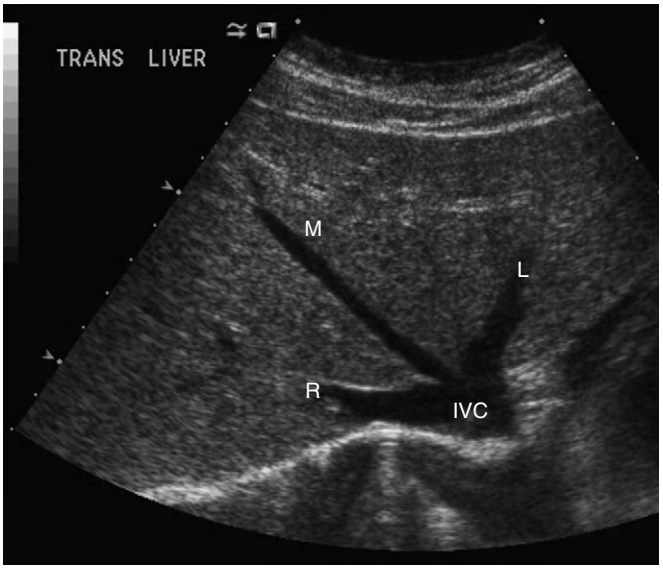

FIGURE 1B.3. Transverse ultrasound image of the hepatic vein confluence shows the left (*L*), middle (*M*), and right (*R*) hepatic veins as they join the inferior vena cava (*IVC*).

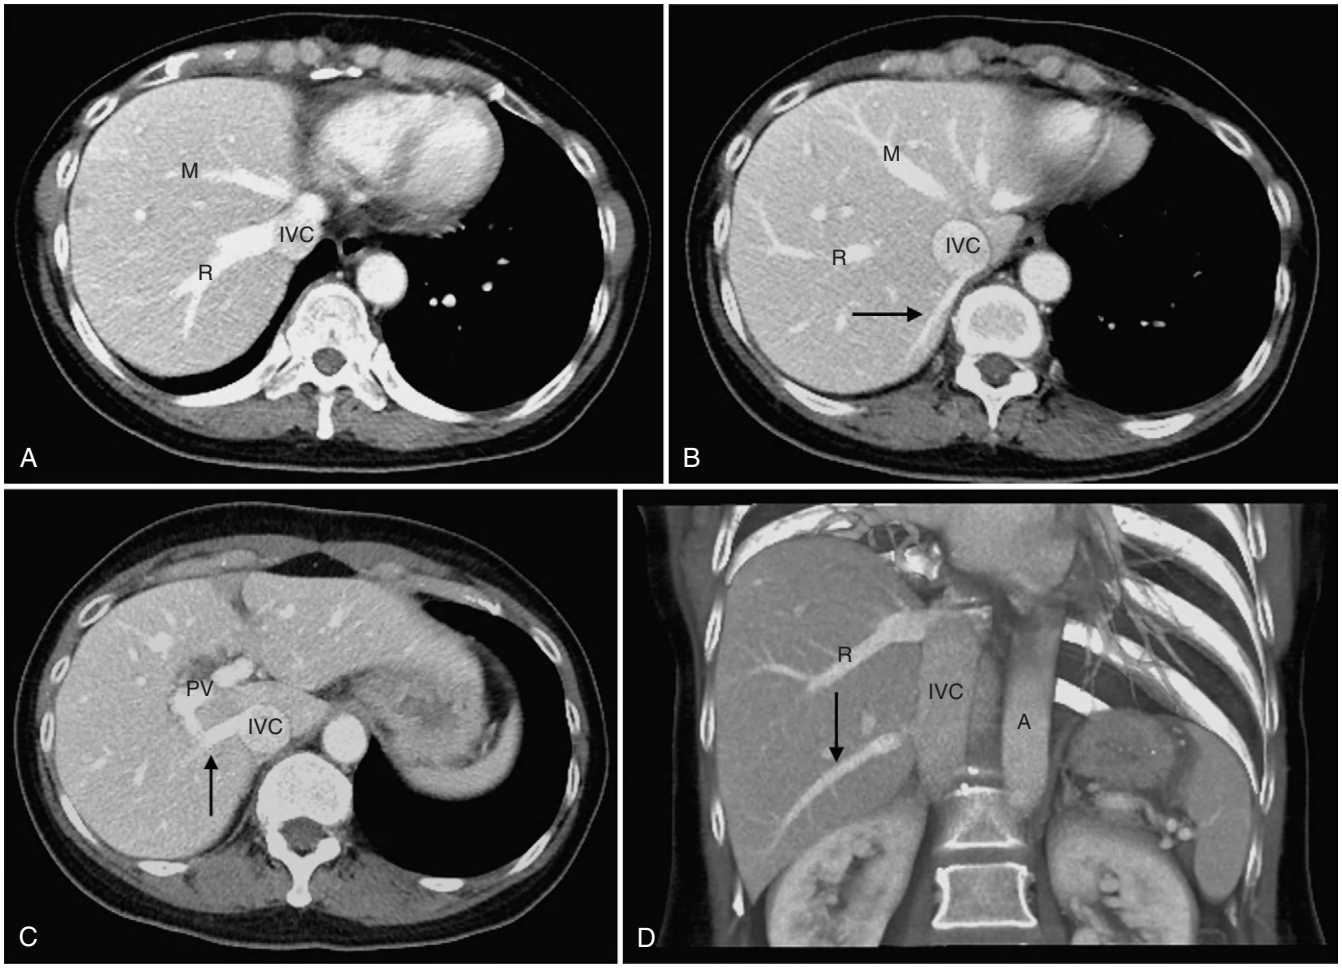

FIGURE 1B.4. Two inferior accessory right hepatic veins. **A,** Contrast-enhanced computed tomographic (CT) image of the hepatic vein confluence. R, right hepatic vein; M, middle hepatic vein; IVC, inferior vena cava. **B,** A small right inferior accessory vein (*arrow*) enters the IVC below the hepatic venous confluence. **C,** The second, larger right inferior accessory right hepatic vein (*arrow*) is seen more inferiorly. PV, portal vein. **D,** CT coronal reconstruction image shows the right hepatic vein (*R*) and one right inferior accessory vein (*arrow*); A, aorta.

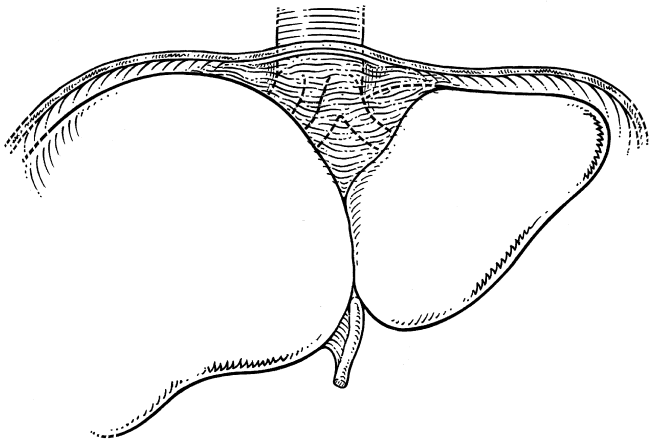

FIGURE 1B.5. The anterior surfaces of the major extrahepatic veins and the inferior vena cava are retroperitoneal and masked behind the layers of the falciform ligament, as it splits and passes to the right and left triangular ligaments.

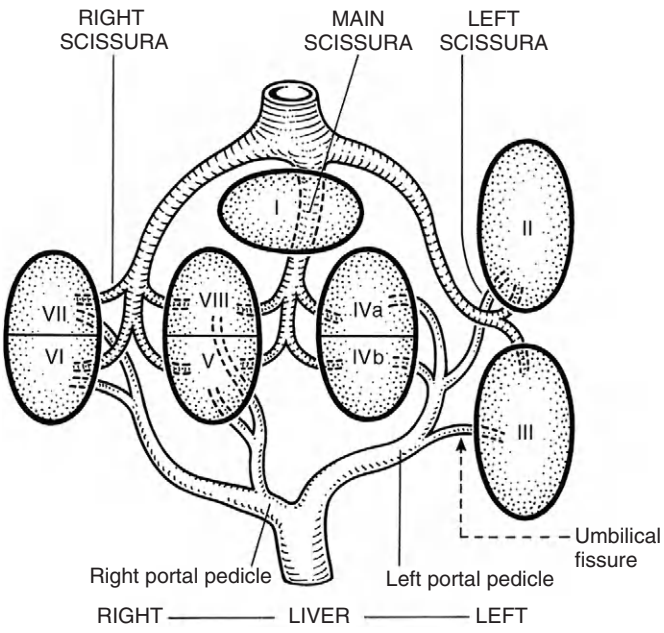

FIGURE 1B.6. The portal vein, hepatic artery, and draining bile ducts are distributed within the liver in a beautifully symmetric pedicular pattern, which belies the asymmetric external appearance. Each segment (I to VIII) is supplied by a portal triad composed of a branch of the portal vein and hepatic artery and drained by a tributary of the right or left main hepatic ducts. The four sectors demarcated by the three main hepatic veins are called the *portal sectors*; these portions of parenchyma are supplied by independent portal pedicles. The hepatic veins run between the sectors in the portal scissurae; the scissurae containing portal pedicles are called the *hepatic scissurae*. The umbilical fissure corresponds to a hepatic scissura. The internal architecture of the liver consists of two hemilivers, the right and the left liver separated by the main portal scissura, also known as *Cantlie's line*. It is preferable to call them the *right* and *left liver*, rather than the *right* and *left lobes*, because the latter nomenclature is erroneous; there is no visible mark that permits identification of a true hemiliver.

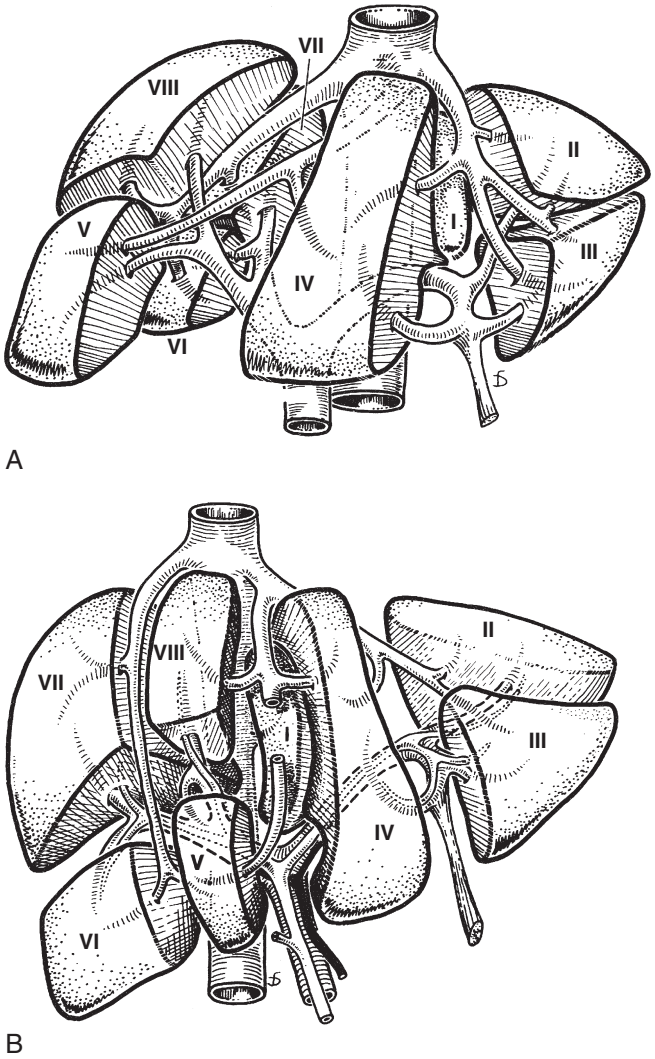

FIGURE 1B.7. The functional division of the liver and its segments according to Couinaud's nomenclature. **A,** As seen in the patient. **B,** In the ex vivo position.

pedicle, with alternation between the hepatic veins and portal pedicles. The main portal scissura contains the middle hepatic vein and progresses from the middle of the gallbladder bed anteriorly to the left of the vena cava posteriorly. The right and left parts of the liver, demarcated by the main portal scissura, are independent in terms of portal and arterial vascularization and biliary drainage (Fig. 1B.7). These right and left livers are themselves divided into two by the remaining portal scissurae. These four subdivisions are referred to as *segments* in the description of Goldsmith and Woodburne (1957), but in Couinaud's nomenclature (1957), they are termed *sectors* (see Figs. 1B.6 and 1B.7).

The right portal scissura separates the right liver into two sectors: *anteromedial* (anterior) and *posterolateral* (posterior). With the body supine, this scissura is almost in the frontal plane. The right hepatic vein runs within the right scissura. The left portal scissura divides the left liver into two sectors, but the left portal scissura is not within the umbilical fissure, because this fissure is not a portal scissura and contains a portal pedicle. The left portal scissura is located posterior to the ligamentum teres

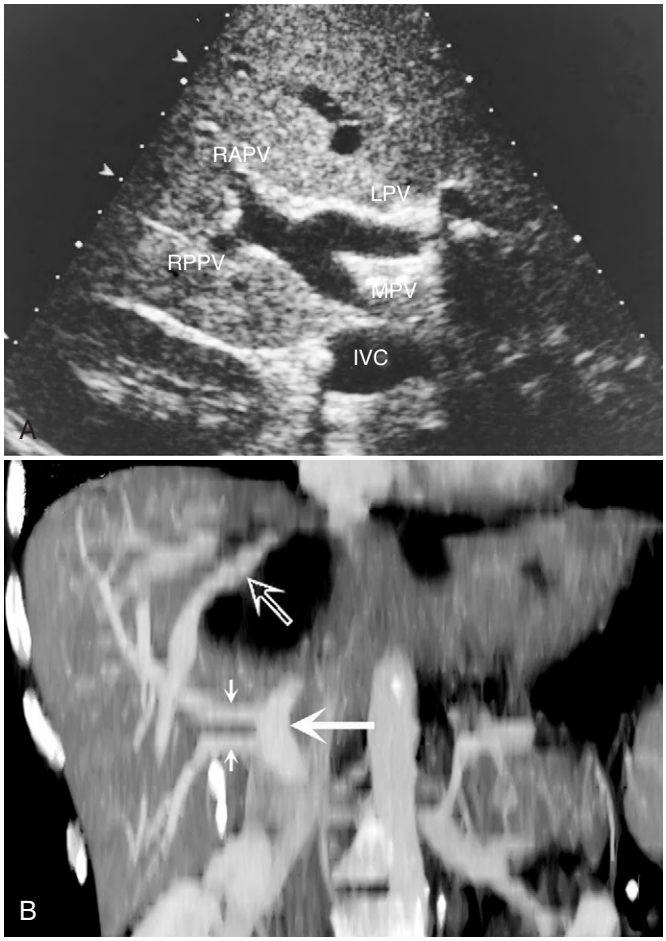

FIGURE 1B.8. A, Transverse sonogram at the level of the portal vein bifurcation. The main portal vein (*MPV*) bifurcates into the left and right portal veins (*LPV* and *RPV*). The RPV bifurcates shortly into the right anterior (*RAPV*) and right posterior (*RPPV*) branches, but the LPV has a longer horizontal course within the hilar plate. The inferior vena cava (*IVC*) is seen posteriorly. **B,** Coronal view of computed tomographic angioportography. Reconstruction shows the right hepatic vein (*open arrow*) and the portal vein (*large arrow*); anterior and posterior sectoral branches of the RPV (*small arrows*) are seen to arise independently from the main portal trunk.

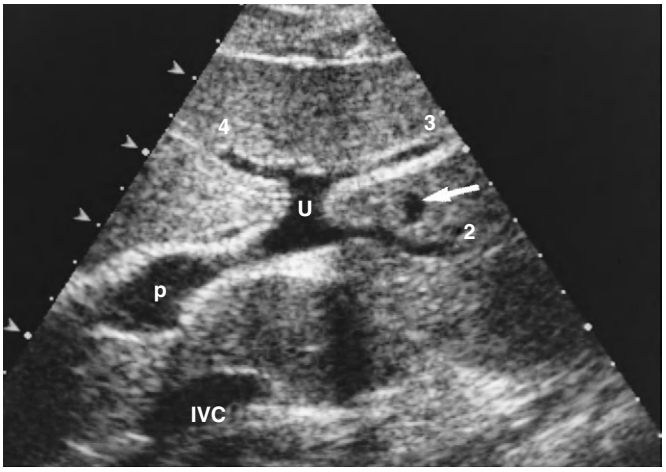

FIGURE 1B.9. Transverse sonogram shows the branching pattern of the left portal vein (*p*), which courses horizontally and into the umbilical fissure. The umbilical portion of the left portal vein (*U*) gives branches to the left hepatic segments (II to IV). The left hepatic vein (*arrow*) and inferior vena cava (*IVC*) also are shown.

and within the left lobe of the liver, along the course of the left hepatic vein. The anterior sector of the left liver—the left medial section, in the terminology of Strasberg and others (2000)—is composed of a part of the right lobe (segment IV), to the left of the main portal scissura, and of the anterior part of the left lobe (segment III; see Figs. 1B.6 and 1B.7). The left posterior sector is the only sector composed of one segment (segment II; the left posterior section in terminology of Strasberg et al).

At the hilus of the liver, the right portal triad pursues a short course of approximately 1 to 1.5 cm before entering the substance of the right liver (Fig. 1B.8A). In some cases, the right anterior and posterior pedicles arise independently, and their origins may be separated by 2 cm (see Fig. 1B.8B). In some cases, it appears as if the left portal vein arises from the right anterior branch (see also Fig. 1B.40). On the left side, however, the portal triad crosses over approximately 3 to 4 cm beneath the quadrate lobe, embraced in a peritoneal sheath at the upper end of the gastrohepatic ligament and separated from the undersurface of the quadrate lobe by connective tissue (hilar plate). This prolongation of the left portal pedicle turns anteriorly and caudally within the umbilical fissure, giving branches of supply to segments II and III and recurrent branches to segment IV (Fig. 1B.9; see also Fig. 1B.6). Beneath the quadrate lobe, the pedicle is composed of the left branch of the portal vein and the left hepatic duct, but it is joined at the base of the umbilical fissure by the left branch of the hepatic artery.

The branching of the portal pedicle at the hilus (Fig. 1B.10; see also Figs. 1B.6, 1B.8, and 1B.9), the distribution of the branches to the caudate lobe (segment I) on the right and left sides, and the distribution to the segments of the right (segments V through VIII) and left (segments II through IV) hemiliver follow a remarkably symmetric pattern and, as described by Scheele (1994), allow separation of segment IV into segment IVa superiorly and segment IVb inferiorly (see Fig. 1B.6). This arrangement of subsegments mimics the distribution to segments V and VIII on the right side. The umbilical vein provides drainage of at least parts of segment IVb after ligation of the middle hepatic vein, and it is important in the performance of segmental resection.

The caudate lobe (segment I) is the dorsal portion of the liver lying posteriorly and embracing the retrohepatic IVC. This lobe lies between major vascular structures: On the left, the caudate lies between the IVC posteriorly and the left portal triad inferiorly and the IVC and the middle and left hepatic veins superiorly (Figs. 1B.11 and 1B.12). This portion of the caudate is sometimes referred to as *segment IX*.

The portion of the caudate on the right varies but is usually quite small. The anterior surface within the parenchyma is covered by the posterior surface of segment IV, the limit being an oblique plane slanting from the left portal vein to the left hepatic vein. Thus, there is a caudate lobe (segment I) with a

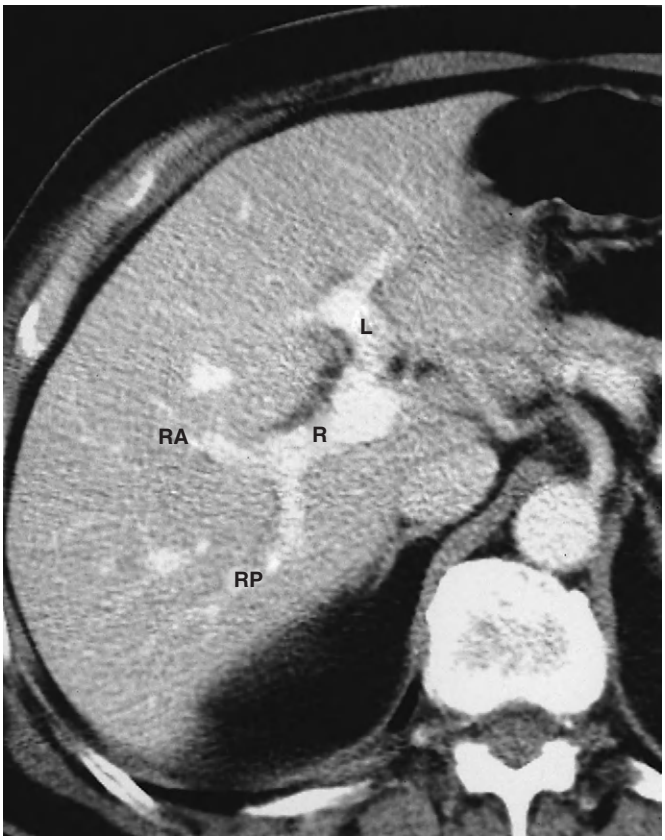

FIGURE 1B.10. Contrast-enhanced computed tomographic image of the portal vein bifurcation. L, left portal vein; R, right portal vein; RA, right anterior portal vein; RP, right posterior portal vein.

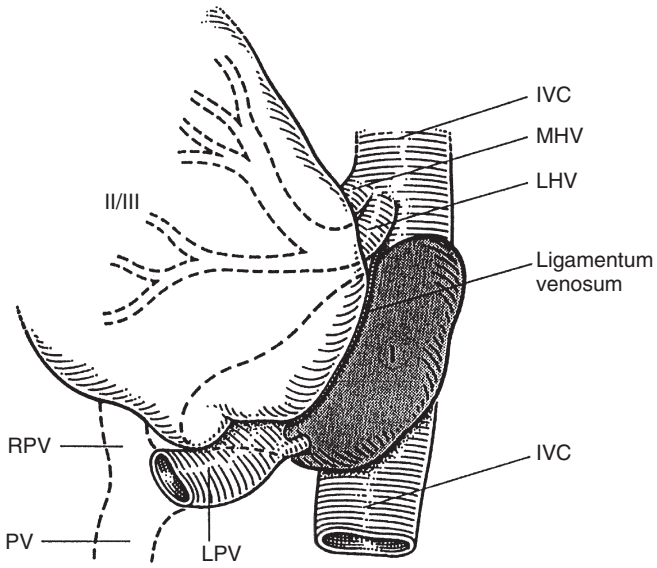

FIGURE 1B.12. The caudate lobe (*shaded*) and segments II and III, rotated to the patient's right. Superiorly, the left portion of the caudate lobe is linked by a deep anterior portion, embedded in the parenchyma immediately under the middle hepatic vein (*MHV*), reaching inferiorly to the posterior margin of the hilus of the liver and fusing anterolaterally to the inferior vena cava (*IVC*) on the right side to segments VI and VII of the right liver. The major blood supply arises from the left branch of the left portal vein (*LPV*) and the left hepatic artery close to the base of the umbilical fissure of the liver. The hepatic veins (MHV, LHV) are short in course and drain from the caudate directly into the anterior and left aspect of the vena cava. LHV, left hepatic vein; RPV, right portal vein; PV, main trunk of portal vein.

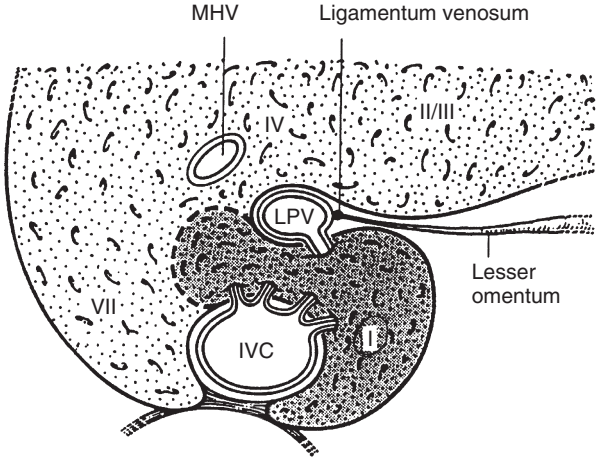

FIGURE 1B.11. The main bulk of the caudate lobe (segment I; *dark area*) lies to the left of the inferior vena cava (*IVC*); the left and inferior margins are free in the lesser omental bursa. The gastrohepatic (lesser) omentum separates the left portion of the caudate from segments II and III of the liver, as it passes between them to be attached to the ligamentum venosum. The left portion of the caudate lobe inferiorly traverses to the right between the left portal vein (*LPV*) and IVC as the caudate process, where it fuses with the right lobe of the liver. Note the position of the middle hepatic vein (*MHV*).

constantly present left portion and a right portion of variable size (see Figs. 1B.11 and 1B.12).

The caudate lobe is supplied by blood vessels and drained by biliary tributaries from the right and left portal triad. Small vessels from the portal vein and tributaries joining the biliary ducts also are found, usually two on the left side and one on the right. The right portion of the caudate lobe, including the caudate process, predominantly receives portal venous blood from the right portal vein or from the bifurcation of the main portal vein, whereas on the left side, the portal supply arises from the left branch of the portal vein almost exclusively. Similarly, the arterial supply and biliary drainage of the right portion is most commonly associated with the right posterior sectoral vessels and the left portion with the left main vessels. The hepatic venous drainage of the caudate is unique in that it is the only hepatic segment that drains directly into the IVC. These veins can sometimes drain into the posterior aspect of the vena cava, if a significant retrocaval caudate component is present.

In the usual and common circumstance, the posterior edge of the caudate lobe on the left has a fibrous component, which fans out and attaches lightly to the crural area of the diaphragm; but it extends posteriorly, behind the vena cava, to link with a similar component of fibrous tissue that protrudes from the posterior surface of segment VII and embraces the vena cava (see Figs. 1B.1C and 1B.11). In 50% of patients, this ligament is replaced by hepatic tissue, in whole or in part, and the caudate may completely encircle the IVC and may contact segment VII

on the right side; a significant retrocaval component may prevent a left-sided approach to the caudate veins. The caudal margin of the caudate lobe has a papillary process that occasionally may attach to the rest of the lobe via a narrow connection. It is bulky in 27% of cases and can be mistaken for an enlarged lymph node on computed tomography (CT) scan (Fig. 1B.13).

To summarize:

1. The liver is divided into two hemilivers by the main hepatic scissura, within which runs the middle hepatic vein.
2. The left liver is divided into two sectors by the left portal scissura, within which the left hepatic vein runs (see Fig. 1B.6). The posterior sector comprises only one segment, segment II, which is the posterior part of the left lobe. This is the only sector that comprises one segment, referred to as the *left posterior section* by Strasberg and others (2000). The anterior sector is divided by the umbilical fissure into two segments: a *medial segment*, the quadrate lobe (segment IV), and a *lateral segment* (segment III), which is the anterior part of the left lobe.
3. The right liver is divided into two sectors by the right portal scissura, containing the right hepatic vein. Each of these *sectors* is further divided into two segments: an anterior segment V inferiorly and segment VIII superiorly, and a posterior segment, segment VI inferiorly and segment VII superiorly (see Figs. 1B.6 and 1B.7).
4. Segment I, the caudate lobe, lies posteriorly and embraces the vena cava, its intraparenchymal anterior surface abutting the posterior surface of segment IV and merging with segments VI and VII on the right (Fig. 1B.14; see Fig. 1B.11).

Further details of segmental anatomy important in sectoral or segmental resection are described in Chapters 90A to 90F and 92.

Surgical Implications and Exposure

All methods for precise partial hepatectomy depend on control of the inflow vasculature and draining bile ducts and of the outflow hepatic veins of the portion of liver to be excised, which may be a segment, a subsegment, or an entire lobe. The remnant remaining after partial hepatectomy must be provided with an excellent portal venous and hepatic arterial supply and biliary drainage and an unimpeded hepatic venous outflow. Under such circumstances, hepatic regeneration is usually prompt. The classification of the various partial hepatic resection procedures, incisions and exposure, necessary mobilization of the liver, and the methods of control of the structures within the portal triads and of the hepatic veins are described in detail in Chapters 90A to 90F and 92.

BILIARY TRACT

Biliary exposure and precise dissection are the most important steps in any biliary operative procedure. A thorough anatomic knowledge is essential if optimal results are to be obtained.

Intrahepatic Bile Duct Anatomy

The right and left livers are drained by the right and the left hepatic ducts, whereas the dorsal lobe (caudate lobe) is

FIGURE 1B.13. Computed tomographic image of the caudate lobe with papillary process. **A,** Caudate lobe (*asterisk*) positioned between the left portal vein (*arrow*) and inferior vena cava (*v*); a, aorta. **B,** Papillary process of the caudate (*p*) represents the lower medial extension of the caudate (*asterisk*) and may mimic a periportal lymph node.

drained by several ducts that join both the right and left hepatic ducts. The intrahepatic ducts are tributaries of the corresponding hepatic ducts, which form part of the major portal triads that penetrate the liver, invaginating the Glisson capsule at the hilus. Bile ducts usually are located above the corresponding portal branches, whereas hepatic arterial branches are situated inferiorly to the veins. Each branch of the intrahepatic portal veins corresponds to one or two bile duct tributaries that join to form the right and left hepatic ductal systems, converging at the liver hilus to constitute the common hepatic duct. The umbilical fissure divides the left liver, passing between segment III and segment IV, where it may be bridged by a tongue of liver tissue. The ligamentum teres passes through the umbilical fissure to join the left branch of the portal vein (see Fig. 1B.1).

The left hepatic duct drains the three segments—II, III, and IV—that constitute the left liver (Fig. 1B.15). The duct that drains segment III is located slightly behind the left horn of the umbilical recess. It is joined by the tributary from segment IVb to form the left duct, which is similarly joined by the duct of segment II and the duct of segment IVa, where the left branch of the portal vein turns forward and caudally. The left hepatic duct traverses beneath the left liver at the base of segment IV, just above and behind the left branch of the portal vein; it crosses the anterior edge of that vein and joins the right hepatic duct to constitute the hepatic ductal confluence. In its transverse portion, it receives one to three small branches from segment IV.

The right hepatic duct drains segments V, VI, VII, and VIII and arises from the junction of two main sectoral duct tributaries (Fig. 1B.16). The posterior or lateral duct and the anterior or medial duct are each accompanied by a corresponding vein. The right posterior sectoral duct has an almost horizontal course and constitutes the confluence of the ducts of segments VI and VII (see Figs. 1B.15 and 1B.16). The duct then runs to join the right anterior sectoral duct, as it descends in a vertical manner. The right anterior sectoral duct is formed by the confluence of the ducts draining segments V and VIII. Its main trunk is located to the left of the right anterior sectoral branch of the portal vein, which pursues an ascending course. The junction of these two main right biliary channels usually occurs above the right branch of the portal vein. The right hepatic duct is short and joins the left hepatic duct to constitute the confluence lying in front of the right portal vein and forming the common hepatic duct.

The caudate lobe (segment I) has its own biliary drainage (Healey & Schroy, 1953). The caudate lobe is divided into right and left portions and a caudate process. In 44% of individuals, three separate ducts drain these three parts of the lobe, whereas in 26% a common duct lies between the right portion of the caudate lobe proper and the caudate process and an independent duct that drains the left part of the caudate lobe. The site of drainage of these ducts varies. In 78% of cases, drainage of the caudate lobe is into the right and left hepatic ducts, but in 15% drainage is by the left hepatic ductal system only. In about 7%, the drainage is into the right hepatic system.

Extrahepatic Biliary Anatomy and Vascular Anatomy of the Liver and Pancreas

The extrahepatic bile ducts are represented by the extrahepatic segments of the right and left hepatic ducts, joining

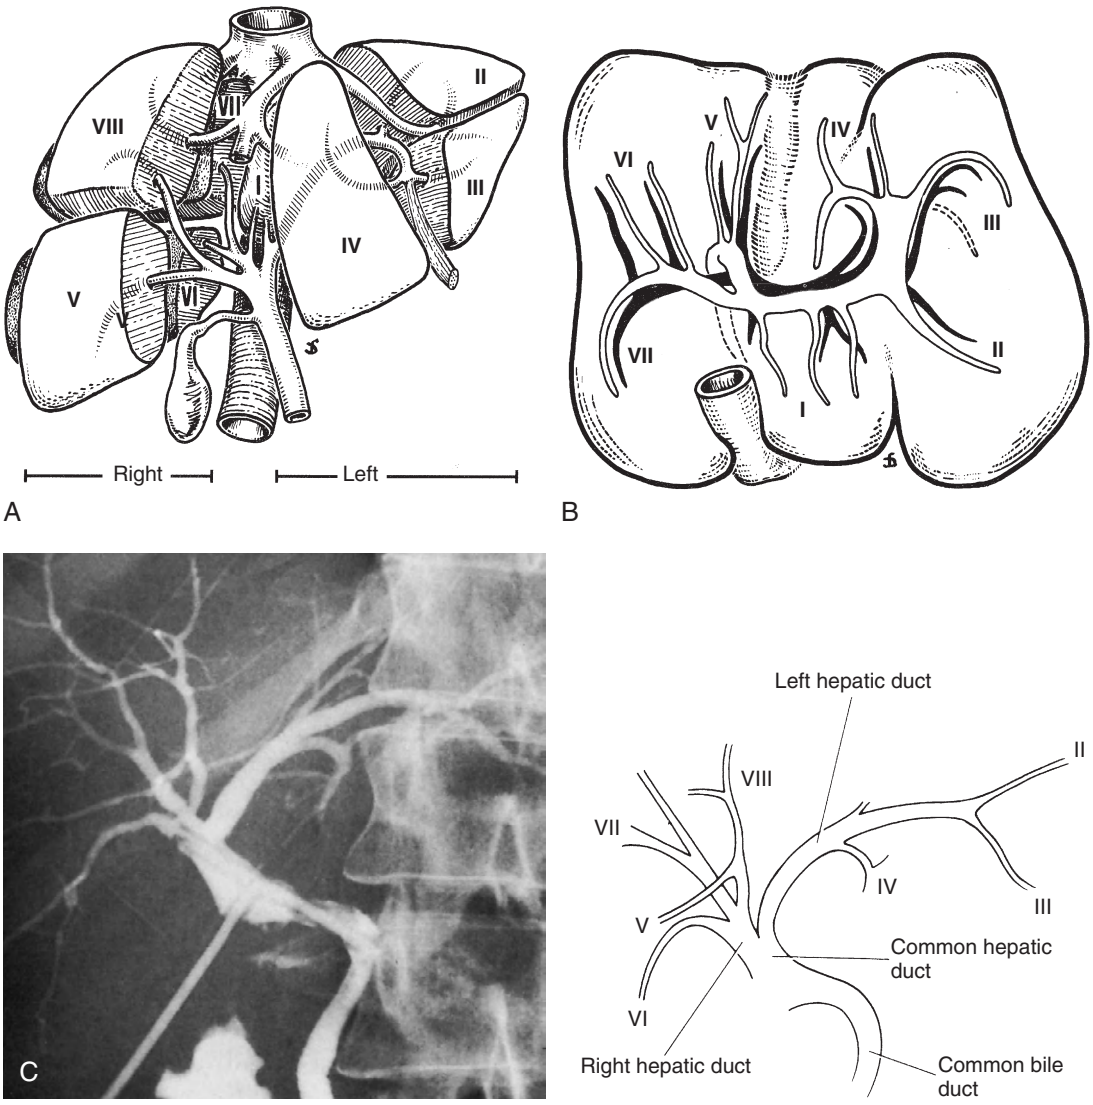

FIGURE 1B.15. **A,** Biliary drainage of the two functional hemilivers. Note the position of the right anterior and right posterior sectors. The caudate lobe drains into the right and left ductal system. **B,** Inferior aspect of the liver. The biliary tract is represented in black, and the portal branches are represented in white. Note the biliary drainage of segment IV (segment VIII is not represented because of its cephalad location). **C,** T-tube cholangiogram shows the most common arrangement of hepatic ducts.

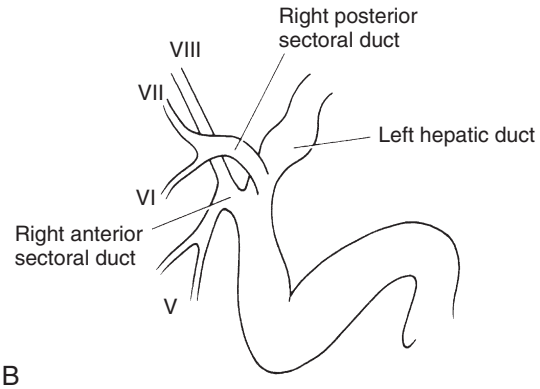
to form the biliary confluence and the main biliary channel draining to the duodenum. The accessory biliary apparatus, which constitutes a reservoir, comprises the gallbladder and cystic duct (Figs. 1B.17 and 1B.18). The confluence of the right and left hepatic ducts occurs at the right of the hilar fissure of the liver, anterior to the portal venous bifurcation and overlying the origin of the right branch of the portal vein (see Fig. 1B.17). The extrahepatic segment of the right duct is short, but the left duct has a much longer extrahepatic course. The biliary confluence is separated from the posterior aspect of the quadrate lobe of the liver by the hilar plate, which is the fusion of connective tissue enclosing the biliary and vascular elements with the Glisson capsule (Fig. 1B.19). Because of the absence of any vascular interposition, it is possible to open the connective tissue constituting the hilar plate at the inferior border of the quadrate lobe and, by elevating it, to display the biliary confluence and left hepatic duct (Fig. 1B.20).



Main Bile Duct and Sphincter of Oddi

The main bile duct (see Fig. 1B.17), the mean diameter of which is about 6 mm, is divided into two portions: the upper is called the *common hepatic duct* and is situated above the cystic duct, which joins it to form the lower portion, the common bile duct (see Fig. 1B.18). The common duct courses downward anterior to the portal vein, in the free edge of the lesser omentum; it is closely applied to the hepatic artery, which runs upward on its left, giving rise to the right branch of the hepatic artery, which crosses the main bile duct usually posteriorly, although in about 20% of cases, it crosses anteriorly. The cystic artery, arising from the right branch of the

A

B

FIGURE 1B.16. A, Biliary and vascular anatomy of the right liver. Note the horizontal course of the posterior sectoral duct and the vertical course of the anterior sectoral duct. **B,** Transtubal cholangiogram shows a common normal variant: the right posterior sectoral duct drains into the left hepatic duct. In this case, the posterior duct is anterior to the posterior sectoral duct. Frequently in this variant, the posterior duct passes posteriorly to the anterior sectoral pedicle.

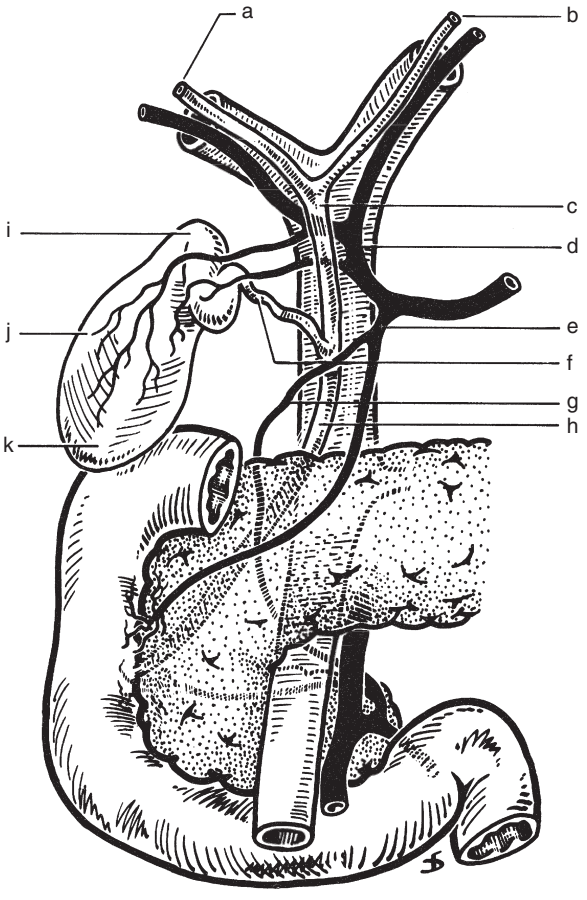


FIGURE 1B.17. Anterior aspect of the biliary anatomy and of the head of the pancreas: right hepatic duct (*a*); left hepatic duct (*b*); common hepatic duct (*c*); hepatic artery (*d*); gastroduodenal artery (*e*); cystic duct (*f*); retroduodenal artery (*g*); common bile duct (*h*); neck of the gallbladder (*i*); body of the gallbladder (*j*); fundus of the gallbladder (*k*). Note particularly the position of the hepatic bile duct confluence anterior to the right branch of the portal vein, the posterior course of the cystic artery behind the common hepatic duct, and the relationship of the neck of the gallbladder to the right branch of the hepatic artery. Note also the relationship of the major vessels (portal vein, superior mesenteric vein, and artery) to the head of the pancreas (see also Figs. 1B.29, 1B.35, and 1B.45).

FIGURE 1B.18. Endoscopic retrograde choledochopancreatogram showing the pancreatic duct (*arrow*), gallbladder, and biliary tree.

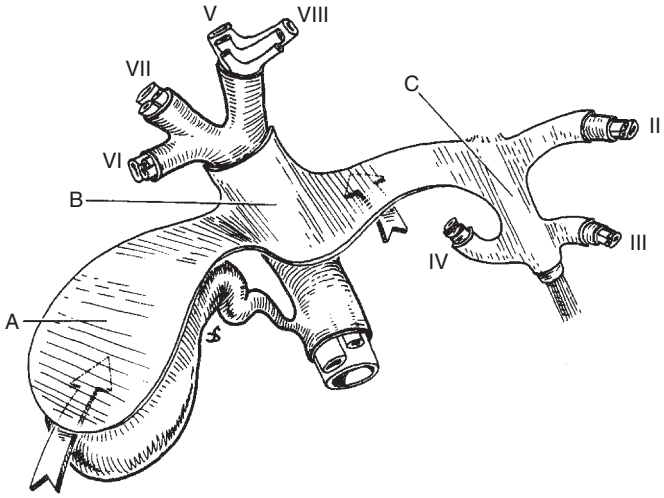

FIGURE 1B.19. Anatomy of the plate system. *A,* Cystic plate, above the gallbladder. *B,* Hilar plate, above the biliary confluence and at the base of the quadrate lobe. *C,* Umbilical plate, above the umbilical portion of the portal vein. Large, curving arrows indicate the plane of dissection of the cystic plate during cholecystectomy and of the hilar plate during approaches to the left hepatic duct.

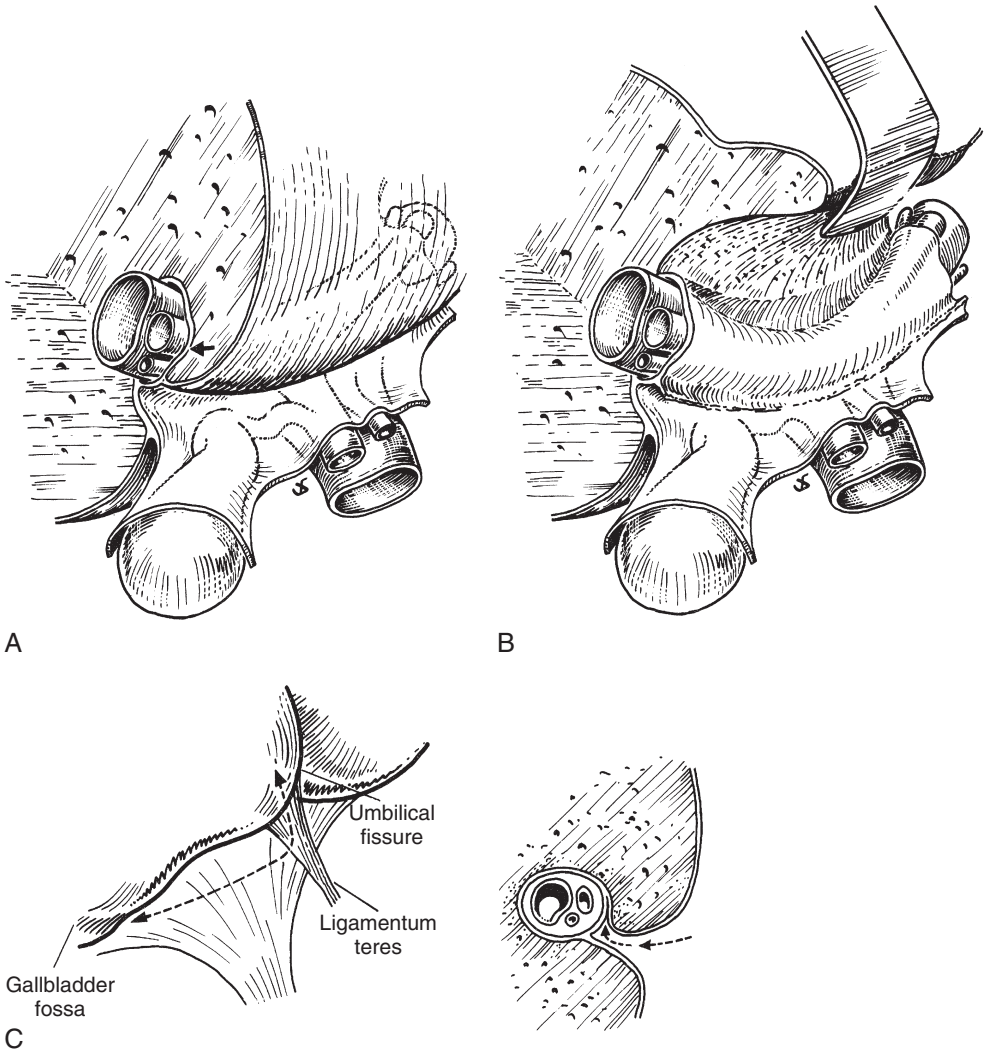

FIGURE 1B.20. A, Relationship between the posterior aspect of the quadrate lobe and the biliary confluence. The hilar plate (*arrow*) is formed by the fusion of the connective tissue enclosing the biliary and vascular elements with the Glisson capsule. **B,** Biliary confluence and left hepatic duct exposed by lifting the quadrate lobe upward after incision of the Glisson capsule at its base. This technique, *lowering of the hilar plate* (Hepp & Couinaud, 1956), generally is used to display a dilated bile duct above an iatrogenic stricture or hilar cholangiocarcinoma. **C,** Line of incision (*left*) to allow extensive mobilization of the quadrate lobe. This maneuver is of particular value for high bile duct stricture and in the presence of liver atrophy or hypertrophy. The procedure consists of lifting the quadrate lobe upward (see **A** and **B**), then not only opening the umbilical fissure but also incising the deepest portion of the gallbladder fossa. *Right*, Incision of the Glisson capsule to gain access to the biliary system (*arrow*).

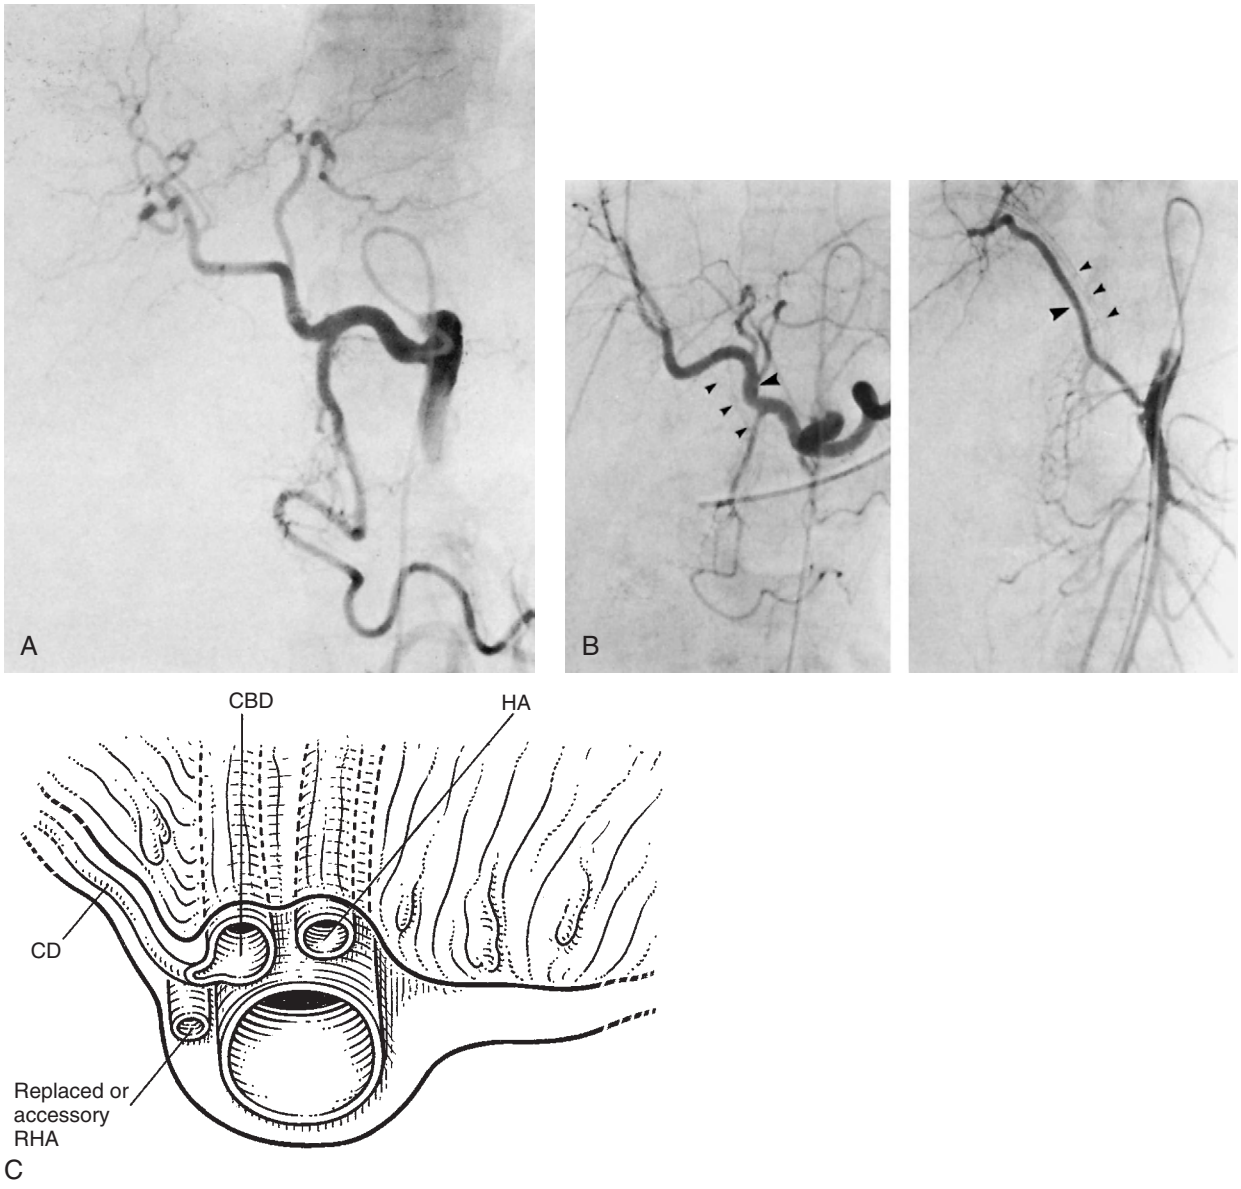

FIGURE 1B.21. Hepatic artery variations shown by angiography. **A,** Replaced common hepatic artery arises from the superior mesenteric trunk. **B,** Angiogram. *Left*, The hepatic artery (*large arrowhead*) arises from the celiac axis. The small *arrowheads* indicate a drainage catheter in the bile duct. *Right*, An accessory right hepatic artery (*large arrowhead*) is arising from the superior mesenteric artery and lies lateral to the catheter (*small arrowheads*) in the common bile duct. **C,** The accessory right hepatic artery usually courses upward in the groove posterolateral to the common bile duct (*CBD*), appearing on the medial side of the triangle of Calot, usually running just behind the cystic duct (*CD*). This common variation occurs in about 25% of individuals. HA, hepatic artery; RHA, right hepatic artery.

hepatic artery, may cross the common hepatic duct posteriorly or anteriorly. The common hepatic duct constitutes the left border of the triangle of Calot, the other corners of which were originally described as the cystic duct below and the cystic artery above (Rocko et al, 1981). The commonly accepted working definition of the triangle of Calot recognizes, however, the inferior surface of the right lobe of the liver as the upper border and the cystic duct as the lower border (Wood, 1979). Dissection of the triangle of Calot is of key significance during cholecystectomy, because in this triangle runs the cystic artery, often the right branch of the hepatic artery, and occasionally a bile duct, which should be displayed before cholecystectomy. If there is a replaced or accessory common or right hepatic artery, it usually runs behind the cystic duct to enter the triangle of Calot (Fig. 1B.21).

The common variations in the relationship of the hepatic artery and origin and course of the cystic artery to the biliary apparatus are shown in Fig. 1B.22. Ignorance of these variations may provoke unexpected hemorrhage or biliary injury (Champetier et al, 1982) during cholecystectomy and may result in bile duct injury during efforts to secure hemostasis. The union between the cystic duct and the common hepatic duct may be located at various levels. At its lower extrahepatic portion, the common bile duct traverses the posterior aspect of

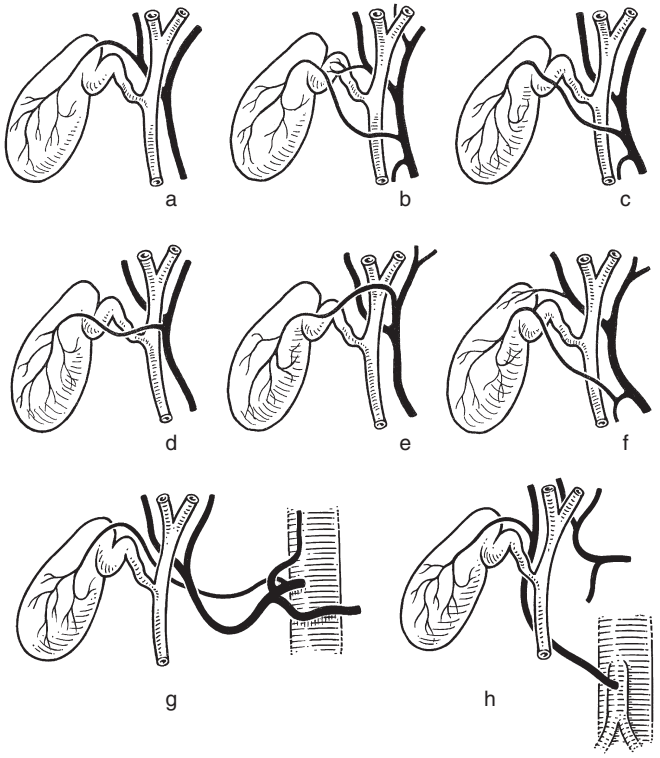

FIGURE 1B.22. The main variations of the cystic artery: typical course (*a*); double cystic artery (*b*); cystic artery crossing anterior to main bile duct (*c*); cystic artery originating from the right branch of the hepatic artery and crossing the common hepatic duct anteriorly (*d*); cystic artery originating from the left branch of the hepatic artery (*e*); cystic artery originating from the gastroduodenal artery (*f*); cystic artery arising from the celiac axis (*g*); cystic artery originating from a replaced right hepatic artery (*h*).

the pancreas, running in a groove or tunnel. The retropancreatic portion of the common bile duct approaches the second portion of the duodenum obliquely, accompanied by the terminal part of the pancreatic duct of Wirsung.

Gallbladder and Cystic Duct

The gallbladder is a reservoir located on the undersurface of the right lobe of the liver, within the cystic fossa; it is separated from the hepatic parenchyma by the cystic plate, which is composed of connective tissue closely applied to the Glisson capsule and elongating the hilar plate (see Fig. 1B.19). Sometimes the gallbladder is deeply embedded in the liver, but occasionally it occurs on a mesenteric attachment and may be susceptible to volvulus. The gallbladder varies in size and consists of a *fundus*, a *body*, and a *neck* (Fig. 1B.23). The tip of the fundus usually, but not always, reaches the free edge of the liver and is closely applied to the cystic plate. The cystic fossa is a precise anterior landmark to the main liver incisura. The neck of the gallbladder makes an angle with the fundus and creates the Hartmann pouch, which may obscure the common hepatic duct and constitute a real danger point during cholecystectomy.

The cystic duct arises from the neck or infundibulum of the gallbladder and extends to join the common hepatic duct. Its lumen usually measures about 1 to 3 mm, and its length varies,

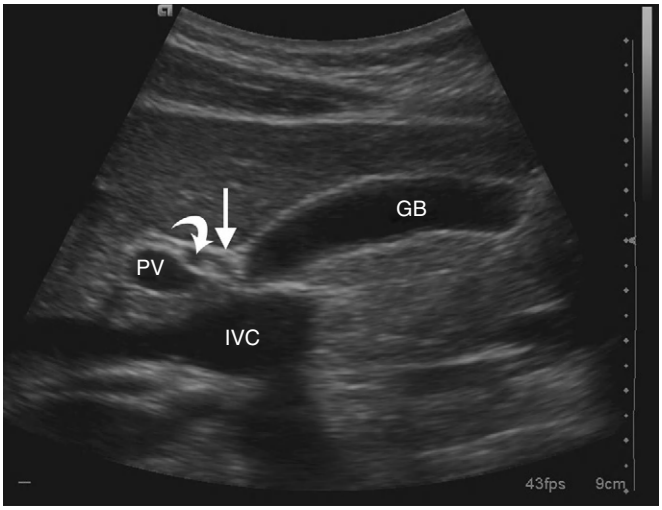

FIGURE 1B.23. Longitudinal sonogram shows the relationship of the liver, gallbladder (*GB*), portal vein (*PV*), inferior vena cava (*IVC*), hepatic artery (*curved arrow*) and common bile duct (*arrow*).

depending on the type of union with the common hepatic duct. The mucosa of the cystic duct is arranged in spiral folds known as the *valves of Heister* (Wood, 1979). Although the cystic duct joins the common hepatic duct in its supraduodenal segment in 80% of cases, it may extend downward to the retroduodenal or retropancreatic area. Occasionally, the cystic duct may join the right hepatic duct or a right hepatic sectoral duct (Fig. 1B.24).

BILIARY DUCTAL ANOMALIES

Full knowledge of the frequent variations from the described normal biliary anatomy is required when performing any hepatobiliary procedure. The constitution of a normal biliary confluence by union of the right and left hepatic ducts as described previously is reported in 72% of patients (Healey & Schroy, 1953). There is a triple confluence of the right anterior and posterior sectoral ducts and the left hepatic duct in 12% of individuals (Couinaud, 1957), and a right sectoral duct joins the main bile duct directly in 20%. In 16% the right anterior sectoral duct, and in 4% the right posterior sectoral duct, may approach the main bile duct in this fashion (Fig. 1B.25A). In 6%, a right sectoral duct may join the left hepatic duct (the posterior duct in 5% and the anterior duct in 1%; see Fig. 1B.16B). In 3%, there is an absence of the hepatic duct confluence, and the right posterior sectoral duct may join the neck of the gallbladder, or it may be entered by the cystic duct in 2% (Couinaud, 1957). In any event, these multiple biliary ductal variations at the hilus are important to recognize in resection and reconstructive surgery of the biliary tree at the hilus and during partial hepatectomy.

Intrahepatic bile duct variations also are common (Fig. 1B.26; Healey & Schroy, 1953). The main right intrahepatic duct variations are represented by an ectopic drainage of segment V in 9%, of segment VI in 14%, and of segment VIII in 20%. In addition, a subvesical duct has been described in 20% to 50% of cases. This duct, sometimes deeply embedded in the cystic plate, joins either the common hepatic duct or the right

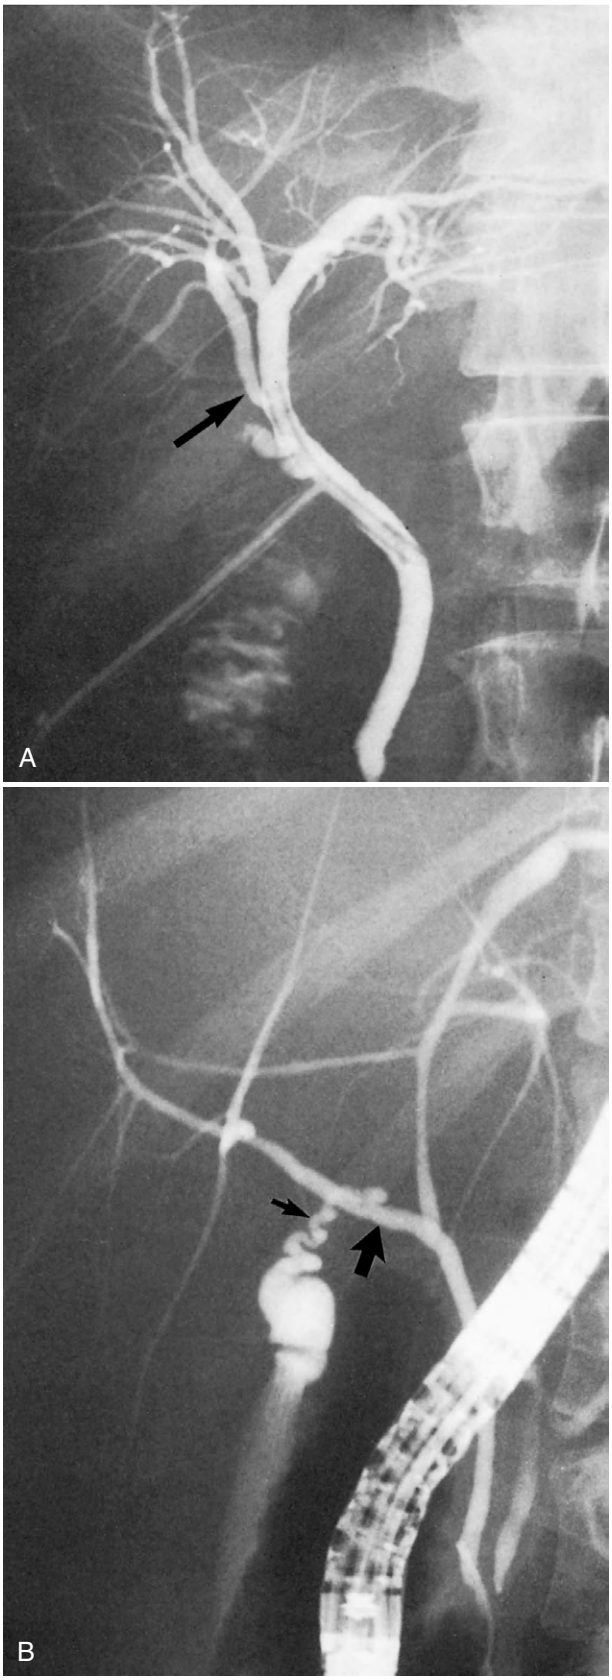

FIGURE 1B.24. **A,** T-tube cholangiogram shows a very low insertion of a right sectoral duct into the common hepatic duct (*arrow*). **B,** Endoscopic retrograde choledochopancreatogram shows a low right sectoral duct (*large arrow*), into which is draining the cystic duct (*small arrow*), an uncommon but important normal variant.

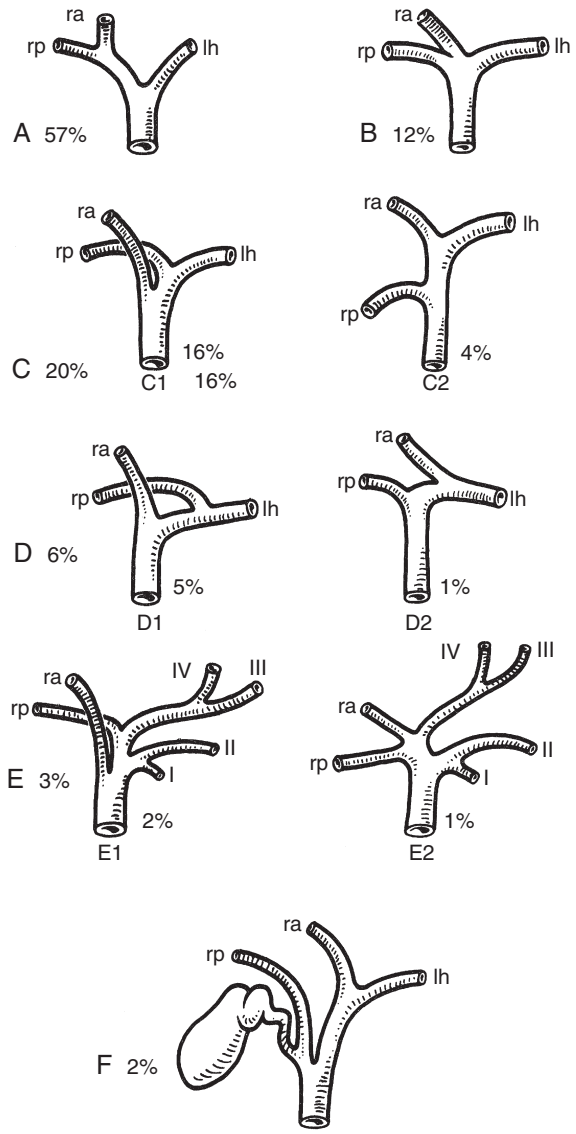

FIGURE 1B.25. Main variations of the hepatic duct confluence (Couinaud, 1957). **A,** Typical anatomy of the confluence. **B,** Triple confluence. **C,** Ectopic drainage of a right sectoral duct into the common hepatic duct (*C1*, Right anterior [*ra*] duct draining into the common hepatic duct; *C2*, Right posterior [*rp*] duct draining into the common hepatic duct). **D,** Ectopic drainage of a right sectoral duct into the left hepatic ductal system (*D1*, Right posterior sectoral duct draining into the left hepatic [*lh*] ductal system; *D2*, Right anterior sectoral duct draining into the left hepatic ductal system). **E,** Absence of the hepatic duct confluence. **F,** Absence of right hepatic duct and ectopic drainage of the right posterior duct into the cystic duct.

hepatic duct. It does not drain any specific liver territory, never communicates with the gallbladder, and is not a satellite of an intrahepatic branch of the portal vein or hepatic artery. Although not of major anatomic significance, injury may occur during cholecystectomy if the cystic plate is not preserved, which may lead to a postoperative biliary leak.

In 67% of patients (Healey & Schroy, 1953) a classic distribution of the main left intrahepatic biliary ductal system exists. The main variation in this region is represented by a common

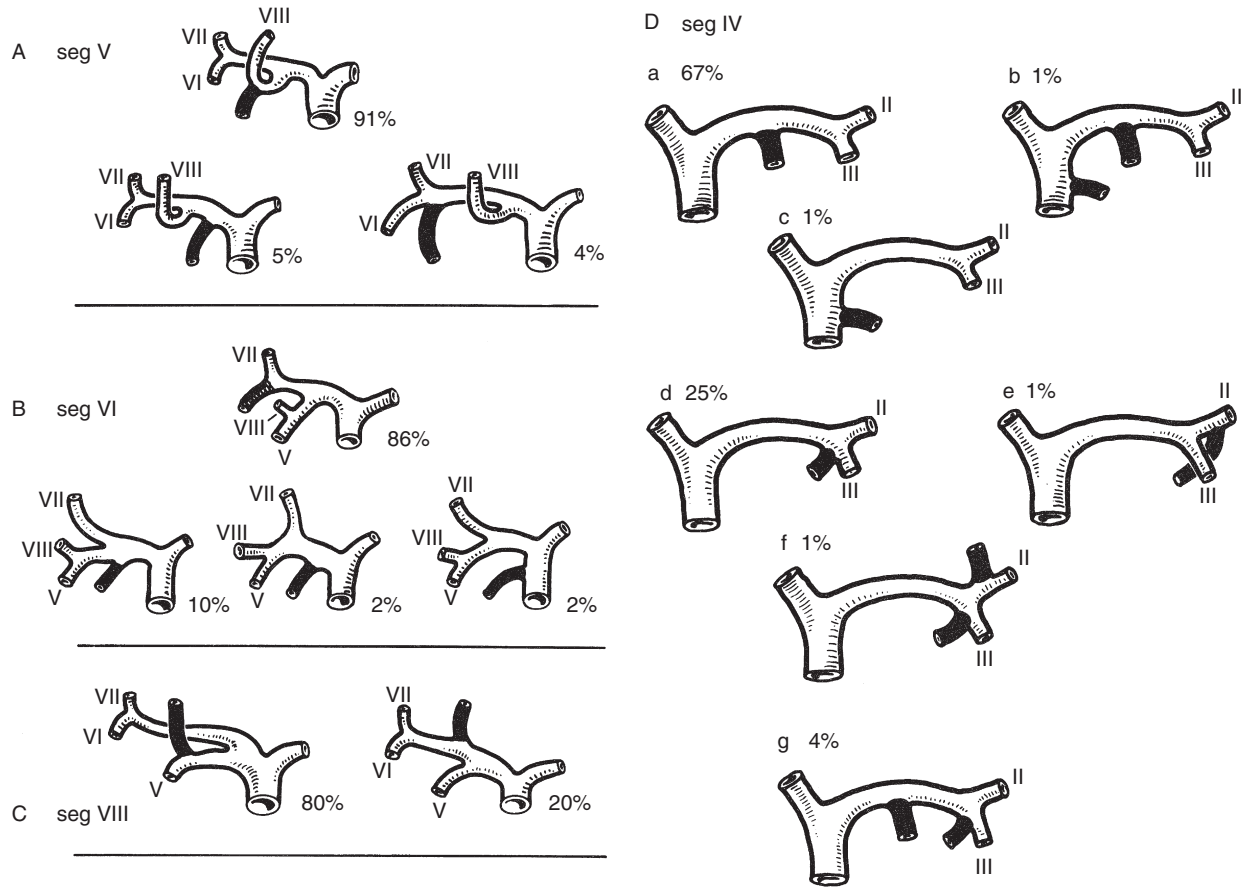

FIGURE 1B.26. Sketch shows the main variations of the intrahepatic ductal system. **A,** Variations of segment V. **B,** Variations of segment VI. **C,** Variations of segment VIII. **D,** Variations of segment IV. There is no variation of drainage of segments II, III, and VII.

union between the ducts of segments III and IV in 25%, and in only 2% does the duct of segment IV join the common hepatic duct independently. Several anomalies of drainage of the intrahepatic ducts into the neck of the gallbladder or cystic duct have been reported (Fig. 1B.27; Albaret et al, 1981; Couinaud, 1957), and these must be kept in mind during cholecystectomy (see Chapter 33).

ANOMALIES OF THE ACCESSORY BILIARY APPARATUS

Many anomalies of the accessory biliary apparatus have been described (Fig. 1B.28A; Gross, 1936). Although rare, agenesis of the gallbladder (Boyden, 1926; Rachad-Mohassel et al, 1973; Rogers et al, 1975), bilobar gallbladders with a single cystic duct but two fundi (Hobby, 1970), and duplication of the gallbladder with two cystic ducts all have been described. A double cystic duct may drain a unilocular gallbladder (Perelman, 1961), and congenital diverticulum of the gallbladder with a muscular wall may also be found (Eelkema et al, 1958). More frequently reported are anomalies of position of the gallbladder, which may be in an intrahepatic position, completely surrounded by normal liver tissue, or it may be found on the left of the liver (Newcombe & Henley, 1964).

The mode of union of the cystic duct with the common hepatic duct may be angular, parallel, or spiral (see Fig. 1B.28B). An angular union is the most frequent and is found in 75% of patients (Kune, 1970). The cystic duct may run a parallel course to the common hepatic duct in 20%, with connective tissue ensheathing both ducts. Finally, the cystic duct may approach the common bile duct in a spiral fashion. The absence of a cystic duct is probably an acquired anomaly, representing a cholecystocholedochal fistula.

BILE DUCT BLOOD SUPPLY

The bile duct may be divided into three segments: *hilar, supraduodenal*, and *retropancreatic* (lower common bile duct). The blood supply of the supraduodenal duct is essentially axial (Fig. 1B.29; Northover & Terblanche, 1979). Most vessels to the supraduodenal duct arise from the superior pancreaticoduodenal artery, the right branch of the hepatic artery, the cystic artery, the gastroduodenal artery, and the retroduodenal artery. On average, eight small arteries, each measuring about 0.3 mm in diameter, supply the supraduodenal duct. The most important of these vessels run along the lateral borders of the duct and have been called the *3 o'clock* and *9 o'clock arteries*. Of the blood vessels vascularizing the supraduodenal duct, 60% run

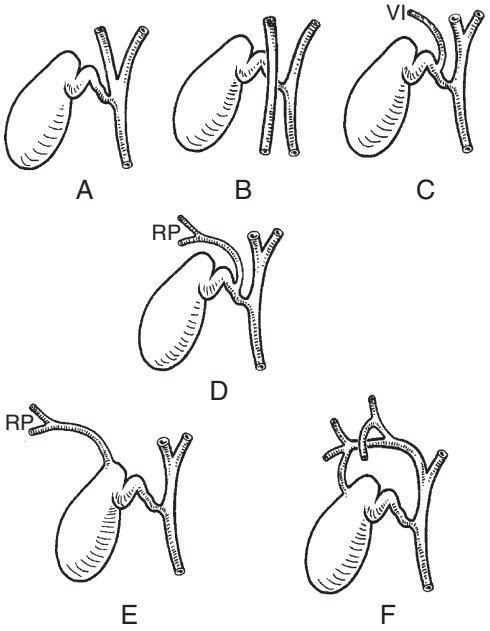

FIGURE 1B.27. The main variations of ectopic drainage of the intrahepatic ducts into the gallbladder and cystic duct. **A,** Drainage of the cystic duct into the biliary confluence. **B,** Drainage of cystic duct into the left hepatic duct, associated with no biliary confluence. **C,** Drainage of segment VI duct into the cystic duct. **D,** Drainage of the right posterior (*RP*) sectoral duct into the cystic duct. **E,** Drainage of the distal part of the right posterior sectoral duct into the neck of the gallbladder. **F,** Drainage of the proximal part of the right posterior sectoral duct into the body of the gallbladder.

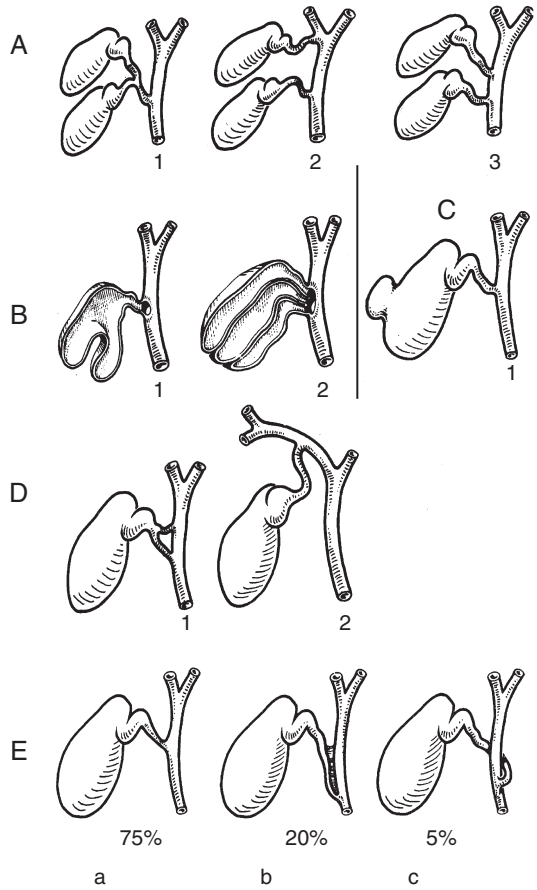

FIGURE 1B.28. Main variations in gallbladder and cystic duct anatomy: **A,** Duplicated gallbladder. **B,** Septum of the gallbladder. **C,** Diverticulum of the gallbladder. **D,** Variations in cystic ductal anatomy. **E,** Different types of union of the cystic duct and common hepatic duct: angular union (*a*), parallel union (*b*), spiral union (*c*).

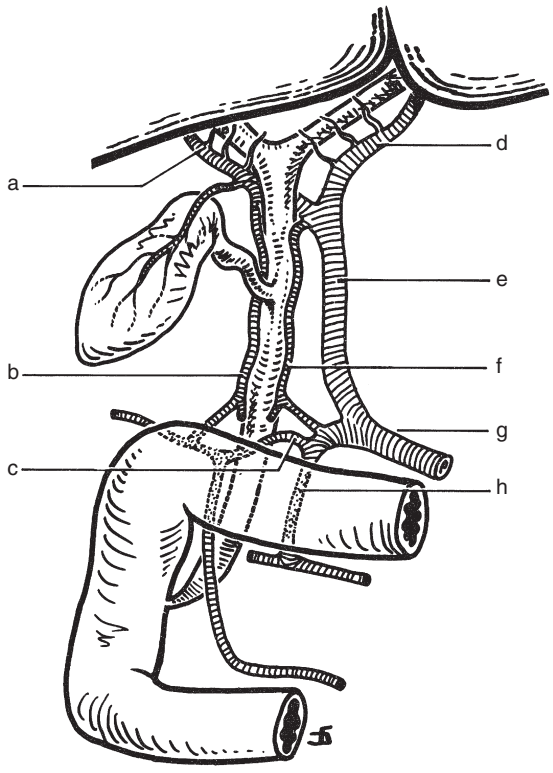

FIGURE 1B.29. The bile duct blood supply. Note the axial arrangement of the vasculature of the supraduodenal portion of the main bile duct and the rich network enclosing the right and left hepatic ducts: right branch of the hepatic artery (*a*); 9 o'clock artery (*b*); retroduodenal artery (*c*); left branch of the hepatic artery (*d*); hepatic artery (*e*); 3 o'clock artery (*f*); common hepatic artery (*g*); gastroduodenal artery (*h*).

upward from the major inferior vessels, and only 38% of arteries run downward, originating from the right branch of the hepatic artery and other vessels. Only 2% of the arterial supply is nonaxial, arising directly from the main trunk of the hepatic artery, as it courses up parallel to the main biliary channel. The hilar ducts receive a copious supply of arterial blood from surrounding vessels, forming a rich network on the surface of the ducts in continuity with the plexus around the supraduodenal duct. The source of blood supply to the retropancreatic common bile duct is from the retroduodenal artery, which provides multiple small vessels running around the duct to form a mural plexus.

The veins draining the bile ducts are satellites to the corresponding described arteries, draining into 3 o'clock and 9 o'clock veins along the borders of the common biliary channel. Veins draining the gallbladder empty into this venous system, not directly into the portal vein, and the biliary tree seems to have its own portal venous pathway to the liver.

ANATOMY OF BILIARY EXPOSURE

Biliary-Vascular Sheaths and Exposure of the Hepatic Bile Duct Confluence

Fusion of the Glisson capsule with the connective tissue sheaths surrounding the biliary and vascular elements at the inferior aspect of the liver constitute the plate system (see Figs. 1B.19 and 1B.20), which includes the hilar plate above the biliary confluence, the cystic plate related to the gallbladder, and the umbilical plate situated above the umbilical portion of the left portal vein (Couinaud, 1957). Hepp and Couinaud (1956) described a technique whereby lifting the quadrate lobe upward and incising the Glisson capsule at its base offers a good exposure of the hepatic hilar structures (see Fig. 1B.20A and B). This technique was referred to as *lowering of the hilar plate*. It can be carried out safely because only exceptionally (in 1% of cases) is there any vascular interposition between the hilar plate and the inferior aspect of the liver. This maneuver is of particular value in exposing the extrahepatic segment of the left hepatic duct, because it has a long course beneath the quadrate lobe. It is not as effective in exposing the extrahepatic right duct or its secondary branches, which are short. The technique is of major importance for the identification of proximal biliary mucosa during bile duct repair after injury. Basically, an incision is required at the posterior edge of the quadrate lobe, where the Glisson capsule is attached to the hilar plate (see Fig. 1B.20B and Chapter 29). The upper surface of the hilar plate can be separated from the hepatic parenchyma and, by lifting the quadrate lobe upward, display of the hepatic duct convergence, which is always extrahepatic, is effected. Bile duct incision allows performance of a mucosa-to-mucosa anastomosis. Rarely, it may be hazardous to approach the biliary confluence in this manner, especially when anatomic deformity has been created by atrophy or hypertrophy of liver lobes and in patients in whom there appears to be a very deep hilus that is displaced upward and rotated laterally. Frequently, by a simultaneous opening of the deepest portion of the gallbladder fossa and the umbilical fissure (see Fig. 1B.20C), good exposure of the biliary duct confluence, and especially the right hepatic duct, can be obtained without the necessity for full hepatotomy.

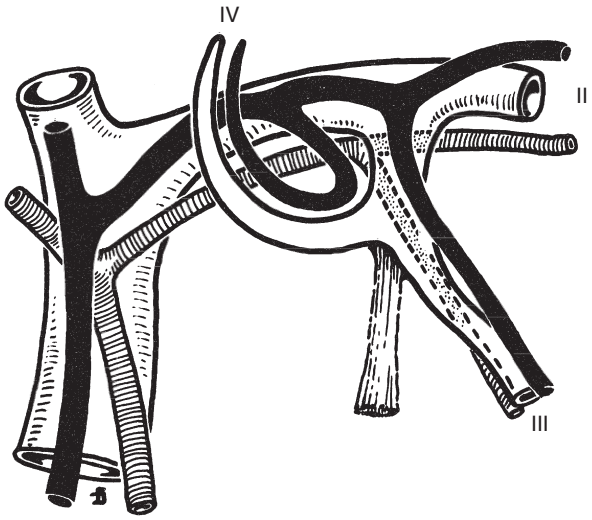

FIGURE 1B.30. Biliary and vascular anatomy of the left liver. Note the location of the segment III duct above the corresponding vein. The anterior branch of the segment IV duct is not represented.

Umbilical Fissure and Segment III (Ligamentum Teres) Approach

The round ligament, which is the remnant of the obliterated umbilical vein, runs through the umbilical fissure to connect with the left branch of the portal vein. The round ligament is sometimes deeply embedded in the umbilical fissure. At the junction of the round ligament and the termination of the left portal vein, elongations containing channels that are elements of the left portal system course into the liver. The bile ducts of the left lobe of the liver (Figs. 1B.30 and 1B.31A) are located above the left branch of the portal vein and lie behind these elongations, whereas the corresponding artery is situated below the vein. Dissection of the round ligament on its left side and division of one or two vascular elongations of segment III allow display of the pedicle or anterior branch of the duct of segment III (see Fig. 1B.31B). In the event of biliary obstruction with intrahepatic biliary ductal dilatation, the segment III duct is generally easily located above the left branch of the portal vein. It is often preferable to split the normal liver tissue just to the left of the umbilical fissure to widen the fissure further, which allows access to the ductal system without having to divide any elements of the portal blood supply to segment III (Fig. 1B.32; see Chapter 29).

Surgical Approaches to the Right Hepatic Biliary Ductal System

Because of the lack of precise anatomic landmarks, exposure of the right intrahepatic ductal system is much more hazardous and imprecise than that of the left. In some cases of hilar cholangiocarcinoma, the planned surgical procedure—partial hepatectomy or segment III duct bypass—seems impossible at operation. In such a critical operative situation, intrahepatic right ductal system drainage is an option. Anatomically, the anterior sectoral duct and its branches run on the left side of the

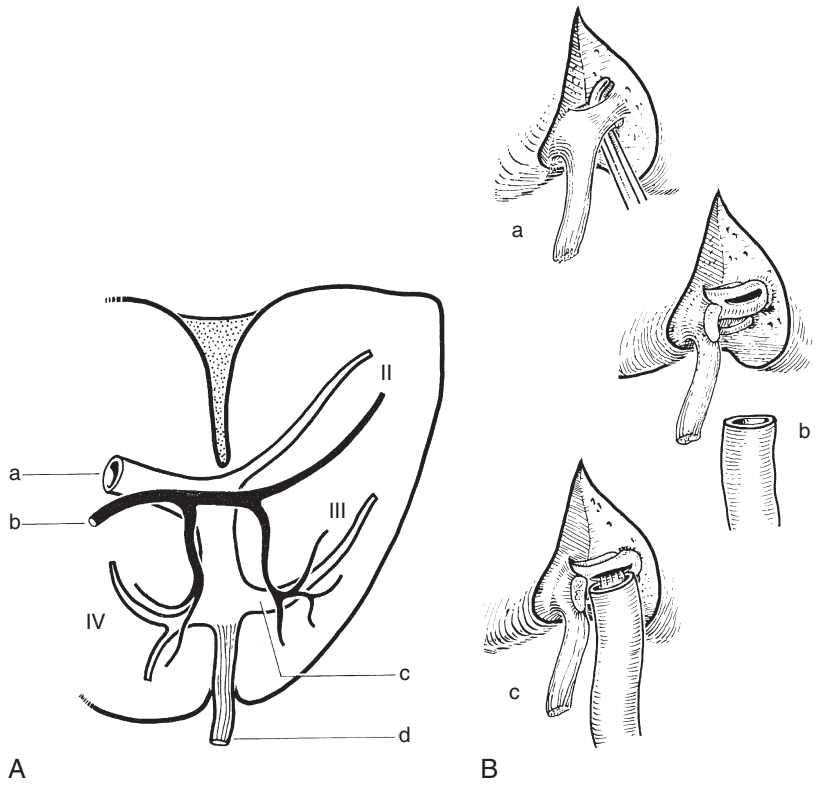

FIGURE 1B.31. A, The biliary and vascular anatomy of the left liver. Note the relationship of the left horn of the umbilical recess with the segment III ductal system: left portal vein (*a*); left hepatic duct (*b*); segment III system—note that the duct (*black*) lies adjacent to the portal venous branch indicated (*c*); ligamentum teres (*d*). **B,** Segment III ductal approach: exposure of the left horn of the umbilical recess (*a*); division of the left horn of the umbilical recess, including segment III portal vein branches (*b*); exposure and opening of segment III duct: hepaticojejunostomy to the segment III ductal system (*c*; see also Chapter 29).

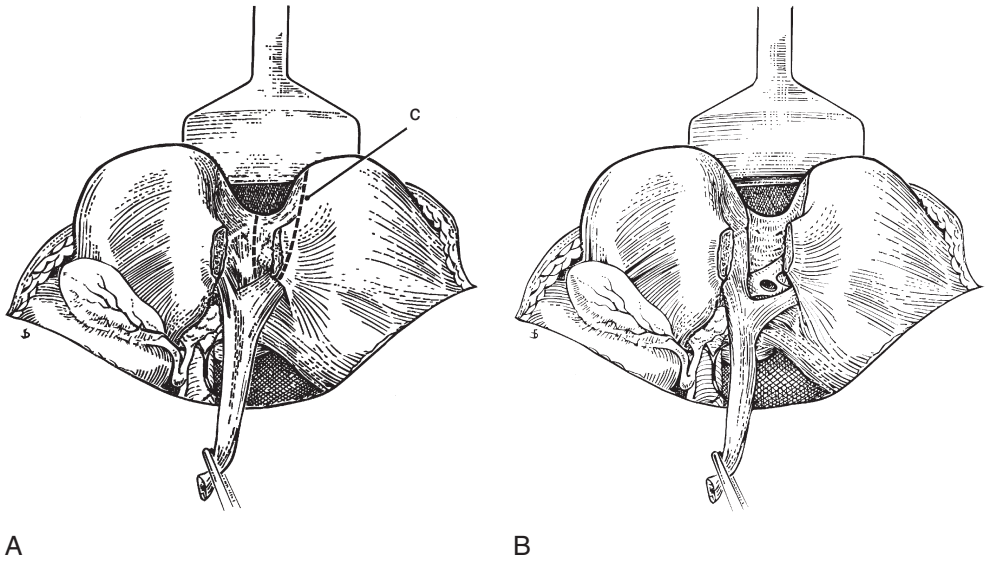

FIGURE 1B.32. A, The liver is split to the left of the ligamentum teres in the umbilical fissure. It may be necessary to remove a small wedge of liver tissue (*c*). **B,** Segment III duct is exposed at the base of the liver split, above and behind its accompanying vein, and is ready for anastomosis (see also Chapters 29 and 42).

corresponding portal vein. In essence, the end of the liver scissura, within which lies the right branch of the portal vein, is opened over a short distance. The anterior sectoral duct is displayed on the left aspect of the vein, and the dilated duct is opened longitudinally and anastomosed to a Roux-en-Y loop of jejunum (Fig. 1B.33). Although this technique is rarely used, it may be valuable in selected cases. An alternative method is to open into the segment V duct through the gallbladder fossa, although we seldom use this approach and prefer the anterior sectoral duct approach.

Exposure of the Bile Ducts by Liver Resection

This chapter does not detail exposure of the bile ducts by resection of liver substance. In essence, a segment of the left lobe may be amputated to expose the segment II or III ducts, or a

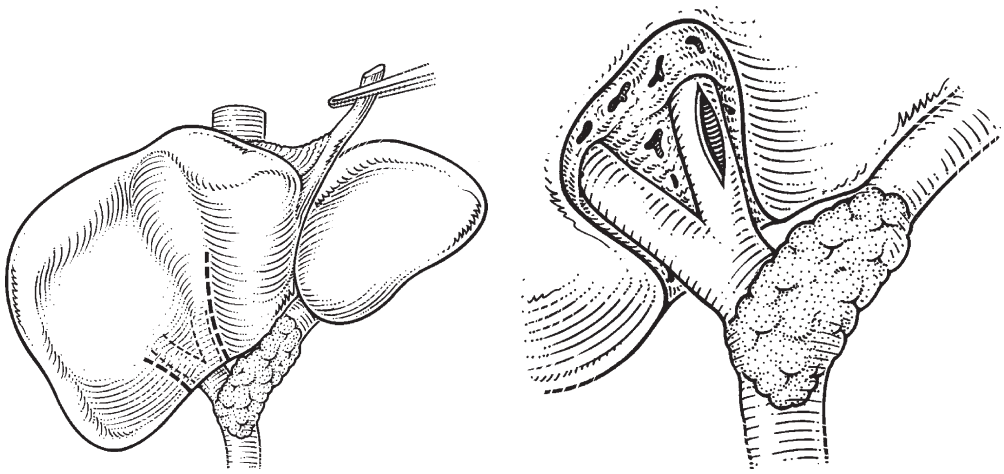

FIGURE 1B.33. **A,** Anterior sectoral approach. If necessary, the liver substance is opened over a short distance in the line of the right anterior sectoral pedicle. **B,** The duct is displayed anterior and to the left side of the corresponding vein. This can be facilitated using a posterior pedicular approach as described by Launois (see Chapters 90A to 90F).

similar procedure may be carried out after removal of the inferior tip of the right lobe. Finally, in some instances, removal of the quadrate lobe may be carried out to effect exposure of the biliary confluence. This procedure really represents a simple extension of the mobilization of the quadrate lobe after opening of the principal scissura and the umbilical fissure as described previously.

EXTRAHEPATIC VASCULATURE

Celiac Axis and Blood Supply of Liver, Biliary Tract, and Pancreas

The usual classic description of the arterial blood supply of the liver, biliary system, and pancreas is found in only about 60% of specimens (Figs. 1B.34 to 1B.36). The right and the left hepatic arteries, the former in the right of the hilus of the liver and the latter in the left at the base of the umbilical fissure, become enclosed in the sheath of peritoneum, forming the right and left portal triads. In this sheath, further branching to the right anterior and posterior sectors of the liver and on the left to segments II, III, and IV occurs within the respective pedicles, which also come to enclose the portal vein branches and the tributary bile ducts from these sectors and segments. The arterial supply of the common bile duct was described earlier; it arises from branches of the hepatic artery, the gastroduodenal artery, and the pancreaticoduodenal arcades.

For practical surgical issues, the most important relationships in the anatomy of the pancreas concern the arterial blood supply and the venous drainage. The dorsal pancreatic artery is a major branch, usually arising from the splenic artery, but it can arise directly from the hepatic artery. When splenectomy is performed, it is important to establish the site of origin of the distal pancreatic artery by proximal arterial ligation to avoid distal pancreatic ischemia. The superior mesenteric artery (SMA) arises from the aorta posteriorly behind the pancreas and runs forward and upward to run first behind and then to the left of the superior mesenteric vein (see Fig. 1B.35).

Variations in the Hepatic Artery

As a result of the complex embryologic development of the celiac axis and SMA, wide variations in the arterial supply of the liver are found (Fig. 1B.37). These variations are important to the angiographer and the surgeon. Failure to show all arteries feeding the liver at angiography may not only result in errors of diagnosis but may also seriously mislead the surgeon or the interventional radiologist. In most cases, the hepatic artery arises from the celiac axis as described earlier, but it may be entirely replaced by a common hepatic artery taking origin from the SMA. In this instance, the hepatic artery passes lateral to the portal vein and lies posterior and lateral to the common bile duct in the hepatoduodenal ligament, where it is susceptible to operative injury if not recognized. This applies to a replaced or an accessory hepatic artery. Other variations in the origin of the common hepatic artery include its origin from the aorta and the persistence of a primitive embryologic link between the celiac and superior mesenteric systems. These variations are of considerable importance in controlling the arterial blood supply to the liver during hepatic resection or enucleative procedures, in the performance of devascularization of the liver, in the placement of intraarterial hepatic infusion devices, and in the resection of the head of the pancreas.

Portal Vein

The portal vein (Fig. 1B.38) is formed behind the neck of the pancreas by confluence of the superior mesenteric and splenic veins (Fig. 1B.39). The venous drainage of the pancreas runs in the main parallel to the arterial supply. There are anterior and posterior and superior and inferior pancreaticoduodenal veins that drain to the portal vein and the superior mesenteric vein (SMV). The left gastric vein and the inferior mesenteric vein (IMV) usually drain into the splenic vein, but they can drain directly into the portal vein, whereas the various small splenic tributaries drain directly to the splenic vein.

The anatomic relationship of the pancreas to the SMV, the splenic vein, and the portal vein (see Fig. 1B.38) is important

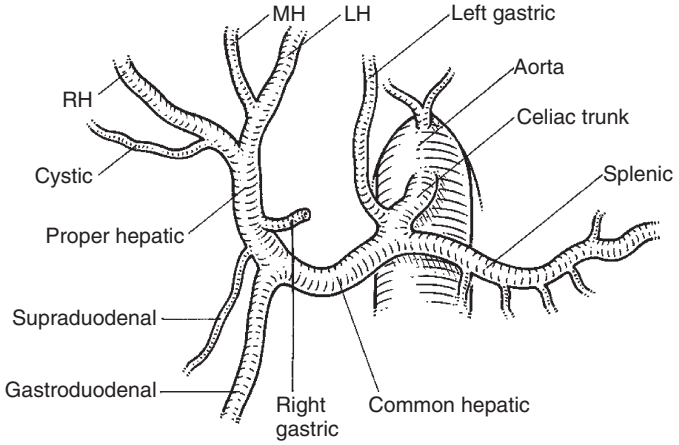

FIGURE 1B.34. The celiac trunk is a short, thick artery originating from the aorta just below the aortic hiatus of the diaphragm and extending horizontally and forward above the pancreas, where it divides into the left gastric, common hepatic, and splenic arteries. An inferior phrenic artery, usually arising from the aorta or the splenic artery, occasionally arises from the celiac trunk. The left gastric artery curves toward the stomach and extends along its lesser curve, forming anastomoses with the right gastric artery. The splenic artery, the largest of the three celiac branches, takes a tortuous course to the left, behind and along the upper border of the pancreas and at the hilus of the spleen, where it splits into numerous terminal branches. The splenic artery usually approaches and runs superiorly to the splenic vein. An uncommon but dangerous abnormality can occur when the splenic artery runs inferiorly and behind the splenic vein, close to the splenic vein–mesenteric vein confluence. The left gastroepiploic artery and the short gastric arteries originate from one of these terminal branches. The common hepatic artery passes forward into the retroperitoneum then curves to the right to enter the right margin of the lesser omentum, just above the pancreas, and ascends; it approaches the common bile duct on its left side and runs usually anterior to the portal vein. As it turns upward just above the pancreas, it gives rise to the gastroduodenal artery, which also may originate from the right hepatic artery. This descends to supply the anterior, superior, and posterior surfaces of the first inch of the duodenum. The gastroduodenal artery can be duplicated and often has a small branch running with it toward the pylorus. The right gastric artery passes to the left along the lesser curve of the stomach, and anastomosis is to the left gastric artery. The continuation of the common hepatic artery, beyond the origin of the gastroduodenal artery and right gastric artery, is known as the *proper hepatic artery* and usually soon divides into a right and a left branch. The left branch extends vertically, directly toward the base of the umbilical fissure, and usually gives off a branch known as the *middle hepatic artery* (*MH*), which is directed toward the right of the umbilical fissure and is destined to supply the quadrate lobe (segment IV) of the liver. A further branch of the left hepatic artery (*LH*) courses to the left to supply the caudate lobe, and further smaller caudate branches arise from the left and right hepatic artery. The right hepatic artery (*RH*) usually passes behind the common hepatic duct and enters the cystic triangle of Calot; in some cases it passes in front of the bile duct, which is important in surgical exposure of the common bile duct. The cystic artery usually arises from the right hepatic artery but has many variations.

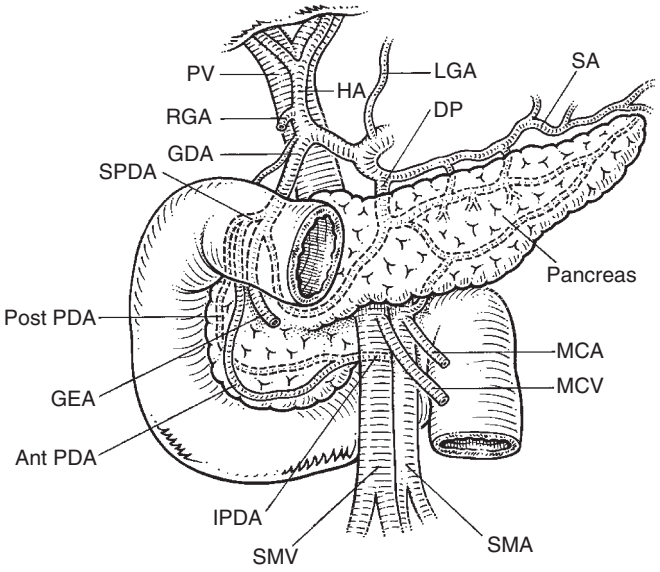

FIGURE 1B.35. The primary arteries supplying the pancreas are the gastroduodenal artery (*GDA*), which arises usually from the common hepatic artery (*HA*) as it crosses the portal vein (*PV*) above the pancreas proper, and the dorsal pancreatic artery (*DP*), arising from the splenic artery (*SA*). The superior pancreaticoduodenal arteries (*SPDAs*) arise from the GDA and join the inferior pancreaticoduodenal arteries (*IPDAs*) from the superior mesenteric artery (*SMA*), forming two arcades along the anterior and posterior aspects of the head of the pancreas. The GDA, after giving rise to the pancreaticoduodenal artery (*PDA*), passes forward and to the left as the right gastroepiploic artery (*GEA*). The GDA is a good landmark for the identification of the portal vein above the pancreas, and surgical division of the GDA just at its origin from the common HA gives much greater access to the anterior surface of the portal vein at this site. The right gastric artery (*RGA*) also usually arises from the common HA just distal to the GDA, but it can arise from various sites. The GDA commonly divides into a larger right GEA and smaller SPDA. The right GEA runs forward between the first part of the duodenum and pancreas; the SPDA divides into anterior and posterior branches. The anterior superior PDA continues downward on the anterior surface of the head of the pancreas to anastomose with the IPDA, which arises from the SMA. The posterior superior PDA behaves similarly. MCA, middle colic artery; MCV, middle colic vein; SMV, superior mesenteric vein; LGA, left gastric artery.

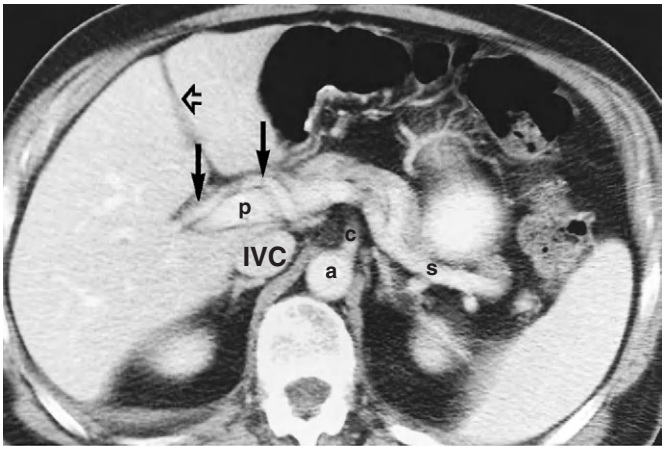

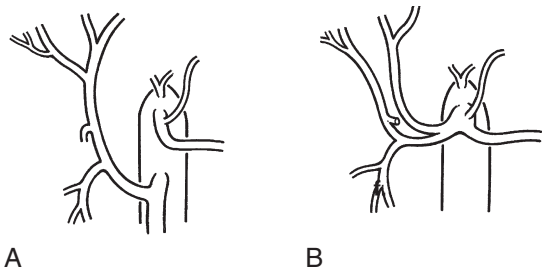

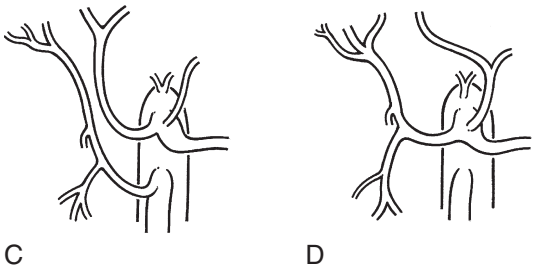

FIGURE 1B.36. Computed tomographic image of the main portal vein shows the hepatic artery (*arrows*) coursing anterior to the portal vein (*p*). The interlobar fissure (*open arrow*), splenic vein (*s*), celiac axis (*c*), aorta (*a*), and inferior vena cava (*IVC*) are also shown.

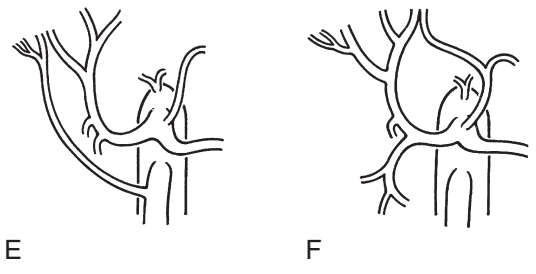

FIGURE 1B.37. In approximately 25% of individuals, the right hepatic artery arises partially or completely from the superior mesenteric artery (**A, C, E**); in a similar proportion of patients, the left hepatic artery may be partially or completely replaced by a branch arising from the left gastric artery, coursing through the gastrohepatic omentum to enter the liver at the base of the umbilical fissure (**D, F**). Rarely, the right or left hepatic arteries originate independently from the celiac trunk or branch after a very short common hepatic artery origin from the celiac, and the gastroduodenal artery may originate from the right hepatic artery (**B, C**).

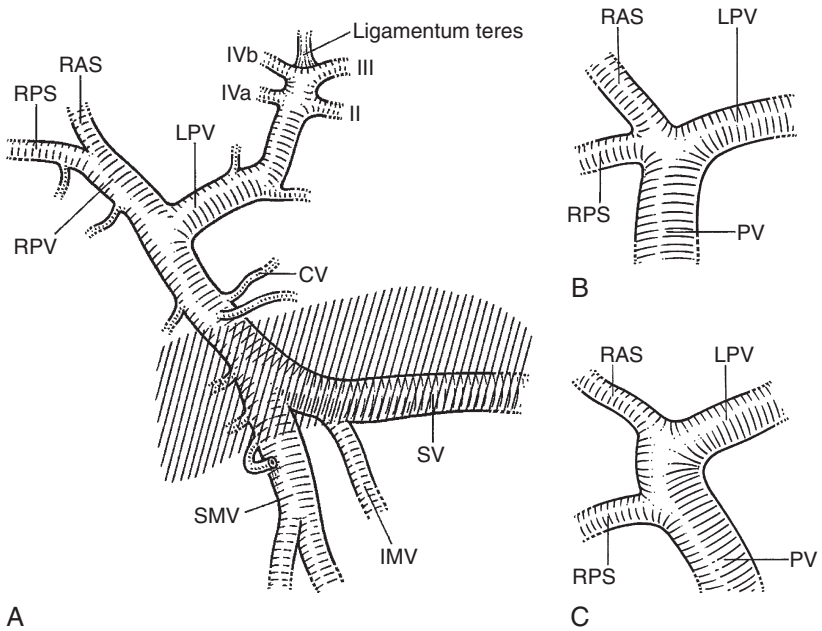

FIGURE 1B.38. **A,** The superior mesenteric vein (*SMV*) at the root of the lesser omentum is usually a single trunk; two or sometimes even three branches may unite as the vessel enters the tunnel beneath the neck of the pancreas (*shaded*) to form a superior mesenteric trunk. This trunk ascends behind the neck of the pancreas and is joined by the splenic vein (*SV*), which enters it from the left to form the portal vein (*PV*), which emerges from the retroperitoneal upper border of the neck of the pancreas and ascends toward the liver within the free edge of the lesser omentum, lying behind the bile duct and the hepatic artery and surrounded by the lymphatics and nodes of the lesser omentum. During this course, it receives blood through the coronary vein (*CV*), which communicates with esophageal venous collaterals, which connect with the gastric vein and the esophageal plexus. Sometimes a separate right gastric vein enters the PV in this area. A superior pancreaticoduodenal vein often enters the PV just above the level of the pancreas, and several smaller veins enter the SMV and PV from the right side beneath the neck of the pancreas. As the PV ascends behind the common bile duct and common hepatic duct, it approaches the hilus of the liver and bifurcates into two branches, a larger right (*RPV*) and a smaller left portal vein (*LPV*). The branch on the left courses below the left hepatic duct to enter the umbilical fissure, in company with the left hepatic artery, and subsequently branches to supply the left liver segments (II-IV). Just before its entry into the umbilical fissure, it gives off a major caudate vein, segment I, which runs posteriorly and laterally to the left. Sometimes this vein consists of two or more branches; the right portal branch, which is much shorter in length before its entry into the liver, divides at the extremity of the hilus into the right anterior (*RAS*) and posterior (*RPS*) sectoral branches and is accompanied by the respective arterial branches and biliary tributaries. **B,** The division of the portal vein may arise more proximally, however, and the right anterior and posterior sectoral portal veins may arise independently from the portal venous trunk. **C,** See also Figs. 1B.8B, 1B.40, and Chapters 90 A through F.

FIGURE 1B.40. Contrast-enhanced computed tomographic scan of variant portal vein branching with trifurcation pattern. *M,* main portal vein; *L,* left portal vein; *RA,* right anterior portal vein; *RP,* right posterior portal vein. *(From Covey AM, et al, 2004: Incidence, patterns, and clinical relevance of variant portal vein anatomy. Am J Roentgenol 183:1055-1064.)*

in pancreaticoduodenectomy (see Chapter 62). The uncinate process can extend behind the SMV to well behind the SMA (see Fig. 1B.35). Access to the portal vein behind the pancreas usually is obtained from below by elevating the pancreas from the surface of the SMV just before it joins the splenic vein. With the exception of the inferior pancreaticoduodenal veins, which enter the SMV at the inferior border of the pancreas, it is uncommon to see branches from the pancreas run directly posteriorly into the SMV. Fixation here is usually by some inflammatory or neoplastic process. Superiorly, the portal vein runs behind the pancreas and is identified first in the gap between the curvature of the splenic vein, splenic artery, common hepatic artery, and gastroduodenal artery. Division of the gastroduodenal artery provides much greater access to the superior surface of the portal vein. If difficulty is encountered in this area, division of the common bile duct, usually above the cystic duct, can provide excellent access to the right lateral aspect and anterior surface of the portal vein. The SMA can be approached behind the pancreas above the point at which it is embraced by the uncinate process at the origin from the aorta. This allows dissection of the most proximal part of the SMA from behind.

Occasionally, the middle colic artery and other vessels of supply to the colon can arise from the more proximal SMA, such that they pass through the pancreas; this abnormality should be searched for carefully. Division of the middle colic artery is usually not a problem, however, because the colon is well supplied, and ischemia typically does not occur.

Of special importance to the surgeon is the direct relationship of the head of the pancreas to the duodenum and posteriorly to the right renal vein and the anterior surface of the IVC, and of the neck and body of the pancreas posteriorly to the SMA and the splenic vessels and their branches, the left renal vein, and, more laterally, the left kidney. The right gastroepiploic vein commonly drains into the anterior surface of the SMV just at the inferior border of the pancreas; this can often be involved by tumor, as can the anterior branch of the inferior pancreaticoduodenal vein; the middle colic vein may also join at this point. In mobilizing the SMV, these vessels are ligated so as to avoid bothersome hemorrhage. Abnormalities of the IVC are uncommon, with duplication of the vena cava and a left-sided vena cava seen rarely.

Several variations in anatomy and rare congenital anomalies of the portal vein are of surgical significance (Figs. 1B.40 to 1B.43). For example, performance of right hepatic resection, with division of what appears to be the right portal vein in a patient with absence of the left portal vein (Fig 1B.42), can deprive the entire liver of blood; this surgical error is usually fatal. Agenesis of the right branch of the portal vein is associated with agenesis of the right hemiliver and left liver hypertrophy. This may be associated with biliary and hepatic venous anatomic changes, which can compromise surgical approaches to the liver and to biliary repair (Fields et al, 2008).

Portal venous blood is derived from the venous drainage of the stomach, small bowel, spleen, and pancreas, and this drainage is important when considering surgery of the pancreas and in patients with portal hypertension; it is described in detail along with the description of the anatomy of the pancreas.

PANCREAS

The pancreas is a posteriorly situated retroperitoneal organ draped across the major vessels and the vertebral column (Fig. 1B.44). The organ is composed of a *head*, *neck*, and *body*; the head is encompassed by the duodenum, and the tail rests in the splenic hilum (Figs. 1B.45 and 1B.46). A portion of the head inferiorly is termed the *uncinate process* and is intimately related to the SMV and SMA (see Figs. 1B.45 and 1B.46). Posteriorly, the pancreas is related to the IVC, aorta, left renal vein and kidney, and spleen (see Figs. 1B.44 and 1B.46B). Usually 4 to 6 inches in length, the relative dimensions of the pancreas have been evaluated more recently. The mean weight is 91.8 g (range, 40.9 to 182 g). To the right of

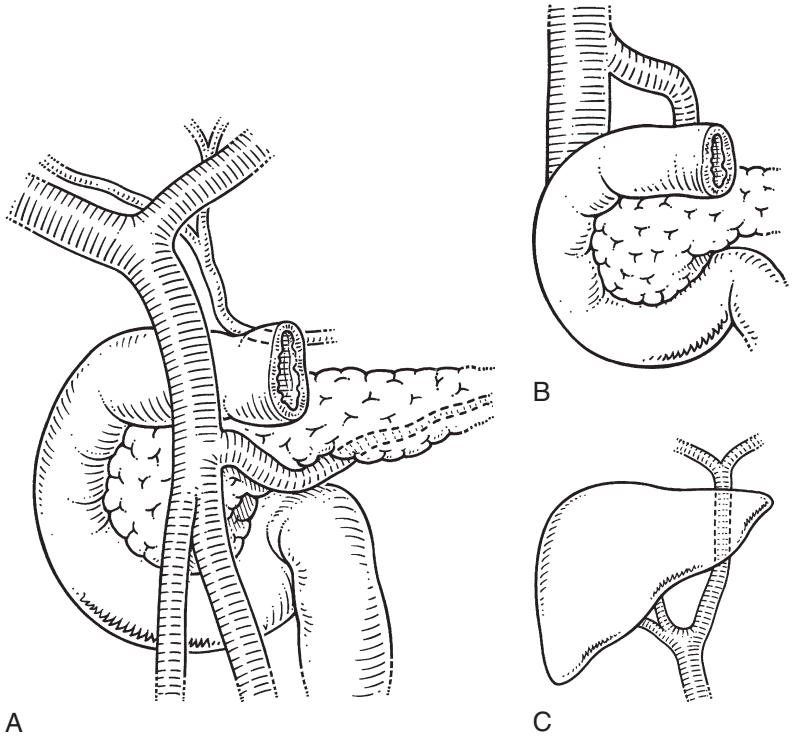

FIGURE 1B.41. **A,** The portal vein anterior to the head of the pancreas and the duodenum may be in an abnormal position. **B,** Another rare but interesting anomaly is the entrance of the portal vein into the inferior vena cava. **C,** Very rare, the entrance of a pulmonary vein into the portal vein.

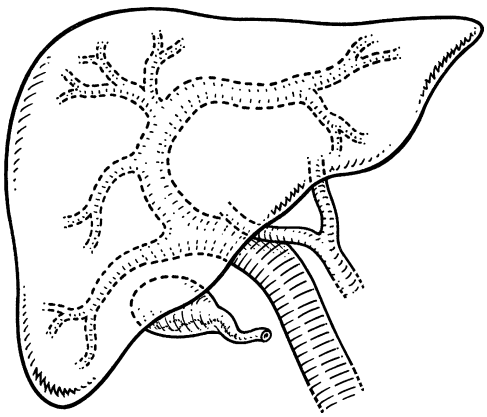

FIGURE 1B.42. In a congenital absence of the left branch of the portal vein as described by Couinaud, the right branch courses through the right lobe of the liver supplying it and curves within the liver substance to supply the left lobe, which in such instances is usually smaller than normal.

FIGURE 1B.43. Computed tomographic scan in a patient with Caroli disease shows a large right portal trunk. The left branch of the portal vein is absent, with findings confirmed at operation for left hepatic lobectomy.

the common bile duct, the average weight of the pancreas is 11.4% of its total weight; the portion lateral to the portal vein averages 56.4% of the total weight. The pancreatic capsule is loosely attached to the surface of the pancreas and is contiguous with the anterior layer of the mesocolon, such that it can be dissected in continuity if necessary. The mesenteric attachments to the pancreas tend to be contiguous (see Fig. 1B.46). The arterial blood supply and venous drainage and the relationships to the common bile duct were described and illustrated earlier (see Figs. 1B.17, 1B.29, 1B.34, 1B.35, and 1B.38).

Pancreatic Duct

The duct of Wirsung, beginning in the distal tail as a confluence of small ductules, runs through the body to the head, where it usually passes downward and backward in close juxtaposition to the common bile duct (see Fig. 1B.45). The sphincter of Oddi (Fig. 1B.47) has been thoroughly studied (Boyden, 1957; Delmont, 1979) and consists of a unique cluster of smooth muscle fibers distinguishable from the adjacent smooth muscle of the duodenal wall. The papilla of Vater at the termination of the common bile duct is a small, nipplelike structure that protrudes into the duodenal lumen and is marked by a longitudinal

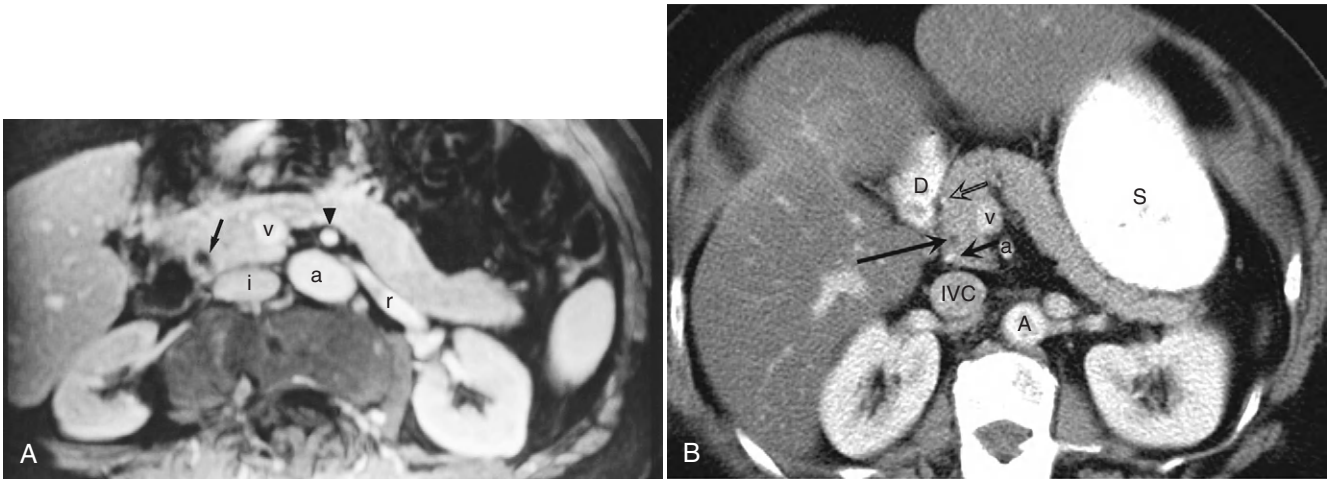

FIGURE 1B.44. A, Magnetic resonance imaging of the pancreas, oblique axial reconstruction, T1-weighted three-dimensional gradient-echo technique. Aorta (*a*), inferior vena cava (*i*), common bile duct (*arrow*), inferior mesenteric vein at the splenoportal confluence (*v*), superior mesenteric artery (*arrowhead*), and left renal vein (*r*) are shown. **B,** Normal pancreatic anatomy. Postcontrast computed tomographic scan at the level of the pancreas. *S,* stomach; *D,* duodenum; *A,* aorta; *v,* superior mesenteric vein; *a,* superior mesenteric artery. *Long arrow*, common bile duct; *short arrow*, inferior pancreaticoduodenal artery; *open arrow*, gastroduodenal artery.

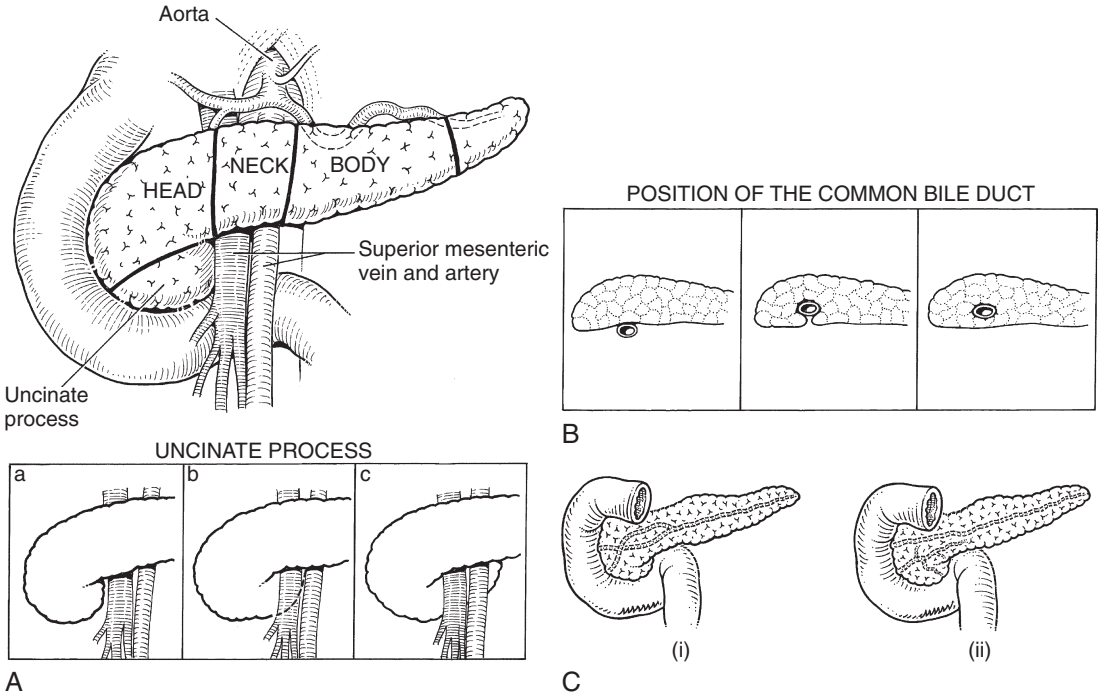

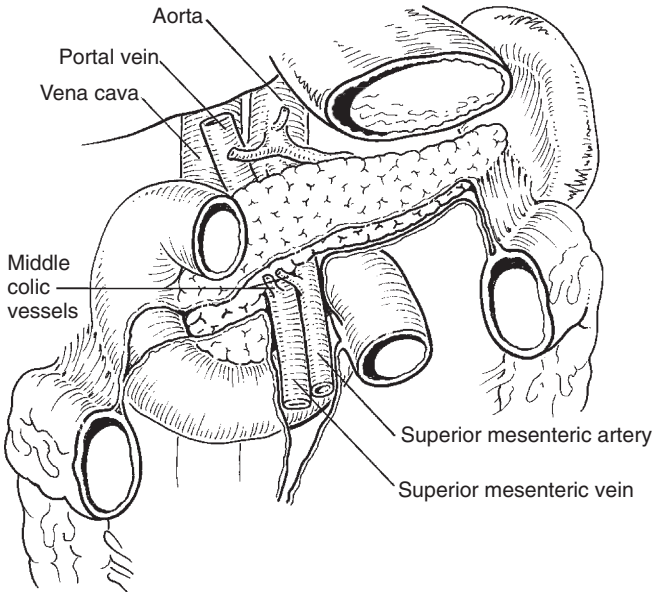

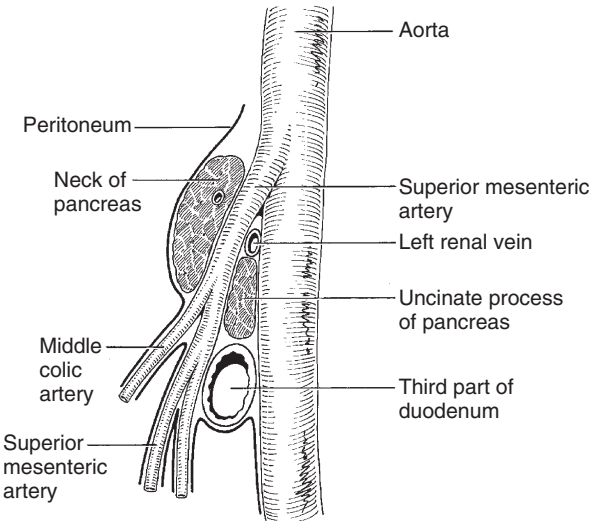

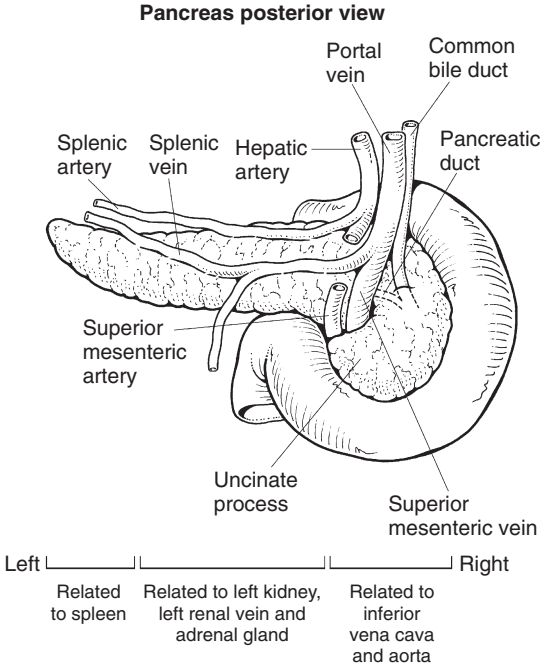

FIGURE 1B.45. A, The head of the pancreas is globular with an extension, the *uncinate process*, which curves behind the superior mesenteric vessels and may end even before it embraces the superior mesenteric vein (*a*), or it may pass completely behind between the aorta and the left of the patient's superior mesenteric artery (*b, c*). All variations are commonly seen. Posteriorly, the head of the pancreas lies in juxtaposition to the inferior vena cava at the level of the entry of the left and right renal veins. The head of the pancreas forms a narrow *neck* in front of the superior mesenteric and splenic vein confluence. The neck joins to the *body* of the gland, which forms a narrow *tail*. **B,** The common bile duct (CBD) passes through the pancreas, either directly in the substance of the gland or initially with a posterior groove. **C,** The *duct of Wirsung* courses from left to right within the pancreas, curves downward approaching the CBD, and runs parallel with but separated from it by the *transampullary septum* to enter the duodenum, 7 to 10 cm distal to the pylorus, at the *papilla of Vater* after traversing the *sphincter of Oddi.* An accessory duct, the *duct of Santorini,* runs more proximally in the head of the pancreas and usually terminates in the duodenum at an accessory papilla. Multiple variations of the ductal system occur, depending on the extent of development of the duct of Santorini, such that rarely the accessory duct can enter the duodenum inferior to the main duct. It can be in communication with the main duct directly (*i*), or it can occur in duplicate version known as *pancreas divisum* (*ii*). The duct of Santorini drains the body and tail of the organ, and the duct of Wirsung drains the head and the uncinate process.

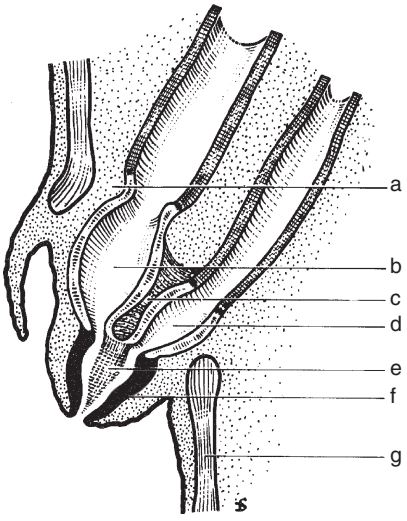
The transverse mesocolon arises from the lower border of the pancreas and envelops the middle colic vessels as they arise from the superior mesenteric vessels just beneath the pancreatic neck. **B,** The relationship of the pancreatic neck and uncinate process to the aorta and superior mesenteric artery. Note the position of the left renal vein and duodenum. **C,** The posterior relationships of the duodenal loop and pancreas. Note the relationship to the inferior vena cava, aorta, and hilum of the spleen.



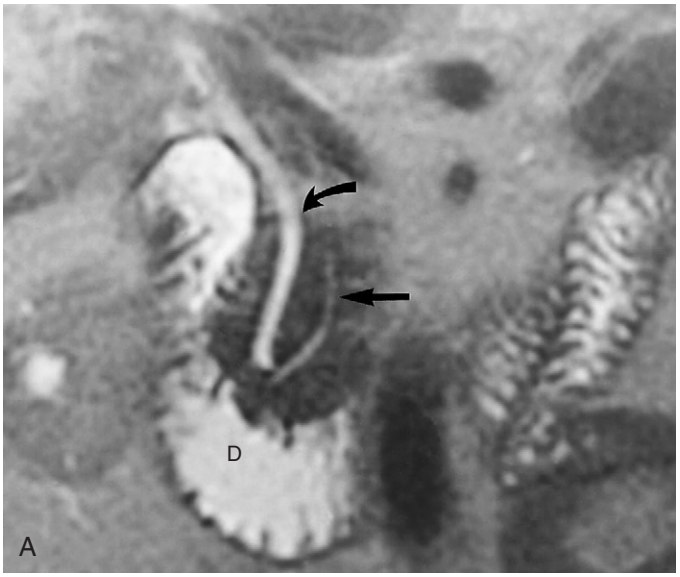


FIGURE 1B.47. Schematic representation of the sphincter of Oddi: notch (*a*); biliary sphincter (*b*); transampullary septum (*c*); pancreatic sphincter (*d*); membranous septum of Boyden (*e*); common sphincter (*f*) ; smooth muscle of duodenal wall (*g*).

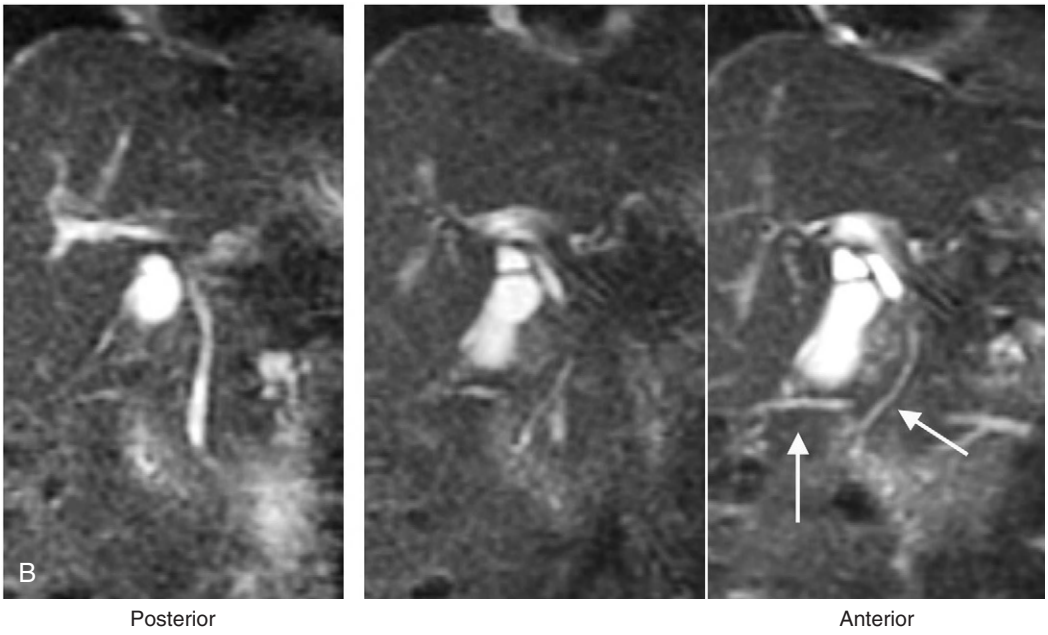

FIGURE 1B.48. **A,** Magnetic resonance imaging (MRI) cholangiography, T2-weighted coronal image at the level of the ampulla, shows the duodenum (*D*) and the pancreatic head with common bile duct (*curved arrow*) and pancreatic duct (*straight arrow*). **B,** MR cholangiopancreatography (*MRCP*) shows pancreas divisum. Anterior projection shows variant anatomy with the duct of Santorini (*vertical arrow*) between the duodenum above the duct of Wirsung (*angled arrow*). The two ducts are separate; the duct of Santorini drains mainly the neck and body of the pancreas, and the duct of Wirsung drains mainly the uncinate process portion of the head of the pancreas.

fold of duodenal mucosa. The duct of Wirsung runs downward and parallel to the common bile duct for approximately 2 cm and joins it within the sphincter segment in 70% to 85% of patients; it enters the duodenum independently in 10% to 13% of patients and is replaced by the duct of Santorini in 2% of patients (Fig. 1B.48; see also Fig. 1B.45). Rarely, the duct of Santorini and the duct of Wirsung are separate, which is known as *pancreas divisum* (see Figs. 1B.45Cii and 1B.48B). The islands or islets of Langerhans, which provide the endocrine component of the gland, are scattered throughout the pancreas.

Annular Pancreas

Annular pancreas is the development of a ring of pancreatic tissue that surrounds and often embraces the duodenum. This ring may contain a large duct and can be firmly affixed to the duodenal musculature. The duodenum beneath this annulus is often stenosed, such that dividing this ring does not always relieve chronic duodenal obstruction. This accounts for the common process of applying duodenojejunostomy to relieve strictures caused by such an annulus.

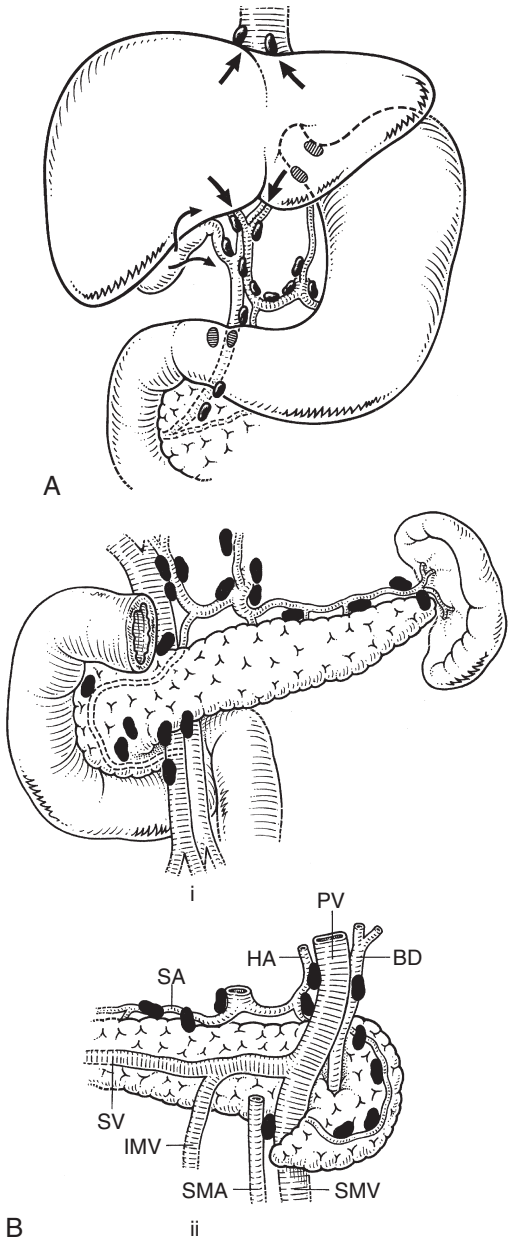

FIGURE 1B.49. A, The liver drains principally to hepatoduodenal nodes at the hilus and along the hepatic artery and portal vein. The gallbladder drains partly to the liver, but it also drains via the cystic node to nodes of the hepatoduodenal ligament and to suprapancreatic nodes. **B,** Numerous nodes (*i*) lie along the superior mesenteric vein along the borders of the pancreas, draining back into the splenic hilar nodes; along the superior border of the pancreas to the superior pancreatic nodes; and to the celiac trunk and nodes at the base of the common hepatic artery. A large node commonly lodges in intimate association with the surface of the superior border of the pancreas and the right side of the common hepatic artery. This node often needs to be dissected and elevated to gain access to the anterior surface of the portal vein. Removal of this node often improves access, as does division of the gastroduodenal artery. Posterior pancreaticoduodenal nodes (*ii*) lie along the posterior pancreatic duodenal arterial arcade. *BD,* bile duct; *HA,* hepatic artery; *IMV,* interior mesenteric vein; *PV,* portal vein; *SA,* splenic artery; *SMA,* superior mesenteric artery; *SMV,* superior mesenteric vein; *SV,* splenic vein.

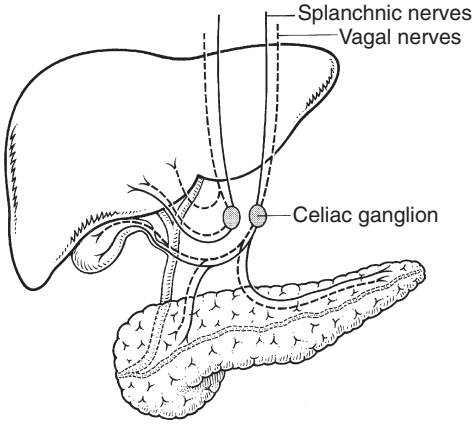

FIGURE 1B.50. Note the distribution of sympathetic and parasympathetic nerves to the liver and pancreas from the celiac ganglion, mainly in association with major arteries.

LYMPHATIC DRAINAGE

Liver and Pancreas

The lymphatic drainage of the liver and gallbladder is mainly to nodes in the hepatoduodenal ligament and along the hepatic artery; this is shown in Fig. 1B.49A. The lymphatic drainage of the pancreas is predominantly to the nodes that lie in juxtaposition to the arteries and veins (see Fig. 1B.50B).

Lymph Node Metastasis and Carcinoma of the Head of the Pancreas

Most patients who have carcinoma of the head of the pancreas have nodal positivity in the infrapyloric and common hepatic nodes, in the nodes along the splenic artery, or in those in the hepatoduodenal ligament. The most common are posterior pancreaticoduodenal lymph nodes, constituting 50% to 60% of all lymph nodes positive for carcinoma of the head of the pancreas. Other common sites are along the SMA and the paraaortic and anterior pancreaticoduodenal areas. In order of frequency, the anterior and posterior duodenal lymph nodes are most commonly involved.

In carcinoma of the distal bile duct or of the ampulla of Vater, the two most common sites for nodal involvement are the suprapyloric and posterior pancreatic lymph nodes. It is important to maximize staging so that at the time of resection, an adequate dissection of the lymph nodes is performed posterior to the pancreas. This is best done by dissection that begins on the anterior surface of the right renal veins and elevates the tissue in front of the vena cava and the left renal vein across to the aorta. The delivery of this soft tissue is not difficult, and it maximizes the likelihood of identifying nodes that can be expected to be positive.

NERVE SUPPLY TO THE LIVER AND PANCREAS

The nerve supply to the liver and pancreas (Fig. 1B.50) is from branches of the celiac ganglion. It is composed of sympathetic and parasympathetic elements.

CHAPTER 8B

Molecular pathogenesis of biliary tract cancer

George Miller

CHOLANGIOCARCINOMA

Cholangiocarcinoma, or biliary tract adenocarcinoma, was first described by Durand-Fardel in 1840 (Olnes & Erlich, 2004). This malignancy arises from the ductal epithelium of the biliary tree, either within the liver (intrahepatic cholangiocarcinoma) or from the extrahepatic bile ducts (extrahepatic biliary adenocarcinoma) or gallbladder. It is a rare disease, and because of its infrequent occurrence, relatively little is known about the underlying biology of these tumors. In addition, this disease is fatal in most cases because of its late clinical presentation and the lack of effective nonsurgical therapeutic modalities (see Chapters 49 and 50) (Ishak et al, 1994). However, in recent years, important work has been done toward understanding the natural history and biology of these tumors and establishing patterns upon which future treatment regimens can be based.

CLASSIFICATION

More than 90% of cholangiocarcinomas are adenocarcinomas (Nakeeb et al, 1996), and they most commonly arise at or near the hepatic duct confluence. These fall under the general category of *extrahepatic cholangiocarcinomas* (see Chapter 50B) but are further subclassified as *hilar cholangiocarcinoma,* or *Klatskin tumors,* after the Yale University pathologist who was one of the first to report a series of patients with this condition (Nakeeb et al, 1996). Bismuth further subclassified hilar cholangiocarcinomas by precise location with reference to the biliary bifurcation and the lobar hepatic ducts (Bismuth et al, 1992). This classification may be useful for descriptive purposes and for operative planning. The remaining extrahepatic cholangiocarcinomas occur in the lower bile duct (periampullary) and are further subclassified as *distal cholangiocarcinomas.* These account for a relatively small fraction of all bile duct tumors. Mid–bile duct tumors are exceedingly rare but do occur in very small numbers, and even less common is disease that diffusely involves the biliary tree.

Cholangiocarcinoma may also arise from the intrahepatic ducts peripherally in the liver, giving rise to the subgroup known as *intrahepatic* or *peripheral cholangiocarcinoma* (see Chapter 50A) (Liver Cancer Study Group of Japan, 2000). Intrahepatic cholangiocarcinomas were poorly understood until recently. These are usually grouped by International Classification of Disease (ICD) codes with hepatocellular carcinoma as primary liver tumors (Khan et al 2002a, 2002b). Furthermore, many cases previously referred to as *liver adenocarcinoma of unknown primary* were likely unrecognized intrahepatic cholangiocarcinomas. Worldwide, intrahepatic cholangiocarcinoma is increasing in incidence and mortality. Intrahepatic tumors have been subcategorized by their growth characteristics into *mass-forming, periductal-infiltrating,* or *intraductal-growing* types (Liver Cancer Study Group of Japan, 2000).

EPIDEMIOLOGY

Although rare, cholangiocarcinoma has a distinctly higher incidence in certain demographic groups and geographic areas. The peak age for cholangiocarcinoma is the seventh decade, with a slightly higher male preponderance (Olmes & Erlich, 2004). The reported incidence in the United States is 1 to 2 cases per 100,000 (3500 new cases per year) with no clear racial predisposition. Cholangiocarcinoma incidence rates vary markedly worldwide, presumably reflecting differences in either local environmental risk factors or genetics. The highest disease incidence rates are in northeast Thailand (96 per 100,000 men), where it occurs approximately 100 times more often than in the West.

Epidemiologic studies have shown that, globally, the mortality and incidence of intrahepatic biliary tract neoplasms are rising, but those of extrahepatic tumors are static or falling. World Health Organization (WHO) mortality data were examined for the United States, United Kingdom, France, Italy, Japan, and Australia from 1979 to 1998 (Ishak et al, 1994). Mortality rates for intrahepatic cholangiocarcinoma were increased in both sexes in all countries except among Japanese women.

A U.S. study examined trends in intrahepatic cholangiocarcinoma incidence using data from the Surveillance, Epidemiology, and End Results (SEER) program, which represents over 10% of the total U.S. population. Data from 1976 to 2000 were analyzed by age, gender, and ethnicity. The incidence of intrahepatic cholangiocarcinoma increased by 165%, from 0.32 per 100,000 from 1975 through 1979 to 0.85 per 100,000 from 1995 through 1999. This increase was reflected in all groups but was highest in black men (139%), followed by white men (124%) and white women (111%). The increased incidence may be attributable in part to increased detection (Olnes & Erlich, 2004). However, increased detection of a tumor is usually associated with an increase in the proportion of patients with early-stage disease or smaller lesions. The rise in intrahepatic cancer was not associated with a significant change in the proportion of early stage cancers, histologically confirmed tumors, or smaller lesions (Broome et al, 1996). Furthermore, the incidence does not seem to be plateauing, as would be expected if the increase were due to an improvement in diagnostic modalities, such as magnetic resonance imaging (MRI) and computed tomography (CT), which have become

established practice in the past several years (Khan et al, 2002a; Shaib & El-Serag, 2004; Taylor-Robinson et al, 2001). Conversely, the incidence of extrahepatic cholangiocarcinoma has shown no such change and may be declining (Tullo et al, 2000). According to the SEER data, U.S. age-standardized mortality rates for extrahepatic tumors fell from 0.6 per 100,000 in 1979 to 0.3 per 100,000 in 1998; and age-standardized incidence rates decreased from 1.08 per 100,000 to 0.82 per 100,000 in the same period.

Most patients have unresectable disease when they are first seen and typically die within 12 months of diagnosis. Sepsis from cholangitis, frequently related to interventions performed for biliary obstruction and progressive liver failure, contribute to the high mortality (Shaib & El-Serag, 2004). Survival is poor, even in resected patients, with less than 5% of patients diagnosed with cholangiocarcinoma surviving to 5 years, a rate which has not changed significantly over the past 30 years. Although cholangiocarcinoma is a relatively rare tumor with an overall dismal prognosis, interest in the biology of this disease has grown in recent years (Khan et al, 2002a; Patel, 2001, 2002; Taylor-Robinson et al, 2001).

CLINICAL RISK FACTORS FOR CHOLANGIOCARCINOMA

Most cases of cholangiocarcinoma, regardless of location, occur without obvious predisposing risk factors. However, there are well-accepted clinical risk factors associated with a minority of cases, and most of these are related to chronic inflammation of the biliary epithelium.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC; see Chapter 41) is the most common condition predisposing to cancer of the biliary tree. Cholangiocarcinoma rates of 8% to 40% have been reported in patients with primary sclerosing cholangitis in follow-up studies and explant specimens (Khan et al, 2002a). Cholangiocarcinoma in such patients tends to present earlier in life, most commonly in the 30- to 50-year age groups, than in sporadic cases (Pitt et al, 1995; Bergquist et al, 1998). Approximately one third of patients with primary sclerosing cholangitis who develop cholangiocarcinoma do so within 2 years of diagnosis, and the risk of carcinogenesis appears to be unrelated to the duration of the inflammatory disease (Pitt et al, 1995; Watanapa & Watanapa, 2002). Two thirds of patients with primary sclerosing cholangitis have associated inflammatory bowel disease, usually ulcerative colitis (Pitt et al, 1995; Watanapa & Watanapa, 2002); however, no association has been found between the risk of cholangiocarcinoma and the severity of inflammatory bowel disease in this cohort of patients (Pitt et al, 1995; Watanapa & Watanapa, 2002).

To date, no reliable factors have been described that reliably stratify cholangiocarcinoma risk in PSC patients, and the clinical diagnosis of cholangiocarcinoma in this setting is difficult. Therefore, molecular markers of cholangiocarcinogenesis, such as *KRAS* or other mutations, may improve the early diagnosis. In a study by Kubicka and colleagues (2001), *KRAS* mutations were analyzed by enriched polymerase chain reaction/restriction fragment length polymorphism in the bile fluid of 56 PSC patients and 20 patients with other cholestatic diseases. To assess the value of *KRAS* mutations as a risk factor for cholangiocarcinogenesis, patients were prospectively investigated over a mean period of 31.5 months. Seventeen patients (30%) with PSC harbored *KRAS* mutations in bile fluid. In contrast to the group of PSC patients with wild-type *KRAS*, four cholangiocarcinomas and two cases of bile duct dysplasia were diagnosed in the group of patients with the mutation during the follow-up investigation. Their results indicate that *KRAS* mutations in bile fluid of PSC patients may represent an early event in cholangiocarcinogenesis; however, most of the PSC patients with *KRAS* mutations remained tumor free after a long follow-up investigation, consistent with the notion that these mutations are not specific for malignancy but may also occur in normal bile duct mucosa or in dysplasias. Therefore, analysis of *KRAS* mutations in bile specimens is not useful to make a definitive diagnosis of cholangiocarcinoma in PSC patients, but it is considered a marker of increased risk.

Parasitic Infection

A large body of experimental and epidemiologic data suggest a pathogenic association between cholangiocarcinoma and liver fluke infestation, especially *Opisthorcis viverrini* and less definitively *Clonorchis sinensis* (see Chapter 45) (Watanapa, 1996). Most epidemiologic data are from Thailand, which has the highest incidence of cholangiocarcinoma worldwide—87 per 100 000 population—and where an estimated 7 million people are infected with opisthorchiasis (Parkin et al, 1991). Human beings become infected by eating undercooked fish, whereupon adult worms inhabit and lay eggs in the biliary system. In addition to a strongly positive correlation between liver flukes and cholangiocarcinoma in case-control studies (Thamavit et al, 1978), malignant change in the biliary epithelium of Syrian hamsters has been shown after infection with *Opisthorcis viverrini*, especially when fed nitrosamines (Thamavit, 1988), which are produced by bacteria in fish and other foods and are thought to act as cofactors in carcinogenesis.

Fibrotic and Cystic Liver Hepatobiliary Diseases

Congenital abnormalities of the biliary tree associated with Caroli syndrome, congenital hepatic fibrosis, and choledochal cysts (cystic dilatations of the bile ducts) carry a 15% risk of malignant change after the second decade, at an average age of 34 years (see Chapter 46) (Scott et al, 1980). The overall incidence of cholangiocarcinoma in patients with untreated cysts is up to 28% (Lipsett et al, 1994; Obtsuka et al, 2001). The mechanism of carcinogenesis is unclear but appears to be related to biliary stasis; reflux of pancreatic juice, causing chronic inflammation; activation of bile acids (van Mil et al, 2001); and deconjugation of carcinogens. Bile duct adenomas and biliary papillomatosis are also associated with the development of cholangiocarcinoma.

Bile Salt Transporter Protein Polymorphisms

Bile salt transporter protein polymorphisms in *BSEP, ATP8B1,* and *ABCB4* genes can lead to unstable bile content and deconjugation of xenobiotics previously conjugated in the liver (Jacquemin, 2001; Thompson & Strautnieks, 2001; Meier et al, 2004). In the background of congenital bile duct abnormalities, this process can lead to the development of cholangiocarcinoma at an early stage in life (Kubo et al, 1995). Individuals who

are heterozygous for bile salt transporter polymorphisms are thought to have an increased predisposition to cholangiocarcinoma as adults after exposure to cofactors that result in chronic inflammation in the biliary tree (Kubo et al, 1995).

Intrahepatic Biliary Stones

Hepatolithiasis, the presence of interhepatic biliary stones (see Chapters 39 and 44), is rare in the West but relatively common in parts of Asia, and it is associated particularly with peripheral intrahepatic cholangiocarcinoma (Shaib & El-Serag, 2004). Up to 10% of patients with hepatolithiasis develop cholangiocarcinoma (Chen, 1999). In Taiwan, up to 70% of patients with cholangiocarcinoma undergoing resection reportedly have intrahepatic biliary stones; in Japan this figure is 6% to 18% (Okuda et al, 2002; Khan et al, 2003). Biliary stones are thought to cause bile stasis, predisposing to recurrent bacterial infections and subsequent inflammation, a potential cofactor for carcinogenesis (Khan et al, 2003).

Chemical Carcinogen Exposure

Several chemical toxins have been associated with cholangiocarcinoma. Promutagenic DNA adducts have been identified in cholangiocarcinoma tissue, indicating exposure to DNA-damaging agents (Sahani, 2003). Thorotrast, a radiologic contrast agent banned in the 1960s for its carcinogenic properties, has been strongly associated with the development of cholangiocarcinoma many years after exposure and has been reported to increase the risk of cholangiocarcinogenesis to 300 times that of the general population (Shaib & El-Serag, 2004; Hardell et al, 1984). Associations have also been made with exposure to byproducts from the rubber and chemical industries, including dioxins and nitrosamines (Sorensen et al, 1998), and with alcohol and smoking (Chalasani et al, 2000), but results have been conflicting, and no firm conclusions can as yet be drawn.

Viral Hepatitis

Chronic liver disease from any cause has also been associated with cholangiocarcinoma (Shin et al, 1996). A cohort study of over 11,000 patients with cirrhosis, followed up over 6 years, showed a tenfold risk compared with the general population (Shin et al, 1996). More specifically, an association has been shown with chronic hepatitis B and C virus infection. A case-control study from Korea reported that 12.5% of patients with cholangiocarcinoma tested positive for hepatitis C virus (HCV) and 13.8% for hepatitis B virus surface antigen (HBsAg) compared with 3.5% and 2.3% of controls, respectively (Donato et al, 2001). In a second case-control study from Italy, 23% of patients with cholangiocarcinoma were positive for anti-HCV, and 11.5% were HBsAg positive compared with 6% and 5.5% of controls, respectively (Kobayashi et al, 2000). A prospective, controlled study from Japan reported the risk of developing cholangiocarcinoma in patients with cirrhosis related to HCV as 3.5% at 10 years—1000 times greater than the risk in the general population (Yin & Chen, 1998). HCV is an established risk factor for hepatocellular carcinoma, and both hepatocytes and cholangiocytes have the same progenitor cell, supporting a role for the virus in cholangiocarcinogenesis. Furthermore, RNA from HCV has been identified in cholangiocarcinoma tissue (Berthiaume & Wands, 2004). A U.S. case-controlled study of risk factors for intrahepatic cholangiocarcinoma showed adjusted odds ratios (ORs) of 6.1 for HCV carriers and 5.9 for HIV-infected individuals. Diabetes was also prevalent in patients with intrahepatic tumors, with an adjusted OR of 2.0; the pathogenic mechanisms are unclear in diabetics but may be related to an associated increased risk of steatohepatitis (Tulio et al, 2000).

MOLECULAR PATHOGENESIS

Genome-wide Analysis

Investigation into the molecular pathogenesis of biliary tract tumors has not been an area of vigorous investigation, but slow progress is being made in the understanding of the genetic basis of this disease. A recent study investigated genome-wide mutations in carcinomas of the biliary tree, including intrahepatic and extrahepatic cholangiocarcinoma and gallbladder cancer, using frozen specimens from patients who underwent surgical resection (Miller et al, 2009). Unsupervised hierarchical clustering analysis revealed that cancers from these different sites did not cluster separately, implying that there was no difference in the global gene expression patterns between the biliary cancer subgroups. Figure 8B.1 depicts the top 40 upregulated and downregulated genes for all cancers combined versus normal biliary epithelia control specimens. Although the individual cancer subtypes did not cluster separately, unique differential expression of many genes was seen, compared with normal biliary epithelium in each of the tumor types.

The relationship of gene transcriptional changes among the three biliary cancer subtypes is depicted in a Venn diagram (Fig. 8B.2). Overall, 165 probe sets were commonly differentially expressed in all three cancer types. Selected commonly differentially expressed genes are listed in Table 8B.1. This study also investigated alterations in gene copy number in biliary tract cancers using array-based comparative genome hybridization (CGH) analysis. Considerable heterogeneity in the extent of chromosomal instability between patients was found, even within the same subtype. For example, some patients had mutations in nearly every chromosomal arm, and other patients with the same diagnosis had structural genomic changes (Fig. 8B.3A). But despite the heterogeneity, segments of chromosomes 3p, 6q, 8p, 9p, and 14q were commonly deleted across subtypes of biliary cancers. Commonly amplified regions across cancer types include segments of 1q, 3q, 5p, 7p, 7q, 8q, and 20q (Fig. 8B.3B).

Oncogenes and Tumor Suppressor Genes

Several studies have shown abnormal expression of the *KRAS* oncogene in 21% to 100% of cases of cholangiocarcinoma and of the *TP53* tumor suppressor gene in up to 37% of archival specimens (Isa et al, 2002). These genetic alterations are associated with a more aggressive phenotype in biliary tract tumors (Isa et al, 2002). *KRAS* and *TP53* mutations have also been identified in bile and pancreatic juice of affected patients (Isa et al, 2002; Itoi et al, 1999), but neither *KRAS* nor *TP53* mutational analysis have been shown to be superior to conventional cytopathology in the diagnosis of pancreaticobiliary tumors, but combined analysis of both can increase sensitivity in tissue biopsy and bile specimens (Isa et al, 2002; Itoi et al, 1999; Aishima et al, 2002). Increased expression of c-*MET* and

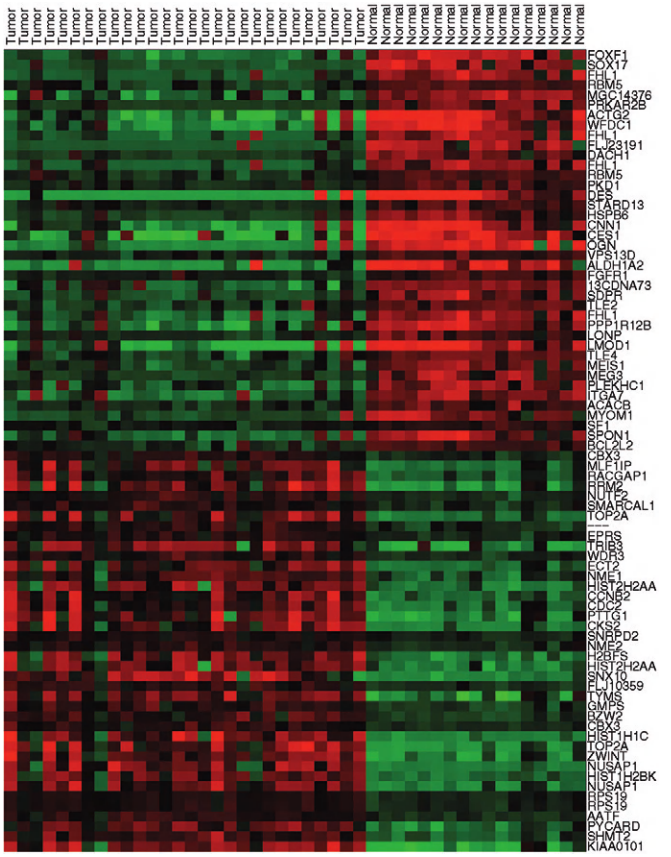

FIGURE 8B.1. Gene expression alterations in biliary tract cancers. The transcript products of more than 22,000 genes were investigated in biliary cancer specimens and compared with control tissue from normal biliary epithelium. Heat maps showing the top 40 overexpressed and underexpressed genes for extrahepatic cholangiocarcinoma, intrahepatic cholangiocarcinoma, and gallbladder cancers combined are compared with benign bile duct and gallbladder controls.

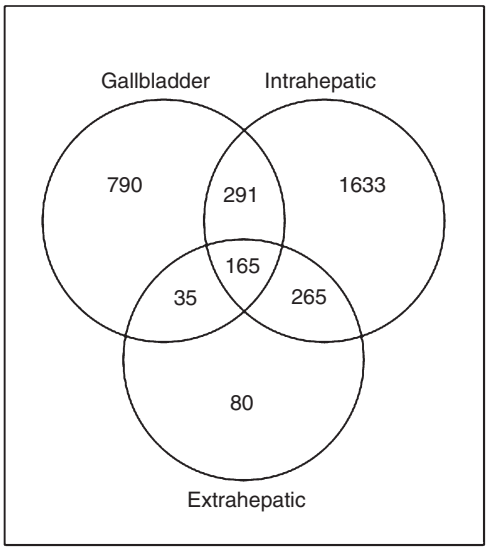

FIGURE 8B.2. Common alterations in gene expression in biliary cancer subtypes. A Venn diagram is used to depict the relationship of transcriptional changes among biliary cancer subtypes. There were 165 common genes with significantly altered expression in intrahepatic cholangiocarcinoma, extrahepatic cholangiocarcinoma, and gallbladder cancer.

c-*ERBB2* protooncogenes have been shown in cholangiocarcinoma specimens, and it has been suggested that they participate in the metastatic transformation of intrahepatic tumors (Aishima et al, 2002). Point mutations leading to promoter methylation of cell-cycle regulators $p16^{INK4a}$ and $p14^{ARF}$ have also been identified in cholangiocarcinoma related to PSC. Overexpression of the protooncogene *BCL2* has been reported to reduce apoptosis in cholangiocarcinoma cell lines (Okaro et al, 2001), and although human cholangiocarcinoma does not express Bcl-2, other antiapoptotic proteins, Mcl-1 and Bcl-xl, are expressed (Taniai et al, 2002).

Genetic Polymorphism at P450

Similar to the development of other tumors, cholangiocarcinogenesis is thought to be a multistep process dependent on the interaction between environmental factors and host genetic factors. Most of the putative environmental risk factors for cholangiocarcinoma cause chronic biliary irritation and can contribute to a promotional stage of carcinogenesis. Genetic polymorphisms in the cytochrome P450 enzymes or in the bile salt transporter proteins are thought to lead to alterations in the efficiency with which environmental toxins (xenobiotics) are handled by the liver. The development of cholangiocarcinoma probably needs a "second hit" to deconjugate such xenobiotics and to expose the bile duct epithelium to damage. Putative secondary hits include chronic inflammation, viral hepatitis, parasitic infestation, and recurrent cholangitis (Khan et al, 2005).

MRP2/ABCC2, MUTYH, NEIL1, *and AID*

Hoblinger and colleagues (2009) reported that multidrug resistance–associated protein 2 (MRP2/ABCC2) is one of the ATP-binding cassette (ABC) transporters expressed on the apical membrane of hepatocytes and cholangiocytes. ABCC2 plays an important role in the biliary clearance of endogenous and exogenous toxic compounds. The ABCC2 variant c.3972C>T in exon 28 has been shown to be associated with the risk of carcinogenesis. Forsbring and colleagues (2009) recently found that the human h-*MUTYH* and *NEIL1* genes encode DNA glycosylases involved in repair of oxidative base damage, and mutations in these genes are associated with cholangiocarcinoma.

Other work has also suggested that chronic inflammation can play a critical role leading up to cholangiocarcinogenesis. Komori and colleagues (2008) from Japan found that the proinflammatory cytokine–induced aberrant production of activation-induced cytidine deaminase (AID), a member of the DNA/RNA-editing enzyme family, might link bile duct inflammation to an enhanced genetic susceptibility to mutagenesis, leading to cholangiocarcinoma. Ectopic AID production is induced in response to TNF-α stimulation via an NF-κB–dependent pathway. Aberrant expression of AID in biliary cells results in the generation of somatic mutations in tumor-related genes, including *TP53,* c-*MYC,* and the promoter region of the *CDK2NA* sequences. In human tissue specimens, reverse transcription polymerase chain reaction (RT-PCR) analyses revealed that AID was increased significantly in 28 of 30

Table 8B.1

cholangiocarcinoma tissues (93%), whereas only trace amounts of AID were detected in the normal liver. Immunohistochemistry showed that all of the cholangiocarcinoma tissue samples examined showed overproduction of endogenous AID protein in cancer cells. Moreover, immunostaining for AID was detectable in 16 of 20 bile epithelia in PSC.

Human CYP1A2 and Arylamine N*-Acteyltransferases (NAT1 and NAT2)*

The *CYP1A2, NAT1,* and *NAT2* genes have been shown to be potential modifiers of an individual's susceptibility to certain types of cancers. Prawan and colleagues (2005) evaluated the relationship between *CYP1A2, NAT1,* and *NAT2* polymorphisms and cholangiocarcinoma in Thailand. A total of 216 cholangiocarcinoma patients and 233 control subjects were genotyped using PCR. Two *CYP1A2* alleles (CYP1A2*1A wild type and *1F), six *NAT1* alleles (NAT1*4 wild type, *3, *10, *11, *14A, and *14B), and seven *NAT2* alleles (NAT2*4 wild type, *5, *6A, *6B, *7A, *7B, and *13), were analyzed. The CYP1A2*1A/*1A genotype conferred a decreased risk of the cancer (adjusted OR, 0.28; 95% confidence interval [CI], 0.08 to 0.94), compared with CYP1A2*1F/1*F. Frequency distributions of rapid NAT2*13 and two slow alleles, *6B and *7A, were associated with lower cholangiocarcinoma risk. This study suggested that the *NAT2* polymorphism may be a modifier of individual risk of cholangiocarcinoma.

Trefoil Factor Family (TFF1)

Trefoil factor family 1 (*TFF1*) is critical for mucosal protection and tumor suppression in the stomach. To examine its role

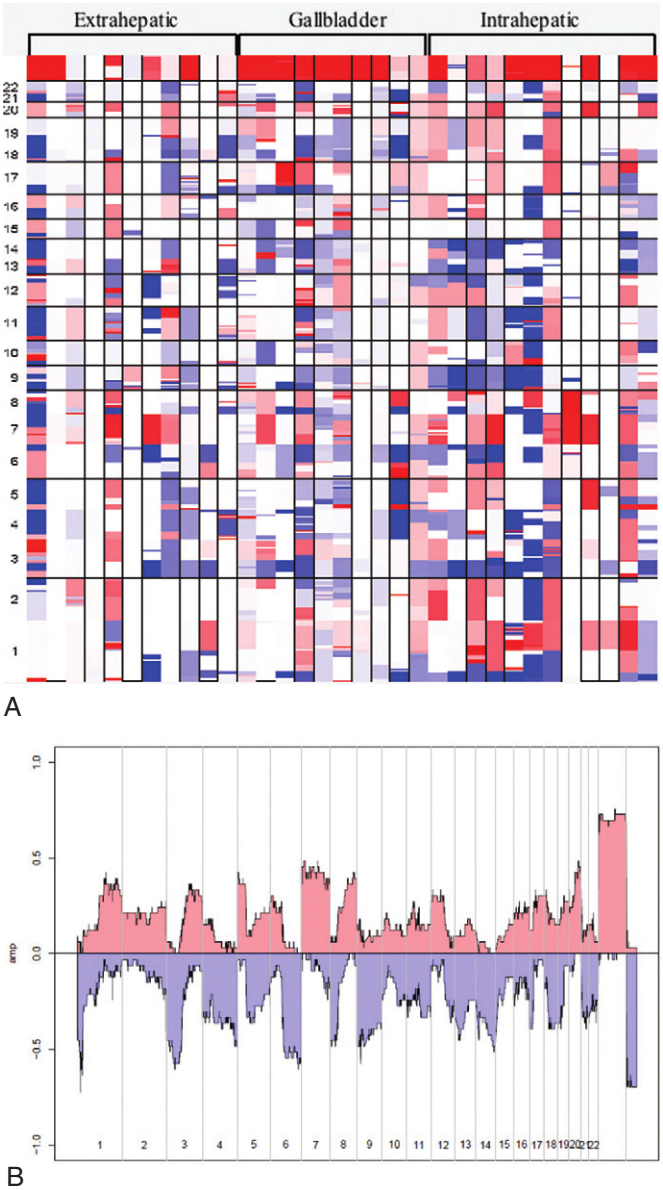

FIGURE 8B.3. Chromosomal structural mutations in biliary tract cancers. Genomic DNA was extracted from biliary tract cancer specimens and subjected to array-based CGH analysis to detect areas of DNA copy number gain or loss. **A,** A cumulative depiction of the copy-number changes across the genome for all biliary cancer specimens is shown. Chromosomal number is listed on the left. White is unchanged from genomic DNA controls. **B,** The percentage of patient specimens that have either amplifications or deletions at each chromosomal locus is shown for extrahepatic cholangiocarcinoma, intrahepatic cholangiocarcinoma, and gallbladder cancer specimens combined.

in cholangiocarcinogenesis, specimens with varying degrees of dysplasia were examined: intrahepatic cholangiocarcinoma (ICC) as a result of hepatolithiasis, biliary epithelial dysplasia with hepatolithiasis, hepatolithiasis without dysplasia or carcinoma, cholangiocarcinoma without hepatolithiasis, and control normal livers (Sasaki et al, 2003). *TFF1* expression in the biliary epithelium was increased in hepatolithiasis compared with control livers ($P < .01$). In biliary epithelial dysplasia and noninvasive intrahepatic cholangiocarcinoma with hepatolithiasis, *TFF1* was extensively expressed, and *MUC5AC* gastric mucin was usually colocalized with *TFF1*. However, *TFF1* expression was significantly decreased in invasive intrahepatic cholangiocarcinoma, despite preserved expression of *MUC5AC*. A total of four missense mutations were detected: three were found in two noninvasive intrahepatic cholangiocarcinomas with hepatolithiasis (29%) and one in invasive ICC (11%). Loss of heterozygosity of the *TFF1* gene was not detectable. The decreased expression of *TFF1* in invasive intrahepatic cholangiocarcinoma may be explained by the methylation of the *TFF1* promoter region. Upregulation of *TFF1* coupled with *MUC5AC* in biliary epithelium in hepatolithiasis, biliary epithelial dysplasia, and noninvasive intrahepatic cholangiocarcinoma may reflect gastric metaplasia and early neoplastic lesion. Under such conditions, decreased *TFF1* expression may lead to increased cell proliferation and then to the invasive character of intrahepatic cholangiocarcinoma.

CHAPTER 8C

Molecular biology of liver carcinogenesis and hepatitis

Masafumi Shimoda and Jack R. Wands

OVERVIEW OF MOLECULAR ETIOLOGY

Recent advances in molecular genetics have emphasized the multistep process of tumorigenesis. It is evident that cancer is a genetic disease involving aberrant chromosome rearrangements, genetic mutations, and epigenetic silencing of tumor suppressor genes (Farazi & DePinho, 2006). Independent of the etiology, hepatocellular carcinoma (HCC; see Chapter 80) generally develops where sustained hepatocyte turnover occurs in the setting of injury-inflammation-regeneration, which leads to the accumulation of chromosomal aberrations. In this context, monoclonal populations of hepatocytes become preneoplastic and, following additional genomic alterations, change into dysplastic cells and eventually HCC (Thorgeirsson & Grisham, 2002). Accumulated genetic alterations in preneoplastic lesions and HCC result in the activation, as well as inactivation, of many growth factor signal transduction pathways involved in hepatic transformation. It is believed that increased hepatocyte turnover associated with chronic liver injury may be a major feature of hepatic oncogenesis. However, another central question is whether hepatitis viruses, the leading cause of HCC worldwide, directly contribute to the development of this disease. Accumulating evidence suggests that chronic hepatitis B (HBV) and hepatitis C virus (HCV) infection play a direct role in the molecular pathogenesis of HCC through specific viral–cellular protein interactions (Branda & Wands, 2006; see Chapter 64).

EPIDEMIOLOGY

Hepatocellular carcinoma is the fifth most common cancer in men and the eighth most common in women worldwide. It is estimated that more than 700,000 new patients with HCC were diagnosed in 2007 (Garcia et al, 2007). The 5-year survival rate is less than 11% in developed countries, and the United States has a survival rate of only 8.9%, making HCC the second most fatal tumor after pancreatic cancer (Hertl & Cosimi, 2005; Garcia et al, 2007). Presumably because of its poor prognosis, HCC is the third leading cause of cancer death in men and the sixth among women in the world. It is estimated that about 680,000 individuals worldwide died from this disease in 2007 (Garcia et al, 2007).

Primary liver cancers consist of numbers of histologically distinct types of tumors that arise from hepatocytes, biliary epithelial cells, and fibroblasts. The most common is HCC, which accounts for 70% to 85% of all hepatic tumors (Perez et al, 2006). Approximately 80% of HCC worldwide is caused by chronic infection with HBV or HCV or both. The HCC burden is unevenly distributed worldwide; areas where tumors are most prevalent include West and Central Africa and East and Southeast Asia, with China alone accounting for more than 50% of the world cases (El-Serag & Rudolph, 2007). It is noteworthy that HBV is highly endemic in these areas, with the exception of Japan, where HCV is more prevalent. Oceania, North and South America, and Northern and Eastern Europe are low-rate areas. Trends in HCC incidence are likely to be different in regions of high and low persistence of HBV and HCV infection (El-Serag & Rudolph, 2007).

Comparative studies performed between 1977 and 1982 and between 1993 and 1997 show that the incidence of HCC in Hong Kong, Shanghai, Singapore, and Japan has begun to decrease (Parkin et al, 2002). The fall in incidence is apparently due to vaccination against HBV, which has been accomplished in over 80% of newborns (Chang et al, 2009), because chronic HBV infection in those countries is usually acquired through mother-to-newborn or sibling-to-sibling transmission at a young age. In contrast, the incidence of HCC has rapidly increased in some countries, such as Australia, the United States, and the United Kingdom, as a result of chronic HCV infection. For example, HCC is the fastest growing cause of cancer-related deaths in the United States, where the annual incidence increased from 1.3 per 100,000 for the years 1978 through 1980 to 3.3 per 100,000 for 1999 through 2001 (El-Serag et al, 2003). Reasons for this increased incidence are not entirely clear but may reflect a greater prevalence and role of persistent HCV infection (McGlynn et al, 2001).

Age-specific rates of HCC peak at 75 years and older in most regions of the world (El-Serag & Rudolph, 2007). With the exception of Africa, the peak incidence in women occurs 5 years later than that found in men. In the United States, recent trends have revealed a peak incidence shifting toward a relatively younger age group (El-Serag & Rudolph, 2007).

Significant gender and ethnic variation in incidence, as well as mortality from HCC, has also been found; male rates are more than double that of females (Perz et al, 2006). The most likely explanation for gender variation is that men have more risk factors, such as exposure to hepatitis virus infection, excessive alcohol intake, smoking, and increased iron stores in the liver (El-Serag & Rudolph, 2007). In addition, androgens may accelerate the progression of HCC (Ma et al, 2008). The incidence of HCC also varies with race and ethnicity in the same area. In the United States, the incidence and subsequent mortality rates from HCC are two times greater in Asians than African Americans, which are two times greater than those

Table 8C.1

Comparison of Epidemiologic Features Between HBV- and HCV-Induced HCC

	HBV	HCV
Virus carriers (% of global population)	350 million (6%)	170 million (3%)
Highly prevalent areas	Southeast Asia, China, sub-Saharan Africa, Alaska, Peru, northwest Brazil	East Asia, Southeast Asia, Africa, Bolivia, Brazil
Relative risk of HCC	5-fold to 15-fold	17-fold
5-Year cumulative incidence rates of HCC from cirrhosis	10% (Europe) 15% (Singapore and Taiwan)	17% (Europe and United States) 30% (Japan)

HBV, Hepatitis B virus; *HCV,* hepatitis C virus; *HCC,* hepatocellular carcinoma.

found in whites (El-Serag & Rudolph, 2007). These variations are explained in part by the accumulation of major risk factors in each ethnic group.

RISK FACTORS

Unlike most malignancies, HCC has well-established extrinsic risk factors that account for at least 80% of tumors, namely chronic infection with HBV or HBC. Key epidemiologic aspects of HBV- and HCV-induced HCC are summarized in Table 8C.1. Chronic HBV infection is the leading cause of HCC, and it has been estimated that there are 350 million HBV carriers, which account for 6% of the global population. About 59% of HCC patients in developing countries and 23% of HCC patients in developed countries are chronically infected with HBV (Garcia et al, 2007). Reported relative risks of HCC among HBV carriers range between 5-fold and 15-fold compared with the general uninfected population (El-Serag & Rudolph, 2007). The 5-year cumulative incidence rates of HCC from HBV-related cirrhosis are 15% in highly endemic areas and 10% in Europe (Fattovich et al, 2004). In addition, approximately 70% to 90% of HBV-related HCC develops in patients with cirrhosis.

Chronic HCV infection is the second leading cause of HCC. The estimated number of HCV carriers worldwide is 170 million, which accounts for 3% of the global population. Approximately 33% of HCC tumors in developing countries and 20% of HCC in developed countries are attributable to persistent HCV infection (Garcia et al, 2007). According to a meta-analysis of case-control studies, HCC risk was increased 17-fold in HCV-infected persons compared with the HCV-negative population (Donato et al, 2002). The 5-year cumulative incidence of HCC with HCV-related cirrhosis in developed countries is 17%, with an exception for Japan, where the 5-year cumulative incidence is 30% (Fattovich et al, 2004). The high incidence of HCV-related HCC in Japan may be due to the prevalence of HCV genotype 1b. Aflatoxin B1 (AFB1) is produced by *Aspergillus flavus* and related fungi that contaminate corn, rice, and peanuts in China and sub-Saharan Africa. High rates of dietary exposure to AFB1 increase the risk of HCC 4-fold. When people with chronic HBV infection are exposed to AFB1, the relative risk for HCC dramatically increases to about 60-fold (Kew, 2003). This synergistic effect between AFB1 exposure and chronic HBV infection is an important observation because in some regions of the world, AFB1 exposure and chronic HBV infection rates are high.

Excessive ethanol consumption (>50 to 70 g/day) is another well-defined risk factor for HCC. In the United States, ethanol-induced HCC accounted for more than 20% of HCC patients between 1996 and 1999 (Davila et al, 2004). The 5-year cumulative HCC incidence in alcoholic cirrhosis without HBV and HCV infection is 8% (Fattovich et al, 2004); however, it is unlikely that ethanol itself has a direct carcinogenic effect. Rather, excessive ethanol ingestion indirectly affects hepatocarcinogenesis through the promotion of cirrhosis. Indeed, more than 80% of HCC tumors found in alcoholics develop in the background of a cirrhotic liver. One case-control study observed a strong synergistic effect between heavy alcohol consumption and chronic HCV infection. The relative risk of HCC attributable to heavy alcohol consumption alone was only 2.4-fold, whereas in combination with chronic HCV infection, it increased to 50-fold (Hassan et al, 2002).

Growing evidence now suggests that metabolic dysfunction—including obesity, diabetes, and nonalcoholic fatty liver disease (NAFLD)—are important risk factors for HCC, especially in developed countries. Several large cohort studies reveal that obese men have 2-fold to 5-fold higher rates of HCC. The association of HCC with obesity in women is controversial. Other investigations suggest that diabetes is a moderately strong risk factor for HCC (El-Serag & Rudolph, 2007). Nonalcoholic steatohepatitis (NASH) is strongly associated with obesity and diabetes; therefore NASH may be a risk factor for HCC (see Chapter 65). Epidemiologic studies have searched for a direct correlation between NASH and HCC, but the results have not been sufficiently convincing to draw a firm conclusion.

Other risk factors for HCC include hemochromatosis and hepatic porphyria. It should be noted that daily coffee intake reduces the incidence of HCC between 25% and 75% in the general population in a dose-dependent manner (Inoue et al, 2005). This effect may be attributable to the inhibition of TGF-β signaling by methylxanthine caffeine, which reduces liver fibrosis (Gressner, 2009).

GENETIC AND EPIGENETIC ALTERATIONS

Chronic inflammation accompanied by sustained cycles of injury and regeneration of hepatocytes over 20 to 40 years promotes the development of liver fibrosis, cirrhosis, and eventually HCC (Fig. 8C.1A; see Chapter 6). Pathologically, HCC occurs early within cirrhotic nodules, which can form in areas of adenomatous hyperplasia or dysplasia. These cells eventually become more atypical, and the malignant transformation process becomes complete (Theise et al, 2002). Hepatocellular carcinoma is like other malignancies and represents a DNA disease with accumulation of many alterations in oncogenes and tumor suppressor genes. The accumulation of genetic aberrations that induces cellular transformation may take 20 to 40 years, suggesting that liver carcinogenesis involves a multistep process. Indeed, the number of genetic alterations in HCC correlates with the histologic differentiation of the tumors. For example, loss of heterozygosity (LOH) of chromosomes 16q, 17p, 13q, and *TP53* tumor suppressor genes was principally found in poorly differentiated HCC, which suggests these chromosomal alterations and mutations tend to occur at a late stage of tumor development (Laurent-Puig & Zucman-Rossi, 2006). In contrast, β-catenin mutations were associated with

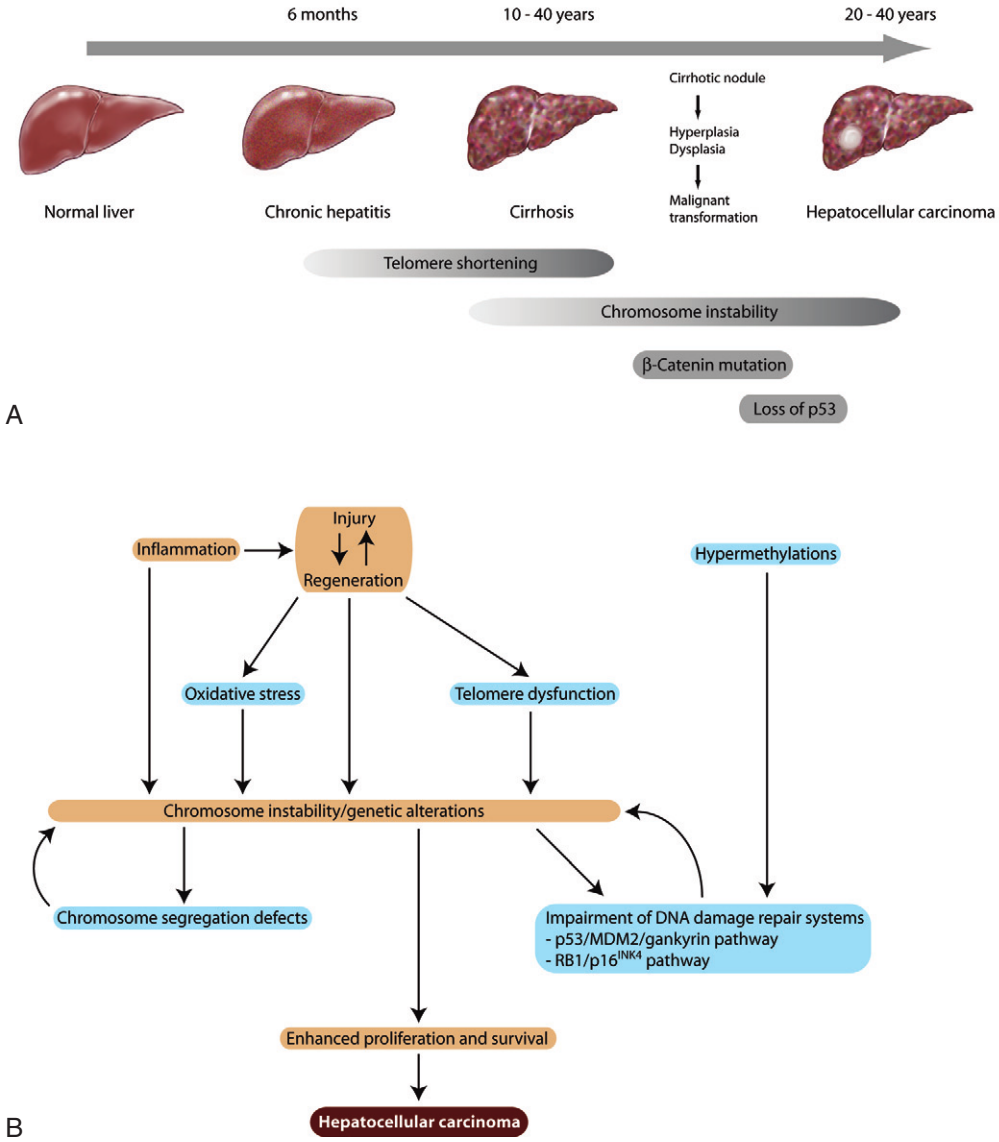

FIGURE 8C.1. A, Diagram showing progression of liver disease and genetic events accompanied by chronic inflammation. **B,** Common mechanisms underlying hepatocarcinogenesis. A number of factors contribute to chromosome instability and other genetic alterations, which lead to the formation of hepatocellular carcinoma.

well-differentiated HCC and a more favorable prognosis, indicating that these mutations may occur at an early developmental stage (Mao et al, 2001).

Cirrhosis may represent end-stage liver disease as a result of persistent HBV or HCV infection. Because 80% to 90% of HCC tumors originate from cirrhotic liver, it is evident that continuous rounds of cellular injury followed by regeneration in the milieu of chronic inflammation fundamentally contributes to the oncogenic processes. The sustained cycles of injury and repair increase the chance of genomic alteration. Furthermore, the host inflammatory response to viral infection, including activation of stellate cells, causes the release of proinflammatory cytokines, which accelerate hepatic carcinogenesis by augmenting oxidative stress and DNA damage (Bataller & Brenner, 2005; Giannelli et al, 2005; Ogata et al, 2006).

Continuous rounds of this process in the presence of inflammation not only increase the chance of genomic alterations but also produce chromosome instability. For example, hyperploidy has been observed in 43% of dysplastic peritumoral regions and in about 50% of HCC tumors (Laurent-Puig & Zucman-Rossi, 2006). Molecular mechanisms underlying such genomic instability include telomerase dysfunction, defective segregation of chromosomes, and an impaired DNA damage response (Fig. 8C.1B).

Telomere shortening is a key feature of chronic liver disease that allows sustained proliferation of hepatocytes (Urabe et al, 1996). In human HCC, telomere shortening has been shown to have a positive correlation with increased chromosome instability—chromosomal gains, losses, and translocations—by promoting chromosomal fusions (Plentz et al, 2004). A study of telomerase-deficient mice reveals that telomere dysfunction initiates tumor formation (Farazi et al, 2003). It is noteworthy that 90% of human HCC shows robust activation of telomerase (Lee et al, 2004; Nagao et al, 1999; Shimojima et al, 2004). In

some HBV-induced HCC tumors, the viral genome was found to be integrated into the *TERT* locus, which results in increased expression of telomerase (Ferber et al, 2003; Murakami et al, 2005). Other findings related to telomerase biology indicate amplification of telomerase RNA component gene (*TERC*) mRNA and allelic loss of chromosome 10p, where a putative telomerase inhibitor resides (Nishimoto et al, 2001; Takeo et al, 2001). Such telomerase reactivation and telomere shortening in HCC cells may be explained in part from investigations performed in *TERC*-knockout mice (Farazi et al, 2003). This study indicates that telomerase reactivation occurred and appeared to be necessary for late-stage tumor progression; thus, the reactivated telomerase enzyme maintains the shortened telomere length in these tumor cells and prevents them from undergoing apoptosis.

Dysregulation of genes involved in chromosome segregation results in altered copy numbers during cell division. Aneuploidy has been frequently found in HCC, suggesting dysfunction of the segregation machinery. Indeed, aurora kinase A, a protein required for proper chromosome segregation, was shown to be abnormal (Smith et al, 2003). Furthermore, the spindle-assembly checkpoint is defective in HCC cell lines (Saeki et al, 2002). These cytogenetic dysfunctions may lead to the aberrant segregation of chromosomes in human HCC.

DNA damage-response pathways are safeguards that regulate cell-cycle checkpoints and prevent DNA-damaged cells from further proliferation. Several studies report that the functions of key regulatory molecules, including p53, Mdm2, Rb1, p16INK4a, and gankyrin, were impaired in human HCC. The p53 protein, encoded by the *TP53* gene, is a master molecule that maintains genome integrity by inducing cell-cycle arrest followed by activation of DNA repair systems. When excessive DNA damage occurs, p53 initiates apoptosis. *TP53* missense mutations in codon 249 (R249S) was the main cause of AFB1-induced liver cancer (Bressac et al, 1991). This specific *TP53* mutation was found in more than 50% of AFB1-related HCC; other mutations of *TP53* are found in 20% to 40% of HCC without molecular evidence of AFB1 exposure (El-Serag & Rudolph, 2007).

The Rb1 pathway also regulates cell cycle checkpoints. The loss of an *RB1* locus, located on chromosome 13q14, has been frequently observed in human HCC; the second allele may then be inactivated by an epigenetic mechanism, such as hypermethylation of promoter sequences to promote cell proliferation (Zhang et al, 1994; Lin et al, 1996). Cellular levels of p53 and Rb1 proteins are low due to rapid degradation. In this regard, Mdm2 an E3 ubiquitin ligase, was shown to be a key regulator of ubiquitin-proteasome degradation of these tumor suppressor proteins. Strikingly, gankyrin, which promotes such protein degradation by Mdm2, was overexpressed in 100% (n = 34) of human HCC (Higashitsuji et al, 2000, 2005). The *CDKN2A* gene encodes for two splice variant products, including p16INK4a and p14ARF, which are components of the p53 and Rb1 signaling pathways. The expression of the *CDKN2A* gene was suppressed in 30% to 70% of human HCC as a result of methylation of the promoter region (Jin et al, 2000; Liew et al, 1999; Matsuda et al, 1999; Weihrauch et al, 2001). LOH of chromosome 9p where *CDKN2A* is located was found in 15% to 20% of tumors (Boige et al, 1997; Laurent-Puig et al, 2001; Nagai et al, 1997). Interestingly, *CDKN2A* deletion rarely occurs in HCC when *TP53* is also mutated (Tannapfel et al, 2001). Taken together, impairment of the p53 and Rb1 pathways is a common genetic feature of HCC. In addition, chromosome instability caused by telomere shortening, as well as defects in chromosomal segregation, contributes to the molecular abnormalities often observed in this disease.

As a result of chromosome instability and impaired DNA repair systems, chromosome gains and losses and gene mutations are frequently found in human tumors, as shown in Table 8C.2. Numerous genetic studies performed during

HBV, Hepatitis B virus; *HCC,* hepatocellular carcinoma.

Data from Laurent-Puig P, Zucman-Rossi J, 2006: Genetics of hepatocellular tumors. Oncogene 25:3778-3786; and Farazi PA, DePinho RA, 2006: Hepatocellular carcinoma pathogenesis: from genes to environment. Nat Rev Cancer 6:674-687.

hepatocarcinogenesis provide an overview of chromosomal aberrations by using karyotypic analysis, LOH mapping, and comparative genomic hybridization (CGH). To summarize, chromosome 17p (*TP53*), 8p (*PINX1*), 16p (*AXIN1*), 16q, 4q (*NAP1L5*), 9p (*CDKN2A*), 13q (*RB1, BRCA2*), 1p, and 6q (*IGF2R*) were often deleted. Chromosomes 1q (*HDGF*), 7q, 8q (*MYC*), and 17q (*ERBB2*) were the most frequent to shown gain of genetic material (Laurent-Puig & Zucman-Rossi, 2006). Some chromosome gains and losses have been reported to be specific to etiologic factors such as chronic HBV and HCV infection. Notably, gains of chromosome 8q and 20q and loss of chromosome 4q have been found in HBV-induced HCC without cirrhosis, indicating that these chromosomal aberrations may enhance hepatocyte transformation (Feitelson et al, 2002; Wong et al, 1999).

It is evident that the expression and function of oncogenes and tumor suppressor genes are affected by copy number because of chromosomal gains and losses and by point mutations in the genes. However, recent studies have revealed that epigenetic mechanisms—such as DNA methylation and short, noncoding RNA (21 to 23 nucleotides) species, or *micro RNA* (miRNA)—also contribute to aberrant expression of oncogenes and tumor suppressor genes. In human HCC, aberrant DNA methylation patterns have been detected (Kanai et al, 1999; Thorgeirsson & Grisham, 2002; Yu et al, 2003). More important, hypermethylation has been observed at the earliest stages of HCC development, and the extent of hypermethylation tends to increase with tumor progression (Lee et al, 2003). Specific gene targets for hypermethylation include *CDKN2A*, *PTGS2, CDH1*, *PYCARD,* and *DLC1*. Among these genetic elements, it has been shown that *CDKN2A* and *PTGS2* expression were directly affected by methylation using human HCC cell lines (Liew et al, 1999; Matsuda et al, 1999; Murata et al, 2004).

In addition, miRNA contributes to messenger (mRNA) instability by hybridizing with its complementary target sequence, followed by mRNA degradation, so that a protein cannot be generated. Several studies reveal aberrant expression of some miRNAs in human HCC compared with the adjacent, nontumorous counterpart. For example, miR-21 was expressed in human HCC; it targets the *PTEN* tumor suppressor gene (Meng et al, 2007). Another example was overexpression of miR-122, which targets the cyclin G_1 cell-cycle regulator (Gramantieri et al, 2007). More recently, evidence was presented that links aberrant expression of miRNA to the multistep process of hepatocarcinogenesis. The expression of miR-26a was diminished in murine and human tumors, resulting in enhanced activity of cyclin D2 and E2 to promote cell proliferation. Moreover, when exogenous miR-26a was overexpressed in mice prone to form multiple HCCs, substantial protection from disease progression was observed, indicating a possible therapeutic approach for this disease (Kota et al, 2009). These findings indicate that epigenetic and posttranscriptional regulation of gene expression plays an important role in hepatic oncogenesis.

SIGNAL TRANSDUCTION PATHWAYS

Genetic alterations of oncogenes and tumor suppressor genes impinge on a wide variety of signal transduction pathways involved in proliferation and tumor cell viability. Although the spectrum of affected signal transduction pathways in HCC cells is more heterogeneous compared with that of affected signals in other tumor types, key pathways are commonly dysregulated in human HCC, such as the Wnt/β-catenin, ErbB/ERK/PI3K, and IGF/IRS/ERK/PI3K cascades (Fig. 8C.2).

The Wnt/β-catenin pathway regulates cell proliferation, motility, and differentiation. Wnt proteins are ligands that bind to Frizzled cell-surface receptors to stabilize β-catenin in the cytoplasm, followed by translocation to the nucleus, where it upregulates Wnt-responsive genes (Thompson & Monga, 2007). In the absence of Wnt signaling, the amount of cytosolic β-catenin is low as a result of proteolytic degradation produced by the action of GSK-3β/APC/Axin kinase destruction complex. However, when Wnt ligands bind to the Frizzled/LRP-5/6/Dishevelled (Dvl) receptor complex, phosphorylation of β-catenin by GSK-3β is inhibited to allow its accumulation in the cytoplasm. The β-catenin molecules are then transported into the nucleus and bind to TCF/LEF transcription factors; this complex acts as transcriptional regulators. Finally, the TCF/LEF/β-catenin complex promotes activation of target genes—including *CCND1, MYC, PTGS2,* and c-*JUN*—which leads to proliferation of HCC cells.

Mutations of β-catenin are found in 13% to 43% of human HCC (Laurent-Puig & Zucman-Rossi, 2006). The frequency of β-catenin nuclear accumulation varies between 17% and 75% as determined by immunohistochemical staining (Fujito et al, 2004; Inagawa et al, 2002; Ishizaki et al, 2004; Mao et al, 2001; Wong et al, 2001). These findings suggest that nuclear accumulation of β-catenin is an excellent biomarker for activation of Wnt signaling in HCC. More important, β-catenin activation occurs at an earlier stage of the oncogenic process in dysplastic cells, suggesting that the Wnt/β-catenin cascade is directly involved in tumor formation (Calvisi et al, 2001, 2004; de la Coste et al, 1998; Merle et al, 2004; Thorgeirsson & Grisham, 2002).

The other cell-surface molecules that play a major role in the activation of Wnt/β-catenin signaling are called *Frizzled receptors.* Indeed, studies reveal that 90% of HBV-related HCC overexpresses the Frizzled-7 receptor. Overexpression of Frizzled-7 correlated with accumulation of wild-type β-catenin in the cytoplasm and nucleus of human tumors and HCC cell lines. The functional consequences of Frizzled-7 overexpression were enhanced cell motility and invasion. In murine HCC models, overexpression of Frizzled-7 occurred in dysplastic nodules and HCC tissue but not in normal liver (Merle et al, 2004, 2005). These findings illustrate that Frizzled-7 overexpression was a common event during hepatic oncogenesis and that it promotes tumor cell motility and invasion. Among other candidate genes involved in stabilization of β-catenin, the scaffold protein AXIN1 of the destruction complex was mutated in 5% to 8% of HCC (Laurent-Puig et al, 2001; Satoh et al, 2000), whereas *APC* mutations were exceptionally rare (Huang et al, 1999).

The ErbB family consists of four receptor tyrosine kinases, including ErbB1/EGFR/Her1, ErbB2/Her2/Neu, ErbB3/Her3, and ErbB4/Her4 (Yarden & Sliwkowski, 2001). When ligands bind to the ErbB1 receptor, autophosphorylation occurs that leads to an association with the Grb2 adaptor molecule and phosphatidyl inositol-3 kinase (PI3K). When phosphorylated ErbB1 binds to Grb2, the complex activates the Ras oncoprotein, resulting in enhancement of Raf serine/threonine kinase activity. Activated Raf kinase triggers MEK/ERK kinases, as well as ERK, which translocates to the nucleus and upregulates the transcription of oncogenes such as c-*FOS,* c-*JUN,* and c-*MYC*. When phosphorylated ErbB1 binds to PI3K, ErbB1 activates PI3K and the downstream Akt kinase. Akt phosphorylates a number of important molecules including mTOR,

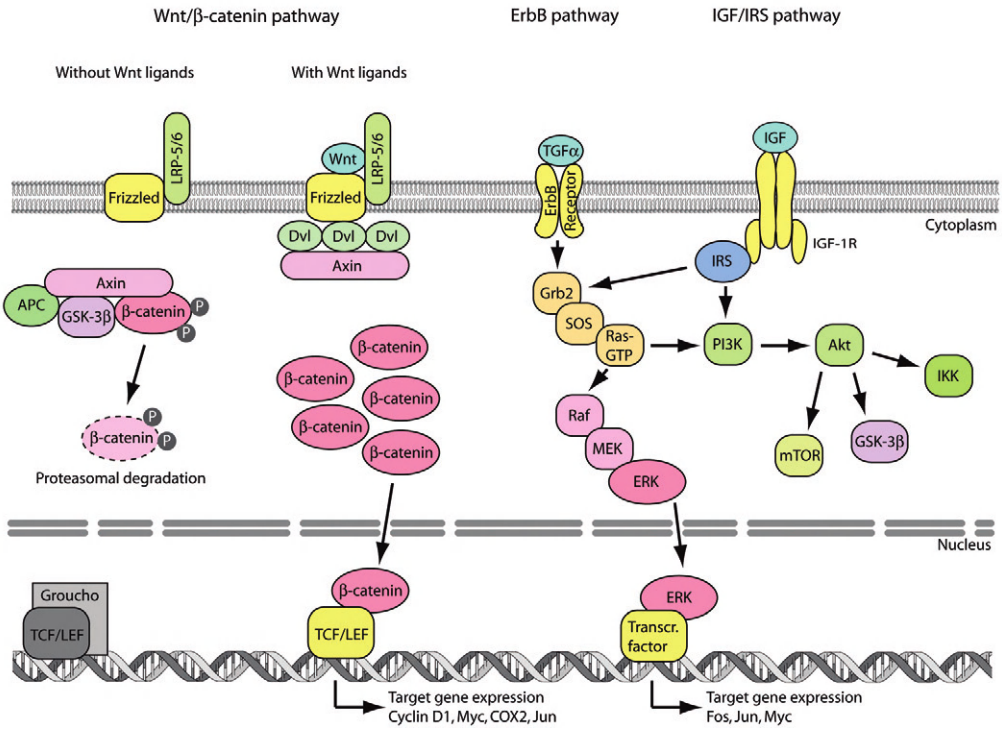

FIGURE 8C.2. Schematic diagram showing the major components of three signal-transduction pathways involved in hepatic oncogenesis. In the Wnt/β-catenin cascade, accumulation of β-catenin is regulated by Wnt ligands. The ErbB and IGF/IRS pathways both use downstream activation of several kinases, including the Ras/Raf/MEK/ERK and PI3K/Akt cascades. APC, antigen-presenting cell; ERK, extracellular signal-regulated protein kinase; GSK, glycogen synthetase kinase; IGF, insulin growth factor; IKK, inhibitor κB kinase; I/R, ischemia/reperfusion; IRS, insulin receptor substrate; LEF, leukocyte enhancer factor; MEK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; TCF, T-cell factor; TGF, transforming growth factor; transcr., transcription.

GSK-3β, and IKK to promote proliferation and viability of tumor cells.

It has been established that ErbB1 and ErbB3 were overexpressed in 68% and 84% of HCC, respectively, which correlated with a more clinically aggressive phenotype (Ito et al, 2001a). Ligands for ErbB include epidermal growth factor (EGF), transforming growth factor-α (TGF-α), heparin-binding EGF (HB-EGF), amphiregulin, β-cellurin, and epiregulin. In this regard, TGF-α and HB-EGF proteins may play a role in the pathogenesis of HCC. TGF-α was frequently upregulated at an earlier stage of tumor formation (Schaff et al, 1994; Yeh et al, 1987; Zhang et al, 2004). In murine models, HCC develops in TGF-α–overexpressing transgenic mice, whereas TGF-α–knockout mice were resistant to chemically induced hepatic neoplasms, indicating that TGF-α upregulation was closely linked to the oncogenic process (Jhappan et al, 1990; Russell et al, 1996). HB-EGF protein was a potent mitogen for hepatocytes, detected in 59% to 100% of HCC (Inui et al, 1994). Moreover, overexpression of HB-EGF was found at an earlier stage of HCC with moderately or well-differentiated features (Ito et al, 2001b), suggesting that HB-EGF is an important ligand in initiation of this disease.

The insulin-like growth factor (IGF)/insulin receptor substrate (IRS) signaling cascade is a well-defined pathway that regulates energy metabolism and cell growth. The IRS proteins are phosphorylated on tyrosine residues after stimulation of the insulin/IGF receptors by insulin, IGF-1, and IGF-2. The IRS-1 protein is the main intracellular substrate for receptor tyrosine kinase activity of the insulin/IGF-1 receptor, emitting downstream signals through interaction with SH2 domain-containing molecules that bind to specific motifs located in the C-terminal region. Such protein–protein interactions activate the Ras/Raf/MEK /ERK cascade involved in cell growth and survival. Phosphorylated IRS proteins also trigger the PI3K/Akt signaling pathway, which results in enhanced proliferation and survival of HCC cells. Thus, evidence has been accumulating to suggest that this pathway plays an important role in tumor development (Pollak, 2008).

In human HCC, the insulin/IGF/IRS pathway was dysregulated because of the overexpression of upstream components. The IGF-2 ligand was also overexpressed in 16% to 40% of tumors, as well as in dysplastic tissue, suggesting that IGF-2 may act by autocrine and/or paracrine mechanisms (Breuhahn et al, 2006). IRS-1 is overexpressed in 80% to 100% of human HCC (Cantarini et al, 2006; Nishiyama & Wands, 1992); overexpression was associated with increased tumor size and progression via activation of the MEK/ERK cascade, which promotes cell proliferation (Tanaka et al, 1997). Constitutive MEK/ERK pathway activation may also occur via downregulation of a Raf kinase inhibitor protein (RKIP); this event promotes HCC cell proliferation and migration (Lee et al, 2006). Indeed, downregulation of RKIP was found in 90% of human HCC and suggests that it plays a role as a tumor suppressor protein in this disease. IRS-2 has also been found to be overexpressed in the majority of human tumors and in HCC cell lines (Boissan et al, 2005).

The importance of the IGF/IRS and signal transduction cascades of ErbB is illustrated by the fact that many antitumor

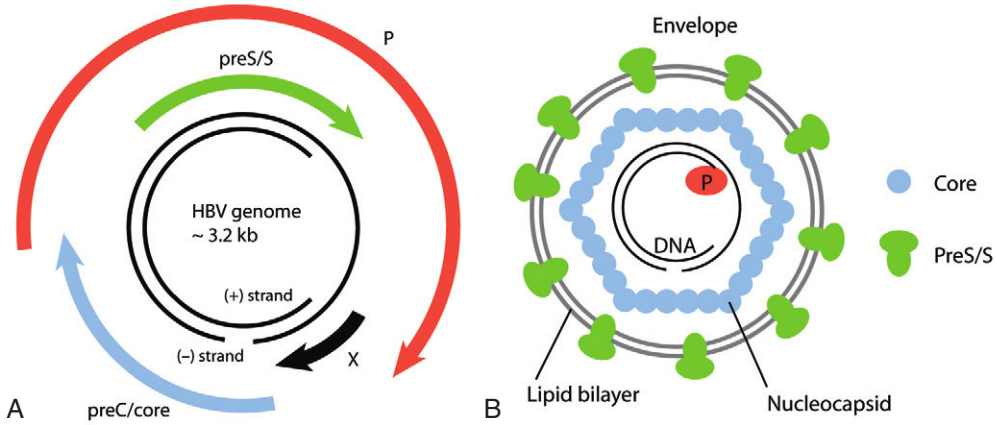
drugs that target one of the components of these cascades have been or are under development. For example, a randomized, controlled trial revealed that sorafenib (Nexavar)—an inhibitor of Raf kinase and downstream MEK/ERK activity—modestly prolonged survival (3 months) in patients with HCC (Llovet et al, 2008). This is the initial report showing some effectiveness of a systemic treatment for HCC. Other potential anti-HCC drugs under development include inhibitors of ErbB1 tyrosine kinase, Ras farnesyl transferase, MEK, and mTOR.

The finding of insulin/IGF/IRS signaling in HCC have led to the development of several monoclonal antibodies that bind and neutralize the IGF-1 receptor as a potential therapeutic approach; such agents are undergoing preclinical and early-phase clinical trials for solid tumors and HCC (Pollak, 2008).

HEPATITIS B VIRUS

HBV is the prototype member of the *Hepadnaviridae* family. Viral members of this group also infect ducks, ground squirrels, and woodchucks. These small, partially double-stranded DNA viruses contain four overlapping open reading frames (ORFs) including preC/core, preS/S, P, and X, except for the duck, in which it is missing (Fig. 8C.3A and B). PreC/core ORF encodes for the precore protein, a precursor of HBeAg and core protein (HBcAg), a component of the nucleocapsid. PreS/S ORF encodes for three proteins, including large (L), middle (M), and small (S; HBsAg) proteins. The S accounts for approximately 90% of all protein produced from preS/S transcripts. The P gene encodes for a DNA-dependent DNA polymerase, which also has reverse transcriptase and RNase H activities. The partially double-stranded HBV genome (approximately 3.2 kb in length) exists within a nucleocapsid. The X region encodes for a multifunctional protein, HBx. Although HBx is not a component of HBV particles, it is believed to play a crucial role in viral replication. Acute and chronic infection of the liver with HBV appears not to produce cytopathic effects on hepatocytes; however, several components of the viral particles activate the host's immune response, and cytotoxic T cells (CTLs) eliminate HBV-infected hepatocytes (Fattovich, 2003; Bertoletti & Ferrari, 2003). Such immune responses induce sustained cycles of hepatocyte injury and regeneration that contribute to cirrhosis and HCC tumor formation.

HBV enters the hepatocyte by means of one or more yet to be defined cell-surface receptors, and the envelope glycoprotein is subsequently removed (Fig. 8C.3C). The partially double-stranded DNA is repaired to form a covalently closed circular DNA (cccDNA) moiety in the nucleus to serve as a stable template for transcription of the pregenomic mRNA and other species required for productive viral replication. This cccDNA template remains in the nucleus during chronic viral infection and may persist in the liver for the lifetime of the individual (Wands, 2004).



The DNA of the HBV integrates randomly into hepatocyte chromosomes and acts as a nonselective insertional mutagenic agent. Secondary chromosomal rearrangements involving duplications, translocations, and deletions reveal that the major oncogenic effect of HBV integration may be increased genomic instability of the host's cellular DNA. In greater than 90% of patients with HBV-related HCC, fragments of viral DNA have been found integrated into the host genome. Most HCCs contain integrated forms of a high molecular weight, as shown by Southern blot analysis of DNA extracted from tumor tissue. This event occurs randomly, because no common chromosomal site of insertion has been detected (Bréchot, 2000). However, a large-scale analysis of HBV DNA integration sites revealed that in some special instances, the integration event can disrupt the function of specific regulatory genes (Murakami et al, 2005). Of note, out of 50 HBV-related tumors studied, insertion of viral DNA into the *TERT* locus was observed in three with HBV-induced HCC. Telomerase reactivation was found, suggesting that the HBV integration event into the *TERT* locus was an important pathologic event in these tumors.

Another gene family recurrently affected by HBV integration includes those involved in calcium signaling. Studies indicate that HBV DNA had inserted into the gene encoding for SERCA (sarco/endoplasmic reticulum calcium adenosine triphosphatase), which plays a pivotal role in regulating intracellular calcium levels and shows as a second messenger involved in cell proliferation and programmed cell-death pathways (Chami et al, 2000). Collectively, cellular genes involved in chromosomal integrity and in growth factor–mediated signaling pathways are occasionally targeted by HBV integration events, but in the vast majority of tumors, the viral integration is random throughout the host genome (Murakami et al, 2005; Paterlini-Bréchot et al, 2003). Thus integration of HBV into hepatocyte DNA produces specific and nonspecific genetic alterations that contribute to hepatocarcinogenesis.

Studies on murine models expressing HBV-related transgenes such as HBx, as shown in Figure 8C.4, as well as truncated preS/S regions, provide evidence for their role in hepatic tumor development (Kim et al, 1991; Chisari et al, 1989). The most well-established transgene in this regard encodes for the HBx protein. This is a 154–amino acid molecule highly conserved among mammalian hepadnaviruses (Chen et al, 1993), and it has multifunctional and pleiotropic properties that modulate cellular functions that include transcription, signaling cascades, DNA repair, protein degradation, and cell cycle control (Murakami, 1999). During viral replication, HBx is localized in the cytosol with a minor fraction present in the nucleus. Cytosolic HBx activates Ras/Raf/MEK/ERK, PI3K/Akt pathway, Src kinase, and JAK/STAT cascades, leading to the increased cell proliferation (Bouchard & Schneider, 2004). Constitutive expression of HBx also promotes hepatocarcinogenesis, in combination with activation of the insulin/IGF-1/IRS-1/MEK/ERK cascade (Longato et al, 2009). In addition, nuclear HBx has been reported to act as a transcriptional coactivator, although it does not directly bind to DNA. Growth molecules known to be influenced by HBx expression include cAMP response element–binding protein (CREB), activating transcription factor 2 (ATF2), AP-2, and CREB-binding protein/p300 (Bouchard & Schneider, 2004).

Several reports indicate an interaction between HBx and p53 tumor suppressor protein. In this context, HBx binds to p53 and may suppress its functions. For example, HBx binds to p53 in the nucleus and inhibits expression of p53 responsive genes. Nuclear HBx also alters the association of p53 with transcription factors, such as ERCC3 and TFIIH, which are involved in nucleotide excision repair (Jia et al, 1999; Wang et al, 1994, 1995). Moreover, HBx expression has been shown to block p53-mediated apoptosis, and it provides a clonal selective advantage to HBV-infected hepatocytes (Elmore et al, 1997; Huo et al, 2001; Wang et al, 1995).

Interestingly, HBx can trigger the release of calcium ion from mitochondria, leading to the enhanced replication of HBV

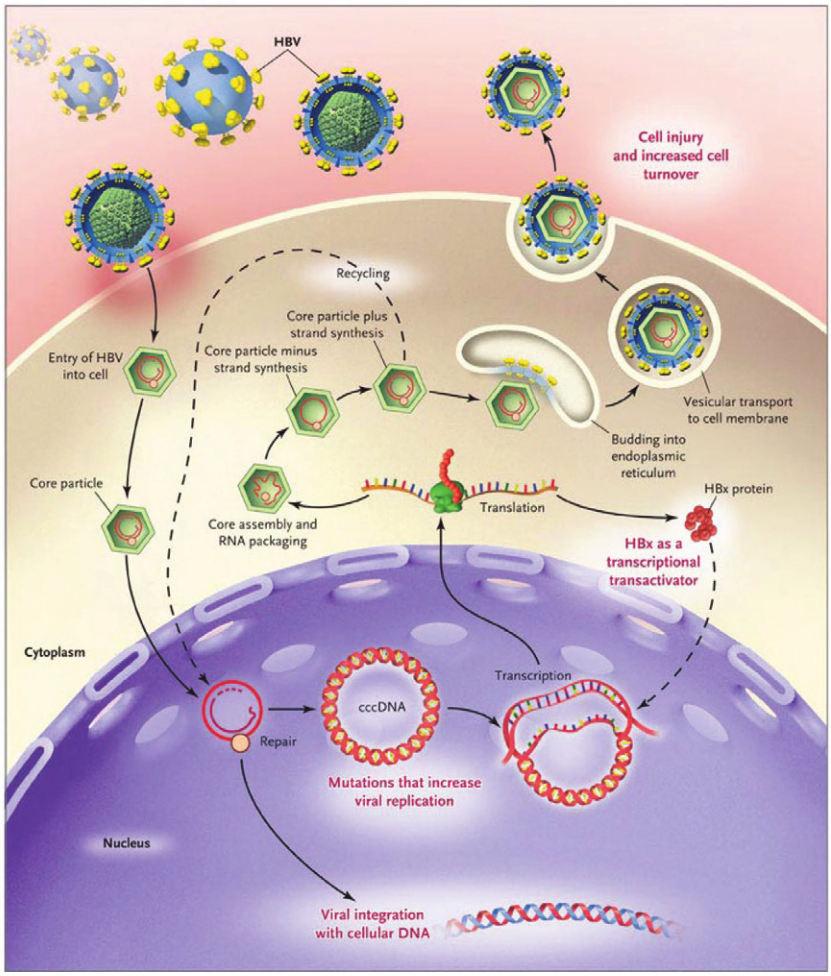


FIGURE 8C.3. **A,** Structure of the hepatitis B virus (*HBV*) DNA genome, showing the four open reading frames involved in generation of preC/core, preS/S, P, and X proteins. **B,** Structure of infectious HBV particle, showing the nucleocapsid containing an HBV genome and polymerase (*P*) and an envelope derived from the lipid bilayer, where preS/S proteins are embedded. **C,** Life cycle of HBV, showing viral entry through receptors, followed by uncoating and translocation of HBV DNA to the nucleus, where it is repaired to generate a cccDNA form that serves as the template for transcription of the pregenomic and other viral mRNA necessary for replication. *(From Wands JR, 2004: Prevention of hepatocellular carcinoma. FIGURE 8C.4. Characteristics of the HBx protein and its involvement in tumor formation. HBx plays a crucial role in hepatitis B virus (*HBV*)-induced carcinogenesis. HBx is located in the cytoplasm and activates cellular signaling cascades. This viral nonstructural protein also inhibits p53-mediated apoptosis. Nuclear HBx modulates a set of transcription factors through interaction with a RNA polymerase complex. The HBV genome integrates into the host genome during persistent viral infection and promotes chromosome instability.

DNA through interaction with a proline-rich tyrosine kinase 2 (Pyk2) and Src kinase (Bouchard et al, 2001). HBx also influences the androgen signaling pathway, which may explain in part the known male predominance of HBV-induced HCC (Chiu et al, 2007). Taken together, these findings indicate that HBx plays a complex and pleiotropic role in the multistep process of tumor development.

Evidence has been accumulating that the risk of HCC is substantially increased by viral factors, such as the level of HBV replication produced by naturally occurring mutations in the core and precore promoter regions (Baptista et al, 1999; Kao et al, 2003; Kuang et al, 2004). A high viral replication phenotype places the infected liver at greater risk for transformation, as shown in Figure 8C.3C. Finally, with the development of diagnostic techniques sensitive enough to detect very low levels of serum HBV DNA (<100 copies/mL), it has become increasingly apparent that many patients with chronic HCV infection also are infected with low levels of HBV. In this setting, HBV maintains its oncogenic properties, and evidence has accumulated that occult HBV infection, defined as less than 10,000 virions per mL of serum, may be associated with chronic hepatitis and cirrhosis of heretofore unknown origin (Wands, 2004).

HEPATITIS C VIRUS

HCV is a member of the *Flaviviridae* family and is the only member of the genus *Hepacivirus* (Tellinghuisen & Rice, 2002). The HCV genome consists of a single positive-strand RNA of approximately 9.6 kb in length (Fig. 8C.5A). HCV RNA contains a large (approximately 9.0 kb) ORF in which structural and nonstructural coding regions are located near the 5′ and 3′ ends of the viral genome, respectively. Both 5′ and 3′ untranslated (UTR) domains have been found to be essential for viral RNA replication. Translation of the HCV RNA can be initiated by an internal ribosome entry site (IRES) located in the 5′ UTR. The single ORF encodes for a polyprotein precursor, consisting of about 3000 amino acids; it is cleaved into 10 smaller proteins by the action of several proteases derived from both host and virus. These 10 viral-related molecules include three structural (core [C], E1, and E2) and 7 nonstructural (NS; p7, NS2, NS3, NS4A, NS4B, NS5A, NS5B) proteins. The core forms a nucleocapsid that contains the HCV genome. The nucleocapsid is covered by an envelope composed of a lipid bilayer, in which the two structural proteins E1 and E2 are embedded. The function of p7 is not well understood, but it appears to be a transmembrane protein with ion channel activity. NS2 is a metalloprotease that cleaves between NS2 and NS3. The NS3 is a serine protease that produces NS4A, NS4B, NS5A, and NS5B viral proteins; it also has RNA helicase and NTPase activity. NS4A acts as a cofactor for NS3 activity, and NS4B is an integral membrane protein located on the cytoplasmic side of endoplasmic reticulum (ER); it has been implicated in the assembly of replicase complex. The NS5A protein is believed to act as a component of RNA replicase complex, and it plays a role in evasion of the host's cellular immune response. The NS5B is an RNA-dependent RNA polymerase essential for the replication of the HCV genome.

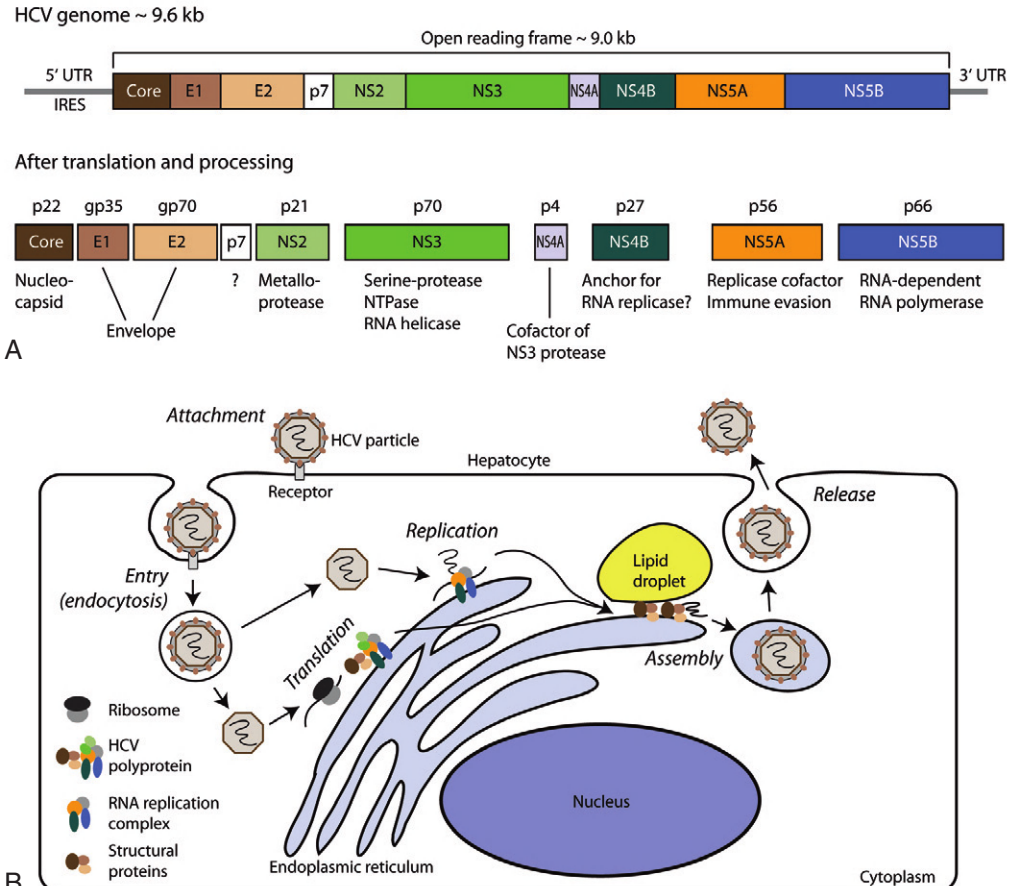

FIGURE 8C.5. Diagram of hepatitis C virus (*HCV*) and the replication process. **A,** Components of the HCV genome, showing the structure of HCV RNA. HCV proteins, including their role in HCV replication, are presented. **B,** Life cycle of HCV, showing the known steps of viral replication, including attachment/entry, translation, replication, processing, assembly, and release of virus into the blood. IRES, internal ribosome entry site; NTPase, nucleoside triphosphatase; UTR, untranslated region.

The life cycle of HCV consists of at least six different stages: *attachment/entry, translation, processing, genome replication, assembly,* and *release* into the circulation (Fig. 8C.5B). HCV particles attach to the hepatocyte cell surface membrane and enter the cell via key proteins such as CD81, SR-BI, claudin-1, and occludin. After entry into the hepatocyte, the nucleocapsid is delivered to the cytoplasm, and the HCV RNA is released and immediately translated. The large polyprotein is processed on the cytoplasmic side of the endoplasmic reticulum (ER), and nonstructural proteins form a complex and initiate replication of the RNA genome in collaboration with some host proteins. Viral particles are assembled from the structural proteins, and the RNA genome becomes encased between membranes derived from lipid droplets and the ER. Assembled particles are delivered to the plasma membrane and released into the blood by exocytosis. Importantly, the entire process related to HCV replication is restricted to the cytoplasm; unlike HBV, the viral RNA does not form a DNA intermediate, thus the HCV genome does not integrate into the host's cellular DNA.

The evolution of chronic hepatitis to cirrhosis during persistent HCV infection may be mediated by the host immune response directed against epitopes that reside on the various viral proteins. Chronic HCV infection may develop as a result of immune evasion as a function of quasispecies formation during active viral replication. The RNA polymerase of HCV lacks proofreading capacity and contributes to rapid diversification of the viral population, therefore mutant HCV can escape from the adaptive immune response because of selection pressure (Rehermann & Nascimbeni, 2005). Moreover, several viral proteins, including NS3 and NS5A, may contribute to viral persistence as a result of attenuation of cellular interferon activity, which appears essential for virus elimination (Foy et al, 2003; Polyak et al, 2001). These immune-evasion mechanisms promote chronicity of HCV infection, which promotes hepatic inflammation, cirrhosis, and HCC (Fig. 8C.6).

At least four HCV proteins—including core, NS3, NS5A, and NS5B—have been proposed to have cellular transforming activity both in vitro and in vivo as depicted in Figure 8C.6. Transgenic mice overexpressing HCV core in the liver have been shown to develop steatosis as well as HCC (Moriya et al, 1998). In addition, the core protein has been shown to have transforming potential in vitro (Ray et al, 1996). HCV core binds numerous cellular proteins and modulates the Raf/MEK/ERK signal transduction pathway (Levrero, 2006). The core protein also augments the TGF-β pathway by upregulating TGF-β expression in hepatic stellate cells to promote fibrosis (Bataller et al, 2004). Enhanced proliferation of HCC cells has been demonstrated by overexpression of the HCV core protein in vitro. This phenomenon was due to upregulation of Wnt-1 expression, suggesting a functional link between HCV core expression during active viral replication and subsequent

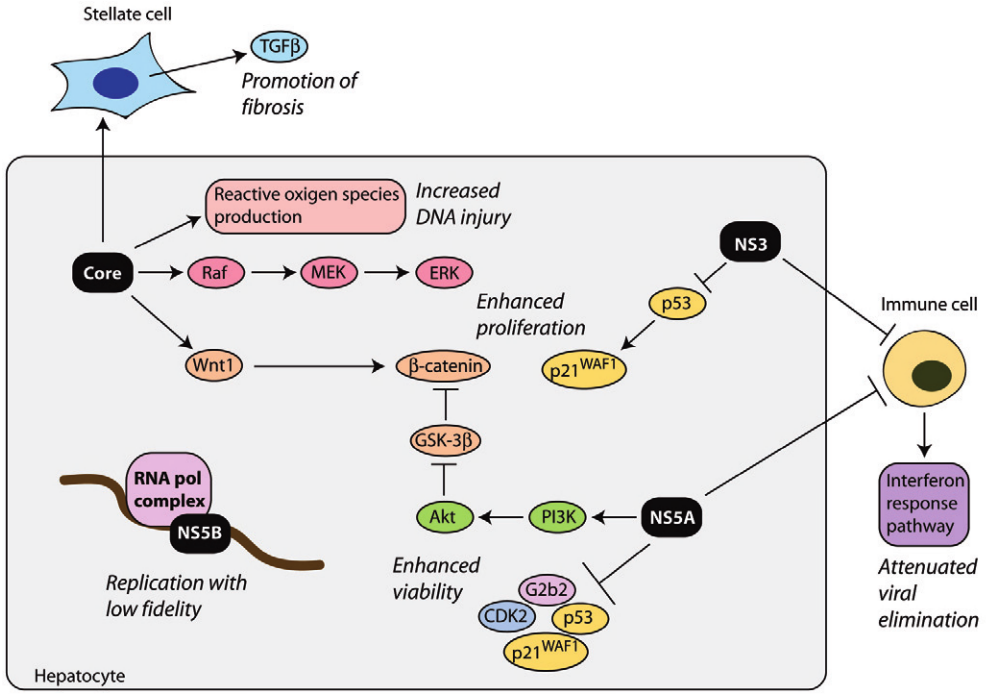

FIGURE 8C.6. Pathogenic role of hepatitis C virus (*HCV*) proteins. This diagram illustrates how HCV proteins—including core, NS3, NS5A, and NS5B—may modulate cellular function. Such proteins promote hepatocarcinogenesis in diverse ways via activation of signaling pathways and stellate cells, and they suppress immune responses to the virus and generate oxidative stress in the liver. ERK, extracellular signal-regulated protein kinase; GSK, glycogen synthetase kinase; MEK, mitogen-activated protein kinase; pol, polymerase; TGF, transforming growth factor.

activation of the Wnt/β-catenin signaling cascade (Fukutomi et al, 2005).

NS3 has been shown to complex with the wild-type p53 protein (Ishido & Hotta, 1998). By modulating the activity of p53, NS3 inhibits transcription of *LCMT2*, a gene encoding for a cell cycle regulator p21WAF1/CIP1. In addition, it has been found to repress *LCMT2* promoter activity in a dose-dependent manner and stimulates cell growth (Kwun et al, 2001).

The NS5A protein may act as a transcriptional modulator through interactions with other cellular proteins, such as Grb2, p53, p21WAF1/CIP1, and CDK2. The functional consequences have been inhibition of hepatocyte apoptosis leading to persistent HCV infection (Reyes, 2002). One potential mechanism by which NS5A may be able to exert an effect on gene expression and cellular growth is through functional associations with p53 and TATA box-binding proteins (TBP). In addition, NS5A can bind directly to the p85 regulatory subunit of PI3K and phosphorylate Akt, resulting in activation of pro-cell survival signals (Street et al, 2004). More recently, it has been observed that NS5A-mediated activation of PI3K resulted in the stabilization and accumulation of β-catenin in the cytoplasm and nucleus through inactivation of GSK-3β (Street et al, 2005).

Another possible pathway activated in HCV-induced HCC involves oxidative stress generated by increased production of reactive oxygen species (ROS) during persistent viral infection. Indeed, ROS production in the liver has been found to be increased in HCV core transgenic mice (Moriya et al, 1998). Moreover, iron loading in transgenic mice expressing the full-length HCV genome promotes HCC formation, again implicating chronic oxidative stress in the pathogenesis of HCV-mediated HCC (Furutani et al, 2006). The mechanisms underlying oxidative stress–induced hepatocarcinogenesis involve increased chromosome instability and mutations in the host cellular DNA produced by the action of ROS (Machida et al, 2006; Naganuma et al, 2004). Collectively, many of the HCV proteins are believed to contribute to hepatocyte transformation during persistent viral infection through stimulation of cell proliferation, increased cell survival, induction of genomic instability, and promotion of immune evasion.

FUTURE DIRECTIONS

In the postgenomic era, comprehensive examination of tumors via microarray gene expression profiles makes it highly likely that molecular genetic changes evolving from normal liver to dysplasia to HCC will be more precisely defined. Moreover, rapid advances in epigenetics analysis, miRNA function, and cancer stem cell biology will greatly enhance our understanding of the molecular pathogenesis of HCC. Traditional anticancer drugs, which target the DNA replication machinery, have marginal therapeutic effect on HCC growth, and new molecular targets will need to be defined. However, understanding altered signaling pathways in tumor cells will provide a stimulus to develop new drugs for treatment of this devastating disease. Such investigations emphasize the importance of unraveling the molecular mechanisms of liver carcinogenesis, which may ultimately result in "personalized" medical approaches for these tumors.

CHAPTER 42B

Biliary fistulae

Carlos U. Corvera, William R. Jarnagin, and Leslie H. Blumgart

OVERVIEW

Abnormal communication may develop between distinct parts of the biliary tract itself or between the biliary tract and other parts of the gastrointestinal (GI) system. These abnormal biliary communications, or fistulae, can be grouped into two main types: internal or external. *Internal biliary fistulae* are usually rare and spontaneous, and they occur without a significant collection of bile. *External biliary fistulae* are more common and are often caused by iatrogenic injury after operations, invasive procedures, or trauma involving the biliary tract; they are characterized by persistent discharge of bile or bile-containing fluid and can be further defined as either controlled or uncontrolled. A *controlled fistula* has bile drainage to the exterior, through the abdominal wall, but no significant intraperitoneal collection; an *uncontrolled fistula* denotes a communication with an internal collection of bile.

Regardless of the nature of the biliary fistula, management of patients with this condition is optimized when treatment is directed by a multidisciplinary team composed of experienced interventional radiologists, gastroenterologists, and surgeons.

INTERNAL BILIARY FISTULAE

Incidence and Etiology

Whether occurring as a consequence of calculous biliary tract disease, trauma, neoplasm, or congenital anomalies, internal biliary fistulae are uncommon. Estimates of incidence are crude, gleaned only from many small series, usually with fewer than 50 patients. If all types of internal biliary fistula are included, calculous biliary tract disease accounts for 90%; peptic ulcer disease, 6%; and neoplasm, trauma, parasitic infection, and congenital anomalies make up the remaining 4% (Piedad & Wels, 1972).

Overall, 1% to 3% of patients with cholesterol cholethiasis in Western countries develop biliary-enteric fistula, with a female/male ratio of 3:1. In 11,808 cases of nonmalignant biliary tract disease encountered at New York Hospital/Cornell Medical Center during the years 1932 through 1978, the incidence of biliary-enteric fistula was 0.9% with a male/female ratio of 2.3:1 (Glenn et al, 1981). A large series from Greece (Lygidakis, 1981) showed an incidence of 2%, and in Native Americans, the incidence is 3.2% (Zwemer et al, 1979). In Japan, where bilirubin stones and primary intraductal disease predominate, the incidence of fistula is between 13% and 18% with a slight male predominance (Urakami & Kishi, 1978). The type of fistula noted in this group of patients usually involves the ductal system rather than the gallbladder. The pathogenic sequence of events for calculous biliary tract disease has been well described by Glenn and Mannix (1957). It consists of pressure necrosis and erosion of part of the biliary tract wall into an adjacent structure to which it has become adherent in the course of repeated bouts of inflammation, often with distal biliary tract obstruction. The likelihood of the branches of the hepatobiliary tree to become inflamed and anatomic proximity to adjacent hollow viscera largely determine the relative incidence of the different types of spontaneous biliary-enteric fistulae secondary to calculous disease.

The various types of biliary-enteric fistulae can best be subclassified from an anatomic point of view, by the names of the principal organs involved (Fig. 42B.1). Some names for a particular fistula between two structures vary in the literature (e.g., *bronchobiliary* vs. *biliobronchial*) but do not connote differences in etiology or pathogenesis.

Fistulae Involving the Gallbladder

In Western countries, where cholesterol cholelithiasis abounds, the gallbladder is most often the site of severe inflammation and obstruction. Cholecystenteric fistulae constitute 70% to 85% of all biliary fistulae reported in the world literature up to 1982 (Rau et al, 1980; Safaie-Shirazi et al, 1973). Of these, 55% to 75% are cholecystoduodenal, 15% to 30% are cholecystocolic, and 2% to 5% are cholecystogastric (see Fig. 42B.1). Multiple fistulae (e.g., cholecystoduodenocolic) are very rare (Shocket et al, 1970). Of the 23 cases reported up to 1978, 21 were secondary to gallstone disease, and one case of each was due to duodenal ulcer and a primary carcinoma of the gallbladder (Morris et al, 1978).

Gallstone ileus, a dramatic clinical presentation of a cholecystenteric fistula, is reported in 8% to 20% of large series of patients with biliary-enteric fistulae (Clavien et al, 1990; Heuman et al, 1980; Kasahara et al, 1980; LeBlanc et al, 1983; Rau et al, 1980; Safaie-Shirazi et al, 1973; VanLandingham & Broders, 1982). As a cause of intestinal obstruction alone, gallstone ileus accounts for 1% to 4% of cases, although in patients older than 65 years, gallstone ileus may account for 25% of cases of small bowel obstruction, regardless of a history of prior abdominal surgery (Clavien et al, 1990; Reisner & Cohen, 1994; Rodriguez-Hermosa et al, 2001; Lassandro et al, 2004; Kirchmayr et al, 2005; Chou et al, 2007).

Although most fistulae between the gallbladder and intestinal tract become obvious preoperatively or intraoperatively, cholecystocholedochal fistulae are insidious and may not be appreciated even at surgery. These biliobiliary fistulae develop between the ampulla of the gallbladder or cystic duct and the proximal common hepatic or common bile duct (CBD; see Fig. 42B.1D). In either instance, the mechanism of formation is the

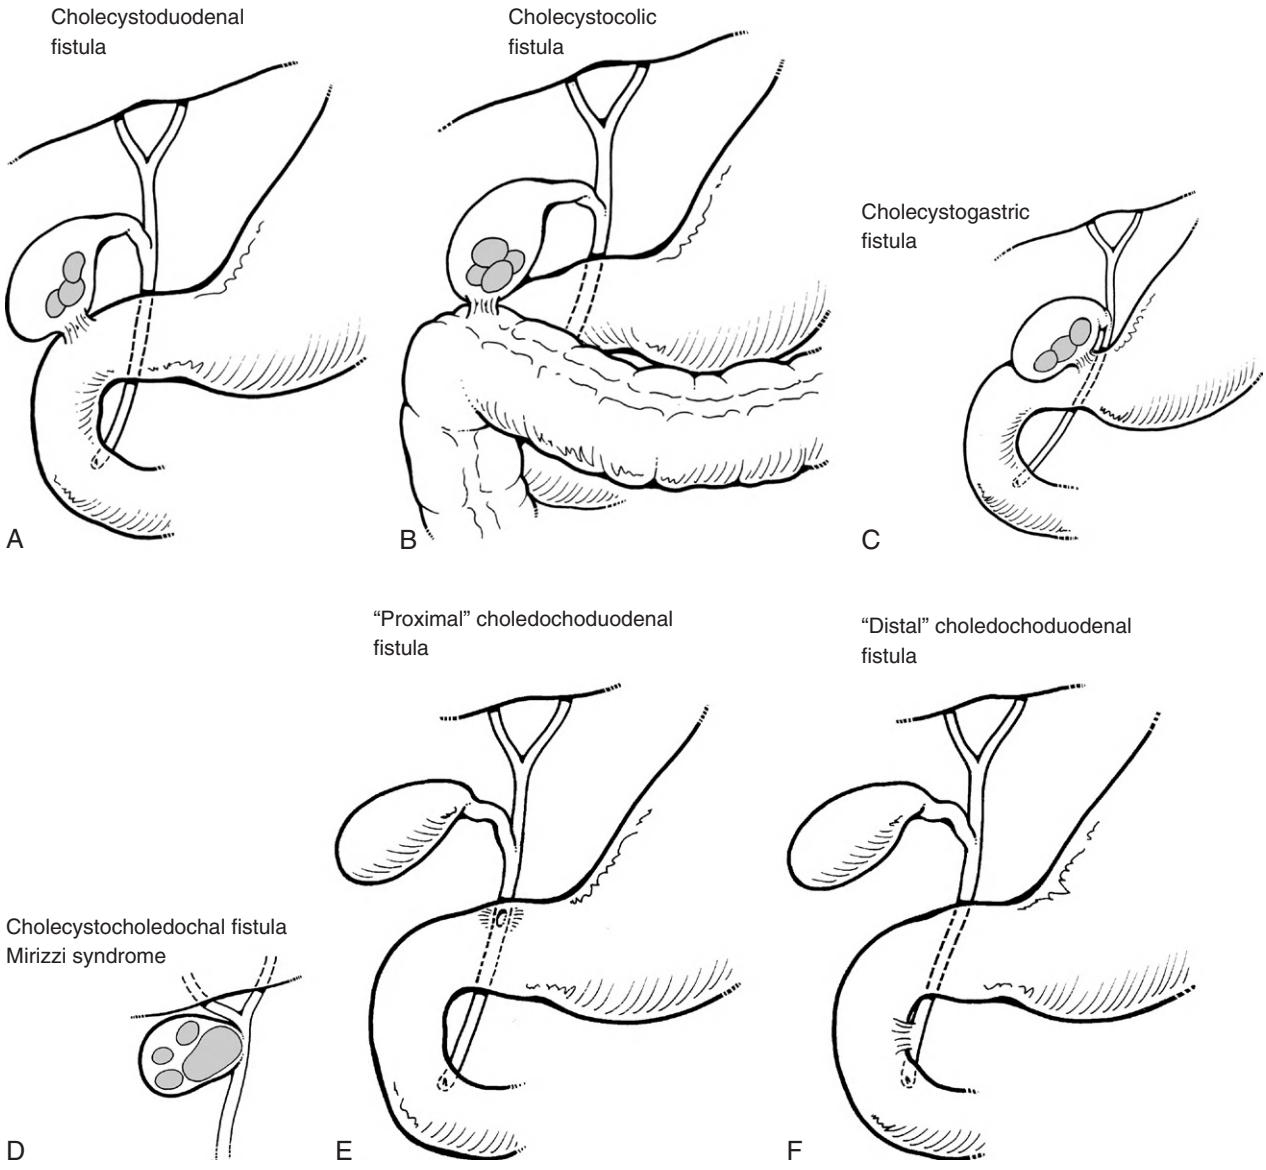

FIGURE 42B.1. **A** through **F,** Various types of biliary-enteric fistulae.

same: pressure necrosis into the common duct by a large solitary calculus impacted in either the ampulla of the gallbladder or the intramural portion of the cystic duct. Cholecystocholedochal fistula has been estimated to occur in 1% to 6% of biliary operations for calculous disease (Corlette & Bismuth, 1975). Although this estimate seems high and is not corroborated by other reports, an awareness of the possibility of cholecystocholedochal fistula is important and may help avoid damage to the common duct at operation.

Fistulae Involving the Common Bile Duct, Cystic Duct Remnant, and Other Extrahepatic Ducts

Choledochoduodenal fistulae are classified as either proximal or distal (see Fig. 42B.1E and 42B.1F). A *proximal choledochoduodenal fistula* is the principal form of abnormal communication between the CBD and adjacent structures and represents 4% to 20% of all biliary-enteric fistulae. At one time, 80% were caused by peptic ulcer erosion from the first portion of the duodenum into the proximal CBD. This cause is now much less common as a result of the development of effective medical therapy with antacid drugs. Other, less common causes of choledochoduodenal fistula include cholelithiasis, operative trauma, duodenal diverticula, echinococcal infection, Crohn disease, and neoplasms of the stomach, distal bile duct, ampullary region, and duodenum (Feller et al, 1980; Sarr et al, 1981; Kuroki et al, 2005). Since the beginning of the acquired immunodeficiency syndrome (AIDS) epidemic, there have only been three known case reports of choledochoduodenal fistula caused by AIDS/human immunodeficiency virus–associated tuberculous infection (Patino et al, 2003).

Distal choledochoduodenal fistulae connect to the duodenum in the distal 2 cm of the CBD, and the fistula opening can be seen during percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP). The incidence of distal choledochoduodenal fistula secondary to cholelithiasis or operative trauma is variable in different parts of the world. With the development of PTC and ERCP studies of pathologic anatomy (see Chapters 18, 27, and

28), it is becoming apparent that many patients with minor or major biliary-digestive complaints and gallstone disease may have a distal choledochoduodenal or parapapillary choledochoduodenal fistula. Large series from Argentina showed the incidence of parapapillary choledochoduodenal fistula to be 0.7%. Jorge and colleagues (1991) reviewed 2012 ERCP studies from 1976 through 1989, and only 14 cases were found: two cases were from stone disease and the other 12 were from iatrogenic causes.

In Japan, where there is a high incidence of primary intrahepatic calculous biliary tract disease, Tanaka and Ikeda (1983) reported a 5.3% incidence of parapapillary fistula in ERCP studies of 1500 patients. The male/female ratio was roughly equal, in keeping with the Japanese sex distribution of gallstone disease. Ikeda and Okada (1975) classified these as *type I fistula*, characterized by a small fistula opening on the longitudinal fold of the duodenum just proximal to the papilla, probably caused by penetration of a small calculus through the intramural portion of the common duct into the duodenum, and *type II fistula*, a larger opening of the duodenum wall adjacent to the longitudinal fold, probably caused by a relatively large stone eroding from the extramural portion of a greatly dilated common duct into the duodenum.

In Turkey, Karincaoglu and colleagues (2003a) reported an incidence rate of 4.9% on review of 1347 ERCP studies in 841 patients. This study also found an intriguing association between peripapillary fistula with common duct stones and complications of cholangitis. The incidence of parapapillary choledochoduodenal fistula is probably less in Western Europe, the United Kingdom, and the United States, and perhaps a greater proportion of these fistulae are not due to spontaneous gallstone disease itself but rather to iatrogenic surgical injury or other instrumental damage to the distal common duct in operations directed against choledocholithiasis. Hunt and Blumgart (1980) and Tytgat and colleagues (1979) published their experience of these fistulous complications of biliary tract surgery.

Unusual choledochal fistulae are mentioned only briefly in this context. Spontaneous fistula formation between the common duct and the colon has been recorded only four times in the English literature (Bose & Sastry, 1983; Rawas et al, 1987; Guitron-Cantu et al, 2001; Anees et al, 2008). We are also aware of one case of a choledochocolonic fistula that developed after blunt abdominal trauma (Benson et al, 2001) and another that developed as a complication from diverticulitis (Blanco-Benavides & Rodriguez-Jerkov, 1992). Peptic ulcer disease has rarely produced fistulae between the common duct, duodenum, and pancreas (Aitken et al, 1986). We have observed one case and are aware of several other cases of severe pancreatitis or pancreatic cancer producing a fistulous communication between pancreatic pseudocysts or necrotic pancreatic cavities and the CBD (DeVanna et al, 1983; Ellenbogen et al, 1981; Lebovics et al, 1990; Miller et al, 1988). Chandar and Hookman (1980) reported one case of GI hemorrhage resulting from a choledochocolonic fistula that developed from a cystic duct remnant 28 years after cholecystectomy, and it was associated with a benign stricture in the ampullary segment of the CBD. More recently, a bile duct stricture associated with a choledochocolonic fistula was reported following an uncomplicated open cholecystectomy four months prior (Munene et al, 2006). Woods and colleagues (1992) reviewed four cases of cystic duct remnant fistulization to the GI tract.

Fistulae Involving the Intrahepatic Ducts, Liver, and Lung

Thoracobiliary and bronchobiliary fistulae are quite rare (Boyd, 1977; Chan et al, 1984; Cleve & Correa, 1958); the former refers to communications between the biliary tree and the pleural cavity and the latter to communications between the bile ducts and the bronchial tree. The three major categories of bronchobiliary fistula are 1) those resulting from infection, especially parasitic, or those acquired, such as from iatrogenic injury as a result of biliary tract surgery or, less commonly, from gastric and pancreatic operations; 2) traumatic fistula; and 3) congenital fistula. The many diverse causes of acquired bronchobiliary fistulae have been well referenced by Sane and colleagues (1971) and more recently by Gugenheim and colleagues (1988). The two main factors responsible for the development of bronchobiliary fistulas are "mechanical" biliary obstruction and infection. Worldwide, the principal cause of bronchobiliary fistula in adults is parasitic disease of the liver, either echinococcal or amebic abscess (see Chapters 67 and 68). In developed countries, iatrogenic injury to the biliary ductal system is the most frequent cause of these fistulae.

The hallmark symptom of a bronchobiliary fistula is biliptysis in conjunction with other pulmonary complaints, jaundice, cholangitis, and external biliary fistula or subphrenic abscess. Radiologic confirmation of the diagnosis is possible by a variety of methods. In the presence of an external fistula, injection of contrast solution (fistulogram) is the most facile and direct approach. PTC and ERCP are equally effective in their ability to show the fistula and have the advantage of offering an avenue for potential therapeutic intervention. The choice of one or the other of these techniques depends on the presence or absence of dilated ducts and the expertise available. Bronchobiliary fistulae also have been shown by cholescintigraphy (Gunlemez et al, 2009; Santra et al, 2009; Uramoto et al, 2008; Andalkar et al, 2004; Savitch et al, 1983; Velchik et al, 1991). Computed tomography (CT) and magnetic resonance imaging cholangiopancreatography (MRCP) have been used to assess bronchobiliary fistulae (see Chapters 16 and 17). These imaging techniques, although helpful in assessing the upper abdomen, rarely visualize the fistula tract (Oettl et al, 1999; Yeatman et al, 2004; Kuroki et al, 2005; Ragozzino et al, 2005).

The surgical treatment of parasitic disease of the liver is discussed elsewhere in this book (see Chapters 67 and 68). In large series of surgically treated cases of hepatic echinococcal disease in Greece and Turkey, only 2% were complicated by rupture into the lung or bronchi (Alestig et al, 1972). Amebic abscess of the liver has been reported in association with bronchobiliary fistula in 8% of cases (Razemon et al, 1963). These complications of parasitic disease are more likely to be suspected in patients from Mediterranean countries, North Africa, Mexico, and some of the southern border states of the United States. The successful treatment of these fistulae depends on the use of appropriate surgical drainage or resection in conjunction with appropriate drug therapy.

The incidence of bronchobiliary fistula as a consequence of surgically treated calculous or neoplastic disease of the hepatobiliary tract and adjacent structures has been decreasing, as patients are operated on earlier in the course of their disease and by better-trained surgeons (Ramesh et al, 1991; Warren et al, 1983). Then again, modern surgical techniques and equipment have contributed to a new cause of biliary fistulae: reports of bronchobiliary fistula caused by new liver tumor ablative therapies, such as radiofrequency ablation (RFA), are

beginning to emerge (Kim et al, 2005; Tran et al, 2007; Yoon et al, 2009; see Chapter 85). In all these case reports, the fistula responded to conservative treatments focused on biliary drainage.

The incidence of bile duct injury in the course of cholecystectomy has increased with the advent of laparoscopic removal of the calculous gallbladder (Davidoff et al, 1992). Most of the injuries are repaired at or shortly after their occurrence. Bronchobiliary fistulae secondary to bile duct injury are a late consequence of the event in patients with neglected or recurrent strictures after unsuccessful operations. Less frequently, gastric or pancreatic procedures may result in injury to the extrahepatic bile ducts.

Untreated choledocholithiasis complicated by repeated episodes of bile duct obstruction and cholangitis is another, albeit infrequent, cause of bronchobiliary fistula. Brem and colleagues (1990) reported the successful treatment of an 87-year-old patient with this clinical situation by endoscopic papillotomy alone. Indeed, bronchobiliary fistulae should be treated first by biliary decompression, either by endoscopic papillotomy or by transampullary drainage to reduce the fistula tract pressure. Some patients with a persistent fistula or infection will require debridement by thoracotomy.

Posttraumatic thoracobiliary fistulae are extremely rare. Although penetrating or blunt trauma to the abdomen and chest is a common enough civilian and wartime occurrence, the number of fistulae resulting has remained small, often because their initial surgical treatment has been excellent, and because no obstruction to proper bile flow existed (Oparah & Mandal, 1978). Ivatury and colleagues (1984) reported on three cases and reviewed 32 previously reported patients. This series included 20 thoracobiliary and 15 bronchobiliary fistulae. Twenty-six patients sustained penetrating injuries, including 16 with gunshot wounds, 6 with stab wounds, and 4 in which the weapon was not specified. Seven patients were admitted because of blunt trauma, and in an additional four patients, the mechanism of injury was not documented. All of the patients in this report had thoracoabdominal injuries, and the causes of the fistulae were nonoperative therapy, missed or overlooked injury to the diaphragm, inadequate drainage, and subphrenic abscess. All patients had pleural effusion, and bile was aspirated by thoracentesis. Successful treatment frequently required pulmonary decortication, repair of the diaphragm, and adequate drainage above and below the diaphragm. More recent publications support the notion that inadequate drainage caused posttraumatic bronchobiliary fistulae (Navsaria et al, 2002; Eryigit et al, 2007; Ball et al, 2009).

Neuhauser and colleagues (1952) first described congenital bronchobiliary fistula in an infant with a tract communicating between the right main stem bronchus and the hepatic duct that passed through the posterior mediastinum. The diagnosis was made antemortem, but the infant died before surgical therapy. Tommasoni and colleagues (2000) described two newborn infants who were promptly diagnosed and successfully treated surgically. These authors emphasized the importance of a high index of suspicion for early diagnosis and recognition of the very high incidence (approximately 36%) of coexisting hypoplasia or biliary atresia. Therefore, all of these patients need laparotomy and thoracotomy for successful treatment (Tommasoni et al, 2000). The fistulous tract in the posterior mediastinum adjacent to the esophagus should also be excised to avoid repeat thoractomy (Gunlemez et al, 2009). Yamaguchi and colleagues (1990) reported one adult patient with a congenital bronchobiliary fistula and summarized the data of 16 previously reported cases, four of them adults. Interestingly, all adults were younger than 32 years (range, 22 to 32 years). The only congentital bronchobiliary fistula in an elderly person was reported recently by Uramoto (2008).

On microscopic examination, the proximal portion of the fistula in most patients resembles the bronchus, and the distal segment resembles the esophagus; the embryologic explanations for this anomaly are conjectural (Dyon et al, 1978; Sane et al, 1971). Transthoracic excision of the fistula and surgical correction of associated biliary anomolies is usually curative.

Diagnostic Tests

Sputum analysis for bilirubin and viable scolices or membranes can be used as laboratory evidence to establish the diagnosis of bronchobiliary fistulae secondary to echinococcosis (Gerazounis et al, 2002). Although no specific serologic tests for biliary-enteric fistula are available, in the evaluation and management of an elderly, high-risk, or critically ill patient with a symptomatic biliary fistula, tests of liver function, electrolytes, and blood count are useful.

Plain and Contrast Radiographs

Pneumobilia, the presence of air in the biliary tree, may be noted on plain films of 30% to 50% of patients with gallstone ileus (Fig. 42B.2A). Other, less common causes of pneumobilia include an incompetent sphincter of Oddi, emphysematous cholecystitis, suppurative cholangitis, and prior biliary-enteric bypass surgery. Hricak and Vander Molen (1978) suggested that the low incidence of pneumobilia in gallstone ileus is due to the cystic duct obstruction that led to the acute cholecystitis and perforation into an adjacent viscus; the obstruction also prevents retrograde passage of air into the extrahepatic and intrahepatic bile ducts.

Other classic radiographic signs of gallstone ileus are visualization of a calcified gallstone in the peritoneal cavity a distance away from the gallbladder (Fig. 42B.2B), change on repeat films in the position of a previously observed calcification, and a change in the level of mechanical intestinal obstruction—the so-called *tumbling obstruction* (Day & Marks, 1975; VanLandingham & Broders, 1982). However, only 30% of gallstones are sufficiently calcified to be radiopaque.

A barium meal or upper GI series shows reflux of contrast material into the fistula in 40% of cholecystoduodenal communications and 75% of choledochoduodenal fistulae of peptic ulcer origin (Balthazar & Gurkin, 1976; Kourias & Chouliaras, 1964). If the plain film and barium swallow are used in concert, more than 60% of biliary enteric fistulae are correctly diagnosed preoperatively (see Fig. 42B.2A; Balthazar & Schechter, 1975). A negative upper GI series in the presence of pneumobilia is an indication for a barium enema, which discloses more than 95% of cholecystocolic fistulae. CT scans with contrast material, endoscopy, radionuclide imaging, and sonography are also useful in the diagnosis of biliary fistulae (Becker et al, 1984); and more recently, MRCP has yielded valuable information.

Endoscopy and Iodinated Dye Studies

Direct injection of contrast material is the best way to outline the normal and pathologic anatomy of the biliary tract.

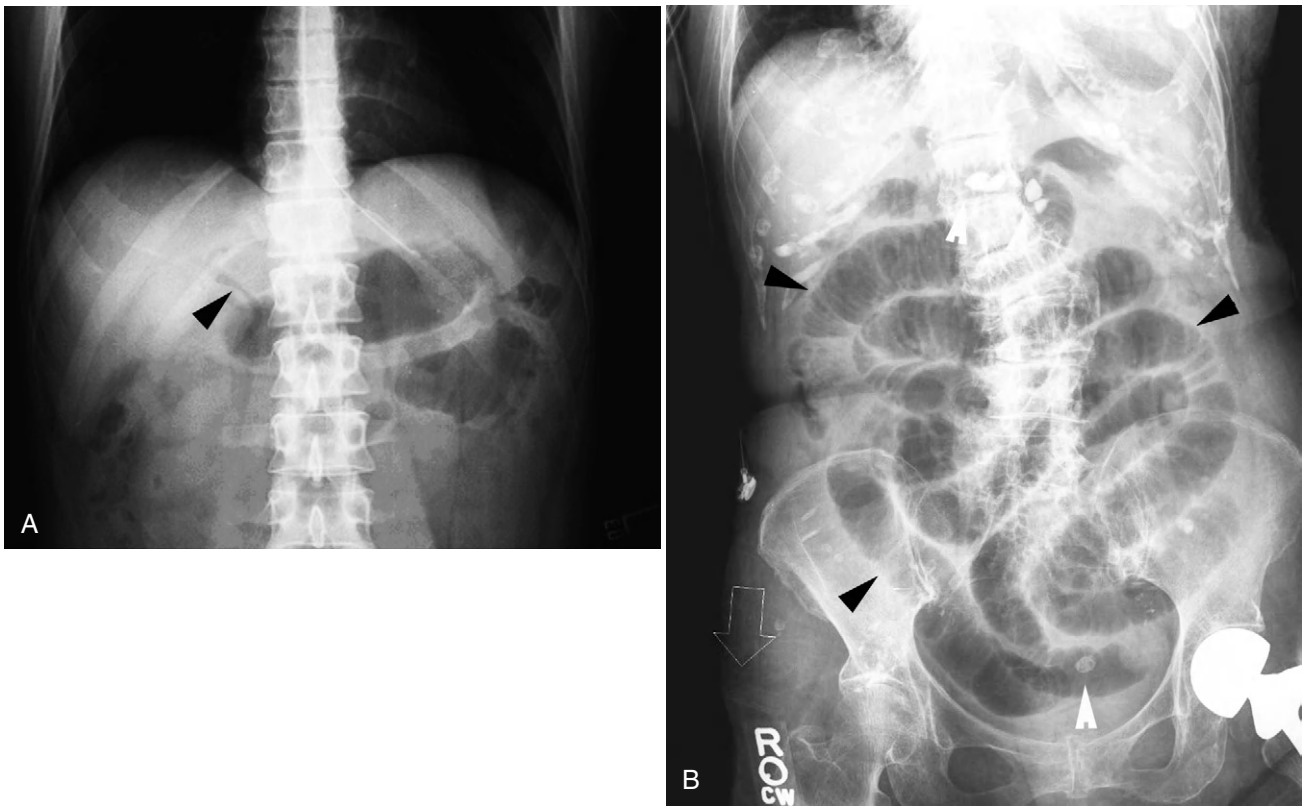

FIGURE 42B.2. A, Plain radiograph shows pneumobilia (*arrowhead*). **B,** Plain radiograph shows multiple dilated loops of small bowel (*black arrowheads*), several calcified gallstones (*white arrowhead*), three gallstones located in small bowel in the upper abdomen, and one obstructing gallstone in the pelvis. *(**A,** Courtesy Dr. Rizwan Aslam. **B,** Courtesy Dr. Fergus V. Coakley.)*

Preoperatively, this imaging is accomplished by ERCP or PTC; when an external bile fistula exists, a fistulogram should be performed. Intraoperative or postoperative cholangiograms are often invaluable.

Since 1970, numerous reports have appeared in the literature supporting the efficacy of ERCP in documenting surgical or spontaneous biliary fistulae (Al Nakib et al, 1982; Tanaka & Ikeda, 1983; Tytgat et al, 1979; Van Linda & Rosson, 1984). Endoscopically, the alimentary side of a fistula can be visualized directly, be it gastric (Stempfle & Diamantopoulos, 1976), duodenal, or colic; the fistula itself or the ampulla of Vater can be cannulated to obtain a high-quality radiograph of the communicating biliary anatomy (Moreira et al, 1984; Watkins et al, 1975; Chatzoulis et al, 2007). Similarly, the largely unappreciated and frequently asymptomatic parapapillary choledochoduodenal fistula has been found to be quite common (Hunt & Blumgart, 1980; Karincaoglu et al, 2003b; Tanaka & Ikeda, 1983; Kuroki et al, 2005). There have been far fewer reports of the role of PTC in showing biliary fistulae, but PTC has been helpful in the diagnosis and treatment of bronchobiliary fistula in association with echinococcal disease of the liver and dilated intrahepatic ducts (e.g., cholecystocholedochal fistula; Cornud et al, 1981; Mannella et al, 1999).

Radionuclide Imaging (See Chapter 15)

With the introduction of the imidoacetic acid agents bound to technetium (p-isopropylacetanilido iminodiacetic acid [PIPIDA] and hepatobiliary iminodiacetic acid [HIDA]), radionuclide scans have rapidly become the preferred method of outlining the normal and pathologic anatomy of the extrahepatic bile passages. These relatively noninvasive procedures do not rely on hepatocellular concentration of bile or on short critical time-flow periods for satisfactory visualization of the biliary tree. Prolonged (24 hours) accumulation of radioactivity, measured by patient scanning or quantitative isotopic counts of body secretions (e.g., sputum), has been used to show very small or intermittent fistulae from the biliary tract to the respiratory passages (Fig. 42B.3) and the colon (Benson et al, 2001; Santra et al, 2009; Uramoto et al, 2008; Andalkar et al, 2004; Bretland, 1983; Edell et al, 1981; Henderson et al, 1981; Savitch et al, 1983; Taillefer et al, 1983).

Sonography

Sonography is a useful noninvasive diagnostic aid in the preoperative evaluation of a patient with a suspected biliary fistula (Porta et al, 1981; Renner et al, 1982) and even gallstone ileus (Davies et al, 1991; Pedersen et al, 1988; see Chapter 13). Although the radionuclide scan may readily show a fistula, the sonogram indicates the presence of calculi in the gallbladder; common duct stones; and inflammatory, cystic, or infiltrative disease of the liver and pancreas (Griffin et al, 1983). Sonography can readily detect pneumobilia, indicating a high likelihood of a biliary-enteric fistula. In gallstone ileus, sonography can detect an ileal stone not seen on plain films and is increasingly being used by emergency room physicians (Zironi et al, 2007). Ripolles and colleagues (2001) reported that 22 of 23 patients who had undergone surgery for gallstone ileus were found on sonogram to have pneumobilia. This information is valuable in

FIGURE 42B.3. A 49-year-old woman with symptoms of pneumonia and clinical evidence of biliptysis. Anterior image from hepatobiliary iminodiacetic acid scan at 40 minutes after injection shows communication of the liver with the right lung and central airways. Radiopharmaceutical is present in the right and left main bronchi (*small curved arrows*) and in the trachea (*large curved arrow*), confirming the presence of bronchobiliary fistula. *(Courtesy Dr. Douglas S. Katz.)*

the decision-making process, such as to evaluate the need for or advisability of cholecystectomy and dismantling of a fistula at the time of operation for gallstone ileus in an elderly or high-risk patient. This information may be obtained more rapidly and safely, and probably with equivalent accuracy, by a preoperative sonogram rather than by intraoperative manipulations about the mass of inflamed tissue in the right upper quadrant. Ultrasound (US) has been used to document the persistence or closure of biliary enteric fistulae after initial emergent surgical or combined endoscopic lithotripter treatment of gallstone ileus, and it has aided the decision for or against further surgery (Clavien et al, 1990).

Computed Tomography and Magnetic Resonance Imaging Cholangiopancreatography (See Chapters 16 and 17)

CT and MRCP are better able to show a moderately calcified ectopic gallstone, air in the biliary tree, the presence of additional stones, and a cholecystoduodenal fistula (Swift & Spencer, 1998). CT is useful also for estimating the size of the impacted stone and determining the site of obstruction for planning the operative approach (Fig. 42B.4). Indeed, new multidector CT scanners that use multiplanar or three-dimensional volume-rendering reconstruction will further improve the diagnostic role of CT in detecting fistulae. Already, modern MRI and MRCP scans with improved image resolution and reduced motion artifact have been shown to accuarately detect a small fistulous tract (Chatzoulis et al, 2007). Although such scanning may disclose fusion of the biliary tract to an adjacent viscus, it may not always precisely show a fistula; but MR scanning should be used to show other important pathologic changes, such as distal common duct stones or other obstructive processes, the presence of a subphrenic abscess, pleural effusion, or parasitic disease of the liver (Porta et al, 1981). Scanning also can be used to verify and localize contrast extravasation after interventional procedures, such as PTC or ERCP, or after contrast injection of an existing controlled external fistula (Fig. 42B.5).

Specific Clinical Presentations and Treatment

Gallstone Ileus

Gallstone ileus is the blockage of the intestinal tract by a gallstone large enough to occlude its lumen partially or completely. This dramatic presentation of intestinal obstruction is too indelibly fixed in the medical imagination to permit amendment of the inappropriate term *ileus*; perhaps this derives from the frequent initial clinical impression of an unexplained ileus, in that many patients with gallstone obstruction are initially seen without any clinical history or physical signs to suggest mechanical intestinal obstruction. Similar to other patients in Western Europe and English-speaking countries, where

FIGURE 42B.4. cholesterol cholelithiasis predominates, patients seen with this manifestation of advanced biliary tract disease are usually elderly, female, and beset by multiple other medical conditions that may delay or complicate prompt diagnosis and appropriate treatment.

When an elderly person presents with typical signs and symptoms of intestinal obstruction or, perhaps less dramatically, an unexplained ileus without obvious incarcerated abdominal wall hernia, scar of a previous laparotomy, and little suspicion of an occult malignancy, calculous obstruction by a gallstone must be considered. Approximately half of such patients presenting with gallstone ileus give a history suggesting prior calculous biliary tract disease. At the time of clinical presentation with gallstone obstruction, however, signs of active gallstone disease—pain, tenderness in the upper abdomen, cholangitis, and jaundice—may be absent. Laboratory data are consistent with fluid and electrolyte disturbances appropriate to the degree and duration of intestinal obstruction, and some abnormalities of liver function tests (LFTs) may suggest chronic disease of the liver and biliary tract in one quarter of patients.

The classic plain abdominal film triad of small bowel obstruction, pneumobilia, and ectopic gallstone is considered pathognomonic of gallstone ileus (Rigler et al, 1941); however, the triad is encountered in only 30% to 35% of cases (Balthazar & Schechter, 1978). Pneumobilia is often not appreciated even in retrospect. If biliary-enteric fistula is suspected, and a barium meal is administered, reflux of barium into the biliary tree yields a correct preoperative diagnosis in 60% of patients (Fig. 42B.6). Calculi large enough to obstruct the intestine usually do so in the last 50 cm of ileum, although sometimes also in the jejunum or duodenum and rarely in the sigmoid colon. Such calculi are usually larger than 2.5 cm; if partially calcified, they are readily apparent on a plain radiographs (see Fig. 42B.2B).

FIGURE 42B.6. Upper gastrointestinal series shows a choledochoduodenal fistula with reflux of contrast medium into the biliary tree. *(Courtesy Dr. Benjamin M. Yeh.)*

Abdominal ultrasound, as mentioned earlier, often establishes the diagnosis of gallstone ileus or provides other information relevant to the diagnosis (Clavien et al, 1990; Davies et al, 1991; Pedersen et al, 1988; Ripolles et al, 2001; Zironi et al, 2007), revealing pneumobilia; the site of the fistula; additional stones still in the gallbladder, or more importantly, in the common duct; and occasionally the location of an ectopic calculus. The diagnositic superiority of CT over abdominal plain films and sonography for gallstone ileus is now well established (Ayantunde & Agarwal, 2007; Lassandro et al, 2005; Loren et al, 1994; Reimann et al, 2004; Swift & Spencer, 1998). In fact, the clinical significance of Rigler's triad has been revitalized by CT, because all three findings are more consistantly detected (approximately 78%) by this method (Kirchmayr et al, 2005; Ayantunde & Agarwal, 2007; Chou et al, 2007).

The clinical presentation of gallstone ileus has not changed in the past 40 years. In patients with intestinal obstruction, preoperative diagnostic accuracy is approximately 75% (Glenn et al, 1981). Preoperative diagnostic accuracy has contributed to an improved outcome of therapy (Deitz et al, 1986). The increased use of CT in patients with symptoms of intestinal obstruction has led to additional improvement in the diagnostic accuracy of gallstone ileus and has resulted in a decrease in the high mortality rate encountered with this disease (Delabrousse et al, 2000; Lassandro et al, 2004; Reimann et al, 2004; Ayantunde & Agarwal, 2007; Chou et al, 2007).

The overriding consideration in patients presenting with gallstone obstruction of the intestine should be relief of the life-threatening cause of obstruction (i.e., enterolithotomy). This surgical emergency should be approached expeditiously and without a period of waiting in the hope that a suspected stone will pass; it will not. The only reason for delay should be to provide adequate preoperative fluid and electrolyte resuscitation of these critically ill patients and, if possible, to assess the presence of other gallstones in the gallbladder and common duct by means of sonography or CT. The use of nasogastric decompression and preoperative antibiotics is strongly recommended to minimize the risks of aspiration and postoperative wound infection.

The terminal ileum is the site of obstruction in 70% of cases (see Figs. 42B.2B and 42B.4B). Unless the obstructed segment is ischemic or has perforated and requires a small bowel resection, the obstructing calculus can be manipulated proximally to a healthy section of bowel, where a safe enterotomy and stone removal may be executed. Jejunal impaction, often by stones larger than 4 cm, occurs approximately 15% of the time, and enterotomy may be made at the site or just proximal to it. Duodenal obstruction, usually in the bulb, is known as *Bouveret syndrome* (Argyropoulos et al, 1979; Bhama et al, 2002; Cooper & Kucharski, 1978; Koulaouzidis & Moschos 2007; Frattaroli et al, 1997; Maglinte et al, 1987; Thomas et al, 1976), which occurs in 10% of patients and may be handled by duodenostomy or pyloroplasty. It occasionally may be possible to manipulate the stone back into the stomach and remove it via gastrotomy. Rarely, a gastroenterostomy is necessary to protect a duodenotomy or severely traumatized duodenum at the site of impaction.

Bouveret syndrome and other cases of gallstone impaction high in the jejunum have been managed successfully by a combination of endoscopy and electrohydraulic lithotripsy (Fujita et al, 1992; Holl et al, 1989; Moriai et al, 1991; Sackmann et al, 1991). We are aware of one case report of a failed endoscopic extraction that led to spontaneous uneventful passage of the stone (Wagholikar & Ibrarullah, 2004). In rare instances, the sigmoid colon is the site of obstruction of a calculus that has managed to pass through the terminal ileum or enter the colon via a cholecystocolic fistula (Anseline, 1981; Clavien et al, 1990). Almost invariably, some other pathologic process, such as diverticulitis, has produced an area of colonic narrowing. A colostomy is necessary to decompress the proximal bowel. If the impacted stone cannot be manipulated proximally to a transverse colostomy, consideration should be given to exteriorization of the impacted segment with a Hartmann closure of the bowel distal to it (Milsom & MacKeigan, 1985).

Open exploration and enterolithotomy has always been the standard surgical approach for the treatment of classical gallstone ileus. It not only allows removal of the obstructing stone but also permits careful palpation of the entire bowel and gallbladder region, to determine whether other gallstones are in transit more proximally or if any still reside in the diseased gallbladder (see Fig. 42B.2B). These calculi may be poised for passage through the fistula, possibly to induce a recurrent episode of gallstone ileus, a phenomenon estimated to occur in 5% of cases; however, by simple maneuvers, this can be prevented (Clavien et al, 1990; Haq et al, 1981; Levin & Shapiro, 1980). More recently, some authors have described laparoscopic or laparoscopic-assisted treatment for patients with gallstone ileus (Allen et al, 2003; Malvaux et al, 2002; Moberg & Montgomery, 2007; Owera et al, 2008). Because of the limited number of laparoscopically treated patients, it is unclear wherther this approach will reduce the associated high mortality and morbidity rates. Therefore it is our opinion that an open surgical approach should remain the standard of practice and that laparoscopic treatment needs further evaluation.

Considerable debate in the surgical literature surrounds whether cholecystectomy or common duct exploration or both, with dismantling and closure of the cholecystenteric fistula, should accompany enterotomy and relief of the obstruction or await a second operation (Kirchmayr et al, 2005; Muthukumarasamy et al, 2008; Zuegel et al, 1997). Historical data of published reports from the years 1953 through 1993 (Reisner &

Cohen, 1994) showed a lower mortality rate of 11.7% in the enterolithotomy-alone group compared with 16.7% for patients who underwent a one-stage operation. Several published reports indicated that operative mortality is lower in these critically ill, elderly patients when only the gallstone obstruction is relieved (Muthukumarasamy et al, 2008; Tan YM et al, 2004; Heuman et al, 1980; Kasahara et al, 1980; VanLandingham & Broders, 1982). This has lead to the general agreement that enterolithotomy alone should be done for fragile patients with significant comorbidities and that the single-stage procedure should be reserved for young, fit, and low-risk patients.

Although some centers have recently published impressively low perioperative mortality rates (0%) for surgical treatment of gallstone ileus, other centers still report rates in the traditional high range (23%; Muthukumarasamy et al, 2008; Tan et al, 2004; Ayantunde & Agarwal, 2007). In a case series from the United Kingdom (Anyantunde & Agarwal, 2007), five deaths occurred in 22 patients; four of the five deaths were patients treated with enterolithomy alone. Seven of 19 patients from YM Tan and colleagues' (2004) series were clinically unstable and underwent enterolithotomy alone; on long-term follow-up, these patients did not have further complications.

Indeed, careful follow-up of patients treated with enterolithotomy alone indicates that one third to one half will have minimal or no symptoms after relief of the gallstone ileus, and no further treatment will be necessary (Clavien et al, 1990; van Hillo et al, 1987; Tan YM et al, 2004). If a patient has jaundice and intestinal obstruction at the outset, common duct exploration, or at least tube decompression of the common duct, may also be necessary as a lifesaving procedure. For patients who continue to be symptomatic after relief of gallstone ileus, careful preoperative evaluation and bowel preparation can precede a later operation, adding to its safety.

Because common duct stones are found in 40% of patients with biliary-enteric fistula, it is likely that patients who continue to be symptomatic would require endoscopic or open surgical removal of their common duct stones in addition to cholecystectomy and repair of the fistula. As mentioned, operative mortality rate slowly declined to 15% to 25% in large reported series until the early 1970s. Further reductions in operative mortality rates have been possible by limiting treatment to enterotomy and stone removal alone without further surgical therapy in high-risk patients (Ayantunde & Agarwal, 2007; Glenn et al, 1981; Muthukumarasamy et al, 2008; Rodriguez-Sanjuan et al, 1997; Tan YM et al, 2004).

Cholecystoduodenal Fistulae

Most cholecystoduodenal fistulae do not result in gallstone ileus (see Fig. 42B.1A). Rather they are asymptomatic or occur in association with the usual digestive complaints consistent with gastric or biliary tract disease. They may be found during an upper GI barium study or under less welcome circumstances, such as at the time of abdominal surgery for an unrelated problem.

If an asymptomatic or mildly symptomatic cholecystenteric fistula is diagnosed preoperatively, many of the management decisions regarding gallstone ileus discussed previously may apply. Elective surgery may never be necessary in a completely asymptomatic individual, and surgery may present an unfavorable risk-to-benefit ratio in an elderly, minimally symptomatic patient. Along with dismantling of the fistula and common duct exploration, other alternatives to cholecystectomy must be considered, such as a period of expectant management with careful observation, endoscopic papillotomy and stone extraction with the gallbladder left in situ, or interval cholecystectomy if symptoms of pain or cholangitis persist after endoscopic biliary surgery. In a relatively healthy patient younger than 70 years, we believe that open surgical extirpation of the gallbladder, closure of the fistula, and treatment of any common duct pathology promise the best long-term therapeutic result, although some authors advocate laparoscopic treatment of preoperatively diagnosed biliary-enteric fistulae (Chikamori et al, 2001; Crouch & Kuhnke, 2000; Kwon & Inui, 2007; Lee et al, 2004; Rohatgi & Singh, 2006).

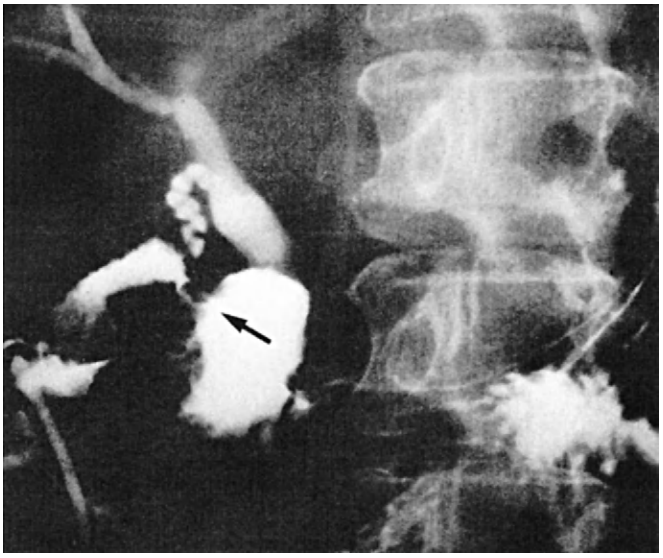

FIGURE 42B.7. Cholecystoduodenal fistula (*arrow*) shown by cholecystostomy tube cholangiogram 1 month after operation for acute cholecystitis.

If an incidental cholecystoduodenal fistula is discovered at the time of surgery, the major intraoperative decision revolves around the patient's need for, and ability to tolerate, additional surgical manipulations. If the patient is judged an unsound risk, or if the biliary tract pathology is not believed to be pertinent to the major indication for operation, nothing need be done. Rarely, a cholecystostomy (Fig. 42B.7) and extraction of large calculi can be accomplished with little additional risk. Usually, the gallbladder is shrunken and barely palpable, however, because it is stuck to the duodenum. If the patient can tolerate additional surgery, and sufficient indication exists to proceed at the present operation, rather than at a subsequent one, an attempt should be made to show the biliary-enteric anatomy and state of the common duct by an operative cholangiogram before proceeding with a definitive procedure.

Cholecystocolic Fistulae and Choleric Enteropathy

A cholecystocolonic fistula may develop acutely in patients with long-standing mild or moderately symptomatic biliary tract disease and may be heralded by a sudden change in bowel habits with multiple, loose stools and the development of fever, chills, and other signs of cholangitis from colonic bacterial reflux into the biliary tract. Many elderly patients either weather or ignore these symptoms without seeking medical attention, and some develop signs and symptoms that may incriminate the entire GI tract. Increased stool frequency persists, particularly

after ingestion of food, and bouts of fever and malaise subside. Other characteristic symptoms then appear, such as eructation, nausea, weight loss, and increasing diarrhea and steatorrhea. These latter symptoms precede the onset of choleric enteropathy, a dramatic complication of cholecystocolonic fistula. This enteropathy also is seen in other major disturbances of bile acid metabolism, such as with major ileal resection or blind loop syndrome (Brandt, 1984).

Choleric enteropathy comprises of a wide spectrum of anatomic, physiologic, and biochemical changes produced by a significant alteration of the enterohepatic circulation of bile acids. The malabsorption syndrome secondary to cholecystocolonic fistula was clinically documented first by Augur and Gracie (1970) and has since been studied by others (Rau et al, 1980). Ordinarily, 95% of bile acids are passed down the jejunum, aiding in fat and cholesterol absorption, before being largely reabsorbed in the terminal ileum as part of an efficent enterohepatic circulation. Two or three cycles of the bile acid pool per meal occur, with further metabolism of bile acids in the colon and very little lost. With a cholecystocolonic fistula, however, a large part of all of the primary bile acid pool is shunted directly into the colon, resulting in a high luminal concentration of bile acids. In the colon, the primary bile acids undergo deconjugation and dehydroxylation by fecal bacteria, and this increased concentration of bile acids causes a water secretory diarrhea.

Interestingly, only the two natural bile acids with two α-hydroxy groups, chenodeoxycholic acid and deoxycholic acid, induce colonic secretion (Keely et al, 2007). Depending on the amount of bile still passing via the common duct into the small bowel, fat absorption is affected, which over time may result in fatty acid diarrhea. More immediately, however, colonic secretion of water and electrolytes is maximally stimulated by the dihydroxy bile acids. Chenodeoxycholic acid gains access to the colon in large quantities, and massively increased amounts of deoxycholic acid are formed by bacterial dehydroxylation of cholic acid. The primary bile acids and their metabolites are no longer actively absorbed and are lost from the body, eventually causing a chronically lowered bile salt pool beyond the liver's capacity to synthesize new bile acids to replete it. At this point, even with a partial shunt to the colon, the bile acid concentration still normally passing down the common duct and through the small intestine may be too small to effect micellar solubilization of dietary fat. In contrast to a blind loop syndrome, in which bacterial overgrowth contributes to the choleric enteropathy and can be largely corrected by antibiotics, at least temporarily, cholecystocolonic fistula does not respond adequately to antibiotics. Until the fistula is dismantled, massive shunting of bile acids to the intestine persists and promotes continued watery diarrhea, diminished bile salt pool, and a variable degree of fat malabsorption.

Cholangitis seems to be a more prominent feature of cholecystocolonic fistula, when the fistula is narrow and prone to intermittent obstruction of bile flow (Edell et al, 1981; Safaie-Shirazi et al, 1973), whereas diarrhea with a lesser incidence of fever and chills is more common with a wide-open fistula (Lygidakis, 1981); we are also aware of one case report of a patient with a cholecystocolonic fistula who was seen with massive lower GI hemorrhage (Kunasani et al, 2003). In any instance, a fistula to the colon is more likely than other biliary-enteric fistulae to have associated cholangitis; if it does, the serum levels of bilirubin, alanine aminotransferase, and γ-glutamyltransferase may be slightly elevated and may direct attention to the biliary and upper digestive tract.

Because of the unusual initial complaints, full investigations for malabsorption that include upper GI studies, GI sonography, and jejunal biopsy may be undertaken but usually do not clarify the diagnosis. A pathognomonic triad consisting of pneumobilia, chronic diarrhea, and vitamin K malabsorption was recently suggested by Savvidou and colleagues (2009) to aid in the diagnosis of cholecystocolonic fistula. Diversion of bile acids into the colon results in malabsorption of fat and fat-soluble vitamins. In particular, vitamin K deficiency can be clinically significant and is easily detected by a prolonged prothrombin time (PT), and it can be corrected by parenteral supplementation (Savvidou et al, 2009). Although the condition of bile acid malabsorption can be easily diagnosed by the selenium-75-homocholic acid taurine (SeHCAT) test, this study is time consuming and is not widely available (Pattni & Walters, 2009). Plain abdominal radiographs have been reported to reveal air in the biliary tree in only 50% of cases, however, the diagnosis becomes evident only if a barium enema examination is done, preferably with air contrast, because barium (Fig. 42B.8) and air fill the gallbladder and extrahepatic bile ducts. In a recent report, a barium enema showing contrast filling of the biliary tract was used to diagnose a patient with a rare choledochocolonic fistula causing severe diarrhea (Anees et al, 2008). Failure of even a barium enema to show a cholecystocolonic fistula has been reported, but this is quite rare. In such cases, the cholecystocolic fistula is diagnosed by ERCP (Arvanitidis et al, 2004; Schoeters et al, 2002).

There is little controversy about the appropriate treatment for cholecystocolic fistulae. Except in the most extenuating circumstances, the fistulae should be dismantled because of the ever-present risk of sepsis. If the diagnosis can be made preoperatively, suitable mechanical and antibiotic bowel preparation reduces the chance of infectious complications of surgery and aids primary closure of the large bowel. Cholecystectomy and, if indicated, common duct exploration should be done at the same time. Centers with significant expertise in laparoscopic surgery have reported successful treatment of preoperatively diagnosed cholecystocolonic fistulae by this method (Chatzoulis et al, 2007; Gentileschi et al, 1995; Hida et al, 1999; Lee et al, 2004; Wang et al, 2006). Regardless of the choice of surgical treatment, preoperative ERCP with sphincterotomy and stone extraction may obviate the need to explore the CBD and, in rare cases, might result in spontaneous closure of the fistula, obviating surgery altogether (Marshall et al, 1990).

Cholecystocholedochal Fistula, Including Mirizzi Syndrome

The pathogenesis of cholecystobiliary fistula is similar to the mechanism of fistula formation between the gallbladder and other adjacent segments of the alimentary tract: the offending calculus remains impacted in the ampulla of the gallbladder or cystic duct, and the resultant inflammation causes adherence and then perforation into the adjacent structure (see Fig. 42B.1D) In 1948, Mirizzi described the clinical picture in detail and called it *functional hepatic syndrome*. It is now commonly referred to as *Mirizzi syndrome* (see Chapters 29 and 43). The mechanism of jaundice was postulated by Mirizzi to be due to spasm of the hepatic sphincter secondary to inflammation in the region of the cystic duct junction with the common hepatic duct (Mirizzi, 1948); however, extensive histologic studies have failed to disclose a "sphincter" in the common hepatic duct.

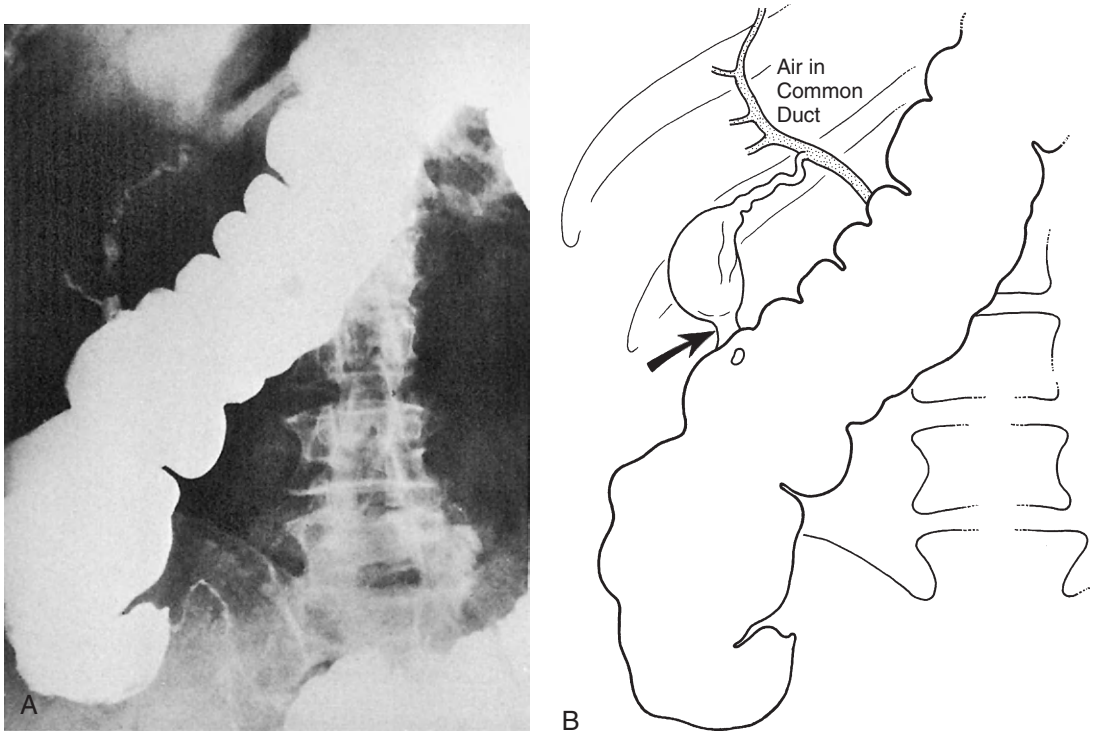

FIGURE 42B.8. **A** and **B,** Cholecystocolic fistula seen by barium enema.

The large size of the stone and the acute cholecystitis with marked pressure necrosis and inflammatory reaction at the site of stone intrusion into the common hepatic duct combine to produce jaundice with variable components of extrinsic compression and intrinsic calculous blockage of bile flow.

The early phase of this cholecystobiliary fistula presumably exists when a large gallstone is impacted in the ampulla of the gallbladder or in the intramural segment of the cystic duct, which often courses parallel to the common duct. The jaundice that occurs as a consequence of this pathologic anatomy is clinically indistinguishable from choledocholithiasis. McSherry and colleagues (1982) suggested that this classic picture (Fig. 42B.9) of Mirizzi's "functional hepatic syndrome" be subclassified as type 1. With progression of the disease, extrusion of the stone into the common hepatic duct may occur, and a fistula may form between the gallbladder and the hepatic duct. This is classified as type 2 (see Fig. 42B.1D), which is characteristically diagnosed intraoperatively by observing a gush of bile on removal of the impacted stone, indicating a biliobiliary fistula. Csendes and colleagues (1989) further subclassified type 2 patients into three categories based on the percentage of the wall of the common duct that was eroded by the offending calculus. In this subclassification, type II is a fistula involving less than one third of the circumference of the bile duct, type III involves two thirds, and type IV is a fistula with complete bile duct destruction. This classification scheme was recently updated to include a type V, which describes cholecystoenteric fistula, with or without gallstone ileus, coexisting with any of the other types (Csendes et al, 2007).

The large and solitary nature of the ampullary and cystic duct stones may be a hint to the preoperative diagnosis. The classic findings on ultrasonography include dilation of the biliary system that includes the common hepatic duct above the gallbladder neck, a stone impacted in the gallbladder, and an abrupt change in the caliber of the common duct below the stone (Hayek et al, 1988). Because most of these patients present with jaundice or some abnormalities on LFTs, a preoperative ERCP or PTC frequently is performed. These imaging studies permit a precise delineation of the condition, markedly altering surgical strategy. Cornud and others (1981) showed the appearance of biliobiliary fistulae at PTC, whereas Heil and Belohlavek (1978) relied on ERCP. In the six patients documented by McSherry and colleagues (1982), PTC and ERCP were equally effective in elucidating the cause of common duct obstruction. Although MRCP has been shown to diagnose Mirizzi syndrome preoperatively, it is limited, because it rarely shows the fistula and does not afford therapeutic stenting (Rappeport, 2002).

Biliobiliary fistulae have been referred to as a "trap" in the surgery of cholelithiasis (Corlette & Bismuth, 1975). This term is appropriate, because the presence of such a fistula frequently is not recognized until the time of surgery, often not soon enough to prevent injury to the common duct in an attempt to dissect the ampulla of the gallbladder or the cystic duct. Lygidakis (1981) emphasized the technical problems in operating on these patients. Other authors (Baer et al, 1990; Dewar et al, 1990, 1991; Yip et al, 1992) emphasized the importance of preoperative direct cholangiography. In patients with jaundice, biliary drainage may be necessary in the preoperative management.

If a large adherent mass about the gallbladder and CBD is encountered at surgery, operative cholangiography, although difficult, may delineate the presence of true choledocholithiasis or of the impacted stone without fistula (Mirizzi type 1) or the biliary fistula itself (Mirizzi type 2). In any event, it is unwise to attempt complete cholecystectomy; it is much better to

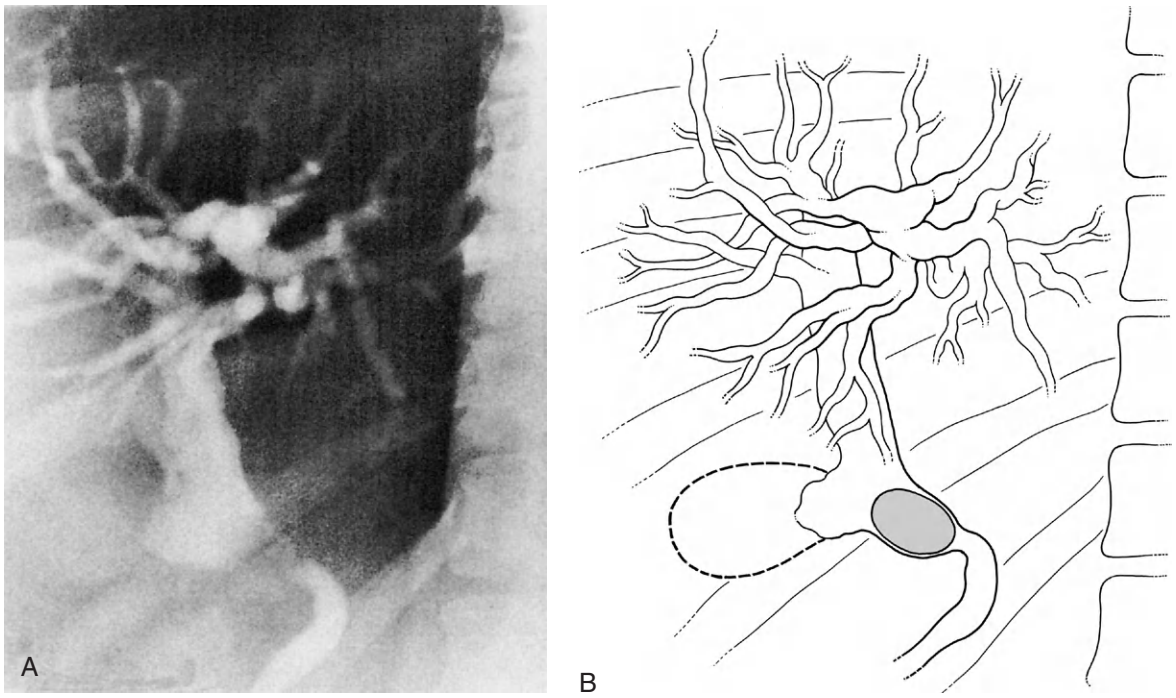

FIGURE 42B.9. **A** and **B,** Mirizzi syndrome type 1 (without cholecystocholedochal fistula). Percutaneous transluminal cholangiography shows an impacted cystic stone with extrinsic compression of the proximal hepatic ducts.

open the gallbladder, remove the stones, and directly assess the presence or absence of a fistula. A portion of the gallbladder wall is sent for frozen section histology to exclude concomitant malignancy, but choledochotomy is seldom necessary, because multiple stones are infrequent in this disease. For Mirizzi type 2 disease, direct choledochotomy may be done, but the obstructing stone usually can be removed via the opened gallbladder. The gallbladder may be dissected 1 to 2 cm proximal to the fistula, between the ampulla and the common hepatic duct, at which point it is transected and sutured closed. T-tube drainage of the common duct may be achieved through the longitudinal choledochotomy, but this is often unnecessary. Alternatively, the opened gallbladder may be anastomosed to the duodenum as described by Hadjis and colleagues (1987) and later advocated by Baer and others (1990) and Mishra and others (1990). Stenosis of the biliary tree often resolves spontaneously in the postoperative period, and choledochotomy is seldom indicated.

Since the introduction of laparoscopic approaches to surgery of the gallbladder and the bile ducts, several cases and small series of laparoscopic treatment of Mirizzi syndrome have been reported (Bagia et al, 2001; Binnie et al, 1992; Chowbey et al, 2000; Paul et al, 1992; Rust et al, 1991; Schafer et al, 2003; Silecchia et al, 1995; Vezakis et al, 2000; Yeh et al, 2003; Rohatgi & Singh, 2006; Kwon & Inui, 2007). To address the utility of laparoscopic treatment of Mirizzi syndrome, Antoniou and colleagues (2010) recently conducted a comprehensive systematic review of the literature on this topic, a query confined to the English and German literature. Because of the strict study criteria, the authors identified only 10 of 66 articles for comparison in the years between 1989 and 2008. The total number of patients treated by laparoscopy was 124, of which 73 (59%) were sucessfully completeted. Conversion to open operation was necessary in 51 (41%) patients. Interestingly, patients from studies reporting a high preoperative diagnosis rate (>80%) had a significantly lower risk for conversion. The main reasons for conversion included technical failure as a result of dense adhesions in the triangle of Calot, unclear anatomy, and unsuccessful stone retrieval. The analysis showed a complication rate of 16%, with residual stones and bile duct injury the most common complications. The authors concluded, and we agree, that laparoscopic treatment of Mirizzi syndome cannot be recommended as a standard procedure because of the high failure rate (Antoniou et al, 2010).

Paul and others (1992) described successful laparoscopic treatment of Mirizzi syndrome by adhering to a luminal approach to the problem, as advocated by Dewar and associates (1991). This approach includes preoperative ERCP and placement of a biliary stent, followed by use of a flexible choledochoscope introduced into the cystic duct high from the open neck of the gallbladder. Stone extraction from the dilated cystic duct via the choledochoscope may avoid carrying the dissection too far down and injuring the common duct. Although such successful laparoscopic approaches to Mirizzi syndrome have been reported, we believe an open approach should be used when the diagnosis is made preoperatively, or a procedure should be converted to open when encountered during laparoscopy. Open technique affords the use of tactile senses, allowing easier removal of the impacted stone and sampling of the gallbladder wall to exclude a coexisting carcinoma (see Chapter 49); an open approach also minimizes the risk of bile duct injury.

Proximal Choledochoduodenal Fistulae Secondary to Peptic Ulcer Disease

Patients with proximal choledochoduodenal fistulae secondary to peptic ulcer disease may be asymptomatic, or they may present with GI complaints suggesting peptic ulcer (see Fig. 42B.1E). Biliary tract symptoms are usually absent, and these

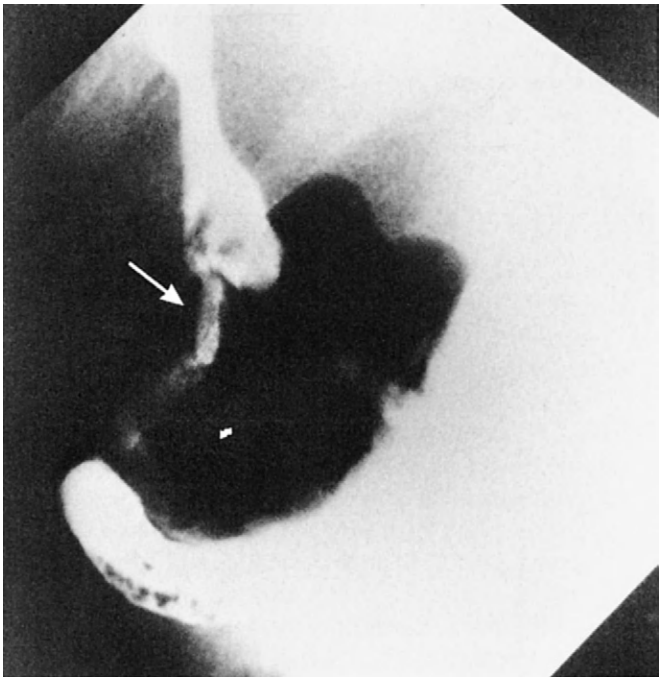

FIGURE 42B.10. Choledochoduodenal fistula secondary to gallstone disease shown by endoscopic retrograde cholangiopancreatography.

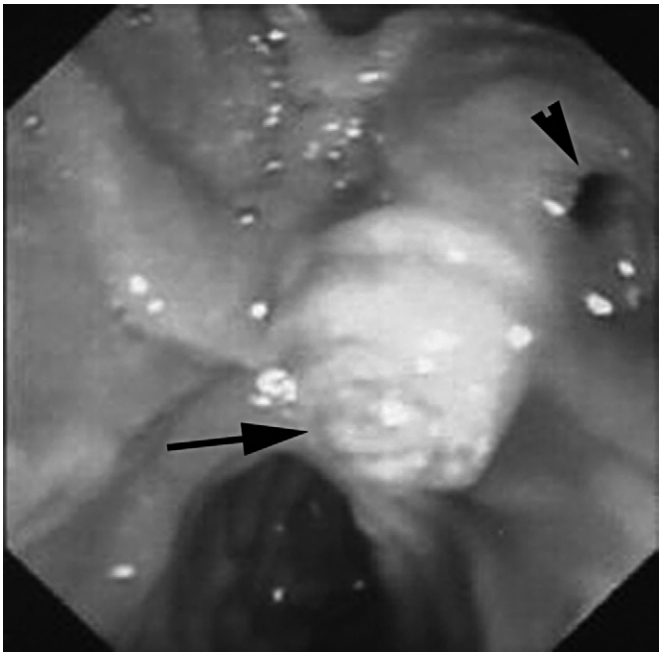

FIGURE 42B.11. Duodenoscopy showing the papilla of Vater (*arrow*) and a distal or peripapillary choledochoduodenal fistula (*arrowhead*). *(Courtesy Dr. Melih Karincaglu.)*

patients generally do not have associated cholelithiasis. In rare instances, cholangitis, jaundice, or abnormal LFTs are part of the clinical picture and indicate concomitant biliary tract infection and obstruction. The diagnosis may be suggested by pneumobilia in 15% to 60% of patients. More often, the diagnosis is made as contrast material from a barium meal refluxes up the common duct to outline a normal-sized, functioning gallbladder. Endoscopy with direct visualization of the ulcer and fistula and ERCP are the best studies to confirm the diagnosis and evaluate the extent of disease (Fig. 42B.10).

Given the paucity of reported experiences with choledochoduodenal fistula (Kourias & Chouliaras, 1964) and longstanding differences of opinion about the correct approach to peptic ulcer disease, it is not surprising that, until recently, treatment recommendations have been controversial. Excellent discussions of the natural history, clinical presentation, and management of these fistulae have been reported by Constant and Turcotte (1968), Feller and colleagues (1980), and Sarr and colleagues (1981). Most authors now agree that treatment should be directed at the ulcer diathesis and not at the biliary tract or the fistula itself. Medical management with proton-pump inhibitors and therapy for *Helicobacter pylori* is often sufficient to control the ulcer disease and even bring closure of the fistula.

More recent high success rates of medical management for peptic ulcer disease have resulted in a drastic reduction in the number of case reports of patients with proximal choledochoduodenal fistulae compared with years before 1990 (H'ng & Yim, 2003; Jaballah et al, 2001; Wong et al, 2004). Although choledochoduodenal fistula as a result of peptic ulcer is now extremely rare, clinicians should remain aware of this clinical entity, especially in symptomatic patients with refactory peptic ulcer disease. In such patients, surgery is indicated to prevent major complications such as hemorrhage and death (La Greca et al, 2008). Otherwise, surgery is not generally indicated for severe ulcer disease, except in the presence of uncontrollable hemorrhage, free perforation, obstruction, or intractability.

Many types of ulcer operations have been performed successfully; however, if technically possible, an exclusion type of gastric resection or duodenal bypass procedure, such as a Billroth II gastrectomy or gastroenterostomy, should be performed in addition to a vagotomy. There is no need to close the fistula, and doing so may injure the duodenum or bile duct. Cholecystectomy and biliary enteric reconstruction may be done, but these are reserved in cases of biliary stricture; such patients are younger and healthier than patients with biliary-enteric fistulae secondary to calculous biliary tract disease, and the results of medical and surgical treatment are usually good.

Distal Parapapillary Choledochoduodenal Fistula

Whether caused by spontaneous gallstone erosion or by iatrogenic damage to the distal common duct, parapapillary fistulae have a clinical presentation similar to that of other advanced calculous biliary tract diseases. In the series reported by Tanaka and Ikeda (1983), the following observations were made: a history of biliary symptoms longer than 10 years' duration in 46%; pain and/or jaundice in 88% and 69%, respectively; prior biliary surgery in 54%; air or barium in the biliary tree in 41%; cholelithiasis in 71%; and choledocholithiasis in 38%. The anatomic diagnosis rests on meticulous endoscopic observation and expertise in the technique of ERCP (Fig. 42B.11; see Fig. 42B.1F). In Japan, the incidence of primary intrahepatic stone disease is reported to be 17% to 30% (Tanaka & Ikeda, 1983; see Chapter 39). Particularly in Japanese patients with parapapillary fistulae, careful and complete evaluation of the intrahepatic ductal system is important.

The management of these biliary fistulae is still evolving, and a variety of endoscopic techniques have been advocated

(Osnes & Kahrs, 1977; Ramsey et al, 1992; Schapira & Khawaja, 1982; Urakami & Kishi, 1978; Van Linda & Rosson, 1984). These techniques involve using endoscopic sphincterotomy to widen the choledochal fistula enough to permit free drainage or to create a common channel between the fistula and natural ampullary orifice. When necessary, open surgical procedures, such as hepaticodochojejunostomy, have been used (Hunt & Blumgart, 1980).

Fistula to the Hepatic Veins or Portal Veins

Biliary-venous fistula is a rare occurrence that results in bilhemia, a condition that can be dangerous (see Chapter 105), and such a fistula can also be associated with interventional transhepatic maneuvers. When a large caliber intrahepatic bile duct is transected, the creation of a transjugular intrahepatic portosystemic stent-shunt (TIPSS) may be complicated by a biliary-venous fistula. The resulting biliary leak plays an important role in the stenosis and occlusion of the portosystemic shunt (Jalan et al, 1996).

EXTERNAL BILIARY FISTULAE

Most clinically significant external biliary fistulae follow some type of surgical procedure on or in the neighborhood of the biliary system. Causes of external biliary fistulae include invasive radiologic procedures, cholecystostomy, cholecystectomy (with or without common duct exploration), liver surgery or injury, intentionally created surgical biliary-intestinal anastomosis, and other abdominal operations. The persistent biliary drainage is the result of some unrecognized disease affecting the bile ducts, a complication of the surgical procedure, or, more importantly, the result of a surgical error. Bile duct injuries and fistulae are always significant, because they can be associated with considerable morbidity or mortality.

Etiology and Prevention

External biliary fistulae are best considered according to the type of previous intervention performed. The following are the more commonly associated surgical antecedents of fistulae.

Fistulae After Cholecystostomy

The first open cholecystotomy was done by Bobbs in 1867 (Sparkman, 1967), but open cholecystostomy is infrequently performed today. Historically, the procedure was used in high-risk patients with acute cholecystitis. In selected cases, cholecystostomy also was used as the first step of a two-stage operation for obstructive jaundice secondary to malignancy (see Chapter 62). Percutaneous cholecystostomy, a less invasive procedure that requires only local anesthesia, is currently the procedure of choice in high-risk elderly patients (Byrne et al, 2003; Ito et al, 2004; Winbladh et al, 2009). Percutaneous placement of a catheter into the lumen of the gallbladder can be performed and can even be done under US guidance at the bedside of critically ill patients (see Chapters 28 and 32). A persistent fistula denotes distal biliary obstruction (e.g., a retained gallstone lodged within a Hartmann pouch).

Biliary Fistulae After Invasive Radiologic Procedures

Biliary leak and fistulae may follow any invasive radiologic procedure involving the hepatobiliary system. Usually these are due to distal biliary tract obstruction, a result of either a retained bile duct stone or an unrecognized malignancy (Fig. 42B.12). Published rates for biliary leak after interventional radiologic procedures vary significantly and depend on patient selection and individual practitioner experience. Complications result from suboptimal puncture location, incorrect selection of biliary catheter size, and inadequate postprocedural tube care (Winick et al, 2001). Burke and colleagues (2003) classified bile leakage, sepsis, and infected biloma as major complications that occur at rates of 2% after PTC and biliary drainage procedures (see Fig. 42B.5). The risk of an internal fistula after radiologic intervention resulting in bilhemia was referred to earlier.

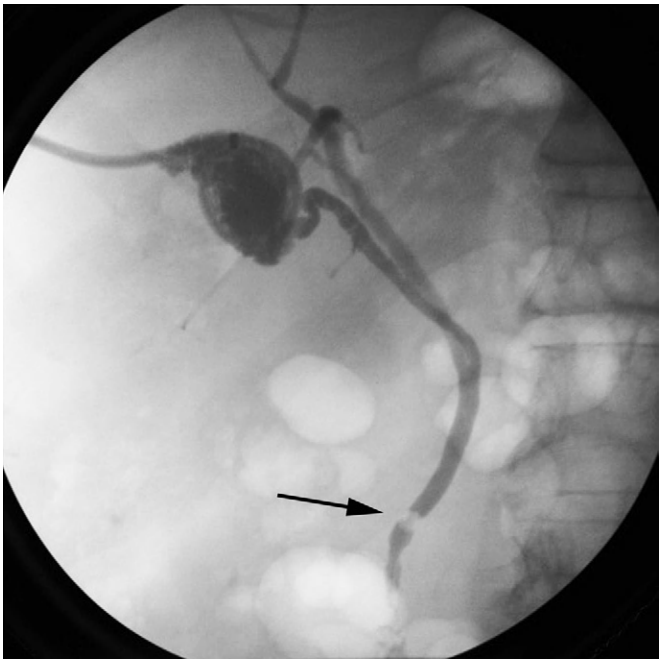

FIGURE 42B.12. An 85-year-old man with severe cardiomyopathy (unfit for surgery) was treated by percutaneous cholecystostomy tube drainage. Six weeks after tube insertion, a cholecystogram shows a retained gallstone impacted in the distal common bile duct (*arrow*). The patient was treated definitively by endoscopic retrograde cholangiopancreatography and papillotomy.

Fistulae After Abdominal Operations

LAPAROSCOPIC CHOLECYSTECTOMY. Laparoscopic cholecystectomy is currently the standard procedure for symptomatic cholelithiasis and for all forms of cholecystitis, including acute cholecystitis, and it is performed even in instances of gangrenous cholecystitis (Kiviluoto et al, 1998; Gharaibeh et al, 2002; Borzellino et al, 2008). However, laparoscopic cholecystectomy is associated with an increased incidence of bile duct injuries, including fistulae, which are reported in 1.3% to 5.5% of cases (see Chapter 34; Adamsen et al, 1997; Kum et al, 1996). Under these difficult circumstances, the procedure should be performed, or at least supervised, by an experienced surgeon. A high conversion rate of 40% in instances of gangrenous cholecystitis should be expected (Eldar et al, 1998; Gharaibeh et al, 2002; Borzellino et al, 2008).

As mentioned previously, the operative treatment of Mirizzi syndrome now includes a laparoscopic option. In accordance with others, however, we believe that when the presence of Mirizzi syndrome, particularly type 2, is suspected or realized,

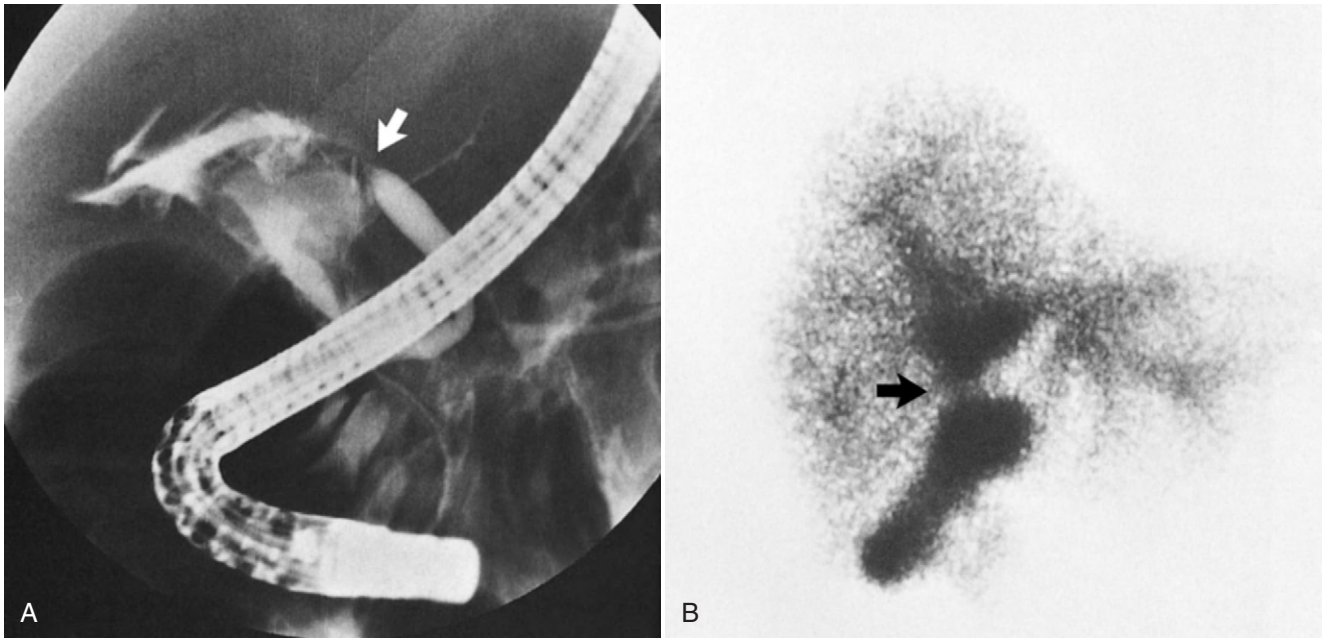

FIGURE 42B.13. Injury to the bile duct at laparoscopic cholecystectomy. The common bile duct was misidentified for the cystic duct, resulting in transection of the common bile duct between the clips. **A,** Endoscopic retrograde cholangiopancreatography shows a transected bile duct at the level of a clip (*arrow*) with extravasation of contrast material. **B,** Hepatobiliary iminodiacetic acid scan shows a total uncontrolled fistula originating from the proximal cut end of the choledochus (*arrow*).

safety demands that the laparoscopic procedure be converted to open laparotomy (Moser et al, 1993; Yeh et al, 2003; Antoniou et al, 2010).

Small amounts of bile leakage may occur occasionally in the immediate postoperative period after inadvertent damage to a subvesical duct (Viikari, 1960), which is present in normal subjects in 20% to 50% of cases (Kune & Sali, 1980). Removal of an intrahepatic gallbladder also may cause damage to tiny bile ducts in the liver around the gallbladder fossa.

Biliary fistula after laparoscopic cholecystectomy may occur as a result of injury to the extrahepatic biliary tree, or it may originate from the cystic duct stump. A leak from the cystic duct stump may occur from burn injury, from pressure necrosis of a metal clip, or in most instances from distal bile duct obstruction caused by a retained stone, resulting in a buildup of pressure and a resultant blowout of the cystic stump. It is important to differentiate patients at risk of having choledocholithiasis. Patients having deranged LFTs or dilated bile ducts on US should undergo imaging of the biliary tree before cholecystectomy. Sphincterotomy and stone extraction should be performed if choledocholithiasis is established.

Most ductal injuries are not recognized during the initial laparoscopic cholecystectomy (Lillemoe et al, 1997) or in the immediate postoperative period, mainly because drains usually are not left in the abdomen, and the patient typically leaves the hospital within 24 hours. The resulting uncontrolled biliary fistula becomes evident within days or sometimes weeks after the operation, with the clinical presentation of abdominal pain, fever, jaundice, and the demonstration of an intraabdominal fluid collection that produces bile on puncture.

Compared with open cholecystectomy, laparoscopic cholecystectomy is associated with an increased rate of bile duct injury (see Chapter 42A; Davidoff et al, 1992; Waage & Nilsson, 2006). Such injuries are common to most reported series of laparoscopic cholecystectomy and may reach an incidence of 0.9%. Reviews by Strasberg and colleagues (2001) and Vecchio and colleagues (1998) that encompass more than 100,000 patients found the incidence of major bile duct injury to be around 0.5%, and this incidence has reached a "steady state" (Walsh et al, 1998; Wherry et al, 1996; Waage & Nilsson, 2006). A large retrospective cohort analysis of nearly 1.6 million Medicare patients in the United States undergoing laparoscopic cholecystectomy from 1992 through 1999 confirmed the incidence rate of bile duct injury at 0.5% (Flum et al, 2003), and a Swedish population-based study of more than 150,000 patients showed a similar bile duct injury rate of 0.4% (Waage & Nilsson, 2006).

The mechanisms resulting in bile duct injuries are now well recognized (see Chapter 42A). The most common injury is caused by misidentification of the common duct for the cystic duct, resulting in complete transection of the common duct, often with some portion of the biliary tree (Fig. 42B.13). A traction injury results from inadvertent lateral traction of the gallbladder and "tenting" of the cystic duct–common duct junction. In this instance, the clip intended for the cystic duct may occlude the CBD, or a portion of the CBD may be removed between clips. An unrecognized anomalous biliary system—in particular, a cystic duct that empties directly into the right hepatic duct or a low-entry right hepatic sectoral duct—may result in similar damage (Fig. 42B.14; see Chapters 1B and 42A; Davidoff et al, 1992; Lillemoe et al, 1997). Other, less common mechanisms include thermal injury resulting from excessive use of the cautery or laser and the application of excessive clips to control bleeding in the triangle of Calot.

The role of operative cholangiography (see Chapter 21) in the prevention of bile duct injuries remains controversial despite two large, population-based studies demonstrating a protective effect (Flum et al, 2003; Waage & Nilsson, 2006).

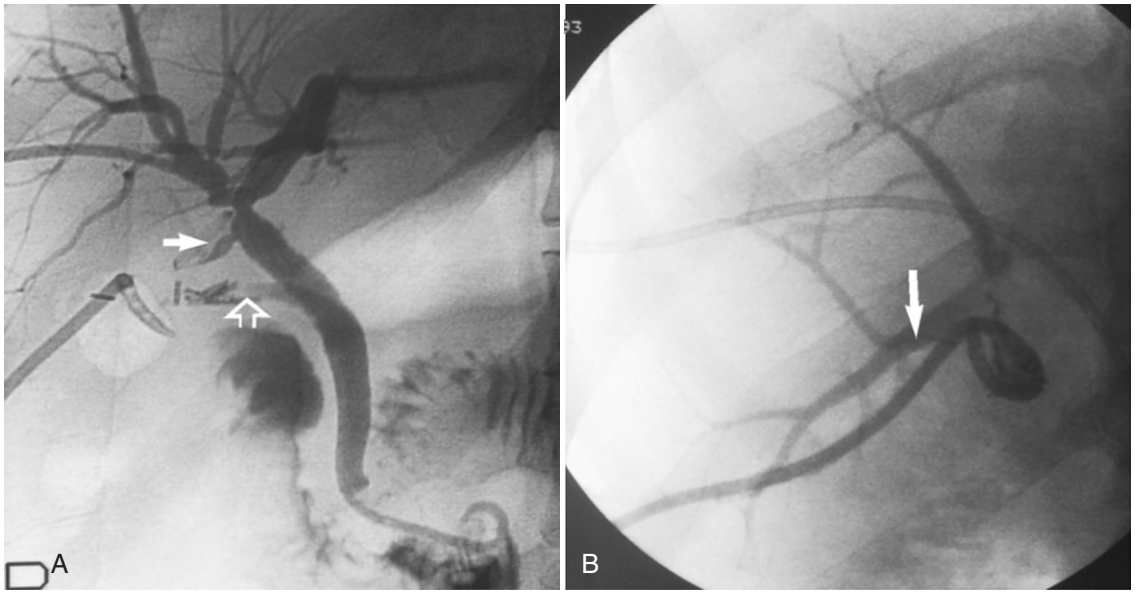

FIGURE 42B.14. Injury to a right sectoral hepatic duct at laparoscopic cholecystectomy. **A,** Percutaneous transluminal cholangiography. Note the remnant of the duct draining into the common bile duct (*solid arrow*) and cystic stump (*open arrow*). Note the low entry of this duct into the common bile duct. **B,** Tube fistulography. The biliary ductal system of the cut sectoral duct is outlined.

Intraoperative cholangiography (IOC) may supply information regarding the presence of unsuspected choledocholithiasis and unexpected anomalous anatomy, and its routine use is recommended by several authors (Fletcher et al, 1999; Flum et al, 2003; Kohn et al, 2004; Stuart et al, 1998; Waage & Nilsson, 2006). The use of IOC has not increased; in reports of laparoscopic cholecystectomy in the United States, IOC was performed in about 40% of cases (Flum et al, 2003; MacFadyen et al, 1998). In a population-based study by Flum and colleagues (2003), the rate of bile duct injury was found to be significantly higher when IOC was not used (0.39% vs. 0.58%). The more recent study by Waage and Nilsson (2006) showed that IOC reduced the risk of bile duct injury by 37%.

Before these reports, evidence that IOC prevented major bile duct injury did not exist (Wright & Wellwood, 1998). In a national survey of American surgeons performing laparoscopic cholecystectomy, Archer and colleagues (2001) found that IOC was helpful for intraoperative detection of bile duct injury. Interestingly, of the 1600 surgeons surveyed in the United States, one third had experienced this complication. A single institutional study by Kohn and associates (2004) examined the use of routine versus selective cholangiography among surgeons performing laparoscopic cholecystectomy. This study found that surgeons performing selective cholangiography were less likely to attempt IOC, even if indications arose resulting in significantly worse adverse events. Regardless of surgeon preference for routine or selective IOC, we recommend a low threshold for early conversion to laparotomy, if the ductal anatomy remains unclear or for any other concern. IOC remains the gold standard to define biliary anatomy, but it cannot prevent all bile duct injuries; and in some rare cases, it may even be the cause.

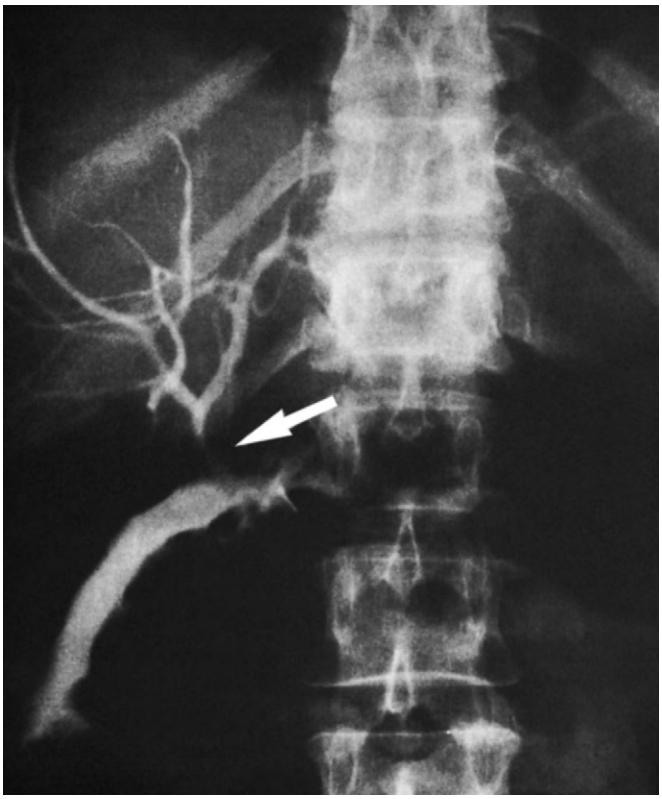

FIGURE 42B.15. Postcholecystectomy fistulography. Biliary fistula caused by accidental transection of the common hepatic duct (*arrow*), the most common cause of a persistent external biliary fistula.

OPEN CHOLECYSTECTOMY. The occurrence of unexpected biliary fistulae after cholecystectomy almost always indicates operative injury to a major bile duct. Such fistulae may arise from damage to the CBD (Fig. 42B.15) or to an anomalous sectoral right hepatic duct (see Chapter 42A). A 0.21% incidence of bile duct injuries was found in a study of 42,474 patients who underwent an open cholecystectomy (Roslyn et al, 1993). Bile duct injury is recognized at the time of cholecystectomy in only a few patients; in approximately 25% to 40% of

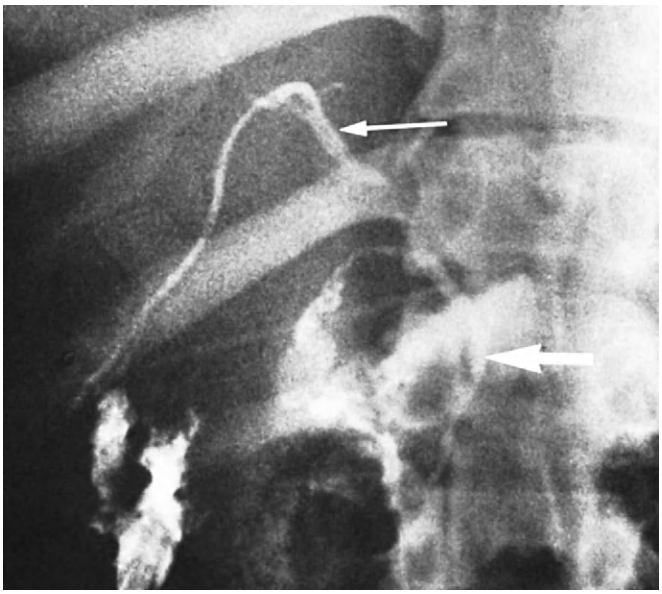

FIGURE 42B.16. Postcholecystectomy fistulography outlining large irregular cavity (*thick arrow*) and connecting with a faintly outlined, but apparently normal, biliary ductal system (*thin arrow*).

patients with unrecognized bile duct injury, the injury becomes apparent only when the presence of a biliary fistula is recognized (Andren-Sandberg et al, 1985a, 1985b). In the remaining patients, the injury is recognized only later, when a biliary stricture develops (Blumgart et al, 1984). The recognition of biliary ductal anomalies and prevention of biliary injury at cholecystectomy are discussed in detail in Chapters 1B and 42A. Inadequately ligated or sloughed ligatures on the cystic duct are rarely responsible for biliary fistulae, and for this reason, transfixion suturing of the cystic stump is recommended. However, the presence of an unrecognized significant distal obstruction may be followed by a blowout of the cystic duct stump, resulting in a biliary fistula or bile peritonitis.

Cholecystectomy is sometimes performed under difficult circumstances, as in the presence of a gangrenous gallbladder associated with fibrosis and inflammation in the region of the triangle of Calot. In these instances, proper identification and transfixion of the cystic stump may not be possible, and the patient is left with a temporary biliary fistula (Fig. 42B.16). As described previously, type 2 Mirizzi syndrome may pose significant technical difficulties, and specific surgical techniques have been devised to deal with this situation (Baer et al, 1990).

If a defect in the bile duct is found during operation, and if immediate repair is impossible, it may be better to end the procedure with adequate drainage, expecting a future controlled fistula. In all these difficult instances in which a biliary fistula is anticipated, it is important to ensure controlled and adequate drainage of bile and to exclude the presence of a distal obstruction to biliary-enteric bile flow. Under these circumstances, most fistulae close spontaneously after conservative treatment.

COMMON DUCT EXPLORATION. The classic open common duct exploration is now less frequently performed, having been replaced by laparoscopic and endoscopic techniques (see Chapter 35; Csendes et al, 1998). Whether it occurs after open or laparoscopic exploration of the CBD or persists after removal of a T-tube, a biliary fistula is almost always due to a residual

FIGURE 42B.17. Postcholecystectomy T-tube cholangiography shows a retained stone obstructing the distal bile duct (*arrow*). The stone was removed 6 weeks after surgery via instrumental basket extraction through the T-tube tract, preventing a persistent external biliary fistula.

common duct gallstone (Fig. 42B.17). It is essential to perform cholangiography and rule out the presence of retained stones before removal of a T-tube or biliary stent.

Less commonly, an overlooked malignant distal obstruction is the causative factor (Fig. 42B.18). In addition, the passage of metal bougies through the papilla during common duct exploration may result in the creation of false tract, which may result in a choledochoduodenal fistula and may cause jaundice, ascending cholangitis, and acute or chronic recurrent pancreatitis. Treatment may be by endoscopic papillotomy or sphincterotomy, joining the fistulous orifice with the papillary opening (Chung & Roberts-Thomson, 2000; Jorge et al, 1991; Karincaoglu et al, 2003b), but a surgical approach may be necessary (Hunt & Blumgart, 1980).

BILIARY-INTESTINAL ANASTOMOSIS. A major biliary fistula after biliary-intestinal anastomosis occasionally occurs, although this is uncommon. Anastomoses created well below the hilus, such as choledochoduodenostomy or choledochojejunostomy, are rarely associated with fistulae (Parrilla et al, 1991), whereas a biliary fistula after hepaticojejunostomy is more common, with a reported incidence of 0.4% to 8% (de Castro et al, 2005). When fistulae do occur, a technical error must be suspected, such as suture line disruption or failure to incorporate a significant bile duct within the anastomosis. Failure of the surgeon to appreciate ductal anatomy is particularly likely to occur in the hilar region, where the mode of confluence of the right and left ducts and caudate lobe ducts is extremely variable (see Chapter 1B). In these instances, the fistula becomes evident immediately after surgery. Meticulous technique with

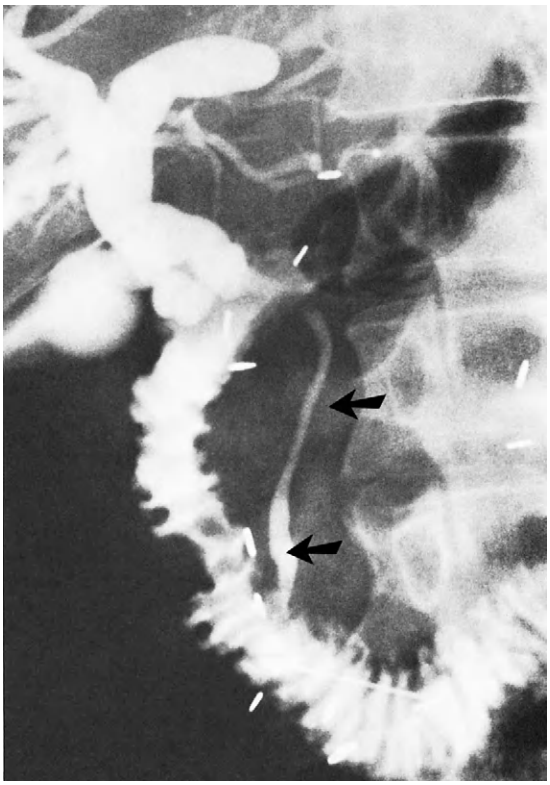

FIGURE 42B.18. Postcholecystectomy fistulography shows the external biliary fistula, which was caused by an extrinsic compression of the pancreatic portion of the bile duct (*arrows*). At reoperation, choledochal compression was shown to be due to cancer of the head of the pancreas.

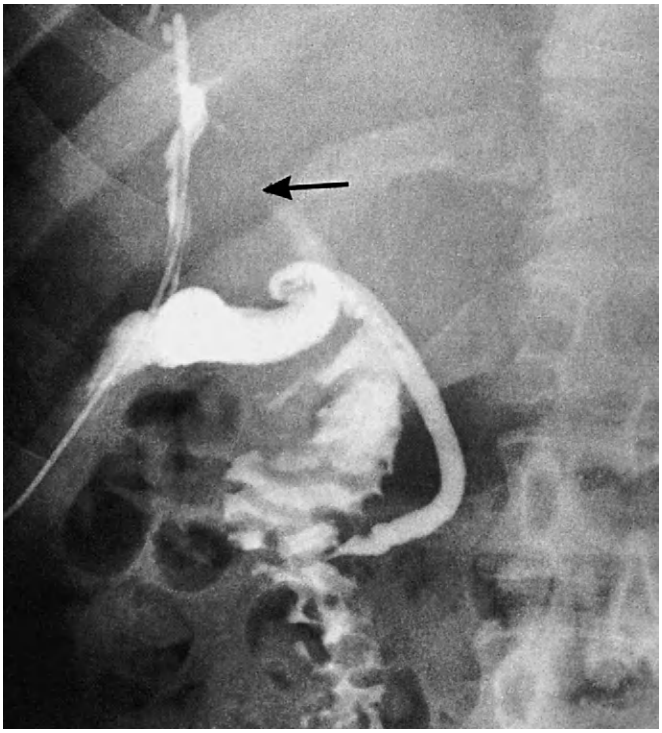

FIGURE 42B.19. External biliary fistula after blunt injury to the right lobe of the liver and subsequent drainage of a large right intrahepatic hematoma. The injury was associated with damage to the right hepatic duct and a subsequent intrahepatic stricture (*arrow*). After external drainage, a high-output biliary fistula developed. The tubogram illustrated was obtained after anastomosis of the fistulous tract issuing from the liver to the adjacent mobilized gallbladder. The cavity within the liver has collapsed, and the gallbladder fills and subsequently outlines the common bile duct. The tube was removed, and postoperative recovery was uneventful. The patient remained symptom free and with normal liver function test results 5 years after surgery. *(From Smith EE, et al, 1982: The management of post-traumatic intrahepatic cutaneous biliary fistulas. Br J Surg 69:317-318.)*

mucosa-to-mucosa anastomosis (see Chapter 29) prevents most such leaks. Alternatively, suture line disruption also may be caused by local factors, such as abscess or ischemic necrosis of the bile duct or bowel wall, and such fistulae may become evident days after surgery. It is important to ascertain whether the fistula is purely biliary or whether it also contains duodenal or pancreatic juice or both.

Fistula After Liver Injury, Liver Resection, and Liver Transplantation

LIVER INJURY. Liver injury (see Chapter 102) may be followed by the formation of biliary fistulae. Such fistulae may occur in association with damage to the liver (Fig. 42B.19) and the bile ducts or may follow sequestration and infection of areas of liver necrosis. Blunt or penetrating grade III or IV liver trauma may be complicated by bile collections and biliary fistulae in 0.5% to 14% of patients (Glaser et al, 1994; Goldman et al, 2003; Gourgiotis et al, 2007; Shahrudin & Noori, 1997; Vassiliu et al, 2004; Wahl et al, 2005). Emergency partial hepatectomy for major liver trauma may result in injury to the bile ducts at the confluence with an early biliary leak and, later, a biliary stricture (Bismuth et al, 1986). Complete transection of the CBD requires immediate hepaticojejunostomy, whereas lacerations of the main biliary channel may be sutured after placement of a T-tube.

Although nonoperative management of blunt liver injury is now firmly established as standard therapy for hemodynamically stable patients (Malhotra et al, 2000; Pachter & Hofstetter, 1995; Christmas et al, 2005), caution should be exercised, because this approach can be hazardous sometimes and demands close observation to avoid delayed surgical treatment of potentially fatal complications (Goldman et al, 2003). Most posttraumatic biliary fistulae can be expected to heal spontaneously (Vassiliu et al, 2004); however, in a case series of 32 patients treated nonoperatively, Carrillo and colleagues (1999) found severe biliary complications in up to 85% of patients with a liver abbreviated injury score (AIS) of grade IV or higher. A study specifically examining the diagnosis and management of bile leaks after liver injury by Wahl and colleagues (2005) confirmed that patients with liver injuries higher than grade IV are more likely to develop bile leaks, especially if treated by arterial embolization. These authors proposed a treatment algorithm for blunt liver injury associated with a bile leak, which includes laparoscopic washout for a diffuse leak. Laparoscopic evacuation and lavage as a new treatment option for bile collections has also been advocated by others to prevent the inflammatory sequelae of bile peritonitis (Franklin et al, 2007). Persistent biliary fistulae may occur from a segment of the liver isolated by the injury. Management of this situation is difficult, particularly when the fistula is associated with a distal stricture. Rarely, the fistula can be identified at operation and oversewn. Alternatively, a well-developed fibrous fistulous tract

FIGURE 42B.20. may be anastomosed to a jejunal loop or to the gallbladder (see Fig. 42B.19; Smith et al, 1982).

Biliovenous fistula with subsequent leakage of bile into the venous system (bilhemia) is a rare but serious complication of liver trauma. After the formation of a necrotic cavity within the liver, an open connection between a vein and an intrahepatic bile duct may occur, allowing bile to leak into the venous circulation (see Chapter 105; Haberlik et al, 1992). Rarely, transjugular intrahepatic portosystemic shunting (TIPS; see Chapter 76E) has been reported to be a direct cause of bilihemia (Jawaid et al, 2003; Singh et al, 2007; Singal et al, 2009).

LIVER RESECTION. The incidence of bile leak after hepatic resection ranges from 1.7% to 12% in large series (Lo et al, 1998; Capussotti et al, 2006; Nagano et al, 2003; Vigano et al, 2008; Tanaka et al, 2002; Yamashita et al, 2001; see Chapters 25 and 90). In most patients, bile leak resolves spontaneously, but sometimes a persistent fistula requires reoperation (Honore et al, 2009). Liver resection done for tumor (see Chapter 90) may be followed by biliary fistula, which may result from inadequate ligation of the bile ducts at the cut liver surface (Thompson et al, 1983) or from failure to secure the bile ducts at the hilus (Fig. 42B.20). This failure is more likely after right hepatectomy, in which the anatomy of the right sectoral ducts is variable in the hilar region. Extended left hepatic lobectomy also has been associated with a high incidence of biliary fistula (see Chapter 90; Starzl et al, 1982). In Japan, Yamashita and colleagues (2001) reported a biliary fistula rate of 4% (31 of 781) after hepatic resection. Their analysis identified operative procedures exposing the major Glisson capsule and including the hilum—anterior sectorectomy, central hepatectomy, and caudate resections—to be high-risk operations for development of postoperative bile leakage. Other factors that may contribute to a persistent bile fistula may include underlying cirrhosis or chronic hepatitis that impair wound healing (Tanaka et al, 2002). Once a posthepatecomy biliary fistula is established, if the drainage output exceeds 100 mL per day 10 days after diagnosis, interventional or endoscopic procedures should be considered to promote definitive closure (Vigano et al, 2008).

Operative injury to the biliary tract that is likely to result in fistula is more common after resection of lesions involving or close to the hilar structures (Fig. 42B.21). It also is more likely to occur after resection of lesions involving the caudate lobe ducts, because the anatomy of these ducts is significantly

FIGURE 42B.21. Fistulography obtained via a tube drain shows a biliary fistula after extended left hepatic lobectomy for primary hepatocellular cancer. The tumor was large and involved the hilar ducts; tumor extension was shown within the left hepatic duct. The fistula was managed conservatively, and it closed within 4 weeks. *Arrows* indicate the fistula and the course of the right hepatic duct and common bile duct.

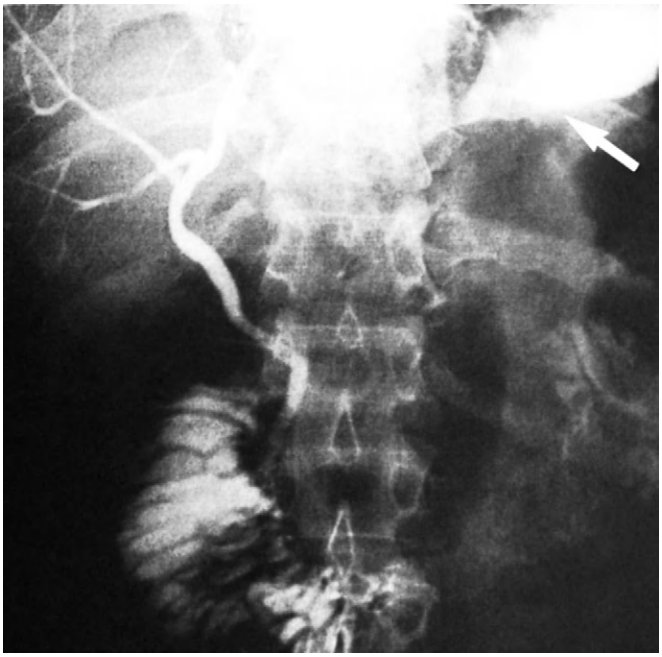

FIGURE 42B.22. Persistent external biliary fistula after external drainage of a hydatid cyst cavity (*arrow*) in the left lobe of the liver. Fistulography shows clear communication between the cyst cavity and the left hepatic duct.

variable in the hilar region. Using major hepatic resection, resection of cholangiocarcinoma combined with biliary-enteric reconstruction may be complicated by a biliary fistula originating from the caudate lobe ducts or from the biliary-enteric anastomosis (see Chapter 90). Hepatic cryotherapy (see Chapter 85B), which may be used at the cut liver surface after hepatectomy or for ablation of deep intrahepatic lesions, may also be complicated by biliary fistula (Sarantou et al, 1998). It may be prudent to leave a drain in situ after this procedure.

LIVER TRANSPLANTATION. Biliary leaks and fistulae are a continuing source of morbidity and mortality after liver transplantation. Pathogenesis usually is related to technical and vascular considerations and, in particular, to hepatic artery thrombosis (see Chapter 100).

GASTRECTOMY. Injury to the bile duct may occur during gastrectomy, particularly when the pyloric region or the first part of the duodenum is grossly distorted and inflamed (Florence et al, 1981). Such an injury becomes apparent either as a biliary fistula or at a later stage with the development of a stricture (see Chapter 42A).

SURGERY FOR HYDATID DISEASE. Surgery is an important treatment option for patients with hydatid disease (Dziri et al, 2004). Operative options include pericystectomy and hepatic resection or simply unroofing of the cyst and treatment of the residual cavity. Patients treated by these methods are prone to all the known complications associated with liver resection. Hydatid disease of the liver (see Chapter 68) is associated with biliary involvement by the disease in approximately 10% of instances (Erguney et al, 1991). An expanding liver cyst results in compression and stretching of adjacent liver tissue, including the bile ducts. It may erode into a stretched bile duct, with the establishment of continuity between the cyst cavity and the biliary system. Hydatid material may enter into the biliary tree, or bile may leak into the cyst. As with other hepatobiliary conditions, a laparoscopic surgical management option for hepatic hydatid disease has been introduced, but it is limited to those few centers where the disease is endemic (Duttaroy et al, 2008; Palanivelu et al, 2006; Sharma et al, 2009).

Biliary fistula may develop after operation for hydatid disease in certain situations. First, a communication between the cyst cavity and the biliary system is missed at operation and is not directly secured (Fig. 42B.22). It is prudent to drain all cyst cavities, particularly those of multiloculated hydatid cysts, to ensure that if a biliary fistula were to develop, it would be controlled. Unless a distal obstruction is present, these fistulae usually close spontaneously. Second, and rarely, the presence of hydatid material within the biliary tract produces biliary ductal obstruction (Fig. 42B.23) that results in a persistent biliary fistula that is relieved only when the hydatid material passes or is removed. Removal is achieved by exploration of the CBD with or without a bypass procedure (Ozmen et al, 1992) or by endoscopic methods (Iscan & Duren, 1991).

Assessment of the biliary tree, preferably by endoscopic cholangiography, should be performed before surgery in patients with a history of jaundice or cholangitis or in the presence of a large cyst located centrally and abutting the hilar structures. Kayaalp and colleagues (2003) in a series of 113

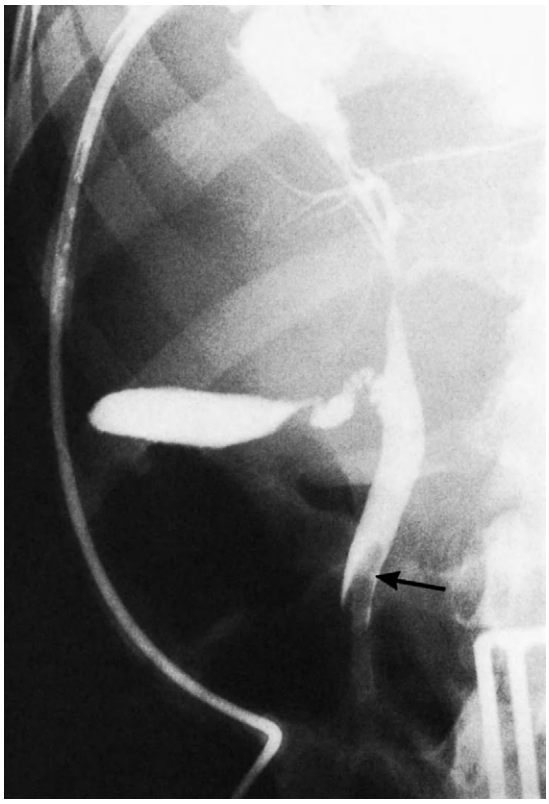

FIGURE 42B.23. Fistulography obtained after excision of a right hepatic hydatid cyst. Note the persistent fistula as a consequence of retained hydatid material in the common bile duct (*arrow*). Treatment was by exploration of the common bile duct and surgical removal of the retained hydatid material. The fistula rapidly closed.

patients showed that the location of the hydatid cyst near the hilum is a risk factor for the development of a cystobiliary communication and cavity-related complications. When a cystobiliary communication is shown, the biliary system should be cleared of all debris and cyst remnants, and endoscopic sphincterotomy should be performed before surgical intervention (Kornaros & Aboul-Nour, 1996). Percutaneous treatment of hydatid cysts is associated with a 10% incidence of biliary fistula (Men et al, 1999). Such fistulae usually close spontaneously after any biliary distal obstruction is relieved.

Clinical Presentation

The clinical presentation of a biliary fistula may be of an excessive, abnormal biliary drainage from the drain site or wound or, alternatively, of a localized or generalized peritonitis resulting from an intraabdominal collection of bile. After a diagnosis of biliary fistula has been established, it is most important to assess clinically the adequacy of bile drainage. In controlled fistulae, external biliary drainage is adequate, with no signs of localized or generalized peritonitis, and the adverse pathophysiologic features associated with cholestasis are not present.

In uncontrolled biliary fistula, biliary drainage is inadequate, resulting in an intraabdominal bilious collection. Because the bile is usually or soon becomes infected, the presentation is mostly of a subphrenic or subhepatic abscess or generalized peritonitis. The situation may be complicated further by cholangitis with or without intrahepatic abscess and septicemia that demands urgent treatment. In some patients with sterile bile, huge volumes may accumulate within the peritoneal cavity with minimal clinical findings apart from a distended abdomen (Fig. 42B.24). A high index of suspicion is important, because minimal abdominal symptoms and slightly deranged LFTs may be the only indicators of biliary damage. The presence of skin excoriation and digestion implies that activated digestive enzymes are present in the fistula effluent, because bile alone contains no digestive enzymes.

Pathologic Consequences of External Biliary Fistulae

The important pathophysiologic effects of an external biliary fistula depend on the volume of bile drained daily, the length of time the fistula has been present, and the degree to which bile is diverted from the GI tract. Consequences of biliary fistulae are mainly due to depletion of electrolytes and fluid, to the absence

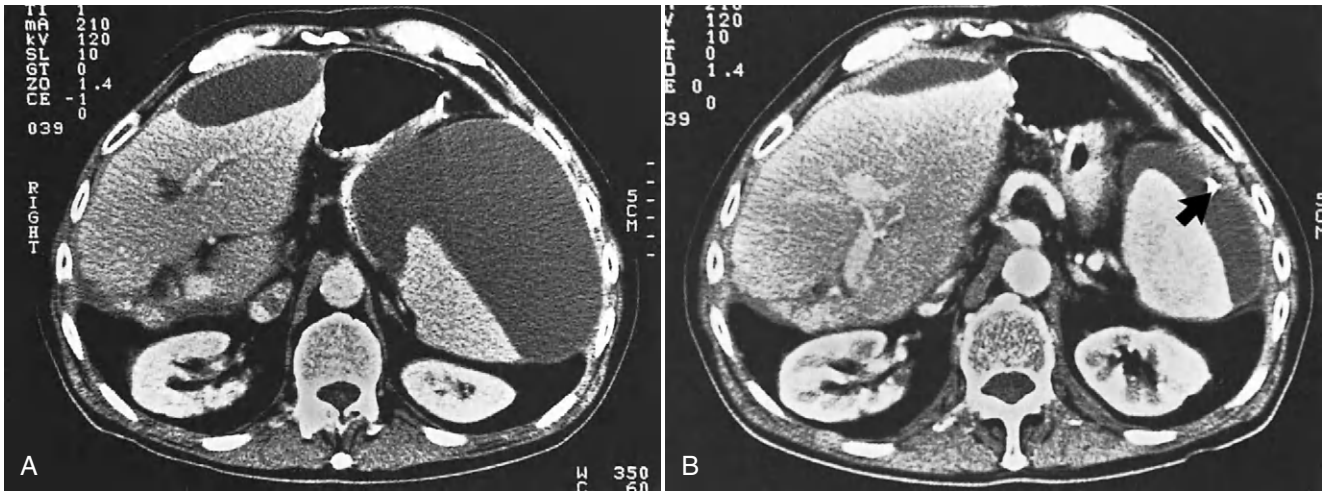

FIGURE 42B.24. **A,** Huge, asymptomatic biloma 3 weeks after partial hepatectomy for hepatocellular cancer. The patient reported abdominal distension only. **B,** Computed tomographic–guided puncture and drainage (*arrow*) converted the uncontrolled fistula into a controlled one. The fistula closed spontaneously after 17 days.

of bile from the gut, and to the possibility of ascending, exogenously acquired biliary infection. The important practical considerations are that the volume of bile secreted daily by the liver is on the order of 1000 mL, and the electrolyte composition of bile is equal to that of blood.

Total biliary loss for short periods (≤3 weeks) may not result in a serious depletion of electrolytes and fluid, because the body is able to compensate for this loss. Long-term total external biliary fistula results in fluid and electrolyte disturbances if replacement therapy is not instituted. Sodium loss is usually greater than chloride loss, leading to metabolic acidosis (Cass et al, 1955). The serum potassium level is initially lowered, but the accompanying fluid loss may lead to a decrease in plasma volume, low-output renal failure, and hyperkalemia (Knochel et al, 1962). Absence of bile from the GI tract causes interference in the absorption of fat-soluble vitamins A, D, and K. Vitamin A and D deficiencies are associated with long-term total biliary fistula and are rarely seen today, whereas vitamin K deficiency is evident earlier and can be easily diagnosed by a prolonged PT. Other adverse effects of total biliary loss are disruption of intestinal barrier function and bacterial translocation (Slocum et al, 1992). These findings are supported by an observation that bile replacement restored intestinal barrier function in patients with malignant obstruction undergoing external biliary drainage (Kamiya et al, 2004). Even in the short term, patients with an external biliary fistula feel unwell, weak, and lethargic. In advanced and neglected cases, caloric and protein malnutrition results in gradual weight loss, whereas the electrolyte changes may result in stupor and vasomotor collapse.

Diagnostic Procedures and Initial Treatment

The presence of a biliary fistula may first become apparent at reoperation. More commonly, and particularly after laparoscopic cholecystectomy, the biliary fistula becomes apparent at ERCP or after percutaneous drainage of a perihepatic collection. Reoperation is usually required for peritonitis or for drainage of an intraabdominal collection that is not amenable to percutaneous treatment. Such collections may be a complication from a previous surgery on the hepatobiliary system, the pancreas, or, rarely, the stomach or duodenum. Rarely, they may follow a spontaneously occurring pathologic process, such as hemorrhagic pancreatitis or rupture of a liver cyst. When the presence of an uncontrolled biliary fistula has been realized, initial management demands conversion of the fistula into a controlled one, usually by means of tube drainage. No attempt at definitive repair should be made at this early stage, because the involved bile ducts are collapsed, friable, and usually embedded within a severe local inflammatory reaction; it is virtually impossible to expose healthy bile ducts for any form of long-lasting definitive repair, and any attempt to do so is bound to fail and renders further operation more difficult (see Chapter 42A; Czerniak et al, 1988).

The early demonstration of an uncontrolled biliary fistula within 24 to 48 hours of laparoscopic cholecystectomy together with a transected or completely occluded CBD is an indication for early surgical intervention. A decision regarding definitive repair is based on operative findings. Rarely, removal of a misplaced clip intended for the cystic duct stump that has caused complete obstruction of the CBD is all that is necessary.

Alternatively, percutaneous CT- or US-guided drainage of a subphrenic or infrahepatic fluid collection may be followed by the establishment of an external biliary fistula. It is important to ensure adequate drainage and to see that the fistula is well controlled. Biliary drainage is ideally carried out using a sealed drainage-bag system (Blenkharn et al, 1981). Drainage initially should be done using a low-pressure, closed-suction system, which is valuable in reducing the cavity of the intraabdominal bile collection or in reducing the abscess of a fistula tract. Improvement of the clinical picture and repeated US or CT studies eventually should show proper positioning of the drain and reveal no residual collection or abscess. HIDA scintigraphy (see Chapter 15) and tubography are helpful in this respect (see Fig. 42B.18).

After the fistula is controlled, conservative treatment is instituted, the patient is nourished, deficits of electrolytes and vitamins (mostly vitamin K) are corrected, and infection is treated. It is important to know whether the biliary fistula contains bile only or whether it also contains duodenal, pancreatic, or intestinal juice; when the latter is present, appropriate measures to protect the skin should be taken. Parenteral nutrition is an essential element in the management of significant duodenal and pancreatic fistulae, in which total prohibition of oral intake is important to allow healing to occur. It has been shown that treatment with somatostatin can reduce bile secretion significantly (Nyberg, 1990; Sahin et al, 1999), and somatostatin has been used successfully in the management of pancreatic and small intestine fistulae (Draus et al, 2006); it may also be valuable in the management of combined biliary-pancreatic-duodenal fistulae. However, the benefit of somatostatin therapy in promoting closure of biliary fistulae arising entirely from the biliary tree remains unproven (Hesse et al, 2002). We are aware of three case reports that describe successful use of octreotide, a somatostatin analogue, in the treatment of bronchobiliary fistulae (Ong et al, 2004; Petrolati et al, 2009; Singh et al, 2002).

After the establishment of a controlled fistula, various radiologic investigations are performed with the aim of assessing the 1) origin of the fistula, 2) presence and extent of an injury to the extrahepatic biliary system, 3) adequacy of drainage, and 4) presence of biliary-enteric bile flow. The anatomy of the entire intrahepatic and extrahepatic biliary tree should be shown, and this is achieved by a variety of radiologic studies. All contrast examinations should be covered with antibiotic prophylaxis to minimize the risk of bacteremic episode.

Tube cholangiography should be performed routinely before removal of cholecystostomy or choledochostomy tubes or tube drainage across biliary-enteric anastomoses. Whenever an obstruction to free biliary-enteric bile flow is present, it should be treated. Removal of a tube in the presence of a distal stricture or a retained bile duct stone invariably results in a persistent biliary fistula.

Fistulography is a simple and effective means of determining whether biliary drainage is adequate and whether a fistulous cavity has converted to a fistulous tract. The site and underlying cause of the biliary fistula often can be clearly shown by fistulography (Fig. 42B.25; see Figs. 42B.13, 42B.14, 42B.19, 42B.21, and 42B.23). PTC is used when the findings of fistulography are equivocal, and the intrahepatic biliary tract, the right system in particular, is not fully shown. Iatrogenic damage to a right sectoral hepatic duct is an example of this problem, and PTC is the only diagnostic modality to yield accurate definition.

ERCP is a useful diagnostic and therapeutic tool where there is a continuity of the extrahepatic biliary system (Davids et al,

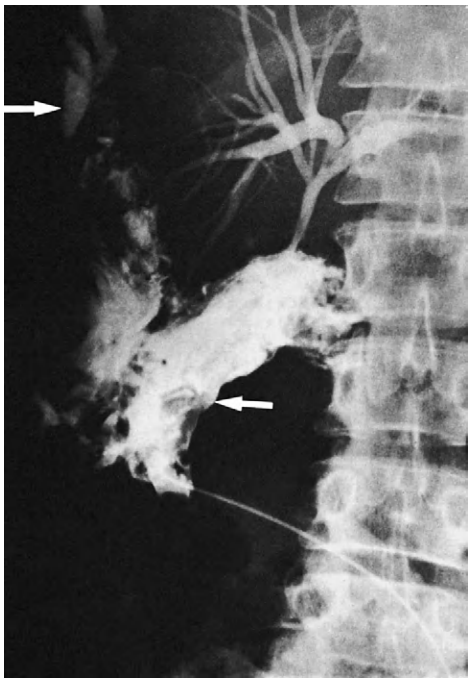

FIGURE 42B.25. Fistulography in a patient with neglected postcholecystectomy biliary fistula caused by accidental transection of the common hepatic duct with associated subphrenic (*top arrow*) and subhepatic (*bottom arrow*) collections of infected bile.

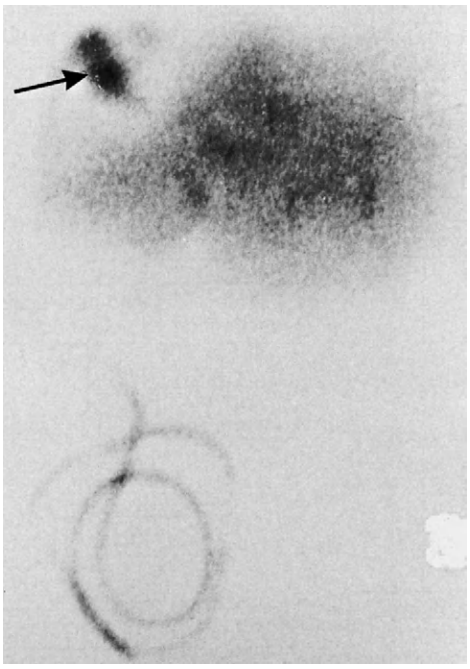

FIGURE 42B.26. Hepatobiliary iminodiacetic acid scan showing a fistula issuing from the liver surface (*arrow*). This is the same patient as is Figure 42B.23. The drainage tube also is shown. *(From McPherson GA, et al, 1984: The role of HIDA scanning in the assessment of external biliary fistulae. Surg Gastroenterol 3:77-80.)*

1992), particularly after laparoscopic cholecystectomy (Agarwal et al, 2006) and after liver transplantation (Sherman et al, 1993). The value of ERCP is limited in fistulae arising at the hilus of the liver and resulting from iatrogenic bile duct injury (see Chapters 18 and 27).

HIDA scintigraphy, as mentioned earlier (see Chapter 15), is a useful noninvasive method of evaluating liver function and bile secretion (Holbrook et al, 1991). Although it may not supply accurate anatomic details, information such as the presence of a fistula, its origin (liver or extrahepatic biliary system; see Figs. 42B.3 and 42B.24), and adequacy of its drainage (controlled or uncontrolled; Figs. 42B.26 and 42B.27; McPherson et al, 1984) can be clearly obtained.

MRCP and CT allow excellent assessment in hepatic biliary, arterial, and portal venous anatomy. In particular, use of CT after fistulography can help verify maturation of a fistula tract and define perihepatic bile collections or isolated liver segments (see Figs. 42B.5 and 42B.20).

Treatment

The principles of management of postoperative biliary fistulae are essentially the same regardless of the initial surgical procedure; these principles are outlined in Figure 42B.28 and are modified slightly according to the initial surgical procedure and the individual patient. ERCP and endoscopic techniques play an integral and indispensable role in the management of biliary fistulae. The individual treatment plan should be made and agreed on jointly by all members of the team involved in the treatment of the patient.

As stated earlier, it is important to establish a controlled fistula; this can be achieved initially by US- or CT-guided drainage of the abscess or collection. Operation is indicated when nonoperative measures are not suitable, such as in a patient

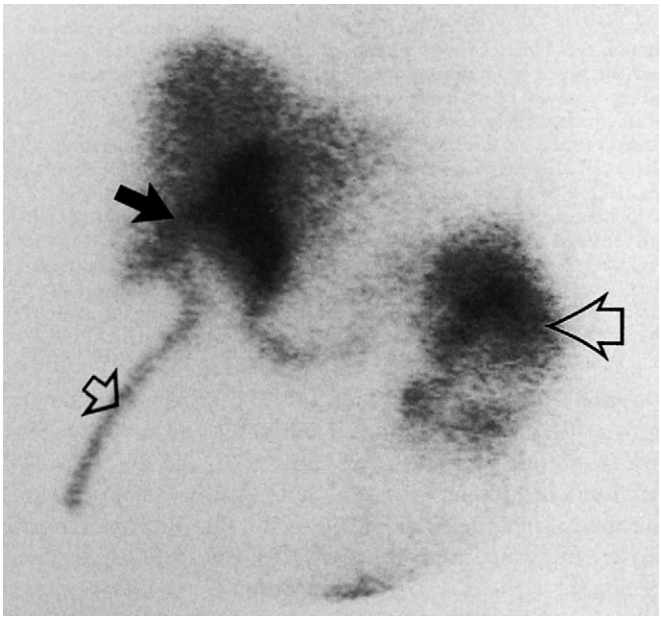

FIGURE 42B.27. Hepatobiliary iminodiacetic acid scan (*right lateral view*) showing a controlled biliary fistula (*small open arrow*) resulting from an incomplete closure of a wide cystic stump (*solid arrow*) at laparoscopic cholecystectomy. Free biliary-enteric bile flow is shown (*large open arrow*). The fistula closed spontaneously after 2 weeks.

with diffuse bile peritonitis, a septic patient with an intraabdominal abscess too large to be drained by the percutaneous route, or a patient with necrotic material and debris within the abscess. Early surgery also is indicated when percutaneous drainage has failed. During the operation, the temptation to

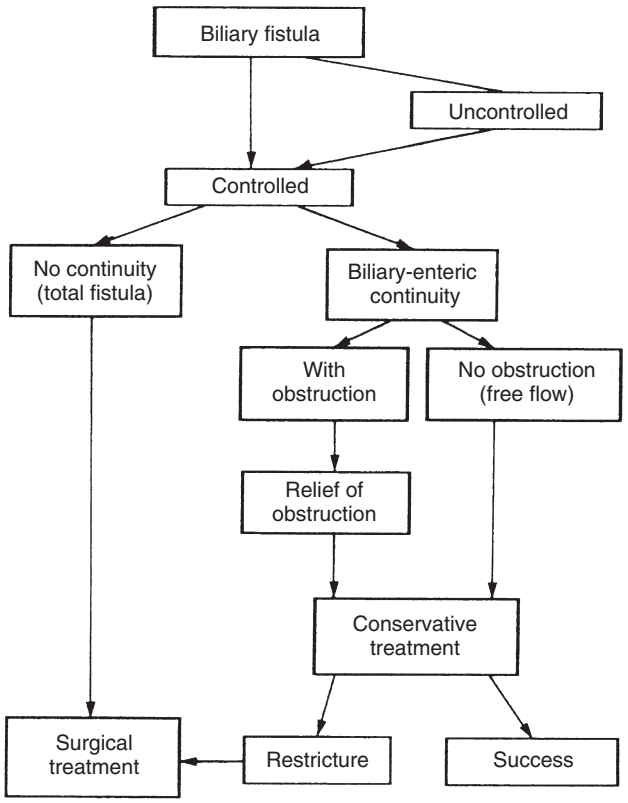

FIGURE 42B.28. Proposed management plan for postoperative biliary fistula. The initial treatment is most important and includes the establishment of a controlled fistula. This is achieved radiologically, by percutaneous drainage of a collection, or surgically, at which time no attempt at primary repair is made. The fistula is evaluated for biliary-enteric continuity. When a total fistula has been diagnosed, it is most important to ensure that it is controlled. Definitive surgical repair is attempted after a reasonable period of conservative treatment. When biliary-enteric continuity is present with free biliary-enteric bile flow, conservative treatment is instituted and results in spontaneous closure in most cases. The presence of biliary-enteric continuity with distal obstruction calls for some form of treatment to relieve the obstruction, and this is done endoscopically or, preferably, percutaneously by balloon dilation. After the establishment of free biliary-enteric bile flow, patients are treated conservatively. In suitable cases, nasobiliary intubation is followed up carefully after fistula closure for early signs of stricture. Highly complex hilar fistulae are treated conservatively with prolonged periods of drainage. The fistula is expected to close, and this usually occurs together with the development of stricture. After a stricture develops, it is treated surgically.

attempt primary repair at this stage must be resisted; only good drainage should be established. Occasionally, drainage of large amounts of bile with significant fluid and electrolyte loss may necessitate early operation, when the external fistula may be converted to an internal fistulojejunostomy using a mobilized and approximated Roux-en-Y jejunal loop (see Fig. 42B.19; Smith et al, 1982). In this procedure, the drainage tube is led from the fistula origin through the jejunal loop to the exterior; this allows control, but it creates an almost certain necessity to reoperate for restenosis at a later stage.

It is important to identify the presence or absence of biliary-enteric bile flow, which differentiates a total biliary fistula from a partial fistula with some residual biliary-enteric continuity. Subsequent management is influenced significantly, because operation is usually unavoidable in the former, and a nonoperative approach may be successful in the latter. A total biliary fistula rarely closes spontaneously when an internal fistula develops between the divided upper duct and the gut (Collins & Gorey, 1984).

When biliary-enteric continuity is present, and bile flow is not obstructed distal to the origin of the fistula, a prolonged period of conservative treatment is indicated, because spontaneous closure of the fistula is common. Fistula closure may be facilitated by temporary placement of a stent across the fistulous opening in the bile duct, excluding bile flow through the fistula. This method may be attempted where the CBD is intact above the fistula origin, and the defect in the common duct is not too large. Stenting may be achieved by endoscopic placement of an endoprosthesis or a nasobiliary tube with its tip above the origin of the fistula. When a short period of stenting is anticipated, nasobiliary intubation is preferred, because it enables follow-up cholangiography, damage to the papilla is minimal, and a second endoscopic procedure is avoided (Barthel & Scheider, 1995; Grala et al, 2009). Using this method, some fistulae close within 2 weeks (Toriumi et al, 1989). It is also useful in patients with liver transplant who have undergone duct-to-duct biliary reconstruction. In patients with concomitant CBD stones or stricture, a papillotomy is indicated. Nasobiliary tubes are cumbersome for the patient, and they may occasionally dislodge; if used for prolonged periods, they may enhance metabolic acidosis resulting from bile loss.

Endoscopic treatment of fistulae with intact biliary-enteric flow by sphincterotomy, stenting, or both is effective in most patients (Agarwal et al, 2006; Rauws & Gouma, 2004). In most instances, a biliary endoprosthesis is used and is left in place for several weeks, until the fistula closes. Closure is verified by HIDA scan before removal of the stent. If standard endoscopic therapy fails, an alternative endoscopic technique using n-butyl-2-cyanoacrylate glue occlusion of the fistula has been shown to be effective and helps avoid the need for surgery (Seewald et al, 2004).

Some authors recommend endoscopic sphincterotomy alone with the intention of reducing the pressure gradient between the biliary system and the duodenum (Ponchon et al, 1989). This procedure is unnecessary, because the fistula will close if no distal obstruction is present. Sphincterotomy may also be associated with short-term and long-term septic and obstructive complications (Kracht et al, 1986), therefore it should be avoided unless specifically indicated (e.g., in patients with a papillary stricture). It also has been shown that stenting is more effective than sphincterotomy alone in the resolution of biliary fistulae (Marks et al, 1998). As stated earlier, we believe that although endoscopic approaches are useful, they generally should be delayed for days to a few weeks to allow spontaneous closure of the fistula, which obviates the need for further intervention and its attendant complications.

After an obstruction distal to the fistula has been diagnosed, it should be dealt with, because until it has been managed, the fistula will not close spontaneously. Obstruction is usually caused by a retained stone or a stricture: retained stones usually are removed by endoscopic means, and relief of a benign stricture can be achieved using balloon dilation, applied either endoscopically or by interventional radiology after PTC. The patient is treated conservatively and expectantly for fistula closure or for restricture, and fistula closure can be facilitated

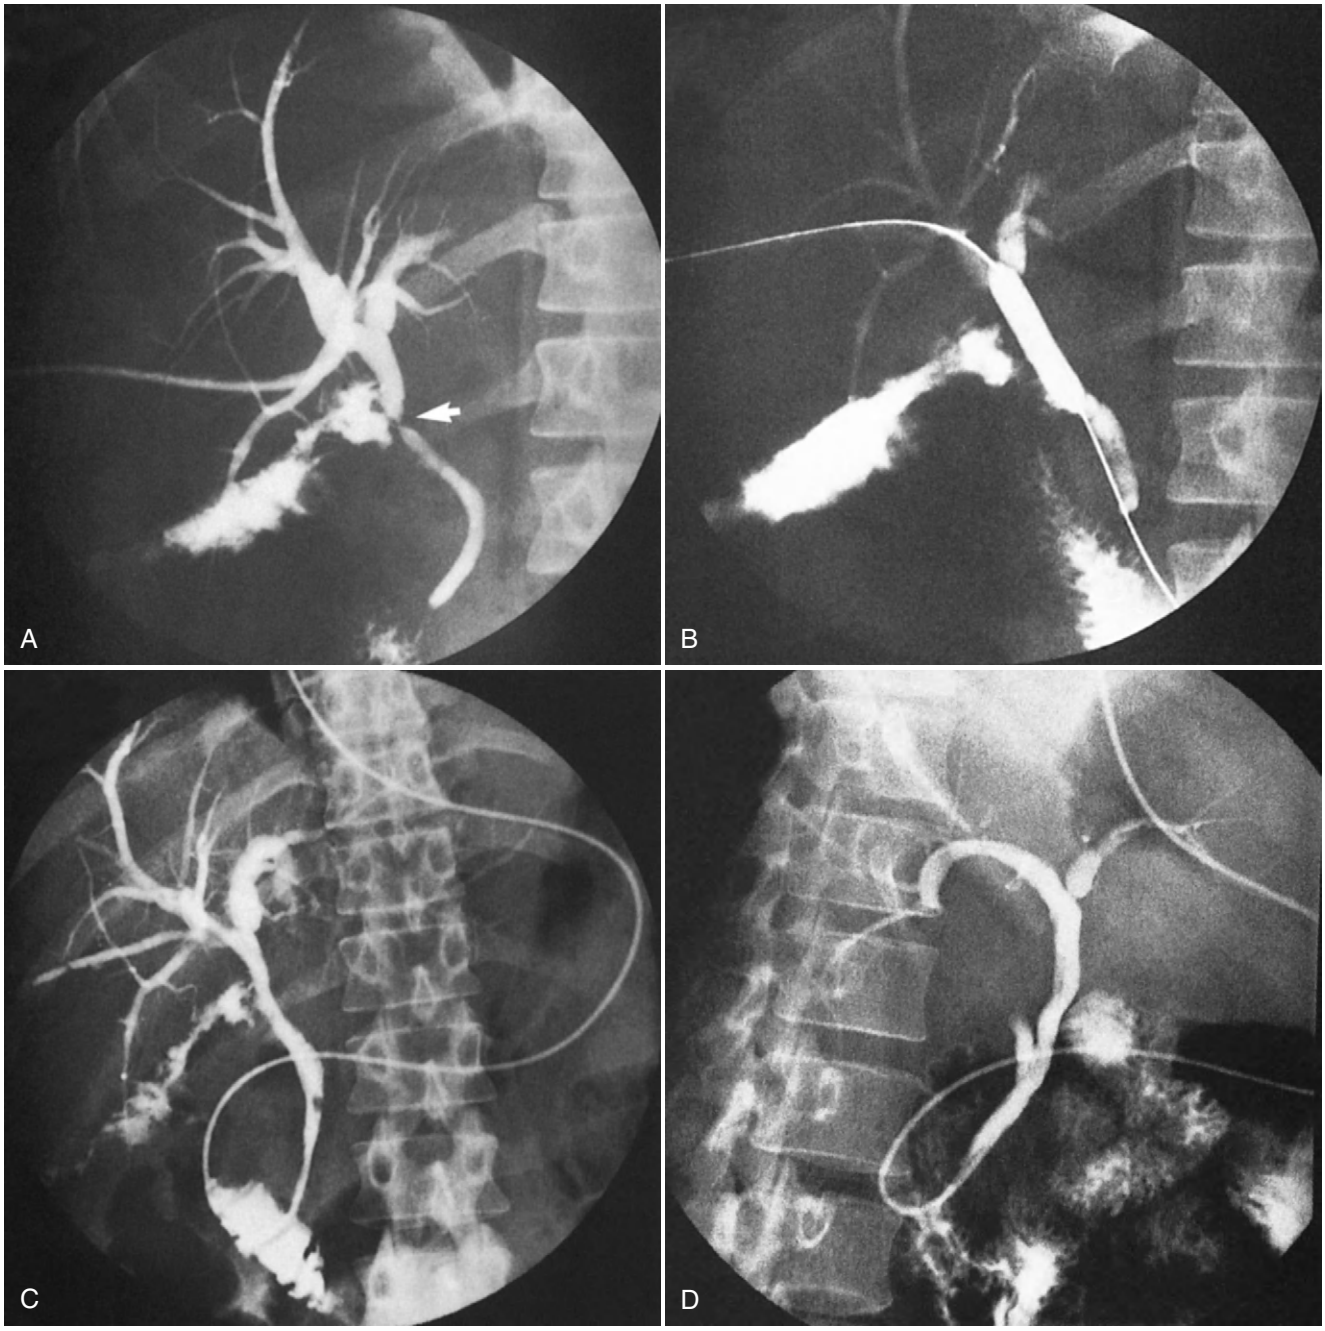

FIGURE 42B.29. Combined surgical/endoscopic/radiologic management of a biliary fistula diagnosed 3 weeks after an open cholecystectomy. **A,** Percutaneous transluminal cholangiography shows a biliary fistula with a significant distal stricture (*arrow*). **B,** Percutaneous transhepatic balloon dilation of the stricture. **C,** Percutaneous transhepatic guide is exchanged for a nasobiliary tube, which is placed endoscopically with its tip above the origin of the fistula. Free biliary-enteric bile flow is obtained. The fistula is still present but is smaller. **D,** Check-up cholangiography (lateral view) after 2 weeks of nasobiliary drainage shows fistula closure. The nasobiliary drain was removed.

by temporary stenting (Fig. 42B.29), if the location and the size of the defect in the bile duct are suitable, and restricture is treated operatively.

The use of temporary stenting is limited in highly complex hilar fistulae combined with stricture, particularly fistulae with separation of a right and left ductal system. Some authors place an endoprosthesis across the stricture and leave it for months (Ponchon et al, 1989), even for more than 1 year, with periodic replacements (Davids et al, 1992). This practice is not only unnecessary but is often harmful, resulting in obstruction and septic complications; the endoprosthesis should be removed when the fistula has closed.

Management of biliary fistula after laparoscopic cholecystectomy follows the same principles. Because early recognition of the biliary fistula or bile duct damage significantly affects treatment, a high index of suspicion is important. Initial evaluation includes abdominal US and HIDA scan to rule out the presence of an abnormal collection and to establish the presence of free biliary-enteric bile flow. Abnormal findings at either study call for ERCP. Treatment of biliary fistula with or without

biliary-enteric continuity follows the guidelines outlined. A biliary fistula associated with malignant distal obstruction is treated with reoperation and surgical excision of the neoplasm or the creation of an appropriate biliary-enteric bypass.

After closure of the fistula, patients are followed up carefully with regular LFTs and HIDA scans to detect early signs of the development of a biliary stricture, which may take months and sometimes years. Stricture is most likely to occur where a stricture has already been present or where a fistula is associated with an injury to a major bile duct (Blumgart et al, 1984). The proposed plan may involve relatively prolonged management, but it improves the chances of a successful and long-lasting bile duct repair, especially after injury at cholecystectomy. In this situation, early and untimely surgical attempts at definitive repair carry a high risk of biliary leak and anastomotic stricture.

Management of the rare patient with excluded or "orphaned" segemental bile ducts following hepatectomy is extremely challenging. This complication results from unrecognized anatomic biliary variations (see Chapter 1B), or when normal anatomic planes are ignored during hepatic transection. The end result is that a portion of liver tissue remains well perfused but entirely disconnected from the biliary tract (see Fig 42B.20). Multiple interventional treatments have been described, the majority consisting of sclerotic agents that are injected directly into the fistula tract. These substances include tetracycline, ethanol, and acetic acid, (Shaw et al, 1989; Shimizu et al, 2006; Park et al, 2005). Other agents such as fibrin glue, thrombin, and n-butyl cyanoacrylate have been used with variable success (Saad & Darcy, 2008; Vu et al, 2006). We are aware of one successful case report of a patient who was treated by percutaneous intraductal laser ablation after failing other treatments (Eicher et al, 2008). When these nonoperative treatments fail, repeat liver resection is necessary and usually definitive (Honore et al, 2009). The authors have successfully used ablation of the liver tissue containing the orphaned biliary segement to treat persistent biliary fistulae.

CHAPTER 50B

Cancer of the bile ducts: extrahepatic biliary tumors

Michael G. House, Michael I. D'Angelica, and William R. Jarnagin

OVERVIEW

Primary tumors arising from the extrahepatic biliary tree are uncommon, typically malignant in nature, and show up with clinical manifestations associated with obstructive jaundice. Bile duct tumors continue to be challenging disease entities that require expertise for proper evaluation and treatment. This chapter focuses on the etiology of bile duct neoplasia, namely cholangiocarcinoma, the appropriate imaging modalities for diagnosing and staging malignant biliary strictures, and the available options for treating resectable and unresectable extrahepatic biliary cancer.

INCIDENCE AND ETIOLOGY

Worldwide, cholangiocarcinoma accounts for approximately 3% of all gastrointestinal cancers. In the United States, where approximately 5000 new cases (gallbladder cancers excluded) are diagnosed each year, the annual incidence of bile duct cancer is estimated at 1 to 2 per 100,000 (Carriaga & Henson, 1995; Greenlee et al, 2001; Khan et al, 2005). Over the past 3 decades, a trend has been seen toward older patient age (median range, 65 to 70 years) at the time of diagnosis and a relative increase in the ratio of intrahepatic to extrahepatic cholangiocarcinoma (see Chapter 50A; Carriaga & Henson, 1995; Endo et al, 2008a; Patel, 2001; Weber et al, 2007).

The molecular changes associated with the pathogenesis of cholangiocarcinoma are poorly characterized (see Chapter 8B). Multiple *KRAS* oncogene mutations at codon 12 have been identified in almost all resected specimens (Levi et al, 1991). These mutations most likely occur at some point along a stepwise progression to malignancy but probably are not the inciting genetic lesion. There are wide epidemiologic variations in the incidence of *KRAS* mutations (Lee et al, 1995; Levi et al, 1991; Nakamura et al, 1981). Many studies have reported differences in various genetic abnormalities according to location within the biliary tree, suggesting anatomic differences in pathogenesis. An in-depth review of the molecular biology of biliary cancer is beyond the scope of this chapter; the interested reader is referred to selected review articles (Rashid, 2002) and to Chapter 8B.

The majority of patients with cholangiocarcinoma have no obvious risk factors, although several conditions are associated with an increased incidence of cholangiocarcinoma. In the United States, the most common risk factor for cholangiocarcinoma is primary sclerosing cholangitis (PSC), an autoimmune disease characterized by periductal inflammation resulting in multifocal strictures of the intrahepatic and extrahepatic bile ducts (see Chapter 41; Broome et al, 1996; Katoh et al, 1988; Pitt et al, 1995a, 1995b). Approximately three quarters of patients with PSC have underlying ulcerative colitis (Broome et al, 1996). The natural history of PSC is quite variable, and the true incidence of cholangiocarcinoma is difficult to calculate but appears to depend on disease duration. In a Swedish series of 305 patients followed for more than 5 years, 8% of patients eventually developed cancer (Broome et al, 1996), and occult cholangiocarcinoma has been reported in 40% of autopsy specimens and 36% of liver explants from patients undergoing orthotopic liver transplantation for PSC (Broome et al, 1996; Katoh et al, 1988; Pitt et al, 1995a). Unfortunately, cholangiocarcinoma arising in the setting of PSC frequently is not amenable to operative resection because of advanced underlying hepatic parenchymal disease or multifocal malignancy. Medical or surgical treatment of coexisting ulcerative colitis in patients with PSC does not alter the subsequent risk of developing cholangiocarcinoma (Broome et al, 1996; Katoh et al, 1988; Pitt et al, 1995a).

Choledochal cysts are associated with an increased risk for cholangiocarcinoma (see Chapter 46; Hewitt et al, 1995; Vogt, 1954). The incidence of bile duct cancer in patients with congenital biliary cystic disease is substantial (15% to 20%), especially in patients who are not treated until after age 20 years and in patients previously treated by cyst drainage (Lipsett et al, 1994; Vogt, 1954). The hypothetical risk for malignant transformation of choledochal cysts may be related to an anomalous pancreatobiliary junction, which is commonly found in these patients and predisposes them to reflux of pancreatic juice into the biliary tree and chronic inflammation of the bile ducts (Lipsett et al, 1994; Jeng et al, 1994; Tanaka et al, 1998a; Vogt, 1954). By similar mechanisms, transduodenal sphincteroplasty and endoscopic sphincterotomy may be associated with an increased risk for cholangiocarcinoma (Tanaka et al, 1998b). In a series of 119 patients subjected to sphincteroplasty for benign disease (sphincter of Oddi dysfunction), Hakamada and associates (1997) found a 7.4% incidence of cholangiocarcinoma over 18 years.

Recurrent pyogenic cholangiohepatitis and hepatolithiasis resulting from chronic portal bacteremia and portal phlebitis are prevalent in Japan and parts of Southeast Asia (see Chapters 39 and 44). Although most cholangiocarcinomas in these patients arise within the intrahepatic ducts, cases of extrahepatic cholangiocarcinoma have been reported (Chen et al, 2004; Chu et al, 1997; Kubo et al, 1995; Meade et al, 1994; Winslet et al, 1990). Biliary parasites—specifically, *Clonorchis sinensis* and *Opisthorchis viverrini*—are endemic in parts of Asia and are associated with an increased risk of cholangiocarcinoma (Pitt et al, 1995a, 1995b). In Thailand, where approximately 7 million people are chronically infected with *Opisthorchis*, the

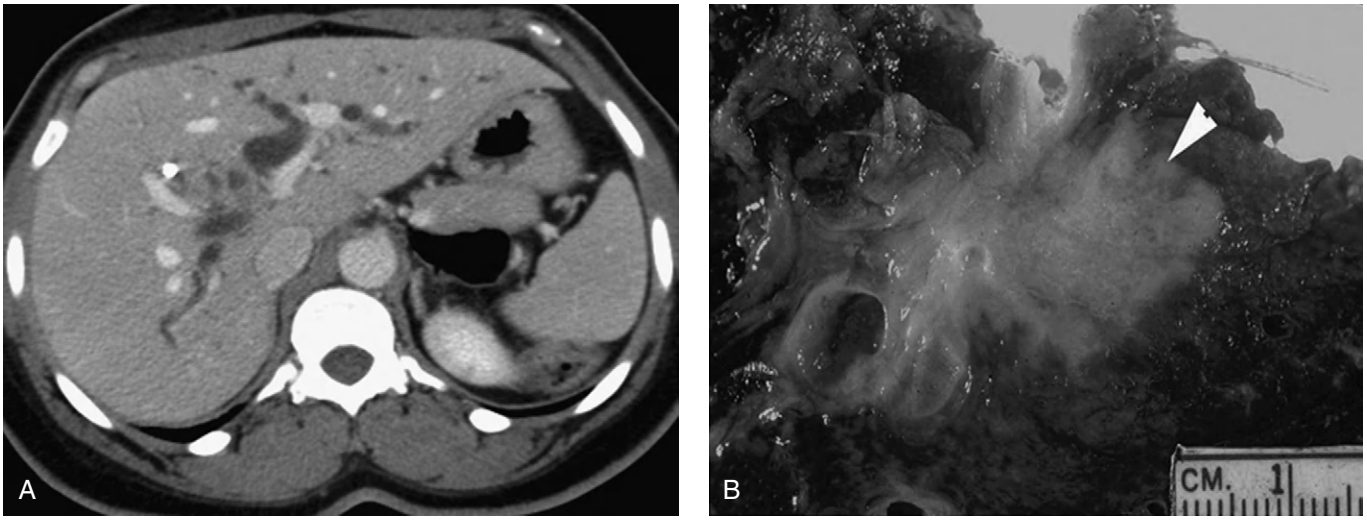

FIGURE 50B.1. A, Contrast-enhanced computed tomographic scan showing hilar bile duct tumor involving the right and left hepatic ducts. **B,** Gross appearance of a nodular-sclerosing tumor invading the hepatic parenchyma.

annual incidence of cholangiocarcinoma is 87 per 100,000 (see Chapter 45; Watanapa, 1996). In addition, several radionuclides and chemical carcinogens may be associated with an increased risk of cholangiocarcinoma, including thorium, radon, nitrosamines, dioxin, and asbestos.

TUMOR LOCATION AND HISTOPATHOLOGY

Adenocarcinoma is the most common neoplasm arising from the biliary tract and accounts for more than three fourths of all bile duct tumors (Are et al, 2006; Jarnagin et al, 2001). Benign neoplasms and strictures occasionally will mimic many of the clinical, radiographic, and operative findings associated with malignant biliary strictures. Other reported tumors of the extrahepatic bile ducts include adenoma, leiomyoma, paraganglioma, lipoma, granular cell tumor, and carcinoid (Felekouras et al, 2009; Holzinger et al, 1999). Benign strictures resulting from autoimmune pancreatitis, granulomatous disease, and PSC can masquerade as biliary neoplasms and should be treated as such (see Chapter 42A; Corvera et al, 2005; Hadjis & Blumgart, 1985). Malignant strictures of the extrahepatic biliary tree may represent secondary involvement from cancers arising from the gallbladder, pancreas, and periportal lymph nodes (see Chapter 49).

Cholangiocarcinoma can arise anywhere within the biliary tree, but tumors involving the biliary confluence are the most common. Retrospective reviews from high-volume centers reveal that between 40% and 60% of cholangiocarcinoma cases involve the perihilar bile ducts (Burke, 1998; Nagorney et al, 1993; Nakeeb et al, 1996a, 1996b; Tompkins et al, 1981). Tumors of the lower bile duct are classified according to their anatomic location, although there may be considerable overlap. Distal bile duct tumors typically arise within the pancreatic portion of the common bile duct (Tompkins et al, 1981) and represent approximately 20% to 30% of all cholangiocarcinomas and 5% to 10% of all periampullary tumors (Fong et al, 1996; Nakeeb et al, 1996a, 1996b; Wade et al, 1997; Yeo et al, 1997). Tumors of the mid–bile duct are rare and arise below the confluence of the hepatic ducts, usually between the upper border of the pancreas at the level of the cystic duct. The majority of such malignant strictures are caused by gallbladder cancer or cystic duct–based tumors.

Cholangiocarcinomas can present with extensive ductal involvement alone or with early metastatic spread to the liver, regional lymph nodes, or peritoneum (Jarnagin et al, 2005; Tsuzuki et al, 1983). Most bile duct cancers demonstrate characteristic invasive spread along ductal subepithelial histologic planes. Perineural and lymphovascular involvement is common, as is direct invasion into the liver or perihepatic structures (Weinbren & Mutum, 1983).

Three distinct macroscopic subtypes of cholangiocarcinoma have been described: 1) sclerosing, 2) nodular, and 3) papillary (Weinbren & Mutum, 1983). *Sclerosing tumors* account for most cases and are more common at the hilus than in the distal bile duct. They are firm and cause an annular thickening of the bile duct, often with diffuse infiltration and fibrosis of the periductal tissues (Fig. 50B.1). *Nodular tumors* are characterized by a firm, irregular nodule of tumor that projects into the lumen of the duct. Features of both types are often seen, hence the frequently used descriptor *nodular-sclerosing.* The *papillary tumors* account for approximately 10% of all cholangiocarcinomas, and although occasionally seen at the hilus, these are more common in the distal bile duct (Weinbren & Mutum, 1983). These tumors are soft and friable and may be associated with little transmural invasion; a polypoid mass that expands the duct, rather than contracting it (Fig. 50B.2), is a characteristic feature. Although papillary tumors may grow to a significant size and appear surgically unapproachable on radiographic studies, they often arise from a well-defined stalk and can be minimally invasive. The bulk of the tumor frequently is mobile within the bile duct. Recognition of this variant is important, because they appear to be more often resectable and have a more favorable prognosis than the sclerosing type (Jarnagin et al, 2005; Pitt et al, 1995a).

Longitudinal spread along the duct wall and periductal tissues is an important pathologic feature of cholangiocarcinomas (Endo, 2008b; Sakamoto et al, 1998; Weinbren & Mutum, 1983). There may be substantial extension of tumor beneath an intact epithelium, and it can extend as much as 2 cm proximally and 1 cm distally (Sakamoto et al, 1998; Shimada et al, 1988).

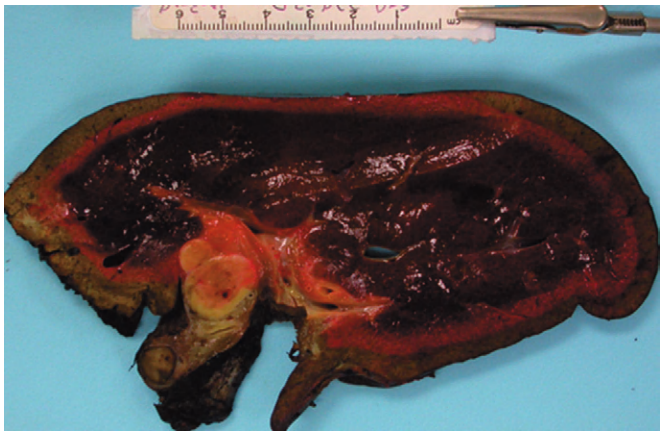

FIGURE 50B.2. Gross appearance of a papillary-type cholangiocarcinoma within the right hepatic duct. Note the expansion of the duct lumen.

The full tumor extent may be underestimated by radiographic studies and may not be appreciated on palpation. This predilection for submucosal extension underscores the importance of frozen-section analysis of the duct margins during resection, although its utility has been called into question (Endo et al, 2008b). Although most of these tumors are adenocarcinomas, in rare instances other malignant cell types may arise primarily in the biliary tree and cause biliary obstruction, such as carcinoid tumors (Jutte et al, 1987; Rugge et al, 1992; Sankary et al, 1995).

CLINICAL PRESENTATION

The early symptoms of hilar and distal cholangiocarcinoma are nonspecific. Abdominal pain, anorexia, weight loss, and pruritus are the most common symptoms, but these are seen only in about one third of patients. Fever is rarely seen at initial presentation but is common once biliary manipulation is initiated (Farley et al, 1995; Katoh et al, 1988; Meade et al, 1994; Nakeeb et al, 1996b; Pitt et al, 1995a; Vatanasapt et al, 1990b). Most patients have few symptoms and come to attention because of jaundice or abnormal liver function tests. Although most patients eventually become jaundiced, this finding is not present initially in cases of incomplete biliary obstruction (i.e., right or left hepatic duct) or segmental ductal obstruction. Segmental obstruction may go unrecognized for a long time, resulting in ipsilateral lobar atrophy without overt jaundice (see Chapter 5). These patients often are further evaluated and diagnosed because of an elevated serum alkaline phosphatase.

The clinical presentation of distal bile duct cancer generally is indistinguishable from that of other periampullary malignancies. Progressive jaundice is seen in 75% to 90% of patients. Abdominal pain, weight loss, fever, or pruritus occur in one third of patients or fewer (Fong et al, 1996; Nakeeb et al, 1996a, 1996b).

In some patients, pruritus precedes jaundice by some weeks; this symptom should prompt an evaluation, especially if associated with abnormal liver function test results. Patients with papillary tumors of the hilus may have a history of intermittent jaundice. Small fragments of tumor may detach from a friable papillary tumor of the right or left hepatic duct and pass into the common hepatic duct. Alternatively, if mobile within the lumen, the main tumor may cause a ball-valve effect at the hepatic duct confluence.

In jaundiced patients, the total bilirubin level may suggest an etiology. In patients with obstruction from cholangiocarcinoma, the serum bilirubin level is often greater than 10 mg/dL and averages 18 mg/dL, whereas patients with obstruction from choledocholithiasis have bilirubin levels 2 to 4 mg/dL and rarely greater than 15 mg/dL (Way, 1994); however, there is likely to be considerable overlap. Furthermore, the degree of jaundice may suggest the level of bile duct obstruction. Hilar obstruction is typically associated with higher levels of serum bilirubin compared with distal tumors. In patients with cholangiocarcinoma and no previous biliary intervention, cholangitis is uncommon at initial presentation despite a 30% incidence of bactibilia (see Chapter 43; Hochwald et al, 1999; Meade et al, 1994). The incidence of bactibilia is nearly 100% after biliary intubation, and cholangitis is also more common (Hochwald et al, 1999). Gallstones or common bile duct stones may coexist with bile duct cancer. In the absence of certain predisposing conditions (PSC, choledochal cyst, hepatolithiasis), however, it is uncommon for choledocholithiasis to cause obstruction at the biliary confluence. It is imperative to investigate fully and delineate the level and nature of any obstructing lesion causing jaundice to avoid missing the diagnosis of carcinoma.

Physical examination findings are usually nonspecific but may provide some useful information. The liver may be enlarged and firm as a result of distal biliary tract obstruction, whereas the gallbladder usually is decompressed and nonpalpable with hilar obstruction. Rarely, patients with long-standing biliary obstruction or portal vein involvement or both may have findings consistent with portal hypertension.

Bactibilia is relatively common in patients with hilar cholangiocarcinoma; however, in the absence of prior biliary manipulation, frank cholangitis is uncommon at initial presentation (McPherson et al, 1984).

DIAGNOSTIC STUDIES

The diagnosis of hilar and distal cholangiocarcinoma usually follows targeted studies for the evaluation of obstructive jaundice or elevated liver enzymes. Most patients are referred after having had some studies done elsewhere, usually computed tomography (CT) and often some form of direct cholangiography, such as percutaneous transhepatic cholangiography (PTC) or endoscopic retrograde cholangiopancreatography (ERCP). In our view, histologic confirmation of malignancy is not mandatory before exploration. In the absence of previous biliary tract surgery, the finding of a focal stenotic lesion combined with the appropriate clinical presentation is sufficient for a presumptive diagnosis of hilar cholangiocarcinoma, which is correct in most instances (Wetter et al, 1991).

Although most patients with hilar strictures and jaundice have cholangiocarcinoma, alternative diagnoses are possible in 10% to 15% of patients (Wetter et al, 1991). The most common of these are gallbladder carcinoma, Mirizzi syndrome, and benign focal strictures, such as lymphoplasmacytic sclerosing pancreatitis/cholangitis, granulomatous disease, and PSC (see Chapters 42, 48, and 49). Distinguishing gallbladder carcinoma from hilar cholangiocarcinoma can be difficult. A thickened, irregular gallbladder wall with infiltration into segments IV and V of the liver, selective involvement of the right portal pedicle, and obstruction of the mid–bile duct with occlusion of the

FIGURE 50B.3. Endoscopic retrograde cholangiopancreatography findings of a mid–common bile duct stricture are typically associated with carcinoma of the gallbladder or cystic duct.

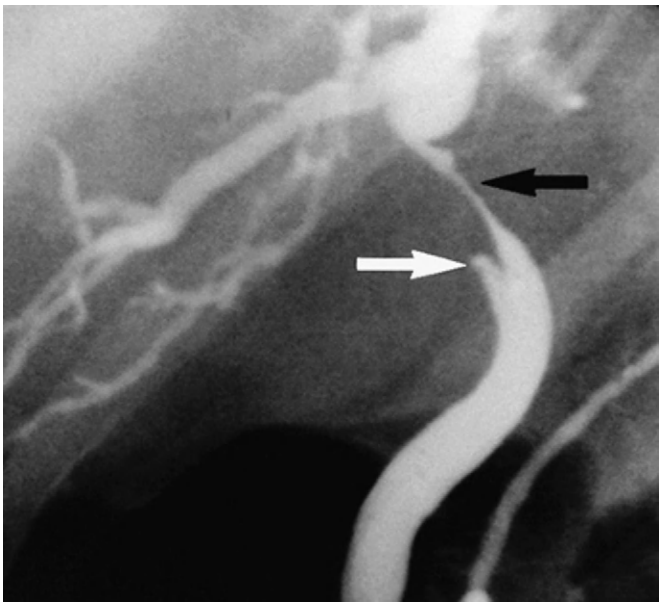

FIGURE 50B.4. Endoscopic retrograde cholangiopancreatography from a patient with a benign stricture of the proximal bile duct. The smooth, tapered appearance (*black arrow*) is in contrast to the irregular stricture typical of a sclerosing tumor. Nonfilling of the cystic duct (*white arrow*) is an important finding, and in the appropriate setting, it should raise the suspicion of gallbladder carcinoma (see Fig. 50B.3). In this patient, the chronic inflammatory process had involved the hepatic duct and cystic ducts. Most cases of benign strictures of the proximal bile duct spare the cystic duct.

cystic duct on endoscopic cholangiography all suggest gallbladder carcinoma (Fig. 50B.3).

Mirizzi syndrome is a benign condition resulting from a large gallstone impacted in the neck of the gallbladder (see Chapters 29 and 42A). The ensuing pericholecystic and periductal inflammation and fibrosis can obstruct the proximal bile duct, which is often difficult to distinguish from a malignant obstruction (Baer et al, 1990; Callery et al, 1997; Cabooter et al, 1990). Other benign focal strictures (malignant masquerade) can occur at the hepatic duct confluence but are uncommon (Fig. 50B.4; Hadjis et al, 1985; Saldinger & Blumgart, 2000; Verbeek et al, 1992; Wetter et al, 1991). The finding of a smooth, tapered stricture on cholangiography suggests a benign stricture. Diagnostic assessments based on the cholangiographic appearance of the stricture are unreliable, and hilar cholangiocarcinoma must remain the leading diagnosis until definitively disproved with operative exploration. The alternative conditions that one may encounter are best assessed and treated at operation. Relying on the results of percutaneous needle biopsy or biliary brush cytology is dangerous, because they often are misleading, and the surgeon may miss the opportunity to resect an early cancer (Enjoji et al, 1998; Rabinovitz et al, 1990). In the absence of clear contraindications, exploration is indicated in all patients with suspicious hilar lesions with concordance of clinical and radiographic findings.

Many tumors express carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9). Serum levels of these markers, although elevated in some patients, have had little diagnostic value (Pitt et al, 1995a). It has been suggested that CEA levels in hepatic bile may help distinguish between benign and malignant strictures in patients with premalignant conditions (Nakeeb et al, 1996a).

Radiographic studies are pivotal in selecting patients for resection. In the past, CT, PTC, and angiography were considered standard investigations; however, magnetic resonance cholangiopancreatography (MRCP) may provide equal anatomic information with less risk.

Direct cholangiography (see Chapter 18) shows the location of the tumor and the biliary extent of disease, both of which are crucial in surgical planning. When performed skillfully, ERCP provides useful duct detail and can effectively drain functional liver segments prior to operative planning. Although invasive, PTC outlines the extent of intrahepatic bile duct involvement reliably and has been the preferred study in the past (Pitt et al, 1995a, 1995b). High-quality cholangiograms are often thought to be essential for accurately diagnosing the extent of cancer (Kondo et al, 2004; Nimura, 1997). In many centers, particularly in Japan, surgeons extend the diagnostic process by performing detailed cholangiography with one or more percutaneous catheters placed in the intrahepatic ducts, often combined with percutaneous cholangioscopy along a mature transhepatic drain tract (Ohkubo et al, 2004; Ozden, 2002). PTC with biliary drainage should be considered not only an effective method of relieving jaundice but also an important diagnostic modality.

MRCP is a powerful investigative tool that has almost replaced endoscopic and percutaneous cholangiography as the initial preoperative assessment of hilar cholangiocarcinoma (see Chapter 17). Several studies have shown its utility in evaluating patients with biliary obstruction (Guthrie et al, 1996; Lee et al, 1997; Schwartz et al, 1998). MRCP may not only identify the tumor and the level of biliary obstruction, but it also may reveal

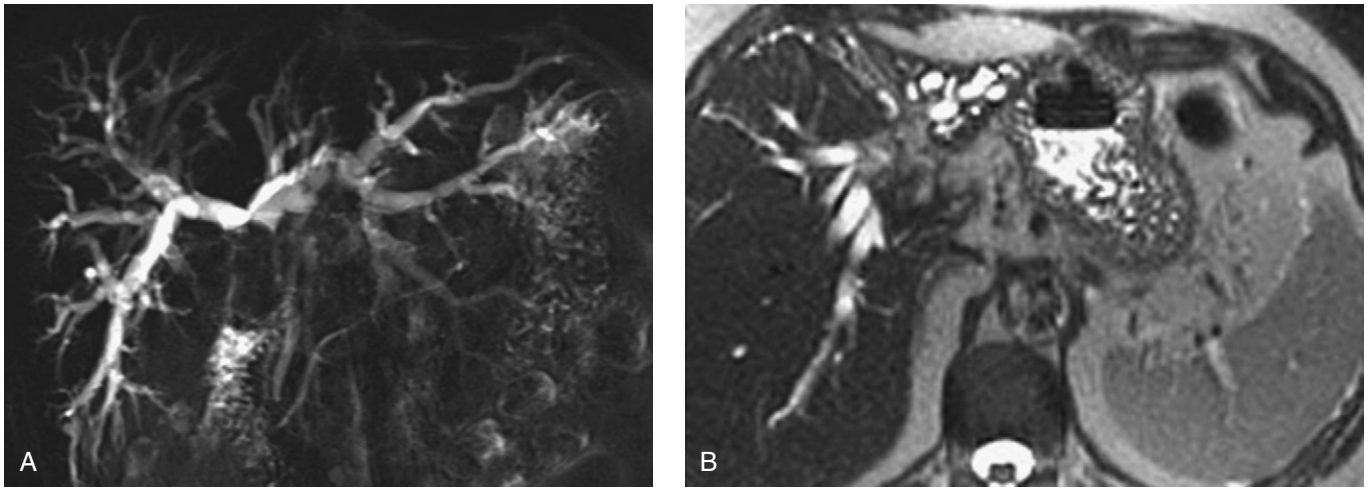

FIGURE 50B.5. Coronal (**A**) and axial (**B**) magnetic resonance cholangiopancreatographic images of a patient with hilar cholangiocarcinoma. The tumor involves the right and the left hepatic ducts. The bile ducts in this study appear white.

obstructed and isolated ducts not appreciated at endoscopic or percutaneous study (Fig. 50B.5). MRCP also provides information regarding the patency of hilar vascular structures, the presence of nodal or distant metastases, and the presence of lobar atrophy (Fig. 50B.6).

CT is an important study for evaluating patients with biliary obstruction. A high-quality CT scan can provide valuable information regarding the level of obstruction, vascular involvement, and liver atrophy (Fig. 50B.7; see Chapter 16). Advances in CT technology permit the acquisition of three distinct circulatory phases—the *arterial*, *pancreatic*, and *portal venous* phases—in the hilar and pancreatobiliary region with 1-mm collimation. These isotropic volume data allow generation of high-quality three-dimensional images—such as CT arteriography, CT cholangiopancreatography, and CT portography—in a single scanning session (Itoh et al, 2005).

Although it is operator dependent, ultrasound (US) is a useful noninvasive diagnostic study (see Chapter 13). When utilized by experienced centers, it often delineates tumor extent accurately. US can not only show the level of biliary ductal obstruction, but it can also provide information regarding tumor extension within the bile duct and in the periductal tissues (Gibson et al, 1986; Hann et al, 1997; Okuda et al, 1988). Duplex US is firmly established as a highly accurate predictor of vascular involvement and resectability (Fig. 50B.8). In a series of 19 consecutive patients with malignant hilar obstruction, US with color spectral Doppler technique was equivalent to angiography and CT portography in diagnosing lobar atrophy, level of biliary obstruction, hepatic parenchymal involvement, and venous invasion (Hann et al, 1997). Duplex US is particularly useful for assessing portal venous invasion. In a series of 63 consecutive patients from Memorial Sloan-Kettering Cancer

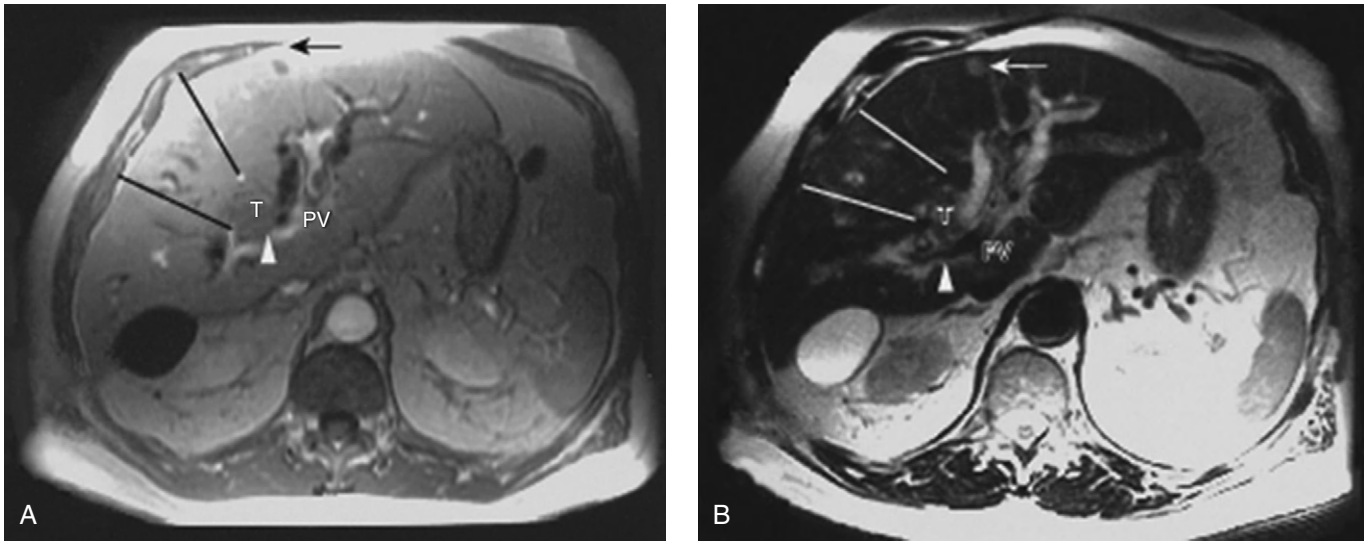

FIGURE 50B.6. **A**, T1-weighted, gadolinium-enhanced magnetic resonance image of a patient with hilar cholangiocarcinoma. The bile ducts appear black. A hilar tumor is seen (*T*), apparently adherent to or encasing the right portal vein branch (*PV; arrowhead*). The tumor has occluded the right anterior sectoral branch of the portal vein, and the anterior sector appears atrophic (*black lines*) with crowded, dilated ducts. The *arrow* points to intrahepatic metastases. **B**, Magnetic resonance cholangiopancreatography cut through the same area of the liver. Similar findings are indicated in this image, in which the bile ducts appear white.

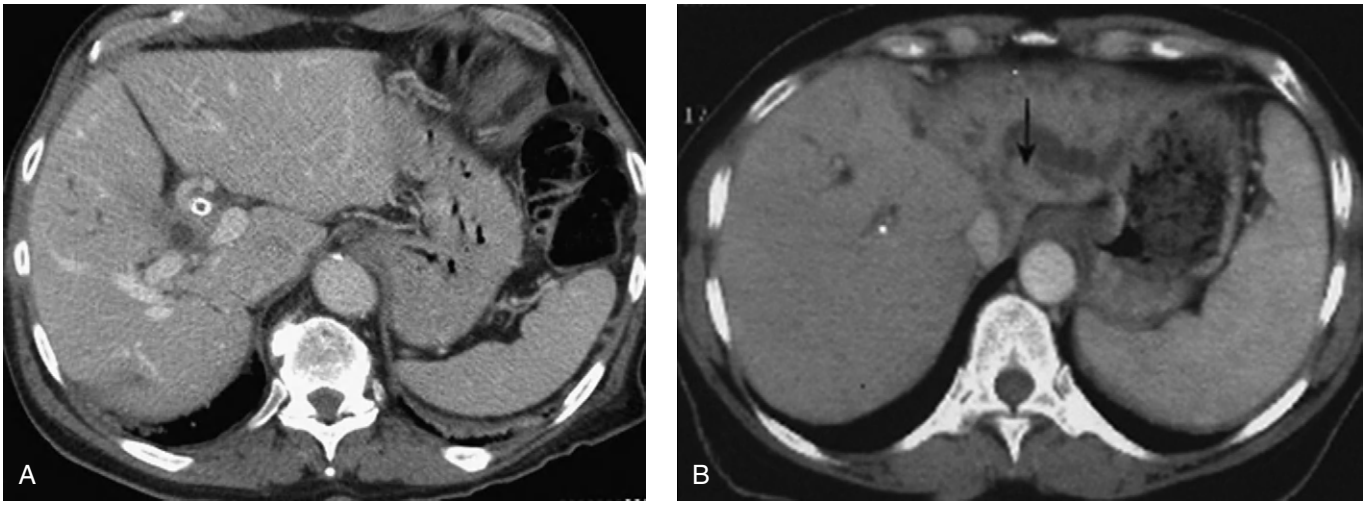

FIGURE 50B.7. Computed tomographic images from a patient with hilar cholangiocarcinoma and jaundice. **A,** The right portal vein is invaded by tumor, and there is right-sided lobar atrophy with compensatory left hemiliver hypertrophy. **B,** The left portal vein is occluded, causing left lobar atrophy with crowding of dilated ducts (*arrow*). Note that there is no defined mass in either image.

Center (MSKCC), duplex US predicted portal vein involvement in 93% of cases, with a specificity of 99% and a positive predictive value of 97%. In the same series, angiography with CT angioportography had a 90% sensitivity, 99% specificity, and 95% positive predictive value (Bach et al, 1996).

The diagnosis of malignancy in patients with bile duct strictures can be challenging and depends on accurate interpretation of ERCP and/or PTC as well as cross-sectional imaging (MRCP and CT) findings. ERCP in particular is a useful tool for assessing biliary tract strictures, as it permits visualization of the biliary tree with the opportunity for therapeutic intervention (biliary drainage) and collection of specimens for cytopathologic and histopathologic evaluation (Fig. 50B.9). Although highly specific, biliary brush cytology is limited by low to moderate sensitivity (15% to 68%; Fritcher et al, 2009). As a result, adjunctive diagnostic techniques including mutation analysis, DNA ploidy analysis, and fluorescence in situ hybridization (FISH) have been studied clinically and experimentally to improve tumor detection sensitivity (Kipp et al, 2010). Two

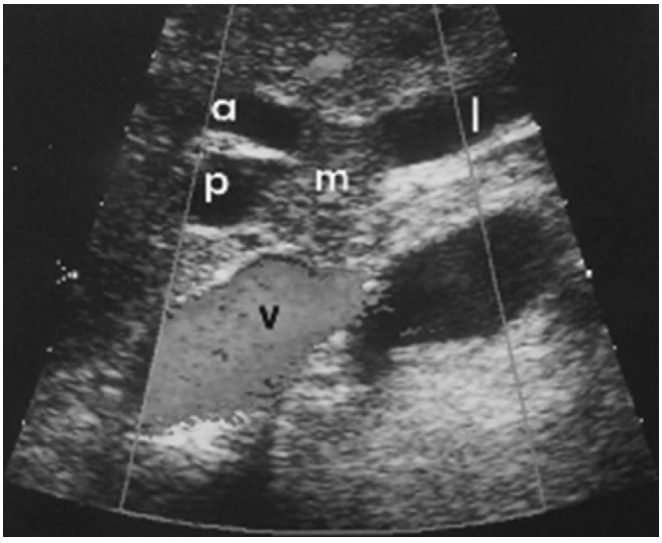

FIGURE 50B.8. Transverse color Doppler ultrasound of the biliary confluence shows a papillary cholangiocarcinoma (*m*) extending into the right anterior (*a*) and posterior (*p*) sectoral ducts and the origin of the left duct (*l*). The adjacent portal vein (*v*) is not involved and has normal flow. *(From Hann LE, et al, 1996: Malignant hepatic hilar tumors: can ultrasonography be used as an alternative to angiography with CT arterial portography for determination of resectability? J Ultrasound Med 15:37-45.)*

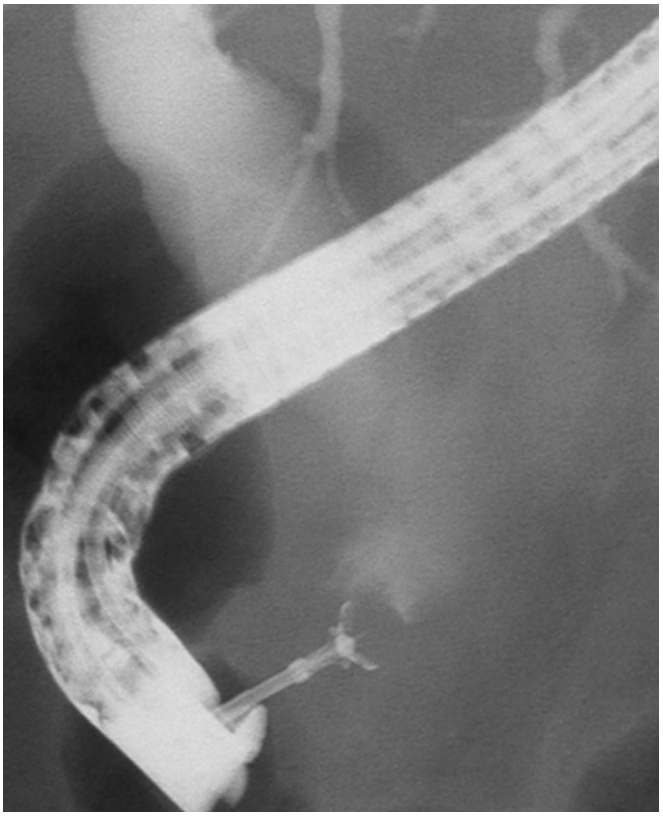

FIGURE 50B.9. Endoscopic retrograde cholangiopancreatography–guided grasp biopsy of a distal bile duct tumor in a patient presenting with obstructive jaundice and requiring biliary drainage. Cross-sectional imaging had previously staged the patient with metastatic disease, and a tissue diagnosis was sought.

types of chromosomal abnormalities are frequently identified with a clinical FISH probe set, namely polysomy and trisomy 7. Polysomy has been defined as a gain of two or more of the four probes in five cells. A large clinical study recently demonstrated that FISH was more sensitive than cytology for detecting biliary tract cancer and was able to detect 49 (22%) of 227 cancers that routine cytology interpreted as nonmalignant, without compromising test specificity (Fritcher et al, 2009).

Distal bile duct tumors frequently are mistaken for adenocarcinoma of the pancreatic head, the most common periampullary malignancy. In a series of 119 periampullary tumors, the site of origin was diagnosed incorrectly in 28% of patients preoperatively and in 20% of patients intraoperatively (Jones et al, 1985). Nevertheless, ERCP can provide valuable information regarding the level of obstruction and may show clearly that the obstruction is arising from the bile duct and does not involve the pancreatic duct. ERCP also may be useful in cases in which choledocholithiasis is suspected and may be therapeutic in these patients. PTC is generally less useful for tumors of the distal bile duct. A good quality cross-sectional imaging study also is required, usually CT, to assess for vascular involvement and metastatic disease. CT commonly does not reveal a mass, however, because these tumors are frequently small at the time of presentation. MRCP increasingly is being used to evaluate periampullary tumors. As is true for hilar lesions, it can provide images of the distal bile duct previously obtainable only with direct cholangiography and without the need for invasive procedures (Georgopoulos et al, 1999). A dilated extrahepatic bile duct terminating abruptly at its distal aspect without a concomitantly dilated pancreatic duct suggests a distal bile duct carcinoma.

In patients with a stricture of the distal bile duct and a clinical presentation consistent with cholangiocarcinoma, histologic confirmation of malignancy is generally unnecessary, unless nonoperative therapy is planned. Benign strictures occur in the lower bile duct, but these are difficult to differentiate definitively from malignant strictures without resection. Percutaneous needle biopsy is difficult, often impossible, because of the small size of these tumors. In addition, endoscopic brushings of the bile duct have an unacceptably low sensitivity, making a negative result virtually useless (Ryan, 1991). Reliance on the results of percutaneous endoscopic US-guided fine needle aspiration or endoscopic brush biopsy serves only to delay operative therapy.

PREOPERATIVE EVALUATION AND MANAGEMENT

When a biliary tract malignancy is suspected on clinical and radiographic grounds, patient evaluation should turn toward an assessment of tumor resectability and of hepatic and overall physiologic reserve. The presence of significant comorbid conditions, chronic liver disease, or portal hypertension generally precludes resection. In patients not fit for operation, biliary drainage is an appropriate intervention to consider, and the diagnosis should be confirmed histologically if palliative therapies focused on local and systemic disease control are anticipated. Patients with potentially resectable tumors occasionally present with biliary tract sepsis, frequently after instrumentation of the biliary tree. These patients require resuscitation and treatment of the infection before operation can be considered. The preoperative evaluation must address the four crucial determinants of resectability: 1) extent of tumor within the biliary tree, 2) vascular involvement, 3) hepatic lobar atrophy, and 4) metastatic disease (Burke, 1998; Jarnagin et al, 2005).

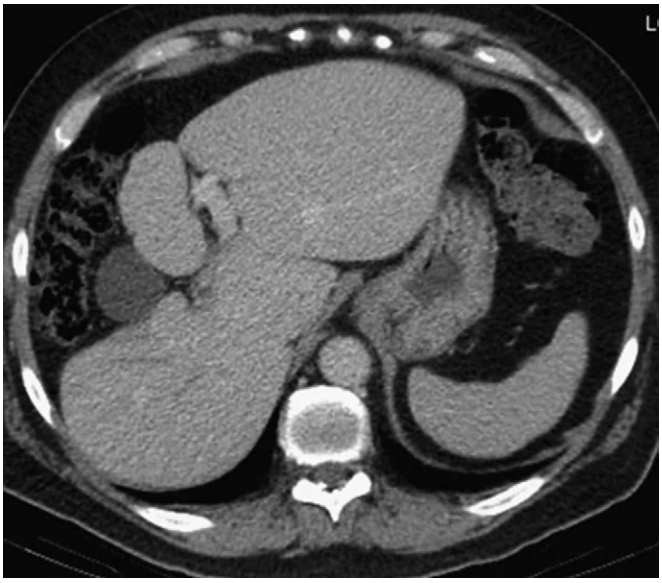

FIGURE 50B.10. Axial computed tomographic imaging demonstrates severe atrophy of the right anterior sector in a patient with a Bismuth type IV hilar cholangiocarcinoma that had invaded the respective sectoral portal vein selectively.

Lobar atrophy is an often overlooked or underappreciated finding in patients with hilar cholangiocarcinoma; however, its importance in determining resectability cannot be overemphasized, because it often influences therapy (Hadjis & Blumgart, 1987; see Chapter 5). Long-standing biliary obstruction may cause moderate atrophy, whereas concomitant portal venous compromise induces rapid and severe atrophy of the involved segments. On cross-sectional imaging, atrophy is characterized by a small, often hypoperfused lobe with crowding of the dilated intrahepatic ducts (Figs. 50B.10 and 50B.5B). The crucial determinants of resectability, including lobar atrophy, can be assessed with noninvasive studies that include cross-sectional imaging. Tumor involvement of the portal vein is usually present if compression, narrowing, encasement, or occlusion is seen on imaging studies.

Preoperative Biliary Drainage

Typically, patients with hilar cholangiocarcinoma will require major liver resection, so their preoperative management must be optimized carefully. Obstructive jaundice associated with perihilar cholangiocarcinoma differs from that associated with middle or distal bile duct cancer. In distal bile duct cancer, a single catheter is enough for biliary drainage, whereas in perihilar cholangiocarcinoma, multiple biliary drainage catheters of the future liver remnant may be necessary. Experienced centers have demonstrated excellent results with endoscopic biliary drainage, but controversy exists as to whether this technique should replace percutaneous transhepatic biliary drainage (Gholson & Burton, 1991; Polydorou et al, 1992; Speer et al, 1987). Endoscopic retrograde biliary drainage offers several advantages, including low procedure-related morbidity and mortality, shorter hospital stay, and improved patient comfort.

The limitations of endoscopic retrograde biliary drainage include a high incidence of cholangitis, especially when multiple obstructed ducts are instrumented but not subsequently drained (Andersen et al, 1989; Chang et al, 1998; Liu et al, 1998; Rerknimitr et al, 2004), and the difficulty in follow-up assessment of the extent of segmental duct involvement once an endobiliary stent is placed. Furthermore, control of which exact segmental ducts are cannulated is imperfect when performed endoscopically. For both endoscopic and percutaneous biliary drainage, a few guiding principles should be followed. The intrahepatic bile duct of the predicted future liver remnant (FLR) is intubated or punctured (Kawasaki et al, 2003; Seyama et al, 2003) and subsequently drained. If the FLR cannot be predicted with certainty in the preoperative setting, the left hepatic duct should be manipulated and drained (Fig. 50B.11). When the intrahepatic bile ducts are isolated into segmental units, PTC and multiple direct segmental transhepatic drainages may be necessary (Nagino et al, 1992; Nimura et al, 1995). If segmental cholangitis develops in patients with endoscopic or transhepatic biliary drainage catheters, urgent drainage of affected ducts should be attempted (Iyomasa et al, 1994; Sakamoto et al, 1995).

Clinical studies of biliary decompression have shown that external drainage has limited benefit, and that by preserving intestinal bile flow, the internal drainage is associated with more advantages (Clements et al, 1993). Superiority of internal drainage was shown in experimental studies, which showed that rat liver regeneration after partial hepatectomy is suppressed under external drainage but not under internal drainage (Saiki et al, 1999; Suzuki et al, 1994). Ogata and colleagues (2003) investigated bacterial translocation in bile duct–ligated rats, finding that bile replacement is essential to maintain intestinal barrier function. Impaired intestinal barrier function does not recover by percutaneous biliary drainage (PBD) without bile replacement. Bile replacement can restore the intestinal barrier function primarily as a result of repair of physical damage to the intestinal mucosa. Bile replacement during external biliary drainage should be recommended for planned hepatectomy for hilar cholangiocarcinoma because of the substantial infectious morbidity associated with these resections.

Many retrospective reports (Denning et al, 1981; Gundy et al, 1994; Nakayama et al, 1978; Norlander et al, 1982) support preoperative biliary drainage, whereas several older, prospective randomized studies (Hatfield et al, 1982; McPherson et al, 1984; Pitt et al, 1985) concluded that drainage did not reduce overall morbidity and mortality following management of proximal cholangiocarcinoma. The pertinence of the these cited randomized studies is questionable, as few major hepatectomies were included in these trials, and preoperative biliary drainage procedures were associated with unexpectedly high morbidity and mortality rates. In addition to accurate assessment of bile duct involvement, preoperative biliary drainage improves cholestatic liver disease and affords safer performance of hepatectomy for hilar cholangiocarcinoma. Lastly, the volume of the future liver remnant should be assessed prior to drainage, because with an atrophic hemiliver, very little functional liver may be removed with the resection, and performance of the operation without drainage should be considered (Kennedy et al, 2009).

FIGURE 50B.11. A percutaneous transhepatic cholangiogram (PTC) shows a left hepatic duct stricture with no apparent isolation of the segment IV and left lateral ducts. PTC guides safe placement of a percutaneous biliary drain, which can permit internalization of bile flow.

Three-Dimensional Computed Tomography

Advances in helical CT technology, such as multiple simultaneous detectors and subsecond rotation, have shown unparalleled capabilities for fast data acquisition and narrow collimation (see Chapter 16). Multidetector CT permits the acquisition of three distinct circulatory phases—arterial, portal, and late venous—in the pancreatobiliary and intrahepatic regions with 1-mm collimation. These isotropic volume data allow generation of high-quality three-dimensional images with CT arteriography, CT cholangiopancreatography, and CT portography in a single scanning session (Itoh et al, 2005).

CT is now a mainstay in the preoperative diagnostic evaluation for patients with perihilar cholangiocarcinoma, and it provides information on resectability and planning of the operation. Three-dimensional understanding of the main hepatic artery distribution may facilitate skeletonization of the hepatoduodenal ligament, and understanding of the intrahepatic artery branching is helpful during resection of the segmental or subsegmental bile ducts as the final step of resection. Hepatobiliary surgeons must appreciate two variations of the hepatic artery distribution: One is the left hepatic artery running right to the umbilical portion of the left portal vein, the other is a posterior branch of the right hepatic artery running cranially to the right portal trunk. Careful attention should be paid to the former variant in extended right hepatectomy with caudate lobectomy, and the same applies to the latter variant in extended left hepatectomy with caudate lobectomy (see Chapter 1B).

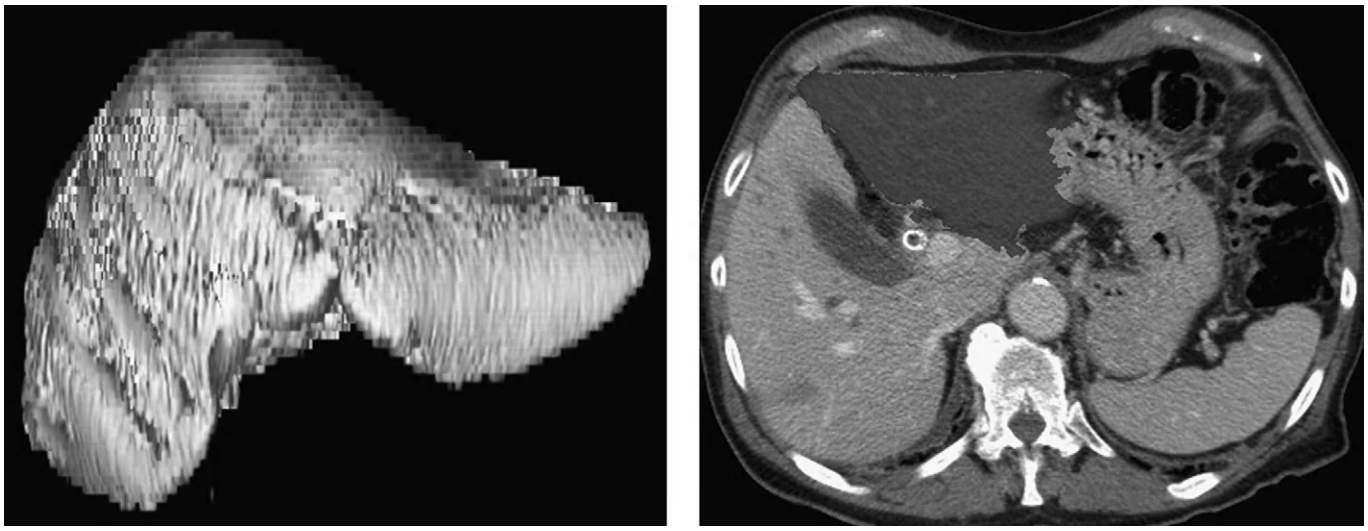

FIGURE 50B.12. Thin-slice, contrast-enhanced computed tomographic imaging can be reformatted into volume-averaged three-dimensional models. Operative planning for the future liver remnant (FLR) allows a calculation of the residual functional liver parenchyma, following hepatic resection, as a percentage of the total liver volume. Here a right trisectorectomy with caudate resection is planned with the FLR consisting of segments II and III only (*shaded area*). In this patient, the FLR represented 22% of the total liver volume prior to portal vein embolization.

Unilateral involvement of the hepatic artery is compatible with resection (Williamson et al, 1980). Bilateral involvement of the hepatic artery usually is associated with nonresectability, when the tumor is located mainly on the right. Hepatic arterial reconstruction to accomplish a complete resection should be reserved for highly selected patients with potentially curable disease. Similarly, although not an absolute contraindication for resection of hilar cholangiocarcinoma, main portal vein invasion will preclude a complete resection with long-term benefit for the majority of patients (Blumgart et al, 1984; Hoevels & Ihse, 1979; Launois et al, 1979; Williamson et al, 1980). Despite the poor prognosis associated with main portal vein invasion in general, several groups have reported reasonable long-term outcomes with portal vein resection for advanced biliary cancer (Ebata et al, 2003; Miyazaki et al, 1998a; Nimura et al, 1991a; Sakaguchi & Nakamura, 1986).

Three-dimensional CT also offers the capacity to generate volumetric models of the total liver for planned hepatic resection and FLR (Fig. 50B.12). Because patients subjected to resection of more than 75% of functional liver parenchyma have substantially higher risk of postoperative liver failure regardless of existing cholestatic liver disease, routine preoperative volumetry may help to identify and select candidates for biliary drainage and portal vein embolization (PVE) who may be at considerable risk for postoperative morbidity and mortality.

Portal Vein Embolization

Devised by Makuuchi and colleagues (1990) and Kinoshita and colleagues (1986), PVE has become important in the presurgical management of patients who are to undergo extensive liver resection (see Chapter 93). The purpose of PVE is to increase the functional liver mass by inducing compensatory hypertrophy in the FLR. The ultimate goal of PVE is to minimize postoperative liver dysfunction, which contributes to mortality. PVE may be approached in two ways: the *percutaneous approach*, or *percutaneous transhepatic portal vein embolization* (PTPE) (Baere et al, 1993; Kinoshita et al, 1986), and the *transileocolic approach*, or *transileocolic PVE* (Makuuchi et al, 1990). PTPE can be accomplished with coil and/or microparticle embolization (Fig. 50B.13) and has established itself as the superior technique for several reasons, two of which are the avoidance of a laparotomy and avoidance of general anesthesia.

FIGURE 50B.13. Portal vein embolization can be utilized to induce hypertrophy of the planned functional liver remnant (*FLR*) after major hepatectomy for hilar bile duct cancer. Percutaneous transhepatic embolization is the most widely used technique. In this patient, right portal vein branches were coil embolized 4 weeks prior to a planned right hepatectomy. Three-dimensional volumetric calculations of the planned FLR were analyzed before and after embolization.

PTPE can produce a sizable compensatory hypertrophy of the nonembolized segments of the liver (Baere et al, 1993; Kawasaki et al, 1994; Nagino et al, 1995; Nagino, 2006). In right PVE, the volume of the left lobe increases by 130 cm^3 on average within 2 weeks after embolization, and the estimated resection volume decreases by an average of approximately 10% (Nagino et al, 1995). Many case series have reported the clinical value of PVE (Abdalla et al, 2002; Elias et al, 2002; Farges et al, 2003; Hemming et al, 2003; Kawasaki et al, 2003; Nagino, 2006). A single prospective trial in patients undergoing right hemihepatectomy demonstrated a benefit in patients with chronic liver disease, but no benefit was reported in patients with normal livers (Farges et al, 2003), thus indications for PVE remain somewhat arbitrary.

Preoperative Staging

Historically, no clinical staging system was available to stratify patients preoperatively into subgroups based on potential for resection. The modified Bismuth-Corlette classification stratifies patients based on the extent of biliary duct involvement by tumor alone (Fig. 50B.14; Bismuth et al, 1992). Although useful to some extent, it does not predict resectability or survival. The American Joint Commission for Cancer (AJCC) tumor-node-metastais (TNM) staging system (Table 50B.1) is based largely on pathologic criteria and has little relevance to preoperative staging, because it can only be determined after resection. The ideal staging system should accurately predict resectability, the need for hepatic resection, and survival. Such a system would assist the surgeon in formulating a treatment plan, and it would help the patient understand the treatment options and likely outcome. Jarnagin and colleagues (2001) proposed such a system, one that improves characterization of tumor extent by taking into account all of the available preoperative data related to local tumor extent including 1) extent of tumor within the biliary tree, 2) vascular involvement, and 3) lobar atrophy. Using such an approach, it is possible to stage tumors preoperatively in a way that correlates with resectability and outcome. This preoperative T-staging system is based on the extent of local disease regardless of N or M status (Table 50B.2; Jarnagin et al, 2001). Longitudinal ductal tumor extension can be assessed by either MRCP, ERCP, or PTC. Duplex US and CT may be useful for assessing radial spread of tumor (Hann et al, 1997, 1998; Voyles et al, 1983).

This preoperative clinical staging system has been compared with the AJCC classification in a series of 87 patients with cholangiocarcinoma, with no correlation seen between AJCC stage and resectability or median survival (Burke, 1998; Jarnagin et al, 2001). By contrast, the proposed staging system correlated closely with resectability, which was highest in the T1

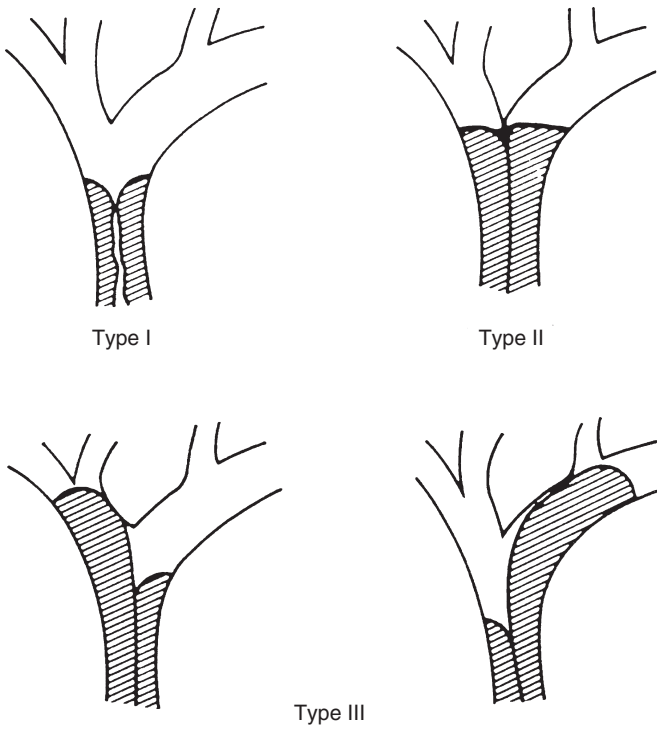

FIGURE 50B.14. Bismuth-Corlette classification scheme of biliary strictures.

Table 50B.1

AJCC Staging System (Seventh Edition) of Hilar Bile Duct Cancer

Primary Tumor (pT)

pTX:	Cannot be assessed
pT0:	No evidence of primary tumor
pTis:	Carcinoma in situ
pT1:	Tumor confined to the bile duct with extension up to the muscle layer or fibrous tissue
pT2a:	Tumor invades beyond the wall of the bile duct to surrounding adipose tissue
pT2b:	Tumor invades adjacent hepatic parenchyma
pT3:	Tumor invades unilateral branches of the portal vein or hepatic artery
pT4:	Tumor invades main portal vein or its branches bilaterally; or the common hepatic artery; or the second-order biliary radicals bilaterally; or unilateral second-order biliary radicals with contralateral portal vein or hepatic artery involvement

Regional Lymph Nodes (pN)

pNX:	Cannot be assessed
pN0:	No regional lymph node metastasis
pN1:	Regional lymph node metastasis (including nodes along the cystic duct, common bile duct, hepatic artery, and portal vein)
pN2:	Metastasis to periaortic, pericaval, superior mesentery artery, and/or celiac artery lymph nodes

Distant Metastasis (pM)

pMx:	Cannot be assessed
pM1:	Distant metastases present

Stage Groupings

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2a or T2b	N0	M0
Stage IIIa	T3	N0	M0
Stage IIIb	T1, T2, or T3	N1	M0
Stage IVa	T4	N0 or N1	M0
Stage IVb	Any T	N2	M0 or M1
	Any T	Any N	M1

Table 50B.2

Preoperative Tumor Staging System for Hilar Cholangiocarcinoma

Stage	Criteria
T1	Tumor involving biliary confluence ± unilateral extension to two biliary radicles
T2	Tumor involving biliary confluence ± unilateral extension to two biliary radicles and *ipsilateral* portal vein involvement ± ipsilateral hepatic lobar atrophy
T3	Tumor involving biliary confluence + bilateral extension to two biliary radicles or unilateral extension to two biliary radicles with contralateral portal vein involvement or unilateral extension to two biliary radicles with contralateral hepatic lobar atrophy or main or bilateral portal venous involvement

From Jarnagin WR, et al, 2001: Staging, resectability, and outcome in 225 patients with hilar cholangiocarcinoma. Ann Surg 234:507-519.

group (59%) and decreased progressively to 0 in the T3 group (nonresectable because of extent of local disease). Other related variables also correlated with T stage, including the likelihood of an R0 resection, presence of metastatic disease, the need for partial hepatectomy, and survival (Table 50B.3). The clinical T-stage grouping was an independent predictor not only of resectability but also of the likelihood of achieving an R0 resection. The proposed clinical staging scheme underscores the importance of considering portal vein involvement and liver atrophy in relation to the extent of ductal cancer spread. Ipsilateral involvement of vessels and bile ducts is usually amenable to resection, whereas contralateral involvement is not.

Despite advances in imaging technology, a large proportion of patients with hilar cholangiocarcinoma are found to have unresectable disease at the time of exploration. Hilar cholangiocarcinoma previously was considered more of a locally invasive disease uncommonly associated with metastases. However, in a report of 225 patients, 73 (32%) had unresectable disease; of the 160 patients submitted to exploration, 47 (29%) had metastases discovered intraoperatively that precluded a curative resection (Jarnagin et al, 2001). Given the high rate of nontherapeutic laparotomy, staging laparoscopy has been investigated as a means of improving resectability and seems to have a defined role.

Early studies examined the role of laparoscopy combined with laparoscopic US in a mixture of hepatobiliary and pancreatic malignancies and detected occult metastases in 30% to 35% of patients (Callery et al, 1997; D'Angelica et al, 2003; Jarnagin et al, 2000), but these studies included a small proportion of patients with hilar cholangiocarcinoma. Two studies showed the utility of staging laparoscopy in patients with biliary tract cancer. In a study that included 23 patients with hilar and distal cholangiocarcinoma, Vollmer and colleagues (2002) reported that laparoscopy identified 57% of patients with unresectable disease and improved resectability by 14%. Another study analyzed 56 patients, all with hilar cholangiocarcinoma, and showed similar benefit; it further showed that the yield of laparoscopy is greatest in patients with more locally advanced tumors (i.e., clinical stage T2 and T3; Weber et al, 2002). Whether fluorodeoxyglucose positron-emission tomography (FDG PET) has a role in preoperative staging is unclear (see Chapter 15). Several studies have suggested that FDG PET may identify occult metastatic disease or advanced regional lymphadenopathy (N2 disease) in a significant proportion of patients (Anderson et al, 2004; Fritscher-Ravens et al, 2001; Kluge et al, 2001); however, larger confirmatory studies are necessary before FDG PET can be recommended as routine.

As mentioned earlier, both direct cholangiography of segmental ducts and percutaneous cholangioscopy have been used to increase resectability rates for hilar cholangiocarcinoma (Kondo et al, 2004; Nimura et al, 2000). Definition of proximal and distal cancer extent and early detection of small lesions and multiple foci of cancer can be accomplished by cholangioscopic observation followed by biopsy and histologic confirmation (Nimura et al, 1988).

TREATMENT

Most patients with unresectable bile duct cancer die within 6 months to 1 year of diagnosis. Death usually results from liver failure or infectious complications secondary to biliary obstruction (Burke, 1998; Kuwayti et al, 1957; Okuda et al, 1977; Sako et al, 1957). In patients with unresectable disease, the prognosis has been considered worse for tumors affecting the confluence of the bile ducts and better for distal tumors close to the papilla. This difference in prognosis may reflect the relatively later presentation and the complexity of managing hilar biliary obstruction rather than a difference in biologic behavior. It has been shown that location within the biliary tree (proximal versus distal) has no impact on survival, provided complete resection is achieved (Allen et al, 2008; Nagorney et al, 1993).

Complete resection is the only effective therapy for cancers of the lower bile duct (Fong et al, 1996; Nagorney et al, 1993;

Table 50B.3

Correlation of Proposed Clinical Tumor Staging System with Resectability, Metastatic Disease, and Survival

T Stage	No. Patients	Explored with Curative Intent	Resected	R0 Resection	Hepatic Resection*	Metastatic Disease	Median Survival (mo)†
1	87	73 (84%)	51 (59%)	38 (44%)	33 (65%)*	18 (21%)	20
2	95	79 (83%)	29 (31%)	24 (25%)	29 (100%)*	40 (43%)	13
3	37	8 (22%)	0	0	0	15 (41%)	8
Total	219	160 (71%)	80 (37%)	62 (28%)	62 (78%)*	73 (33%)	16

*Percentage figures for hepatic resection represent the proportion of all resections; all other percentage figures represent the proportion of the total number of patients within each stage group.

†Median survival for all patients within each stage group, including patients not submitted to resection

From Jarnagin WR, et al, 2001: Staging, resectability, and outcome in 225 patients with hilar cholangiocarcinoma. Ann Surg 234:507-519.

Nakeeb et al, 1996b; Tompkins et al, 1981; Wade et al, 1997; Yeo et al, 1997). Meaningful experience with these relatively uncommon tumors has been limited to a few centers. In reports containing significant numbers of patients, 5-year survival rates of 40% have been reported after complete resection. In most studies, survival beyond 1 year was uncommon in patients subjected to palliative bypass or biliary intubation (Fong et al, 1996; Nakeeb et al, 1996b; Tompkins et al, 1981; Wade et al, 1997).

Operative Resection for Hilar Cholangiocarcinoma

The two objectives in the therapy of hilar cholangiocarcinoma are complete tumor excision with negative margins if possible and restoration of biliary-enteric continuity from an adequate liver remnant. Patients should be evaluated fully for possible curative resection before any intervention is performed, because stent-associated infection and inflammation renders assessment and exploration difficult. If resection is clearly not feasible, biliary drainage with some form of endoluminal or transhepatic stenting offers satisfactory palliation, and this can be combined with nonoperative measures to control local tumor growth.

Orthotopic liver transplantation has been attempted for hilar cholangiocarcinoma considered unresectable (see Chapter 97E). Klempnauer and colleagues (1997b) reported four long-term survivors out of 32 patients who underwent transplantation for hilar cholangiocarcinoma. The same group also reported a 5-year survival of 17% for their overall transplant group (Pichlmayr et al, 1996). Iwatsuki and colleagues (1998) reported comparable results. Data from the Mayo Clinic suggest good results with transplantation in highly selected patients with no metastatic disease on imaging or at laparotomy when combined with an intensive pretransplant treatment regimen that includes chemoradiotherapy (Heimbach et al, 2004; Rea et al, 2005). Although the data are compelling, this approach is applicable to only a small fraction of patients because of the high incidence of lymph node metastases and distant occult metastases.

In patients with potentially resectable tumors based on preoperative imaging, the primary goal should be complete resection with intent to cure. Our criterion for curative resection is complete removal of all gross disease with clear histologic margins (R0 resection). Achieving an R0 resection almost always requires a partial hepatectomy for hilar cholangiocarcinoma (Jarnagin et al, 2001). Bile duct excision with en bloc partial hepatectomy, often with en bloc caudate lobectomy (Nimura et al, 1990), is frequently necessary to achieve negative histologic margins.

Several studies show a parallel between the number of patients undergoing partial hepatectomy and negative resection margins (Table 50B.4). We routinely use hepatic resection but perform caudate resection selectively in cases with suggested tumor extension into the ducts of the caudate lobe. The principal caudate lobe ducts drain into the left hepatic duct, and tumors extending into the left hepatic duct almost always involve the caudate duct and usually require caudate resection (Mizumoto & Suzuki, 1988). A dilated caudate duct suggestive of tumor involvement may occasionally be seen on preoperative imaging. In some cases, intraoperative frozen section of the caudate duct margin may help in making the decision to proceed to caudate resection. The importance of negative resection margins for long-term survival is confirmed by the results of several studies (see Table 50B.4). In the MSKCC experience, survival after an R1 resection (histologically involved resection margins) is similar to survival in patients with unresectable, locally advanced tumors identified at exploration (Fig. 50B.15; Endo et al, 2008b; Jarnagin et al, 2001).

Table 50B.4

Influence of Partial Hepatectomy on Histologic Margins in Patients Who Underwent a Potentially Curative Resection for Hilar Cholangiocarcinoma

Reference	Potentially Curative Resection (No.)	Hepatectomy (%)	Negative Margins (%)
Cameron et al, 1990	39	20	15
Tsao et al, 2000	25	16	28
Hadjis et al, 1990	27	60	56
Neuhaus et al, 1999	95	85	61

Nimura et al, 1990	55	98	83

Distinguishing resectable from nonresectable tumors demands careful consideration of all available clinical and imaging data. Bilateral tumor extension to second-order intrahepatic biliary radicles and, in many patients, encasement or occlusion of the main portal vein preclude a resection. The individual determinants of resectability must be considered within the context of all of the imaging findings. Ipsilateral involvement of the portal vein and bile ducts may be amenable to resection, whereas contralateral involvement usually is not. Likewise, ipsilateral lobar atrophy does not preclude resection, whereas atrophy of the contralateral lobe does. Other factors that influence resectability include the presence of significant comorbid medical conditions, significant hepatic parenchymal disease, and distant metastatic spread of tumor (Table 50B.5).

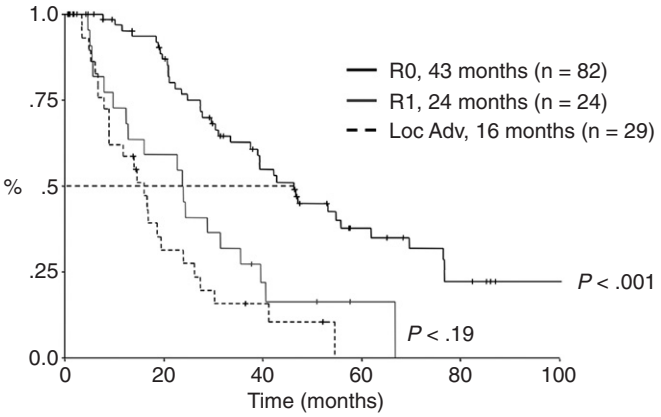

FIGURE 50B.15. Actuarial survival curves after resection of hilar cholangiocarcinoma. *R0* indicates complete resection with histologically negative resection margins (median survival, 43 months). *R1* indicates histologically involved resection margins (median survival 24 months; $P < .001$ R0 vs. R1). *Loc Adv* indicates a patient explored but found to have unresectable tumors owing to local invasion (no metastatic disease; median survival, 16 months; $P < .19$ R1 vs. Loc Adv).

Table 50B.5

Criteria of Nonresectability in Patients with Hilar Cholangiocarcinoma

Patient Factors
Medically unfit for operation
Cirrhosis/portal hypertension
Local Factors
Hepatic duct involvement up to secondary radicles bilaterally
Encasement or occlusion of the main portal vein proximal to its bifurcation
Atrophy of one lobe with encasement of contralateral portal vein branch
Atrophy of one lobe with contralateral involvement of secondary biliary radicles
Distant Disease
Histologically proven metastases to lymph node groups beyond the hepatoduodenal ligament (celiac, paraaortic, retropancreatic)
Histologically proven metastases to liver, lung, or peritoneum

Invasion of the main portal vein or its branches by tumor is a major determinant of resectability. The preoperative assessment of vascular involvement and ductal extension of tumor is an essential part of operative planning and gives valuable information to the surgeon with respect to the extent of operation and operative strategy. Limited tumor involvement of the portal venous confluence or the main portal vein may be amenable to resection and portal vein reconstruction (see Chapter 91B).

Several technical steps during the exploration and resection of hilar cholangiocarcinoma are crucial to the success of the operation. Local resection—that is, resection of the extrahepatic biliary apparatus without concomitant partial hepatectomy—for small Bismuth-Corlette type I tumors not involving the major vessels may be possible. In this situation, resection must include removal of the entire supraduodenal bile duct, gallbladder, cystic duct, and extrahepatic hepatic ducts with clearance of the supraduodenal tissues, including the related lymph nodes. Even if a complete resection can be achieved without an en bloc partial hepatectomy, such local resections seem to be inferior with respect to long-term survival. In 106 resections at MSKCC, 19 were local resections, and 9 of these were considered complete or R0; however, no patient submitted to an R0 bile duct resection was among the 5-year survivors (Jarnagin et al, 2005). In most patients, the option of a local resection does not exist, however, because of intrahepatic extension of the tumor, right or left portal vein involvement, or both. In these cases, en bloc liver resection, often with caudate lobectomy, is necessary to achieve tumor clearance. In some patients, tumor adherence to the portal vein can be managed by segmental portal vein resection and reconstruction (Blumgart et al, 1984; Neuhaus et al, 1999; Nimura et al, 1991b). This procedure can be done only if intraoperative assessment shows that a tumor-free remnant with intact biliary drainage and blood supply can be left in situ. Some centrally located tumors may be amenable to a more limited hepatic resection. Such resections, which include segments IV and V or IV and I, are limited in their application (Grune et al, 1991; Miyakawa et al, 1996; Miyazaki et al, 1998a, 1998b) and are inappropriate in the face of lobar atrophy and involvement of a main portal vein branch, both of which are common findings.

Operative exploration is carried out through a right subcostal incision with proximal extension to the xiphoid, a so-called "hockey stick" incision. The exploration should begin with a thorough inspection of the peritoneal cavity and distant nodal sites, because metastatic disease is common in patients with hilar cholangiocarcinoma. In our experience, 73 (50%) of 145 unresectable patients had metastases to regional lymph nodes or distant sites (Jarnagin et al, 2001). These findings are supported by results from other series (Cameron et al, 1990; Lai et al, 1987). Careful bimanual palpation of the liver and intraoperative US are performed to rule out unsuspected masses in the liver. Palpation of the caudate lobe is performed after incision of the lesser omentum, allowing access to the lesser sac. A Kocher maneuver is performed to allow access to the retroduodenal lymph nodes, and the ligamentum teres is elevated, exposing the undersurface of the liver and allowing thorough examination of the subhilar and retroduodenal area. Precise assessment of tumor extension and biopsy of any suspicious lesions or distant lymph nodes with frozen-section analysis should be performed. Evidence of intrahepatic metastases, multicentricity within the liver, or spread to distant sites precludes resection. With any of these findings, the patient should be considered for palliative biliary drainage.

Although a segmental bile duct resection and biliary reconstruction are possible in some patients, most require partial hepatectomy to achieve complete tumor clearance. In all cases, the surgeon must be prepared to perform a liver resection. The general principles of intraoperative management are discussed in detail in other chapters within this text (see Chapters 90 and 91). Preparation for surgery includes suitable intraoperative monitoring and the possibility for rapid transfusion. The patient's central venous pressure is kept at less than 5 mm Hg during the operation to keep blood loss from hepatic veins at a minimum during retrohepatic dissection, dissection of the hepatic veins, and parenchymal transection (Cunningham et al, 1994; Melendez et al, 1998).

The following description summarizes the initial steps of dissection, exposure of the hilar structures, dissection and resection of the hilar structures, and subsequent biliary-enteric reconstruction as performed for a segmental bile duct resection. The specifics of en bloc liver resection, including caudate lobectomy, are discussed in other chapters.

To reach the confluence of the bile ducts and assess its relationship to the portal vein, the common bile duct first must be transected above the duodenum and turned upward. The liver hilus is fully exposed anteriorly by taking down the gallbladder and lowering the hilar plate by incising the Glisson capsule along the base of segment IV. Exposure of the left hepatic duct is improved by dividing the bridge of liver tissue that often connects the base of segment IV and the left lateral segment; this may be quite substantial in some patients. The entire extrahepatic biliary apparatus and adjacent lymphatic tissues are turned upward to expose the portal vein. A plane can be developed easily between the posterior aspect of the bile duct tumor and the portal vein, provided no tumor has invaded into the vessels (Fig. 50B.16). The dissection is continued upward toward the hilus, skeletonizing the portal vein and hepatic artery.

At this point, the surgeon should assess the proximal extent of tumor by palpation and, if necessary, by biopsy. Segmental bile duct resection is possible only if an adequate length of the hepatic ducts can be achieved beyond the tumor, and if no vascular involvement is evident. If the tumor extends to the

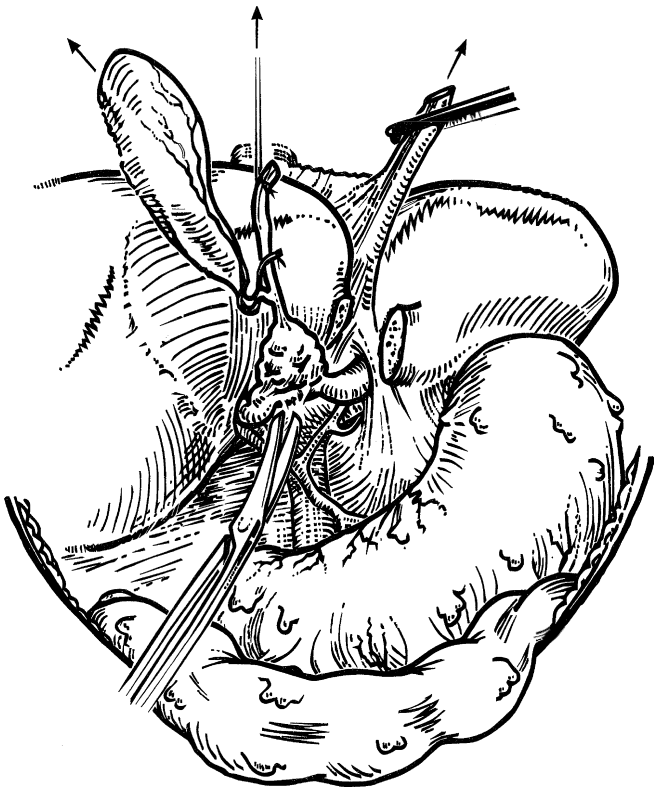

FIGURE 50B.16. The entire extrahepatic biliary apparatus is elevated together with associated portal connective tissue and nodes to allow dissection anterior to the bifurcation of the portal vein and elevation of the tumor, which is now completely mobilized. The hepatic artery and portal vein are skeletonized.

second-order biliary radicles unilaterally such that clearance cannot be achieved, or if the ipsilateral portal vein branch is involved, partial hepatectomy must be performed. Tumors extending well into the left hepatic duct may involve the caudate ducts as well and require en bloc caudate lobectomy (Mizumoto et al, 1986; Mizumoto & Suzuki, 1988). If partial hepatectomy is required, inflow control is obtained by ligation and transection of the ipsilateral branch of the portal vein and hepatic artery. Extrahepatic control and division of the ipsilateral hepatic vein are performed before parenchymal transection.

When it has been established that segmental bile duct excision is feasible and will result in an R0 resection, the left and right hepatic ducts are divided above the tumor. Occasionally, unresectability as a result of main portal vein invasion or extensive bilateral intrahepatic duct involvement (see Table 50B.5) will not be determined until the extrahepatic biliary tree has been divided and mobilized. In both of these situations, biliary-enteric continuity is restored by hepaticojejunostomy to a Roux-en-Y loop of jejunum. When residual disease remains at the final level of the transected duct, appropriate consideration should be made for placement of retrograde transhepatic biliary stents (Fig. 50B.17). After removal of the tumor, the surgeon may be faced with multiple exposed duct orifices, all of which require suitable drainage (see Chapters 29 and 42A). Frequently, removal of the tumor results in discontinuity of the right anterior and posterior sectoral ducts, separation of one or more caudate ducts from the left hepatic duct, or both. The sidewalls of adjacent ducts can be brought into apposition with sutures and regarded as a single duct for purposes of anastomosis. In cases of multiple exposed ducts, it is often possible to make it so that no more than two or three separate ducts need to be anastomosed. A Roux-en-Y loop of jejunum is prepared and brought up, usually in a retrocolic fashion, and anastomosis is carried out in an end-to-side fashion between the exposed ducts and the side of the jejunal loop using a single layer of 4-0 interrupted polyglactin 910 (Vicryl) sutures (Blumgart & Kelley, 1985; Voyles & Blumgart, 1982). Anastomotic techniques are illustrated and discussed in more detail in other chapters.

High biliary anastomoses to multiple ducts can be exceedingly difficult and require careful planning. Multiple disconnected ducts that cannot be approximated should be similarly viewed as a single duct for purposes of the anastomosis. It is usually impossible to perform sequential anastomoses in this location. The safest and most reliable method is to place the entire anterior row of sutures to all exposed ducts and separately place the entire posterior row of sutures to the duct and jejunum. The jejunum is railroaded up on the posterior sutures so that the back wall of the duct is flush with the back wall of the jejunum. The posterior layer of sutures to all exposed ducts is tied first, and the previously placed anterior sutures are passed sequentially through the anterior jejunal wall to complete the anastomosis. We routinely employ dependent drainage near the anastomosis.

Operative Resection for Distal Cholangiocarcinoma

Resection of most distal bile duct cancers requires pancreatoduodenectomy (see Chapter 62A). Compared with patients with pancreatic cancer, those with distal bile duct cancer are more often amenable to resection, less often have microscopic disease at the resection margin, and less frequently have spread of tumor to adjacent lymph nodes (Fong et al, 1996; Nakeeb et al, 1996a, 1996b; Yeo et al, 1997). In addition to completeness of resection, lymph node status is a crucial determinant of outcome. Fong and colleagues (1996) found that lymph node status was the only independent predictor of long-term survival in resected patients, with positive nodes conferring a 6.7 times greater likelihood of recurrence and death. Similarly, Wade and colleagues (1997) identified no survivors beyond 3 years with involved regional lymph nodes, and Nakeeb and colleagues (1996a, 1996b) found that lymph node status and tumor differentiation were independent predictors of outcome.

OUTCOMES AFTER OPERATION

Long-term survival can be achieved with an acceptable operative mortality (Ahrendt et al, 1998; Baer et al, 1993; Hadjis et al, 1990; Hasegawa et al, 2007; Haswell-Elkins et al, 1991; Hemming et al, 2005; Jarnagin et al, 2001; Klempnauer et al, 1997a; Kondo et al, 2004; Nagata et al, 1990; Nagorney et al, 1993; Nakeeb et al, 1996a, 1996b; Neuhaus et al, 1999; Nimura et al, 1990, 2000; Parc et al, 1997; Pichlmayr et al, 1996; Rosen et al, 1991; Sano et al, 2006; Wolber et al, 1991). Five-year survival rates range from 25% to 40%, and status of the resection margins is crucial to obtaining such results. Several studies have shown that patients resected with negative histologic margins survive significantly longer than those with involved

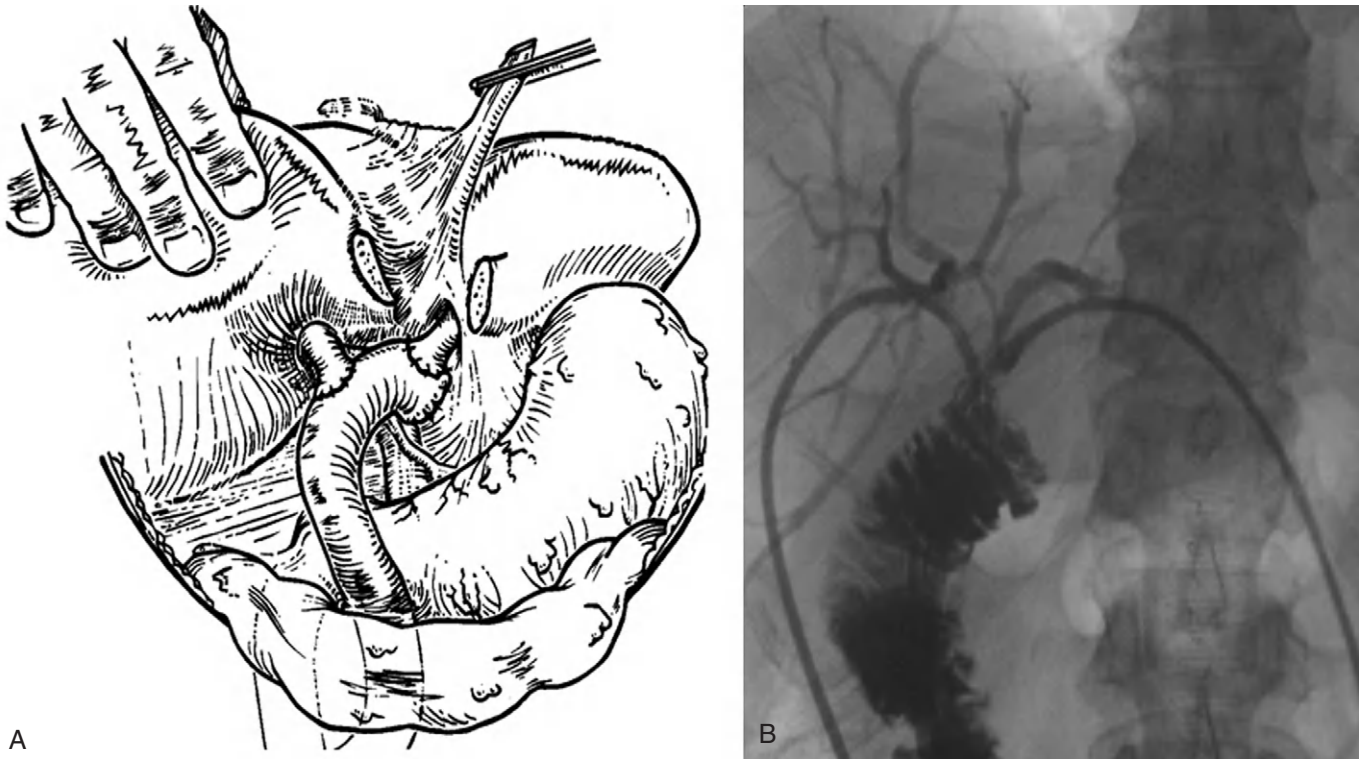

FIGURE 50B.17. A, In rare circumstances, the extrahepatic biliary tree can be excised alone with curative intent without the need for partial hepatectomy. In other situations, tumor unresectability may not be determined until the extrahepatic bile ducts are divided. The exposed right and left hepatic ducts are anastomosed individually to a retrocolic Roux-en-Y loop of jejunum. **B,** Retrograde transhepatic biliary stents can be passed at the time of operation to provide long-term palliation of obstructive jaundice and facilitate photodynamic therapy.

margins (Ahrendt et al, 1998; Endo et al, 2008b; Hadjis et al, 1990; Jarnagin et al, 2001; Lupi et al, 1990; Pichlmayr et al, 1996).

Since the 1980s, the use of hepatic resection in patients with hilar cholangiocarcinoma has increased steadily. We believe this increase is responsible for the increase in the percentage of R0 resections (negative histologic margins) and the observed improvement in survival after resection (Saldinger & Blumgart, 2000). In addition to status of the resection margin, many other variables have been shown to have an impact on outcome, including tumor involvement of regional lymph nodes, tumor grade or differentiation, and tumor morphology (e.g., papillary versus nodular sclerosing) (Ebata et al, 2003; Jarnagin et al, 2005). The issue of lymph node metastases, their impact on outcome, and extent of lymphadenectomy remain points of some controversy. Some authors have reported long-term survivors, even with involved paraaortic lymph nodes, and have argued for extended lymphadenectomy as a routine part of the resection procedure (Kitagawa et al, 2001). Examination of several series in which 5-year survival is documented suggests, however, that involved lymph nodes are a powerful adverse prognostic variable. We do not advocate extended lymph node dissection, and we consider metastatic involvement of distant lymph node basins (N2 disease) to represent unresectable disease.

In many prior studies, the operative mortality associated with hilar cholangiocarcinoma, including partial hepatectomy, was on the order of 10%. In an effort to improve these figures, numerous centers have adopted an approach that combines extensive preoperative biliary drainage and PVE, as discussed previously. Using such an approach, Sano and colleagues (2006) reported 102 consecutive resections without operative mortality. A major rationale for using these preoperative procedures is to reduce the incidence of postoperative hepatic failure associated with extended resections in the setting of biliary obstruction.

The combined data from the literature suggest that survival after resection of adenocarcinoma of the distal bile duct is at least as good as and probably better than that for pancreatic cancer (Fong et al, 1996; Wade et al, 1997). It has long been assumed that survival after resection of distal bile duct tumors is greater than after resection of hilar cholangiocarcinomas (Tompkins et al, 1981). This assumption is almost certainly erroneous and likely evolved from older reports that did not take into account the status of resection margins in patients with hilar tumors. If adjusted for stage and completeness of resection, the survival rates seem to be comparable (Allen et al, 2008; Nagorney et al, 1993).

ADJUVANT THERAPY AFTER OPERATIVE RESECTION

Several single-arm studies have investigated the benefit of postoperative adjuvant radiation therapy in patients with hilar cholangiocarcinoma. Two separate reports from Johns Hopkins (Cameron et al, 1990; Pitt et al, 1995b) showed no benefit of adjuvant external beam and intraluminal radiation therapy. Kamada and associates (1996) suggested that radiation might improve survival in patients with histologically positive hepatic duct margins. Additionally, in a small series of patients (five

with hilar cholangiocarcinoma), resectability was reportedly greater in patients given neoadjuvant radiation therapy before exploration (McMasters et al, 1997). None of these studies was randomized, however, and most consist of a small, heterogeneous group of patients. At present, no data are available to support the routine use of adjuvant or neoadjuvant radiation therapy except in the context of a controlled trial.

Takada and associates (2002) reported results of a Phase III multicenter randomized study evaluating the potential benefit of adjuvant systemic chemotherapy after resection of pancreatobiliary tumors. This study found no benefit of adjuvant systemic 5-fluorouracil (5-FU) and mitomycin C compared with surgery alone for patients with bile duct carcinoma. Whether newer agents, such as gemcitabine and/or oxaliplatin, have a role in the adjuvant setting remains to be determined.

Adjuvant therapy (chemotherapy and/or radiation therapy) after resection has not been shown to improve survival for distal bile duct cancer, although this issue has not been evaluated in a prospective fashion for a homogeneous population of patients with distal cholangiocarcinoma only (Nakeeb et al, 1996b).

PALLIATIVE THERAPY

Most patients with hilar cholangiocarcinoma are not suitable for resection. In this setting, management options include some form of biliary decompression or supportive care. Jaundice alone, without pruritus or cholangitis, is not an indication for biliary decompression. For biliary decompression in inoperable patients, our current indications are to relieve intractable pruritus, treat cholangitis, gain access for intraluminal radiotherapy, and allow recovery of hepatic parenchymal function in patients who are potential candidates for chemotherapy. Supportive care alone is probably the best approach for elderly patients with significant comorbid conditions, provided that pruritus is not a major feature. Patients who are found to be unresectable at operation represent a different group, and operative biliary decompression usually is performed successfully (Burke, 1998) and can be constructed to provide access to the biliary tree for postoperative irradiation (see Fig. 50B.17; Kuvshinoff et al, 1995).

Assessment of palliative biliary drainage procedures is difficult, because the spectrum of patients ranges from those critically ill and unresectable to those in relatively good health with potentially resectable tumors. All patients should be assessed properly by experienced personnel with a view toward possible resection. This point cannot be overemphasized: ***If the patient is deemed unresectable, the diagnosis should be confirmed with a biopsy.*** Biliary decompression can be achieved by percutaneous transhepatic puncture or by endoscopic stent placement (see Chapters 27, 28, and 50D). Hilar tumors are more difficult to traverse with the endoscopic technique, which should only be approached by skilled endoscopists with extensive ERCP experience. The failure rates and incidence of subsequent cholangitis after endoscopic drainage can be high (Liu et al, 1998). For this reason, initial endobiliary drainage, even in the palliative setting, should utilize plastic stents. Exchange for metallic stents can be considered after close monitoring for adequate palliative biliary drainage with plastic stents in the short and intermediate term.

Percutaneous transhepatic biliary drainage and subsequent placement of a self-expandable metallic endoprosthesis can be performed successfully in most patients with hilar obstruction. Satisfactory results, even with experienced interventional radiologists, are more difficult to achieve in patients with hilar tumors than in patients with distal biliary obstruction (Becker et al, 1993; Cheung & Lai, 1995; Miyazaki et al, 1998a, 1998b; see Chapters 28 and 50D). Satisfactory drainage of only 25% to 30% of functional hepatic parenchyma is required for resolution of jaundice. Still, hilar tumors frequently isolate all three major hilar ducts—left hepatic, right anterior sectoral hepatic, and right posterior sectoral hepatic—and two or more uncovered stents must be placed for adequate drainage (Fig. 50B.18;

FIGURE 50B.18. Unresectable hilar cholangiocarcinoma tends to isolate all major hilar bile ducts from one another. In this patient, two expandable metallic stents were required for adequate biliary drainage. Self-expanding metal stents are shown here on plain radiography and coronal computed tomographic imaging.

Schima et al, 1997). Bilateral drainage is not better or more effective than unilateral drainage, provided that an adequate volume of liver parenchyma can be decompressed (De Palma et al, 2001). It also must be considered that jaundice may result from hepatic dysfunction secondary to portal vein occlusion. Jaundice in this setting, without intrahepatic biliary dilation, is not correctable with biliary stents. In addition, lobar atrophy is an important factor when considering palliative biliary procedures. Percutaneous drainage through an atrophic lobe does not relieve jaundice and should be avoided. The presence of multiple intrahepatic metastases or ascites also may add to the technical difficulty of the procedure.

The median patency of metallic endoprostheses at the hilus is approximately 6 months (Glattli et al, 1993), significantly less than that reported for similar stents placed in the distal bile duct. Becker and colleagues (1993) reported 1-year patency rates of 46% and 89% for metal stents placed at the hilus and at the distal bile duct. Similarly, Stoker and Lameris (1993) documented occlusion in 36% of patients at the hilus compared with 6% of patients with self-expanding metal stents (SEMS) in the distal bile duct. In most series of SEMS placed for hilar obstruction, documented stent occlusion requiring reintervention occurs in 25% of patients (Becker et al, 1993; Bergquist et al, 1998; Glattli et al, 1993; Hurlimann & Gardiol, 1991; Rossi et al, 1994; Schima et al, 1997; Stoker & Lameris, 1993). This percentage concurs with our findings of a mean patency of 6.1 months in 35 patients palliated for malignant high biliary obstruction by placement of expandable metallic endoprostheses. The periprocedural mortality was 14% at 30 days, and seven patients (24%) had documented stent occlusion that required repeated intervention (Glattli et al, 1993). In a recent prospective trial, patients presenting for percutaneous biliary drainage for malignant biliary obstruction had a dismal survival and experienced no improvement in quality of life with drainage. The exception in this trial was an improvement in pruritus-related quality of life, which was significantly better (Robson et al, 2010).

Palliating distal biliary obstruction in unresectable patients can be achieved with an operative bypass (hepaticojejunostomy or choledochojejunostomy) or with placement of a biliary stent. Endoprostheses for distal biliary obstruction are typically easy to place and have a greater long-term patency than endoprostheses placed for hilar obstruction (Becker et al, 1993). Operative biliary-enteric bypass, either open or laparoscopic, will provide excellent relief of jaundice and can be done with an acceptably low morbidity and mortality. Patients who are found to have unresectable disease at the time of operative exploration should undergo biliary-enteric bypass. Planned palliative operative bypass should be reserved for patients expected to survive greater than 6 months (van den Bosch et al, 1994), and endoscopic SEMS should be used in patients with clear-cut metastatic disease on cross-sectional imaging or discovered with staging laparoscopy.

Patients with hilar tumors who are found to be unresectable at operation may be candidates for hepaticojejunostomy or intrahepatic biliary-enteric bypass. The segment III duct usually is the most accessible and is our preferred approach, but the right anterior or posterior sectoral hepatic ducts also can be used (Jarnagin et al, 1998; see Chapter 42A). Typically, a segment III bypass is used to restore biliary-enteric continuity after the bile duct has been divided and a locally invasive, unresectable tumor has been discovered. Segment III bypass provides excellent biliary drainage and is less prone to occlusion by tumor than a SEMS (Stoker & Lameris, 1993), because the anastomosis can be placed some distance away from the tumor (Fig. 50B.19). Relief of jaundice is achieved if at least one third of the functioning hepatic parenchyma is adequately drained. Communication between the right and left hepatic ducts is unnecessary, provided the undrained lobe has not been percutaneously drained or otherwise contaminated (Baer et al, 1994). In this circumstance, there is a high risk of persistent biliary fistula and cholangitis. Bypass to an atrophic lobe or a lobe heavily involved with tumor is ineffective. In a report of 55 consecutive bypasses in patients with malignant hilar obstruction, segment III bypass in patients with hilar cholangiocarcinoma (n = 20) yielded the best results. The 1-year bypass patency in this group was 80%, with no perioperative deaths (Jarnagin et al, 1998).

FIGURE 50B.19. Transhepatic cholangiography obtained via a temporary percutaneous drainage tube shows a widely patent anastomosis from the segment III duct to a Roux-en-Y loop of jejunum (*arrows*).

Patients with unresectable, locally advanced tumors but without evidence of widespread disease may be candidates for palliative radiation therapy. A combination of external beam radiation (5000 to 6000 cGy) and intraluminal iridium-192 (2000 cGy) delivered percutaneously is typically used. Several authors have shown the feasibility of this approach, but improved survival compared with biliary decompression alone has not been documented in a controlled study (Bowling et al, 1996; Cameron et al, 1990; Kuvshinoff et al, 1995; Nagano et al, 1990; Vallis et al, 1996; Vatanasapt et al, 1990a). In a group of 12 patients treated with this regimen over 3 years at MSKCC, the median survival was 14.5 months. Episodes of cholangitis and intermittent jaundice were relatively common, but the incidence of serious complications was low, and there

were no treatment-related deaths (Kuvshinoff et al, 1995). Cameron and colleagues (1990) reported improved survival in irradiated patients compared with a group of patients not irradiated; however, the median survival in both groups was less than 1 year. Other investigators reported no benefit and questioned the routine use of radiation, given the increased incidence of complications and greater time spent in the hospital (Bowling et al, 1996). Radiation therapy is inappropriate in patients with widespread disease. Systemic chemotherapy is the only option for these patients, but response rates are low (Patt et al, 1996).

Ortner and colleagues (1998) evaluated the efficacy of photodynamic therapy in unresectable hilar cholangiocarcinoma. This method has been used in the treatment of tumors of the esophagus, colon, stomach, bronchus, bladder, and brain. It is a two-step procedure. First, a photosensitizer is injected; second, direct illumination via cholangioscopy activates the compound, causing tumor cell death. Ortner and colleagues (1998) treated nine patients in this fashion who had not responded to endoscopic stenting. They reported zero mortality for the procedure; however, a 25% mortality rate was related to the initial endoscopic stenting, which must be considered. These investigators did not mention their indication for biliary drainage. This information is important to assess the extent of disease before therapy. Detailed reasons for nonresectability were not discussed, and the reported median survival of 439 days is difficult to interpret. The data presented in this report, including decrease in bilirubin and some improved quality of life, are insufficient to advocate routine use of this method. Two randomized studies in patients with unresectable cholangiocarcinoma suggested improved survival with biliary stenting combined with photodynamic therapy compared with biliary stenting alone (Ortner et al, 2003; Zoepf et al, 2005). The improved survival observed with photodynamic therapy is likely related to better biliary decompression and avoidance of early segmental duct isolation and subsequent cholangitis, rather than any significant reduction in tumor burden (Quyn et al, 2009).

Palliative systemic chemotherapy has been investigated. Two phase II studies analyzing the effect of 5-FU combined with interferon alfa-2b and the effect of paclitaxel failed to show any benefit (Jones et al, 1996; Patt et al, 1996). In more recent studies, gemcitabine and irinotecan seemed to have limited efficacy, although they may offer a higher response rate than that seen with 5-FU–based regimens, (Alberts et al, 2005; Park et al, 2005; Sanz-Altamira et al, 2001). A recent Phase III study by the investigators of the Advanced Biliary Cancer (ABC) 02 trial randomized 410 patients with locally advanced or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer to receive either cisplatin followed by gemcitabine or gemcitabine alone for up to 6 months (Valle et al, 2010). This study showed an improvement in median survival from 8.2 to 11.7 months for patients receiving cisplatin plus gemcitabine without the addition of substantial toxicity.

SUMMARY

Improvements in high-resolution cross-sectional imaging have permitted better patient selection and enhanced preoperative planning and preparation prior to the safe performance of operations for hilar cholangiocarcinoma. Long-term disease-free survival, rather than palliation, is now the primary goal of operative resection. Judicious use of adjunctive preoperative interventions that include biliary drainage and portal vein embolization may help to improve outcomes, especially when major perioperative and postoperative complications are anticipated. Selection of appropriate nonoperative therapies for palliation of unresectable tumors arising from the proximal and distal bile ducts should be tailored, according to the patient's expected longevity and technical expertise of the multidisciplinary team charged with treating bile duct cancer.

CHAPTER 50C

Cancer of the bile ducts: perihilar cholangiocarcinoma with emphasis on presurgical management

Tomoki Ebata and Masato Nagino

OVERVIEW

Perihilar cholangiocarcinoma is often diagnosed as advanced disease at initial presentation and is difficult to treat (de Groen et al, 1999). Hepatobiliary resection represents the definitive surgery and most effective treatment for this disease (Bismuth et al, 1992; Blumgart et al, 1984; Burke et al, 1998; Hemming et al, 2005; Kawasaki et al, 2003). Combined portal vein resection (Ebata et al, 2003; Nimura et al, 1991a), combined hepatic artery resection, or hepatopancreatoduodenectomy (Ebata et al, 2007; Nimura et al, 1991b) have also been aggressively used at leading hepatobiliary centers in Japan, Korea, Europe, and the United States (Igami et al, 2010; Lee et al, 2010; Miyazaki et al, 2010; Rocha et al, 2010; Unno et al, 2010; Young et al, 2010). However, hepatobiliary resection for perihilar cholangiocarcinoma is well known to result in higher morbidity or mortality rates than those for simple hepatectomy because of impaired liver function with cholestasis or cholangitis (Belghiti et al, 2000; Nagino et al, 1993, 2001). To eradicate the involvement of the hilar duct, extensive hepatectomy should be designed based on tumor extension and individual liver functional reserve. It is of particular importance that the presurgical management is optimized. Perioperative management and surgical techniques have evolved over the past 30 years, which has succeeded in reducing postoperative complications. Current methods and recommendations for the presurgical management of perihilar cholangiocarcinoma are outlined in this section.

BASIC ANATOMIC PATHOLOGY DICTATES SURGICAL STRATEGY (SEE CHAPTER 47)

According to the Johns Hopkins classification for cholangiocarcinomas (Nakeeb et al, 1996), *perihilar cholangiocarcinomas* are defined as cholangiocarcinomas involving or requiring resection of the hepatic duct conference. Because the boundary between the intrahepatic and extrahepatic bile duct is unclear, perihilar tumors are potentially composed of two types of tumors: *extrahepatic hilar cholangiocarcinomas,* which arise from the large hilar bile duct, and *intrahepatic hilar cholangiocarcinomas,* which have an intrahepatic component and involve the hepatic hilum. These two tumors exhibit the same clinical presentation, demonstrate similar radiologic features, require an identical surgical intervention, and have comparable histologic characteristics (Ebata et al, 2009). In addition, they can be well classified by the American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) staging for extrahepatic bile duct cancer (Greene et al, 2002), providing well-stratified survival (Ebata et al, 2009). Thus these two tumor categories overlap considerably, as already suggested by Klatskin (1965); therefore both tumors should be treated under the banner of perihilar cholangiocarcinoma (Ebata et al, 2009; Nakeeb et al, 1996).

Cholangiocarcinoma microscopically infiltrates the surrounding tissue beyond the macroscopic tumor extent (main tumor) (Ebata et al, 2002; Sakamoto et al, 1998). The lateral extension of invasive cancer is limited within 1 cm in both directions beyond the main mass in most tumors, and noninvasive cancer extension is limited within 2 cm in 90% of tumors (Ebata et al, 2002). These observations indicate that a 1-cm margin and a 2-cm margin of the duct are recommended for eradication of invasive and noninvasive cancer cells, respectively.

However, in perihilar cholangiocarcinomas, it is often difficult to obtain a satisfactory margin length that meets the above requirements because of the anatomy of the liver, especially in the proximal direction. Therefore a proximal resection line is set at the farthest proximal point as technically possible, and pathologic assessment with frozen sections of the ductal stump is widely used to confirm a negative ductal margin. Flaws in the results of intraoperative frozen section have been reported, including 1) the diagnostic difficulty of differentiation between intraepithelial neoplasm and reactive/regenerative epithelial changes, 2) the absence of a standard histologic classification (Konishi et al, 2008), 3) difficulty in obtaining sufficient material for diagnosis because of crushing and exfoliation resulting from manipulation (Konishi et al, 2008), and 4) relatively low diagnostic accuracy, ranging from 25% to 57% (Okazaki et al, 2002; Yamaguchi et al, 2005). These limitations suggest an inherent limitation of frozen-section examination. When the ductal margin is positive by intraoperative frozen-section diagnosis, several factors must be taken into account. First, prognostic indicators after surgery are nodal metastasis, poor histologic grade, portal vein invasion, and positive surgical margins (Ebata et al, 2003, 2009). Of these predictors, nodal involvement is observed most frequently, in more than 50% of patients (Ebata et al, 2003; Igami et al, 2009; Kitagawa et al, 2001). Second, a positive ductal margin with noninvasive cancer, unlike invasive cancer, may not have a negative impact on survival (Igami et al, 2009; Nakanishi et al, 2010; Sasaki et al, 2007; Wakai et al, 2005). It has been noted that residual in situ carcinoma does not result in early fatal recurrence; however, over time, it steadily and insidiously progresses to an anastomotic tumor mass (Nakanishi et al, 2010). Third, additional resection of more than 5 mm of the proximal duct is difficult, practically, after maximal or near-maximal resection of the duct. Such limited resection of a margin-positive proximal duct

does not improve survival, even when a negative margin can be achieved after additional resection (Shingu et al, 2010). Overall, the clinical value of additional resection of the proximal duct in perihilar cholangiocarcinoma is limited.

A right hemihepatectomy or trisectionectomy with en bloc resection of the caudate lobe is generally recommended for perihilar cholangiocarcinomas (Kawasaki et al, 1994; Neuhaus et al, 1999). This right-sided resection satisfies the nontouch technique, en bloc resection, and wide tumor-free margins and consequently leads to good local control and a favorable prognosis (Jonas et al, 2008). However, the optimal procedure (extensive vs. limited surgery) for Bismuth type I and II tumors is still under debate. Tumor configuration is classified into *papillary, nodular,* or *diffusely infiltrating* tumors (Henson et al, 2000). Papillary tumors display less invasive behavior and, accordingly, they have a more favorable survival than other tumor types (Albores-Saavedra et al, 2000; Jarnagin et al, 2005). Recently, the surgical strategy for Bismuth type I and II tumors were reappraised based on gross tumor type (Ikeyama et al, 2007). When optimizing by the gross tumor configuration, right-sided hepatectomy is suitable for nodular or flat tumors that display an infiltrating nature in the advancing margin; whereas a limited surgery—including resection of S1, S1+4, or bile duct resection alone—is acceptable for papillary tumors, provided the surgical margin is negative (Ikeyama et al, 2007).

In addition, there is a specific tumor type called *superficial spreading type cholangiocarcinoma* (Igami et al, 2009; Nakanishi et al, 2008; Sakamoto et al, 1998), which is defined as cholangiocarcinoma with superficial spread; that is, a noninvasive cancer extension longer than 2 cm. The mean length of the superficial spread is 54 mm, suggesting that this tumor often requires extensive resection to obtain a negative ductal margin. In contrast, superficial spreading-type cholangiocarcinomas are also characterized by less advanced pT and pN classifications and a more differentiated histologic grade, which leads to a favorable prognosis (Igami et al, 2009; Nakanishi et al, 2008). In such patients, complete eradication of the superficial spreading lesion (in situ carcinoma) is necessary. Taken together, these findings suggest that a patient with this specific tumor may benefit from extensive surgery, such as hepatopancreatoduodenectomy (Ebata et al, 2007; Nimura et al, 1991b).

Hepatobiliary surgeons should keep the possibility of multiple synchronous cancers in mind. Multiple tumors are more common than previously thought: the incidence ranges from 5% to 9% (Gertsch et al, 1990; Kozuka et al, 1984; Kurosaki et al, 1997). Thus, multiplicity is a feature of biliary neoplasia that may be clinically relevant in some patients. Gertsch and colleagues (1990) proposed three criteria for multiplicity: 1) no direct continuity between the two tumors, 2) a growth pattern typical of a primary tumor, and 3) clear histologic differences between the two tumors. However, a true synchronous tumor and metastatic tumor originating from a biliary site elsewhere cannot always be clinically distinguished. Interestingly, a second tumor may not be identified by the preoperative radiologic workup but rather by pathologic assessment. Most second biliary tumors are an incidental early stage gallbladder cancer (Gertsch et al, 1990; Kurosaki et al, 1997). This indicates a need for intraoperative surveillance, meticulous inspection of the specimen immediately after resection, and appropriate sampling of the tissue for pathology.

The concept of *field cancerization* potentially explains the multiplicity of biliary tumors. Recently, pathoepidemiologic evidence for multiple biliary tumors has been reported (Henson et al, 2009). The age-specific incidence of biliary tract and gallbladder tumors in the United States demonstrates a parallel incline pattern, indicating that the rate of cancer development is identical and that the sequential molecular/cellular events toward the carcinogenesis among multiple isolated lesions share common pathways.

BILIARY DRAINAGE IN THE PREOPERATIVE SETTING (SEE CHAPTERS 7 AND 18)

It is well known that chronic obstruction of the bile duct causes hepatic fibrosis, secondary biliary cirrhosis, and portal hypertension. When biliary obstruction is appropriately relieved, the fibrosis and portal hypertension can be ameliorated (Hammel et al, 2001). Furthermore, prolonged obstruction often induces acute obstructive suppurative cholangitis (Glenn & Moody, 1961), which can only be treated by biliary drainage (Berliner & Burson, 1973). The purposes of biliary drainage are summarized as follows: 1) treatment of biliary sepsis (Kanai et al, 1996), 2) relieving jaundice and recovery of functional capacity, 3) diagnosis of lateral tumor extension (Nimura et al, 1989), 4) liver function assessment using bile samples (Higuchi et al, 2005; Kurumiya et al, 2003; Maeda et al, 1999; Takeuchi et al, 1997; Uesaka et al, 1996), and 5) improvement of poor food intake (Padillo et al, 2001).

Obstructive jaundice associated with perihilar cholangiocarcinoma differs from jaundice associated with distal tumors. In the latter, a single catheter is enough for biliary decompression of the entire liver; in the former, multiple drainage catheters are necessary because perihilar cholangiocarcinomas frequently isolate the intrahepatic biliary tree into several subunits (Klatskin, 1965). Under such difficult conditions, it remains controversial which method is better: an endoscopic approach versus a percutaneous approach or unilateral versus bilateral drainage. Several authors (Gholson & Burton, 1991; Polydorou et al, 1991; Speer et al, 1987) have stressed the advantages of endoscopic retrograde biliary drainage (ERBD) because it is associated with low procedure-related morbidity and mortality rates, a shorter hospital stay, and good quality of life (external tube free). However, ERBD is associated with a high incidence of cholangitis because of catheter occlusion and/or inability to perform multiple drainages (Andersen et al, 1989; Chang et al, 1998; Liu et al, 1998; Rerknimitr et al, 2004). Hence, percutaneous transhepatic biliary drainage (PTBD), rather than ERBD, may be indicated for perihilar cholangiocarcinomas (Nomura et al, 1997).

Recently, endoscopic nasobiliary drainage (ENBD) has been recommended as a preoperative drainage procedure for perihilar cholangiocarcinomas (Arakura et al, 2009; Maguchi et al, 2007). Arakura and colleagues (2009) reported that a single ENBD was enough to relieve jaundice in 46 of 62 patients (74%) with perihilar cholangiocarcinoma, and additional PTBD was necessary in only eight patients. Early complications, such as acute cholangitis, dislodgement, and hemobilia, occur 14.5%, 0%, and 0% of the time, respectively, indicating the low morbidity associated with ENBD. Furthermore, ENBD carries no risk of seeding metastases along the catheter tract, which could compromise the results of curative resection (Fig. 50C.1). In our experience, seeding metastases are encountered in up to 5% of patients with cholangiocarcinoma who underwent resection after PTBD.

Obstructive jaundice appears when more than 75% of the liver is involved (Abraham et al, 2002), and based on the

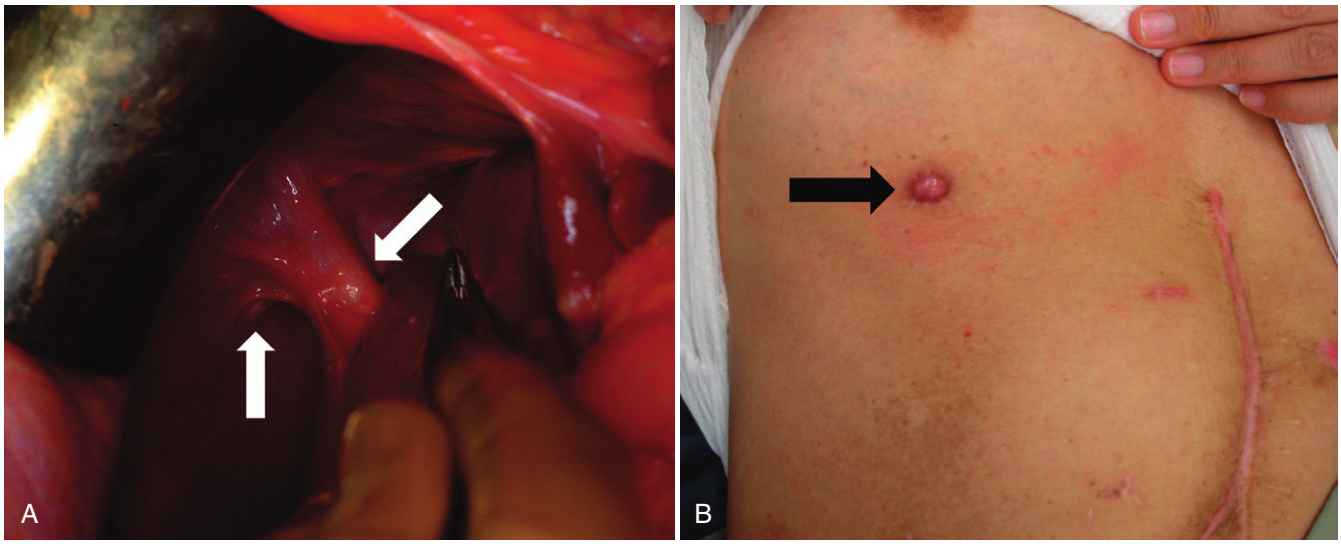

FIGURE 50C.1. Percutaneous transhepatic biliary drainage (PTBD)-related seeding metastasis from perihilar cholangiocarcinoma. **A,** At laparotomy, peritoneal dissemination is observed at the sinus tract of PTBD catheter (*arrows*). **B,** A skin nodule emerges (*arrow*) just at the PTBD wound scar 6 months after curative surgery.

experience of palliative biliary drainage, it is usually relieved by drainage of a single liver segment (Abraham et al, 2002; Ballinger et al, 1994; Van Laethem et al, 2003). In addition, unilateral drainage promotes hypertrophy of the future liver remnant (FLR), which leads to a good functional reserve (Ishizawa et al, 2007). Thus the current strategy of preoperative biliary drainage for perihilar cholangiocarcinoma is summarized as follows: first, all ducts in the FLR should be drained; second, ENBD is superior to PTBD. Previously, we preferred PTBD (Nagino et al, 1992; Nimura, 1993; Nimura et al, 1995, 1998) but have not changed the policy for preoperative drainage since 2007. The first-line treatment is currently a single ENBD placed in the FLR alone, irrespective of the Bismuth tumor type. PTBD is performed as a second-line procedure only when 1) multiple, separated ducts are present in the FLR; 2) total liver drainage is necessary for prolonged cholestasis or segmental cholangitis of the undrained lobe; or 3) the ENBD tube is dislodged or kinked. As a result, the proportion of patients treated with ENBD has recently increased, but PTBD has decreased, although it is still needed for approximately half of the patients (Table 50C.1).

Table 50C.1

Type of Biliary Drainage in Patients with Perihilar Chlangiocarcinoma Who Underwent Surgery from 2001 to 2009

	2001–2005 (n = 164)	2006–2007 (n = 83)	2008–2009 (n = 93)
PTBD	131 (80%)	55 (66%)	48 (52%)
ERBD	3 (2%)	3 (4%)	2 (2%)
ENBD	4 (2%)	12 (15%)	35 (38%)
Without drainage	26 (16%)	13 (16%)	8 (9%)

PTBD, percutanenous transhepatic biliary drainage; ERBD, endoscopic retrograde biliary drainage; ENBD, endoscopic nasogastric biliary drainage

The current role of PTBD is mainly to salvage the procedure if ENBD fails. In this difficult scenario, multiple PTBD is frequently required to decompress the whole liver, except for the caudate lobe (Nagino et al, 1992; Nimura et al, 1995). Our favorite method for PTBD is Takada's direct anterior approach (Takada et al, 1976), using a Takada needle, approximately 3 mm in diameter, which is composed of an internal metallic needle and an outer Teflon sheath (Fig. 50C.2). First, the target duct is opacified with a fine needle; next, the needle is advanced parallel to the radiograph into the duct; and finally, a 6-Fr soft catheter is installed through the sheath. Previously, the intrahepatic bile duct of the FLR was directly punctured; however, vascular injury is possible with such an approach (Fig. 50C.3). A large series of PTBD between 1991 and 2006 (Dowsett, 1989; Fidelman et al, 2008) showed that the risk of

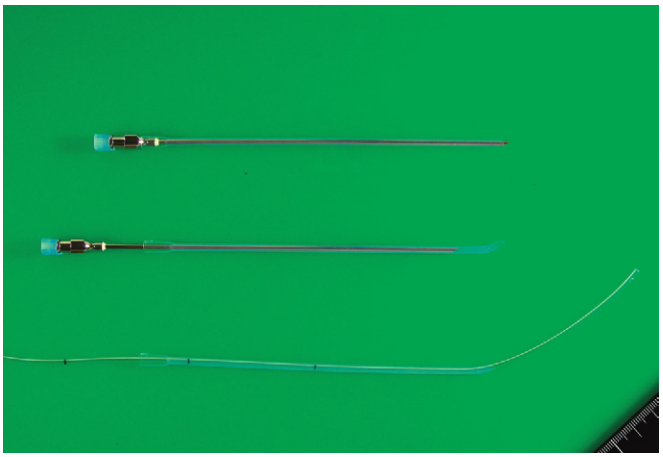

FIGURE 50C.2. Needle device specific for percutaneous transhepatic biliary drainage, Takada's direct anterior approach. The needle consists of an inner metallic needle and outer Teflon tube (*top*). The tip of the outer tube is curved; consequently, a 6-Fr catheter is easily introduced into the duct via the outer tube (*bottom*).

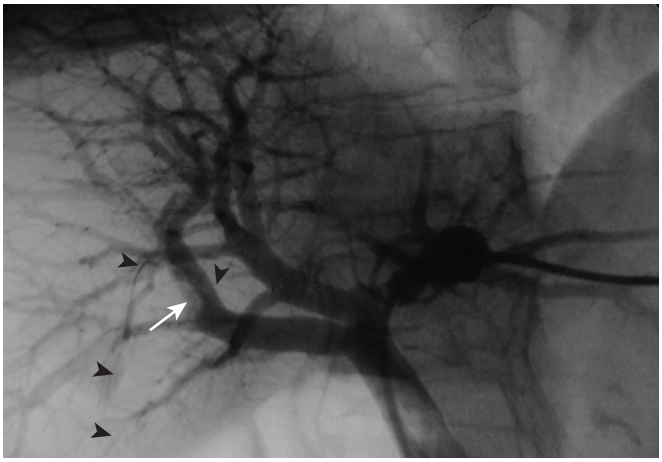

FIGURE 50C.3. Percutaneous transhepatic biliary drainage (PTBD)-related vascular injury. The PTBD catheter is introduced to the right posterior sectorial duct (*arrowheads*), because the patient is scheduled for left trisectionectomy. Portogram reveals a small thrombus (*arrow*) in the right poster portal vein as a result of PTBD-related injury.

procedure-related arterial injury is 2.2%, and the incidence has not changed since the 1970s and 1980s. To prevent accidental vascular injury, the ipsilateral approach, similar to portal vein embolization (Nagino et al, 1996), is recommended when it is possible. In this approach, the bile duct in the sector to be removed is punctured, and the straight single catheter is introduced into the duct in the FLR via the hilar duct, which is stenotic as a result of tumor. Although this procedure requires a meticulous searching technique using a flexible guidewire, it offers complete bilateral drainage with the least numbers of single catheters (Fig. 50C.4). PTBD with the ipsilateral approach should be considered when total liver drainage is necessary.

Although biliary drainage is the routine preoperative management strategy for jaundiced patients in Japan (Nagino et al, 2008), randomized control trials (RCTs) conducted in Western countries have raised questions about the effectiveness of preoperative biliary drainage (see Chapters 7 and 50B). The results of these trials showed no significant difference in postoperative morbidity and mortality among patients who received preoperative biliary drainage and those who did not. These RCTs concluded that, considering the potential risk related to PTBD, preoperative biliary drainage has no advantage (Hatfield et al, 1982; McPherson et al, 1984; Pitt et al, 1985). However, these studies involved patients undergoing bypass surgeries or palliative small resections. In addition, PTBD-related complications were very common. These flaws in the previous RCTs made it difficult to accept their conclusions. In Western centers, preoperative biliary drainage is performed in selected patients (Laurent et al, 2008; Kennedy et al, 2009). Over time, the bile is contaminated after biliary drainage (Nomura et al, 1999): the incidence of bacterobilia and fungobilia is 85% and 40%, respectively (Jethwa et al, 2007), leading to surgical site infection, cholangitis, and bacteremia after hepatectomy (Hochwald et al, 1999; Jethwa et al, 2007; Nomura et al, 1999; Shigeta et al, 2002). These observations may partly support the limited indications for biliary drainage; however, the mortality rate after extended hepatectomy for jaundiced patients is still high at near 10%, and the cause of death is mainly hepatic failure (Nagino et al, 1993b, 2001). Therefore, preoperative biliary drainage followed by portal vein embolization is recommended before extended hepatectomy, in spite of a lack of clear evidence based on previous RCTs. This is the Japanese standard of care (Henson et al, 2000; Kawasaki et al, 2003).

CHOLANGIOGRAPHY (SEE CHAPTER 18)

Cholangiograms precisely delineate the segmental anatomy of the intrahepatic bile duct (Ohkubo et al, 2004), the tumor configuration, and the extent of the tumor border. To avoid misinterpretation related to overlap of segmental ducts, cholangiograms should be taken in various projections (Fig. 50C.5). Most perihilar cholangiocarcinomas are infiltrating tumors, in which cancer cells are likely to extend predominantly in the submucosal layer rather than in the mucosal layer. Histologically, direct and lymphatic invasion are common routes of invasion to the ductal wall, evoking reactive fibrosis (Sakamoto et al, 1998; see Chapter 47). These changes cause rigidity,

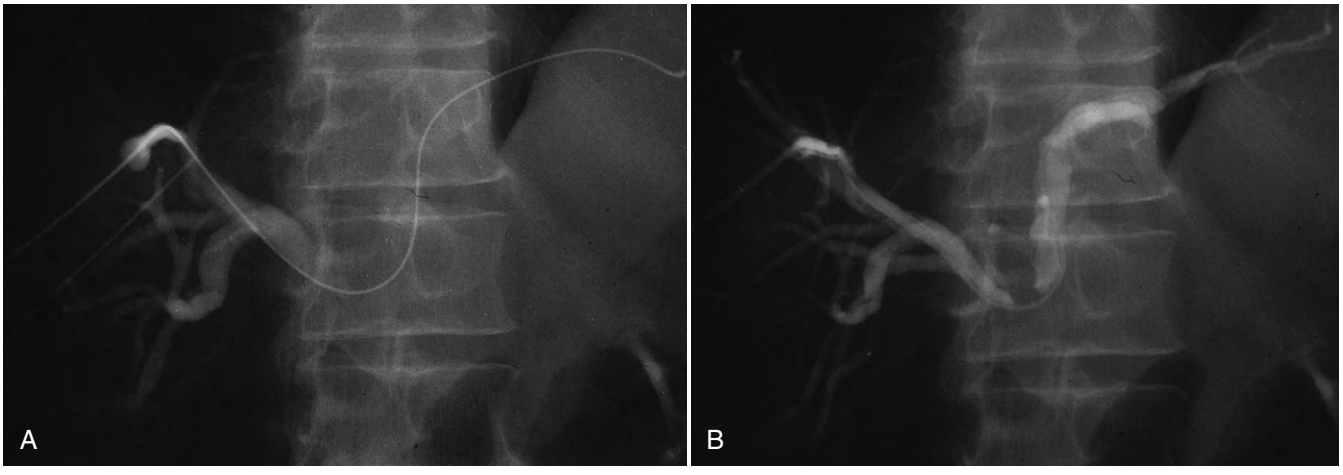

FIGURE 50C.4. Bilateral biliary drainage using ipsilateral approach. Patient has a Bismuth type II tumor, requiring biliary drainage of the left liver. **A,** The right anterior sectorial duct is targeted for puncture. A guidewire is advanced to the left lateral superior sectional duct (*B2*) through the hilar stenosis. **B,** Bilateral drainage is completed. Theoretically, unilateral drainage of the left liver is enough; however, this approach will decrease the risk of the vascular injury of the left liver.

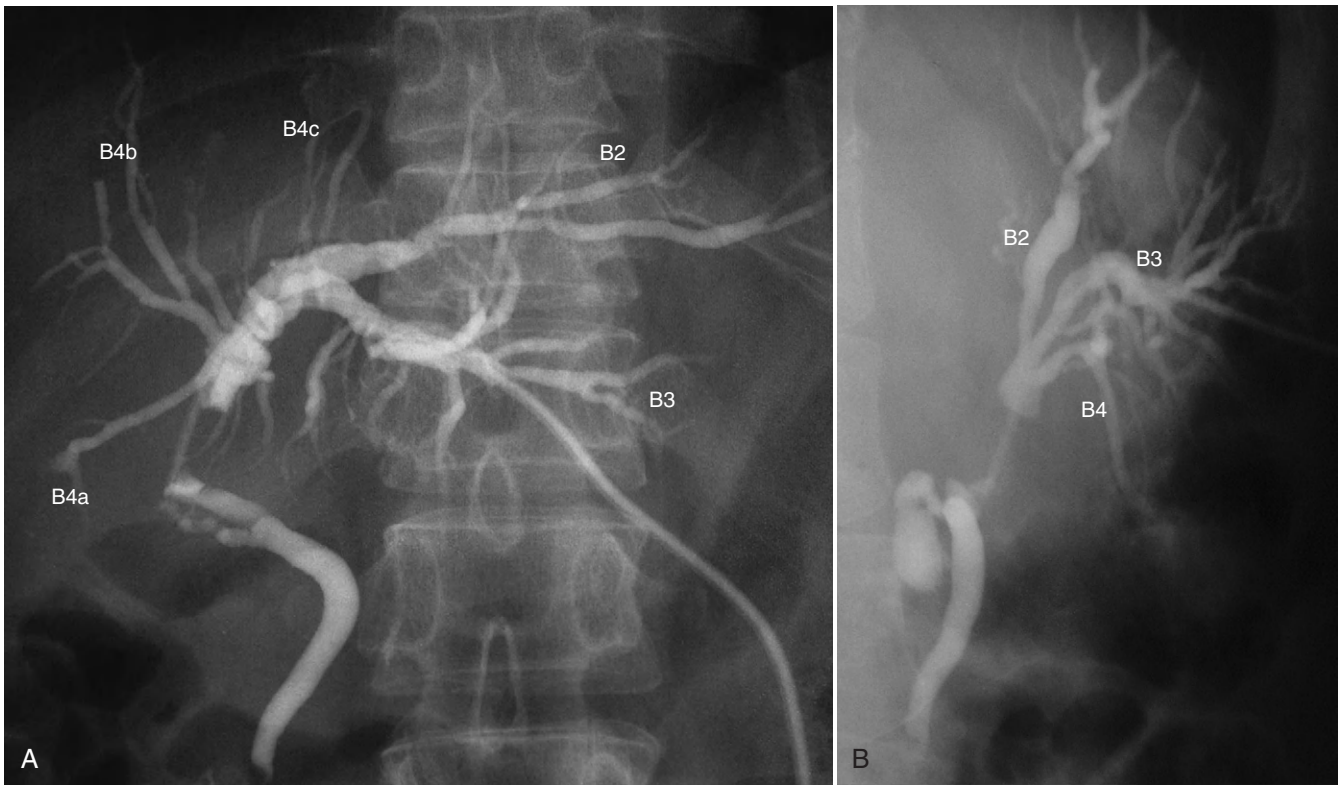

FIGURE 50C.5. Cholangiography specific for right-sided hepatectomy. **A,** In a routine spine position, the nodular tumor is demonstrated at the hepatic bifurcation, but the definitive information for lateral tumor extension is not obtained. **B,** Right anterior oblique position with cranial tilting clearly demonstrates the confluence of segment II duct (*B2*), segment III duct (*B3*), and segment IV duct (*B4*).

narrowing, tapering, and obstruction of the duct on the cholangiogram. The border of these findings on cholangiograms correspond to the leading edge of cancer infiltration (Sakamoto et al, 1998).

In hilar biliary obstruction, direct cholangiography frequently shows insufficient opacification of the proximal ductal system. However, MR cholangiography (MRC) delineates the whole biliary system, and its ability to diagnose the Bismuth classification is superior, with an accuracy of 81% (Yeh et al, 2000). Overestimation is a common pitfall of MRC, which may preclude patients from potentially curative surgery (Otto et al, 2004). The limitations of MRC include lower spatial resolution, longer acquisition time, and sensitivity to motion.

CHOLANGIOSCOPY

Despite the advent of new diagnostic modalities, cholangioscopic examination with biopsy sampling plays an important role in the diagnosis of biliary malignancies (see Chapter 28). Differentiation between malignant and benign lesions, evaluation of proximal and distal cancer extent, and early detection of small lesions and multiple cancer foci can be accomplished by cholangioscopic observation with biopsy sampling (Nimura et al, 1989). Irregularly dilated and tortuous vessels are characteristic of malignancy. A fine granular/papillary mucosa extending continuously from a main lesion is a characteristic finding of superficial spread (Nimura & Kamiya, 1998). Papillary tumors are often associated with the superficial spread of carcinoma (Igami et al, 2009; Sakamoto et al, 1998), and mucosal extension is easily detectable by cholangioscopy. Therefore, cholangioscopy should be considered for patients with papillary tumors. Attention should be paid not only to the intrahepatic extension but also to the distal extension of the tumor.

Percutaneous transhepatic cholangioscopy (PTCS) is performed through the PTBD sinus tract. One week after PTBD, the drainage catheter is replaced by a 9- or 10-Fr PTCS catheter, and then the sinus tract is gradually dilated by replacing the preceding catheter with a larger catheter two or three times a week. A small-caliber cholangioscope (Olympus XP-20) can be used via the sinus tract of the 12-Fr catheter; a standard-type cholangioscope (Olympus, P-20) requires placement of a 15-Fr catheter. This preparation process for PTCS is time consuming and painful; therefore PTCS has recently been replaced by peroral cholangioscopy (POCS). With technical advances in endoscopy, POCS with biopsy gives a high diagnostic accuracy of the extent of the superficial spreading lesion (Kawakami et al, 2009).

MULTIDETECTOR ROW COMPUTED TOMOGRAPHY

Recent advances in helical CT technology, such as multislice detectors and subsecond rotation, have dramatically reduced scanning times in comparison with single-slice CT and have provided unparalleled capability for fast data acquisition and narrow collimation. Thus, multidetector row computed tomography (MDCT) permits the acquisition of three distinct circulatory phases, consisting of the arterial, pancreatic, and portal venous phases in the pancreatobiliary region with 1-mm

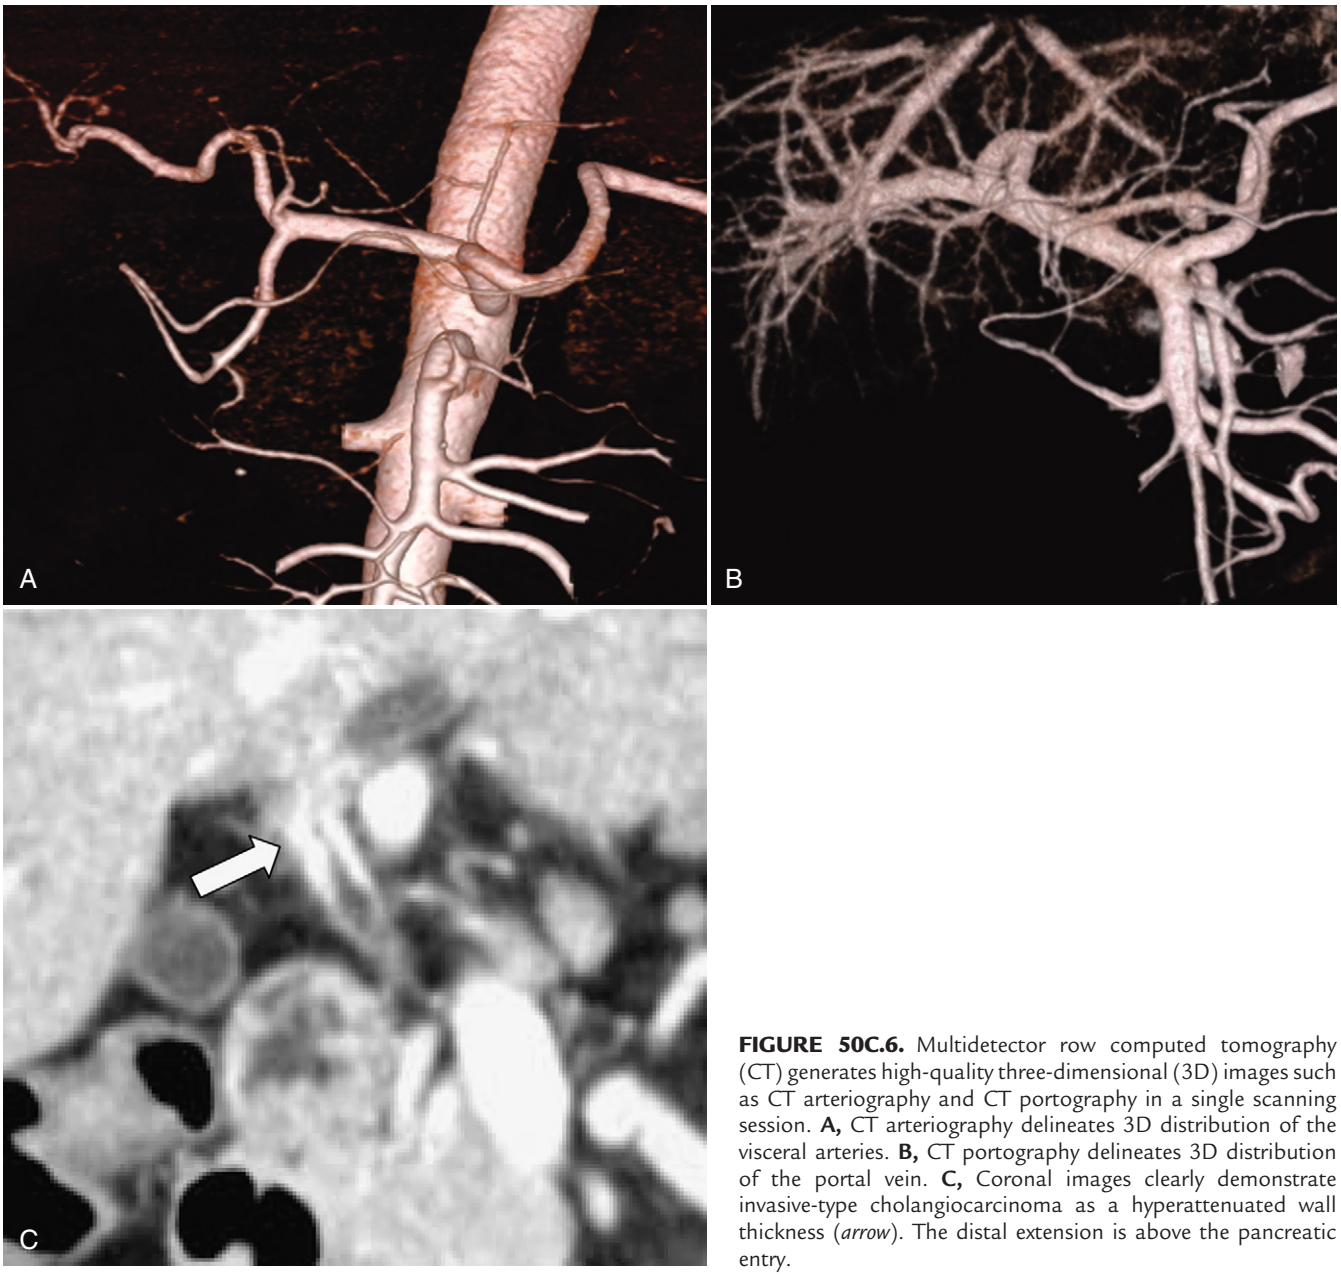

FIGURE 50C.6. Multidetector row computed tomography (CT) generates high-quality three-dimensional (3D) images such as CT arteriography and CT portography in a single scanning session. **A,** CT arteriography delineates 3D distribution of the visceral arteries. **B,** CT portography delineates 3D distribution of the portal vein. **C,** Coronal images clearly demonstrate invasive-type cholangiocarcinoma as a hyperattenuated wall thickness (*arrow*). The distal extension is above the pancreatic entry.

collimation (Itoh et al, 2003; see Chapter 16). These isotropic volume data allow multiplanar reformation (MPR), which can demonstrate complex anatomic relationships and three-dimensional volume rendering (3DVR) images, such as CT arteriography and CT portography, in a single scanning session (Fig. 50C.6). These postprocessing techniques enhance the diagnostic capability of CT (Choi et al, 2007). In patients with perihilar cholangiocarcinoma, preoperative MDCT is used to diagnose 1) distant metastasis, including dissemination, liver metastasis, and nodal metastasis; 2) tumor lateral extension or Bismuth classification; 3) vascular invasion with or without lobar atrophy; 4) anatomic variation of the vascular system; and 5) the liver volume of each sector. MDCT is now a pivotal element of the preoperative staging of perihilar cholangiocarcinoma, and it provides definitive information about resectability and design of resectional procedure. Previously, we used PTCS, celiac angiography, and percutaneous transhepatic portography (PTP) for staging (Nimura, 1993; Nimura et al, 1995, 1998; Nishio et al, 1999). However, these procedures are invasive in nature and have been replaced by MDCT.

With MDCT, cholangiocarcinoma can be correctly identified in nearly 100% of patients, and the accuracy in prediction of resectability has improved to 75% to 100% (Chen et al, 2006; Lee et al, 2006). MDCT with or without enhancement prior to biliary drainage often displays the tumor as a ductal thickness. To evaluate the value of MDCT on longitudinal extension in one study, the authors analyzed 73 patients with cholangiocarcinoma who underwent MDCT prior to biliary drainage (Senda et al, 2009). Of the 73 patients, 40 showed a hyperattenuated tumor, and the remaining 33 had a hypoattenuated tumor; in the latter group, it was difficult to identify the border between normal and thickened duct. Hence, the

extent of lateral extension could be assessed in only those 40 patients (55%) with a hyperattenuated tumor. The diagnostic accuracy of the extent of ductal cancer infiltration was 76% and 82% in the proximal and distal direction, respectively. The extent of cancer was underestimated by 24% and 15% at the proximal and distal border, respectively, because of superficial spread, minimal invasive cancer extension, or both. Thus the ability of MDCT to diagnose lateral extension is limited, and cholangiography is still the standard tool.

A belief has persisted that involvement of the main portal trunk denotes irresectability of the cholangiocarcinoma (Blumgart et al, 1984; Lee et al, 2006). Hoevels and Ihse (1979) emphasized that a portography showing portal vein invasion suggests irresectability. Launois and colleagues (1999) also reported that the main reason for irresectability of hilar cholangiocarcinomas is invasion of the portal bifurcation; however, several surgeons have recently reported portal vein resection for advanced biliary cancer (Kondo et al, 2004; Miyazaki et al, 2007; Nimura et al, 1991a; Sakaguchi & Nakamura, 1986). We have carried out combined portal vein and hepatobiliary resection in nearly 200 patients with advanced perihilar cholangiocarcinoma and have demonstrated significantly better survival in patients who underwent portal vein resection than in those with unresectable disease (Ebata et al, 2003; Igami 2010; Nimura et al, 1991a). Currently, portal vein resection and reconstruction are more or less routine in leading centers. Some surgeons have reported the clinical significance of prophylactic portal vein resection for all patients, irrespective of invasion of the portal vein, based on the nontouch technique (Kondo et al, 2004; Neuhaus et al, 1999). We do not think that this strategy improves survival, and they emphasize that portal vein resection should be performed only in patients with gross invasion of the portal vein.

We assessed the value of MDCT on *portal vein invasion,* defined as absence of a visible hypoattenuated layer between the portal bifurcation and the adjacent tumor on an MPR image. The diagnostic accuracy for macroscopic portal vein invasion (i.e., the requirement for portal vein resection) was 98%, showing the high sensitivity of MPR images for macroscopic portal vein invasion. Meanwhile, 3D portography clearly demonstrates the portal branch anatomy and the site and length of the portal vein invasion. Three-dimensional portography facilitates the design of the resection and the reconstruction procedure: wedge versus segmental resection and direct end-to-end anastomosis versus autologous vein grafting. In practical terms, the presence or absence of portal vein invasion should be first assessed by using MPR images; 3DVR images should then be used to plan the surgical procedure. When the right portal vein is markedly involved, if contralateral involvement does not reach the umbilical portion of the left portal vein, curative resection is possible by using a right-sided hepatectomy with portal vein resection and reconstruction (Fig. 50C.7). In contrast, when the left portal vein is considerably involved, if contralateral involvement is limited within the right portal trunk, a left hepatectomy with portal vein resection and reconstruction is indicated (Fig. 50C.8). If the bifurcation of the right anterior and posterior portal veins is involved, a left trisectionectomy with portal vein resection and reconstruction may be required.

Three-dimensional understanding of the hepatic artery distribution expedites skeletonization resection of the hepatoduodenal ligament; 3D understanding of the intrahepatic artery branching is helpful when the segmental or subsegmental bile ducts are divided as the final step of hepatobiliary resection. Hepatobiliary surgeons must appreciate two variations of the hepatic artery distribution that may be associated with potential injury (Fig. 50C.9): one is the left hepatic artery (LHA) running *right* to the umbilical portion of the left portal vein; and the other is a posterior branch of the right hepatic artery (RHA) running *cranially* to the right portal trunk. Careful attention

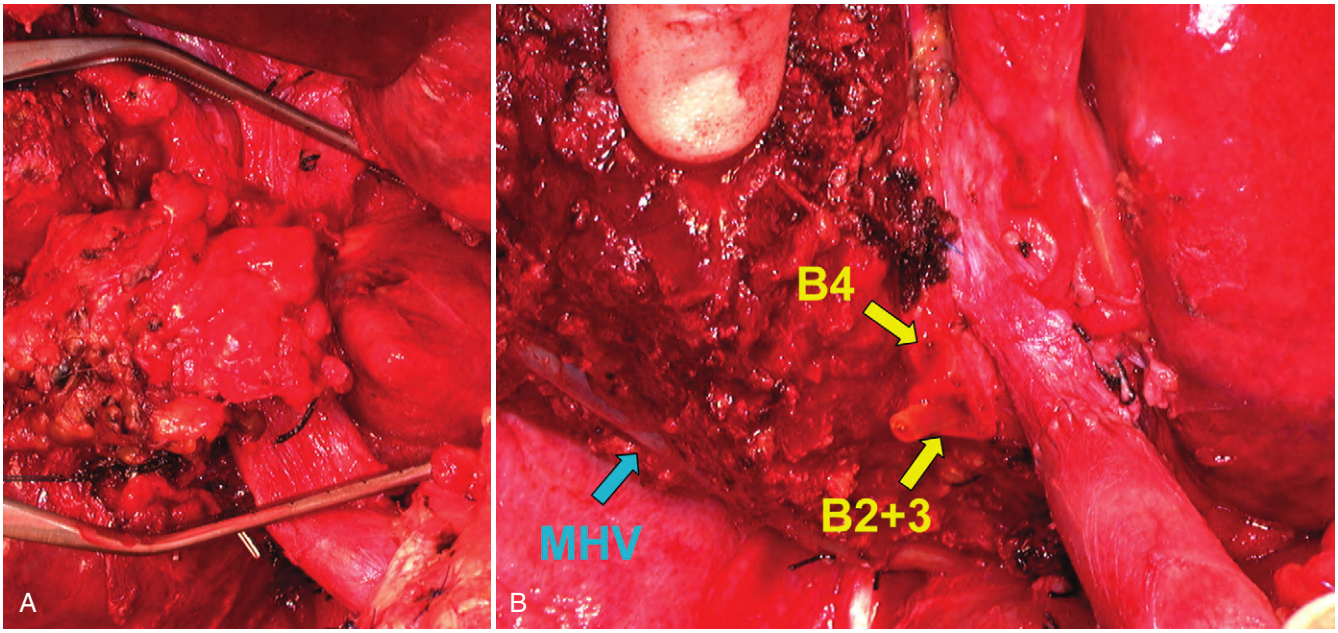

FIGURE 50C.7. A patient with perihilar cholangiocarcinoma involving the portal bifurcation. **A,** The vascular clamps are placed on both sides of the involved portal bifurcation. **B,** Completion photograph after a right hepatectomy, caudate lobectomy, and portal vein resection/reconstruction. *MHV,* middle hepatic vein; *B4,* resected stump of the left medial segmental bile duct; *B2+3,* resected stump of the left lateral segmental bile duct.

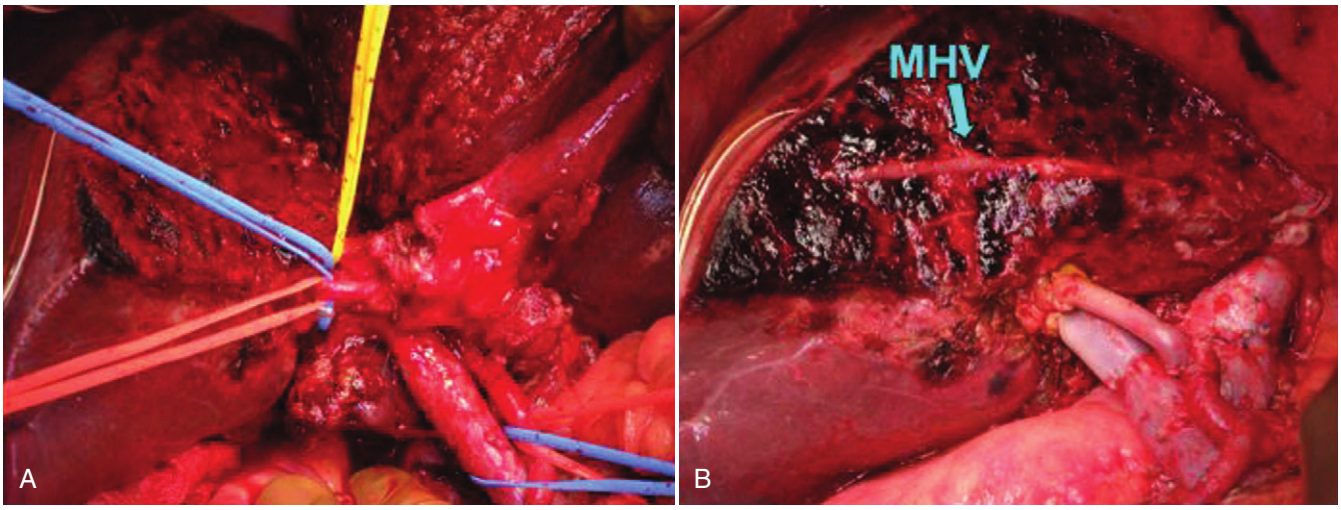

FIGURE 50C.8. A patient with perihilar cholangiocarcinoma involving the portal bifurcation. The tumor was curatively resected by a left hepatectomy and caudate lobectomy with simultaneous resection and reconstruction of the portal vein and the hepatic artery. **A,** Tumor involved the portal bifurcation and the right hepatic artery. The right hepatic duct, the right portal vein, and the right hepatic artery are encircled by tape, from the top. **B,** Completion photograph after resection. The portal vein is reconstructed using an external iliac vein graft, and the hepatic artery is also reconstructed using the greater saphenous vein graft. *MHV,* middle hepatic vein.

should be paid to the former variant in right hepatic trisectionectomy (extended right hepatectomy) with caudate lobectomy (Nagino et al, 2006a) and to the latter variant in left hepatic trisectionectomy (extended left hepatectomy) with caudate lobectomy. These variations can be clearly identified on a CT arteriography prior to surgery.

In general, unilateral involvement of the hepatic artery is compatible with resection. Because the RHA is usually just behind the common hepatic duct, it is likely to be involved by a cancer of the hepatic bifurcation. In cases of a right-sided tumor, bilateral involvement signifies local irresectability, because the LHA runs along the left border of the hepatoduodenal ligament. However, when the tumor is located on the left side, a left-sided hepatectomy with resection and reconstruction of the RHA can be performed in selected patients (see Fig. 50C.8; Fig. 50C.10). Hepatic artery reconstruction using microscopy is now well established and safely performed by experienced cosmetic or vascular surgeons; however, it remains unclear whether combined hepatic artery and liver resection offers a better chance of long-term survival. From 2001 to 2008, Igami and colleagues

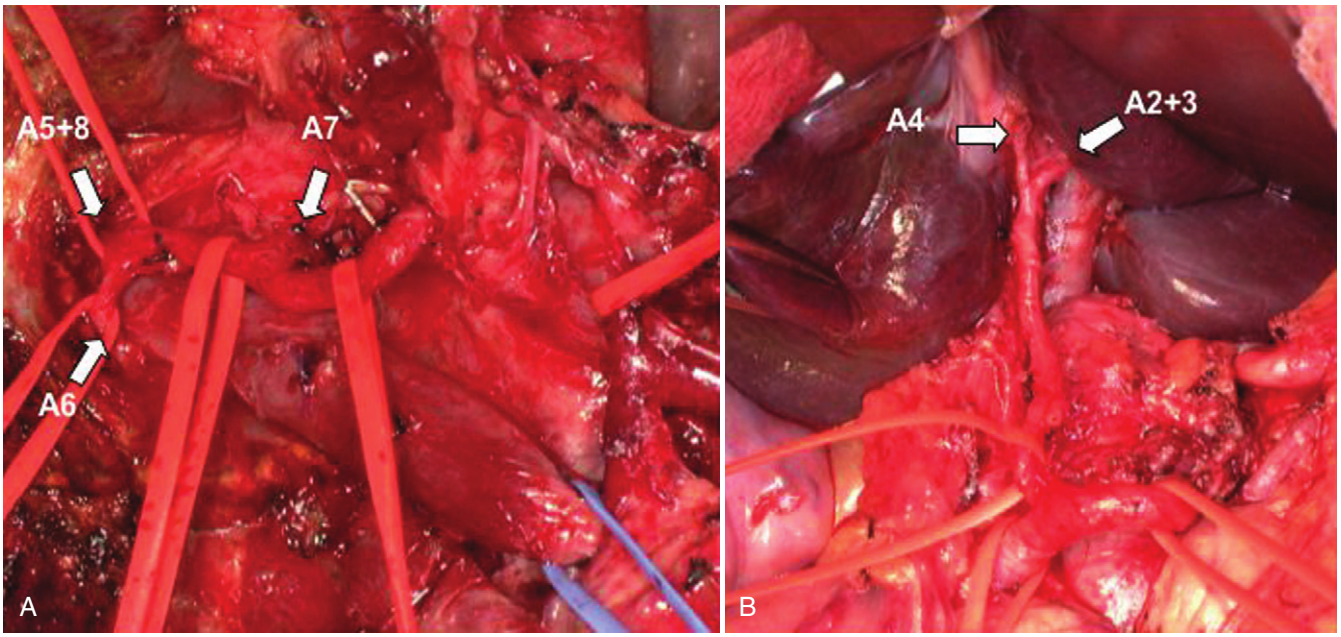

FIGURE 50C.9. Intraoperative view of two different variations of the hepatic artery distribution. **A,** The superior branch of the right posterior hepatic artery (*A7*) runs cranially to the right portal trunk. The inferior branch (*A6*) runs caudally to the right portal trunk. **B,** The left hepatic artery runs right to the umbilical portion of the left portal vein.

FIGURE 50C.10. A patient with perihilar cholangiocarcinoma invading bilateral hepatic arteries. The tumor was curatively resected by a left hepatectomy and caudate lobectomy with resection and reconstruction of the right hepatic artery. **A,** Three-dimensional volume-rendered image showing encasement of the right hepatic artery (*arrow*). **B,** Multiplanar reconstruction image showing the right hepatic artery eroded by tumor (*arrow*). **C,** Microscopic image of the resected specimen demonstrating cancer cells around the right hepatic artery.

(2010) performed combined hepatic artery resection and reconstruction in 53 patients. Despite the risky nature of this procedure, only one of the 53 patients died of complications, and the 5-year survival rate was 33%. This satisfactory result may encourage hepatobiliary surgeons to attempt this aggressive surgery.

PORTAL VEIN EMBOLIZATION

Portal vein embolization (PVE), introduced by Makuuchi and Kinoshita in the 1980s (Kinoshita et al, 1986; Makuuchi et al, 1990), can induce hypertrophy of the nonembolized lobe, has the potential to enhance the safety of extended hepatectomy, and has been considered the standard of care in preoperative management (see Chapter 93). Some authors have reported that PVE can be safely performed without serious complications, and it can minimize postoperative liver dysfunction. A recent meta-analysis involving 37 highly selected reports from the literature also supports the utility of PVE (Abulkhir et al, 2008). However, because no RCT has been conducted, the indication for PVE still remains undefined. The choice of device, technique, or embolic agent is generally based on the operator's preference.

Belghiti (2004) summarized the indication for PVE as follows: 1) a percentage of FLR of 25% or less in normal liver; 2) scheduled concomitant extrahepatic surgery or complex hepatectomy; and 3) any major hepatectomy in patients with underlying chronic diseases or with an injured liver (chemotherapy, major steatosis, or cholestasis). In this context, most patients with perihilar cholangiocarcinoma may be candidates for preoperative PVE because they require extensive hepatectomy, frequent vascular resection, and have a cholestatic liver requiring biliary drainage. In our department, PVE is

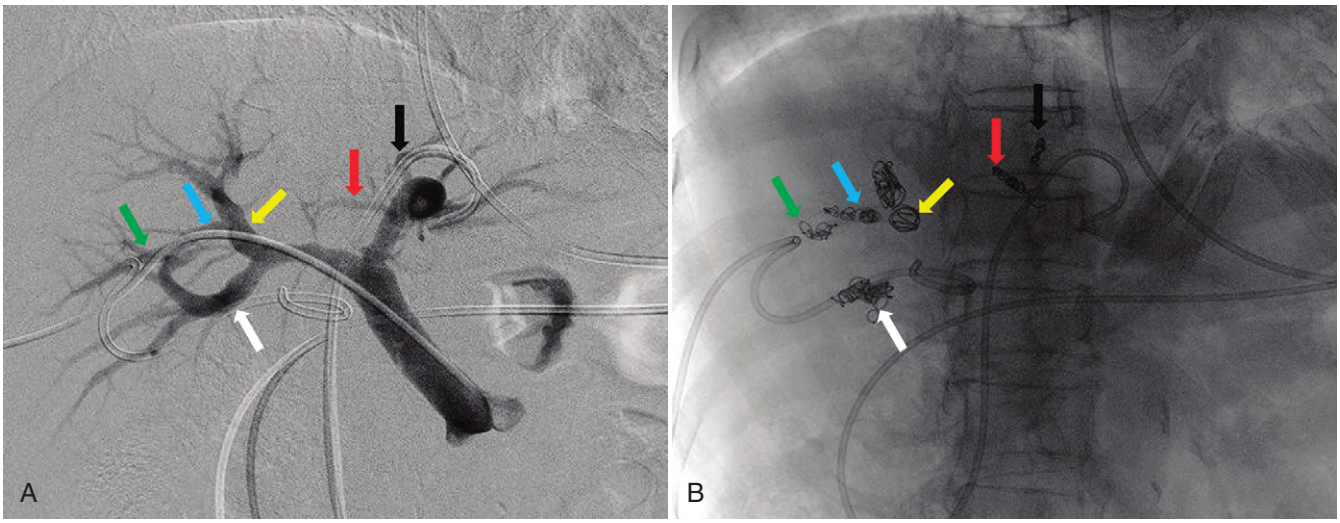

FIGURE 50C.11. Right trisegment portal vein embolization. **A,** The right anterior portal vein was punctured. The right oblique position clearly demonstrates the portal bifurcation. *Arrows* show the site of the placed steel coil. **B,** Plain film after completion of portal vein embolization.

performed when the estimated FLR is below 40% (Nagino et al, 2006b).

The two most common techniques for PVE are *transileocolic portal vein embolization* (TIPE) (Makuuchi et al, 1990) and *percutaneous transhepatic portal vein embolization* (PTPE) (Kinoshita et al, 1986). Many surgeons prefer TIPE to PTPE (Imamura et al, 1999; Makuuchi et al, 1990) for three main reasons: First, surgeons can perform a minilaparotomy. Second, catheterization is easier because of the straightforward ramification of the portal branches. Third, a diagnostic laparotomy and intraoperative ultrasound provide further accurate staging of the disease (Imamura et al, 1999). However, TIPE has some disadvantages; it requires general anesthesia, and it comes with a theoretical higher risk of postoperative complications such as ileus (Imamura et al, 1999). In contrast, PTPE can be performed in the radiologic suite with the patient under local anesthesia and conscious sedation. Because general anesthesia is avoided, cost is reduced, and recovery time is short. Overall, PTPE is superior to TIPE and, accordingly, TIPE should be used only when interventional radiologic facilities are not available.

As an alternative to the conventional transhepatic contralateral approach, in which the umbilical portion of the left portal vein is punctured for right-sided PTPE access, we developed a different approach for PTPE, termed the *ipsilateral approach* (Nagino et al, 1996). In this approach, the portal branch of the sector to be resected is punctured, thereby minimizing the risk of vascular injury in the FLR. This is the main advantage of the transhepatic ipsilateral approach. Furthermore, there is no risk of portal bleeding after removal of the catheter sheath. As PTPE is indicated in patients who are to undergo right hemihepatectomy or right or left trisectionectomy, the right anterior sector will always be resected. Hence, the right anterior portal branch is recommended for puncture using any type of PVE. Importantly, to confirm the individual anatomy of the portal system, a portogram is obtained with at least three different projections: 1) supine position, 2) right anterior oblique projection, and 3) right anterior oblique projection tilting caudally 20 degrees (Nishio et al, 2003). The third projection provides the best visualization of the right anterior/posterior portal vein and the left portal vein. Selective catheterization of the right portal branches is also important for complete occlusion without migration of the embolic material. In the case of a right PVE, a proximal segment at least 1 cm long must remain unembolized to facilitate the division and closure of the right portal vein during surgery.

We have developed an extensive PTPE procedure called *trisegment portal vein embolization* (Madoff et al, 2005; Nagino et al, 1995, 2000a). Right or left trisectionectomy is the most extensive hepatectomy performed and is often associated with major sacrifice of parenchyma (Nagino et al, 1995). The ipsilateral approach through the right anterior portal vein makes trisegment PVE possible (Fig. 50C.11). It allows catheterization of the segment IV branch (P4) in the case of right trisegment PVE (P4 plus right anterior and posterior portal vein) and of the left portal vein in the case of left trisegment PVE (left and right anterior portal vein). The use of a coaxial catheter system or a curved catheter adjusted for the angulation helps to advance the catheter into P4, which often has two to three branches (Takayasu et al, 1985). Although additive P4 embolization prior to right trisectionectomy still remains controversial, the volume gain of the left lateral segment is larger in patients with right trisegment PVE than in those with conventional right PVE (Madoff et al, 2005; Nagino et al, 2000a). On the other hand, left trisectionectomy is a technically demanding and challenging procedure with higher morbidity than other anatomic hepatectomies (Nishio et al, 2005). With left trisegment PVE, a demarcation between the right anterior and posterior sector appears on the liver surface just after temporary clamping of the RHA. This is simple and useful in patients with locally advanced perihilar cholangiocarcinoma requiring combined hepatic artery and portal vein resection, in which hilar dissection cannot be completed before liver resection. Therefore, we recommend use of left trisegment PVE before this complex surgery.

From 1991 to 2005, we performed PTPE in 240 patients with biliary cancer, which included 150 perihilar cholangiocarcinomas and 90 gallbladder cancers involving the hepatic hilus (Nagino et al, 2006b). All patients were scheduled to undergo

Table 50C.2

Type of Planned Hepatectomy and Embolized Portal Vein

Planned Hepatectomy	Embolized Portal Vein	No. Patients
Right trisectionectomy	Right and left medial	23
	Right	4
Left trisectionectomy	Left and right anterior	26
Left		5
Right anterior		8
Right hepatectomy	Right	160
Right anterior		9
Right posterior		5
Total		240

extended major hepatectomy, and all procedures were performed using the ipsilateral approach. The PTPE was done 2 to 4 weeks before surgery, when the total serum bilirubin levels were lower than 5 mg/dL. Details of the PTPEs performed are listed in Table 50C.2. From 1991 to 2000, fibrin glue mixed with iodized oil was injected thorough two different types of triple-lumen balloon catheters (Nagino et al, 1993a). Recently, absolute ethanol injection followed by placement of steel coil has been used. Because absolute ethanol is not radiopaque, and it permeates into the peripheral portal system and induces endothelial injury/thrombosis, it must be carefully and slowly administered in 0.5- to 2.0-mL increments, meeting the extent of the liver volume fed by the target portal branch. After ethanol injection, steel coils are placed at the second- or third-order portal branch for permanent and complete occlusion. Although the rate of recanalization was slightly higher with fibrin glue (8.3%) than with ethanol and coils (5.1%), no significant difference was reported in either the hypertrophy ratio of the nonembolized lobe or the atrophy ratio of the embolized lobe. No procedure-related serious complications requiring a blood transfusion or interventions occurred. In addition, unexpected tumor growth after PVE was not observed.

Our strategy for unsatisfactory volume gain of the nonembolized liver after PVE is straightforward. In the case of revascularization, repeat PVE should be performed. When sufficient hypertrophy cannot be achieved despite complete PVE, second-line interventions should be considered for further hypertrophy. Sequential hepatic artery embolization of the ipsilateral liver or hepatic vein embolization may be useful to boost liver regeneration (Hwang et al, 2009; Nagino et al, 2000b). Selective intrahepatic biliary ablation with absolute ethanol can also be applied for this purpose, when the biliary duct in the embolized lobe is completely separated from the duct of the FLR (Kyokane et al, 2001). Because all of these optional interventions are empiric, technically demanding, and still experimental, the indication should be strictly selective.

OTHER SPECIFIC MANAGEMENTS

Internal Drainage and Bile Replacement

The superiority of internal biliary drainage is shown in experimental and clinical studies that have demonstrated that liver regeneration after partial hepatectomy is suppressed under external drainage but not under internal drainage (Clements et al, 1993; Saiki et al, 1999; Suzuki et al, 1994). Ogata and colleagues (2003) investigated bacterial translocation in bile duct–ligated rats and found that bile replacement is essential to maintain intestinal barrier function. Recently, we studied the effect of bile replacement on intestinal permeability, integrity, and microflora in 25 biliary cancer patients who underwent PTBD as a part of presurgical management (Kamiya et al, 2004). Impaired intestinal barrier function did not recover using PTBD without bile replacement, but bile replacement did restore intestinal barrier function. Our results strongly support that bile replacement during external biliary drainage is beneficial in preoperative patients with perihilar cholangiocarcinoma, because this type of hepatectomy is complicated and still a high-risk procedure. We ask all patients to drink their own externally drained bile juice.

Inchinkoto and Ursodeoxycholic Acid

Plants contain abundant bioactive materials. In Japan, oriental herbal medicines are now manufactured under modern scientific quality controls and have been empirically administered to many kinds of patients for more than 30 years. Inchinkoto, one such medicine, has been traditionally recognized as a "magic bullet" for jaundice. In experimental rat models, inchinkoto attenuates gene expression for inflammatory cytokines and inducible nitric oxide synthase and also upregulates antioxidants genes (Kawai et al, 2010). We confirmed the choleretic effect of inchinkoto in a prospective controlled trial involving 27 patients with cholangiocarcinoma (Watanabe et al, 2009). The biliary concentration of total bilirubin and total bile acids were significantly increased after administration of inchinkoto, and the protein levels of MRP2, a bilirubin transporter expressed in the canalicular membrane of hepatocytes, was also significantly higher in patients treated with inchinkoto. Thus, inchinkoto has a therapeutic potential in obstructive cholestasis associated with cholangiocarcinoma.

Ursodeoxycholic acid (UDCA) is a major primary bile acid in some species of bear (Hagey et al, 1993). For centuries, dried bear bile has been used in traditional Chinese medicine as a remedy for liver disorders. In humans, UDCA is considered a minor secondary bile acid that is formed in the gut by intestinal bacteria and accounts for less than 3% of the whole bile acid pool (Hofmann, 1994). Pathophysiologically, UDCA has several effects on hepatocytes: protection against oxidative stress, inhibition of apoptosis, stimulation of bile flow, detoxification of cholephilic compounds, and immunomodulation (Perez & Briz, 2009). Therefore, UDCA is widely used for cholestatic liver disease. In our department, UDCA and Inchinkoto are routinely used in jaundiced patients undergoing biliary drainage.

Synbiotic Administration

Infections in immunocompromised hosts often arise from their intestinal microflora (Tancrede & Andremont, 1985; Wang et al, 1993). Indigenous enteric gram-negative bacteria, such as the *Enterobacteriaceae*, are among the leading causes of infections. Lilly and Stillwell first introduced the term *probiotics* for bacteria that benefit the host by improving the intestinal microbial balance. *Lactobacilli* and *Bifidobacteria* are widely used as probiotics (Fuller, 1991). In addition, *prebiotics* are nondigestive food

Table 50C.3

Supplemental Protocol for Preoperative Patients Who Are to Undergo Hepatobiliary Resection in Nagoya University Hospital (14 Days to 1 Day Before Surgery)

Regular diet
Replacement of bile
Inchinkoto 7.5 g/3 × 1
Ursodeoxycholic acid 600 mg/3 × 1
Prebiotics: oligomate 15 mL/3 × 1
Probiotics
Yakult 400 1 pack/day
Bifile 1 pack/day

Oligomate, galactooligosaccharides; Yakult 400, *Lactobacillus casei* strain Shirota 400 × 108; Bifile, *Bifidobacterium breve* strain Yakult 100 × 108 plus galactooligosaccharides 0.6 g

constituents that selectively alter the growth and/or activity of a limited number of beneficial bacteria in the colon, thus potentially improving the health of the host (Collins & Gibson, 1999; Fuller, 1991; Gibson et al, 1995). Several types of ingredients, such as fructooligosaccharides, galactooligosaccharides, and inulin, are used as prebiotics. The combined use of probiotics and prebiotics is called *synbiotics* (Collins & Gibson, 1999). Synbiotic combinations have beneficial effects on human health, but their clinical value in surgical patients remains unclear because, to date, only a few clinical studies have been conducted on synbiotics (Rayes et al, 2002a, 2002b). We investigated the effect of postoperative synbiotics, combined with early enteral nutrition, in biliary cancer patients undergoing hepatectomy (Kanazawa et al, 2005). The primary result of this RCT was that the incidence of infection was 19% in the synbiotics group and 53% in the control group ($P < .05$), demonstrating that synbiotics can reduce postoperative infections. This beneficial effect encouraged us to schedule the next RCT, which investigated the benefit of perioperative use of synbiotics compared with postoperative use only (Sugawara et al, 2006). The incidence of postoperative infection was 30% in the former group and 12% in the latter group ($P < .05$), showing that perioperative synbiotics can decrease postoperative infections. Our latest protocol for perioperative supplementation is presented in Table 50C.3.

CHAPTER 50D

Cancer of the bile ducts: interventional techniques in hilar and intrahepatic biliary structures

Karen T. Brown

OVERVIEW

Malignant disease resulting in high bile duct obstruction (Fig. 50D.1)—that is, obstruction above the junction with the cystic duct—is not uncommon. Although frequently related to primary tumors of the biliary tree (see Chapters 49, 50A, and 50B), hilar obstruction, and even intraductal tumor, can be seen with other common malignancies such as breast, pancreatic, and colorectal cancers. Significant technical progress has occurred in both endoscopic and percutaneous biliary drainage, allowing safer palliative treatment of patients with such obstructions. Because these patients are often asymptomatic at presentation, the goals of treatment should be clearly defined prior to committing the patient to even a minimally invasive procedure. First and foremost, whether the patient is a surgical candidate should be determined. With the exception of patients who are clearly in a palliative situation, we prefer to discuss these patients in a multidisciplinary group with hepatobiliary surgeons, interventional radiologists, oncologists, and gastroenterologists to outline a plan of treatment. A thorough understanding of this plan and of the patient's prognosis facilitates the development of a strategy for drainage. Accepted indications for palliative biliary drainage in these patients include intractable pruritus, cholangitis, the need to restore liver function to allow for administration of chemotherapeutic agents with biliary metabolism/excretion, access for intraluminal brachytherapy or choledochoscopy, and diversion for bile leak. Given the availability of high-quality magnetic resonance cholangiopancreatography (MRCP), direct cholangiography as a diagnostic tool is rarely warranted (see Chapters 17 and 18; Choi et al, 2008; Park et al, 2008).

INDICATIONS FOR BILIARY DRAINAGE

Neither hyperbilirubinemia alone nor the computed tomographic (CT) or ultrasound finding of dilated bile ducts is an indication for biliary drainage. Pruritus, cholangitis, and the need to lower the bilirubin to administer certain chemotherapeutic agents, on the other hand, are all accepted indications for biliary drainage. Patients who have undergone biliary-enteric bypass as part of curative resection for a benign or malignant lesion may develop postoperative bile leaks that require drainage for diversion. In some cases, access to the biliary tree may be undertaken as a method of delivering local treatment for primary bile duct cancer, such as brachytherapy or photodynamic therapy. Many physicians have the impression that patients feel better and have improved performance status after relief of jaundice; however, this has not been confirmed in clinical studies. Indeed, in a prospective trial, we have shown that in patients with malignant biliary obstruction, percutaneous drainage does not significantly improve quality of life (QOL), except for improving pruritus (Robson et al, 2007). Controversy remains in regard to the role of biliary drainage prior to surgery (Johnson & Ahrendt, 2006; Mezhir et al, 2009; Wang et al, 2008).

ENDOSCOPIC VERSUS PERCUTANEOUS DRAINAGE (SEE CHAPTERS 18, 27, AND 28)

Patients with low bile duct obstruction are typically treated endoscopically. Patients with high bile duct obstruction, particularly when the obstruction extends above the hilus, have traditionally been treated percutaneously. This is because the success rate of percutaneous drainage has been higher, and the complication rate lower, when compared with endoscopic methods (Rerknimitr et al, 2004). This perspective is evolving as endoscope technology becomes more advanced, and endoscopists become better trained and more experienced in wire-guided procedures and have better guidewires and stents with which to work.

The two biggest drawbacks to endoscopic drainage for high bile duct obstruction have been the lack of ability to reliably target a specific area of the liver for drainage and the risk of contamination, by retrograde injection of contrast, of parts of the biliary tree that will not be drained. It is not uncommon to see a patient who is thought to have undergone successful endoscopic stenting of the right and left liver only to find, upon repeat imaging, that is not the case at all (Fig. 50D.2). Despite this, endoscopic management is indicated in some cases of high bile duct obstruction. This is particularly so when the risk of the patient having a permanent exteriorized catheter is high or when a patient has a higher risk of contaminating the entire biliary tree if approached percutaneously.

One exciting new endoscopic approach is the placement of a transgastric segment III stent using endoscopic ultrasound. This procedure is considered when a patient is best treated by draining the left lateral segment, and the percutaneous approach is technically difficult, or where the risk of contaminating the right-sided bile ducts is thought to be high with or without being able to cross the obstruction. This is particulary indicated when draining the right liver would be of no clinical benefit, either because of replacement of right liver by tumor or occlusion of the right portal vein (Fig. 50D.3). When technically feasible, this procedure can be gratifying for the patient, with relief of pruritus and lowering of bilirubin without the added burden of a percutaneous catheter. Endoscopic drainage is almost never indicated in patients with papillary intraductal tumor because it can easily grow into a metallic stent and result

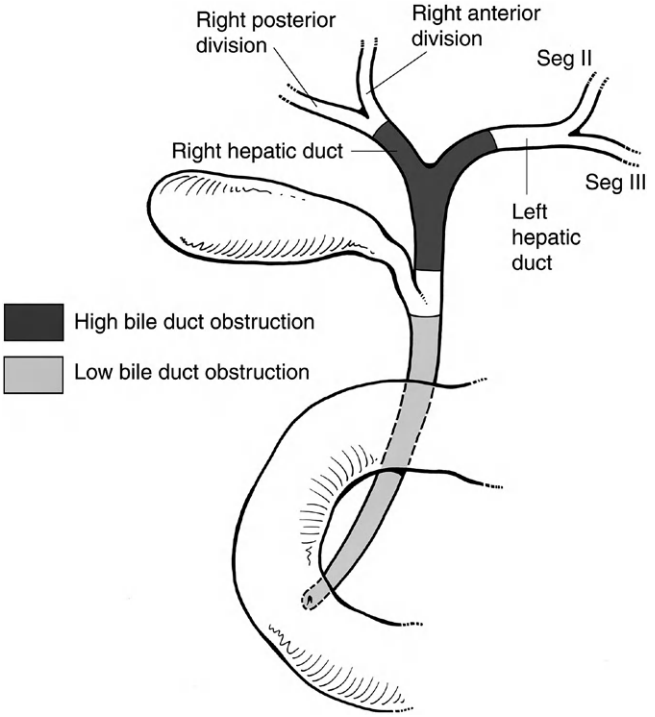

FIGURE 50D.1. High bile duct obstruction refers to obstruction at or above confluence (*dark gray area*); low bile duct obstruction occurs below the common hepatic duct (*light gray area*). Seg, segment. *(Courtesy Memorial Sloan-Kettering Cancer Center Medical Graphics.)*

in early stent occlusion. Intraductal tumor can be seen from cancers other than papillary cholangiocarcinoma. When intraductal tumor occurs in the setting of metastatic colorectal cancer, it is usually the direct extension of a parenchymal metastasis into the duct. Patients with intraductal tumor often require permanent indwelling catheter drainage. The indwelling multiple sidehole catheter allows bile to drain around the intraductal tumor, and it can be changed every 10 to 12 weeks to maintain catheter patency (Fig. 50D.4). Having a realistic idea of what is feasible endoscopically and percutaneously is very important when making the initial decision regarding who will treat the patient. This depends on a thorough understanding of the goal of treatment as well as knowledge of the skill level of the interventional radiologists and endoscopists available to care for the patient.

Preprocedure Preparation

Imaging

The importance of excellent preprocedure imaging in patients with bile duct obstruction cannot be overemphasized. This imaging should include at a minimum a contrast-enhanced CT scan of the abdomen. Ultrasound is often used to establish the presence of dilated bile ducts, identify the level of obstruction, evaluate portal vein patency, and demonstrate intraductal tumor, but ultrasound is not adequate for drainage planning. Although MRCP provides an excellent three-dimensional (3D) rendering of the obstructed bile ducts and is excellent at delineating intraductal abnormalities and depicting isolated bile duct (Fig. 50D.5), it excludes certain things that can serve as targeting aides at the time of drainage, such as surgical clips, dystrophic calcifications, and bone landmarks. CT scans performed on multislice scanners in a picture archiving and communication system (PACS) environment allow the development of a 3D understanding of the anatomy while identifying relevant landmarks that can be used for targeting, and it also demonstrates other structures that should be avoided, such as liver lesions and bowel. Of course, as with MRI, one may also identify ascites, hepatic atrophy, and portal vein occlusion or encasement. All of this information is important in making prognostic assessments and in determining the best approach for drainage.

When planning drainage in patients with high bile duct obstruction, it is important to determine the amount of functional parenchyma that can be drained. Functional parenchyma is the part of the liver that is not replaced by tumor, and it has an intact portal venous supply. If 75% of the hepatic parenchyma is replaced by tumor, even if it were possible to drain the entire biliary tree, it is unlikely that normal hepatic function or normalization of serum bilirubin level would be restored. The portal vein provides the trophic blood supply to the liver, and occlusion results in atrophy of the affected segment or segments, particularly when the ipsilateral bile duct is also occluded (see Chapter 5; Hann et al, 1996). Atrophy may be recognized by the diminutive size of the involved part of the liver, accompanied by crowding of the bile ducts (Fig. 50D.6; see also Chapter 50B and Figs. 50B.6 and 50B.7). When portal vein occlusion causes atrophy, drainage of the atrophied liver does not improve liver function. In addition, it is frequently difficult to cross out of the obstructed/atrophied portion of the liver. The end result is an external drainage catheter that provides no clinical benefit to the patient but degrades QOL.

Central tumors frequently obstruct the right and left biliary tree, isolating them from one another. Obstruction may extend even higher, isolating the ductal system at the sectoral, segmental, or subsegmental level. When drainage is undertaken for relief of pruritus, draining even a segment of the liver may result in relief of symptoms (Abraham et al, 2002; Van Laethem et al, 2003). When isolation is present, and drainage is undertaken to lower the serum bilirubin, it is important to estimate how much functional parenchyma can be drained with one catheter. *Functional liver parenchyma* is defined as hepatic parenchyma with intact portal venous inflow and hepatic venous drainage. Analogous to a surgeon resecting no more than 75% of the liver to ensure an adequate liver remnant, it seems that at least 30% of functional hepatic parenchyma must be drained to improve liver function for chemotherapy, returning the serum bilirubin to normal or near-normal levels. In some cases, this goal may be impossible to achieve, unless more than one drainage catheter or stent is placed. Recognition of this allows for informing both the patient and referring physician about the potential need for more than one catheter or stent.

Cholangitis is rarely the primary indication for drainage in patients with malignant bile duct obstruction, except in patients who have undergone instrumentation and in those who have reason to have a contaminated biliary tree by virtue of previous biliary-enteric bypass, cross ampullary stenting, or sphincterotomy (Ozden et al, 2005). When draining a hemiliver or a segment, either percutaneously or endoscopically, it is possible to contaminate functionally "isolated" parts of the biliary tree. In this case, subsequent cholangitis may drive the placement of additional catheters. Widespread contamination of a severely isolated biliary tree with drainage of only part of the obstructed system can result in chronic recurrent cholangitis. Whether induced by endoscopic or percutaneous means, this situation

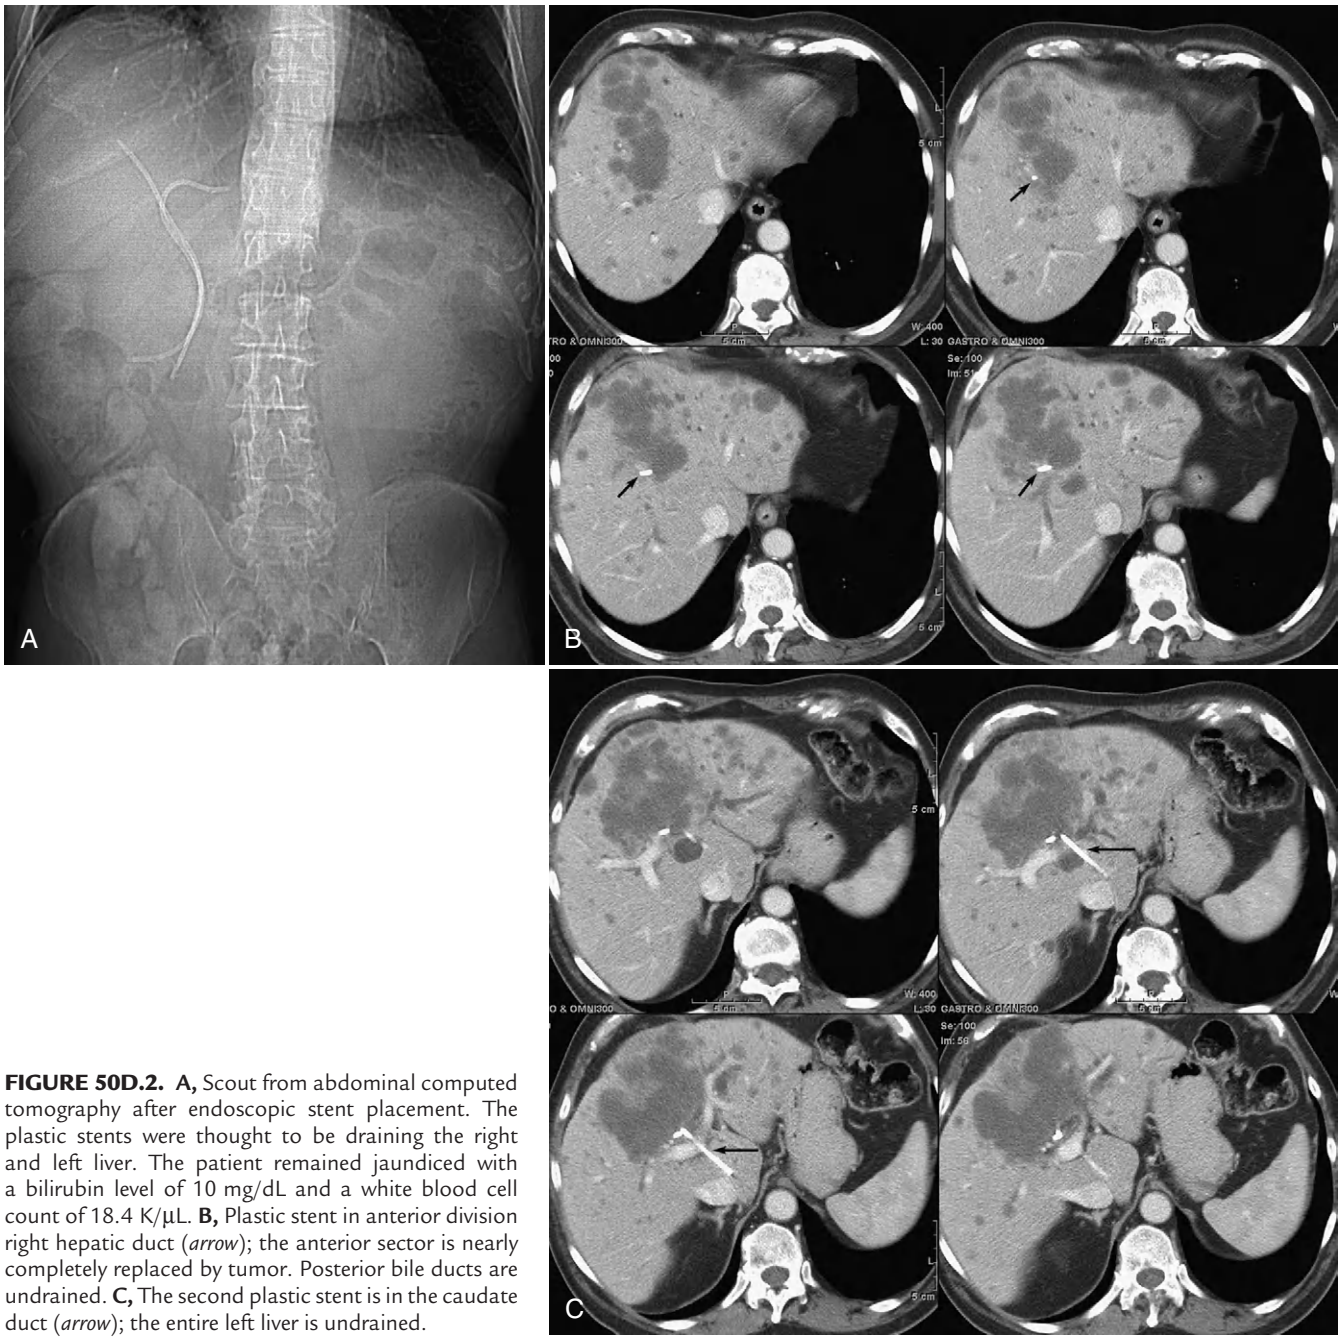

FIGURE 50D.2. **A,** Scout from abdominal computed tomography after endoscopic stent placement. The plastic stents were thought to be draining the right and left liver. The patient remained jaundiced with a bilirubin level of 10 mg/dL and a white blood cell count of 18.4 K/μL. **B,** Plastic stent in anterior division right hepatic duct (*arrow*); the anterior sector is nearly completely replaced by tumor. Posterior bile ducts are undrained. **C,** The second plastic stent is in the caudate duct (*arrow*); the entire left liver is undrained.

can be difficult to manage and should be anticipated and avoided if possible.

Laboratory Studies

Patients undergoing biliary drainage need a complete blood count, hepatic function panel, and coagulation studies. The serum bilirubin can change rapidly when patients become obstructed. Because decisions regarding the need for further drainage in high obstruction and isolated bile ducts depend in part on the serum bilirubin, it is important to draw this reference laboratory value within 24 hours prior to drainage. Because this value is typically increasing at the time of drainage, it is common for the serum bilirubin to be higher the morning after the drainage procedure than it was the morning of the procedure. Serum bilirubin values drawn 48 hours after drainage more accurately predict effectiveness of drainage. Poor hepatic synthetic function may result in elevation of the prothrombin time (PT) and international normalized ratio (INR) and the partial thromboplastin time (PTT). If needed, underlying coagulopathy may be corrected by the administration of vitamin K or fresh frozen plasma, depending on the urgency of drainage.

Antibiotics

Preprocedure antibiotic prophylaxis is given to all patients undergoing biliary drainage, even if the patient does not have an elevated white blood cell count or fever, as bactibilia is present in 30% to 40% of patients without these signs (see Chapter 11;

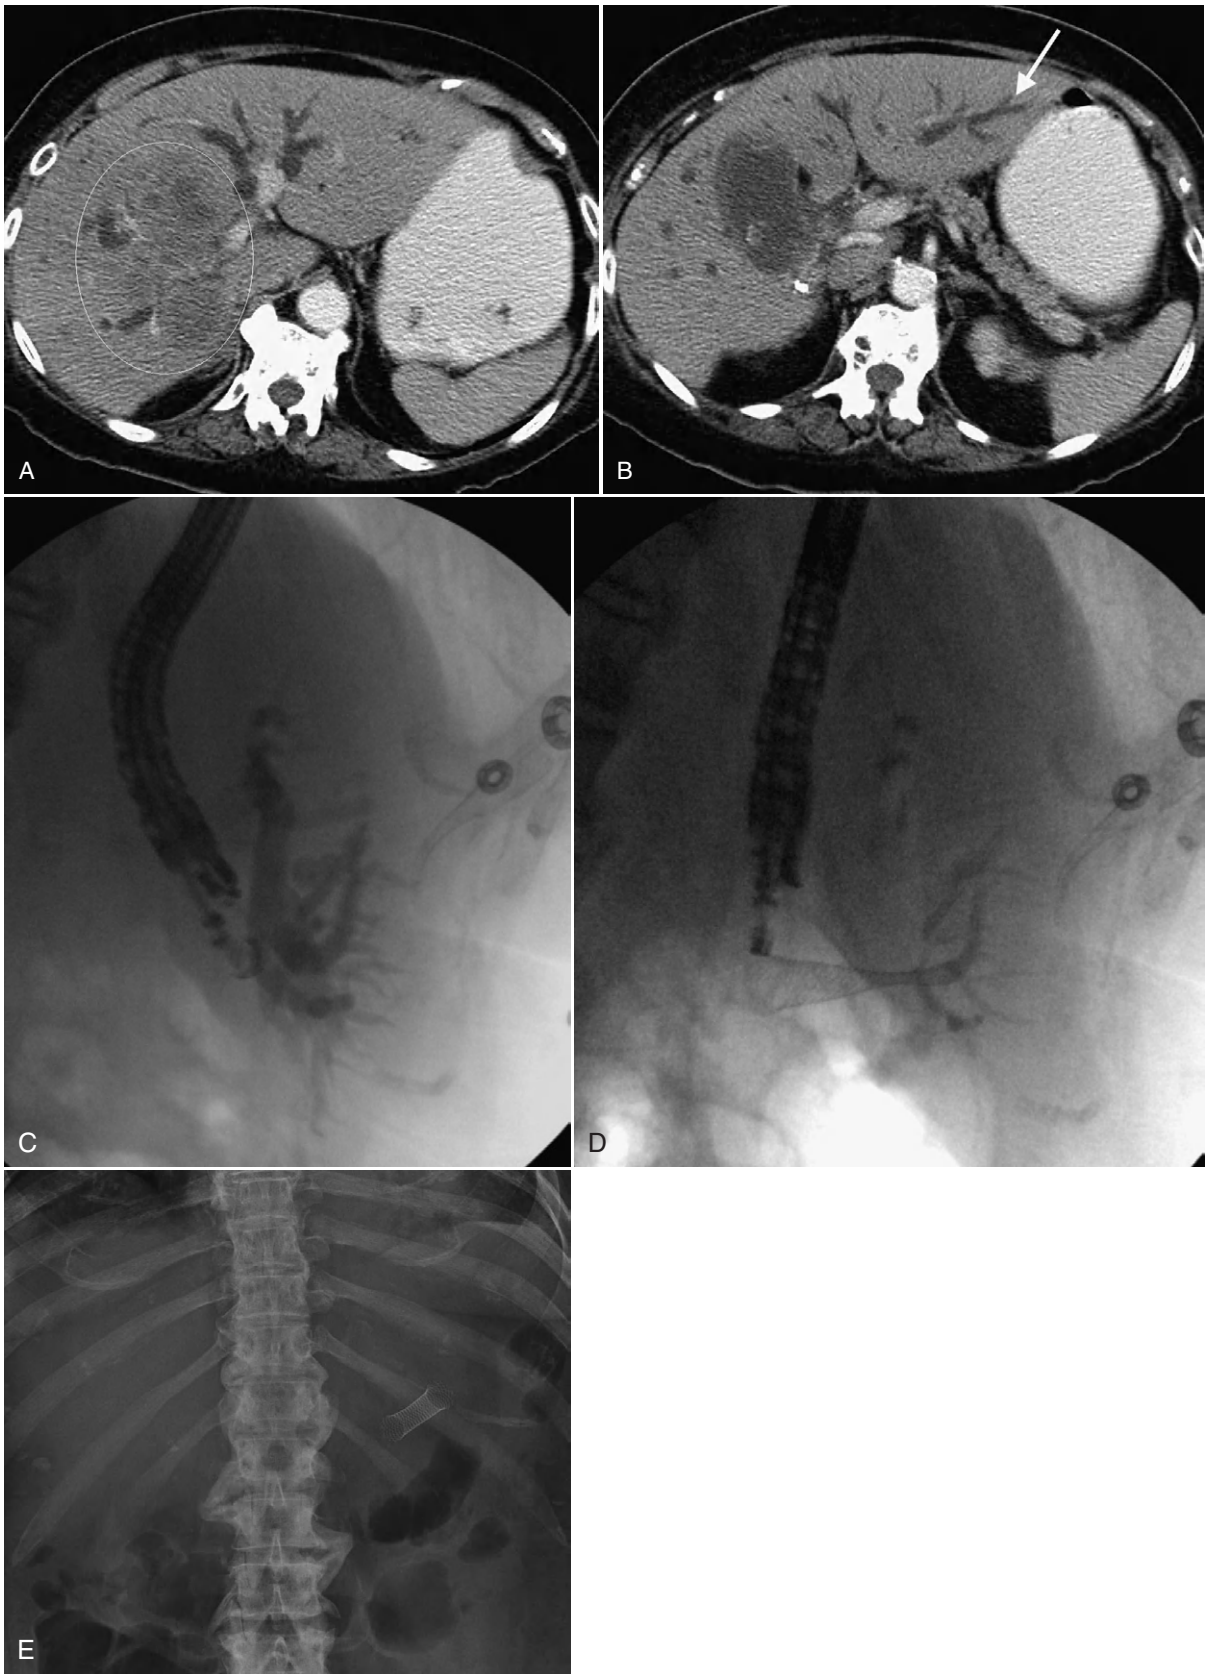

FIGURE 50D.3. A, Central mass in right liver (*circled*) encasing the right portal vein and isolating right anterior and posterior bile ducts. **B,** Segment III duct (*arrow*) in close proximity to the stomach. **C,** Endoscopic image after puncture into segment III duct and injection of contrast. **D,** Image following placement of transgastric segment III stent. **E,** Image of the kidney, ureter, and bladder the next day demonstrates a well-expanded stent between the lesser curvature of the stomach and the segment III bile duct.

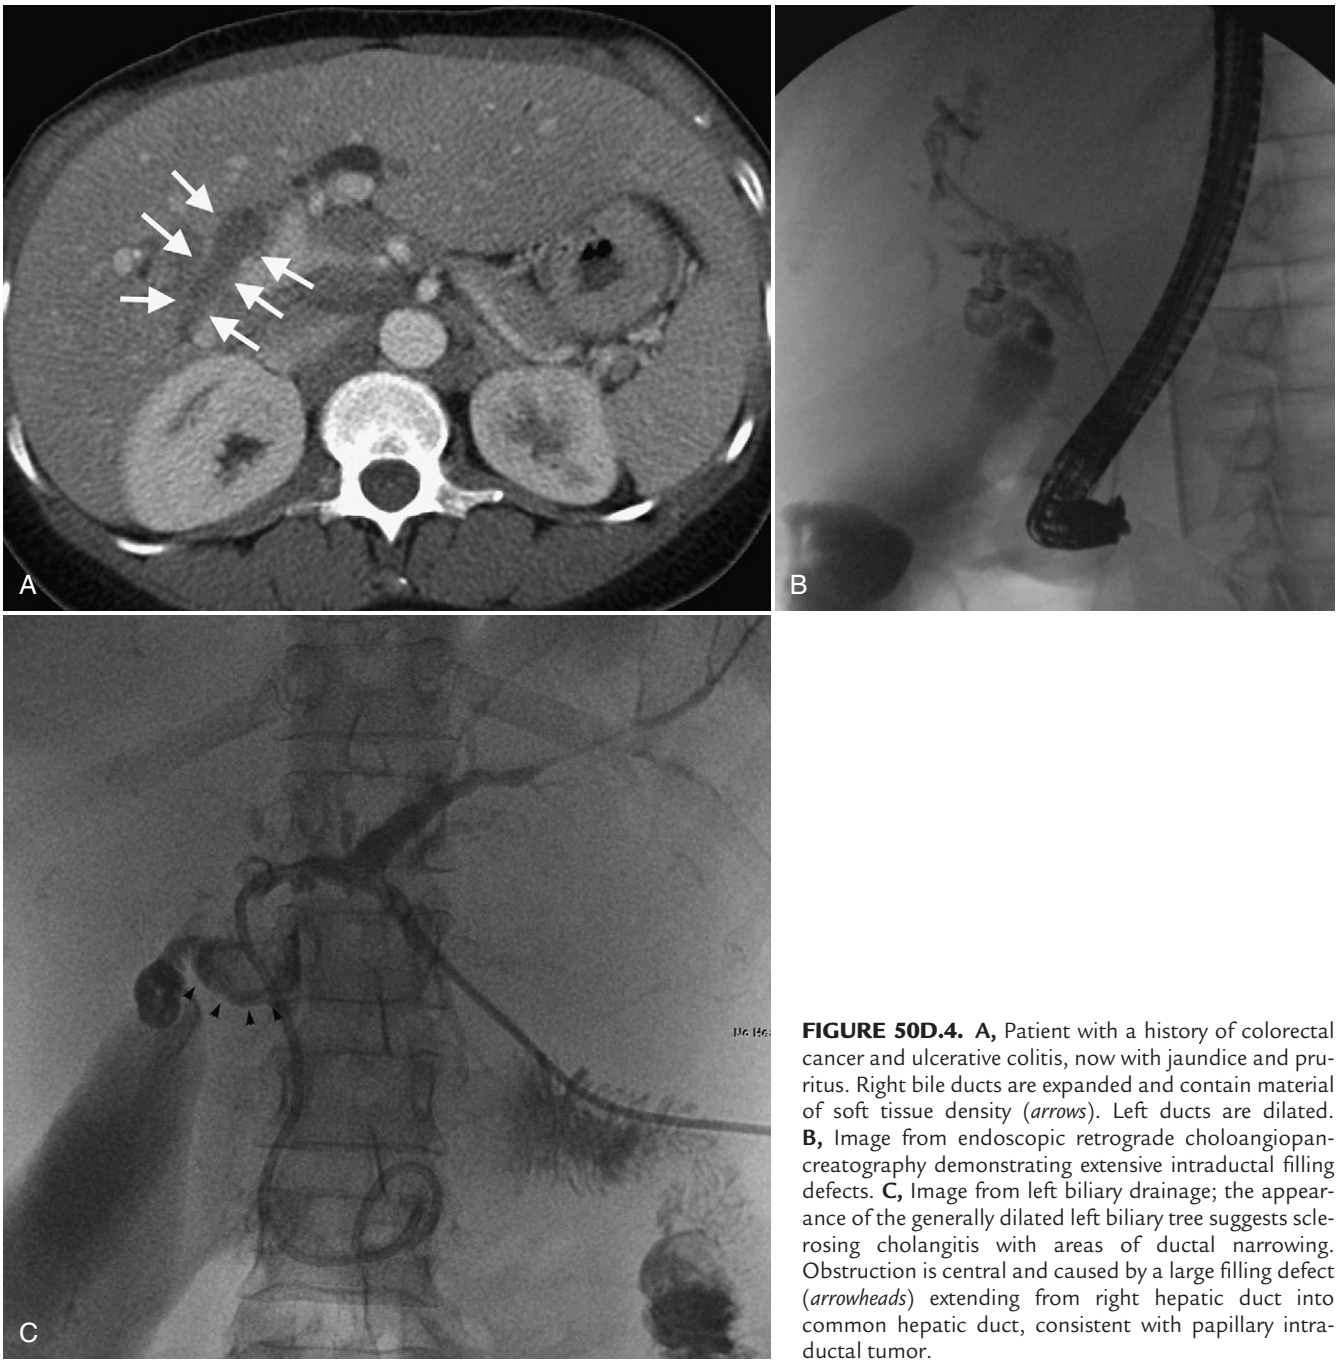

FIGURE 50D.4. A, Patient with a history of colorectal cancer and ulcerative colitis, now with jaundice and pruritus. Right bile ducts are expanded and contain material of soft tissue density (*arrows*). Left ducts are dilated. **B,** Image from endoscopic retrograde choloangiopancreatography demonstrating extensive intraductal filling defects. **C,** Image from left biliary drainage; the appearance of the generally dilated left biliary tree suggests sclerosing cholangitis with areas of ductal narrowing. Obstruction is central and caused by a large filling defect (*arrowheads*) extending from right hepatic duct into common hepatic duct, consistent with papillary intraductal tumor.

Brody et al, 1998). Many patients become bacteremic during the procedure, even in the absence of preintervention signs or symptoms of infection. Generally, patients receive broad coverage with an agent such as ticarcillin-clavulanate or ceftriaxone. When cholangitis is not present, administration of intravenous antibiotics beyond 24 hours is not warranted. Patients with a history of cholangitis or sepsis or those presumed to have a contaminated bilary tree related to transampullary stenting, biliary-enteric bypass, sphincterotomy, or recent instrumentation should receive prophylactic coverage with an agent such as piperacillin-tazobactam (Zosyn), which is excreted into the bile. Appropriate postprocedure coverage should be determined based on bile cultures obtained at the time of drainage.

Psychological Preparation

A thorough discussion of possible outcomes is particularly important prior to biliary drainage in patients with high bile duct obstruction. Patients should understand that, although every effort will be made to establish internal drainage with stents, this may not be straightforward. Although it is usually possible to cross an obstructing lesion into the common bile duct, internalization might be precluded by extensive isolation of the biliary tree, intraductal tumor, concomitant duodenal obstruction, or other factors. Two or more catheters or self-expanding stents may be required when the tumor extends beyond the secondary confluence on one side or the other, depending on the clinical objective. Such a discussion is not

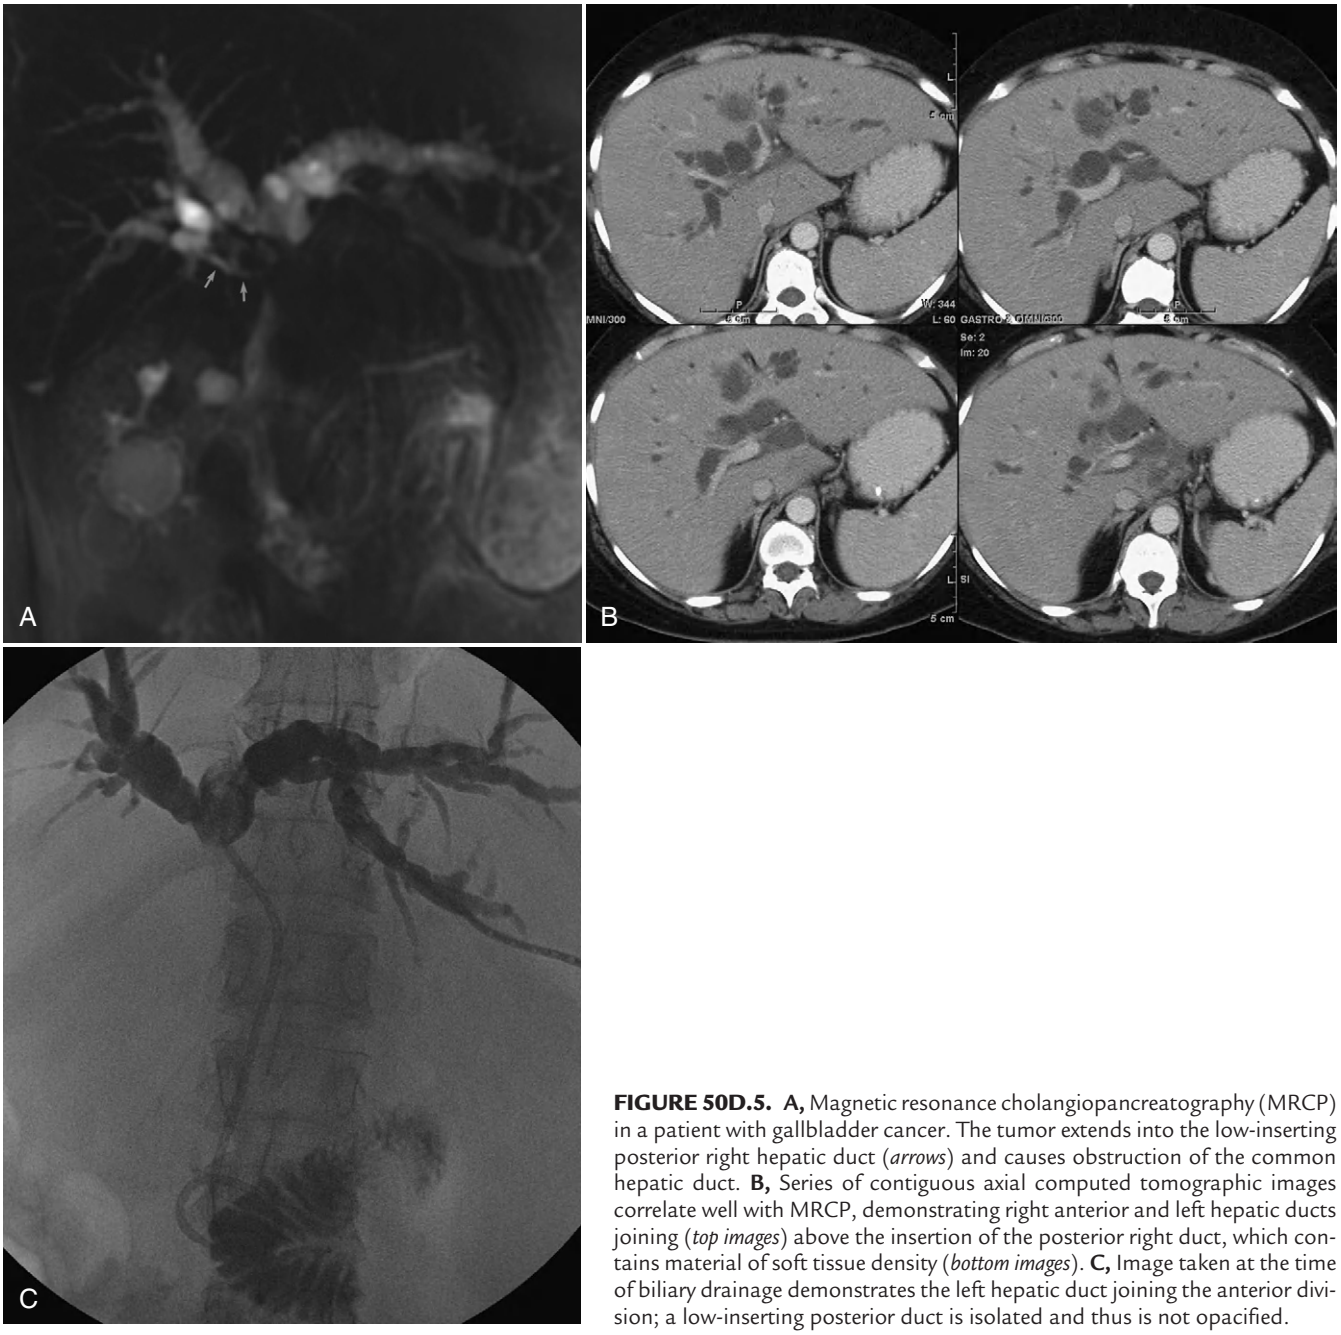

FIGURE 50D.5. **A,** Magnetic resonance cholangiopancreatography (MRCP) in a patient with gallbladder cancer. The tumor extends into the low-inserting posterior right hepatic duct (*arrows*) and causes obstruction of the common hepatic duct. **B,** Series of contiguous axial computed tomographic images correlate well with MRCP, demonstrating right anterior and left hepatic ducts joining (*top images*) above the insertion of the posterior right duct, which contains material of soft tissue density (*bottom images*). **C,** Image taken at the time of biliary drainage demonstrates the left hepatic duct joining the anterior division; a low-inserting posterior duct is isolated and thus is not opacified.

intended to frighten the patient but rather to promote an understanding of the complexity of the situation to mitigate sentiments of surprise or anger if stent placement is not possible at the initial encounter and subsequent procedures are necessary.

Even in the presence of segmental isolation, pruritus often resolves following biliary drainage. Unfortunately, it is not always possible to lower the serum bilirubin, particularly to levels that would allow for the administration of certain chemotherapeutic agents. In certain situations, two or more biliary drainage catheters may be placed without a significant decrease in bilirubin; sometimes, the bilirubin may even increase. It is possible that a single biliary drainage catheter may drain one portion of the liver well, while converting near-complete obstructions in other areas to complete obstructions (Fig. 50D.7). It also is conceivable that intervening cholangitis or progression of disease may play a role. Patients who have realistic expectations and some understanding of these issues before the initial biliary drainage procedure are less likely to become distressed if multiple procedures are required, or if the ultimate outcome is less than satisfactory.

INTRAPROCEDURAL ISSUES

Approach

Many interventional radiologists prefer a right-sided approach to the biliary tree. The right side of the liver is larger and more accessible than the left. Approach from the right side more

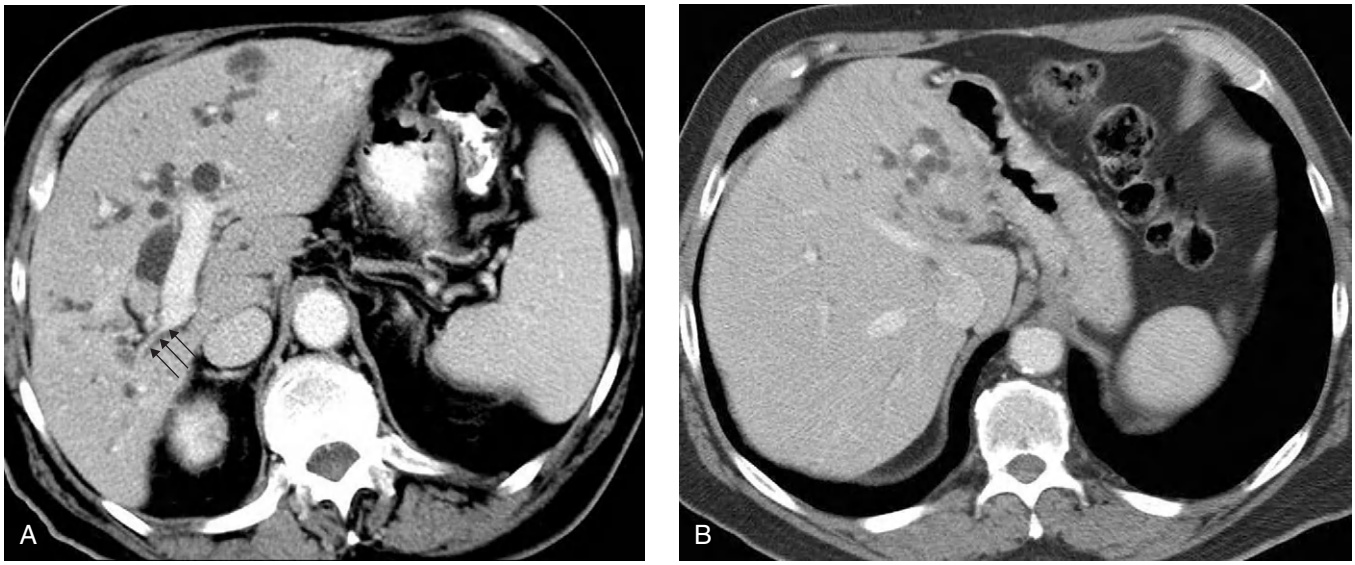

FIGURE 50D.6. A, Right hepatic atrophy. Volume of the right hemiliver is markedly diminished, with severe attenuation of the right portal vein (*arrows*). **B,** Left hepatic atrophy. Note the small size of the left hemiliver (anterior to middle hepatic vein) and crowding of dilated bile ducts.

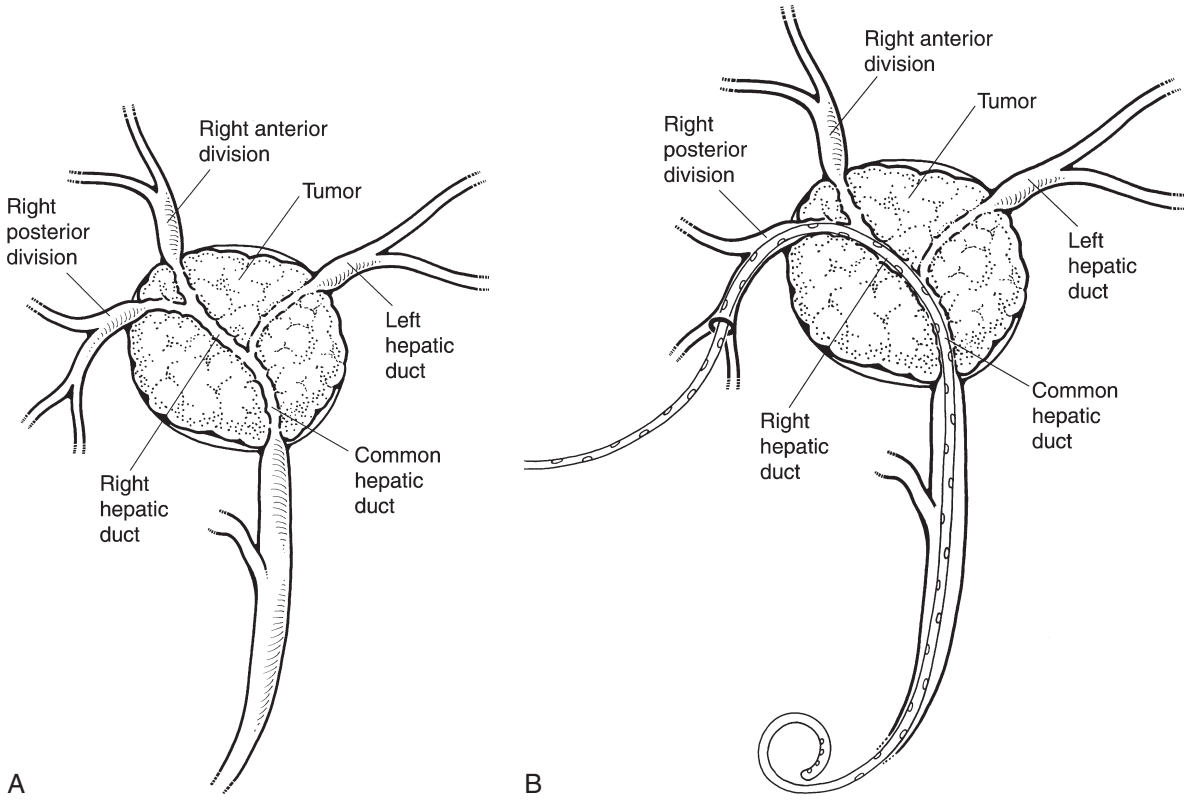

FIGURE 50D.7. A, Obstruction caused by tumor severely narrows the biliary tree up to the secondary confluence on right. **B,** After placement of a multiple sidehole catheter, the right posterior sector is well drained by the catheter, which converts near-complete obstruction of the right anterior division duct and left hepatic duct into complete obstruction by further compromising an already narrowed lumen. *(Courtesy Memorial Sloan-Kettering Cancer Center Medical Graphics.)*

easily avoids direct x-ray exposure to the hands of the operator and allows a direct approach to the hepatic hilus and common bile duct, making catheter and guidewire manipulations easier and often more successful. In addition, the approach from the right side is thought to be safer, because there are fewer structures between the skin and right liver that may be injured. Patients with low bile duct obstruction that cannot be drained endoscopically may be approached from either side.

The direct approach from the right is sometimes complicated, when the site of puncture is the right posterior duct, and that duct enters the left hepatic duct. This anatomic variant is often evident on preprocedure imaging studies (see Chapter 1B); it occurs in 20% of patients and may add a 180-degree turn to the approach to the hepatic hilum, making it more difficult to traverse the obstruction. On the other hand, when the obstruction extends to the left-right confluence but no higher, approach from the posterior right duct will drain the right posterior sector as well as the entire left liver. The main disadvantages to a right-sided approach are the discomfort associated with intercostal catheters, leaking of ascites around a more gravity-dependent right-sided catheter, and the fact that tumors are more likely to extend to the secondary confluence on the right.

A left-sided approach to the biliary tree is preferred in several instances. When an obstructing tumor extends above the biliary confluence, it may isolate the right and left bile ducts and may extend toward a secondary confluence or higher. As alluded to above, the right hepatic duct is typically shorter than the left (see Chapter 1B); as a result, tumor is more likely to extend to and isolate the right anterior and posterior sectoral ducts, while the left medial and lateral sectors continue to communicate. In such cases it may be possible to drain more functional hepatic parenchyma by placing a single catheter or stent on the left. Patients with ascites are less likely to leak around a left anterior catheter, so a left approach is preferred when possible. When atrophy or compromise of the portal vein is present, the patient will always derive more benefit from drainage of the contralateral functional liver, as previously discussed.

Image Guidance

In most cases, biliary drainage is performed with fluoroscopic guidance. Ultrasound is often used for duct puncture from a left-sided approach; a right-sided approached is used less often because bile duct orientation and the need to image through an intercostal space make the use of ultrasound more challenging and therefore less useful. Careful review of a high-quality CT scan is helpful for identifying radiopaque landmarks that may be used to target a specific region of the biliary tree or even a specific bile duct. This review is particularly important when isolation is suspected and the objective is to target a specific duct. If the right anterior duct is the target, it would be unfortunate to enter a segment IV duct by being too anterior or medial. Previously placed stents, surgical clips, or other radiopaque landmarks can frequently be used to facilitate targeting.

Sedation

In most cases, general anesthesia is not warranted, and biliary drainage can be performed with conscious sedation, often with midazolam (Versed) combined with a narcotic. For this reason, patients receive only a clear liquid diet for 4 hours before the procedure. Patients should be well hydrated and have functional venous access, particularly if cholangitis is part of the clinical picture; these patients can become septic and hypotensive, requiring rapid administration of intravenous fluids.

Technical Aids

The most significant technical development to facilitate biliary drainage and other fluoroscopically guided procedures in recent years has been the advent of multidetector CT scans (MDCT), particularly when used within a PACS environment. The ability to scan the liver in a single breath hold and then cine through the images facilitates identification of the level of obstruction and the likelihood of isolation. It also enables the formulation of a three-dimensional mental image of the biliary tree much more easily than looking at hard copy scans, and understanding the biliary anatomy facilitates a successful, uncomplicated procedure. It is frequently possible to anticipate normal variants of bile duct anatomy, which can have a significant impact on preprocedure planning (see Chapter 1B). In addition, most PACS workstations allow cross-reference to the axial images (Fig. 50D.8A) with the "scout" image (Fig. 50D.8B), which is a simulated frontal radiograph used for programming the extent of the scan. In this way, targeting of a specific region, or even a specific duct, is made much easier—and the final catheter resides within the planned segment of the liver (Fig. 50D.8C). Although this degree of sophistication is unnecessary for obstruction below the hepatic hilum, MDCT facilitates drainage in patients with complex high bile duct obstruction such that it is sometimes worth performing MDCT, even when the patient has had a recent hard copy CT scan from the referring institution.

Drainage Catheter Versus Primary Stent Placement

The suitability of a patient for primary stent placement is determined at the time of biliary drainage based on the indication for the drainage, evidence of infected bile, presence of blood or tumor within the biliary tree, and cholangiographic findings. The goal of biliary drainage is to solve the patient's clinical problem by placing as few catheters or stents as possible, intending that the bile should drain internally when the intervention is complete. Patients with obstruction below the common hepatic duct without cholangitis may be stented primarily, at the time of the initial drainage procedure, provided significant blood is not present within the biliary tree. Blood clot within the intrahepatic bile ducts impairs drainage and can cause stent obstruction that may result in bile leaking into the peritoneal cavity from the site of duct puncture. When hemobilia occurs (see Chapter 105), a drainage catheter is placed until the bile clears, at which time the patient can be easily stented. Patients undergoing drainage for cholangitis cannot be stented primarily in most cases. Catheter manipulation in this group of patients is kept to a minimum to diminish the risk of procedure-related sepsis. Once the biliary tree is drained and cholangitis resolves, a stent can be placed.

Having dispensed with the straightforward decisions regarding patients who clearly can or cannot be stented, the more difficult situations that occur in patients with high bile duct obstruction must be addressed. In 1975, Bismuth and Corlette (1975) classified obstruction of the hepatic confluence as types

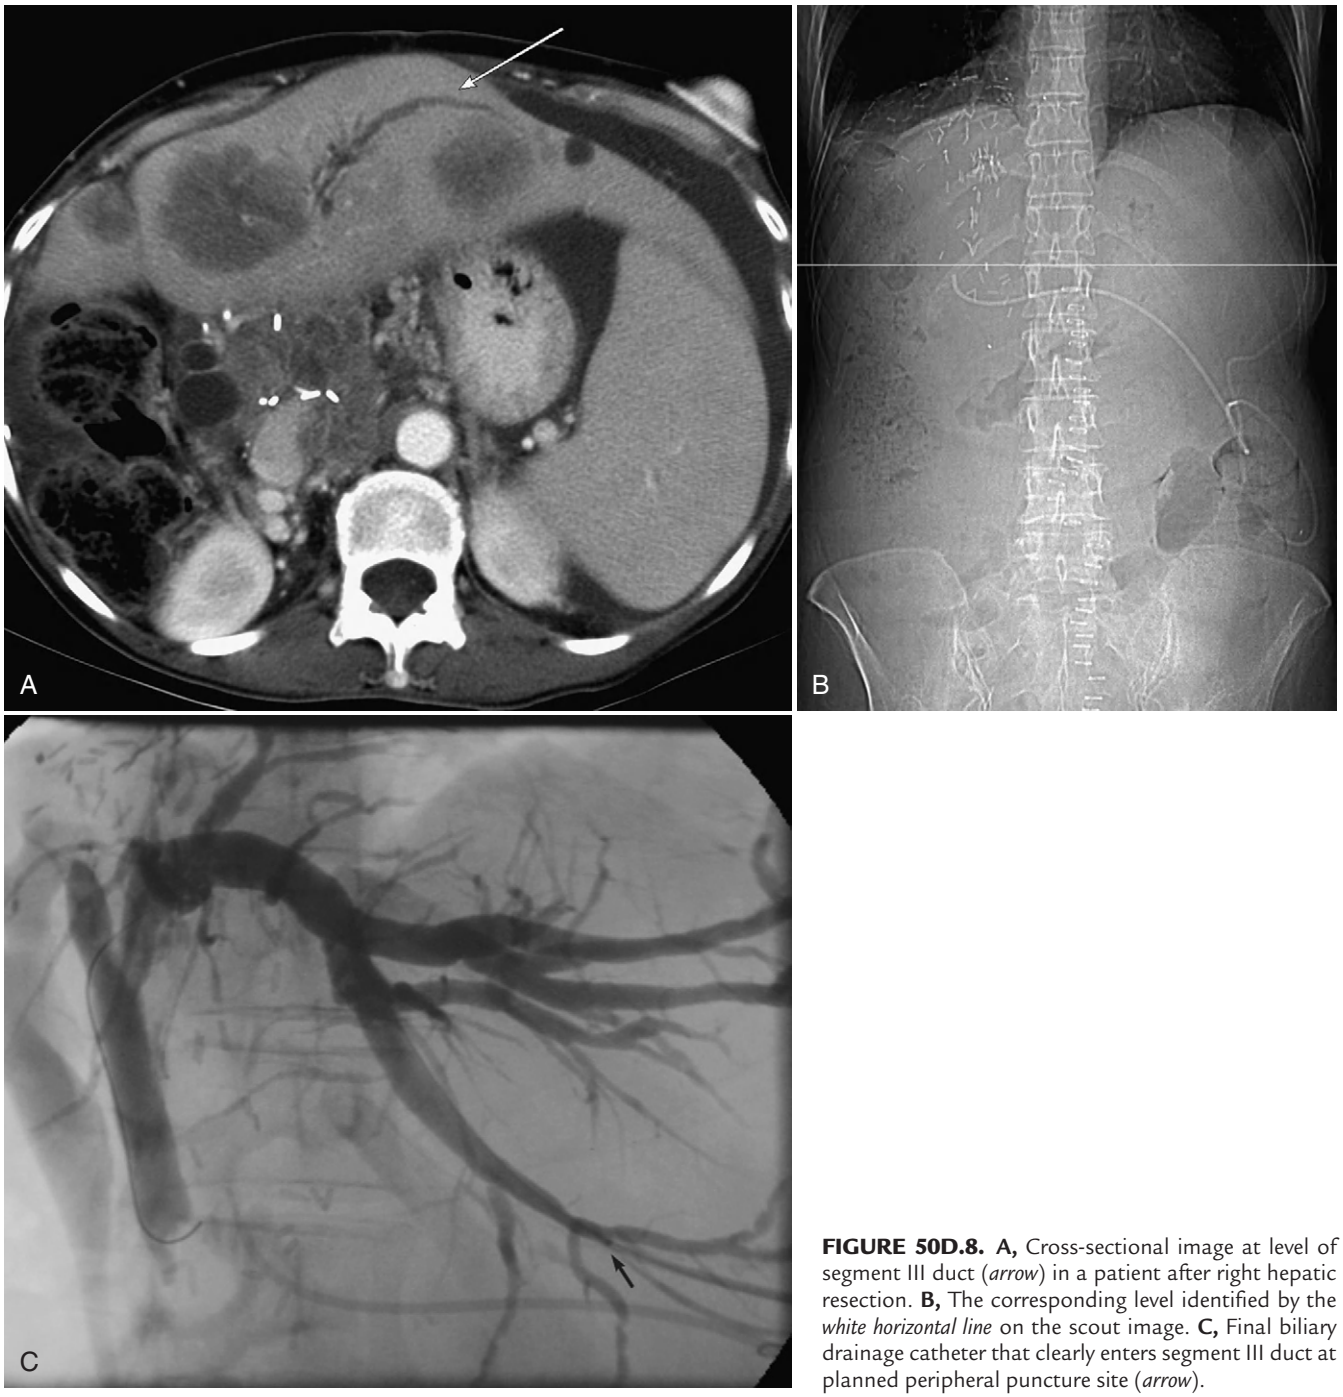

FIGURE 50D.8. **A,** Cross-sectional image at level of segment III duct (*arrow*) in a patient after right hepatic resection. **B,** The corresponding level identified by the *white horizontal line* on the scout image. **C,** Final biliary drainage catheter that clearly enters segment III duct at planned peripheral puncture site (*arrow*).

I through IV (Fig. 50D.9; see Chapter 42A). Predictions about the level of obstruction and degree of isolation of the biliary tree can be made based on the preprocedure imaging studies. These predictions are not always accurate, however, and it is sometimes necessary to modify the stenting approach based on cholangiographic findings; in rare instances, it may be necessary to abandon the procedure altogether. Patients with type I obstruction can have the entire liver drained with one catheter or stent, because right and left ducts communicate freely. Barring one of the previously mentioned contraindications, these patients have a primary stent placed.

Patients with type II obstruction cannot be completely drained with one catheter, although it is sometimes possible to opacify ducts in both sides of the liver. Some suggest that survival is better when both sides of the liver are drained (Chang et al, 1998), although even in Bismuth type II and III hilar obstructions, Inal and colleagues (2003a) saw no significant difference in clinical response to treatment or stent patency rate with unilobar versus bilobar drainage.

When contrast material enters the obstructed side opposite the puncture, it usually does not drain effectively, and that side is considered contaminated. These patients can be stented from

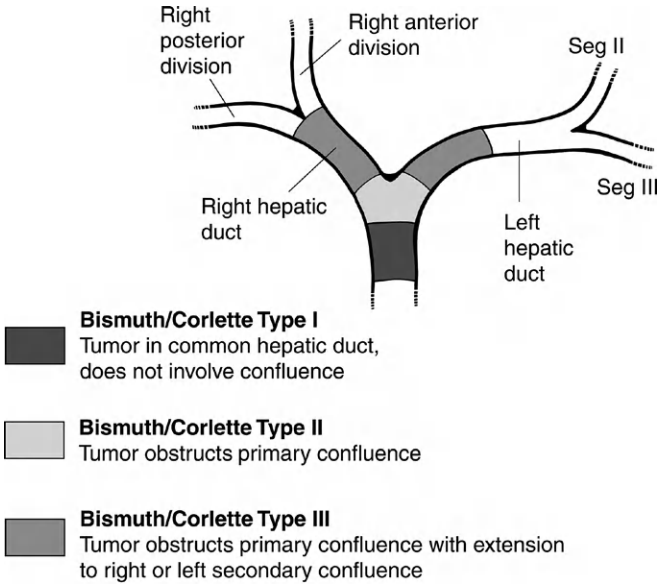

FIGURE 50D.9. Bismuth-Corlette classification for high malignant bile duct obstruction. Type IV involves both right and left ducts to secondary confluence. Seg, segment. *(Courtesy Memorial Sloan-Kettering Cancer Center Medical Graphics.)*

the ipsilateral approach by inserting one stent from the ipsilateral side to the contralateral side and a second stent from the ipsilateral side into the common bile duct or duodenum (Fig. 50D.10), in a T-shaped configuration. The other option is to puncture the contralateral side and place side-by-side stents (Fig. 50D.11), in a Y-shaped configuration. In either case, we prefer to stent into the common bile duct and not into the duodenum if possible so as to preserve function of the sphincter of Oddi. Barring any contraindication, this could be done primarily at the time of initial drainage, as advocated by Inal and colleagues (2003b). These authors found that whether stents were placed primarily or at a second sitting, patients without cholangitis at the time of stenting did not develop cholangitis subsequently, and in all patients with a type I or II obstruction, the serum bilirubin decreased to 2 mg/dL or less. One advantage of the more anatomic Y-shaped configuration stent placement is that if stent occlusion occurs, both stents are approachable endoscopically. In addition, the patency rate of the Y-shaped configuration may be better in patients with type IV obstruction (Inal et al, 2003a). Specially constructed stents have been developed that allow placement of one stent through an opening in the midbody of the other (Kim et al, 2004).

Sometimes the contralateral biliary tree is not opacified, precluding knowledge of the type of obstruction, or the ipsilateral obstruction is a type III obstruction or worse. In this case, and in the absence of some other contraindication, a patient being drained for pruritus alone might have a primary stent placed,

FIGURE 50D.10. A, Patient with cholangiocarcinoma that resulted in Bismuth-Corlette type II obstruction, with near-complete isolation of right and left hepatic ducts. **B,** Same patient treated with side-by-side T-shaped configuration. Wallstents were placed simultaneously, with one stent placed from the left hepatic duct to the right hepatic duct and the other from the left hepatic duct into the common bile duct. The stent from the left hepatic to common bile duct ends well short of the duodenum but extends several centimeters on either side of the obstructed segment.

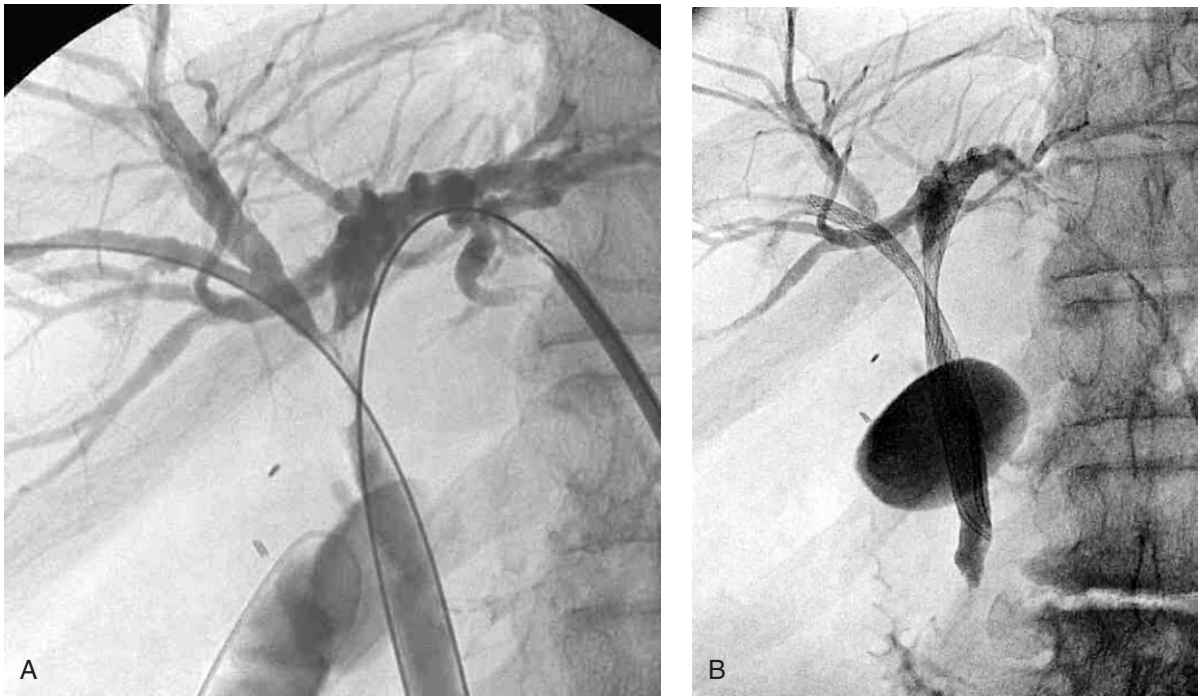

FIGURE 50D.11. **A,** Patient with history of pancreatic cancer after a Whipple procedure with recurrence at the biliary-enteric anastomosis and type II obstruction. **B,** Same patient after simultaneous placement of side-by-side Y-shaped configuration stents.

because only a small portion of the liver need be drained to alleviate pruritus. If the patient is being drained in an attempt to lower the bilirubin level for chemotherapy, a stent should be considered, if it is thought that 30% or more of the liver will be drained. We use this as a rule of thumb, despite the fact that in a series of 149 patients drained at Memorial Sloan-Kettering Cancer Center, we found only a marginally significant difference in the number of patients attaining a bilirubin less than 2 mg/dL based on the estimated volume of liver drained. In this analysis, 6 (29%) of 21 patients with less than a third of the liver drained attained a bilirubin level below 2 mg/dL, whereas this was achieved in 65 (51%) of 128 patients with more than one third of the liver drained ($P = .06$; Ulrich et al, 2009). Following stent placement, if the bilirubin fails to fall to the desired level, a second drainage procedure can be performed. Given the QOL issues for the patient, as well as the risk of contaminating an undrained part of the liver by having an externalized catheter in place, the slight inconvenience of working through a previously placed stent seems warranted.

If an internal/external drainage catheter is placed, and subsequently the serum bilirubin normalizes without evidence of cholangitis, the patient can undergo stenting of that portion of the liver drained by the catheter. If an internal-external catheter has been placed, and the bilirubin does not fall to a level that allows treatment or cholangitis develops, it will be necessary to drain more of the isolated undrained liver before stent placement.

When the initial drainage has been on the right side, and the tumor has extended up the right hepatic duct so as to isolate the anterior and posterior divisions from each other and from the left hepatic duct, side-by-side self-expanding metallic stents can be placed on the right to drain both the anterior and posterior ducts. Alternatively, when the left side of the liver is functional, a left drainage can be performed as the next step; then one stent can be placed from the left, and another can be placed from the right. If instead of a stent, a second catheter has been placed on the left, and the serum bilirubin still does not decrease to an appropriate level or cholangitis develops, stents can be placed from the right to the common bile duct, from the left to the common bile duct, and from the left to the residual undrained right system (Fig. 50D.12). Although a significant difference in patency is reported when more than one stent is placed in a noncoaxial fashion (Maybody et al, 2009), the mean patency is almost 6 months, which justifies stent placement. Even when one part of the liver is not functional, drainage may be necessary to eliminate a source of ongoing cholangitis.

The concepts of biliary drainage are simple, but when high bile duct obstruction is present, the planning is complex, and execution can be difficult. The patient must have enough of the liver drained to be free of cholangitis and pruritus and to effect a reduction in serum bilirubin to receive chemotherapy if indicated. Given the fact that no difference in stent patency is reported if the stent is inserted for proximal or distal obstruction, a significant difference in patency is seen when more than one stent is placed, and lower complication rates are reported when stents are placed primarily, primary stent placement should be considered whenever possible (Inal et al, 2003a, 2003c; Maybody et al, 2009). Additional stents can be placed later if necessary. Patients with Bismuth type I or II obstructions may be treated with a single stent, whereas patients with type III or IV obstructions may ultimately require placement of additional stents (Inal et al, 2003a).

FIGURE 50D.12. Stents placed from right anterior hepatic duct to the common bile duct, from the left hepatic duct to the common bile duct, and from the left hepatic duct to the residual undrained posterior right duct. **A,** Without contrast. **B,** After injection of contrast.

POSTPROCEDURE CARE

Patients are monitored carefully for the first 24 hours after drainage for signs of bleeding or sepsis. With proper technique, including peripheral bile duct puncture, serious bleeding complications are uncommon. Because the hepatic artery, portal vein, and bile duct travel side by side within portal triads, it is common for blood to enter the bile duct during catheter exchanges, resulting in hemobilia in the immediate postprocedure period (see Chapter 105). Hemobilia usually clears within 24 hours, and new or recurrent hemobilia within the first few days of drainage typically is related to catheter malposition. If the catheter is pulled out from its original position, it is possible for a catheter sidehole to become positioned adjacent to a portal vein branch; this problem can be corrected by simply repositioning the catheter, but the catheter is often upsized as well. Significant arterial bleeding during this period is rare. No matter where the initial puncture is performed to opacify the biliary tree, attempts are always made to puncture a peripheral bile duct for catheter placement, preferably a fourth-order or fifth-order branch. The more peripheral the bile duct punctured, the smaller the accompanying hepatic artery branch, and the lower the risk of arterial injury and postprocedure bleeding.

When bleeding occurs a week or more after biliary drainage—especially when the event is sudden in onset, and not only hemobilia but bleeding also occurs around the catheter entry site—arterial injury should be suspected, and the patient should be studied angiographically (see Chapter 19). Although a pseudoaneurysm or extravasation of contrast is sometimes seen, as in any other case of vascular trauma, any abnormality of a hepatic arterial branch adjacent to the biliary drainage catheter should be taken as presumptive evidence of injury to the branch, and the vessel should be selectively embolized (Fig. 50D.13). If the clinician is determined to demonstrate extravasation of contrast material angiographically, it is sometimes necessary to remove the biliary drainage catheter over a guidewire during the angiogram. In the correct clinical setting, empiric superselective embolization of the arterial branch corresponding to the bile duct punctured is acceptable. There is little down side to this approach, and the patient's bleeding is stopped; the biliary catheter is exchanged at this point, because it is usually at least partially occluded by thrombus.

Despite prophylactic antibiotic coverage, sepsis may occur immediately after or within several hours of drainage and should be treated appropriately (Smith et al, 2004). This is most commonly manifested by the development of rigors with normal or low body temperature, but hypotension and fever may also occur. Sepsis is managed with continued administration of appropriate antibiotics, expansion of intravascular volume, and pressor support if necessary. Blood cultures should be drawn to identify organisms responsible for the bacteremia. Cultures of bile obtained at the time of drainage are routinely sent in for all patients. This is particularly important for those with preprocedure fever, biliary-enteric anastomosis or sphincterotomy, previous endoscopic retrograde cholangiopancreatography, or

FIGURE 50D.13. A, Proper hepatic angiogram in patient with hemobilia and bleeding around biliary drainage catheter 1 week after drainage. an indwelling stent or catheter. Although positive bile cultures are more common in patients with benign bile duct obstruction, cultures are positive in more than half of patients with malignant obstruction. Five percent of patients without fever, previous biliary surgery, or endoscopic or percutaneous intervention have positive bile cultures (Brody et al, 1998).

Bile may leak around a biliary drainage catheter. Leaking is most commonly related to the catheter becoming malpositioned so that one or more sideholes are no longer within the biliary tree but are in the catheter tract or even outside the patient. This problem is easily managed by repositioning the catheter. Leakage may also be seen with lack of adequate sideholes above the level of obstruction. Anything that impedes the flow of bile from above the obstruction, either through the catheter to below the obstruction or into a drainage bag, will result in bile leaking back along an established tract. For a properly positioned catheter with an appropriate number of sideholes, the problem is easily remedied by catheter exchange. Patients with capped internal-external catheters may have bile leak back along the catheter tract when egress of bile is obstructed internally. Distal sidehole occlusion is the most common cause, and this problem is easily remedied by catheter exchange. Patients with duodenal obstruction or impaired small bowel motility may be relegated to obligate external drainage.

Ascites may leak around the catheter and may be mistaken for bile. This occurs most often in the presence of jaundice, when the ascitic fluid is bile colored. Leaking of ascites can be difficult to manage. The best treatment is to establish internal biliary drainage with stent placement as expeditiously as possible. If the patient cannot be stented, the catheter may be upsized to tamponade the site more effectively. In addition, ascites can be tapped frequently or drained by a Tenckhoff catheter in an attempt to allow time for tract maturation. These strategies often fail eventually, and as a last resort, a stoma is created around the entry site to contain the ascites.

SUMMARY

Treatment of malignant high bile duct obstruction presents unique challenges to the interventional radiologist. The outcome depends on the condition of the underlying hepatic parenchyma, the degree of isolation of the biliary tree, and the technical skills of the operator. A thorough understanding of functional biliary anatomy and the availability of high-quality imaging are necessary to optimize outcome. Although pruritus may be palliated by draining even one segment of the liver, lowering the serum bilirubin to normal or near-normal requires adequate drainage of at least 30% of the liver, assuming the underlying parenchyma is relatively normal. Contamination of undrained parts of the biliary tree may occur as a result of drainage catheter placement, with ongoing or recurrent cholangitis becoming a problem. For this reason, primary stent placement should be considered when 30% or more of the liver can be drained at the time the initial procedure.

CHAPTER 55B

Management of chronic pancreatitis: conservative, endoscopic, and surgical

Werner Hartwig, Oliver Strobel, Markus W. Büchler, and Jens Werner

OVERVIEW

Chronic pancreatitis (CP) is a progressive, destructive, inflammatory process that ends in total destruction of the pancreas and results in malabsorption, diabetes mellitus, and severe pain. Incidence and prevalence of CP varies between continents and countries. Most studies from Western countries show comparable incidence and prevalence rates of around 7 per 100,000 and 28 per 100,000, respectively (Lankisch et al, 2002; Levy et al, 2006). The numbers reported from Asia are markedly higher with a rapidly rising incidence (Otsuki & Tashiro, 2007; Wang et al, 2009). The etiologic factors associated with CP are commonly summarized using the TIGAR-O classification: ***t***oxic–metabolic (in the West, alcohol and tobacco are associated in approximately 80% to 90% of cases), ***i***diopathic, ***g***enetic (*PRSS1, CFTR,* or *SPINK1* gene mutations), ***a***utoimmune, ***r***ecurrent and severe acute pancreatitis, or ***o***bstructive (pancreas divisum, sphincter of Oddi dysfunction, or neoplasm) (Etemad & Whitcomb, 2001). Tropical CP is a common entity in India, southern Africa, and parts of South America and typically affects younger patients. Tropical CP is often classified as idiopathic but may in fact have a mixed etiology that includes nutritional, metabolic, and genetic factors (Mohan et al, 2003). Current evidence suggests that a combination of predisposing factors—environmental, toxic, and genetic—is likely involved in most cases rather than a single factor. The sentinel acute pancreatitis event (SAPE) hypothesis proposes a sentinel event of acute pancreatitis that initiates the inflammatory process, which is then sustained by a combination of the mechanisms mentioned above (Whitcomb, 1999).

Repeated episodes of inflammation initiated by autodigestion, oxidative stress, one or more episodes of severe pancreatitis, and toxic-metabolic factors can lead to activation and continued stimulation of pancreatic stellate cells. Histologically, CP is characterized by inflammatory infiltration, acinar atrophy, formation of metaplastic ductal lesions (tubular complexes and pancreatic intraepithelial neoplasia), extended fibrosis, and in some cases by focal necrosis and cysts (Klöppel, 2007). Furthermore, neural hypertrophy and perineural inflammation can frequently be observed and are the correlate of neuropathic pain (Ceyhan et al, 2009a).

Clinically, the course of CP is characterized by recurrent episodes of upper abdominal pain, which represents the most common indication for endoscopic and surgical intervention. Although pain attacks and intensity might decrease over time, the so called "burnout" of the gland does not regularly occur, and more than 50% of patients will come to medical attention with persistent pain even 15 years after initiation of the disease. Furthermore, patients may be seen with symptoms of endocrine insufficiency (diabetes mellitus) and exocrine insufficiency (diarrhea, steatorrhea, malnutrition, and weight loss).

In the natural course of CP, endocrine and exocrine insufficiency frequently develops secondary to the fibrotic changes of the pancreas. As a result of morphologic changes of the pancreas, patients frequently develop local complications. Inflammatory ductal changes and intraductal calculi (pancreatolithiasis) may result in obstruction of the pancreatic duct or of the intrapancreatic portion of the bile duct. An inflammatory mass of the pancreatic head, as it is regularly observed in European and American series (Beger et al, 1999; Jimenez et al, 2000), frequently results in obstruction of the duodenum and affects the splenic, superior mesenteric, or portal vein with subsequent thrombosis. Development of pancreatic pseudocysts represents another local complication, which results in obstruction, abscess formation, or in ascites or pleural effusions in cases of rupture (see Chapter 54). A rare but severe local complication of CP is vascular erosion presenting as gastrointestinal hemorrhage or, less frequently, as intraabdominal bleeding (see Chapter 19). Finally, CP is a risk factor for the development of pancreatic cancer (see Chapter 58); patients with CP have a fourfold higher risk of cancer than individuals without it. Especially in the management of patients with an "inflammatory mass," this differential diagnosis has to be considered (Pedrazzoli et al, 2008).

The treatment of CP is complex; in the majority of cases, an interdisciplinary approach is indicated that includes conservative, endoscopic, and surgical therapy.

CONSERVATIVE TREATMENT

Pancreatic Exocrine Dysfunction

In Western countries, the number of patients suffering from pancreatic exocrine insufficiency has increased. The most common cause is an increase in alcohol consumption with a concomitant increase of CP (FitzSimmons, 1993). The main goal of therapy for pancreatic exocrine dysfunction is to avoid fat maldigestion. Reasons for earlier and more severe impairment of fat digestion, compared with protein and carbohydrate digestion, in patients with pancreatic insufficiency are that 1) impairment of pancreatic lipase synthesis and secretion occurs earlier; 2) more rapid and complete inactivation of lipase occurs in the acidic duodenum as a result of impaired bicarbonate output; 3) proteolytic degradation of lipase occurs earlier during aboral transit than with amylase and proteases; 4) impairment of pancreatic bicarbonate secretion decreases duodenal pH,

resulting in precipitation of glycine-conjugated bile acids and further deterioration of fat digestion; and 5) extrapancreatic sources of lipase are unable to compensate for loss of pancreatic lipase activity.

For all of the reasons listed, steatorrhea is the leading symptom in patients with pancreatic exocrine insufficiency.

Pancreatic Exocrine Enzyme Supplementation

When weight loss or steatorrhea (≥15 g/day) or both develop, supplementation of pancreatic enzymes is indicated. Dyspepsia, diarrhea, meteorism, and malabsorption of proteins and carbohydrates also have been cited as indications. Another interesting indication for pancreatic enzyme supplementation, although not formally studied, is in the treatment of pain (discussed in the next section). The main goal of the treatment of pancreatic exocrine dysfunction is to ensure that optimal amounts of lipase reach the duodenum with the delivered food. With the currently available pancreatic enzyme supplement preparations, azotorrhea (protein malabsorption) can be eliminated (Brady et al, 1991), whereas steatorrhea usually can be reduced but not totally corrected.

Four different types of pancreatic exocrine enzyme preparations are available. *Uncoated preparations* show only poor effects because of their inactivation by gastric acid. Huge doses of enzymes are required to have any effect on fat malabsorption. These preparations should be used only in patients with pancreatic exocrine insufficiency and hypochlorhydria or achlorhydria. The use of *enteric-coated tablets* is strongly discouraged, because these preparations are ineffective for decreasing fat excretion owing to erratic enzyme release. The superiority of *enteric-coated microsphere preparations* over conventional enzyme preparations with regard to decrease in stool fat excretion has been firmly established (Layer & Holtmann, 1994). Pancreatic enzymes in these preparations are protected at low pH by a special polymer coating. The release of the enzymes occurs only at a pH of at least 4.5. Simultaneous administration of antacids, H2-receptor antagonists, or proton pump inhibitors is unnecessary. Unfortunately, microencapsulation results in a considerable increase in costs. Another problem concerning enteric-coated microspheres might be considerable differences in the diameter of the microspheres and in their physical nature as a result of differences in the manufacturing process; however, clinical differences in the various enteric-coated microsphere preparations have not yet been proofed.

The use of *enzyme preparations in combination with acid-reducing compounds* also is not justified for many reasons, although additional administration of proton pump inhibitors or H2-receptor antagonists reduces fecal nutrient loss. These preparations are expensive, there is a variability of the effects owing to the acid-reducing therapy, and especially in children, the safety of long-term administration has not been firmly established (Lebenthal et al, 1994).

Certain *bacterial and fungal lipases* have shown no benefit in the treatment of pancreatic steatorrhea, although they are resistant against acid denaturation and proteolytic digestion. Decreased lipolytic activity of fungal lipase in the presence of bile acids could explain the fact that no superiority over enteric-coated microsphere preparations has been demonstrated to date (Griffin et al, 1989; Zentler-Munro et al, 1992).

Although rare, possible side effects of pancreatic exocrine enzyme supplementation are sourness of the mouth, perianal irritation, abdominal pain, diarrhea, constipation in infants, allergic reactions to pork proteins, hypersensitivity reactions after inhalation, and fibrosing colonopathy in cystic fibrosis patients (Lebenthal et al, 1994; Loser & Folsch, 1995). In regard to fibrosing colonopathy, it has been recommended that the maximum dose of lipase should not exceed 10,000 IU/kg body weight per day, or 2500 IU/kg body weight per meal.

Substitution Therapy in Chronic Pancreatitis

Approximately 80% of patients with CP can be managed by dietary means and pancreatic enzyme supplements. Some patients (10% to 15%) need oral supplements (polymeric or semielemental), 5% need enteral tube feeding, and approximately 1% need total parenteral nutrition (TPN). Reduction of steatorrhea and supplementation of calories are the main goals of nutritional therapy in CP. Treatment of exocrine insufficiency starts with dietary therapy and pancreatic enzyme supplementation (DiMagno, 1979).

Total abstinence from alcohol and partaking of frequent meals are basic dietary recommendations. The diet should be rich in proteins (1.0 to 1.5 g/kg body weight/day) and carbohydrates, although carbohydrates must be limited when diabetes mellitus is present. In addition, 30% to 40% of calories should be in the form of fats. Medium-chain triglycerides may be used to increase fat absorption, because they are absorbed directly across the small bowel into the portal vein, even in absence of lipase, co-lipase, and bile salts. Vitamins should be supplemented if serum levels indicate a deficiency (Havala et al, 1989). Patients with protein maldigestion and steatorrhea must be supplemented individually with exogenous pancreatic enzymes. Weight control, symptomatic relief of diarrhea, and a decrease in 72-hour fecal fat excretion are practical end points of therapy.

Enteral nutrition (EN) is indicated when a patient is unable to eat, has progressive weight loss despite an adequate dietary regimen, or develops acute complications; EN may also be indicated preoperatively and postoperatively. Only rarely is TPN indicated in patients with CP, such as when gastric emptying is blocked, when the patient needs gastric decompression, when the feeding tube cannot be introduced into the jejunum, or when a complicated fistula is present. In most cases, surgical intervention can solve these problems.

Conservative Treatment of Pain

Pain significantly reduces patients' quality of life, and pain relief should be one of the main goals of conservative treatment in CP. Pain also may be treated interventionally or surgically, but medical treatment is generally the first-line therapy in patients with painful CP.

Different medical treatment options and therapeutic interventions are available, and these must be integrated into an individualized treatment plan. The pathogenesis of pain especially influences the therapeutic procedure. Two mechanisms are suggested for the generation of pain in the absence of local complications: 1) inflammatory changes of pancreatic parenchyma with intrapancreatic and peripancreatic neural alterations (Bockman et al, 1988; Ceyhan et al, 2009a, 2009b; Di Sebastiano et al, 1997), and 2) ductal and intraparenchymal hypertension (Di Sebastiano et al, 2003; Ebbehoj et al, 1990).

As for the second mechanism, options that reduce the intrapancreatic pressure may lead to a significant reduction of

pancreatic pain. In the case of inflammation, a significant number of inflammatory mediators in pancreatic parenchyma and pancreatic nerves are detected in patients with pain (Ceyhan et al, 2009b; Di Sebastiano et al, 2000). Several medical, analgesic, and antiinflammatory treatment options are available, which may be combined with or supported by interventional methods.

Alcohol Abstinence and Diet

Besides alcohol abstinence, no specific dietary measures have been found to be effective in preventing pancreatic pain. Even total abstinence from alcohol may achieve pain relief in only 50% of patients with moderate to mild CP (Gullo et al, 1988).

Suppression and Inhibition of Pancreatic Secretion

The effect of pancreatic enzyme preparations on pain is uncertain. A meta-analysis of six studies on enzymes for pain treatment concluded that there is no positive effect, but this conclusion is unreliable because of the heterogeneity of the study groups and significant differences in drug preparations (Brown et al, 1997). A more recently published review that also included data from studies published in abstract form came to a similar conclusion (Winstead & Wilcox, 2009). Further studies are needed to prove whether somatostatin and its analogue octreotide have any impact on pain in patients with CP. A proper placebo randomized controlled trial (RCT) must be performed, which should include 1) the classification of patients as to the etiology of their CP, 2) the systematic assessment of quality of life of patients prior to the initiation of therapy and at regular intervals throughout the study, 3) a priori power analysis estimating a placebo response rate of at least 25%, and 4) multiple planned subgroup analysis (Winstead & Wilcox, 2009).

Analgesics

Guidance for analgesic treatment in patients with CP is based on the consensus report of the German Society of Gastroenterology (Mössner et al, 1998) and the recommendation of the World Health Organization (WHO, 1990). One physician should be responsible for the administration of analgesics. For the first step in pain management, nonnarcotic agents, such as acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs), are recommended. Opioids are often necessary further along. Every patient requires an individualized type and dose of analgesic drug, starting with the lowest dose necessary to control pain. In patients with pain mainly caused by inflammation and by invasion of inflammatory cells, antiinflammatory drugs such as NSAIDs may be helpful. Some patients with CP have depression, which lowers the visceral pain threshold. An additional antidepressant therapy may have an effect on pain and generally increases the effects of opiates.

Interventional Procedures to Treat Pancreatic Pain

Of patients with pancreatic pain, 40% to 70% seem to benefit from medical treatment (Ammann et al, 1984). This percentage may increase by combining medical therapy and interventional procedures (van der Hule et al, 1994). Pancreatic pain may also be improved by the combination of interventional endoscopy and lithotripsy, although a recent RCT demonstrated increased costs but no outcome benefit when systematic endoscopy was added to lithotripsy (Dumonceau et al, 2007). Some studies showed a significant difference in improvement of pain among patients with successful or unsuccessful lithotripsy (Delhaye et al, 1992; Costamagna et al, 1997; Johanns et al, 1996; Ohara et al, 1996; Sauerbruch et al, 1992; Schneider et al, 1994; Smits et al, 1996). Other studies did not report this difference (Adamek et al, 1999).

Celiac plexus neurolysis and celiac block involve injecting an agent at the celiac axis, with the aim of either selectively destroying the celiac plexus or temporarily blocking visceral afferent nociceptors. Agents most commonly used for this purpose include alcohol or phenol for neurolysis and bupivacaine and triamcinolone for a temporary block. Methods to administer such agents to the celiac ganglion include CT imaging, percutaneous ultrasound, fluoroscopy, or endoscopic ultrasound (EUS). Whereas the EUS-guided technique may be superior compared with the other methods, response rates in general are relatively low (Gress et al, 1999; Noble & Gress, 2006; Santosh et al, 2009).

Autoimmune Pancreatitis

A type of CP that might be caused by an autoimmune mechanism was first described by Sarles and collegues (1961) and was termed *primary inflammatory sclerosis of the pancreas.* Since then, a growing body of evidence suggests that autoimmune pancreatitis (AIP) is distinct from obstructive or calcifying forms of CP. Two clinical and histologic patterns of AIP can be distinguished (Park et al, 2009). Type 1 is characterized by the histologic key features of dense periductal lymphoplasmacytic infiltrate, swirling or storiform fibrosis, and obliterative venulitis; serum levels of the immunoglobulin G4 (IgG4) subclass of IgG are typically increased (Hamano et al, 2001). Type 1 AIP fits the classic description of the disease reported in Japan, also known as *lymphoplasmacytic sclerosing pancreatitis.* Type 1 AIP appears to be the pancreatic manifestation of a systemic disease that may also affect other organs, including the bile duct, retroperitoneum, kidney, lymph nodes, and salivary glands. Type 2 AIP is typically characterized by a duct-destructive pathology with infiltrating neutrophils, lymphocytes, and plasma cells. Typical serologic markers seen in type 1 AIP are not elevated in type 2 AIP (Park et al, 2009). Typical imaging features—a diffuse, sausage-shaped, enlarged pancreas with delayed and peripheral enhancement—only show up in about 50% of patients. Furthermore, classic features of lymphoplasmacytic sclerosing pancreatitis are found in just 20% of core biopsies, and false-positive IgG4 immunostaining has also been reported in the setting of cancer. Thus the preoperative differentiation from pancreatic carcinoma is a diagnostic challenge. In highly suspected or histologically confirmed cases of AIP, steroid therapy (prednisolone, initially 30 to 40 mg/day) may ameliorate symptoms and imaging findings within two weeks. Importantly, the similarity to pancreatic carcinoma and the absence of specific diagnostic parameters may result in surgical treatment of this disease. Because reports about patients misdiagnosed as having AIP are increasingly encountered, surgery should always be considered in doubtful cases (Gardner et al, 2009).

ENDOSCOPIC TREATMENT IN CHRONIC PANCREATITIS

Pancreatic ductal obstruction by fibrotic stenoses and/or calculi are the most frequent indications for endoscopic therapy.

Interventional treatment modalities aim to decompress and drain the pancreatic ductal system. Endoscopic interventions (see Chapters 14 and 27)—such as stone extraction, dilations, and stenting—have to be repeated on a regular basis in almost all patients. As a consequence, patients suffer from frequent rehospitalizations.

Two recent RCTs demonstrated the superiority of surgical versus endoscopic therapy in primary success rate, pain relief, and quality of life in patients with duct obstruction in the pancreatic head (Cahen et al, 2007; Dite et al, 2003). On the other hand, a large multicenter study in 1018 patients reported success of endoscopic therapy (multiple sessions) in 65% of patients, with the necessity for surgery in only 24% (Rösch et al, 2002). A study of 61 patients with CP and bile duct stenosis reported a 1-year success rate of 59% with endoscopic stenting and stent replacement every 3 months, but failure of endoscopic therapy occurred in the majority of cases with presence of calcifications, with a success rate of only 7.7%; moreover, 49% of patients who had an unsuccessful interventional therapy underwent surgery within a year (Kahl et al, 2003). In patients with symptomatic pseudocysts and no ductal obstruction, endoscopic drainage procedures may be as safe and effective as surgical drainage but superior to external drainage, as reported in a recent retrospective study (Johnson et al, 2009). However, this result needs confirmation in a larger-scale randomized trial.

Available data suggest recommendations concerning endoscopic versus surgical treatment in CP as follows:

1) Patients with proximal stenosis and no calcifications or inflammatory mass may be treated endoscopically. If two to three repetitive endoscopic treatments fail, the option of surgery must be evaluated.

2) In patients with distal duct obstruction, calcifications, or local complications, surgery is superior to endoscopic treatment. Patients should undergo surgery early in the course of the disease to prevent further deterioration of exocrine or endocrine function.

3) Pancreatic pseudocysts may be treated endoscopically. If endoscopic treatment fails, a surgical drainage procedure is recommended.

Endoscopic treatment options and their possible indications are summarized in Table 55B.1. Endoscopic therapy for pancreatic pseudocysts and common bile duct stenosis associated with CP is discussed in detail here.

Table 55B.1

Interventional and Endoscopic Therapy: Options and Indications

Options	Indications
Interventional External Drainage	Temporary treatment of a pancreatic abscess or an infected pseudocyst Frequently followed by definitive surgical treatment If internal drainage is not possible
Internal Drainage	Effective therapy of pseudocysts; no RCTs with comparison to surgery
Endoscopic cystogastrostomy/ cystroduodenostomy	If anatomically possible: less invasive than surgery Problems with recurrence and catheter dislocation
Endoscopic Ductal Drainage	
ePT	Pancreas divisum, sphincter of Oddi dysfunction
ePT plus dilation + stenting of pancreatic duct	Proximal stenosis of pancreatic duct
ePT plus lithotripsy and stone extraction	Pancreatolithiasis
ePT plus bile duct stenting	Bile duct stenosis
Indicators of Poor Outcome	
Distal stenosis of pancreatic duct	
Parenchymal calcifications	
Unsuccessful management after 1 year	

RCT, Randomized, controlled trial; ePT, endoscopic papillotomy

Decompression of Pancreatic Pseudocysts

Pancreatic pseudocysts are a late complication of CP. The main techniques for decompression of pancreatic pseudocysts include *transgastric* and *transduodenal* approaches (Sahel, 1990; Dohmoto & Rupp, 1992); these require a clear bulging of the cyst into the gastric or duodenal cavity to ensure a short distance between the cystic wall and the intestinal tract. In this context, endosonography has been shown to reduce the risk of cyst perforation and hemorrhage (Binmoeller et al, 1994; Etzkorn et al, 1995; Grimm et al, 1992).

The technical success rate appears to be better for cystoduodenostomy than for cystogastrostomy owing to a higher complication rate (Binmoeller et al, 1994; Sahel, 1991). In more recent articles, the mortality appears to be almost zero, whereas morbidity rates are reported between 3% and 11% (Binmoeller et al, 1994; Dohmoto & Rupp, 1992; Etzkorn et al, 1995; Grimm et al, 1992; Sahel, 1990, 1991). A more recent approach to access the cystic cavity is indirectly via the papilla and the ductal system (Pinkas et al, 1994). For this reason, a selective endoscopic pancreatic sphincterotomy and a retrograde pancreatography must be performed to introduce a guidewire, over which the dilation of the cannulation can be performed. A double-pigtail endoprothesis should be inserted through the papilla into the cyst. No deaths (Dohmoto & Rupp, 1992; Pinkas et al, 1994; Sahel, 1990) and very low morbidity (2% to 7%) have been reported. A major problem of this approach is its nonfeasibility in patients with strictures or stones located between the papilla and the pseudocyst. Because these procedures call for a highly specialized endoscopist, cases with poor anatomic conditions or with contraindications determined by preliminary endosonography should be referred to a specialized center.

Common Bile Duct Stenting

Common bile duct stenosis is a mechanical complication of CP. A team approach that includes endoscopists and surgeons should guide the treatment of common bile duct stenosis in patients with CP. The decision for either interventional or surgical treatment depends on the patient's age, comorbidities, the course of CP, and the cause of the stricture. A subgroup of patients has been reported to benefit from endoscopic stenting, with permanent regression of the stenosis reported after stent removal. Endoscopic stenting should be performed as first-line therapy in those patients with CP-induced acute cholestasis, when malignancy can be excluded. Especially for patients who

refuse surgery or those who have significant comorbidities, the endoscopic approach might be the therapy of choice. Kahl and associates (2003) reported in a prospective follow-up study that endoscopic drainage of biliary obstruction provides excellent results in the short term but offers only moderate long-term results. Patients without calcifications of the pancreatic head benefit from biliary stenting; patients with calcifications were identified to have an increased risk of failure within a 12-month course of endoscopic stenting. Major limitations, such as plastic stent clogging, migration, and cholangitis, frequently occur in the long-term follow-up. Alternatively, self-expanding Wallstents may improve the results, and metal stents that cannot migrate offer a stent effectiveness greater than 80% (Ng & Huibregtse, 1998). At present, long-term follow-up data to clarify the role of endoscopic approaches and to identify the preferred stent for the management of cholestasis in CP are unavailable. The placement of Wallstents used to be irreversible, but results with the latest generation of stents that are covered, and therefore removable, are awaited. However, for young patients with CP and no comorbidity, adequate and definitive therapy for recurrent cholestasis is provided by a surgical drainage procedure or pancreatic head resection (Eickhoff et al, 2001).

SURGERY

The surgical treatment of CP is based on two main concepts: *preservation of tissue via drainage* aims to protect against further loss of pancreatic function, and *pancreatic resection* is performed for nondilated pancreatic ducts, pancreatic head enlargement, or if a pancreatic carcinoma is suspected in the setting of CP. An overview on the common surgical procedures and the indications for surgery are listed in Table 55B.2.

Drainage Procedures

Pancreatic duct sphincterotomy was one of the first surgical procedures proposed for patients with CP and stenosis at the papilla of Vater. This procedure was recognized as a dangerous approach, however, with lower success rates for amelioration of pain, indicating that a stenosis at the papilla Vater is not the cause of pain in CP. The original Puestow procedure, and its modification by Partington and Rochelle (1960), proved more successful in patients with CP and a dilated pancreatic duct. The procedure includes resection of the tail of the pancreas, followed by a longitudinal incision of the pancreatic duct along the body of the pancreas and an anastomosis with a Roux-en-Y loop of jejunum. The modification by Partington and Rochelle abandons the resection of the pancreatic tail. Preservation of tissue and reduction of mortality to less than 1% and of morbidity to less than 10% are the advantages of this operation (Evans et al, 1997; Izbicki et al, 1999; Prinz & Greenlee, 1981; Proctor et al, 1979). Although these ductal drainage operations have good primary success rates (Duval, 1956; Partington, 1952), their long-term outcome is poor (Markowitz et al, 1994). Moreover, these procedures are only promising if the duct is substantially dilated (>7 mm), which is the case in about 25% of patients (Büchler & Warshaw, 2008), and in patients who do not show a dominant mass in the head of the pancreas. For these reasons, pure drainage procedures have been replaced by techniques that combine resection and drainage for the majority of patients.

Table 55B.2

Surgical Therapy: Techniques and Indications

Indications for Surgery in Chronic Pancreatitis

- Intractable pain
- Symptomatic local complications
- Unsuccessful endoscopic management
- Suspicion of malignancy

Surgical Techniques	Indications and Recommendations
Pure Drainage Operations	
Cystojejunostomy (see Fig. 55B.1A)	Surgical procedure of choice for isolated pseudocysts*
Laterolateral pancreatojejunostomy	Ductal dilation >7 mm without inflammatory mass
Partington-Rochelle procedure (see Fig. 55B.1B)	
Caudal drainage/Puestow procedure	Rare indications, replaced by other procedures
Resection Procedures	
Pancreatic head resection (see Fig. 55B.2)	Always include a ductal drainage
	Procedure of choice if inflammatory mass is in the head of the pancreas
	All techniques have comparable results
PD and ppPD (see Fig. 55B.2A)	Procedure of choice in suspected malignancy and in irreversible duodenal stenosis
DPPHR Techniques†	
DPPHR, Beger (see Fig. 55B.2B)	Procedures of choice if inflammatory mass in the head of the pancreas
DPPHR, Bern (see Fig. 55B.2D)	Technically less difficult than Beger but equal in long-term outcome
DPPHR, Frey (see Fig. 55B.2C)	Patients with ductal obstruction in the head and tail and a smaller inflammatory mass in the head of the pancreas
V-shaped excision	Small duct disease (diameter of pancreatic duct <3 mm)
Pancreatic left resection	Rare cases, such as isolated chronic pancreatitis in the tail (e.g., posttraumatic)
	Rare cases of large psudocysts in the tail
Segmental resection	Rare cases, such as isolated ductal stenosis in the body (e.g., posttraumatic) in patients without diabetes
Total pancreatectomy	Rare cases with severe changes in the entire pancreas and preexisting IDDM

**Caution:* intraoperative frozen section must be done to exclude a cystic neoplasm.
†*Caution:* intraoperative frozen section must be done to exclude malignancy.
PD, pancreatoduodenectomy; ppPD, pylorus-preserving pancreatoduodenectomy; DPPHR, duodenum-preserving pancreatic head resection; IDDM, insulin-dependent diabetes mellitus

In patients with isolated pancreatic pseudocysts, and often in those with a history of a severe episode of acute pancreatitis, a drainage procedure in the form of a cystojejunostomy with Roux-en-Y reconstruction (Fig. 55B.1) is still the surgical procedure of choice.

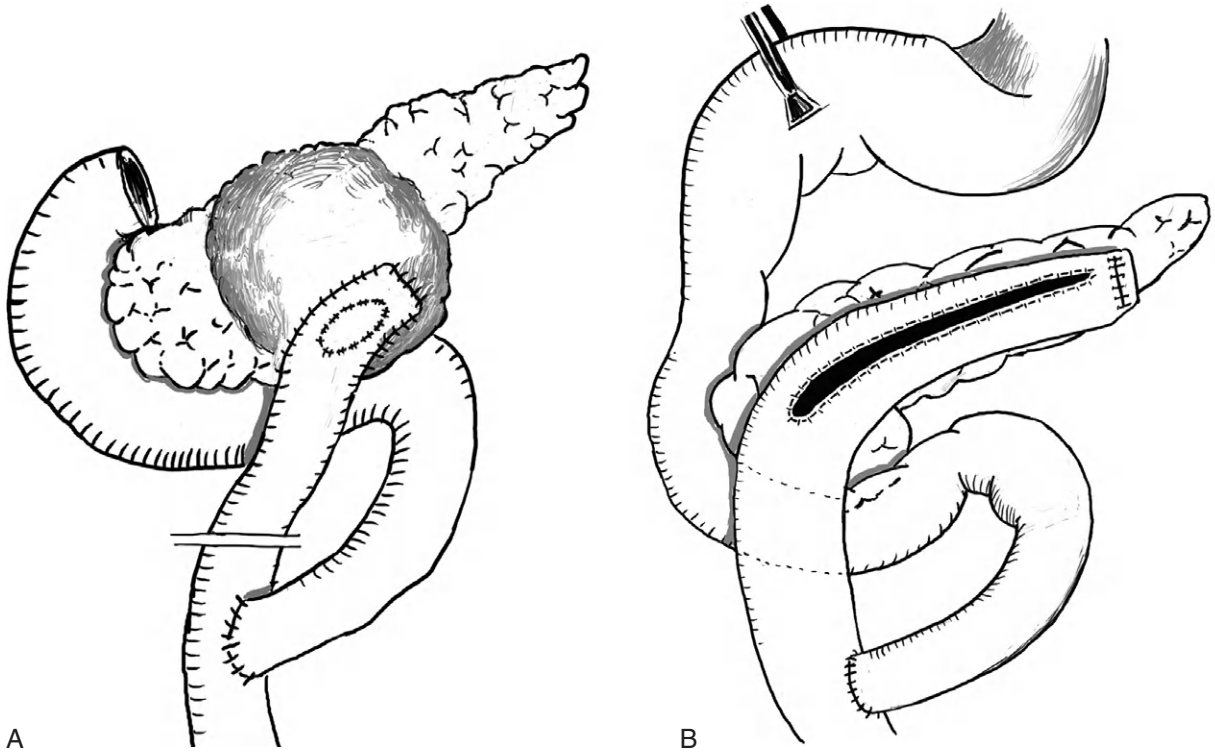

FIGURE 55B.1. Drainage procedures in chronic pancreatitis. **A,** If the cyst wall is thick enough, a pancreatic pseudocyst can be safely and effectively treated by drainage with a cystojejunostomy and Roux-en-Y reconstruction. **B,** In rare patients with a dilation of the pancreatic duct >7 mm and no inflammatory mass, a laterolateral pancreatojejunostomy (Partington-Rochelle procedure) may be performed.

Resective Procedures

The vast majority of patients are seen with a ductal obstruction in the pancreatic head, frequently associated with an inflammatory mass. In these patients pancreatic head resection is the procedure of choice; the available techniques are shown in Figure 55B.2. The partial pancreatoduodenectomy, or Kausch-Whipple procedure, in its classic or pylorus-preserving variant, has been the procedure of choice for pancreatic head resection in CP for many years (Jimenez et al, 2000, 2003). The duodenum-preserving pancreatic head resections and its variants—the Beger (Beger et al, 1985), Frey (Frey & Smith, 1987), and Bern procedures (Gloor et al, 2001)—represent less invasive, organ-sparing techniques with equivalent long-term results (see Table 55B.2).

Only very few patients come to medical attention with small duct disease (diameter of the pancreatic duct <3 mm) and no mass in the pancreatic head. In these cases, a V-shaped excision of the anterior aspect of the pancreas is a safe approach and offers effective pain management (Yekebas et al, 2006). In the rare case of a patient seen with segmental CP in the pancreatic body or tail, such as that seen as a result of posttraumatic ductal stenosis, a middle segment pancreatectomy or a pancreatic left resection may be the best approach. The most frequently applied resection techniques are detailed here.

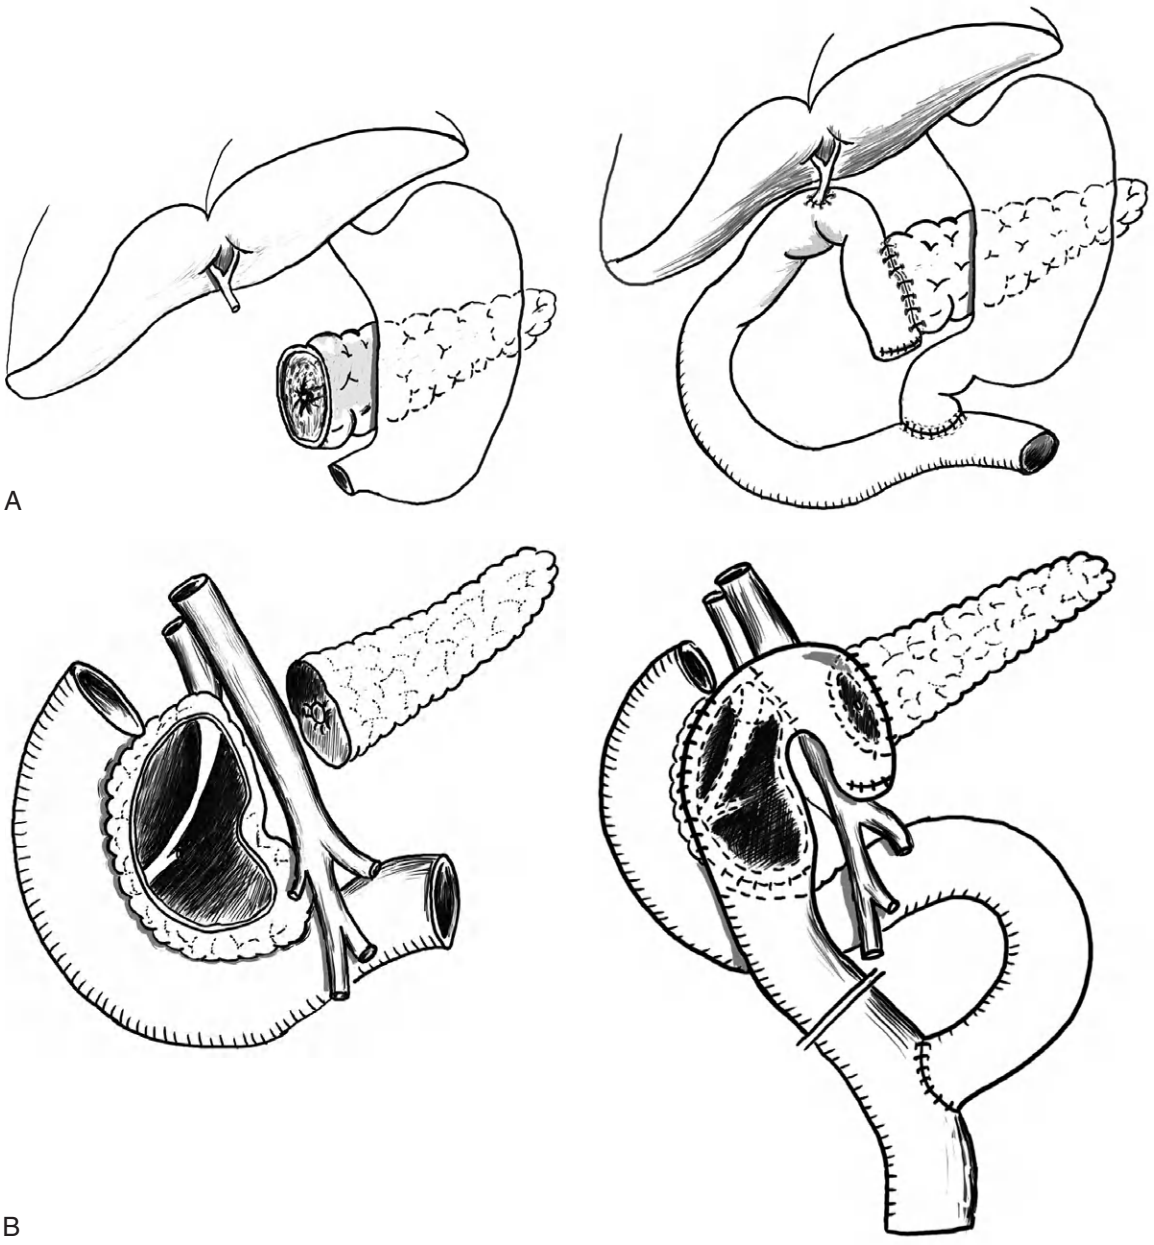
Partial Pancreatoduodenectomy: Kausch-Whipple Procedure (See Chapter 62)

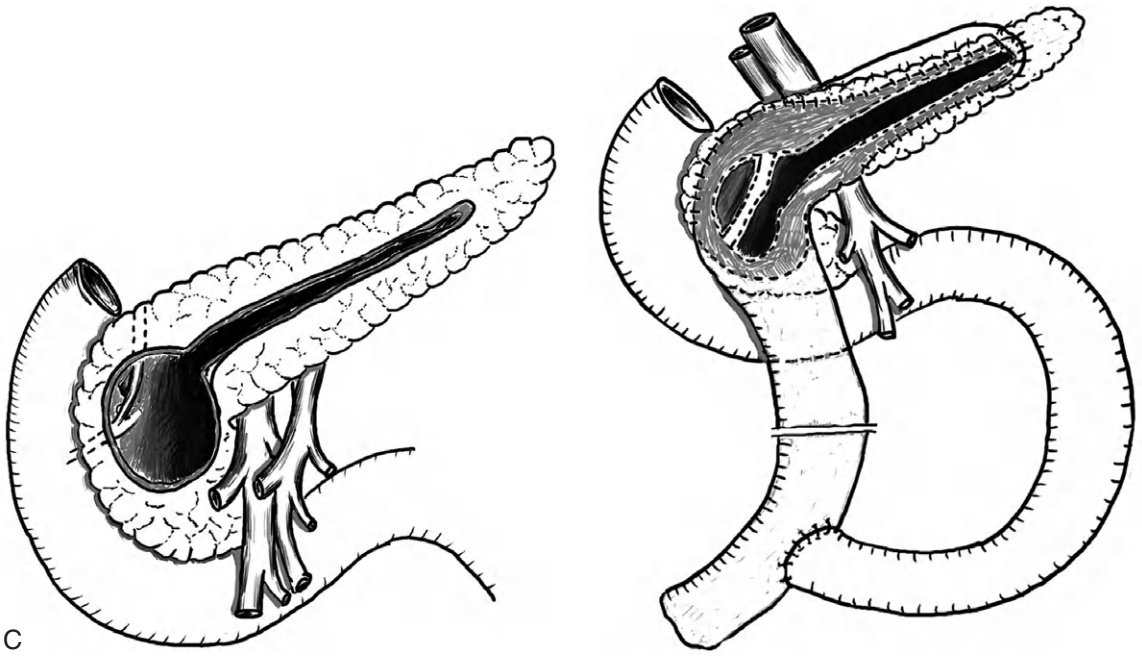
The most frequent indications for a pancreatoduodenectomy in patients with CP and pain are 1) the head of the pancreas is enlarged, often containing cysts and calcifications; 2) a previous endoscopic intervention or drainage procedure was ineffective; or 3) a malignancy is present in the head of the gland. Concerning the latter subgroup, it is commonly accepted that the distinction between benign and malignant disease remains an unsolved dilemma in some patients (up to 6% to 8%) (Büchler & Warshaw, 2008). The extent of resection in the classic Kausch-Whipple pancreatoduodenectomy (PD) includes the pancreatic head with duodenum and the lower third of the stomach. PD was initially designed for malignancies in the pancreatic head and was associated with high morbidity and mortality rates. With increasing safety the procedure has also been used for patients with CP (Traverso & Kozarek, 1993).

With the pylorus-preserving pancreatoduodenectomy (ppPD), a less invasive procedure for resection of cancer or CP was introduced, in which the stomach is preserved (see Fig. 55B.2A) (Traverso & Longmire, 1978). Today, PD and ppPD are safe and effective procedures in experienced hands, with an operative mortality of 2% to 5% and lasting pain relief in about 80% of patients (Büchler & Warshaw, 2008; Jimenez et al, 2000).

With regard to quality of life, the data after the Kausch-Whipple procedure are promising, although poor postoperative digestive function has been reported, including gastric dumping, diarrhea, peptic ulcer, and dyspeptic complaints in some patients. In up to 20% of the patients with CP, the Kausch-Whipple resection results in diabetes mellitus and subsequently in increased late postoperative morbidity and mortality (Izbicki et al, 1998).

The drawbacks of the Kausch-Whipple procedure may be ameliorated by the ppPD. The rate of gastric dumping, marginal ulceration, and bile-reflux gastritis can be reduced by





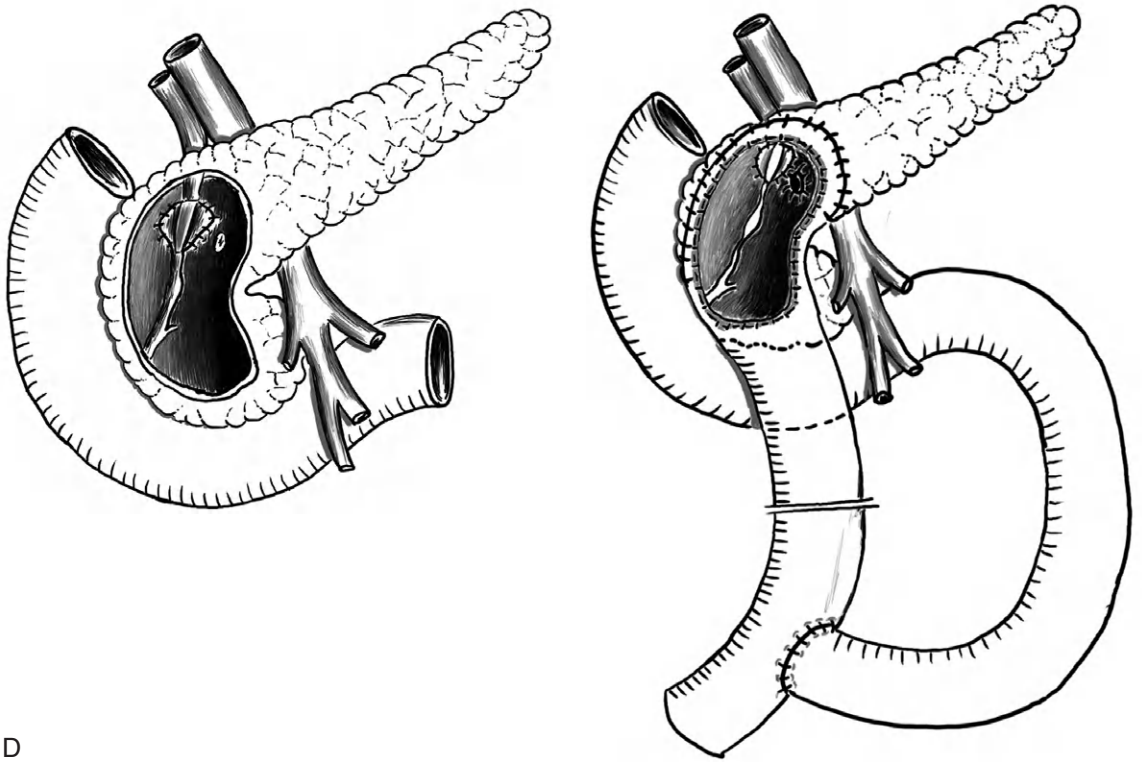


FIGURE 55B.2. Techniques of pancreatic head resection for chronic pancreatitis. Resections are shown on the left side, reconstructions on the right side. **A,** Partial pancreatoduodenectomy; the pylorus-preserving procedure is shown. The pancreatic head and duodenum are removed, reconstruction is performed by pancreatojejunostomy, hepaticojejunostomy, and a duodenojejunostomy. **B,** Duodenum-preserving pancreatic head resection (DPPHR)-Beger procedure. The pancreas is dissected on the level of the portal vein, the pancreatic head is excavated, and the duodenum is preserved with a thin layer of pancreatic tissue. If the bile duct is obstructed, it can be opened, and an internal anastomosis with the excavated pancreatic head can be performed (not shown). The reconstruction is performed with a Roux-en-Y jejunal loop, including two anastomoses, one to the pancreatic tail remnant and one to the excavated pancreatic head. *Continued*

C

D

FIGURE 55B.2, cont'd C, DPPHR-Frey procedure. A circumscript excision in the pancreatic head is combined with longitudinal dissection of the pancreatic duct toward the tail. Reconstruction is performed with an anastomosis to a Roux-en-Y jejunal loop. Compared with the Beger procedure, pancreatic head resection is less extensive; reconstruction is easier, because only one anastomosis to the pancreas is required. **D,** DPPHR-Bern modification. A technical simplification of the Beger procedure, the extent of resection of the pancreatic head is comparable, except the pancreas is not dissected on the level of the portal vein. Thus reconstruction can be performed with a single anastomosis of the pancreas to a Roux-en-Y jejunal loop. The bile duct may be opened if necessary, with an internal anastomosis to the loop (shown). The pancreatic duct toward the tail is probed to rule out distal stenosis.

preserving the stomach, pylorus, and the first part of the duodenum. Regarding quality of life, the ppPD provides better results than the classic PD, specifically with weight gain in around 90% of patients postoperatively. Furthermore, the operation leads to long-lasting pain relief in 85% to 95% of patients during the first 5 years postoperatively (Martin et al, 1996). The postoperative sequelae of transient delayed gastric emptying, which is observed in 30% to 50% of patients, and the risk of cholangitis and long-term occurrence of exocrine and endocrine pancreatic insufficiency seen in more than 45% of patients represent the possible drawbacks of this operation in CP patients (Müller et al, 1997). The relevant studies (level I and II) concerning delayed gastric emptying comparing classic Kausch-Whipple and ppPD could not show a clear advantage of the classic Whipple procedure (van Berge Henegouwen et al, 1997; Büchler et al, 2000; Di Carlo et al, 1999; Izbicki et al, 1998; Jimenez et al, 2000; Klempa et al, 1995; Lin & Lin, 1999; Roder et al, 1992). Although three studies favored the ppPD, two showed no difference, and two showed lower delayed gastric emptying rates after a classic Whipple procedure compared with the ppPD.

It should be kept in mind that both the classic PD and the ppPD resection were originally introduced to radically resect malignant pancreatic or periampullary tumors. Therefore for a benign disorder such as CP, other than the occasional inability to exclude pancreatic cancer definitively, there is no reason to remove organs adjacent to the pancreas—part of the stomach, the duodenum, and the extrahepatic bile duct; these may just be secondarily involved in the disease.

Duodenum-Preserving Pancreatic Head Resection: Beger Procedure

The duodenum-preserving pancreatic head resection (DPPHR) was introduced by Beger and colleagues as a less radical, organ-sparing procedure designed specifically for patients with CP and an inflammatory mass in the head of the pancreas (Beger et al, 1985, 1989, 1999). Similar to PD, the pancreas is divided at the level of the portal vein (see Fig. 55B.2B). In contrast to PD, the pancreatic head is excavated with preservation of the duodenum and a layer of pancreatic tissue. In most cases, it is possible to free the bile duct from surrounding scar tissue. In patients with biliary obstruction (approximately 24%), the common bile duct must be opened so that the bile drains into the cavity of the resected pancreatic head (Beger et al, 1985). The mesoduodenal vessels should be respected, while removing the uncinate process. The standard reconstruction consists of a pancreatojejunostomy to the pancreatic tail and a side-to-side pancreatojejunostomy to the remnant of the pancreatic head using a Roux-en-Y loop of proximal jejunum. In about 10% of patients, DPPHR is combined with lateral pancreatojejunostomy as a consequence of multiple stenoses of the pancreatic main duct; the mortality rate is lower than 1%, and the morbidity rate is approximately 15% (Beger et al, 1985).

Compared with the Kausch-Whipple procedure, the DPPHR offers the advantage of preserving the duodenum. Its superiority over pylorus-preserving resection has been demonstrated in prospective studies (Beger et al, 1985; Büchler et al, 1995; Müller et al, 1997, 2008a). Patients who underwent DPPHR had greater weight gain, better glucose tolerance, and a higher insulin-secretion capacity (Büchler et al, 1995; Müller et al, 1997, 2008a). Over long-term follow-up, 20% of the patients developed new-onset diabetes mellitus. Compared with the natural course of CP, with normal glucose metabolism in 17% of patients (Lankisch et al, 1993), preserved endocrine function is seen in 39% following DPPHR.

With regard to pain status, DPPHR promotes the transformation of clinically manifest CP into a silent disease in around 91% of patients. In terms of quality of life, 69% of the patients were professionally rehabilitated, 26% retired, and only 5% were still in the status of disease after DPPHR (Köninger et al, 2004). Taking into account the better pain status, lower frequency of acute episodes of CP, decreased need for further hospitalization, low early and late mortality rates, and the restoration of quality of life, DPPHR seems to be able to delay the natural course of CP.

Duodenum-Preserving Pancreatic Head Resection: Frey Procedure

Frey and colleagues developed a modification of the DPPHR that represents a hybrid technique between the Beger and the Partington–Rochelle procedures (Frey & Amikura, 1994; Frey & Smith, 1987). Compared with the Beger procedure, the resection in the pancreatic head in the Frey modification is smaller and is combined with a laterolateral pancreatojejunostomy to drain the entire pancreatic duct toward the tail (see Fig. 55B.2C). Unlike the Beger procedure, the reconstruction can be performed with a single anastomosis. This procedure appears advantageous in patients with less severe inflammation in the head of the pancreas that is combined with an obstruction in the left-sided pancreatic duct.

Duodenum-Preserving Pancreatic Head Resection: Bern Modification

The Bern modification of the DPPHR represents a technical simplification of the Beger procedure with equal outcome (Gloor et al, 2001; Köninger et al, 2008; Müller et al, 2008b). The excavation of the pancreatic head can be performed to the same extent as the Beger procedure (see Fig. 55B.2D). However, unlike the Beger procedure, the pancreas is not divided at the level of the portal vein, which is often difficult because of inflammation and portal hypertension. In patients with portal hypertension, the risk of intraoperative bleeding is reduced by this modification (Gloor et al, 2001). The reconstruction after pancreatic head excavation can be performed by a single anastomosis between a jejunal loop and the pancreatic resection rim (Gloor et al, 2001). As in the Beger procedure, a bile duct obstruction can be managed by internal bile duct anastomosis. Thus the Bern modification of the DPPHR appears ideal for patients with an inflammatory mass and no stenosis in the left-sided duct. Adequate drainage of the pancreatic tail has to be verified by probing of the duct. If a stenosis is discovered, the resection can be extended toward the left, similar to the Frey and Partington-Rochelle procedures, until adequate drainage is achieved. In our collective experience, we have found this to be necessary in about 2% to 3% of patients (Strobel et al, 2009).

Left Pancreatic Resection in Chronic Pancreatitis

As long as the pancreatic head is the pacemaker of CP, the DPPHR or the two variants of the pancreatoduocenectomy are the favored surgical treatment options. However, for a small and carefully selected group of patients, pancreatic left resection can be a viable alternative. Good indications for pancreatic left resection are inflammatory complications, such as pseudocysts and fistulae, and main pancreatic duct stenosis in the tail of the

pancreas. Furthermore, the suspicion of a left-sided neoplasm may indicate pancreatic left resection. Overall, less than 5% of all patients who have surgical interventions for CP may benefit from distal pancreatectomy.

Pancreatic left resection can be performed with and without splenectomy. Distal pancreatectomy with conservation of the splenic artery and vein is time consuming. The advantage of avoiding a postsplenectomy syndrome and the importance of the spleen for the host defense system should be taken into consideration. If no clear indication for splenectomy is present, such as perisplenic pseudocyst or inflammatory or fibrotic encasement of the splenic vessels, preservation of the spleen may be appropriate (Aldridge & Williamson, 1991; Bauer et al, 2002; Warshaw, 1988). Importantly, in patients with spleen-preserving distal pancreatectomy in whom the splenic vessels have been resected or in whom the splenic vein showed postoperative thrombosis, the development of left-sided portal hypertension with subsequent formation of gastric varices and potential variceal bleeding demands close follow-up (Balzano et al, 2007; Miura et al, 2005).

The surgical approach concerning the optimal closure technique of the pancreatic remnant after distal pancreatectomy includes stump closure by sutures or stapler application or by creating a Roux-en-Y pancreatojejunostomy. Because the postoperative outcome is similar in both groups (Shankar et al, 1990), the drainage procedure should be reserved for patients with a dilated duct and/or a stricture in the pancreatic head (Aldridge & Williamson, 1991). Distal resection should not exceed 40% to 60% of the pancreatic gland to avoid postoperative insulin-dependent diabetes mellitus (IDDM) (Eggink et al, 1983). IDDM seems to be more of a long-term complication after pancreatic left resection, however, and it is difficult to differentiate whether this is due to pancreatic resection or simply the natural course of the disease.

Evidence-Based Surgery in Chronic Pancreatitis: Pancreatoduodenectomy and DPPHR

Irrespective of the technique, if carried out by experienced personnel, pancreatic head resection is a safe and effective therapy with good short- and long-term results in patients with CP and an inflammatory mass in the head of the pancreas. Various techniques of pancreatic head resection were compared in several RCTs (Table 55B.3; Büchler et al, 1995; Izbicki et al, 1995, 1997, 1998; Klempa et al, 1995; Köninger et al, 2008; Müller et al, 2008a; Strate et al, 2003, 2008), in which their safety and efficacy were confirmed. The RCTs that compared PD and DPPHR (Büchler et al, 1995; Izbicki et al, 1998; Klempa et al, 1995; Müller et al, 2008a; Strate et al, 2008), as well as a recent meta-analysis (Diener et al, 2008), demonstrated comparable mortality and efficacy rates in terms of pain relief and endocrine insufficiency. The less invasive DPPHR was superior in terms of duration of hospital stay, exocrine insufficiency, weight gain, and quality of life in medium-term follow-up. In recent studies with long-term follow-up, these metabolic advantages appear to decrease over time, and long-term results of PD and DPPHR are equal in terms of pain management, quality of life, and endocrine and exocrine function (compare results reported in the initial trials and the latest follow-ups in Table 55B.3). Of interest, the resection techniques remain effective in terms of pain relief and quality of life but may not stop the progress of exocrine and endocrine insufficiency in the long term (Müller et al, 2008a; Strate et al, 2008). One explanation may be that resection effectively treats duct obstruction and hypertension but does not completely stop continued cellular damage and parenchymal loss (Büchler & Warshaw, 2008). Certainly these observations stress the importance of continued postoperative therapy, including the reduction of etiologic factors, substitution of exocrine and endocrine insufficiency, and possibly antioxidant therapy (Bhardwaj et al, 2009).

The RCTs that compared the various techniques of DPPHR demonstrated equal outcomes regarding pain control, quality of life, and metabolic parameters after the Beger procedure versus

Table 55B.3

RCTs Comparing Techniques for Pancreatic Head Resection in CP

Reference	Technique	N	Results
ppPD vs. DPPHR			
Klempa, 1995	Beger ppPD	21 22	Shorter hospital stay, less exocrine insufficiency, less need of analgesics
Büchler, 1995	Beger ppPD	20 20	Less-impaired glucose metabolism, greater weight gain, more frequent pain relief
Follow-up			
Müller, 1997	Beger ppPD	10 10	More frequent delayed gastric empting, more frequent pathologic secretion of enteral hormones
Follow-up			
Müller, 2008b	Beger ppPD	20 20	Equal in pain relief, exocrine, and endocrine function Equal in QoL
Izbicki, 1998	Frey ppPD	31 30	Lower morbidity, better QoL Better professional rehabilitation, equal in pain relief
Follow-up			
Strate, 2008	Frey ppPD	23 23	Equal in pain relief and QoL, equal in exocrine and endocrine function
Different Techniques of DPPHR			
Izbicki, 1995	Beger Frey	20 22	Comparable in pain relief, QoL, exocrine and endocrine function, management of local complications
Follow-up			
Izbicki, 1997	Beger Frey	38 36	Comparable in pain relief, QoL, professional rehabilitation, exocrine and endocrine function
Follow-up			
Strate, 2005	Beger Frey	34 33	Comparable in pain relief, QoL, exocrine and endocrine function
Köninger, 2008	Beger Bern	32 33	Shorter operative time and hospital stay, comparable in QoL

RCT, randomized, controlled trial; PD, pancreatoduodenectomy; ppPD, pylorus-preserving pancreatoduodenectomy; DPPHR, duodenum-preserving pancreatic head resection; QoL, quality of life

the Frey and Bern procedures (see Table 55B.3; Izbicki et al, 1995, 1997; Köninger et al, 2008; Strate et al, 2005). However, the trial by Köninger and colleagues (2008) demonstrated that the Bern modification of the DPPHR represents a technically simpler alternative, as reflected by a significantly shorter operative time (by 46 minutes) and a significantly shorter hospital stay (11 vs. 15 days). Thus the Bern technique represents a modification of the DPPHR that will find a broader acceptance in the future because of technical and economic advantages.

CONCLUSIONS

The adequate therapy of CP is adjusted to the symptoms of the patient, the stage of the disease, and the morphology of pathologic changes of the pancreas. Conservative therapy is the basis of treatment in all patients, and it must accompany both interventional and surgical therapy. Endoscopic therapy appears to be effective for internal drainage of pseudocysts and for proximal ductal stenosis in patients without calcifications. Importantly, endoscopic therapy requires frequent reinterventions, and if not sufficiently effective after a year of treatment, the patient should be referred to surgery. The surgical technique must be adjusted to the pathomorphologic changes of the pancreas. For patients with CP and an inflammatory mass in the head of the pancreas, the DPPHR is less invasive than a pancreatoduodenectomy and is associated with comparable long-term results. The Bern modification of the DPPHR represents a technical variation that is equally effective but technically less demanding. Surgical therapy provides effective long-term pain relief and improvement of quality of life, but it may not stop the decline of endocrine or exocrine pancreatic function. Strategies to improve or maintain endocrine and exocrine function in CP remain an interesting field of research.

CHAPTER 58B

Pancreatic cancer: clinical aspects, assessment, and management

Eugene P. Kennedy and Charles J. Yeo

CLINICAL PRESENTATION

The diagnosis of pancreatic cancer is typically a devastating experience for patients. These malignancies often arise silently, invade locally, and spread distantly prior to any clinical signs or symptoms. The symptoms that bring these tumors to clinical attention vary, based upon the location of the tumor within the pancreas and the stage at presentation. The majority of resectable pancreas cancers occur in the right side of the pancreas, in the head or uncinate process of the gland. Classic symptoms from these right-sided tumors include jaundice from biliary obstruction, often accompanied by pruritis, and epigastric pain radiating to the back from tumor involvement of the celiac plexus. Less commonly, persistent nausea or vomiting as a result of gastric outlet obstruction from tumor narrowing at the duodenal C-loop is the initial symptom. Additionally, pancreatitis in the absence of cholelithiasis or ethanol abuse should arouse suspicion for cancer in patients age 60 years or older. Tumors arising in the left side of the pancreas typically cause few symptoms until they are locally advanced or metastatic. For such left-sided tumors, pain is the most common presenting symptom, and jaundice is rare.

Nonspecific symptoms often occur in association with pancreatic cancer. Nausea, anorexia, weight loss, and fatigue are commonly reported and often are present for some time before diagnosis. Because of the generalized and quite common nature of these symptoms, they rarely lead directly to a diagnosis unless they become profound. Significant weight loss without gastric outlet obstruction is often indicative of advanced disease.

Typically, jaundice is the only physical finding in "early" stage pancreatic cancer. The classic physical findings of left supraclavicular adenopathy (Virchow node), periumbilical adenopathy (Sister Mary Joseph node), or a firm circumferential rim of tumor at the top of the rectum on digital rectal examination (Blumer shelf from drop metastases) are found only with advanced, disseminated disease. Less specific findings that also typically indicate advanced disease include temporal wasting, ascites, hepatomegaly from metastatic disease, or a palpable abdominal mass.

Laboratory analysis is of limited benefit in the diagnosis of pancreatic cancer. Elevated liver function tests are nonspecific and require imaging to investigate their etiology. It is not uncommon to have hyperbilirubinemia with marked increases in the alkaline phosphatase and γ-glutamyl transpeptidase (GGT), with mild elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). New-onset diabetes mellitus is often associated with pancreatic cancer. However, such new-onset diabetes has a low sensitivity and specificity for the diagnosis of pancreatic cancer, and significant overlap is found between the typical age of onset of diabetes mellitus and pancreatic cancer. The incidence of diabetes mellitus is also much greater than that of pancreatic cancer, further limiting its utility as a diagnostic sign.

Ongoing research has produced a multitude of potential biomarkers for pancreatic cancer (Harsha et al, 2009). The only biomarker that has recognized clinical utility is carbohydrate antigen 19-9 (CA19-9); however, its usefulness has two significant limitations. First, it is not specific for pancreatic cancer because it can be elevated in benign conditions, particularly those that cause obstructive jaundice. Second, its sensitivity is reduced by the fact that patients who test negative for Lewis blood group antigens A and B are unable to synthesize CA19-9 and therefore do not express it in their serum. The percentage of pancreatic cancer patients who fall into this group has been reported to range from 10% to 34% (Berger et al, 2008; Tempero et al, 1987). Thus CA19-9 best serves as a marker of treatment response and recurrence in patients who have a pathologic diagnosis of pancreatic cancer.

DIAGNOSIS

Once suspicion is sufficient for pancreatic cancer, high-quality imaging is critical for diagnosis and treatment planning. Many patients initially undergo an abdominal ultrasound (US) or a limited computed tomography (CT) scan of the abdomen. These modalities will suggest processes in the pancreas that require appropriate evaluation. Currently, the best diagnostic modality for imaging the pancreas is a pancreas protocol multidetector CT with dedicated arterial and venous phases and three-dimensional (3D) reconstruction (see Chapter 16; Buchs et al, 2010; Horton & Fishman, 2002). Water is given orally, and contrast is given intravenously. Such scans typically demonstrate the tumor as a low-density (hypodense) lesion within the pancreas, best seen during the venous phase of contrast enhancement. Importantly, these high-quality imaging studies show the important relationship between the tumor and the surrounding visceral vessels, including the superior mesenteric vein, portal vein, splenic vein, superior mesenteric artery (SMA), and the branches of the celiac axis. Such high-quality CT imaging can reliably predict visceral vessel involvement, and thereby surgical respectability, approximately 80% to 90% of the time (House et al, 2004; Karmazanovsky et al, 2005). Additionally, the arterial phase with 3D reconstruction can assist in surgical planning by identifying variations in hepatic arterial anatomy and other vascular anomalies preoperatively, most notably a "replaced" right hepatic artery originating from the SMA, which is seen in one of six patients (see Chapter 1B).

Continuing improvement in the technology that produces magnetic resonance imaging (MRI) has resulted in image quality and resultant diagnostic sensitivities that approach those of CT (see Chapter 17). A recent meta-analysis of 68 articles calculated an overall diagnostic sensitivity of 91% for CT, compared with 84% for MRI, and reported diagnostic specificities of 85% and 82%, respectively (Bipat et al, 2005). Regarding determination of resectability, CT had a sensitivity and specificity of 81% and 82% compared with MRI at 82% and 78%, respectively. No advantage has been demonstrated by obtaining both CT and MRI for uncomplicated patients who display classic symptoms of pancreatic cancer, and this practice should be discouraged. We typically reserve the use of MRI for patients with renal impairment or sensitivity to the intravenous contrast used for CT. The use of MR cholangiopancreatography (MRCP) is valuable in evaluating and following small cystic lesions of the pancreas, but a detailed discussion of these lesions is outside the scope of this chapter (see Chapters 17 and 57).

Endoscopic evaluation of patients with classic symptoms of pancreatic cancer is appropriate in specific situations. Esophagogastroduodenoscopy (EGD) is appropriate in cases of gastric outlet obstruction to assess the anatomy and presence of other diagnoses. In the presence of metastatic or unresectable disease, or when a patient is not physiologically appropriate for immediate surgical intervention, a therapeutic EGD combined with duodenal stenting can be of some benefit, allowing the patient to return to oral intake (see Chapter 27). Endoscopic retrograde cholangiopancreatography (ERCP) was once commonly used as a diagnostic modality for patients with a suspected periampullary pancreatic cancer. With the improvement of cross-sectional imaging, the use of strictly diagnostic ERCP is currently unsupported. Therapeutic ERCP with stenting of biliary strictures can be of benefit in the same patient population (metastatic, unresectable, or physiologically unfit) as therapeutic EGD (see Chapters 14, 18, and 27). However, the routine placement of a biliary endoprosthesis for all patients seen with jaundice without cholangitis should be discouraged. Multiple studies have shown a doubling of the wound infection risk and a slight increase in overall complication risk with preoperative biliary stenting (Pisters et al, 2001a; Sohn et al, 2000). For most patients seen initially with a pancreatic mass and jaundice, early surgery is preferable to endoscopic stenting and delayed surgical resection (Kennedy et al, 2010).

Endoscopic ultrasound (EUS) is a relatively new imaging and diagnostic technology compared with those previously discussed (see Chapter 14). Well established at specialty referral centers, it is rapidly becoming more widely available. Interpretation of EUS imaging is operator dependent, a factor that may account for the wide range of diagnostic sensitivities reported in the literature and encountered in real-world clinical settings (Ahmad et al, 2000; Gress et al, 1999; Hunt & Faigel, 2002; Palazzo et al, 1993; Rösch et al, 1991; Varadarajulu & Eloubeidi, 2010). Reported sensitivities for the diagnosis of pancreatic neoplasia have ranged from 69% to 94%. Several studies have found EUS to be superior to CT for the detection of lesions smaller than 2 cm. EUS is of particular utility when a patient has a presentation consistent with pancreatic cancer (biliary or pancreatic duct obstruction) but no evidence of mass on cross-sectional imaging. The ability of EUS to accurately estimate T-stage decreases compared with CT for larger lesions. Additionally, EUS has shown some superiority over CT for the detection of venous invasion, but it is less useful for the determination of arterial involvement (Varadarajulu & Eloubeidi, 2010). An important additional advantage of EUS is the ability to obtain tissue via fine needle aspiration (FNA) for diagnostic purposes at the time of evaluation. This can be of great benefit to unresectable or marginally resectable patients who need a confirmed tissue diagnosis prior to the initiation of chemotherapy. However, for the vast majority of patients with a symptomatic pancreatic mass that appears completely resectable by CT or MR imaging, EUS with FNA is not needed; in most cases the mass will require resection regardless of the EUS and FNA results.

^{18}Fluorodeoxyglucose-positron emission tomography (^{18}FDG-PET) is a functional imaging modality based on the observation that neoplastic cells exhibit accelerated glucose uptake and metabolism (see Chapter 15). Once transported into the cell and phosphorylated by hexokinase, the first step in glycolysis, ^{18}FDG remains trapped within the cell. Although studies suggest ^{18}FDG-PET is sensitive for the detection of pancreatic cancer, the precise role of this technique in the diagnosis and staging of patients with localized pancreatic cancer is limited. Its use is confounded by the difficulty ^{18}FDG-PET has in distinguishing benign from malignant masses as a result of localization, both to sites of inflammation and infection and to neoplasms. ^{18}FDG-PET is of greater utility in evaluating indeterminate masses in the liver that are not amenable to biopsy. A tissue diagnosis of a primary mass made by EUS, when combined with a PET-positive liver lesion, is adequate to initiate palliative chemotherapy at many centers.

DIAGNOSTIC BIOPSY

As mentioned above, in low-risk patients with resectable lesions suspicious for periampullary cancer, a tissue diagnosis is not required prior to surgical resection, because a negative or inconclusive biopsy result will not affect the decision to operate. Pancreatic biopsy should be reserved for patients with locally unresectable or metastatic disease or for those clinical situations in which a true diagnostic or management dilemma is present. Such situations would include patients with a history of other cancers that have a realistic chance of having a metastasis to the periampullary region (renal cell cancer, melanoma) or patients with marginal physiologic reserves at prohibitive risk for surgical intervention.

Whenever possible, biopsy of a pancreatic lesion should be performed endoscopically with EUS-FNA. Percutaneous US- or CT-guided pancreatic biopsy should be discouraged, and patients should be referred to centers where EUS-FNA is available. Percutaneous biopsy should be reserved for evaluation of suspected metastatic lesions, typically liver metastases. In the presence of suspected metastatic disease, biopsy of the distant lesion if accessible is preferred over biopsy of the primary pancreatic lesion.

STAGING

Pancreatic cancer is staged by the seventh edition (2010) of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual, according to clinical parameters that are available from high-quality CT imaging (Edge, 2010). Classic T, N, and M parameters are used for tumor size, nodal involvement, and distant metastases, but stage grouping is performed according to resectability. Patients are classified as having localized

Table 58B.1

AJCC Staging of Pancreatic Cancer

Stage	Primary Tumor (T)	Regional Lymph Nodes (N)	Distant Metastases (M)	Description
0	Tis	N0	M0	Carcinoma in situ, includes PanIN3
IA	T1	N0	M0	Tumor limited to the pancreas, ≤2 cm in greatest dimension
IB	T2	N0	M0	Tumor limited to the pancreas, >2 cm in greatest dimension
IIA	T3	N0	M0	Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
IIB	T1, T2, T3	N1	M0	Regional lymph node metastasis
III	T4	Any N	M0	Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)
IV	Any T	Any N	M1	Distant metastasis

resectable disease (stages I and II), locally advanced unresectable disease (stage III), or distant metastatic disease (stage IV; Table 58B.1). A resectable tumor is characterized on CT by no evidence of metastatic disease, a clear tissue (fat) plane between the tumor and the visceral arteries (celiac axis and SMA), and 180-degree or less circumferential involvement of the superior mesenteric vein–portal vein confluence (Fig. 58B.1). In contrast, patients with unresectable disease exhibit distant metastases, ascites, or involvement of the celiac axis or SMA (Fig. 58B.2). Venous vascular involvement is considered potentially resectable in the AJCC system and is therefore categorized as stage II disease, and arterial involvement is considered unresectable and is categorized as stage III disease. A small subset of patients with complete occlusion of the superior mesenteric vein–portal vein confluence and significant collateralization that precludes safe venous resection and reconstruction are typically deemed unresectable but are still classified as stage II in the current AJCC system. This system has been validated by correlation to overall survival (OS) using the National Cancer Database (Table 58B.2; Bilimoria et al, 2007a).

LAPAROSCOPY

Diagnostic laparoscopy for suspected or confirmed pancreatic cancer has the potential to detect small surface liver or peritoneal metastases (see Chapter 21). It is limited, however, in its ability to evaluate locally advanced disease. Prior to the development of current imaging techniques, namely three-dimensional MDCT, unresectability rates at laparotomy exceeded 30%. Modern cross-sectional imaging has reduced that rate considerably, as discussed above.

Disagreement exists in the literature about the role of diagnostic laparoscopy in the evaluation of pancreatic cancer.

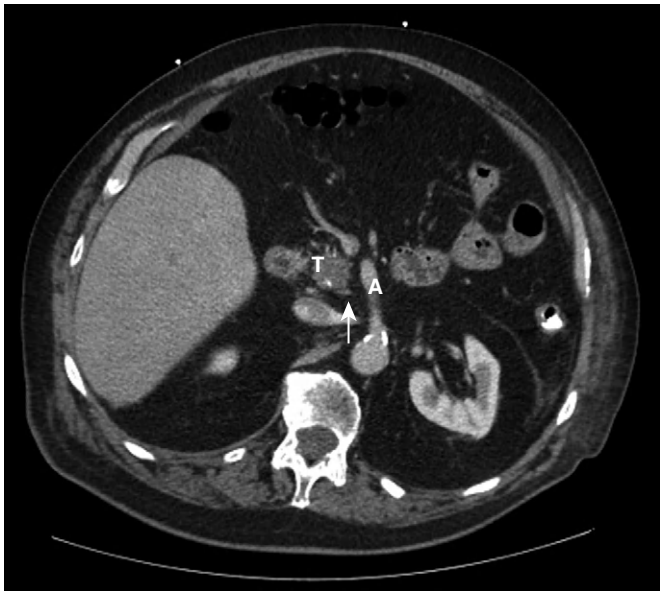

FIGURE 58B.1. Resectable pancreatic adenocarcinoma in the head and uncinate process, showing well-preserved fat plane (*arrow*) between tumor (*T*) and superior mesenteric artery (*A*).

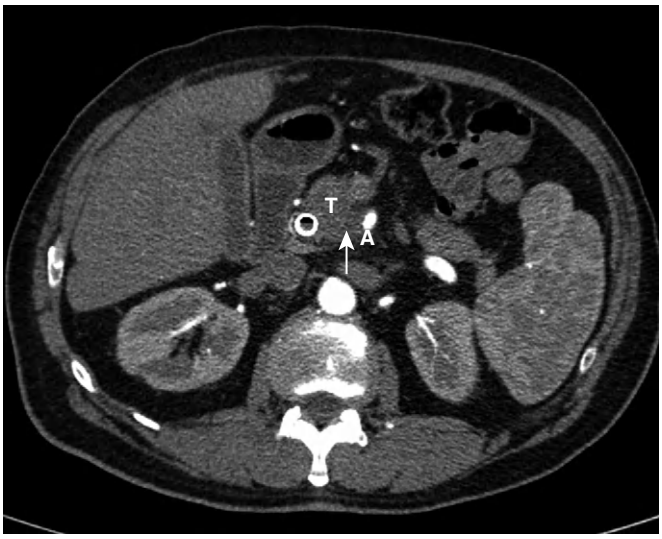

FIGURE 58B.2. Unresectable pancreatic adenocarcinoma in the head and uncinate process, showing loss of fat plane (*arrow*) between tumor (*T*) and superior mesenteric artery (*A*). A metallic endoprosthesis is seen as a hyperintense circular structure in the distal common bile duct.

IV	2.5	4.5	2.5
Total	**3.5**	**12.6**	**4.4**

AJCC, American Joint Commission on Cancer.

Data from Bilimoria KY, et al, 2007a: Validation of the 6th edition AJCC pancreatic cancer staging system: report from the National Cancer Database. Cancer 110(4):738-744.

Multiple authors have reported series evaluating the utility of diagnostic laparoscopy. The rate at which diagnostic laparoscopy alters subsequent management is reported at between 4% and 40% (Pisters et al, 2001b; Shah et al, 2008; Stefanidis et al, 2006). Taking the data as a whole, diagnostic laparoscopy seems best reserved for selected patients, in whom an increased likelihood of intraabdominal dissemination exists. Such cases include tumors greater than 4 cm, particularly those on the left side of the pancreas; ascites; markedly elevated CA19-9 (>1000 U/mL); and small, indeterminate liver or peritoneal lesions seen on CT, which are too small to investigate with percutaneous biopsy or PET imaging. We rarely use diagnostic laparoscopy for right-sided lesions, and our use of diagnostic laparoscopy for left-sided tumors has declined in recent years, as CT staging has become more accurate.

SURGICAL TREATMENT

Resectable Disease (See Chapters 62A and 62B)

The goal of the initial evaluation process for patients with pancreatic cancer is classification into one of three broad groups: *resectable*, *locally advanced/borderline resectable*, or *unresectable*. This determination should be made in consultation with an expert in pancreatic surgery. Standards as to what constitutes resectable disease have broadened, as more experience is gained with pancreatic resection. A 2007 study by Bilimoria and colleagues revealed that of the more than 9500 U.S. patients identified in the National Cancer Database as having clinical stage 1 pancreatic cancer, more than 70% did not undergo surgery. In this group, the reason for not undergoing surgery could not be identified in more than 50% of patients, and a minority were deemed too old or unfit for pancreatectomy. This represents a gross underutilization of surgical intervention for potentially curable pancreatic cancer in the United States, which the authors postulate may be due to a nihilistic attitude toward pancreatic cancer care.

Surgical resection of pancreatic cancer remains the only potentially curative therapy. Unfortunately, only a minority of patients (approximately 20% to 30%) diagnosed with pancreatic cancer are candidates for curative resection at the time of diagnosis. Hopefully, as early detection schemes improve and gain widespread use, and our ability to identify high-risk groups improves, the percentage of patients who are candidates for resection will increase. Resectional approaches are based on tumor location and extent. Resection of right-sided tumors typically requires pancreatoduodenectomy, most often performed with pylorus preservation. Distal pancreatectomy is used to resect left-sided tumors. In a small group of patients with extensive parenchymal involvement of the pancreas, total pancreatectomy may be required. The specific techniques of such resectional procedures can be found in Chapter 62.

Results

Recurrent controversies have persisted over the effectiveness of surgical resection for pancreatic cancer (Crile, 1970; Gudjonsson, 1995). The preponderance of recent data that have emerged from large specialized centers refute claims of futility and lack of long-term survival. A recent publication by Riall and colleagues (2006) examines the actual 5-year survival rates after pancreatoduodenectomy, all stages combined, for pancreatic and periampullary cancer and reports actuarial 10-year survival. The actual 5-year survival for resected pancreatic cancer (all stages combined) was 17%, but the actuarial 10-year survival was 9% (Fig. 58B.3). This analysis included a positive lymph node rate of 48% and a positive margin rate of 8% in the overall periampullary cohort. A similar study by Ferrone and colleagues (2008) revealed an actual 5-year survival rate of 23% for resected stage Ia disease, and all-stage actual 5-year and 10-year survival rates of 12% and 5%, respectively, were reported (Ferrone et al, 2008).

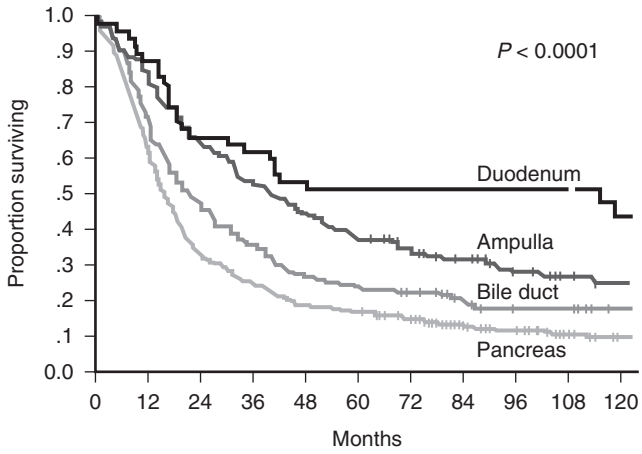

FIGURE 58B.3. Kaplan-Meier actuarial 10-year survival by site of tumor origin after right-sided pancreatectomy for pancreatic and periampullary adenocarcinoma. Results from a cohort of 890 patients treated by pancreatoduodenectomy (pancreas, n = 564; ampulla, n = 144; bile duct, n = 135; duodenum, n = 47). The first 5 years of the curve represent the actual 5-year survival because no patients were censored during that time. Five-year actual survival rates were 17% for pancreas, 37% for ampulla, 23% for bile duct, and 51% for duodenum. Ten-year actuarial survival rates were 9% for pancreas, 25% for ampulla, 17% for bile duct, and 44% for duodenum. All patients were censored after 5 years, so all 890 were at risk for recurrence. Censoring points are shown. *(Modified from Riall et al, 2006: Resected periampullary adenocarcinoma: 5-year survivors and their 6- to 10-year follow-up. Surgery 140[5]:764-772.)*

ADJUVANT THERAPY

Because of the great propensity of pancreatic cancer to recur or persist even after optimal surgical resection, clinicians have used adjuvant chemotherapy with or without radiotherapy in an attempt to prolong disease-free survival and increase OS (see Chapter 63A). The most noteworthy of the early trials was a prospective, randomized trial from the Gastrointestinal Tumor Study Group (GITSG) using split-course irradiation (40 Gy) with concurrent bolus 5-fluorouracil (5-FU) followed by maintenance 5-FU for a duration of up to 2 years (Kalser & Ellenberg, 1985). Patients were randomized to treatment versus a no-treatment control arm. The trial showed a survival advantage for adjuvant chemoradiotherapy (median survival, 20 months) compared with surgery alone (median survival, 11 months; $P = .01$). Although criticized for its small numbers (43 total patients), slow accrual, and failure to meet accrual targets, the GITSG trial was the first trial to document a survival advantage for adjuvant therapy in pancreatic adenocarcinoma.

Subsequent to this initial study, six additional randomized adjuvant chemotherapy or chemoradiotherapy trials have been published (Table 58B.3; Klinkenbijl et al, 1999; Neoptolemos et al, 2004, 2009; Neuhaus et al, 2008; Regine et al, 2008; Ueno et al, 2009). A randomized controlled trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) showed a trend toward improved survival with adjuvant 5-FU–based chemoradiation compared with surgery alone in patients with periampullary and pancreatic cancer (Klinkenbijl et al, 1999). However, this study was statistically underpowered and initially reported as a negative trial.

The results of the European Study Group for Pancreatic Cancer (ESPAC-1) trial were met with controversy (Neoptolemos et al, 2004). In this randomized controlled trial of adjuvant therapy for pancreatic cancer, patients were assigned to one of four groups: treatment with 5-FU–based chemoradiation alone, chemotherapy alone (5-FU plus leucovorin), chemoradiation followed by chemotherapy, or observation. Using a two-by-two factorial design, the authors concluded that adjuvant chemotherapy conferred a survival benefit, whereas adjuvant chemoradiation had a deleterious effect on survival. This study is often criticized for methodologic problems, such as a high rate of nonadherence for the patients assigned to receive chemotherapy, and for radiation therapy quality control issues (Choti, 2004). Because of the study design, statistical power was insufficient to compare each of the four treatment groups individually. However, when compared to the observation group, patients who received chemoradiation alone appeared to have a worse median survival, suggesting a possible role for treatment-related toxic radiation effects.

The Radiation Therapy Oncology Group (RTOG) protocol R97-04 was designed to determine whether the addition of gemcitabine to postoperative adjuvant 5-FU chemoradiotherapy improved survival for patients with resected pancreatic adenocarcinoma (Regine et al, 2008). This phase III multi-institution trial randomized resected pancreatic adenocarcinoma patients to either one cycle of continuous infusion 5-FU, followed by continuous infusion 5-FU during radiotherapy (50.4 Gy), followed by two additional cycles of continuous 5-FU or one cycle of gemcitabine, followed by continuous infusion 5-FU during radiotherapy (50.4 Gy), followed by three additional cycles of gemcitabine. Patients with pancreatic head tumors had a median survival of 20.5 months and a 3-year survival of 31% in the gemcitabine group versus 16.9 months and 22% in the 5-FU group (hazard ratio [HR], 0.82; 95% confidence interval [CI], 0.65 to 1.03; $P = .09$). After adjusting for the protocol-specified stratification variables of nodal status,

which strongly affected survival (P = .001), tumor diameter, and surgical margin status, the multivariate analysis for patients with pancreatic head tumors treated with gemcitabine yielded an HR of 0.80 (95% CI, 0.63 to 1.00; P = .05), reflecting improved survival for the gemcitabine group.

The Charité Onkologie study (CONKO-001) compared adjuvant gemcitabine therapy to no postoperative anticancer therapy in patients undergoing surgical resection of pancreatic cancer (Neuhaus et al, 2008). Patients in the treatment arm received six cycles of gemcitabine therapy over 6 months with acceptable toxicity. Overall, 368 patients were randomized and 354 were included in the intention-to-treat analysis. Patients in the treatment arm had a statistically significant increase in OS on final analysis, with a median OS of 22.8 months and a 5-year survival of 21% compared with a 20.2-month median survival and a 5-year survival of 9.0% for the control arm (P = .005).

ESPAC-3 is the largest randomized trial of adjuvant postresection treatment of pancreas cancer to date (Neoptolemos et al, 2009). The trial randomized patients who had undergone either an R0 or R1 resection to adjuvant 5-FU plus leucovorin versus adjuvant gemcitabine. Radiation therapy was not used. Over a 6.5-year period, 1088 patients from 16 countries were randomized. Median survival for the 5-FU/leucovorin arm was 23.0 months, and median survival for the gemcitabine arm was 23.6 months. The authors concluded that no significant difference in survival was evident between the two treatment arms.

A study recently published by the Japanese Study Group of Adjuvant Therapy for Pancreatic Cancer (JSAP) ran concurrent with the CONKO-001 trial and was of similar design (Ueno et al, 2009). It also randomized resected pancreas cancer patients to either observation or adjuvant gemcitabine therapy. OS was extended in the gemcitabine group (22.3 months vs. 18.4 months in the control arm), but the difference did not reach statistical significance. The authors reported their belief that their study was underpowered to detect a difference, given its smaller enrollment than the CONKO-001 trial.

Taken together, the preponderance of evidence indicates that adjuvant therapy for pancreatic cancer has a survival benefit. Controversy remains, however, as to the optimal chemotherapeutic regimen and the role of radiotherapy; RTOG-0848 has been designed to address these questions. Opened in November 2009, it has a target enrollment of 950 patients. This Phase III trial is a double-randomization design, assigning patients first to either adjuvant gemcitabine or adjuvant gemcitabine plus erlotinib. Patients receive five cycles of chemotherapy and are then assessed by cross-sectional imaging for evidence of disease progression. Patients without progression then undergo a second randomization to continue chemotherapy alone or to proceed to chemoradiotherapy. All patients receive one additional cycle of the chemotherapy they received under the first randomization. Patients randomized to receive chemoradiotherapy then receive external beam radiotherapy to a dose of 50.4 Gy in 28 fractions. This radiotherapy is given in combination with either oral capecitabine or infusional 5-FU. The organizers hope to have evaluable data by April 2015.

NEOADJUVANT THERAPY AND BORDERLINE RESECTABLE DISEASE

When preoperative imaging reveals either tumor encroachment with significant compromise of the mesenteric venous structures that is not amenable to reconstruction or encroachment on the superior mesenteric artery or celiac axis, patients are classified as borderline resectable. A skilled pancreatic surgeon can often remove such tumors safely, however, it is statistically unlikely that an R0 resection can be accomplished in such settings. Therefore, neoadjuvant chemotherapy or chemoradiotherapy is usually initiated with the goal of downstaging the tumor such that an R0 resection is possible. In theory, therapy administered in the preoperative neoadjuvant versus the postoperative adjuvant setting offers several potential advantages: the therapy would be given up front, eliminating the risk of delayed or incomplete treatment postoperatively; patients who manifest metastatic disease following neoadjuvant therapy would avoid an operation unlikely to be beneficial; and, because radiation efficacy is dependent on oxygenation, it may be more effective given before tissues are devascularized by surgery. The M.D. Anderson group has recently published reports of two phase II trials of either gemcitabine-based neoadjuvant chemoradiotherapy or preoperative gemcitabine and cisplatin chemotherapy in addition to chemoradiation (Evans et al, 2008; Varadhachary et al, 2008). They report resection rates of 74% and 58%, respectively, for patients entered into each protocol. Median survival for the subset of patients who actually underwent resection is promising, at 34 months and 31 months, respectively.

Another report from the same group described three types of borderline patients: *type A* is borderline resectable by objective anatomic criteria; *type B* is borderline resectable because of findings suggestive but not diagnostic of metastatic disease; and *type C* is borderline operable because of marginal performance status or extensive comorbidity (Katz et al, 2008). The 160-patient group was composed of 84 type A, 44 type B, and 32 type C patients classified as borderline resectable. After neoadjuvant treatment and restaging, 66 patients (41%) underwent pancreatectomy. The median survival was 40 months for the 66 borderline patients who completed all therapy but only 13 months for the 94 patients who did not undergo pancreatectomy (P < .001).

PALLIATIVE THERAPY

Unresectable Disease (see Chapters 63A and 63B)

The first goal in treating patients with unresectable and/or metastatic disease is to provide adequate palliation for symptoms related to their diagnosis, particularly obstructive jaundice, gastroduodenal obstruction, and abdominal pain. A more detailed discussion of these topics is provided in Chapters 63A and 63B. Modern endoscopic therapy and interventional radiology procedures can often provide substantial palliation of biliary obstruction and gastric outlet obstruction. When patients cannot be palliated in this fashion, surgical palliation through gastrojejunostomy and Roux-en-Y hepaticojejunostomy is indicated to relieve symptoms of duodenal and biliary obstruction and allow physiologic improvement such that patients can subsequently receive palliative chemotherapy or chemoradiotherapy. Additionally, when patients are determined to be unresectable at the time of exploration with curative intent, the opportunity exists to provide surgical palliation of duodenal obstruction or tumor-associated pain, two symptom complexes that can cause suffering and interrupt other cancer-directed therapies. Prophylactic gastrojejunostomy at the time of initial exploration has been shown to predispose to symptomatic

duodenal obstruction in this population of patients (Lillemoe et al, 1999).

Another beneficial intervention that can be provided at the time of exploration is celiac plexus nerve block. This simple intervention has been shown to decrease pain and postoperative narcotic use, and, in the subset of unresectable patients who present with pain, to prolong survival (Lillemoe et al, 1993). The procedure is simple and carries minimal risk and expense when done during surgical exploration. It can also be done endoscopically or percutaneously, with pain relief that is often superior to that suggested by the stepwise analgesic ladder provided by the World Health Organization (WHO) (Wong et al, 2004).

Palliative Chemotherapy

Chemotherapy is provided in the unresectable and metastatic setting with the intention of prolonging life while preserving or improving quality of life. The current standard of care for advanced pancreatic cancer was set in 1997 by Burris and colleagues in their landmark study, which showed a significant prolongation in OS, as well as a concurrent clinical benefit response, in patients with advanced pancreatic cancer treated with gemcitabine compared with the previous standard chemotherapy (5-FU). The efficacy measure was clinical benefit response, which was a composite of measurements of pain, specifically, analgesic consumption and pain intensity; Karnofsky performance status; and weight. Clinical benefit required a sustained (≥4 weeks) improvement in at least one parameter without worsening in any others. Since that time, only one other chemotherapeutic, erlotinib, has been granted a Food and Drug Administration (FDA) therapeutic indication for use against pancreatic cancer (Moore et al, 2007). Of note, the inclusion of erlotinib as standard of care has been controversial, given the minimal improvement in OS (only 0.33 months) when evaluated in the context of the drug's expense and side effects.

Multiple studies continue to be done in this area that examine combination therapies involving currently available chemotherapeutics and investigational agents (Stathis & Moore, 2010). Most have failed to show any evidence of benefit to patients with advanced pancreatic cancer, although recently, some enthusiasm attended the preplanned interim analysis of the PRODIGE 4/ACCORD 11 trial, presented at the Spring 2010 American Society of Clinical Oncology meeting (Conroy et al, 2010). This randomized Phase III trial compared a combination of 5-FU, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX) versus gemcitabine as first-line therapy for advanced pancreas cancer. At the preplanned interim analysis, the median OS for the FOLFIRINOX group was 10.5 months compared with 6.9 months for the gemcitabine group ($P < .001$). FOLFIRINOX is the first therapy not containing gemcitabine that has shown a significantly longer OS, progression-free survival, and higher response rate than gemcitabine alone. Determination of the role of this regimen as standard of care will await the full results of the trial and detailed reporting of the toxicity associated with FOLFIRINOX therapy.

Multiple targeted therapies that focus on matrix metalloproteinas, farnesyl transferase in the RAS pathway, epidermal growth factor receptor, and vascular endothelial growth factor, as well as a host of novel strategic targets, have shown promising preliminary results. However, with the exception of erlotinib, these have not been translated to usual care. The rational use of these powerful and potentially beneficial agents awaits the development of appropriate predictive biomarkers that can guide therapy. As promising biomarkers are validated, they can be used to guide future therapy. Then, the treatment of pancreatic cancer can evolve into a future of individualized patient care based on the combined efforts of the hundreds of investigators working worldwide.

CHAPTER 62A

Resectional techniques: pancreaticoduodenectomy, distal pancreatectomy, segmental pancreatectomy, total pancreatectomy, and transduodenal resection of the papilla of Vater

Jens Werner and Markus W. Büchler

OVERVIEW

The previous chapters in this section have outlined the definition, classifications, pathogenesis, clinical aspects, diagnostic assessment, and management of acute pancreatitis, chronic pancreatitis, and periampullary and pancreatic tumors that include pancreatic cancer and cystic and endocrine tumors. This chapter describes the different pancreatic resection procedures available today and is mainly focused on technical aspects.

Pancreatic resection ranks as one of the most, if not *the* most, complicated and technically challenging surgical procedures known to surgeons. It is not only a demanding technical exercise, it also exerts a substantial logistical strain on health care resources. Add to this equation the typical surgical candidate, who may already be profoundly jaundiced and malnourished preoperatively, not to mention the heavy physiologic toll any operation will take on such patients, let alone pancreatic surgery.

The modern surgeon can certainly appreciate the trepidations felt by early surgical pioneers faced with such a clinical situation. Early series on pancreatic operations for cancer published in the late 1960s reported postoperative morbidity rates of 60% and mortality rates approaching 25%, with dismal long-term outcomes. Consequently, Crile (1970) opined that patients would be better served by a bypass procedure rather than putting them through a futile and risky resection. Such a nihilistic view was the prevailing attitude prior to the 1980s, to the point that surgeons asked themselves whether pancreatoduodenectomy (PD) should be abandoned as treatment for pancreatic cancer (van Heerden et al, 1981).

In the ensuing decades, however, a dramatic decline was seen in surgical mortality and morbidity rates. High-volume pancreatic surgical centers are consistently reporting mortality rates of less than 2% and morbidity rates of 36% (Büchler et al, 2003; Cameron et al, 2006; Wagner et al, 2004). Certainly, continual improvements in surgical technique have played a role, but credit cannot be claimed solely by the surgical profession; significant advances were achieved in tandem in other fields that included better understanding of pancreatic diseases, advances in diagnostics, better patient selection, and improvements in perioperative care. Perhaps one of the main contributors to this phenomenon was the establishment of high-volume centers (Birkmeyer et al, 2003; Fong et al, 2005). Such centers tend to boast larger facilities and therefore have a broader range of specialist- and technology-based services, with better staffed intensive care units. This also implies that complications are better recognized and managed.

Although the question of the safety of pancreatic resection has been effectively addressed, the long-term outcome is more controversial as far as pancreatic adenocarcinoma is concerned. The concept of cure following "curative" resection has recently been challenged (Gudjonsson, 1995), but surgical resection is the only therapy that offers significantly increased survival. A randomized multicenter trial affirmed the superior results of resection on survival compared with various forms of nonsurgical therapy (Imamura et al, 2004). The median survival following resection was 14.3 months, whereas patients who did not undergo surgery died at 4.9 months (Conlon et al, 1996); 10% to 30% of patients will be true 5-year survivors (Cameron et al, 2006; Wagner et al, 2004). Furthermore, although pancreatic cancer is the most common of the periampullary tumors, cancers of the ampulla, duodenum, and distal bile duct, as well as intraductal papillary mucinous neoplasm–associated adenocarcinoma, have a better long-term survival following curative PD (Poultsides et al, 2010). In addition, more and more cystic pancreatic and endocrine tumors are diagnosed today, and simple enucleation or segmental resection of the tumors at the appropriate stage can cure the disease. Even with advances in multimodal treatment, surgery remains the centerpiece of the treatment algorithm for pancreatic cancer because no truly effective chemotherapeutic agents for treating nonresectable disease have been developed (Gillen et al, 2010; Postier, 2003).

Technical refinements have led to a variety of surgical techniques that have allowed a more individualized, disease-directed approach. These modifications were partly responsible for the decline in surgical morbidity. This chapter focuses on some of these surgical techniques, as practiced in our institution, as well as some of the more pertinent perioperative issues for patients subjected to pancreatic resection. Surgical techniques specific

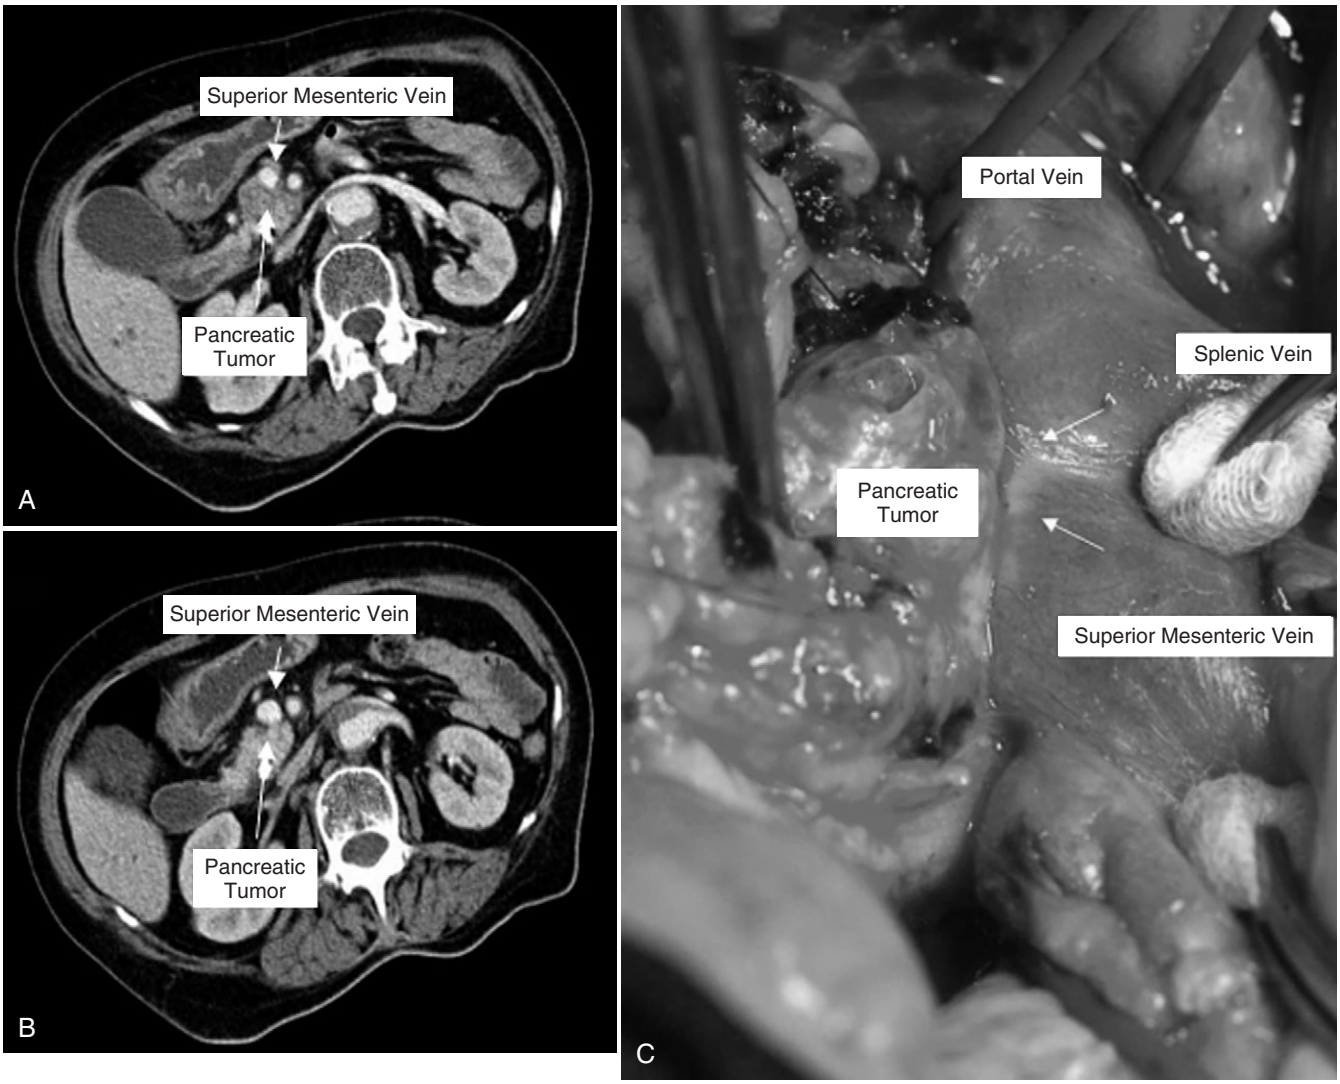

FIGURE 62A.1. **A** and **B,** Computed tomographic scan with axial cuts showing a pancreatic head carcinoma with involvement of less than 50% of the circumference of the superior mesenteric vein without involvement of the superior mesenteric artery (note the rim of fat tissue around the artery). **C,** Intraoperative findings confirm the scan findings with tumor infiltration of the superior mesenteric vein (*arrows*). Subsequently, a portal vein resection and reconstruction with a venous graft was carried out.

for the treatment of acute pancreatitis (open and minimally invasive necrosectomy) and chronic pancreatitis (duodenum-preserving pancreatic head resection) are described in detail in Chapters 54 and 55B.

PREOPERATIVE WORKUP AND MANAGEMENT

Diagnosis and Staging of Disease

Clinical staging should reliably define the extent of disease, thereby avoiding unnecessary intervention and the accompanying morbidity, mortality, and diminished quality of life in patients with advanced disease (Spanknebel & Conlon, 2001). Although the tumor-node-metastasis (TNM) staging system is most often used in clinical trials, physicians in practice typically classify patients as having resectable, locally unresectable, or metastatic disease (Haller, 2002). *Resectable pancreatic cancer* is universally defined as a pancreatic tumor without evidence of involvement of the superior mesenteric artery (SMA) or the celiac axis and no evidence of distant metastasis. Tumors with infiltration of one of these central arteries are defined as *locally irresectable,* but those with infiltration of the superior mesenteric vein or abutment of visceral arteries are defined as *borderline resectable* (Adler et al, 2007; Katz et al, 2008). Portal vein (PV) involvement, although somewhat controversial, should not be a contraindication for surgery; today, this is still center dependent. In general, PV involvement does not preclude an R0 resection (Fig. 62A.1).

Imaging

Imaging is now the mainstay in diagnosis and staging of pancreatic tumors, unlike the traditional approach of surgical exploration and a hands-on intraoperative examination to determine resectability.

Helical computed tomography (CT) scanning has been established as the single most effective initial staging study (Freeny, 2001; Klauss et al, 2008) and is often used as the entry

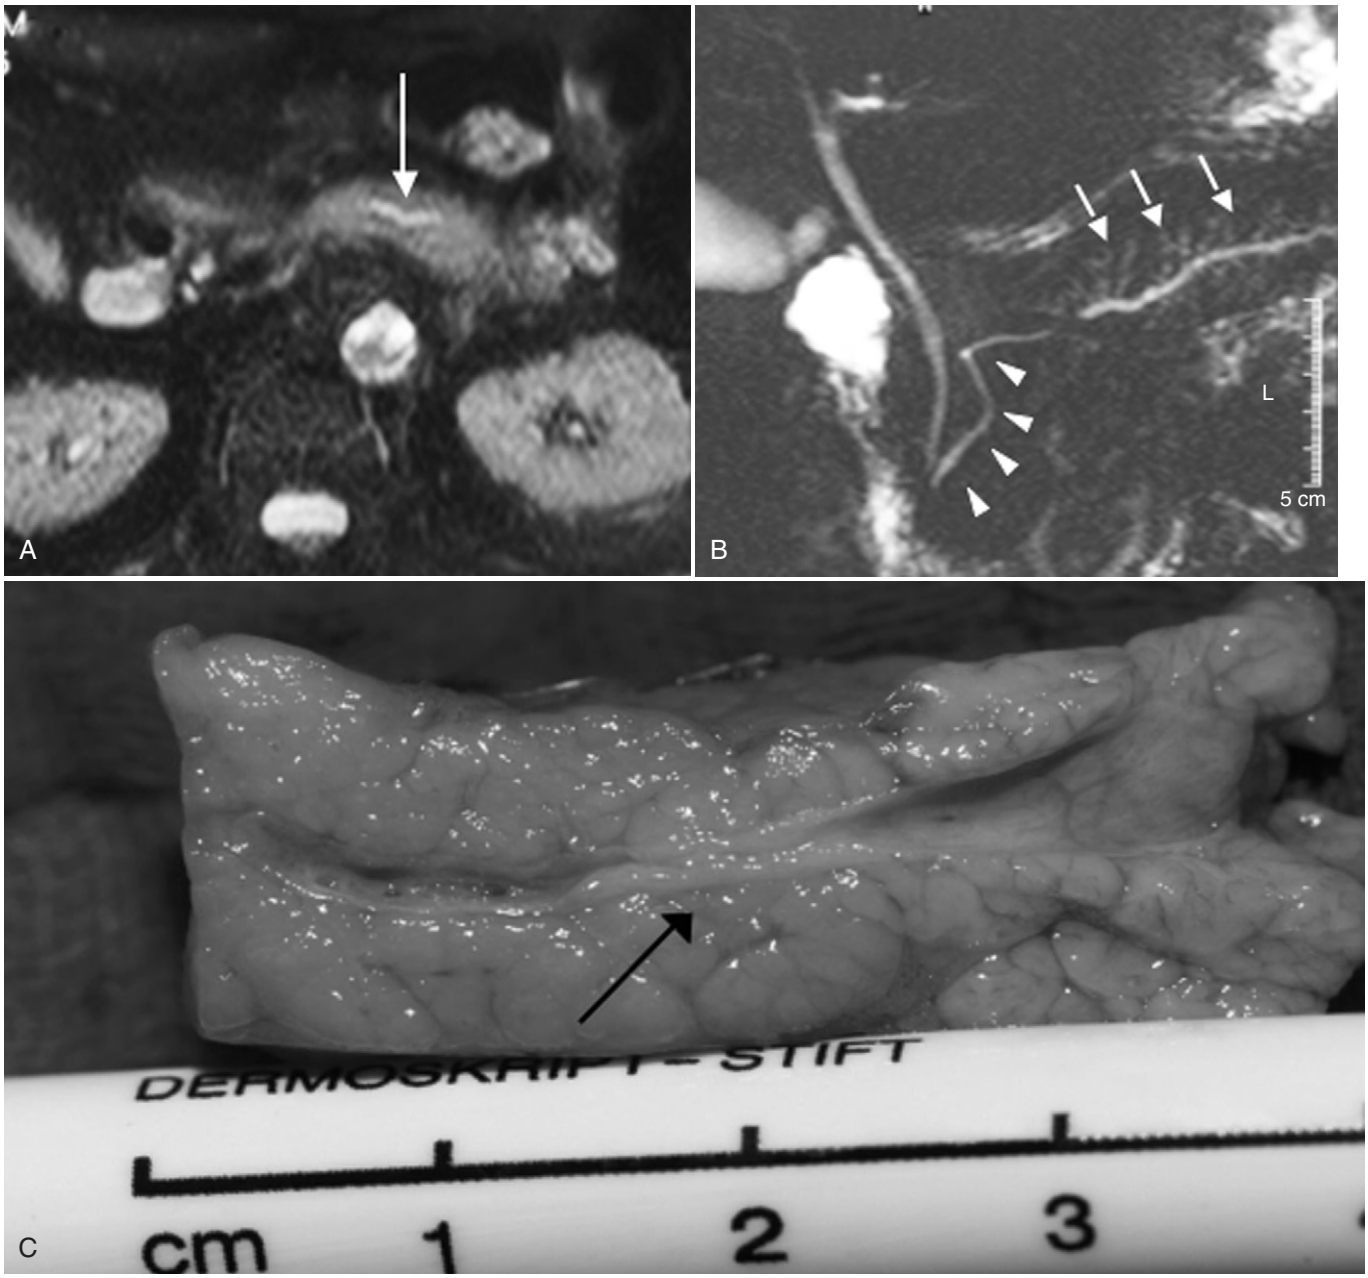

FIGURE 62A.2. A, Magnetic resonance image showing a dilated pancreatic duct (*arrow*) secondary to a small tumor. **B,** Magnetic resonance cholangiopancreatography shows a clearer delineation of the pancreatic duct. It demonstrates a normal pancreatic duct in the pancreatic head (*arrowheads*), a filling defect in the pancreatic body, and distal dilation of the pancreatic duct in the tail with appearance of first- and second-order side branches (*arrows*). **C,** Specimen photograph. The cause of the ductal obstruction was later shown to be a T1 pancreatic ductal adenocarcinoma (*arrow*) in the final histology.

point to a management algorithm. The findings then dictate the subsequent management, including additional diagnostics (see Chapter 16).

The previous selling point of magnetic resonance imaging (MRI) (see Chapter 17) was its being a one-stop modality that combines pancreatography, cholangiography, and angiography and also assists in the evaluation of tumors. However, MRI is being progressively overshadowed with the advent of the multidetector CT, which has nearly the same offerings. As such, MRI offers no added benefit over CT for evaluating pancreatic cancer, except perhaps in patients in whom a contrast-enhanced CT cannot be performed (White et al, 2003), and MRI seems to be superior for the differential diagnosis of pancreatic cystic lesions (see Chapter 57).

MR cholangiopancreatography (MRCP) offers a noninvasive delineation of the pancreatic and biliary ducts. It detects pancreatic or ampullary carcinoma by demonstrating the effect of a space-occupying lesion on the ducts, namely obstruction or displacement (Fig. 62A.2). The classic feature is the "double-duct" sign. However, even a strictly defined double-duct sign is only 80% to 85% specific for malignancy (Menges et al, 2000). More recent applications include secretin-enhanced MRCP,

which can improve pancreatic duct and side-branch delineation. Furthermore, such pharmacologic stimulation of pancreatic juice secretion can potentially allow the evaluation of pancreatic flow dynamics and assessment of pancreatic exocrine function (Kalra et al, 2003).

Endoscopic ultrasonograpy (EUS) allows a sonographic transducer to be placed in close proximity to the pancreas (see Chapter 14). In doing so, interference from overlying bowel gas is eliminated, thus allowing higher frequencies to be used and resulting in markedly improved resolution of the imagery. Consequently, EUS is more sensitive in detecting smaller lesions (<20 mm), with a sensitivity in the range of 93% to 100% (Tamm et al, 2003). In a meta-analysis of studies comparing staging by EUS to results with other modalities, EUS without fine needle aspiration (FNA) more accurately predicted T stage, N stage, and PV involvement than did CT scanning. EUS also allows image-guided FNA of the primary tumor and the regional lymph nodes without the possible risk of tumor seeding along the needle tract, unlike FNA via the percutaneous route (Gress et al, 2001).

EUS-guided FNA biopsy has been reported to have a high sensitivity (93%) and specificity (100%) (Wiersema, 2002); however, EUS with FNA is only of diagnostic value if histology confirms a pancreatic tumor. The major limitations of this technology are operator dependence and a limited field of visualization for the detection of distant metastasis. In fact, in resectable pancreatic cancer, but also in cystic or endocrine tumors, preoperative biopsies are of no value (Hartwig et al, 2009a). Therefore, we use this modality on a highly selective basis, such as in obtaining tissue biopsy for patients scheduled for neoadjuvant therapy with locally advanced pancreatic cancer, or before palliative chemotherapy is applied in metastatic disease.

With the advent of MRCP, EUS, and multidedector CT with multiplanar three-dimensional (3D) reconstruction, the role of endoscopic retrograde cholangiopancreatography (ERCP) as a diagnostic tool has become increasingly limited. Furthermore, it has potentially high complication rates compared with other procedures (Ciocirlan & Ponchon, 2004). Such concerns have been summarized in a recent report by the American Society of Gastrointestinal Endoscopy (ASGE, 2003). In light of these data, the current view is that purely diagnostic uses of ERCP should be limited, a view affirmed by the National Institutes of Health (NIH) State of the Science Conference Statement (Cohen et al, 2002), which recommended that for patients with pancreatic or biliary cancer, the principal advantage of ERCP is palliation of biliary obstruction when surgery is not elected.

General Preoperative Patient Assessment

Pancreatic resections exert a significant physiologic stress on patients, many of whom are elderly; the peak incidence of pancreatic cancer falls in the 65- to 75-year age group (Lankisch et al, 2002). With the improvement of the safety profile of pancreatic operations, many centers have offered surgery to octogenarians, although in such patients the incidence of comorbidities is higher.

In our center, we found that systemic complications, chiefly cardiopulmonary complications, have become the main cause of operative death (Büchler et al, 2003). As such, we routinely subject our patients to a rigorous preoperative assessment of their cardiac, pulmonary, and renal functions. Cardiopulmonary exercise testing has been shown to more accurately evaluate the ability of the cardiorespiratory system to deliver oxygen under stress (Davies & Wilson, 2004). We have also included a pulmonary function test in our algorithm. Optimization of afterload and myocardial contractility take equal importance, and pulmonary artery catheters are occasionally inserted to facilitate this. The operation will only proceed when we can achieve an optimal hemodynamic profile.

Perioperative Management (See Chapters 22, 23, and 24)

Perioperative Anticoagulation

Meta-analysis of the role of low-molecular-weight heparin (LMWH) in the prevention of venous thromboembolic events in general surgery has shown that LWMH can significantly reduce the incidence of asymptomatic deep vein thrombosis (DVT), clinical venous thromboembolism, and pulmonary embolism, with a trend toward a reduction in overall mortality rate (Mismetti et al, 2001). Consequently, we routinely administer LMWH in a prophylactic dose to our patients, starting the evening before the day of surgery, until the patient is ambulant postoperatively. In addition, our patients are prescribed compression stockings to wear intraoperatively and for their entire inpatient stay because such stockings reduce pooling of blood in deep veins by mechanically preventing venous distension (Morris & Woodcock, 2004) and are thus a simple and cost-effective method of DVT prophylaxis.

Antibacterial Prophylaxis

Antibacterial prophylaxis is instrumental in the reduction of infection-related morbidity with clean-contaminated procedures (de Lalla, 2002); as such, it is recommended for all patients who undergo hepatobiliary or pancreatic surgery (Sganga, 2002). Drugs with antianaerobic activity are added if anaerobe encounter is anticipated during the procedure, in particular procedures involving the gastrointestinal (GI) tract. The general guideline is to use the highest licensed dosage of the chosen antimicrobial agent, administered at induction of anesthesia so as to achieve high peak tissue concentration at the site of the wound before the first incision, which should be maintained until the time of closure (Polk et al, 2000). For our pancreatic operations, in addition to 500 mg metronidazole, we routinely give 4 g mezlocillin, an ureidopenicillin with activity against both gram-positive and gram-negative organisms, including enteric bacilli. We generally do not give postsurgical doses unless the patient has had a recent bout of cholangitis or if the bile was found to be turbid or purulent intraoperatively. In any event, in all procedures that require entry into the biliary tract, bile is sent for microbiologic examination to guide postoperative antimicrobial treatment if the need arises.

Octreotide Analogues

The pancreatoenteric anastomosis is considered the Achilles heel of PD, a testimonial to the potentially disastrous sequelae of life-threatening intraabdominal sepsis and hemorrhage (Stojadinovic et al, 2003) in the event of a pancreatic leak. The secretion capacity of the remnant gland has been found to be a determining factor for the development of a leak because continuous pancreatic secretion has been hypothesized to hinder healing of the pancreatic stump. This led to the hypothesis that

by reducing exocrine secretion, perhaps the incidence of pancreatic fistula could be reduced accordingly.

Octreotide, the octapeptide analogue of somatostatin, is a powerful inhibitor of pancreatic exocrine secretion. A number of randomized prospective trials have examined the role of prophylactic, perioperative octreotide and its impact on outcome after pancreatic surgery. The results seemed to display an intercontinental difference: level 1 studies from Europe generally showed that perioperative somatostatin has a protective effect, whereas all the North American studies failed to demonstrate any benefit. A recent systematic review of this topic came to the conclusion that the prophylactic administration of somatostatin or its analogue does not uniformly reduce the incidence of pancreatic anastomotic leak, overall morbidity, or mortality after pancreatic resection (Li-Ling & Irving, 2001). Based on the findings of the trials conducted by our center (Büchler et al, 1992; Friess et al, 1995), we believe that some benefits may still be reaped from the use of prophylactic somatostatin in high-risk patients (soft pancreas, small duct), in whom a PD is performed. If the pancreas is deemed to be high risk by the surgeon, because of a soft consistency and a pancreatic duct size of less than 2 mm in diameter, somatostatin is applied intraoperatively (200 μg subcutaneously), followed by three daily doses of 200 μg octreotide for 5 days. Other indications for applying somatostatin are when segmental resections or enucleations must be performed in patients with a soft pancreas, as is frequently observed with cystic or endocrine lesions.

Preoperative Biliary Drainage

Patients with pancreatic cancer who have jaundice are also at risk for associated coagulopathy, malabsorption, malnutrition, and immune dysfunction. Using a multiple-variant regression analysis, we had previously determined that jaundice (bilirubin level >5.8 mg/dL) is a significant risk factor for postoperative hemorrhage (Martignoni et al, 2001). This calls into question the role of preoperative biliary drainage (PBD) in reducing surgical morbidity through the normalization of liver function and the correction of coagulopathy. Sewnath and colleagues (2002) found in a meta-analysis no difference in the overall death rate among patients who had PBD and those who had surgery without PBD. Instead, the overall complication rate was adversely and significantly affected by PBD, and the hospital stay was also prolonged, so they concluded that PBD carries no benefit. Recent studies also demonstrate that routine PBD should not be performed because of the high rate of procedure-associated complications (Mezhir et al, 2009; van der Gaag et al, 2010). We concur with the opinion that ERCP should only be undertaken with therapeutic intent and believe that PBD as a routine practice should be halted. We would refer a patient for PBD in the presence of cholangitis or other severe complication of jaundice that would preclude a safe, early resection. An absolute indication for PBD is jaundice that requires induction therapy prior to surgical extirpation.

Fast-Track Surgery

Studies on so-called *fast-track GI surgery* have shown that epidural analgesia, combined with an intensive and standardized regimen of early feeding and mobilization, can reduce hospital stay (Basse et al, 2002). Epidural analgesia has been found to have many attributes, including a shorter duration of postoperative ileus, attenuation of the stress response, fewer pulmonary complications, improved postoperative pain and mobility, and patient perception of a quicker recovery (Fotiadis et al, 2004). Thoracic epidural analgesia is of particular benefit to patients with a high risk of cardiac or pulmonary morbidity, and it can reduce hospital stay and costs in this subgroup of patients.

Attracted by the promising results published in the literature,and encouraged by the concept of fast-track surgery, we have since recommended thoracic epidural analgesia to all our patients who undergo pancreatic resection. We use a combination of local anesthetic and opioids; the former blocks sympathetic outflow, resulting in less cardiac stress, and at the same time promotes the return of bowel motility. The addition of opioids allows adequate analgesia with less local anesthetic, thereby reducing local anesthetic–related hypotension and motor deficits. Alternative methods of analgesia can be used when epidural analgesia is contraindicated or declined. We have also established postoperative pain teams to assist in patient care and monitoring and have realized some of the published benefits, including earlier and better tolerance of oral feeding, less postoperative pain, and earlier mobilization.

RESECTIONAL TECHNIQUES

Pancreatoduodenectomy

Ductal adenocarcinoma is by far the most prevalent tumor of the pancreas, with a predominant localization within the pancreatic head (78%) (see Chapters 58 and 59; Schäfer et al, 2002). Furthermore, adenocarcinoma of the body or tail is seldom resectable on presentation. It is thus not surprising that PD is the best-studied pancreatic surgical procedure.

Technique

In thin patients, we prefer a midline incision beginning from the xiphoid process, but we perform a rooftop incision in patients with a short torso and a wide abdominal girth. After we have ruled out liver metastasis, the peritoneal surfaces are carefully inspected for metastatic deposits. Particular attention is paid to the pelvis for drop metastasis and to the root of the mesentery for evidence of tumor extension or matted nodes. A wide Kocher maneuver is then performed to assess the retroperitoneum and appraise the tumor and its relationship to the SMA (Fig. 62A.3). The mesenteric artery is inspected from the ligament of Treitz and dissected on its right hemicircumference to exclude any tumor infiltration of the artery. This technical approach, the so-called *artery-first approach* (Fig. 62A.4; Weitz et al, 2010), helps avoid R2 resections because any infiltration of the central arteries can be diagnosed early during exploration. We proceed with the resection only if we find no evidence of infiltration of the celiac trunk and SMA.

Access to the lesser sac is achieved by division of the gastrocolic ligament. On the left side, we divide the gastrocolic ligament only as far as the most medial branch of the short gastric vesssls. This is to ensure an alternative venous egress for the splenic blood flow in the event of any venous resection of the SMV-PV trunk. Moving to the right, the hepatic flexure is mobilized caudally. Careful dissection in the avascular plane between the hepatic flexure and the duodenum and extension of the Kocher maneuver will allow the third part of the duodenum to be freed from the colonic mesentery. The gastroepiploic vein is then divided where it empties into the gastrocolic trunk, and the SMV is traced to the inferior margin of the pancreas. Two stay sutures are then placed at the inferior border of the

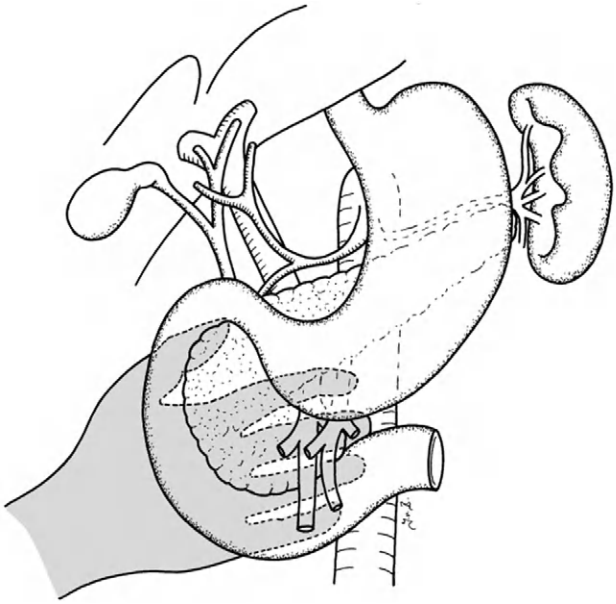

FIGURE 62A.3. Adequate kocherization to facilitate assessment of the retroperitoneum and the relation of the tumor to the vascular structures.

pancreas to aid in the creation of the tunnel between the pancreatic neck and the SMV-PV trunk. Attention is now turned to the supraduodenal compartment.

Cholecystectomy is performed in a typical fashion. The cystic duct is traced to its origin from the common bile duct (CBD), which is transected just cephalic to this point. Extreme care must be taken to avoid any iatrogenic injury to the right hepatic artery, which usually runs posterior to the hepatic duct (see Chapter 1B; Skandalakis et al, 2004). In addition, it is important to assess for an aberrant right hepatic artery, present in 20% of patients, by palpation of the posterior aspect of the hepatoduodenal ligament. The cystic artery is isolated and closed with ligation.

The lymphadenectomy of the hepatoduodenal ligament is performed with great caution and completed along the common hepatic artery toward the celiac trunk. The distal end of the CBD and its adjoining fibrous fatty tissues are then dissected free from the rest of the hepatoduodenal ligament and retracted caudally. A small, noncrushing clamp is then applied to the proximal bile duct stump to prevent any further bile spillage for the rest of the operation. The proper hepatic artery is identified and looped then traced proximally toward the common hepatic artery. The right gastric artery (RGA) and the gastroduodenal artery (GDA) can be isolated during this dissection. Nodal tissues surrounding the proper hepatic artery and the common hepatic artery are excised. The RGA and GDA are then divided near the origin of the GDA. A potential pitfall here is the misidentification of a replacing common hepatic artery or even a replacing right hepatic artery as the GDA. A technique to avoid this mistake is to place a vascular clamp across the presumed GDA and check for pulsations at the porta hepatis before this vessel is divided.

If preservation of the pylorus is planned, which is our usual practice, the right gastric and right gastroepiploic arteries are divided and the duodenum is skeletonized 2 cm beyond the pylorus. The suprapancreatic portion of the PV will now be widely exposed, and two stay sutures are similarly placed on the superior border of the pancreas; these sutures at the superior and inferior pancreatic borders also serve to ligate the superior and inferior pancreatic vessels respectively, running longitudinally in the parenchyma. Hence bleeding from the cut edges is reduced after transection. A tunnel is cautiously created between the SMV-PV trunk posteriorly and the pancreatic neck anteriorly. A silicon drain is then insinuated into this tunnel to loop up the neck (Fig. 62A.5).

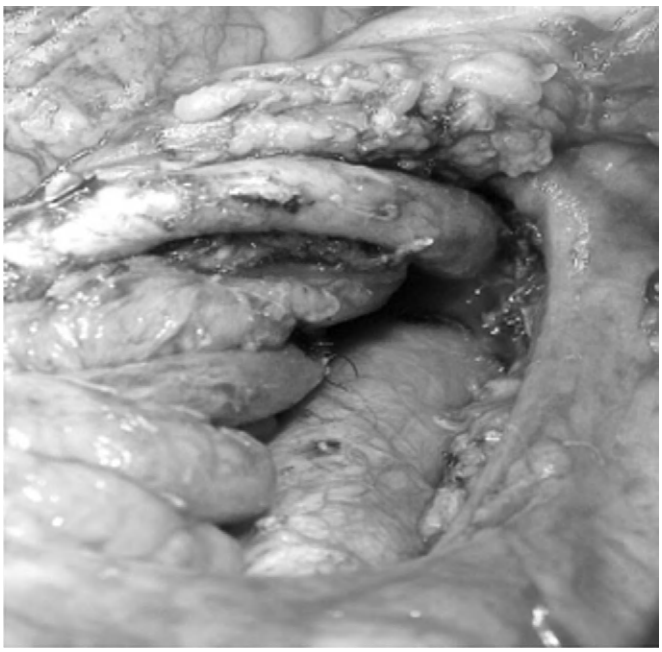

FIGURE 62A.4. Artery-first approach. The superior mesenteric artery is dissected, and infiltration of the artery is ruled out as one of the first steps of the operation.

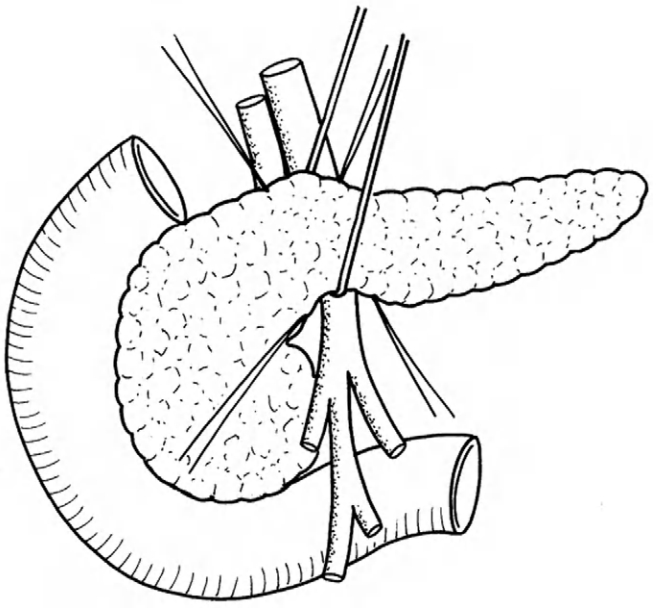

FIGURE 62A.5. Clearance of the surrounding fibrofatty tissues around the pancreatic stump for a distance of 2 cm allows adequate visualization of the pancreatic capsule. Cannulation of the pancreatic duct facilitates subsequent ductal sutures.

Because the medial margin is the most crucial with regard to tumor infiltration and the R status of the resection (Esposito et al, 2008), we now perform the uncinate process–first approach (Hackert et al, 2010). After having exposed and evaluated the SMA, the ligament of Treitz is mobilized, and the mesenteric branches to the fourth part of the duodenum are divided to allow it to be delivered into the inframesocolic compartment under the SMA. The mesenteric window is extended to the proximal jejunum, which is transected at a point that allows a tension-free loop of jejunum to be brought into the supramesocolic compartment in a retrocolic fashion through a window created on the right side of the middle colic pedicle. The dissection is performed along the SMA and SMV with bipolar cautery and clips.

If venous resection is required, it is reserved as the last step in the extirpative phase. The PV is then gently retracted medially to expose the underlying tissues, and any venous branches are divided. At the same time, the specimen is retracted to the right. The tissue and branch arteries arising from the SMA are serially clamped, divided, and clipped or stitch ligated. During this step, the specimen that comprises the pancreatic head, duodenum, and proximal jejunum is cupped in the surgeon's nondominant hand, and the fingers continuously appraise the position of the SMA to avoid any injuries to it. The anterolateral aspect of the SMA is completely skeletonized of its investing tissues.

After complete transection of the pancreatic mesentery along the SMA and SMV, a scalpel is used to transect the neck of the pancreas. Bleeding vessels from the transected pancreatic ends are ligated using nonabsorbable monofilament polybutester sutures. We do not use any form of electrical cautery on the pancreas for hemostasis; we believe this to be an insecure form of hemostasis when used on the pancreatic parenchyma. We also suspect that this will be detrimental to the tissues and that it may compromise the subsequent anastomosis. The venous trunk is then examined for any tumor involvement on its posterolateral aspect, and margins are harvested from the proximal pancreatic stump and bile duct for margin analysis by frozen section.

At last, the duodenum is transected by using a linear stapler. The stomach is then retracted to the left upper quadrant of the abdomen, and the specimen is sent for histologic examination. The pancreatic stump is cleared over a distance of 2 cm from the cut end to provide a clear, all-around visualization of the pancreatic capsule and to allow a safe pancreatojejunostomy; this also facilitates the subsequent construction of the pancreatoenteric anastomosis. Next, hemostasis is ensured, and the operative field is washed with warm water before proceeding to the reconstructive phase.

Standard Pancreatoduodenectomy Versus Pylorus-Preserving Pancreatoduodenectomy

In addition to the known postoperative complications associated with PD, the performance of a distal gastrectomy in the standard procedure also brings with it the possible long-term morbidities of gastric dumping, marginal ulceration, and bile-reflux gastritis (Poon & Fan, 2001). First introduced by Kenneth Watson (1944), it was not popular until 1978, when Traverso and Longmire (1978) reintroduced it. They hypothesized that the preservation of the stomach and pyloric function would improve GI function and hence reduce the morbidities associated with a gastroenterostomy. Indeed, better long-term digestive function and quality of life have been found after pylorus-preserving pancreatoduodenectomy (PPPD) in some retrospective studies. To retain a functioning pylorus, the entire stomach, 2 cm of the first part of the duodenum, and the neurovascular supply to both are preserved. Following the division of the right gastric and right gastroepiploic arteries at their origin, the duodenum is skeletonized 2 cm distal to the pylorus (Farnell et al, 2001), taking care to preserve the nerve of Latarjet. The duodenal bulb is then transected.

A recent meta-analysis demonstrated that the classical Kausch-Whipple procedure and the pylorus-preserving Whipple procedure are comparable with regard to perioperative morbidity and mortality and long-term outcome (Diener et al, 2008b). Hence, in the light of the available evidence, PPPD should be designated the "standard" procedure for pancreatic and periampullary neoplasm because no study to date has demonstrated any advantage to the removal of the stomach and the proximal duodenum (Bell, 2004). Hemigastrectomy should be performed only when gastric or proximal duodenal invasion or grossly abnormal peripyloric nodes are evident.

Vascular Resection

Over 30 years ago, Fortner (1973) reasoned that a more radical resection should improve survival by improving tumor clearance, specifically that tumor adherence to the PV or SMV, often regarded as a criterion of unresectability, could be overcome by en bloc resection of the involved vessels. Randomized evaluation of portal and superior mesenteric vein resection in patients with tumors adherent to these vessels is difficult because considerable intersurgeon variation in the interpretation of adherence is likely. Thus no randomized trial evaluates this topic.

A recently published systematic review (Siriwardana & Siriwardena, 2006) evaluated 52 manuscripts with 6333 patients in whom pancreatic resection was performed for pancreatic cancer; 1646 of these patients (26%) underwent synchronous portal and superior mesenteric vein resection. The median number of resections per publication evaluated was 82; of those, 23 patients underwent portal and superior mesenteric vein resection. The proportion of portal and superior mesenteric vein resection per publication varies widely, ranging from 2% to 77%, which mirrors the various treatment approaches of pancreatic cancer in different institutions today.

Information on the operation was available in 39 studies with 1334 patients. The operations performed included PD (71%), total pancreatectomy (24%), subtotal pancreatectomy (3%), and distal pancreatectomy (2%). The median operation time was 513 minutes (range, 168 to 1740 minutes), median blood loss was 1750 mL (range, 300 to 26,000 mL), and the median time for PV occlusion was 20 minutes (range, 7 to 302 minutes). The perioperative mortality rate was 5.9%, varying between 0% and 33%, and postoperative morbidity rate was 42%, ranging from 9% to 78%. PV invasion was detected in 64% of all portal and superior mesenteric vein resection specimens, and the range varied widely between 3% and 86% in the different series, and 67% of all patients with portal and superior mesenteric vein resection had positive lymph nodes detected on histology. The long-term survival was 13 months (range, 1 to 109 months) after portal and superior mesenteric vein resection. The 1-, 3-, and 5-year overall survival rates of 1351 patients undergoing portal and superior mesenteric vein resection was 50%, 18%, and 8%, respectively.

The assessment of pooled data is critically influenced by the quality of the single reports. The reports included have been published over the last 25 years, and the standards of perioperative care, surgical technique, and adjuvant therapy have developed dramatically. Thus the wide variations of outcome parameters—perioperative death, operative time, blood loss—mirror the nonhomogenous collective included in this review. However, the long-term survival rate demonstrates that resection of the portal or superior mesenteric vein is a potentially curative operation. It seems that patients who need a portal or superior mesenteric vein resection for cure include a high percentage of patients with a positive nodal stage. Because adjuvant treatment has been proven to increase survival but has only recently been introduced as standard care for patients with pancreatic cancer, the survival rates of patients with portal or superior mesenteric vein resection today should be even better than those reported in this review (Neoptolemos et al, 2004; Oettle et al, 2007).

In addition, surgical expertise has improved over the past few decades, and the quality of high-volume centers—especially for technically demanding surgeries, such as pancreatic resection—has been proven (Birkmeyer et al, 2003; Büchler et al, 2003). Thus it is not surprising that perioperative morbidity and mortality rates reported for pancreatic resections with portal or superior mesenteric vein resection are identical to those without it (Bachellier et al, 2001; Carrere et al, 2006; Leach et al, 1998; Nakao et al, 2006; Riediger et al, 2006; Wagner et al, 2004).

These latest reports also demonstrate that extended resections with portal or superior mesenteric vein resection improve long-term survival. However, histologically confirmed tumor infiltration into the tunica media of the PV has a worse prognosis and a long-term survival of less than 2 years.

Tumor infiltration of the SMA, celiac trunk, or hepatic arteries are well-accepted criteria for unresectability of pancreatic adenocarcinoma. However, because adherence of tumors to the arteries does not automatically mean infiltration—in fact, the arterial wall is resected much longer than the venous wall—several published series of pancreatic resections included resection and reconstruction of visceral arteries (Hartwig et al, 2009a; Li et al, 2004; Sasson et al, 2002; Varadhachary et al, 2006). A recent review states that in 15% of pancreatic operations in which portal or mesenteric vein resection had to be performed, arteries were also resected. These included the common hepatic artery (50%), SMA (20%), celiac axis (10%), and other arteries (Siriwardena & Siriwardena, 2006).

In summary, resection of the portal and superior mesenteric vein should be performed when adherence or infiltration of the tumor is present, because perioperative morbidity, mortality, and long-term survival are identical to those patients in whom an R0 resection can be performed without PV resection. Moreover, the long-term survival of patients who have had pancreatic resection in combination with PV resection is far superior compared with those in whom only palliative surgical management was performed. In contrast, with arterial adherence of the pancreatic tumor, arteries can only rarely be resected in a curative way. Although resection of the SMA, celiac trunk, or hepatic arteries is technically feasible, no data suggest that this leads to any improvement of long-term outcome. Thus, resections of arteries during pancreatic resections are an experimental approach that cannot be recommended as a standard technique today.

Multivisceral Resections

The benefit of radical surgical resection of contiguously involved structures for locally advanced pancreatic cancer has been addressed in several reports (Hartwig et al, 2009; Sasson et al, 2002). In fact, about 35% of patients are seen initially with locally advanced pancreatic cancers with involvement of surrounding structures and organs. Although several reports in the past showed that morbidity of extended resection was increased and survival benefit limited, more recent publications demonstrate that en bloc resection of contiguously involved organs can be performed safely (Sasson et al, 2002). No difference was reported with regard to perioperative morbidity (35%) and mortality (3%) compared with standard resection. Although operation time is clearly longer because of the extended resection—which includes mesocolon, colon, adrenal glands, liver, and stomach—blood loss and hospital stay are not different from what is observed after the standard procedure. The main aim of the extended procedure must be an R0 resection because this is the most important predictor of long-term survival (Wagner et al, 2004). The survival rate after resection of mesocolon and colon, as well as stomach, is not significantly decreased compared with the standard procedure (Sasson et al, 2002). The 5-year survival rate was 16%, and the median survival of 26 months is much better than the 6 to 9 months reported for patients who are not resected at all.

Similarly, another study demonstrated that patients with pancreatic adenocarcinoma of the body or tail need extended resection for contiguous organ involvement more frequently because these tumors are generally detected later and have therefore reached a greater size than cancers of the pancreatic head by the time of diagnosis. The median survival in these patients was 15.9 months, and the survival at 5 and 10 years was 22% and 18%, respectively. In our series of more than 100 patients with multivisceral resections, we showed that perioperative mortality rate and long-term outcome are similar to those of standard resections (median survival, 20 months), but that the morbidity is increased. Thus these patients need careful postoperative observation in an experienced pancreatic center (Hartwig et al, 2009).

In summary, patients undergoing extended resection for adenocarcinoma of the pancreas have long-term survival rates similar to those undergoing standard resection. The main aim is to achieve a curative (R0) resection, and resected patients have improved survival compared with patients with advanced disease who are not resected or considered unresectable; thus extended pancreatic resection for contiguous organ involvement is justified.

Lymphadenectomy

The rationale for extended lymphadenectomy is that lymph node studies have confirmed positive lymph nodes may be found outside the confines of the standard dissection (Cubilla et al, 1978). Even for small cancers, lymph nodes of the paraaortic region, between the celiac trunk and the origin of the inferior mesenteric artery, frequently harbor metastases; it has been suggested that these should be dissected en bloc during radical resections (Nagakawa et al, 1993). These revelations initiated a movement of extended lymphadenectomy among Japanese surgeons. A few studies reported similar surgical morbidity and mortality rates, but improved survival results were seen with extended surgery compared with the standard PDs

(Ishikawa et al, 1993). However, these were all retrospective, nonrandomized studies.

What constitutes extended lymphadenectomy is still widely debated; this is epitomized by the multitude of terminologies used in the literature. In an attempt to harmonize this subject, a consensus conference on the surgical treatment of pancreatic cancer took place in Castelfranco Veneto, Italy (Pedrazzoli et al, 1999). This consensus provided a standardized definition of the different extent of lymphadenectomy that used the Japanese Pancreas Society rules for the study of pancreatic cancer to define the lymph node stations to be removed for the various procedures (Japan Pancreas Society, 1993). The three stages of radicality for PD have been named *standard, radical,* and *extended radical,* depending on the nodal stations removed. For cancers of the body or tail, according to the extent of lymphadenectomy, two different procedures are identified: standard and radical. It is hoped that this standardization of surgical procedures will facilitate comparison of results between different centers.

Between 1988 and 1999, eight retrospective studies were published on the extent of lymphadenectomy for PD. The data on survival are largely heterogeneous, but neither morbidity nor mortality seems to be altered. Altogether, two studies reported on morbidity rates, whereas five studies reported perioperative mortality rates. Especially in Japan, extended lymphadenectomy was widely used in the late 1980s and 1990s because of the initial reports of Ishikawa and colleagues (1988) and Manabe and colleagues (1989), who advocated an extension of the PD. In these studies, survival rates were significantly increased in the extended lymphadenectomy groups. Interestingly, some long-term survivors were seen in the extended lymphadenectomy groups, but none (Manabe et al, 1989) or very few (Ishikawa et al, 1988) of the patients in the standard lymphadenectomy arm survived for more than 5 years.

In terms of operative techniques, total pancreatectomies were used in many patients, which may have also altered the outcome. Interestingly, the largest retrospective studies (Hirata et al, 1997; Mukaiya et al, 1998), which together included 1330 patients, did not reproduce these results. The 1- and 3-year survival rates were comparable in the standard lymphadenectomy and extended lymphadenectomy groups, but data on morbidity and mortality were not provided. A study by Kawarada and colleagues was the only one to reproduce the results of Manabe and Ishikawa. However, patients included in the standard lymphadenectomy arm had been operated on between 1976 and 1981, whereas extended lymphadenectomy was performed between 1981 and 1993. Because the perioperative outcomes were significantly improved in the late 1980s, the survival benefit shown for extended lymphadenectomy may be due solely to generally advanced perioperative management. Hence, it cannot be concluded from the retrospective studies that extended lymphadenectomy provides a survival benefit.

Six prospective, nonrandomized studies have been published on this topic. A prospectively conducted study from Henne-Bruns and colleagues (1998), in which the decision to perform a standard or extended lymphadenectomy was made based on the clinical status of the patient, revealed no significant differences in mortality rate and long-term survival but did show a trend toward a better outcome in the standard lymphadenectomy group. This may be due to a higher percentage of patients with advanced-stage tumors in the extended lymphadenectomy group. Furthermore, extended lymphadenectomy was associated with an increased rate of severe diarrhea in the early postoperative phase. Gazzaniga and colleagues (2001) showed that morbidity, mortality, and long-term survival were unaltered between standard and extended lymphadenectomy. Interestingly, a third group of patients received extended lymphadenectomy and additional adjuvant chemoradiation and fared significantly better, with a 5-year survival rate of 17.6%. However, this promising concept of multimodal therapy was not confirmed by randomized trials. Another retrospective study from Italy showed a tendency toward increased survival rates with an extended lymphadenectomy, but morbidity was comparable (Iacono et al, 2002). Studies from both Popiela and colleagues (2002) and Capussotti and colleagues (2003) confirmed the results of the previous reports with unchanged morbidity, mortality, and survival rates. However, for node-negative cancer, extended lymphadenectomy significantly improved the 5-year survival rates (Popiela et al, 2002), and a slight improvement in short-term survival was also seen for patients in the extended lymphadenectomy group (Capussotti et al, 2003). Overall, the number of resected lymph nodes was significantly higher in the extended lymphadenectomy groups.

Four randomized controlled trials have been conducted so far and were summarized in a meta-analysis (Farnell et al, 2005; Michalski et al, 2007; Nimura et al, 2004; Pedrazzoli et al, 1998; Yeo et al, 2002). Interestingly, these four level I studies are from centers on three different continents. The first study by Pedrazzoli and colleagues did not reveal any differences with regard to morbidity, mortality, and survival between the standard and extended lymphadenectomy groups. Standard lymphadenectomy included the dissection of lymph nodes at the anterior and posterior pancreatoduodenal side, at the pylorus, bile duct, and superior and inferior part of the pancreatic head and body. For the extended procedure, additional lymph nodes were dissected within the complete circumference at the aorta, the inferior and superior mesenteric arteries, and the celiac trunk. Interestingly, a retrospective subgroup analysis revealed a significantly prolonged survival for node-positive patients who received an extended lymphadenectomy. This statement has since been intensively discussed because of the small difference in the number of resected lymph nodes between the standard and extended lymphadenectomy groups (13.3 vs. 19.8).

The largest study on this subject enrolled 294 patients; it was published in 2002 and updated in 2005 by Yeo and colleagues and was preceded by a preliminary evaluation in 1999. The authors randomized 294 patients into standard and extended lymphadenectomy arms after intraoperative frozen section with tumor-negative margins. However, the study encompasses the different entities of periampullary malignancies, and only 57% of the tumors were of pancreatic origin. Thus conclusions with regard to survival have to be critically reviewed because ampullary and distal bile duct tumors were also included. A pylorus-preserving PD was performed in 86% of the patients in the standard lymphadenectomy group; in the extended lymphadenectomy arm, the classic Whipple operation was mainly used. Mortality and survival rates were unaltered, whereas a significant increase in morbidity was reported in the extended lymphadenectomy group (29% vs. 43%; $P < .01$), which was mainly due to higher rates of delayed gastric emptying and pancreatic fistula.

Considering the large number of patients and the detailed analysis of many variables, the conclusion that extended lymphadenectomy does not improve survival but may increase

morbidity is to be supported. These data and conclusions are underlined by their follow-up publication and a study on quality of life (QOL) of the same patient group (Riall et al, 2005). Additional studies from the Mayo Clinic by Farnell and colleagues (2005) and from Japan by Nimura and colleagues (2004) supported those results. The Mayo Clinic trial included 79 patients randomized in two groups (lymphadenectomy: standard [n = 40] vs. extended [n = 39]). When performing an extended lymphadenectomy, the number of lymph nodes resected was greater (36 vs. 15), but morbidity and mortality rates were comparable. No significant differences were observed for the 1-, 3-, and 5-year survival rates. However, at 4 months postoperatively, diarrhea was significantly increased, and bowel control and body appearance were worse in the extended lymphadenectomy group. The multicenter trial from Nimura and colleagues revealed similar results with comparable mortality and survival rates but increased morbidity, which was due to severe diarrhea in 48% of the patients (Nimura et al, 2004). Of interest, the number of lymph nodes resected varies considerably between the studies. For examples, Nimura and colleagues resected about twice as many lymph nodes in the extended lymphadenectomy group as did Pedrazzoli and colleagues, which may reflect different operative techniques as well as differences in pathologic analysis.

In summary, none of the randomized, controlled trials (RCTs), except for a retrospective subgroup analysis within the study of Pedrazzoli and colleagues, showed any survival benefit for extended lymphadenectomy, whereas overall morbidity with diarrhea and delayed gastric emptying as particular complications tended to occur more frequently. Interestingly, both Yeo and colleagues and Farnell and colleagues particularly report a reduction in QOL in the extended lymphadenectomy group, primarily because of high rates of postoperative diarrhea with subsequent development of malnutrition (Michalski et al, 2007). Thus mortality and morbidity may be at best unaltered for the extended radical operation compared with the standard procedure. The randomized studies are altogether underpowered and lack standardization with regard to the actual extent of the performed lymphadenectomy. As for the potential survival benefit, further adequately powered randomized studies will need to be impractically large, thus precluding their realization. Therefore, the current standard of surgery for pancreatic head tumors remains PPPD without extended lymphadenectomy.

Reconstruction After Pancreatic Resection and Management of the Pancreatic Remnant

A pancreatic leak is the major cause of procedure-related death. Simply occluding the duct has been shown to result in higher fistula rates in addition to increasing the risk of pancreatic exocrine and endocrine insufficiency (Tran et al, 2002). Hence, drainage of the pancreatic remnant to the GI tract remains a crucial step, but it runs the risk of anastomotic breakdown. It is thus not surprising that the pancreatoenteric anastomosis has fascinated surgeons, motivating them to search for a more reliable technique to avoid this dreaded complication. Many techniques have been described, and the literature will continue to report novel techniques that promise to be even safer. However, more so than the choice of the variant used, successful management of a pancreatic anastomosis is most dependent on the surgeon's concentration on meticulous execution of the chosen technique (Trede et al, 2001). For as long as the basic tenets of a safe anastomosis are met—namely, careful handling of the pancreatic tissues, a tension-free adaptation, good perfusion, and no distal obstruction—any pancreatoenteric anastomotic technique can have a good outcome.

One of the most commonly used techniques is a pancreatojejunal anastomosis, which can be performed by invaginating the transected pancreas into the end of the jejunum, the so-called *dunking procedure*. Another variant is to anastomose the pancreatic duct directly to a proper opening in the jejunum, the so-called *duct-to-mucosa technique*. The technique of pancreatojejunal anastomosis—whether end-to-side or end-to-end, duct-to-mucosa or dunking—does not seem to significantly influence the anastomotic leak rate. Another strategy is to anastomose the pancreatic stump to the stomach, and proponents of pancreatogastrostomy (PG) have cited various reasons to choose this method (Zenilman, 2000); it is easier to perform given the close proximity of the stomach to the pancreas, and the anastomosis is less prone to ischemia because of the rich gastric perfusion. Because the exocrine enzymes enter an acidic environment, it was once thought that the leak rate would be lower because the enzymes do not get activated, but this idea has since been debunked. In a prospective randomized trial comparing pancreatojejunostomy (PJ) to PG, the leak rates were not significantly different (PJ, 11%; PG, 12%) (Yeo et al, 1995).

The authors' institution uses a standardized technique of PJ performed in an end-to-side fashion with a retrocolic jejunal limb (Z'graggen et al, 2002). The anastomosis is performed in two layers with duct-to-mucosa adaptation using monofilament absorbable polydioxanon sutures (PDS 5/0) with an atraumatic JRB-1 (5/8) needle. The first step is the placement of the ductal sutures, first anteriorly from the outside in, then posteriorly from the inside out (Fig. 62A.6). We endeavor to place at least three ductal sutures on each side. This is generally no problem, because the duct is dilated in cases of pancreatic head tumors. Only in patients with very small ducts that cannot be cannulated with a small ductal probe, the duct sutures should be omitted to avoid obstruction of the duct.

Because the pancreatic stump is dissected over 2 cm toward the left, good visualization of the posterior capsule can be achieved. A row of interrupted sutures is then placed through the dorsal capsule, with the needle entering the pancreatic

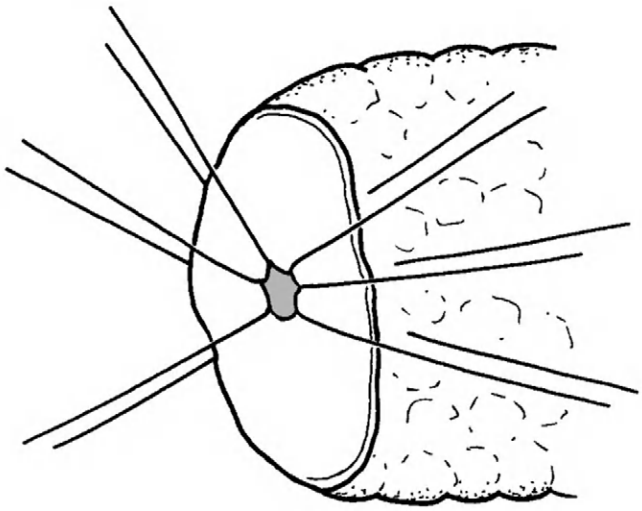

FIGURE 62A.6. Three anterior and three posterior ductal sutures.

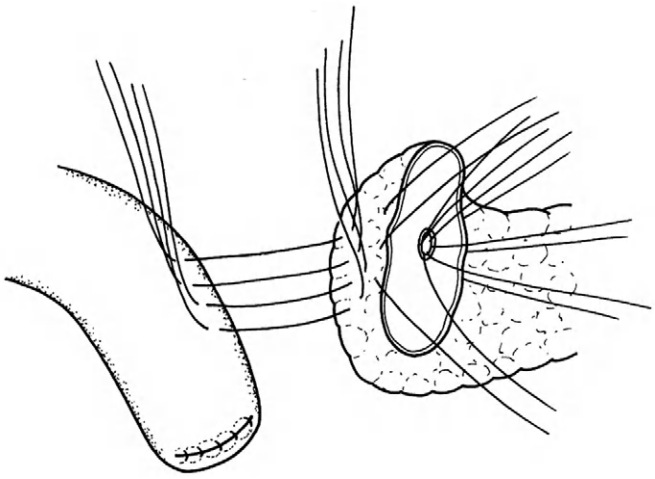

FIGURE 62A.7. The first layer of the posterior suture row performed in an interrupted fashion.

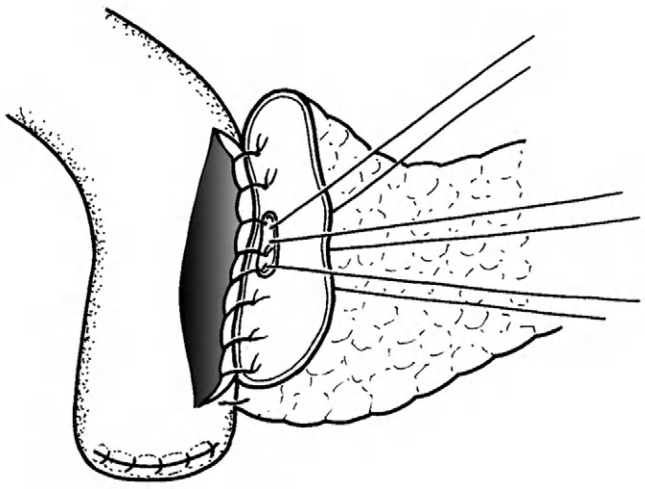

FIGURE 62A.9. The completed second layer of the posterior suture row demonstrates the integration of the previously placed ductal sutures into the suture row.

tissues about 1 cm from the cut end of the stump and taking an adequate bite of the parenchyma. The needle is then driven through the seromuscular layer of the jejunal limb about 1 to 2 mm from the mesenteric border. The intersuture distance is about 4 to 6 mm (Fig. 62A.7). The jejunum is carefully adapted to the pancreas following meticulous and gentle tying of the knots. A longitudinal enterotomy is then performed about 5 mm from the posterior row of sutures (Fig. 62A.8) with the width of the opening tailored to the size of the pancreatic stump.

The posterior inner row of sutures is then constructed, first catching the pancreas in an inside-out fashion, ensuring an adequate bite of the parenchyma, and exiting just at the cut edge of the remnant pancreas. The suture is then driven through the posterior edge of the enterotomy in an outside-in fashion, ensuring a full-thickness bite. The previously placed ductal sutures are integrated in order, and each suture is clipped with an artery clamp (Fig. 62A.9). All knots are tied after completion of the suture row.

This is followed by the anterior inner row of sutures, which is driven through the pancreas in an outside-in manner, entering just at the anterior cut edge of the stump and ensuring an adequate bite of the pancreatic parenchyma. The suture is then placed through the anterior edge of the enterotomy in an inside-out fashion with a full-thickness bite (Fig. 62A.10). All knots are, again, only tied following completion of the suture row.

The final step is the second row of anterior sutures, the aim of which is to cover the inner suture line by imbricating the jejunal serosa over it (Fig. 62A.11). The suture first catches the anterior capsule of the pancreas close to the anterior inner row. A seromuscular bite is then taken of the jejunum at a point that will allow a fold of the jejunal wall to cover the inner row of sutures in a tension-free manner (Fig. 62A.12).

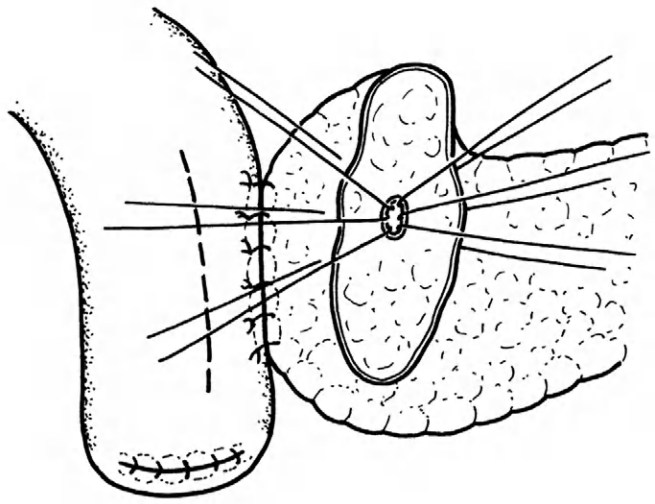

FIGURE 62A.8. Following apposition of the pancreas to the jejunal limb via the posterior serocapsular suture row, a longitudinal enterotomy is planned, tailored to the width of the pancreatic stump.

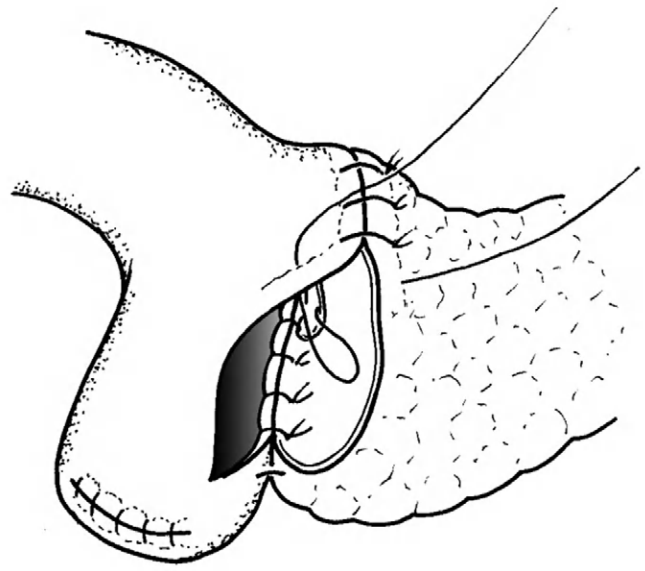

FIGURE 62A.10. Placement of the first layer of the anterior suture row.

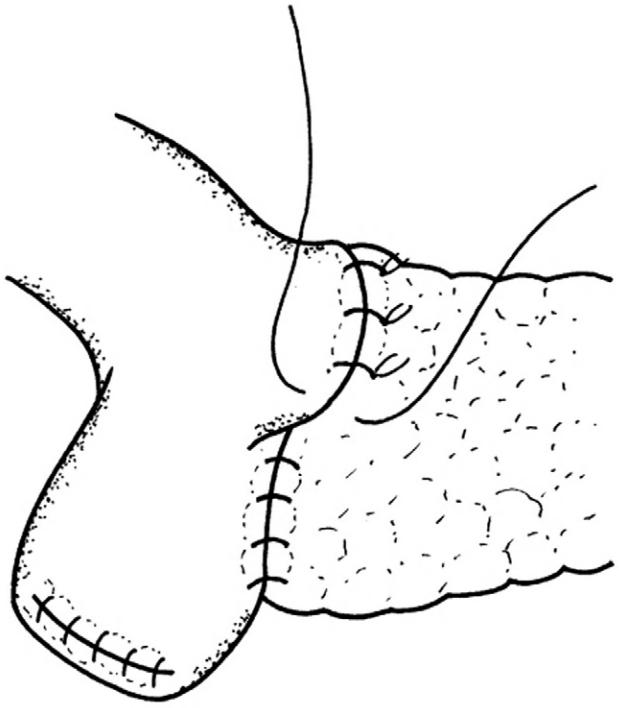

FIGURE 62A.11. The second layer of the anterior suture row, which serves to imbricate the first layer.

The end-to side technique allows the adaptation of the jejunal opening to the specific requirements of the pancreatic remnant. Separate duct-to-mucosa adaptation also keeps the duct orifice open, thereby ensuring the unobstructed flow of pancreatic secretions through the anastomosis. Consequently we see no need for the placement of any pancreatic stents. This technique was used in 93% of patients undergoing pancreatic head resection, with an overall leak rate of 3.2% (Büchler et al, 2003).

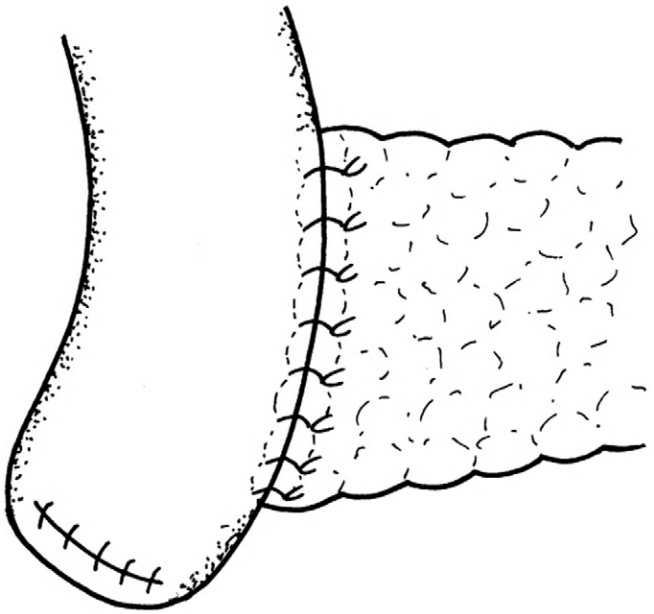

FIGURE 62A.12. Completion of the pancreatojejunostomy.

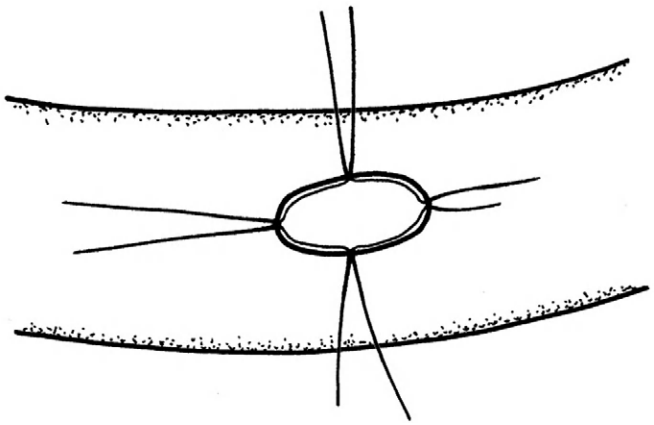

FIGURE 62A.13. Jejunal mucosal fixation stitches.

Bilioenteric Anastomosis

Unlike the pancreatoenteric anastomosis, fewer variations are used for a bilioenteric anastomosis, which is usually constructed in an end-to-side fashion with a single layer of sutures using monofilament absorbable sutures (PDS 5/0) with a C1 needle. This needle, with its smaller rounding radius, enables easier handling, especially within the confines of the bile duct, particularly when the caliber of the duct is small.

We position this anastomosis about 10 to 15 cm downstream from the PJ. The cut edge of the bile duct is freshened to obtain well-perfused healthy tissues, after which a small enterotomy is made at the antimesenteric border of the jejunal loop, with removal of a small cuff of mucosa. The protruding mucosa is then fixed at four quadrants of the enterotomy using 6/0 PDS sutures (Fig. 62A.13). These mucosa-fixation sutures ensure a full-thickness bite in the subsequent suture placement and thus guarantee a secured duct-to-mucosa coadaptation. The posterior suture layer is first constructed, with each individual suture held in clamps, until the entire suture row is completed and before knotting begins (Fig. 62A.14). This is then followed by the anterior suture row (Fig. 62A.15), and the final step is closure of the mesocolic opening around the jejunal limb.

Reconstitution of Gastrointestinal Continuity

Depending on whether a distal gastrectomy or PPPD is performed, the reconstruction ends either with a gastrojejunostomy or a duodenojejunostomy, respectively. Some concern has surrounded the question of whether an intact pylorus will lead to higher delayed gastric emptying (DGE) rates postoperatively following a PPPD; however, this controversy seems to have been finally laid to rest following the results of several controlled trials that to which we have previously alluded. Therefore, based on evidence available in 2004, it is apparent that pylorus preservation does not seem to increase the frequency of DGE (Horstmann et al, 2004).

The technique used to reconstitute GI continuity may have an impact on the incidence of DGE, however. One group speculated that a retrocolic reconstruction predisposes the jejunal limb to venous congestion and bowel edema, which can consequently retard recovery of jejunal peristalsis at the duodenojejunostomy (Park et al, 2003). Postoperative gastroparesis may also lead to temporary gastric distension, which can lead to angulation of the anastomosis because it lies relatively fixed through its retrocolic position (Horstmann et al, 2004).

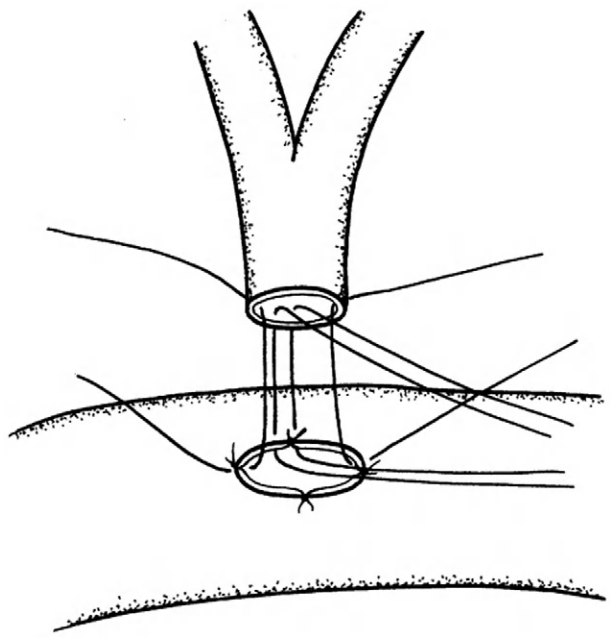

FIGURE 62A.14. Posterior suture row of the biliojejunal anastomosis in interrupted fashion.

Additionally, the close proximity of the duodenojejunostomy to the PJ also predisposes the occurrence of DGE in the event of a small PJ leak or transient postoperative remnant pancreatitis. Opponents to this theory have suggested that the real culprit is an antecolic reconstruction (Riediger et al, 2003) that predisposes the relatively fixed stomach to angulation or torsion. The risk of DGE caused by local inflammation is reduced by placing the duodenojejunstomy in the infracolic compartment through a separate mesenteric window, away from the pancreatic and biliary anastomoses, which lie in the supracolic compartment.

Our unit's philosophy is more in line with the first group, substantiated by the results of a retrospective review conducted in our center, in which we compared the outcomes following retrocolic placement of the duodenojejunostomy with those following an antecolic placement of the anastomosis. We found that the incidence of DGE was lower after using the second surgical strategy. After PPPD, we now routinely perform an antecolic end-to-side duodenojejunostomy about 50 cm downstream from the hepaticojejunostomy, using the transverse colon to splint the duodenojejunostomy away from the PJ. The anastomosis is constructed in two layers using monofilament absorbable sutures in a continuous fashion (PDS 4/0 or 5/0) (Fig. 62A.16).

Abdominal Drains and Nasogastric Tubes

Intraperitoneal drains have been placed in relation to the biliary and pancreatic anastomoses with the intention of controlling leakage of blood and biliary, lymphatic, or pancreatic secretions. Such a practice has been prophylactic in nature, and the reason for it stems more from habit than evidence. But this has been challenged by a randomized trial that addressed the value of drains following pancreatic resection and found that placement of drains did not translate into a reduction in surgical morbidity (Conlon et al, 2001). Rather, a significantly higher proportion of patients randomized to the drain group developed intraperitoneal sepsis, fluid collection, or fistula, although this trial was not sufficiently powered to determine whether the drain was the cause of these intraabdominal complications. Consequently, based on this trial alone, our unit has not found sufficient evidence for us to abandon this practice.

Our hesitancy to embrace a no-drain policy is further vindicated by the findings of a recently published meta-analysis of prophylactic drainage after GI surgery (Petrowsky et al, 2004). This evidence-based review found that drains do not reduce

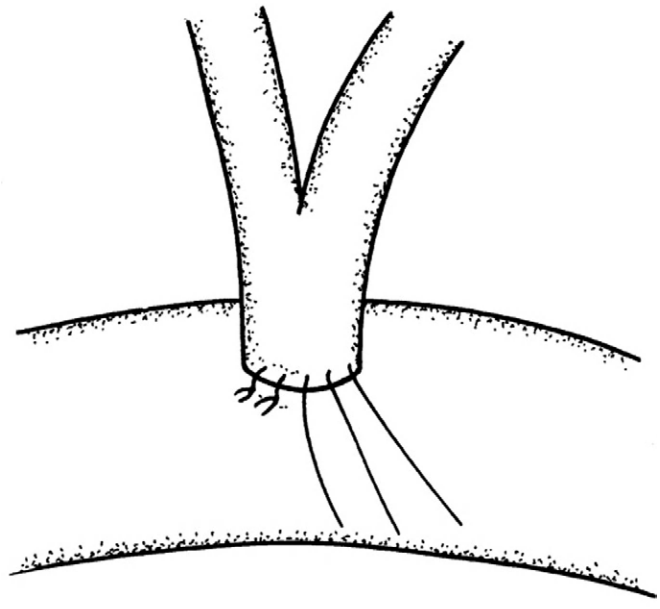

FIGURE 62A.15. Anterior suture row of the choledochojejunostomy.

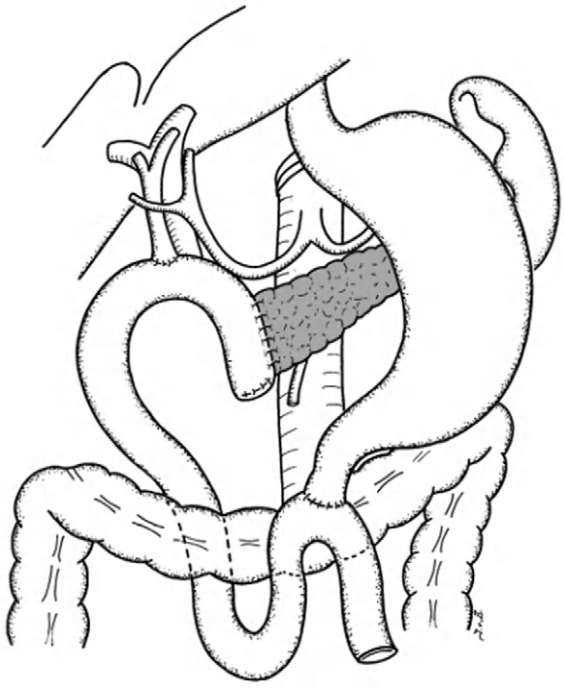

FIGURE 62A.16. Completion of the reconstruction following the pylorus-preserving pancreatoduodenectomy.

complications following hepatic, colorectal, or rectal resection with primary anastomosis, and drains should not be used following such procedures. With regard to many other GI procedures, including pancreatic resections, the jury is still out, and we have concluded that more well-designed trials are needed to clarify the role of prophylactic drainage. For our participation in a multicenter randomized (PANDRA) trial evaluating this issue, we routinely place two passive drainage tubes (Easy-flow; Dahlhausen & Company, Cologne, Germany): one below the diaphragm and the other in close proximity to the hepaticojejunostomy and the PJ.

We also routinely place nasogastric (NG) suction tubes for our patients during the operation and anesthesia, which are immediately removed at extubation. A meta-analysis on the need for NG decompression has quashed the long-held belief that routine NG decompression decreases the risk of postoperative nausea, vomiting, aspiration, wound dehiscence, and anastomotic leak (Cheatham et al, 1995). Instead, it was found that fever, atelectasis, and pneumonia were significantly less common, and days to first oral intake were significantly fewer, in patients managed without NG tubes. Although patients may develop abdominal distension or vomiting without an NG tube, this does not necessarily translate into an increase in complications or length of stay.

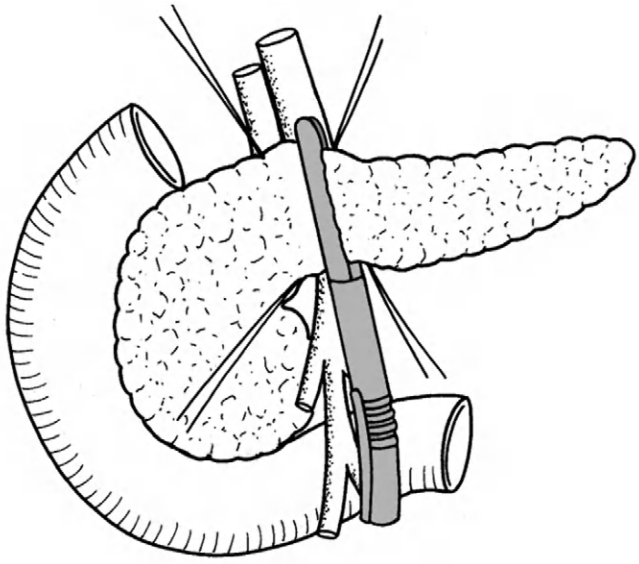

FIGURE 62A.17. Staple transection of the pancreas.

Distal Pancreatectomy

The surgical procedure of choice for tumors arising in the body or tail of the pancreas is the distal pancreatectomy. This operation entails the removal of that portion of the pancreas extending to the left of the midline, not including the duodenum and distal bile duct. The pancreas is usually divided to the left of the SMV-PV trunk, the exact line of transection depending on the location of the tumor.

Technique

Following a thorough examination of the peritoneal cavity, the gastrocolic ligament is divided sufficiently to allow full visualization of the pancreas to its tail and the hilum of the spleen. Extreme care is taken here to preserve the short gastric vessels and the gastroepiploic arcade. The point of division is selected in the proximal normal pancreas, and the overlying peritoneum is divided along the superior and inferior borders of the pancreas. Stay sutures are then placed on either side of the planned transection line on both the superior and inferior borders. A plane is then developed posterior to the pancreas by blunt dissection, aided by upward tension on the stay sutures, until the splenic vein (SV) is identified. The splenic vein is situated posterior to the pancreas and lies fairly deep in the pancreatic parenchyma distally. Therefore, if problems in identifying the SV are encountered, one suggestion is to identify the SV-PV junction under the pancreatic neck, which is technically easier, and subsequently follow the SV toward the spleen. The splenic artery can usually be located along the superior border of the pancreas. The artery and the vein are then individually encircled with vascular loops. Following vascular control, our preference is early division of the pancreas.

Management of the Pancreatic Remnant

Pancreatic fistula remains the most common surgery-related complication after distal pancreatectomy (Benoist et al, 1999; Ferrone et al, 2008). Many techniques have been described in the literature with regard to the management of the residual transected pancreatic parenchyma and the divided pancreatic duct to lower the risk of leak. These include direct duct ligation, enteric drainage, prolamine injection, sealing with fibrin glue, and transection with linear stapling devices. The plethora of surgical strategies described in the medical literature simply underlies the fact that no one technique has been convincingly shown to reduce the incidence of pancreatic leak consistently.

When the pancreas has a soft texture and is not too thick, we transect it with a linear stapling device (Fig. 62A.17). This device gives a staple line consisting of a triple row of closely placed staples. In all other cases, the pancreas is dissected by a knife, and the resection margin is closed with single PDS stitches; the pancreatic duct should be identified and closed by separate sutures. A meta-analysis comparing the safety of hand-sewn sutures versus staple closure of the pancreatic remnant after pancreatic left resection did not show a significant difference with regard to morbidity, including postoperative fistula (Knaebel et al, 2005). Results of a European multicenter randomized trial comparing the two techniques over the last several years will be available shortly (Diener et al, 2008a).

Alternatives to these standard techniques are to cover the pancreatic remnant with omentum, small bowel, or the falsiform ligament and to perform a PJ to the left remnant. However, none of these techniques has been evaluated in larger randomized trials.

Splenic Preservation

Conventionally, the spleen has been removed en bloc with distal pancreatectomy. This was believed to be necessary because of the close relationship of the splenic artery and vein to the body of the pancreas; splenic preservation might compromise the oncologic resection (Shoup et al, 2002). Furthermore, this was thought to be technically simpler. Splenic preservation can be performed either with the division of the splenic artery and vein or with preservation of the entire length of both vessels. The paramount prerequisite in the former surgical approach is preservation of the gastrosplenic vessels to ensure splenic perfusion

and allow venous drainage. In the latter technique, the splenic artery and vein must be uninvolved by tumor. Because of the important immune function of the spleen, it is not surprising that the incidence of infectious complications that require intervention is significantly higher in the splenectomy group (Shoup et al, 2002). More importantly, Schwarz and colleagues (1999) found that in their patients undergoing resection of pancreatic adenocarcinoma with curative intent, the median actuarial survival was 12.2 months with splenectomy versus 17.8 months without splenectomy. Such an adverse effect of splenectomy on survival was also evident when it accompanied surgical resection for gastric and colon cancer. Based on the available evidence, we concur with Conlon and colleagues (2001) in concluding that splenic preservation should be attempted in patients with low-grade malignancies or other more indolent tumors of the pancreatic body/tail, but we feel that splenic preservation may compromise oncologic clearance if performed for pancreatic adenocarcinoma.

Our preference is to attempt to preserve the splenic artery and splenic vein to reduce the risk of splenic necrosis and abscess formation; because splenic perfusion based on the short gastric vessels alone has been shown to be potentially inadequate (Gurleyik et al, 2000). Following division of the pancreas, the distal stump is elevated and rotated gently to the left. Multiple small, short branches of the splenic artery and vein are then identified and clipped serially with hemostatic clips and cut. The dissection proceeds from the proximal to distal pancreas, until the tail of the pancreas can be separated from the splenic hilum (Fig. 62A.18). This separation of the splenic vein from the pancreas can only proceed in the direction of the spleen because the vein has already divided into small vessels that can easily be injured at the level of the hilum. On the other hand, isolation of the pancreas from the splenic artery is described to be easier when performed from the hilum toward the pancreatic head (Jovine et al, 2004). This is also a less tedious task because there are fewer branches from the splenic artery, and they are all on one side. Any vessel injuries can be repaired by suturing with monofilament 5/0 vascular sutures. If attempts at hemostasis of such vascular injuries are unsuccessful, we divide the splenic pedicle. We avoid mobilizing the spleen medially into the operative field, as this step is unnecessary and carries the risk of iatrogenic splenic injury.

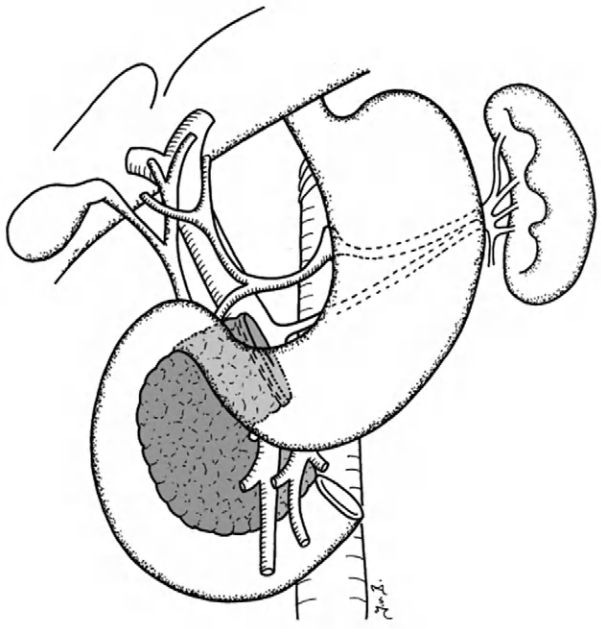

FIGURE 62A.18. Spleen-preserving distal pancreatectomy.

Distal Pancreatectomy with Splenectomy

The division of the gastrocolic ligament is extended to include the division of all the short gastric vessels. The splenic artery is then identified and divided close to its origin, thereby removing the surrounding fibro-fatty tissues. Based on the surgeon's discretion, the subsequent dissection can be performed in either a retrograde or antegrade fashion. For the former approach, the lienorenal ligament is cut and the spleen is retracted inferiomedially. The surgical specimen is then dissected off the retroperitoneum in a plane just superficial to the left renal vein and the left adrenal gland. If the planned transection margin lies very medially, the inferior mesenteric vein may have to be ligated and divided. The pancreas is then transected with a stapling device. For an antegrade approach, the peritoneum overlying the superior and inferior borders of the pancreas is incised. A plane is then developed by blunt dissection to create a tunnel deep to the SV, after which the jaws of the stapling device are insinuated across the gland, encompassing the SV to transect the gland and the vein en masse. The distal stump is then elevated to allow the separation of the specimen off the retroperitoneum as the dissection proceeds to the left. Drains are then placed near the pancreatic remnant, and the abdomen is closed.

We routinely perform lymphadenectomy when the indication for the operation is a malignant tumor of the body or tail. This involves excision of the nodal tissues along the common hepatic artery, left gastric artery, celiac axis, and along the SMV, as well as the peripancreatic and retroperitoneal lymph nodes and the left adrenal gland (Kleeff et al, 2007). A similar approach called the *radical antegrade modular pancreatosplenectomy* (RAMPS) allows a more comprehensive lymphadenectomy of the N1 nodes and reduces the risk of positive posterior resection margins (Strasberg et al, 2003).

Segmental Pancreatectomy

Letton and Wilson (1959) were the first to describe the technique of segmental pancreatectomy for two cases of traumatic transection of the pancreatic isthmus. Following a central segmental resection, the cephalic stump was oversewn, and a Roux-en-Y jejunal limb was constructed and anastomosed to the distal stump. Pancreatic surgeons were quick to recognize the versatility of this procedure and have since adapted it to the treatment of benign or borderline lesions of the pancreas situated in the neck. Benign or low-malignancy tumors arising from this region present a unique challenge. Conventionally, if the lesion is small, enucleation would be the optimal strategy. However, if the lesion measures more than 2 cm, or when it is situated deep within the parenchyma such that damage to the pancreatic duct becomes a real risk, the surgeon may have to resort to either an extended distal pancreatectomy or PD simply to remove the lesion. Such operative strategies for a small lesion come at the cost of a significant waste of normal tissue, not to mention the inherent risk of morbidity and mortality that accompanies such extended pancreatectomies.

Segmental pancreatectomy represents an organ-preserving extirpation technique that offers the advantages of avoiding the morbidity and mortality associated with PD; preserving splenic function by avoiding splenectomy, which often accompanies distal pancreatectomy; and preserving maximal pancreatic endocrine and exocrine function (Efron et al, 2004). Perhaps the most beneficial attraction seems to be the excellent preservation of endocrine function. This is not surprising because the risk of diabetes is proportional to the extent of resection and length of follow-up observation (Warshaw et al, 1998). On the other hand, the prime concern was whether pancreatic fistula rates would be significantly higher with two possible sources of pancreatic leakage. In the literature, the frequency of pancreatic leak in segmental pancreatectomy ranged from 14% to 30%, whereas in distal pancreatectomy, it ranged from 5% to 15%. These findings notwithstanding, in almost all reports patients do well with conservative management.

Iacono and colleagues (1998) succinctly summarized the prerequisites that allow segmental pancreatectomy to be considered as a reasonable approach: small lesions (<5 cm in diameter) (1) that are benign or low-grade malignant tumors (2) located in the neck or its contiguous portion (3), and a distal pancreas stump of at least 5 cm in length (4). A critical adjunct is the availability of frozen-section examination to confirm that the lesion is benign and to verify a free resection margin (Müller et al, 2006).

Technique

The lesser sac is entered, and the anterior aspect of the pancreas is widely exposed by dividing the adhesions between the posterior surface of the stomach and the pancreas. This is followed by intraoperative pancreatic ultrasonography to better delineate the lesion and to exclude concomitant lesions that may necessitate a change of plan. The pancreas is then elevated off the SMV-PV trunk. Stay sutures are placed in the superior and inferior pancreatic margins to indicate the proximal and distal limits of division and to aid in the subsequent dissection of the pancreas from the splenic vein. The pancreas is then divided proximally with a vascular stapler at least 1 cm from the lesion. The distal stump is then gently retracted toward the left to allow the cautious and tedious process of freeing the splenic vein from the posterior surface, clipping and cutting all the fine venous tributaries lying between the splenic vein and the pancreas. The pancreas is then divided distal to the lesion with a blade (Fig. 62A.19), and a specimen is sent for analysis and margin assessment.

Our usual technique of reconstruction follows that described in most other series and consists of the closure of the proximal stump and a Roux-en-Y PJ for the distal stump as described. The duct in the proximal pancreatic stump is closed by PDS single stiches, and the resection margin is covered by a serosal patch by apposing the serosa of the jejunal limb to the stump and taking seromuscular bites of the jejunum and the pancreatic capsule (Figs. 62A.20 to 62A.24).

However, in cases in which stenosis or obstruction of the proximal pancreatic duct is suspected, we prefer to perform jejunal anastomosis for both the proximal and distal stumps. Such proximal ductal abnormalities can be rather prevalent in patients with chronic pancreatitis; therefore, by anastomosing the proximal stump to the jejunum, an alternative outflow route is created for the pancreatic secretions. We also prefer a double anastomosis when we have doubts about obtaining a secured stapled closure, such as when the proximal pancreas is found to be large and bulky.

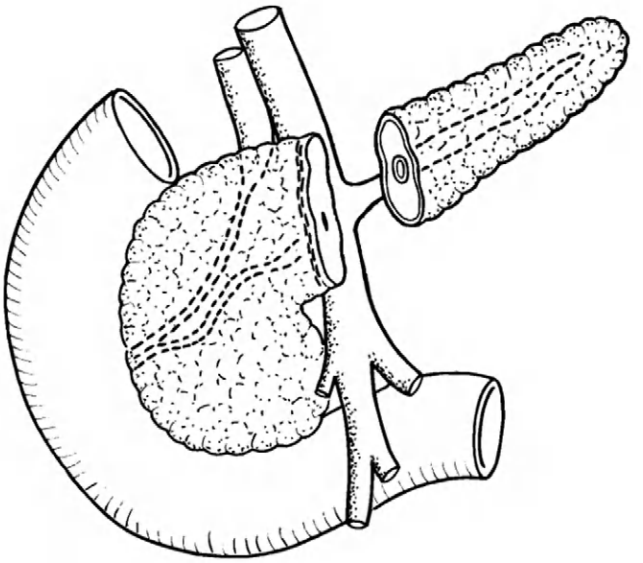

FIGURE 62A.19. Excision of a segment of the pancreas with identification of the underlying splenic vein prevents iatrogenic injury to the vein.

A jejunal Roux limb is created by dividing the proximal jejunum 15 to 20 cm past the ligament of Treitz. This is then brought to the supracolic compartment in a retrocolic fashion, through a mesenteric window created on the left side of the middle colic vessels. The distal pancreatojejunal anastomosis is

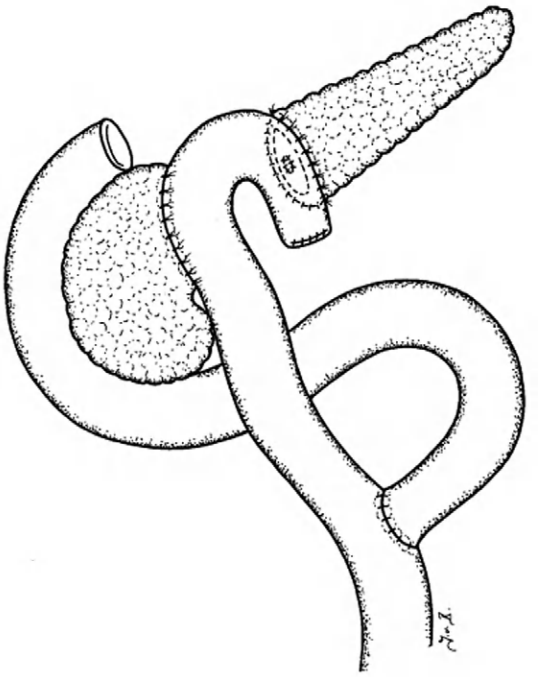

FIGURE 62A.20. Following a two-layer pancreatojejunostomy to the distal stump, a serosal patch is performed on the stapled end of the proximal stump.

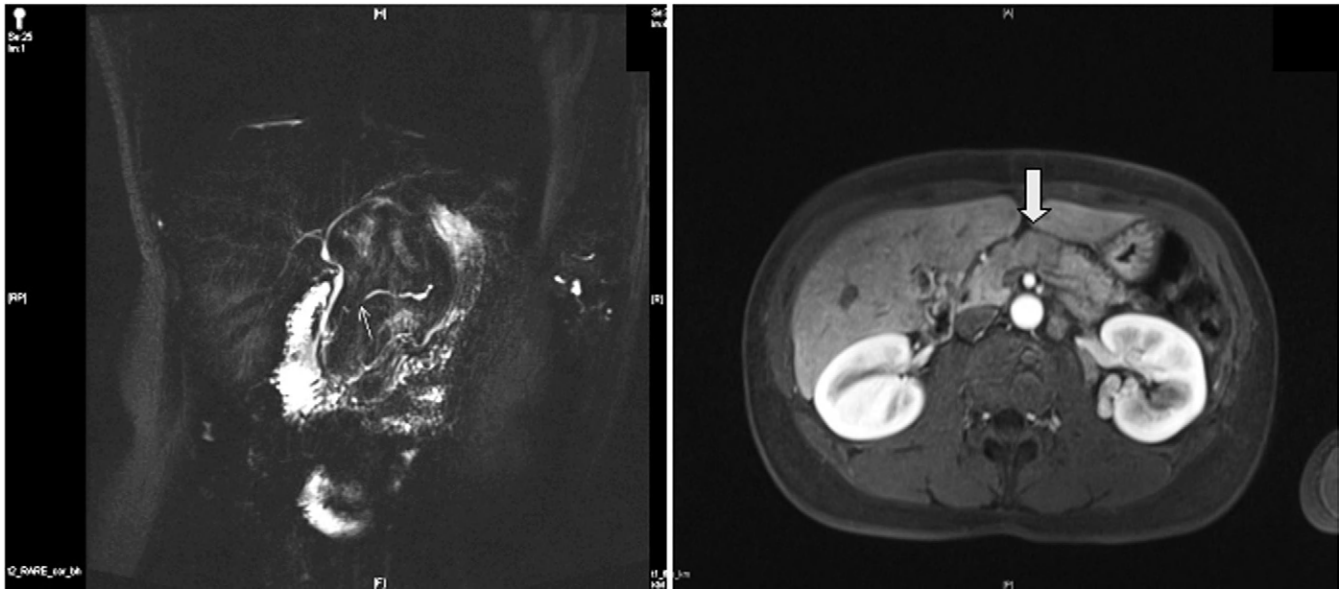

FIGURE 62A.21. Segmental chronic pancreatitis secondary to trauma with stenosis of the pancreatic duct. The patient presented with recurrent pancreatitis.

constructed first in the same two-layer fashion as previously described (see Management of the Pancreatic Remnant). This is then followed by the proximal anastomosis using the same jejunal Roux limb. The reconstruction is completed by an end-to-side jejunojejunostomy, and drains are placed.

Total Pancreatectomy

In the 1960s and 1970s, dissatisfaction with the early results of PD for cancer of the head of the pancreas led surgeons to look for an alternative operation. Total pancreatectomy (TP) was proposed by some to be a rational choice for several reasons: It can eliminate multifocal disease, achieve wider resection margins, and achieve a more extensive lymphadenectomy. It also avoids complications emanating from the pancreatic remnant. However, recent evidence has shown that multicentric disease is actually uncommon, seen only in perhaps 9% of cases (Karpoff et al, 2001). Furthermore, randomized trials on extended lymphadenectomy have shown that no tangible benefits could be reaped from such procedures, especially because the lymph nodes around the body and tail of the gland are rarely involved with metastatic disease from a cancer of the pancreatic head. Conversely, removal of the entire pancreas is associated with severe metabolic consequences as a result of the loss of pancreatic endocrine and exocrine functions. One of the more serious metabolic aftermaths is brittle diabetes and severe recurrent hypoglycemia. Indeed, Yeo and associates (1995) have shown that the median survival for patients who had TP performed for pancreatic head cancer was 10 months, as opposed to 16 months in the PD group. Likewise, researchers at Memorial Sloan-Kettering

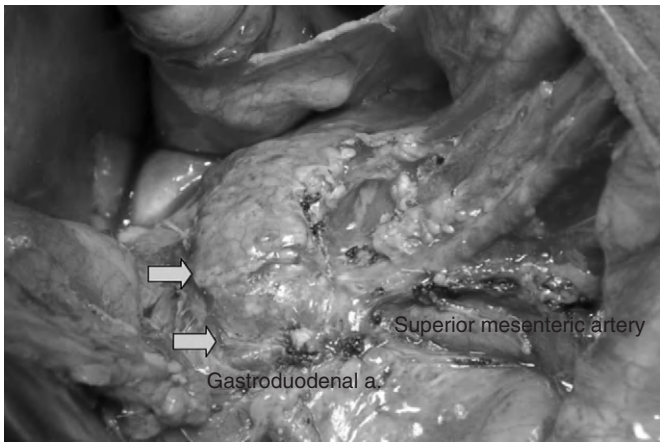

FIGURE 62A.22. Intraoperative finding of segmental inflammation secondary to trauma. The gastroduodenal artery (*a.*) and the superior mesenteric vein are demonstrated. The *arrows* indicate the margin of the inflamed area.

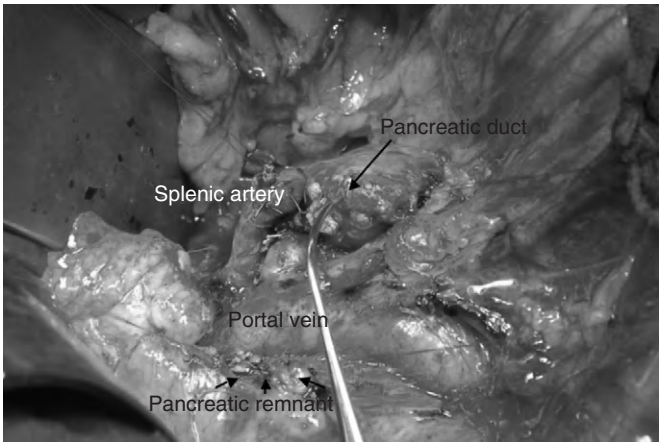

FIGURE 62A.23. Intraoperative finding after the segmental resection has been performed. The resection margin on the right has been closed with monofilament absorbable polydioxanon single stitches; the pancreatic duct is to the left.

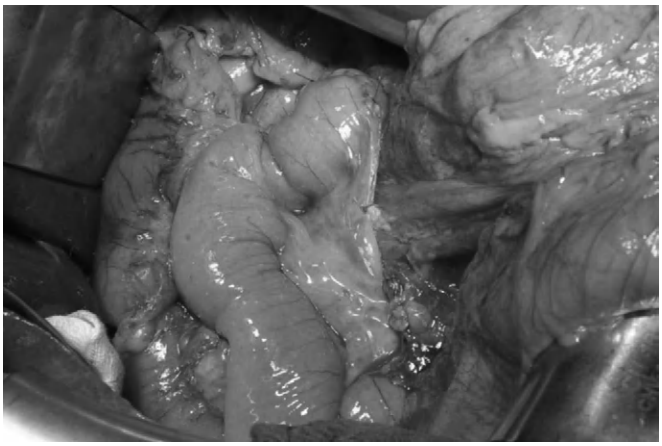

FIGURE 62A.24. After reconstruction, the end-to-side pancreatojejunostomy and the coverage of the resection margin at the pancreatic head with a serosal layer with the same jejunal loop can be seen.

Cancer Center (MSKCC) have shown that patients with TP had a significantly lower overall survival compared with a contemporary cohort of patients who underwent PD and distal pancreatectomy (Karpoff et al, 2001). The length of stay was markedly prolonged, emphasizing the greater morbidity of this procedure. No apparent effect of positive margins on outcome was shown, and hence it was concluded that a positive margin of resection at the time of PD should not compel the extension of the resection to a TP.

We are of a different opinion, as we had previously shown that a curative resection (R0) is the single most important factor in determining outcome in patients with pancreatic adenocarcinoma (Wagner et al, 2004). Hence, positive resection margins on frozen-section surgical margin analysis remains one of the few indications for us to proceed with a TP. Similarly, longitudinal involvement of the pancreatic duct in cases of intraductal papillary mucinous neoplasm (IPMN) is another reason to cut back until lesion-free margins are obtained; on some occasions, TP becomes necessary (see Chapter 57). Recent evidence has also shown that the presence of atypia or carcinoma in situ at the ductal resection margin was not associated with a poor outcome (D'Angelica et al, 2004), suggesting abandonment of this obsession with clear margins in cases of IPMN. However, our center and others (Gigot et al, 2001) have held that surgical resection should be tailored to the longitudinal spreading into the pancreatic duct as established by routine frozen section of the surgical margins. It will be interesting to follow this debate as more evidence emerges. Another indication for TP is the presence of an atrophic, soft, friable pancreatic remnant that does not hold sutures. Most recent reports demonstrate that morbidity and mortality of TP have decreased dramatically and that the perioperative and oncologic long-term outcome are comparable to standard pancreatic resections (Müller et al, 2007; Reddy et al, 2009).

Besides rendering a patient diabetic, TP also has a nutritional toll as a consequence of the loss of exocrine function, leading to persistent diarrhea and steatorrhea. If TP is accompanied by gastric resection by a standard Whipple procedure, further nutritional compromise will ensue from decreased dietary intake as a result of the loss of gastric reservoir function. It is our center's policy to preserve the pylorus whenever we perform a TP, unless tumor infiltrates into the proximal duodenum or suspicious peripyloric nodes are present that preclude an R0 resection if left in situ. This philosophy is the result of a study comparing patients who had a pylorus-preserving TP with those who had a classic TP in which a distal gastrectomy was performed. Patients in the first group showed a significantly faster rate of recovery of body weight compared with those in the second group, and no difference in survival was reported between these two groups (Wagner et al, 2001). Sugiyama and Atomi (2000) also demonstrated improved recovery of body weight and serum albumin at 6 months after surgery following pylorus-preserving TP, with a low incidence of persistent diarrhea and lower hyperalimentation requirements. Not surprisingly, the postoperative QOL was somewhat better in the pylorus-preserving group than in those who had a standard TP (Sugiyama & Atomi, 2000).

Technique

In cases of main duct IPMN, an en bloc total pancreatectomy without transaction of the pancreas may be necessary. In this case, the mobilization of the pancreatic head and the transection of the jejunum and duodenum are performed first. The pancreatic tail is mobilized together with the spleen, and the dissection of the pancreatic mesentery along the PV and the SMA is the last step of resection (Werner & Büchler, 2010).

In cases with a positive pancreatic resection margin, we would already have resected the pancreatic head along with the adjoining duodenal loop and the distal CBD. The distal duodenum is then delivered into the infracolic compartment after taking down the ligament of Treitz, and the proximal jejunum is transected to complete the resection of the duodenum. The pylorus is preserved in the same manner as in a PPPD. If a TP is necessary because of cancer involvement of the distal stump, we would resect the pancreas together with the spleen to ensure radicality. The short gastric vessels are divided, the splenic artery is divided at its origin, and the splenic vein is divided at its confluence with the SMV-PV trunk with a vascular stapler or suture closure. The distal pancreatic stump and underlying splenic vein are retracted to the left, and the specimen is dissected off the retroperitoneum toward the spleen. The inferior mesenteric vein is ligated and divided, and the lienorenal ligament is divided.

For more low-grade tumors, such as IPMNs, we would attempt to preserve the spleen. In this case, we would preserve all the short gastric vessels in the event that the splenic vessels need to be divided. This is followed by the tedious process of ligating or clipping and cutting the multiple branches that connect the splenic vein and the splenic artery to the pancreas in an attempt to preserve both splenic artery and vein. Reconstruction after TP consists of an interrupted end-to-side, single-layer hepaticojejunal anastomosis with a retrocolic jejunal limb. An antecolic end-to-side duodenojejunostomy is then constructed about 50 to 60 cm downstream from the bilioenteric anastomosis (Kulu et al, 2009).

Transduodenal Resection of the Papilla of Vater

All ampullary tumors should be resected. Such a sweeping statement governing the strategy of managing such neoplasia stems from several observations. The most common benign tumors of the ampulla of Vater are villous and tubulovillous adenomas, and although they are classified as benign, they are truly premalignant neoplasms whose malignant transformation

can only be confidently prevented by their complete removal. These tumors are also highly deceptive; consequently, distinguishing adenoma from carcinoma becomes an exceedingly difficult problem. Adenomas are known to harbor occult foci of carcinoma, with a reported incidence of coexistent carcinoma in duodenal or ampullary tumors ranging from 35% to 60% (Martin & Haber, 2003). Furthermore, preoperative endoscopic diagnosis is notoriously unreliable. False-negative results from endoscopic biopsies have been described in 25% to 60% of patients with carcinoma (Posner et al, 2000); thus complete excision is the only sure way of establishing whether an ampullary adenoma harbors undetected foci of carcinoma. Finally, among the various types of periampullary cancers, overall 5-year survival is greatest for ampullary cancers and duodenal cancers (Sarmiento et al, 2001). A recent series from de Castro and associates (2004) reported that overall 5-year actuarial survival of patients with adenocarcinoma after PD was 37%, which is considerably superior to that of patients with pancreatic adenocarcinoma. Another recent series echoed this finding; the authors found that survival after resection of ampullary cancer was far better than that after resection of other periampullary cancers, with a 5-year survival rate of 36% as opposed to 14% in the other group (Bettschart et al, 2004). Furthermore, the resectability rate of ampullary carcinoma is higher than the other periampullary tumors, with a 92% resection rate reported in this series. Adopting an aggressive approach toward ampullary tumors therefore appears justifiably warranted.

Although it is generally agreed that PD is the operation of choice for ampullary adenocarcinoma, the ideal treatment for benign neoplasms, with or without dysplasia, and lesions with microinvasion remains controversial. Some have argued that a radical resection should also be applied to benign lesions, citing a high incidence of malignancy in ampullary tumors and an increased tendency for these lesions to recur after local excision. Recurrence of villous tumors after transduodenal excision (TDE) is reportedly 32% at 5 years and 43% at 10 years; more importantly, it may recur as invasive cancer (Farnell et al, 2001). An added bonus is that PD obviates the need for endoscopic surveillance during the postoperative follow-up in cases of sporadic adenomas. Detractors, however, believe that TDE is an acceptable and adequate form of treatment with markedly decreased morbidity and mortality rates compared with radical resection. Posner and colleagues (2000) have shown that TDE of benign ampullary tumors, even those with varying degrees of dysplasia, can have low recurrence rates. Beger and colleagues (1999) also observed that TDE of lesions with only submucosal invasion does not compromise long-term survival. The transduodenal approach is also associated with a significantly shorter operation time, a significantly lower incidence of surgery-related morbidity and, consequently, a significantly shorter postoperative hospital stay (de Castro et al, 2004). Even after recurrence, most benign lesions do not lead to the patient's demise, and many can be treated endoscopically or with reexcision.

The emergence of endoscopic ampullectomy has added a new dimension to the issue of local resection. It is an attractive alternative for patients unfit for general anesthesia as a result of prohibitive comorbidities or for those who refuse surgery. The main limitation is that this option is restricted to a few select centers with expertise in interventional endoscopy. With the low incidence of ampullary adenomas, combined with the more widespread and established availability of surgical resection at most medical centers, the number of endoscopists who have accumulated a sizable experience in this technique will remain low. Therefore, at least in the near future, TDE is unlikely to be relegated as a result of the emergence of endoscopic ampullectomy.

We have established certain indications for which TDE would be a reasonable option (Paramythiotis et al, 2004), such as large (≥2 cm) villous or tubulovillous adenomas of the papilla, adenomas of the papilla with high-grade dysplasia, and adenomas with carcinoma in situ. Beger and colleagues (1999) have also offered TDE for pT1N0M0/G1 and G2 cancer of the mucosa with the caveat of additional lymphadenectomy of the anterior and posterior nodal groups of the pancreatic head and the supraduodenal lymph nodes. However, even in pT1 tumors, lymph node involvement has been observed in 6% to 10% of patients (Klein et al, 1996). Hence, we would recommend PD even for superficially invasive cancer of the ampulla, especially with the good safety profile of this procedure in experienced hands. However, in patients who are unfit for PD, we concede that TDE offers a chance for good palliation and even cure.

As with military operations, good planning prior to surgical operations requires good intelligence. We consider the ERCP critical in the preoperative workup. Besides being able to obtain tissues for histologic diagnosis, the endoscopic visualization may give some clues as to the biologic behavior of the lesion. Reliable endoscopic signs that indicate the likelihood of malignant transformation have been described such as induration and rigidity of the papilla on probing, ulceration, and a submucosal mass effect suggestive of tumor extension into the duodenal wall (Martin & Haber, 2003). Although not conclusive, the presence of such signs will certainly raise the index of suspicion. With its ability to clearly delineate the layered anatomy of the duodenal wall, EUS can identify the depth of tumor invasion with an accuracy of 75% to 85% (see Chapter 14; Posner et al, 2000). If a T2 tumor (invasion of duodenal wall) or involvement of contiguous structures is clearly demonstrated on EUS despite a negative biopsy, we would proceed with a radical procedure.

Technique

Because the ampulla is absent in nearly two thirds of patients (Sarmiento et al, 2001), it would be more often correct anatomically to use the term *TDE of the papilla of Vater.* The abdomen is entered through a midline incision in case a conversion to a more radical procedure is required. A generous Kocher maneuver is then performed to completely mobilize the second part of the duodenum, and three to four stay sutures are placed alongside the antimesenteric border on its anterior aspect to help elevate the duodenum toward the abdominal wound to facilitate the duodenotomy. A 6- to 8-cm long longitudinal duodenotomy is then made in a lazy-S fashion along the antimesenteric border opposite the pancreas; the incision is kept open with stay sutures (Fig. 62A.25). Circumferential stay sutures, using monofilament absorbable PDS (5/0), are placed about 1 cm beyond the gross border of the lesion and are kept long. Excision of the lesion is undertaken with electrocautery to minimize bleeding, along a resection margin just inside the circle formed by the circumferential stay sutures. A heavy stay suture is placed through the tumor mass to allow the tumor and the papillary region to be drawn upward. The dissection is carried around the tumor area in a stepwise fashion, and the incision must allow a full-thickness excision of the tumor that includes the biliopancreatic ductal junction. Ductal resection can be safely performed up to 1 cm (Nikfarjam et al, 2001); this is to

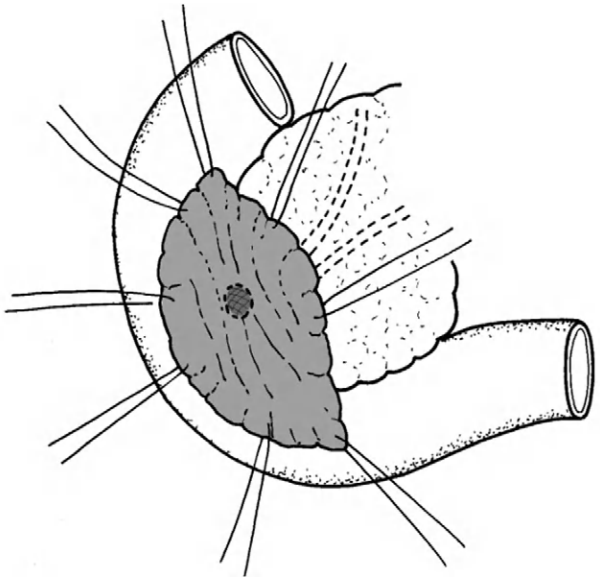

FIGURE 62A.25. A generous duodenotomy and the use of stay sutures allow good access to the papilla.

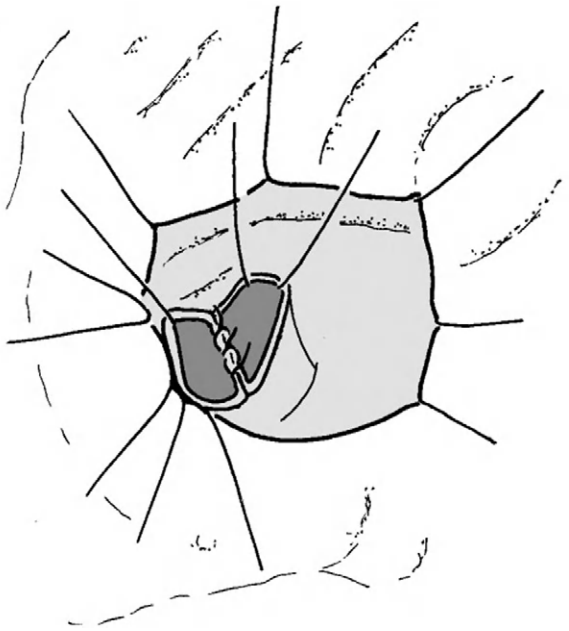

FIGURE 62A.27. Apposition of the pancreatic duct and bile duct to form a common septum.

safeguard against any possible tumor infiltrations of the bile and pancreatic ducts. As each duct is identified, stay sutures are placed through the ductal wall following complete transection (Fig. 62A.26). Following complete excision, the specimen is carefully oriented for the pathologist to facilitate frozen-section examination. If clear margins are reported, we would proceed with the reconstruction, which begins with the suturing together of the pancreatic and common bile ducts in a common septum (Fig. 62A.27). This is followed by the reimplantation of this new common channel back into the duodenal wall with 5/0 monofilament absorbable sutures to approximate the duodenal wall to the joined pancreatic and bile duct openings (Fig. 62A.28). Patency of the ducts is ensured before closure of the duodenotomy. The duodenal opening is then closed in two layers (Fig. 62A.29), and drains are routinely placed in the vicinity of the duodenotomy.

Postoperative Management

Following operation, we routinely monitor our patients in the intensive care unit or the high-dependency unit for the first 24 hours. The NG tube is usually removed at extubation or, at the latest, within the first 12 hours after extubation, when the patient has regained a reasonable level of consciousness and has an intact cough reflex. Intravenous antiemetics are given prophylactically. The abdominal drains are usually removed within the first 3 days after operation, based on the volume and the amylase/lipase content (Bassi et al, 2005; Molinari et al, 2007).

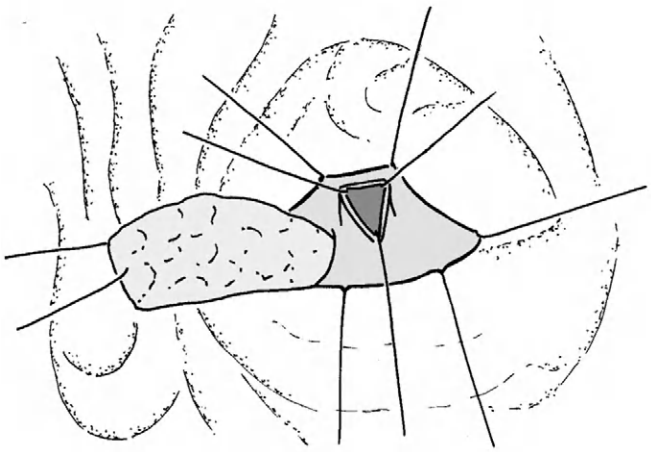

FIGURE 62A.26. Ductal sutures are placed once each duct is identified.

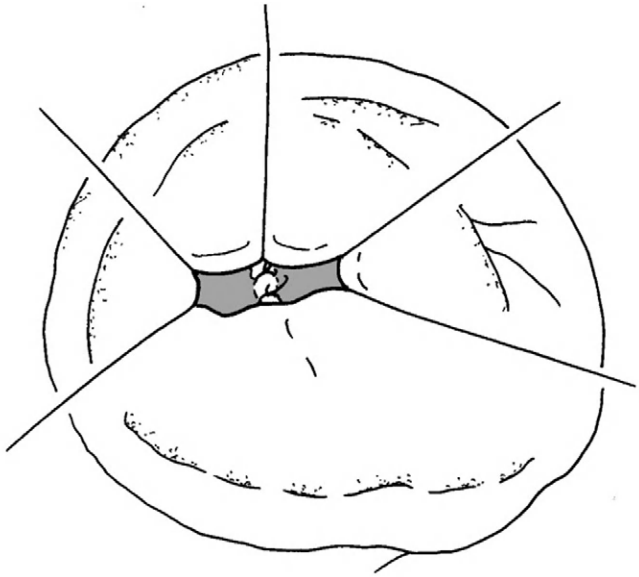

FIGURE 62A.28. Reimplantation of the ducts to the duodenal mucosa.

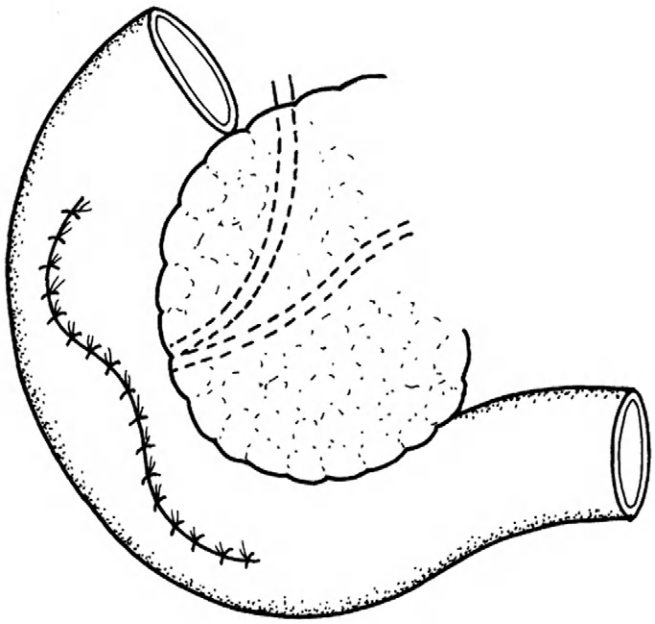

FIGURE 62A.29. Closure of the lazy S–shaped duodenotomy in two layers.

However, if the volume is excessive (>700 mL/day), the drains should be kept in place. If the fluid amylase level is three times the serum amylase level or higher, the drains are kept in and the patient is treated as for a pancreatic leak.

The issue of postoperative nutritional support has been a popular topic for research, which seems justified, since many patients with pancreatic disease present with significant weight loss. Two issues are critical with regard to the provision of nutrients postoperatively: *timing* and *method* of administration. Lewis and colleagues challenged the long-held practice of "nil by mouth" after GI surgery and conducted a systematic review of the topic and a meta-analysis of controlled trials. They showed that early feeding within 24 hours after surgery, whether by mouth or directly into the small bowel, can significantly reduce both the risk of any type of infection and the mean length of hospital stay. Risk reductions were also seen for anastomotic dehiscence, wound infection, pneumonia, intraabdominal abscess, and mortality, but these failed to reach significance.

On the question of the ideal route of administration, investigators at MSKCC conducted a prospective randomized trial of early enteral feeding (EEN) with an immune-enhancing formula in patients with upper GI malignancies. They found that EEN via a jejunostomy tube did not provide any benefit over postoperative crystalloid support in well-nourished patients (Heslin et al, 1997). A more recent publication echoed similar findings. Braga and colleagues (2001) observed that EEN did not improve outcome compared with total parenteral nutrition (TPN) in the overall population; however, they did find that in a subgroup of malnourished patients, EEN was associated with a significantly shorter length of stay. This was probably secondary to a lower overall complication rate, particularly the rate of infectious complications—noted in the EEN group compared with the TPN group. The prevalence of glucose and electrolyte disturbances was also lower during EEN than during TPN. In addition, researchers were able to demonstrate better gut oxygenation with EEN, not to mention significant cost savings compared with TPN. This makes EEN the ideal method for nutritional support, albeit in a selective manner.

EEN is not without risks, however. We previously demonstrated a significantly higher incidence of DGE in the enteral nutrition (EN) group compared to the no-EN group (Welsch et al, 2010). Furthermore, the use of a feeding jejunostomy tube is itself subject to the risk of adverse events, including tube dislocation, blockage, and leakage. Looking at the risk/benefit ratio, we agree with Braga and colleagues that the use of EEN should be targeted selectively at the group of patients with malnourishment, defined as the involuntary weight loss of more than 10% of the patient's usual body weight in the preceding 6 months. In general, 25 to 30 kcal/kg/day and 1.2 to 1.5 g/kg/day of protein are reasonable goals in these patients (Sampliner, 2001). TPN is used when nutritional goals cannot be met with enteral feedings because of GI dysfunction.

On the other hand, positive effects have been demonstrated by mere institution of early oral intake. In the group randomized to clear liquids *ad lib* after surgery, followed by a soft diet for patients who can tolerate 500 mL of liquid. Steed and colleagues (2002) showed that length of stay was significantly reduced, but the rates of ileus, emesis, and morbidity remained identical with the control group.

Clear liquids may be served to the patient following extubation on the first postoperative day. Thereafter, the amount and type of oral intake is progressively tailored, according to the patient's tolerance. Most of our patients are able to tolerate solids by the third or fourth postoperative day. Oral feeding is suspended or reverted back to a liquid-only diet if the patient vomits, and the NG tube is reinserted if the patient vomits on more than one occasion.

Blood glucose level must be closely monitored, with 4 to 6 hourly blood glucose level measurements for the first 24 to 48 hours. For patients who had a TP, blood glucose was regulated with intravenous administration of insulin. After starting oral food intake, patients received either semi–long-acting insulin or a combination of long-acting insulin as baseline therapy with premeal short-acting insulin. This must be done in consult with an endocrinologist and it may entail transfer of the patient to the endocrine unit once surgically fit for discharge. Patients should also be taught self-monitoring of their blood sugar and self-administration of insulin by the diabetic nurse educator.

Following TP, pancreatic enzyme substitutes are also be prescribed to this group of patients to treat their expected exocrine insufficiency. Although many patients complain of some form of diarrhea, this symptom resolves rapidly with high-dose enzyme substitution (Müller et al, 2007; Wagner et al, 2001).

Epidural analgesia or patient-controlled analgesia is continued for the first 72 hours. Oral analgesia is started concurrently once the patient can tolerate oral intake. Active chest physiotherapy with incentive spirometry should commence on the first postoperative day. Abdominal binders are occasionally provided for patients to minimize wound pain during deep-breathing exercises. Patients must be assisted to sit out of their beds on the first postoperative day, and a graded mobilization exercise regimen will allow the patient to begin limb exercises before progressing to supervised mobilization and finally to independent mobilization. Urinary catheters are removed following the discontinuation of the epidural analgesia. All patients who had their spleen removed should be vaccinated against *Streptococcus pneumoniae* and *Hemophilus influenzae* type B.

CONCLUSION

In the short but illustrious history of pancreatic surgery, pancreatic resection has evolved from a procedure synonymous with high mortality rates and poor quality of life for the survivors to one that is now recognized as the standard of care because of its vastly improved safety profile and efficacy. Modern pancreatic resection is one in which the extent of resection can be tailor made to the individual needs of the patient based on the disease process. All these are the fruits of hard work and research over the last century in the areas of surgical technique refinements, perioperative care, and diagnostics, just to name a few. The management of patients with pancreatic diseases will continue to require a multispecialty approach, with the surgeon in a central and coordinating role.

Pancreatic resection is now an accepted form of therapy for a large spectrum of pancreatic diseases, both benign and malignant. In sharp contrast with the nihilistic views that permeated the profession during the 1970s, the medical profession and patients alike have now recognized that pancreatic resection is a worthwhile undertaking, and that it is able to cure sometimes, and with regard to pancreatic cancer, to relieve often.

CHAPTER 63B

Palliation of pancreatic and periampullary tumors

Dirk J. Gouma

OVERVIEW

Pancreatic and periampullary tumors are the fifth most common cause of cancer-related death in the Western world (DiMagno et al, 1999; Greenlee et al, 2000). The incidence in the United States is approximately 10 per 100,000 persons per year. Most of these tumors are pancreatic adenocarcinoma, and the survival is poor (DiMagno et al, 1999; Greenlee et al, 2000; Gudjonsson, 1995, 2009; Kuhlmann et al, 2004). Despite surgical treatment with or without radiotherapy and chemotherapy, the overall 5-year survival is approximately 4% and has barely improved over the last few decades (Fig. 63B.1; Gudjonsson, 2009; Kuhlmann et al, 2004). Most patients are seen initially with "incurable" disease, owing to extensive local disease or metastases at the time of diagnosis (Sener et al, 1999). Confusion surrounds the terminology, however, with the words *incurable, inoperable,* and *unresectable* having a variety of interpretations. Use of the term *unresectable* partly depends on the local surgical philosophy (e.g., accepting a resection of the mesenteric artery portal vein and macroscopically nonradical R2 resections). This surgical philosophy is not only a country-related or regional pattern, it also may be influenced by the experience at the center and the local tradition of the surgeons. The strong relationship between outcome and hospital mortality may play a role in the indication for resection and acceptance of palliative resections (Alexakis et al, 2004; Birkmeyer et al, 2003; Gouma et al, 2000).

It has been questioned whether cure is possible at all in patients with pancreatic cancer (Gudjonsson, 1995, 2009). Gudjonsson summarized the literature, and after adjusting for calculations and duplications, suggested that the total number of 5-year survivors is hardly more than 700 to 800.

There is consensus, however, that patients who undergo resection have the best chance for long-term survival (Alexakis et al, 2004). A recent study showed up to 20 years survival after resection (Adham, 2008). Survival data for patients with distal bile duct carcinoma do not differ from data for patients with pancreatic cancer. Patients with ampullary tumors have a 5-year survival of 20% to 45%, and only a few go straight to palliative treatment (de Castro et al, 2004).

Overall, most patients have palliative treatment, and palliation of symptoms is still the major focus. According to the World Health Organization (WHO, 2002), palliative care is aimed at the improvement of the quality of life (QOL) of patients who face a life-threatening illness and at the prevention or relief of pain and symptoms. The three most important symptoms that should be treated in advanced pancreatic and periampullary cancer are 1) obstructive jaundice, 2) duodenal obstruction, and 3) pain.

The decision to aim for palliative treatment can be made at two different points during the disease (Nakakura & Warren, 2007). The first decision generally is made after staging procedures, and a selection is made for potential curative surgery, palliative surgery, or nonsurgical (endoscopic) palliation. Recently, another option, preoperative radiochemotherapy and subsequent exploration, has been introduced for patients with borderline resectable lesions in an attempt to reduce local tumor ingrowths (Abrams et al, 2009; Bjerregaard et al, 2009).

The second decision is the selection of treatment strategy made during surgery, which can be an attempt for a resection with curative intent (R0/RI), a resection for palliation (RII), or other surgical procedures for palliative treatment, such as drainage.

Accurate initial staging is the crucial step for the selection of surgical and nonsurgical (palliative) treatment. Radiologic imaging techniques have evolved rapidly in the last decade. Various methods, such as contrast-enhanced spiral computed tomography (CT) and endoscopic ultrasonography (EUS), have enhanced the accuracy of radiologic staging, and noninvasive staging procedures are currently the first choice (Alexakis et al, 2004; McMahon et al, 2001; Phoa et al, 2000). Recent evaluation has identified the "new group" of patients, the borderline resectable patients, for pretreatment assessment, and criteria have been described (Callery et al, 2009). Endoscopic retrograde cholangiopancreatography (ERCP) is no longer used as a diagnostic procedure.

The role of diagnostic laparoscopy in combination with laparoscopic sonography has been studied extensively in the past (Bemelman et al, 1995; Friess et al, 1998; Nieveen van Dijkum et al, 2003; Pisters et al, 2001; Tilleman et al, 2004), but its role has diminished. A review showed that no data justify the routine use of staging laparoscopy (Pisters et al, 2001). In a recent series, however, metastasis or local ingrowth was found in 27%. Some authors therefore suggest that it should be used selectively for patients with larger tumors and tumors located in the body and tail (Chang, 2009).

Depending on local philosophy, patients who are found to have a resectable tumor at preoperative noninvasive diagnostic workup should undergo an exploratory laparotomy immediately without preoperative biliary drainage (van der Gaag et al, 2010). Patients with unresectable or incurable disease found during exploration (11% to 50%) are generally considered to be best treated with surgical palliation (Nieveen van Dijkum et al, 2003; Pisters et al, 2001; Sohn et al, 1999). This chapter evaluates the current knowledge of different aspects of surgical and nonsurgical palliative treatment for the symptoms

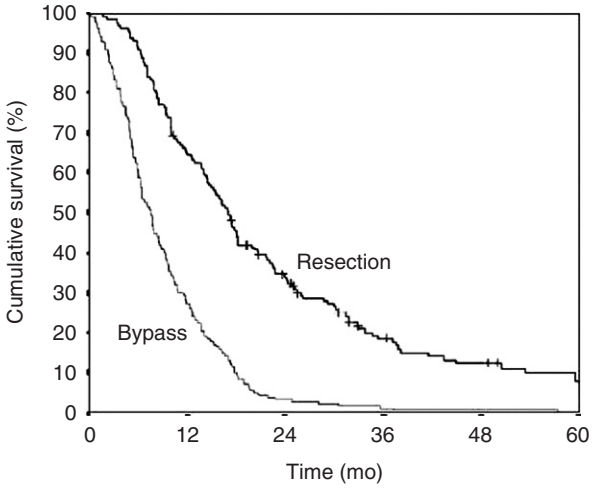

FIGURE 63B.1. Kaplan-Meier survival curves of patients who underwent a resection (n = 160) or a palliative bypass (n = 183) between 1992 and 2002. The median survival after resection and bypass were 17 and 7.5 months, respectively ($P < .01$). *(Modified from Kuhlmann KF, et al, 2004: Surgical treatment of pancreatic adenocarcinoma: actual survival and prognostic factors in 343 patients.* Eur J Cancer *40:549-558.)*

mentioned above: obstructive jaundice, duodenal obstruction, and pain.

OBSTRUCTIVE JAUNDICE

At the time of diagnosis, 90% of patients with pancreatic and periampullary tumors present with obstructive jaundice. Obstructive jaundice is associated clinically with jaundiced skin and sclerae, nausea, pruritus, dark-colored urine, and decoloring of the stool. More severe consequences are liver dysfunction and eventually hepatic failure secondary to bile stasis and cholangitis, which is found more frequently in patients with ampullary lesions compared with patients with pancreatic cancer. Relief of obstructive jaundice causes a dramatic increase in the QOL of patients and should always be achieved (Abraham et al, 2002; Crippa et al, 2008).

Biliary drainage can be achieved nonsurgically by placement of a biliary stent (endoscopic or percutaneous; see Chapter 18) or surgically by performing a biliary bypass (see Chapter 29). The success rate for short-term relief of biliary obstruction is comparable for surgical and nonsurgical biliary drainage procedures and ranges from 80% to 100%.

In the past, endoscopic biliary drainage was widely performed with plastic stents (polytef [Teflon] and polyethylene). Plastic stents can cause complications such as migration and occlusion, reported in 40%. A new stent type for endoscopic treatment is the self-expandable, covered metallic stent. Compared with plastic stents, expandable stents have a longer patency, but they generally cannot be removed after placement (Davids et al, 1992; Kaassis et al, 2003; Weber et al, 2009).

A surgical bypass can be performed by a hepaticojejunostomy alone or by a double bypass including a gastroenterostomy. In earlier studies, surgical bypass was associated with high rates of morbidity and mortality (Watanapa & Williamson, 1992).

Surgical Palliation of Obstructive Jaundice

Different surgical approaches can be used to obtain adequate biliary drainage. External biliary drainage by a T-tube has been used in the past but results in loss of appetite, and electrolyte and fluid imbalances frequently accompany external drainage. Internal biliary drainage generally is preferred and is performed by a cholecystojejunostomy, choledocho(hepatico)jejunostomy or choledochoduodenostomy (Watanapa & Williamson, 1992). In the past, cholecystojejunostomy was preferred because it is a relatively simple procedure (Rappaport & Villalba, 1990). In an extensive review, the success rate of cholecystojejunostomy to relieve obstructive jaundice was lower, however, compared with choledochojejunostomy (Watanapa & Williamson, 1992). A randomized controlled trial by Sarfeh and colleagues (1988) also showed that the technically more difficult choledochojejunostomy is preferred over a cholecystenterostomy, owing to the lower rate of recurrent jaundice and cholangitis and better patency of the bypass.

A choledochoduodenostomy is not recommended because it is generally believed that this drainage procedure frequently results in recurrent jaundice from local tumor ingrowth into the duodenum and the distal common bile duct, including the entrance of the cystic duct. A few cohort studies show low procedure-related complication rates and low rates of recurrent jaundice after choledochoduodenostomy (Di Fronzo et al, 1999).

At our institution, a side-to-side Roux-en-Y choledochojejunostomy is routinely performed after removal of the gallbladder in case of detection of advanced disease or metastases. According to the extension of dissection, in an attempt to prove locally advanced disease by ingrowth at the proximal portal vein, the common bile duct may be transected in an early phase of the procedure, and an end-to-side anastomosis is made by a one-layer running suture. This procedure can be performed with a low mortality rate and acceptable morbidity. The mortality rate in earlier studies, as well as most "outdated" randomized controlled trials from the 1990s (see below), was high and varied between 15% and 24%. However, recent studies showed mortality rates between 1% and 8%, morbidity rates between 21% and 29%, and shorter hospital stay (10 to 17 days) with a relatively low incidence of recurrent jaundice. The mean survival varied between 7 and 9 months (Table 63B.1).

Surgical or Endoscopic or Percutaneous Drainage of Obstructive Jaundice

Five prospective, randomized controlled trials have been performed, four of which compared surgical biliary drainage and endoscopic drainage (Andersen et al, 1989; Bornmann et al, 1986; Nieveen van Dijkum et al, 2003; Shepherd et al, 1988; Smith et al, 1994). In the first trial by Bornmann and associates (1986), percutaneous biliary drainage was used, and no differences were found between percutaneous and surgical palliation (Table 63B.2). The other studies were performed between 1988 and 1994, except for the study done by Nieveen van Dijkum and colleagues (2003), in which patients underwent a diagnostic laparoscopy as a final staging procedure, and randomization was performed after pathology had proven metastasis. The small number of patients randomized hampered the studies by Shepherd and associates (1988) and Andersen and colleagues (1989). Shepherd and colleagues predominantly used 7-Fr endoprotheses, which are known to have a higher occlusion rate than 10- or

12-Fr endoprotheses or Wallstents currently used (Davids et al, 1992). A study by Shepherd and colleagues (1988) had a relatively high rate of recurrent jaundice and cholangitis. The length of follow-up in both studies was unclear, and the registration of complications and the readmission rate were limited. In the study by Smith and coworkers (1994), 201 patients were randomized. A higher procedure-related mortality rate was found after bypass compared with stenting (14% vs. 3%), and the 30-day mortality rate was not significantly different (8% vs. 15%) but was still relatively high. Major complications after bypass versus stenting were significantly different (29% vs. 11%), but minor complications were comparable (29% vs. 18%). The recurrence of jaundice and cholangitis during follow-up was significantly higher after stenting (36% vs. 2%), but survival was comparable between groups (Smith et al, 1994).

Taylor and associates (2000) conducted a meta-analysis using the three above-mentioned studies of endoscopic stenting and concluded that more treatment sessions were required after stent placement than after surgery, with a common odds ratio (OR) estimated to be 7.23. This ratio indicates a more than sevenfold increased risk of additional treatment sessions after stenting. No significant difference between the two treatment strategies was found concerning 30-day mortality rate.

The more recent randomized study by Nieveen van Dijkum and colleagues (2003) analyzed the value of diagnostic laparoscopy for patients with a periampullary carcinoma. Patients who were found to have incurable disease owing to pathology-proven metastases were allocated to either surgical (double bypass) or endoscopic palliation by a Wallstent. No difference was found in procedure-related morbidity or number of readmitted patients between the surgically and endoscopically palliated patients (see Table 63B.2). The survival was 192 days and 116 days in the surgical and endoscopic groups, respectively ($P = .05$; Fig. 63B.2). This study concerns a select group of patients who were believed to have a resectable tumor after conventional radiologic staging, leading to a low (zero) procedure-related mortality.

So far, a few general conclusions can be drawn from the available studies. Surgical treatment of biliary obstruction in unresectable pancreatic cancer is associated with higher early morbidity, a longer hospital stay, and probably a higher initial mortality rate, but long-term results are better. Endoscopic treatment is associated with lower initial mortality and morbidity, but it more frequently leads to late biliary complications and reinterventions resulting from clotting of the stent, infection, and gastric outlet obstruction (GOO).

GASTRIC OUTLET OBSTRUCTION

Symptoms of GOO, such as nausea and vomiting, are reported in 11% to 50% of patients with pancreatic cancer at the time of diagnosis (DiMagno et al, 1999). For the optimal palliative treatment, it is important to determine the origin of these symptoms. The first cause is motility dysfunction of the stomach and duodenum secondary to tumor infiltration of the celiac nerve plexus (Thor et al, 2002) or probably dysfunction of the small bowel owing to tumor infiltration around the mesenteric artery. The second cause of GOO is mechanical obstruction of the duodenum from direct tumor ingrowth into the duodenum or secondary to compression of the duodenum by a tumor in the direct vicinity. At presentation, mechanical obstruction is reported in only approximately 5% of patients with pancreatic or periampullary tumors.

Surgical palliation should be performed only when GOO has a mechanical cause. When there is no mechanical cause, pharmaceutical treatment options should be investigated (Yeo et al, 1993). It is important to confirm mechanical GOO radiologically or endoscopically. Approximately 3% to 20% of patients with unresectable pancreatic cancer eventually develop mechanical GOO (Espat et al, 1999; Lillemoe et al, 1999). In a review by Watanapa and Williamson (1992) that included 1086 patients, 17% developed mechanical GOO, and an additional gastrojejunostomy was performed on these patients. In patients who are found to have an unresectable tumor at laparotomy, a gastrojejunostomy, in addition to a biliary bypass, is often performed and is not associated with increased morbidity and mortality (see Table 63B.1).

Endoscopic duodenal stenting also is accepted as a nonsurgical palliative treatment of duodenal obstruction (Holt et al, 2004; Telford et al, 2004). In a multicenter study, the success rate after stent placement was 84%, and oral intake in patients with successful stent placement resumed for a median time of 146 days (Telford et al, 2004). Recently, a systematic review was performed to analyze medical outcome and costs of gastrojejunostomy and stent placement. No difference was found in technical success rate (96% vs. 100%), early and late major complications (7% vs. 6% and 18% vs. 17%, respectively), and persisting symptoms (8% vs. 9%). Hospital stay was longer after surgical gastrojejunostomy, 13 versus 7 days after stent placement. The mean survival time after gastrojejunostomy was 164 days versus 105 days after stenting. The authors concluded that a stent should be used for patients with a relatively short life expectancy, and gastrojejunostomy should be performed for patients with a prolonged prognosis (Jeurnink et al, 2007).

Among surgeons and gastroenterologists, it is debated whether a prophylactic gastrojejunostomy should be performed. This is an important topic because only 40% to 80% of patients with pancreatic cancer who initially undergo an exploratory laparotomy with the intention to perform a pancreatoduodenectomy undergo a resection (Alexakis et al, 2004; Kuhlmann et al, 2004; Pisters et al, 2001; Sohn et al, 1999). Two randomized controlled trials evaluated the role of a prophylactic gastrojejunostomy in patients who were found to have an unresectable periampullary or pancreatic tumor during exploratory laparotomy (Lillemoe et al, 1999; Van Heek et al, 2003). Lillemoe and colleagues (1999) analyzed 87 patients who were found to have an unresectable tumor and were believed to not be at risk for duodenal obstruction. These patients received either a prophylactic retrocolic gastrojejunostomy and a biliary (double) bypass or a biliary (single) bypass alone. Both groups also underwent a chemical splanchnicectomy during the laparotomy. The addition of a prophylactic gastrojejunostomy did not increase procedure-related mortality and morbidity rates and did not extend hospital stay (Table 63B.3). None of the patients who received a gastrojejunostomy developed late GOO during follow-up compared with 19% of patients who did not undergo a gastrojejunostomy in the initial procedure, which was a significant difference. No significant difference in survival was found between both groups.

Van Heek and colleagues (2003) also randomly assigned patients found to have a resectable tumor during exploration to either a single bypass or a double bypass in a multicenter trial. The outcome of the interim analysis after 50% (n = 70) of the inclusion was comparable with the outcome of the study by Lillemoe and colleagues (1999), and it was decided to discontinue the trial. During follow-up, clinical GOO was diagnosed in 5.5% of patients after double bypass and in 41.4% of patients after single bypass, which was a significant difference (Fig. 63B.3). The study by Van Heek and colleagues (2003) also longitudinally evaluated the QOL of these two patient groups using the EORTC-C30 and Pan 26 questionnaires. Overall, no major differences were observed in the QOL between the two surgical treatment groups (Fig. 63B.4). After surgery, most QOL scores deteriorated temporarily and were restored to their preoperative levels within 4 months. This

Survival (mo)	8.3	8.3	7.2	8.4

pattern of a temporary deterioration of the different domains of QOL score and restoration after a few months also was found in patients undergoing a Whipple procedure and was comparable to the temporary deterioration of QOL after bypass surgery (Nieveen van Dijkum et al, 2005).

The results of a recent meta-analysis also favor prophylactic gastroenterostomy. The chance of GOO during follow-up was significantly lower (OR, 0.06; 95% CI, 0.02 to 0.21; $P < .001$) with no difference in postoperative morbidity and mortality rates (Hüser, 2009). In these studies, endoscopic stenting of duodenal obstruction during follow-up was not attempted routinely, which could influence the outcome in the near future. A new trial should focus on nonsurgical palliation, including stenting of the common bile duct and the duodenum and adding a celiac plexus block by EUS versus the "optimal" surgical palliation described above, including the double-bypass procedure.

PAIN MANAGEMENT

At the time of diagnosis, approximately 40% to 80% of patients report pain. As the disease progresses, more than 90% of patients eventually have moderate to severe pain. The pain of advanced pancreatic cancer is located most frequently in the upper abdomen (epigastric region) and the back and may be caused by tumor ingrowth into the mesenteric and celiac nerve plexus.

Another phenomena, such as neurogenic inflammation, well known from patients with chronic pancreatitis, could also lead to pain generation in this group of patients. These different

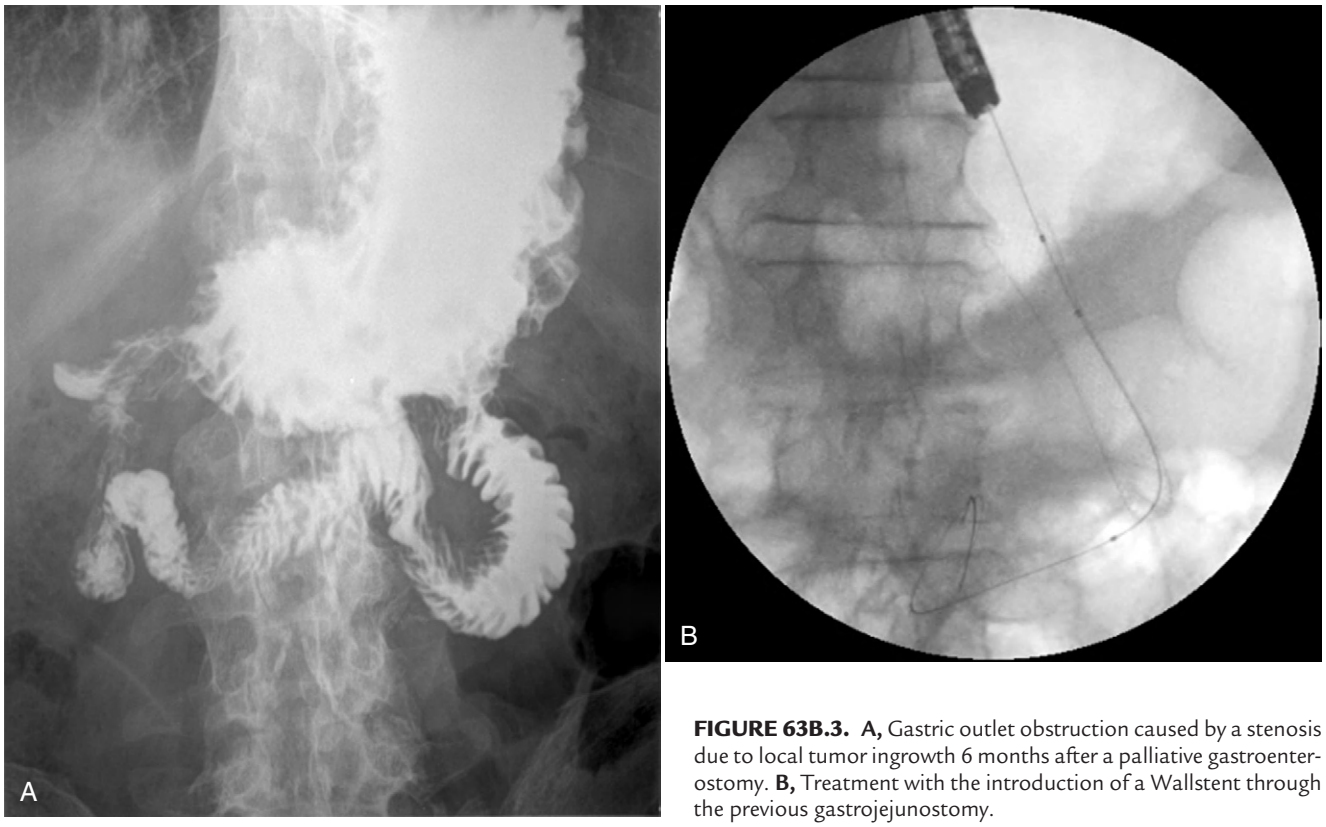

FIGURE 63B.3. A, Gastric outlet obstruction caused by a stenosis due to local tumor ingrowth 6 months after a palliative gastroenterostomy. **B,** Treatment with the introduction of a Wallstent through the previous gastrojejunostomy.

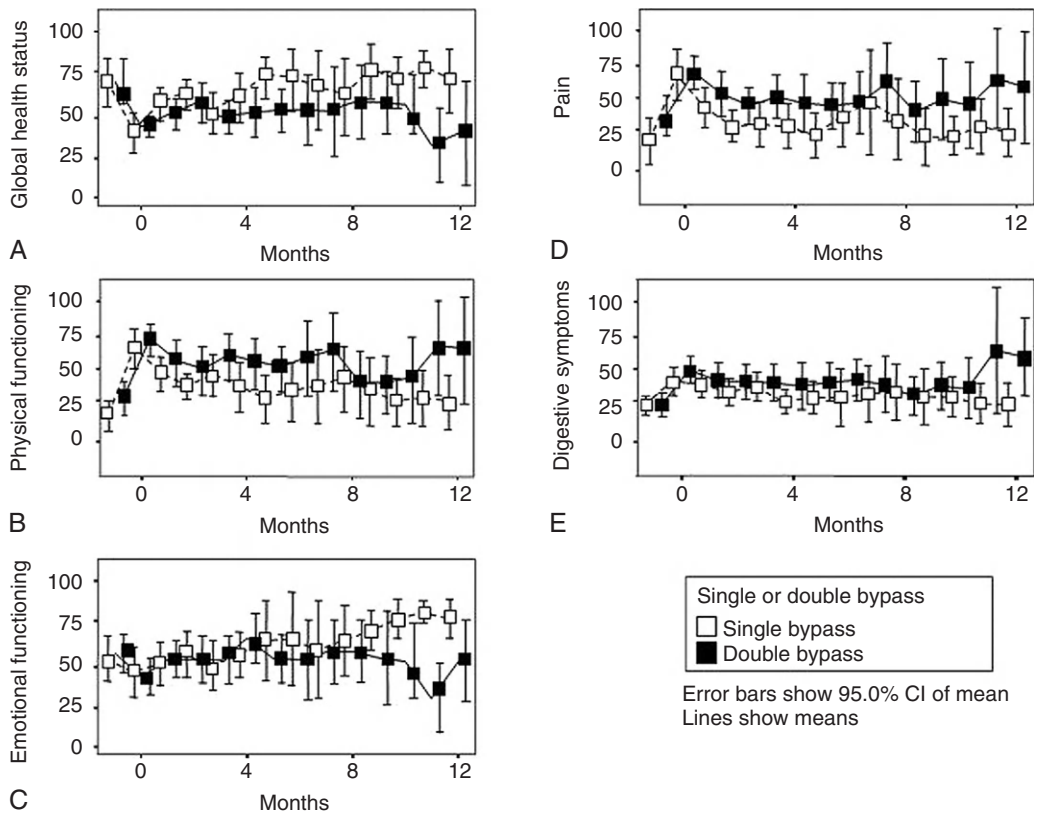

FIGURE 63B.4. Quality of life graphs representing the 12 months after surgery of patients randomized to receive a double or single bypass. The *left side* of the graph represents the time of the operation. The nonimputated subscales of the following subscales are presented: **A,** Global health status. **B,** Physical functioning. **C,** Emotional functioning. **D,** Pain. **E,** Digestive symptoms. *(Modified from van Heek NT, et al, 2003: The need for a prophylactic gastrojejunostomy for unresectable periampullary cancer: a prospective randomized multicenter trial with special focus on assessment of quality of life.* Ann Surg *238:894-902.)*

mechanisms have been summarized nicely in a recent report on pain generation (di Mola & di Sebastiano, 2008). Initial pain management should be pharmacologic and should be composed of analgesics such as nonsteroidal antiinflammatory drugs (NSAIDs) and oral or transdermic narcotic analgesics (Cruciani & Jain, 2008). Side effects of these drugs are frequently reported, however, and eventually pharmaceutical pain management alone may be insufficient (Caraceni & Portenoy, 1996). The next step is a celiac plexus nerve block, which was first described by Kappis in 1914. The nerve block interrupts the innervation of the pancreas and prevents painful stimuli from reaching the brain. This is a relatively straightforward procedure, but it can cause side effects, such as diarrhea and orthostatic hypotension, in approximately 40% of patients (Eisenberg et al, 1995). Currently, the celiac plexus block can be performed percutaneously, by EUS, or during laparotomy. Permanent paraplegia is uncommon (0.15%) but is the most dramatic complication of this procedure, which results from an infarct/occlusion of the art spinalis anterior (Abdalla & Schell, 1999).

Percutaneous Celiac Plexus Block

The percutaneous route to block the celiac plexus has been investigated extensively. It can be performed under fluoroscopic, CT, or US guidance. Multiple studies, mostly uncontrolled, have evaluated the accuracy and techniques of percutaneous celiac plexus block. In a meta-analysis of 24 publications that included 1145 patients treated with a percutaneous neurolytic celiac plexus block (NCPB) for cancer pain (63% pancreatic cancer), 70% to 80% of patients had long-lasting benefit from the procedure (Eisenberg et al, 1995).

Only a few randomized controlled trials on NCPB have been done (Ischia et al, 1992; Polati et al, 1998; Wong et al, 2004). The best evidence is in the most recent study by Wong and associates (2004), who randomly assigned 100 patients with unresectable pancreatic cancer to receive either NCPB or a sham NCPB procedure. After the randomized procedure, both groups could receive systemic analgesic therapy according to the WHO guidelines. End points were pain relief, QOL, and survival. The major findings were that NCPB significantly improved pain relief in patients with pancreatic cancer compared with optimized analgesic therapy, but it did not affect QOL or survival. NCPB had no effect on the consumption of analgesics, and significantly more patients needed a rescue NCPB in the analgesic therapy group (10 vs. 3 patients; $P = .01$).

These results suggest that the application of an aggressive pain management protocol, regardless of NCPB, can effectively control pain, although NCPB can provide significantly better analgesia than optimized analgesic therapy alone. Polati and colleagues (1998) performed a small, randomized, controlled

trial (n = 24) comparing percutaneous NCPB with pharmacologic therapy; mean analgesic consumption was lower, and drug-related side effects—constipation, nausea, and vomiting—were significantly less frequent in the group that underwent a nerve block. Ischia and colleagues (1992) randomized 61 patients to receive either a transaortic block, a classic retrocrural block, or a bilateral chemical splanchnicectomy. In 60% to 75% of patients, both techniques abolished pain until the patient's death.

Endoscopic Ultrasound-Guided Celiac Plexus Block

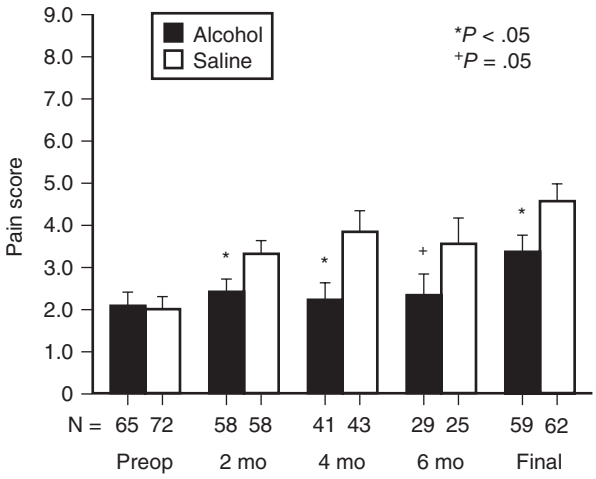
More recently, EUS-guided fine needle injection therapy has been developed (Giovannini, 2004; Klapman & Chang, 2005), and various techniques have been described. Generally, 5 to 10 mL of 1% lidocaine and 15 to 20 mL of 95% alcohol are injected at two areas of the celiac trunk. Results from nonrandomized studies showed a significant reduction of pain in 85% to 90% of the patients. Studies and follow-up are limited, however, and trials comparing the efficacy of this endoscopic procedure with the other techniques should be performed.

Celiac Plexus Block During Surgery

Celiac plexus block during surgery has been performed for many years. Lillemoe and colleagues (1993a) conducted a double-blind, randomized, controlled trial that compared a chemical splanchnicectomy during laparotomy with alcohol versus saline placebo. Chemical splanchnicectomy was performed perioperatively by injection of 20 mL of either 50% alcohol or saline solution on each side of the aorta at the level of the celiac axis. No differences were observed between the two groups concerning mortality rate, procedure-related complications, and hospital stay. Long-term complications and side effects were not investigated. Compared with the placebo group, alcohol injection significantly reduced the mean pain score for surviving patients at 2, 4, and 6 months (Fig. 63B.5). In the alcohol group, significantly more patients never reported pain (56% vs. 34%). However, the analgesic effect was not permanent: 10% of patients in the alcohol group required an additional percutaneous celiac axis block compared with 12% in the saline group. The time interval between the initial operative and additional percutaneous block varied significantly (11.8 ± 3.2 vs. 4 ± 1.1 months) in the alcohol group and saline group, respectively. Actuarial survival was improved in the subgroup of patients who reported significant preoperative pain and underwent a splanchnicectomy with alcohol ($P < .001$). The authors suggested that the difference could be caused by the progressive physical deterioration secondary to persistent pain, which eventually leads to impaired survival. These findings confirm other reports that state the presence of pain is associated with a poor prognosis (Kelsen et al, 1997).

The Amsterdam group retrospectively analyzed pain in 74 patients who underwent a palliative bypass for pancreatic adenocarcinoma (Van Geenen et al, 2002). The investigators found a significant difference in survival between patients who reported preoperative pain and patients who did not (4.9 vs. 9.5 months, respectively; $P = .01$; Fig. 63B.6). The association of persistent pain with a more advanced stage of the tumor could also explain this difference.

Another strategy to palliate pain is the thoracoscopic splanchnicectomy. A bilateral thoracoscopic splanchnicectomy or a unilateral left-sided thoracoscopic splanchnicectomy can be performed. Ihse and colleagues (1999) performed a prospective study analyzing the follow-up of patients with pancreatic cancer (n = 23) or chronic pancreatitis (n = 21) who underwent a bilateral thoracoscopic splanchnicectomy. Within 1 week, the average pain scores were reduced by more than 50% and remained stable throughout the follow-up period of 4 months.



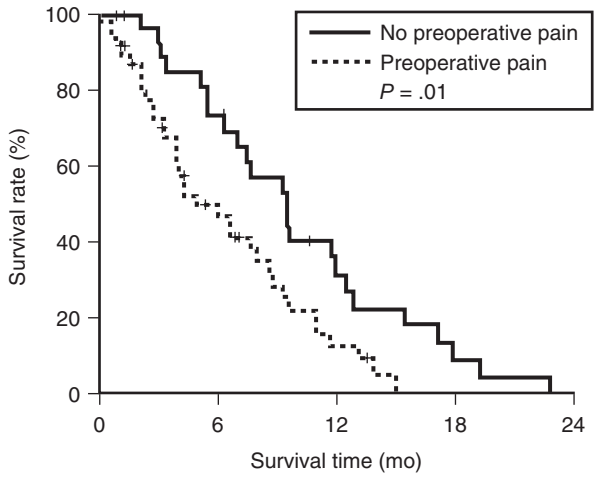


FIGURE 63B.5. Mean pain scores (visual analog scale) measured preoperatively at 2, 4, and 6 months with final assessments for all randomized patients surviving at each point. *(Modified from Lillemoe KD, et al, 1993: Chemical splanchnicectomy in patients with unresectable pancreatic cancer: a prospective randomized trial.* Ann Surg *217:447-455.)*

Number of patients alive/number of patients evaluable

28/28	19/26	7/24	2/24	No preoperative pain
46/46	17/39	4/37	0/36	Preoperative pain

FIGURE 63B.6. Survival of 74 patients with or without preoperative pain who underwent a palliative bypass for nonresectable pancreatic adenocarcinoma. *(Modified from Van Geenen RC, et al, 2002: Pain management of patients with unresectable peripancreatic carcinoma.* World J Surg *26:715-720.)*

Four patients (9%) required a thoracotomy because of a bleeding complication. Leksowski (2001) showed adequate and consistent pain relief in 26 patients who underwent a unilateral splanchnicectomy. Follow-up was also limited to 6 months, and recurrent pain after that period was not analyzed.

Radiotherapy can also be applied to reduce pancreatic cancer pain. It may take several weeks before pain relief is achieved, however, and side effects are common. Most studies are limited because of small patient numbers and poor pain assessment methods. Ceha and colleagues (2000) investigated the feasibility of high-dose conformal radiotherapy (70 to 72 Gy, 35 to 36 fractions) in 44 patients with nonresectable pancreatic cancer. Pain relief was experienced in 68% of patients, with a median duration of 6 months to pain progression.

In accordance with the results from previous studies, a chemical splanchnicectomy should be considered during the initial double-bypass procedure for patients with nonresectable pancreatic carcinoma. In other patients, pharmacologic pain management as described earlier is the first step, followed by percutaneous or US-guided celiac plexus block. For recurrent pain problems, radiotherapy and incidental thoracoscopic splanchnicectomy are performed.

PANCREATODUODENECTOMY FOR PALLIATION

Several reports have discussed the indications to perform a pancreatoduodenectomy as a palliative treatment option (Fusai et al, 2008; Gouma et al, 1999; Köninger et al, 2008; Lavu et al, 2009; Lillemoe et al, 1996; Reinders et al, 1995; Schniewind et al, 2006). This controversial question results from the observation of reduced morbidity and mortality associated with pancreatoduodenectomy in high-volume centers (Cameron et al, 1993; Kuhlmann et al, 2004; Lillemoe et al, 1996). This decreased mortality rate is partly due to improved management of severe complications (de Castro et al, 2005), but mainly to a hospital volume effect (Alexakis et al, 2004; Cameron et al, 1993; Gouma et al, 2000).

Frequently, the term *palliative resection* has been used to describe patients in whom the palliative resection was regarded as a macroscopically radical resection, which appeared to be microscopically nonradical after pathologic examination, a so-called *R1 resection* (Table 63B.4). Although the resection was undertaken with a curative intention, it can be considered palliative (Fig. 63B.7). In this case, the resection is called *palliative in retrospect*. The percentage of these patients from cohort studies depends heavily on the quality of the pathology examination of the specimen. It is debatable whether these patients should be included, if the role of a palliative resection per se is discussed, because these patients underwent a resection with a *curative* intent. The term *palliative resection* probably should be used only for R2 resections, those with macroscopically residual tumor. In a few of these situations, the tumor is found to be nonresectable after a point of no return (e.g., after transection of the pancreatic neck), or resection is required because of preoperative tumor bleeding. As a result of improved staging strategies by CT and MRI, and the nonsurgical management of bleeding by selective embolization, this indication is limited in current practice (Alexakis et al, 2004; de Castro et al, 2005; Phoa et al, 2000; WHO, 2002). However, some authors consider this an optimal palliative treatment (Köninger et al, 2008). No prospective studies in which a resection was performed or planned as a palliative procedure after adequate preoperative staging showed advanced disease leading to R2 resection.

The benefit of surgical resection in the subset of patients with advanced pancreatic cancer, including those with vascular ingrowth in portal vein and/or mesenteric vein, should be balanced against the potential benefits and complications of palliative chemoradiotherapy. Because no randomized controlled trials have been done, a decision analysis was provided comparing the survival after pancreatic resection, including portal vein resection, for locally advanced pancreatic cancer with survival after palliative chemoradiotherapy. It was concluded that surgical resection might confer a survival advantage over palliative chemoradiotherapy in selected patients with presumed local venous ingrowth. However, it was also found that if the probability of an R1 or R2 resection is greater than 77%, resection is no longer the favored strategy (Abramson et al, 2009). Another group of patients is a very small, well-selected group in which (palliative) resection is performed: patients with metastatic disease, mainly patients with solitary (small) liver metastasis, limited peritoneal metastasis, or interaortacaval/intermesenteric lymph node metastasis. A few small studies have been published that show combined pancreatic resection with hepatic resection is technically possible and relatively safe (Gleisner et al, 2007; Shrikhande et al, 2007). These studies showed no long-term survival, and it might be questioned whether survival in this highly selected group of patients is better compared with that of patients who receive other palliative procedures. The study from

Table 63B.4

†Bypass including patients with metastasis.

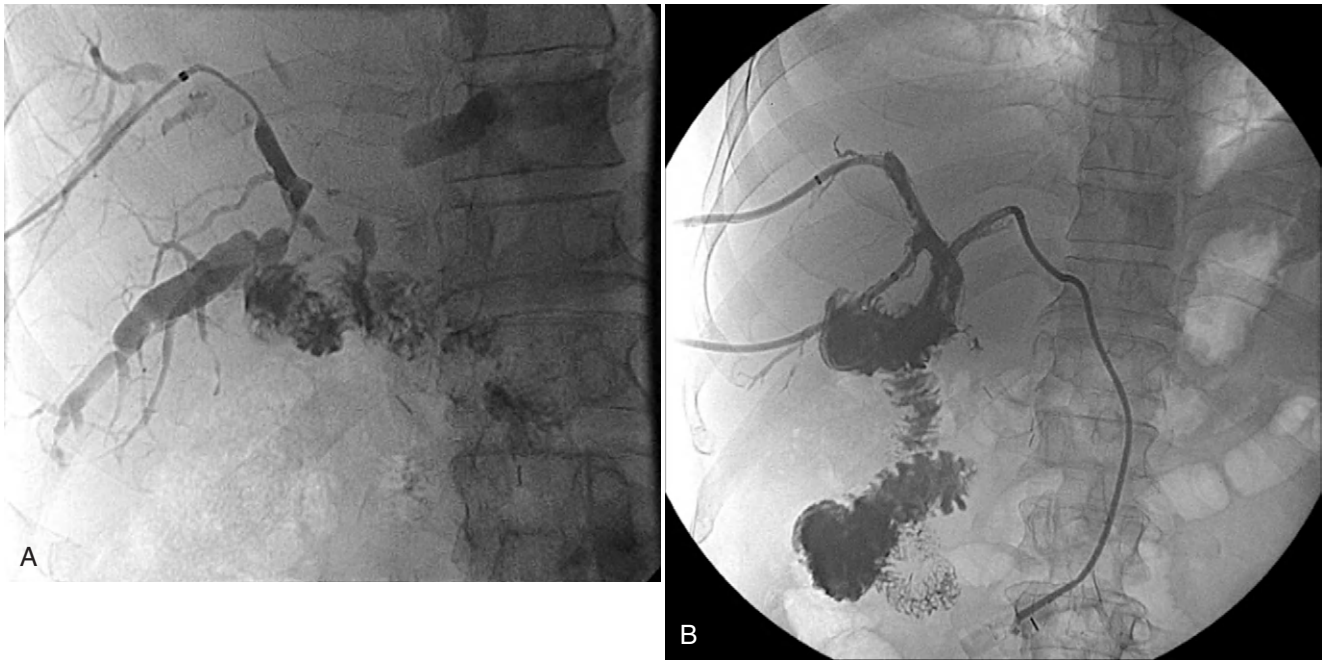

FIGURE 63B.7. Obstructive jaundice after a palliative pylorus-preserving pancreaticoduodenectomy. **A,** Stenosis occurred secondary to recurrence at the bifurcation. **B,** Palliative treatment was given for another 4 months by a percutaneous Wallstent and three percutaneous drainage catheters. Eventually the patient died as a result of recurrent cholangitis.

Hopkins (Fleiser, 2007) showed similar overall survival of the combined resection, compared with palliative bypass alone, but increased morbidity and hospital stay.

It can be concluded that controversy remains regarding the role of pancreatic resection for palliation. The available data confirm that, in the case of questionable radical resectability, a resection will offer relatively good palliation and longer survival compared with chemoradiotherapy, so a more aggressive approach can be advocated in patients whose tumor resectability is doubtful. R2 resections should only be performed in a highly select patient group and after passing the point of no return because no data prove a survival benefit. In addition, no data support resection in patients who are found to have liver metastasis at the preoperative diagnostic workup.

LAPAROSCOPIC PALLIATION

Diagnostic laparoscopy has been frequently used in the diagnostic workup for patients with suspected pancreatic tumors. The use of diagnostic laparoscopy also facilitated the introduction of the minimally invasive approach for subsequent palliation if metastases or local ingrowth of tumors is found. The procedures include palliation of obstructive jaundice by cholecystojejunostomy or choledochojejunostomy and palliation of GOO by gastroenterostomy.

Although a cholecystojejunostomy as a biliary bypass is considered to be less suitable because of the higher incidence of recurrent jaundice, this strategy is easier and safer compared with a hepaticojejunostomy (see Chapter 29). To prevent short-term obstruction of the cholecystojejunostomy, the tumor status in relation to the cystic junction anatomy always should be assessed by performing cholangiography; otherwise, a laparoscopic common bile duct exploration and bypass is indicated. The available data from five relatively small studies showed that laparoscopic double bypass can be performed safely with acceptable morbidity and low mortality rates (Table 63B.5). The long-term follow-up concerning recurrent jaundice and GOO is highlighted only briefly in these studies, however (Hamade et al, 2005; Kuriansky et al, 2000; Rhodes et al, 1995; Rothlin et al, 1999; Suzuki et al, 2007). As previously mentioned, new endoscopic techniques, including duodenal stenting for GOO (Mittal et al, 2004; Nassif et al, 2003; Wong et al, 2002), should be compared with new, minimally invasive laparoscopic approaches.

Table 63B.5

Result of Combined Laparoscopic Biliary and Gastric Bypass for Advanced Pancreatic Cancer

Reference	No. Patients	Operating Time (min)	Mortality (%)	Morbidity (%)	Hospital Stay (Days)	Survival (Days)

CONCLUSION

Although new treatment modalities for pancreatic cancer are being continuously developed, survival remains poor. Because symptoms develop late in the course of the disease, more than 80% of patients are not eligible for treatment with a curative intent. Survival of patients with unresectable tumors is even worse, and the best efforts must be made in the optimal palliative treatment of these incurable patients. The most common symptoms that must be palliated are obstructive jaundice, GOO, and pain.

To palliate obstructive jaundice, a biliary bypass should be performed in relatively fit patients. Compared with endoscopic biliary stenting, a biliary bypass provides optimal long-term prevention of biliary obstruction, but it is associated with higher initial morbidity. Stents are preferred in patients in whom survival is expected to be relatively short (3 to 6 months). In addition to biliary bypass, gastric bypass should be performed routinely to prevent GOO secondary to tumor ingrowth or compression of the duodenum. Novel techniques for palliation of GOO are being developed, such as endoscopic duodenal stenting. These techniques still must be validated, however.

More than 90% of patients have severe pain during the course of their disease. Initial treatment may be analgesic, but when the disease progresses, this is insufficient. NCPB can be performed percutaneously or during laparotomy. When the tumor is found to be unresectable during exploration, a plexus block is a relatively straightforward procedure. Radiotherapy also can be applied to treat pain, but data are limited. Palliative R1 resections for patients with borderline resectable tumors are generally accepted now as palliative care; however, so far the role for R2 palliative resection and resection for patients with metastatic disease is limited.

CHAPTER 69B

Simple cysts and polycystic liver disease: surgical and nonsurgical management

Olivier Farges and Béatrice Aussilhou

OVERVIEW

Most patients with simple cysts or polycystic liver disease (PCLD) are asymptomatic and require no treatment. When indicated, the aim of treatment in patients with single cysts is to either destroy the epithelial lining of the cyst with sclerotherapy or create a communication between the cyst lumen and the peritoneal cavity by fenestration. In patients with PCLD, treatment aims at promoting the regeneration of noncystic liver (hepatectomy) or at replacing the entire liver (transplantation). For patients with PCLD, the treatment is a major procedure, and medical alternatives are under development.

SINGLE CYSTS

Asymptomatic liver cysts, even when large, need no treatment and do not require surveillance. A small percentage of patients have symptoms related to an increase in the size of cysts (see Chapter 69A). Caution must be exercised when considering whether a simple cyst is symptomatic when it is smaller than 8 cm or when it does not protrude outside of the liver surface. If this is not the case, or if symptoms are vague, ultrasound-guided aspiration of the cyst may be attempted as a therapeutic test. If this does not result in improvement of symptoms, further treatment is not required. When aspiration is effective at relieving symptoms, the cyst is symptomatic. Improvement, however, is transient, as the cyst inevitably recurs after simple aspiration (Saini et al, 1983), and more radical treatment, such as sclerotherapy or fenestration, can be considered.

It is unclear whether treatment is indicated in patients who are asymptomatic but nevertheless have evidence on imaging of compression of the bile ducts, or of portal or hepatic veins, by the cysts. If these anomalies are unilateral—that is, at least one hemiliver has normal biliary drainage and normal inflow and outflow—our opinion is that treatment is not required, as the stenosis is not always reversible (Fig. 69B.1).

Treatment of symptomatic cysts relies on the destruction of the epithelial lining (sclerotherapy) or on the creation of a communication between the cyst and the peritoneal cavity (unroofing, also known as fenestration). Sclerotherapy is performed under ultrasound (US) guidance, whereas unroofing is currently mostly performed by laparoscopy. Hence symptomatic patients today are most likely to undergo a minimally invasive procedure. This should not lead to an extension of the indications because complications, occasionally severe ones, may occur. It is also important to warn patients early on that these treatments aim at transforming a large, symptomatic cyst into a small, asymptomatic one, and that they should not worry if some anomalies persist on imaging after the procedure.

Sclerotherapy

Method

Sclerotherapy aims at destroying the epithelium lining the inner surface of the wall to stop intracystic fluid secretion (see Chapter 28). Under US guidance, the cyst is located and punctured, and a small drainage catheter is introduced by the Seldinger technique. Injection of water-soluble contrast media ensures that no communication with the bile duct exists and that no leak into the peritoneal cavity is present, both of which are contraindications (Tikkakoski et al, 1996).

The most frequently used sclerosing agent is 95% ethanol, as for renal cysts. Minocycline hydrochloride, otherwise used for pleurodesis or, more recently, ethanolamine oleate (Miyamoto et al, 2006; Nakaoka et al, 2009) have been proposed as alternatives. Radiofrequency ablation (RFA) has also been performed, although reports are only anecdotal.

The amount of ethanol injected should be limited because alcohol sclerotherapy is associated with an increase in blood alcohol concentration, peaking 3 to 4 hours after treatment (Yang et al, 2006). As massive ethanol intoxication leading to coma has been reported after injection of 240 mL in a 3500 mL cyst (Wernet et al, 2008), the volume of alcohol should not exceed 100 to 120 mL. To ensure that the sclerosant comes in contact with the entire surface, the patient is rolled in different positions. Alcohol is then aspirated and the catheter removed. The procedure is performed with the patient under light general anesthesia because it is painful.

Several protocols have been designed that differ in the duration of alcohol retention in the cyst (from 10 to 240 minutes) and in the number of sessions (single or multiple) (Larssen et al, 2003; Simonetti et al, 1993; Tikkakoski et al, 1996; Yang et al, 2006). Comparative studies are lacking, but a single study showed that 120- and 240-minute retention times yield comparable results (Yang et al, 2006).

Recently, prolonged catheter drainage with negative pressure of the cyst without sclerotherapy has been shown to be as effective as alcohol injection in a randomized study (Zerem, 2009). This result mainly shows that an important aspect of percutaneous treatments in general is to achieve collapse of the cystic cavity.

Limitations

Although the alcohol injected should not exceed a certain amount, the size of the cyst in itself is not a limitation. Provided the cyst collapses after aspiration, the sclerosant will come into contact with the epithelial lining. It is also possible to repeat the procedure if required.

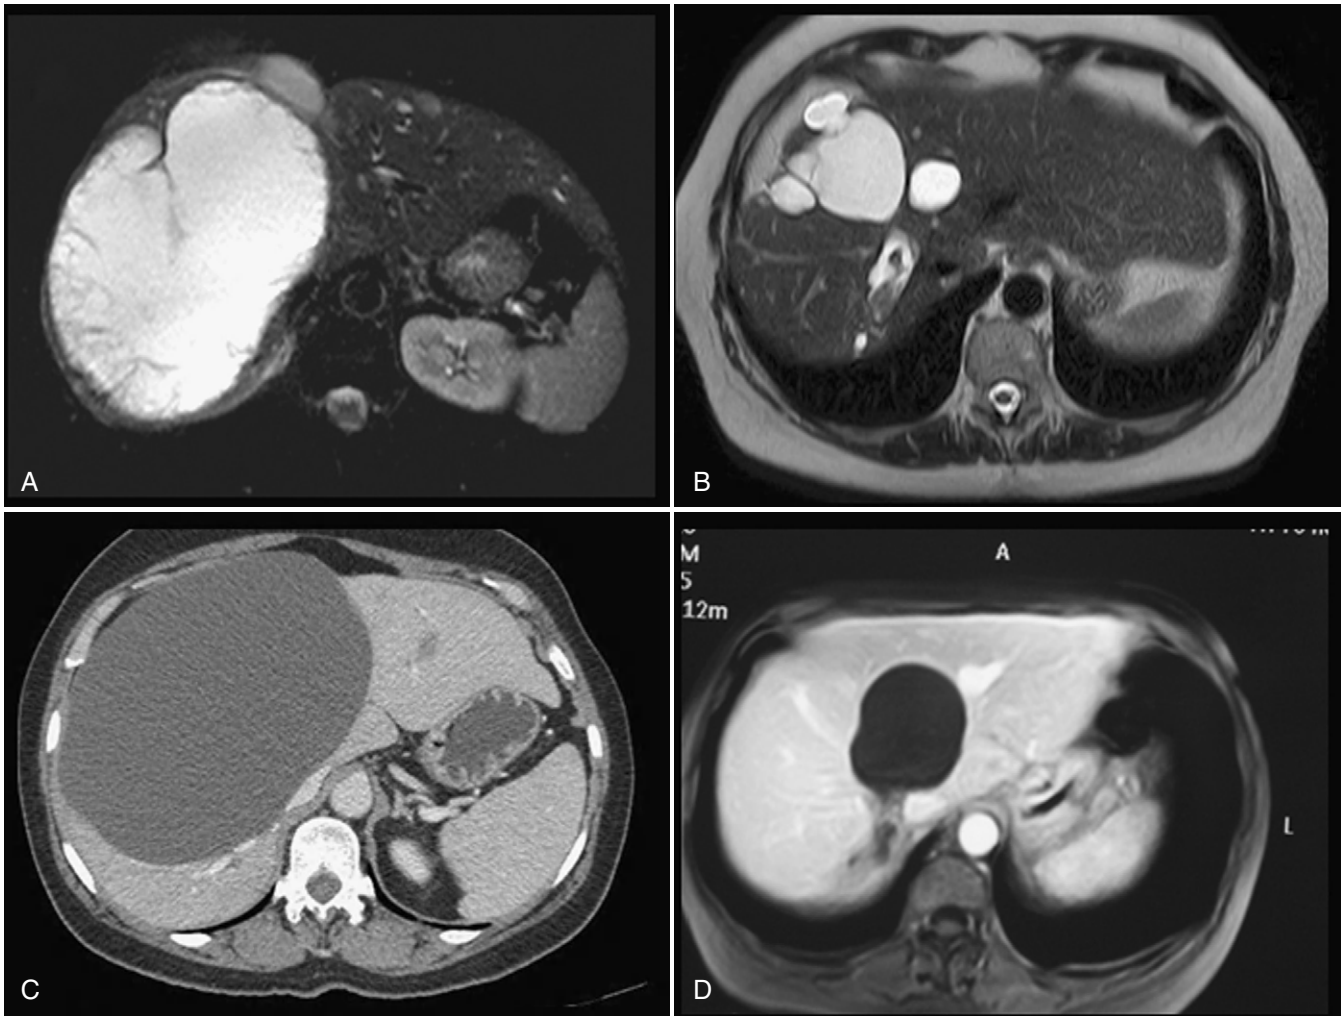

FIGURE 69B.1. Biliary cysts before (**A** and **C**) and after (**B** and **D**) alcohol sclerotherapy. In the first patient (**A** and **B**), vascular pedicles were compressed, and marked atrophy persisted despite reduction in the size of the cyst. In the second patient (**C** and **D**), hepatic vein compression persisted despite size reduction.

An absolute contraindication, which should be formally and completely excluded before the injection, is the presence of a communication between the cyst and the biliary tract. Simple cysts do not normally communicate, but fistulization may occur, presumably by erosion. Recent intracystic bleeding with fresh blood in the cyst is also a contraindication for most physicians; in such cases, sclerotherapy should be delayed.

Complications

Although the injection is painful, pain resolves rapidly and most patients are discharged the following day. Transient neuropsychic disorders secondary to diffusion of alcohol through the cyst wall have been reported. Intracystic bleeding is rare but potentially severe (Fig. 69B.2). It should be realized that vessels are compressed at the periphery of enlarged cysts because of the high intracystic pressure and are therefore not visible; however, bleeding may occur once the cysts have emptied if a vessel has been inadvertently punctured.

Inflammatory changes are frequent after sclerotherapy and may interfere with follow-up. They may also increase the difficulty of subsequent fenestration if sclerotherapy has been ineffective.

Long-Term Outcome

A systematic literature review published in 2001 identified 112 patients treated by alcohol sclerotherapy and 17 treated with minocycline hydrochloride instillation (Moorthy et al, 2001). In most patients, a complete or partial regression of the cyst was seen, but follow-up was short overall. Although the reported experience since then has been limited, the efficacy has been confirmed, with a symptomatic recurrence rate requiring additional treatment of less than 5% (Erdogan et al, 2007).

An early morphologic assessment, usually by US, is frequently performed. However, patients should be warned that this is likely to show the persistence of the cyst, although at a smaller size; this is not predictive of symptomatic recurrence. In practice, several months—perhaps up to a year—may be required to achieve optimal efficacy after alcohol sclerotherapy (Fig. 69B.3).

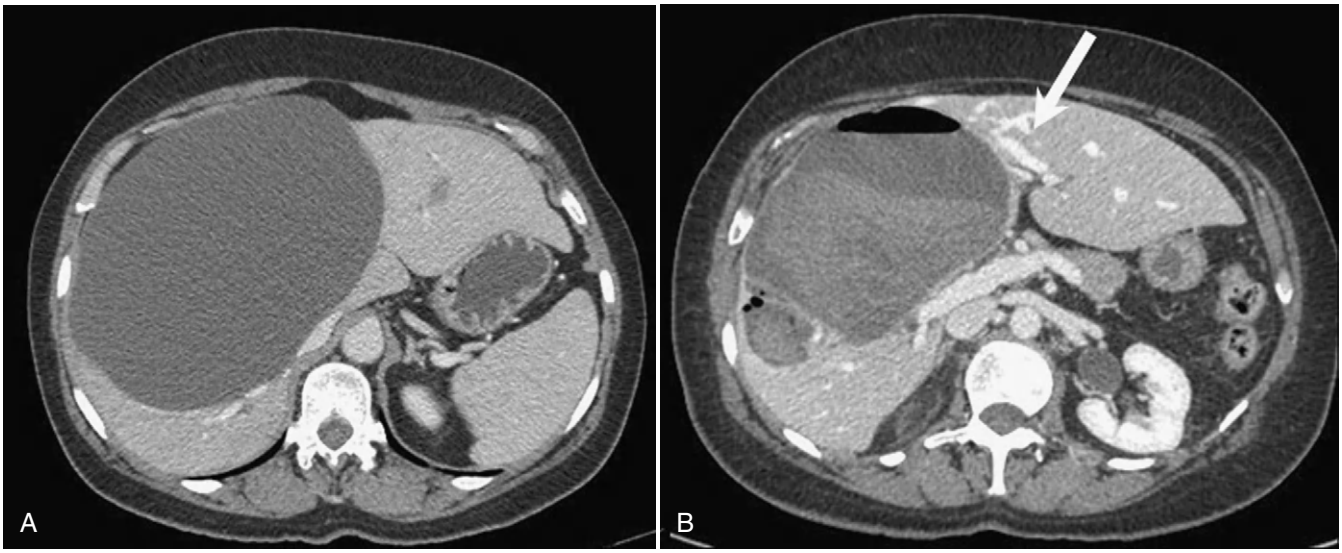

FIGURE 69B.2. Biliary cyst before (**A**) and after (**B**) sclerotherapy by ethanol. Sclerotherapy was complicated by hemorrhage (dense content). Note the presence of hepatic vein collateral circulation adjacent to the cyst that could have been inadvertently injured during sclerotherapy (*arrow*).

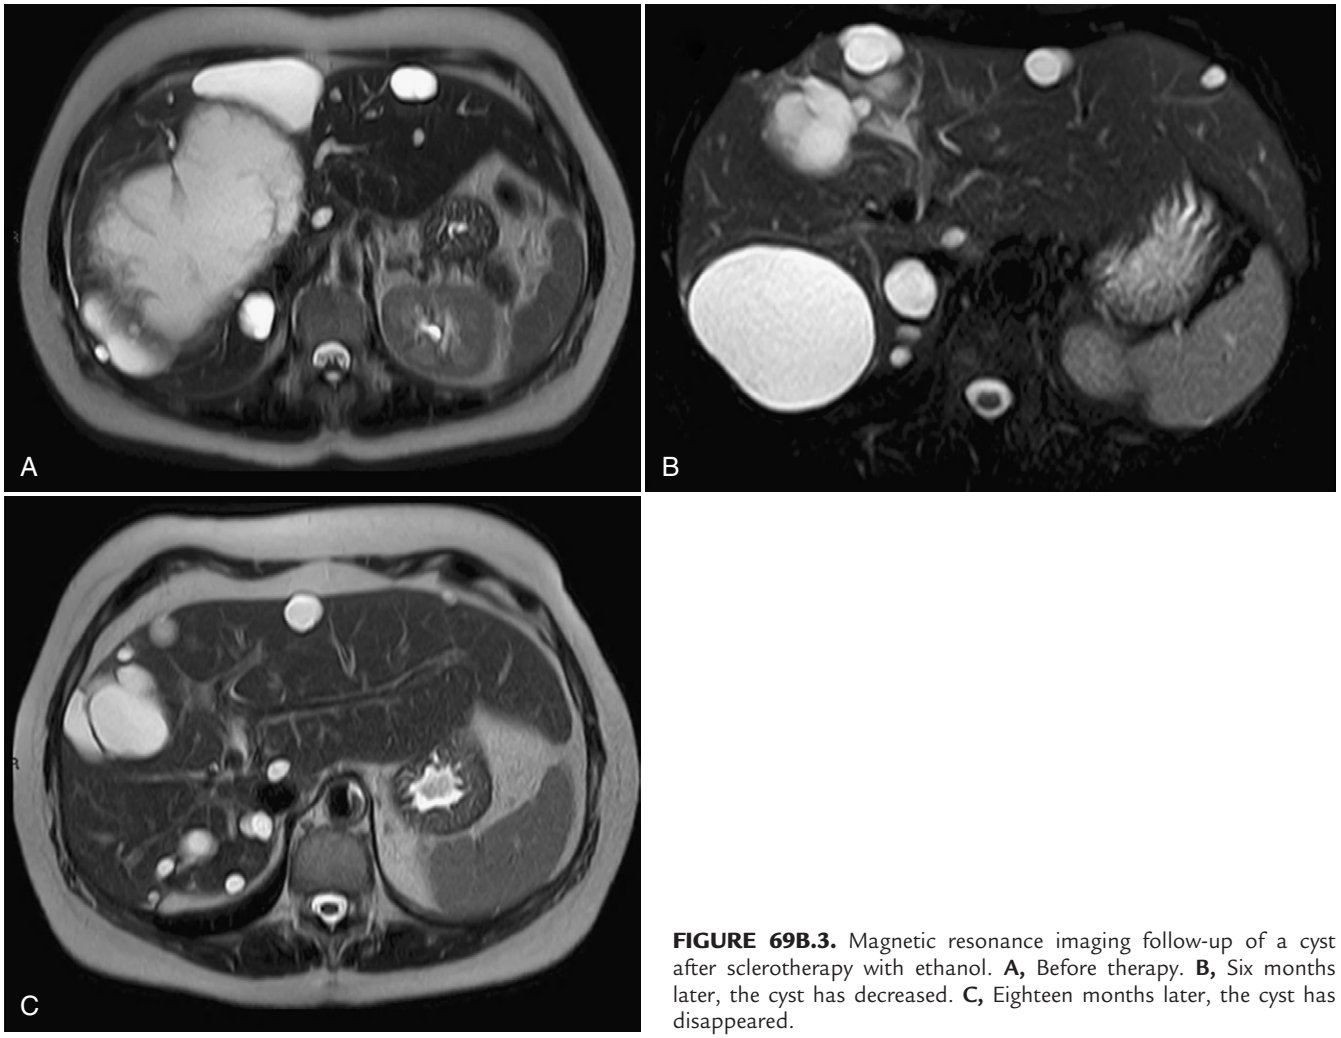

FIGURE 69B.3. Magnetic resonance imaging follow-up of a cyst after sclerotherapy with ethanol. **A,** Before therapy. **B,** Six months later, the cyst has decreased. **C,** Eighteen months later, the cyst has disappeared.

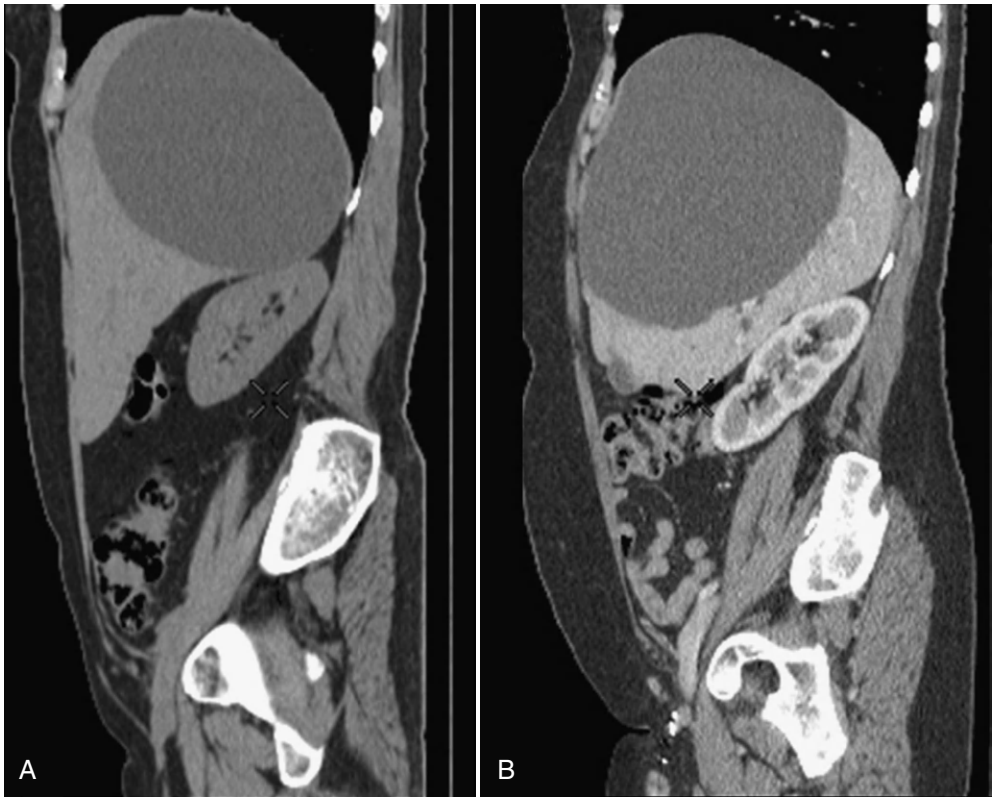

FIGURE 69B.4. Two examples of large cysts located in the right liver (transverse view). A cyst with a predominantly posterior development (**A**) may be more difficult to fenestrate by laparoscopy than an anterior cyst (**B**), and sclerotherapy may be more successful.

Fenestration

Method

The surgical treatment of choice for a single, large, symptomatic cyst is fenestration that consists of an excision of the roof of the cyst to establish a large communication between the cyst and the peritoneal cavity. Fluid continues to be produced by the epithelial lining, but it is reabsorbed by the peritoneum and the cyst cavity collapses. This treatment is extremely simple because symptomatic cysts are virtually always large and have a protrusion of part of their wall outside the liver. Only the protruding part of the cyst wall should be excised; there is no need to enter the liver parenchyma, which is the main cause of intraoperative and postoperative bleeding of biliary leaks, nor is there a need to remove the cyst completely.

The procedure has been described by laparotomy but is currently most often performed by laparoscopy, which offers the advantage of being less invasive and ensuring a quicker recovery. A pneumoperitoneum is established, the cyst is punctured and incised with either scissors or electrocautery, and the cyst wall is widely excised. If transection is performed along a thin part of adjacent parenchyma to ensure a wider opening—that is, if the protruding part of the cyst is small—endovascular staplers may occasionally be used to secure vasculobiliary structures that are compressed at the periphery of the cyst wall. The internal lining of the cyst is examined, and if a biliary communication is suspected, intraoperative cholangiography should be performed. Some investigators have advocated treating the remnant cyst epithelium by argon laser beam coagulation or electrocoagulation to destroy the epithelium. In any case, the excised portion of the cyst is sent for pathologic analysis. Suction drainage is optional.

Limitations

Cysts protruding into segments VII or VIII are not formal contraindications to laparoscopic fenestration, but the procedure is unlikely to be very successful in such a case because limited access will prevent wide unroofing. In addition, the margins of the opening may adhere to the diaphragm, and the risk of cyst recurrence is increased as a result of contained secretion (Fig. 69B.4). Open fenestration is a wise alternative in this circumstance.

Complications

The most severe intraoperative complication is bleeding, and transfusion has occasionally been required (Loehe et al, 2010). This occurs when the liver parenchyma, not the cyst wall, is opened. Conversion, the most frequent indication for which is bleeding, is required in less than 5% of patients.

Postoperative complications are rare, and patients are usually discharged after 1 to 3 days. No deaths have been reported, and morbidity ranges between 0% and 15% (Gall et al, 2009; Loehe et al, 2010). The most severe complications include biliary leak and hemorrhage, which result from reexpansion of biliary and vascular structures that were compressed at the interface between the cyst wall and the parenchyma and that were inadequately secured. If the periphery of the opened cyst is thick, it should be closed with running sutures; an alternative is to use an endovascular stapler on these portions of the cyst wall because it allows wide fenestration while maintaining hemostasis. Ascites is very rare after fenestration of simple cysts, unlike PCLD (see below).

Long-Term Outcome

Long-term efficacy of fenestration for simple cysts is still somewhat unclear. Reported experience is limited, follow-up is usually short, and results are not always stratified according to the number of cysts (i.e., simple cysts vs. PCLD). Furthermore, cyst recurrence, symptomatic recurrence, and the need for additional treatment are not always distinguished. It is usually assumed that although cysts may recur in one third to one half of patients, symptomatic recurrence occurs in less than 5% (Hansman et al, 2001; Morino et al, 1994; Tan et al, 2005); however, higher figures of symptomatic recurrence (15% to 20%) have been reported (Erdogan et al, 2007; Gall et al, 2009; Martin et al, 1998).

A more precise comparison of preoperative and postoperative symptoms has recently been published (Loehe et al, 2010). Abdominal pain was improved in 91% of patients and disappeared in 68%. Other symptoms—including impaired gastrointestinal transport, early satiety, nausea, vomiting, and acid reflux—disappeared in 53% of the patients. Overall, within 1 year of surgery, 32% of the patients developed or had persistent subjective symptoms in this series, but this rate decreased to 7% and 2% after 3 and 5 years, respectively. During follow-up, 9% required reoperation.

Persistent symptoms may be related to technical failure or reflect inaccurate selection, with some patients undergoing surgery for non–cyst-related symptoms (see Chapter 69A).

Sclerotherapy Versus Fenestration

Although both techniques have been used for years, no randomized or prospective comparative analysis has been done. As a rule, the severity of symptoms that leads to treatment has not been standardized, and recurrence is poorly defined. It would seem that both methods are almost as effective (Erdogan et al, 2007; Furuta et al, 1990; Moorthy et al, 2001). Our policy is to systematically attempt sclerotherapy first; fenestration is indicated in cases of recurrence, but location of the protruding part of the cyst may influence this choice (see Fig. 69B.4).

POLYCYSTIC LIVER DISEASE

Symptoms in PCLD are related mainly to the volume of the entire liver rather than to the volume of a specific cyst. Although palliation with percutaneous alcohol sclerotherapy or laparoscopic fenestration has been reported, neither proves effective in the long term in the most frequent forms of PCLD (Robinson et al, 2005). The aim of treatment is instead to decompress and reduce the size of the entire liver or to remove as many cysts as possible. In highly symptomatic patients, these objectives can be achieved by open fenestration, liver resection, or liver transplantation. Patients should be carefully informed of the limitations and risks of these procedures. Medical alternatives have been recently introduced, although larger studies are required to confirm their clinical impact.

Nonsurgical Treatments

Medical Treatment

AVOIDANCE OF ESTROGEN REPLACEMENT THERAPY. Avoidance of estrogen replacement therapy (ERT) would seem logical as medical treatment for PCLD because hepatic cystic disease may worsen under the influence of hormones of pregnancy or exogenous female steroid hormones (Shrestha et al, 1997). However, proof that avoidance is effective is lacking, and the benefits and drawbacks should be discussed on an individual basis.

SOMATOSTATIN ANALOGUES. Cyclic adenosine monophosphate (cAMP) is a potent mediator of cholangiocyte proliferation and secretion of fluid into cysts (see Chapter 69A). Somatostatin receptors are expressed on cholangiocytes; when triggered, this activates a signaling cascade that suppresses cAMP. Somatostatin blunts hepatic cyst expansion by blocking secretin-induced cAMP generation (Masyuk et al, 2007). It also suppresses the expression of insulin-like growth factor 1 (IGF-1), vascular endothelial growth factor (VEGF), and other cystogenic growth factors and downstream signaling from their receptors (Pyronnet et al, 2008). Two randomized controlled trials have recently demonstrated that 6 or 12 months of treatment with lanreotide, a long-acting somatostatin analogue, was associated with a significant reduction of liver volume in patients with PCLD, with or without autosomal dominant polycystic kidney disease (ADPKD), compared with placebo-treated controls (Hogan et al, 2010; van Keimpema et al, 2009). This was especially the case in patients with larger livers; however, this decrease in volume was limited overall, on average 3% to 5%. Severity of abdominal symptoms was not improved (Van Keimpema et al, 2009), although some features of quality of life scores were.

MTOR INHIBITORS. Although mTOR-mediated signaling has been shown to play a role in cyst expansion (see Chapter 69A), sirolimus inhibits this pathway and promotes apoptosis. Follow-up of transplant recipients with ADPKD whose immunosuppression contained sirolimus has shown that both the native kidney (Shillingford et al, 2006) and liver volume (Qian et al, 2008) decreased compared with those of patients who received the more classic calcineurin inhibitor immunosuppression. The clinical impact of this size reduction was not assessed. Trials have been lauched in ADPKD patients to halt the progression of kidney disease (Perico et al, 2010), but long-term efficacy and safety studies are required. This treatment should not be used outside these trials.

ARTERIAL EMBOLIZATION. Transcatheter embolization, also known as *renal contraction therapy,* has been advocated in Japan since the mid-1990s for patients with ADPKD (Ubara et al, 2002), and it has been applied to PCLD since the early 2000s (Takei et al, 2007). The rationale is that kidney cysts are supplied by well-developed arteries, but hepatic cysts in ADPKD patients are mostly supplied from hepatic arteries but not from portal veins. Embolization may use microcoils or polyvinyl alcohol particles, ranging in size between 150 and 250 μm, and targets hepatic artery branches supplying the hepatic segments mainly replaced by the cysts (Park et al, 2009;Takei et al, 2007). Considering the extent of the disease and the number of small-branch arteries to occlude, the procedure is demanding. Reported experience is limited, but the largest series includes 30 patients in whom intrahepatic cyst volume was significantly reduced (from $6.667 \pm 2.978\ cm^3$ to $4.625 \pm 2.299\ cm^3$), whereas the volume of hepatic parenchyma increased (Takei et al, 2007). Improvement of symptoms was observed in most patients but required several months to be optimal. No major complications were related except for classic but occasionally severe postembolization syndrome (Takei et al, 2007; Park et al,

2009). Because targeted segments are those that also have an occluded portal flow, it is possible that the procedure acts as a hepatectomy, favoring regeneration of noncystic parenchyma.

Cyst-Targeted Treatments

As a rule, percutaneous sclerotherapy and laparoscopic fenestration are futile in highly symptomatic patients with massive, diffuse involvement of the liver. However, some patients may have one to five large cysts coexisting with a varying number of very small cysts. In these patients, symptoms are related only to the large cysts, which should be treated individually, as if they are a single cyst. The small cysts, which are often located deep in the liver, should not be treated.

PERCUTANEOUS SCLEROTHERAPY. Percutaneous sclerotherapy is usually considered ineffective in patients with PCLD because symptoms are related to the multiplicity of the cysts, which cannot all be targeted. Furthermore, the rigid architecture of the parenchyma, as well as the presence of smaller adjacent cysts, prevents cyst collapse. Symptomatic recurrence requiring additional treatment occurs in most patients (Erdogan et al, 2007); however, a small subset of patients have one or a few strategically located large cysts (>6 cm) that may account for at least part of the symptoms and can be managed as simple cysts (see Fig. 69B.3). The technique and results do not differ from those for simple cysts. Cyst resolution is gradual and may only be optimum within 1 year of therapy.

Fenestration

Technique and Indication

Initially described by Lin and colleagues (1968), the aim of fenestration is to unroof as many cysts as possible, starting with superficial cysts and proceeding stepwise to the deeper cysts. Open fenestration was historically the standard therapy, but a laparoscopic approach has also been used recently; with few exceptions, this does not allow sufficient and safe access to the deeper cysts and, as a rule, a laparoscopic approach is contraindicated (Kabbej et al, 1996; Morino et al, 1994). The exceptions are patients with a limited number of large and superficial cysts that can be individually treated as single cysts (Fig. 69B.5).

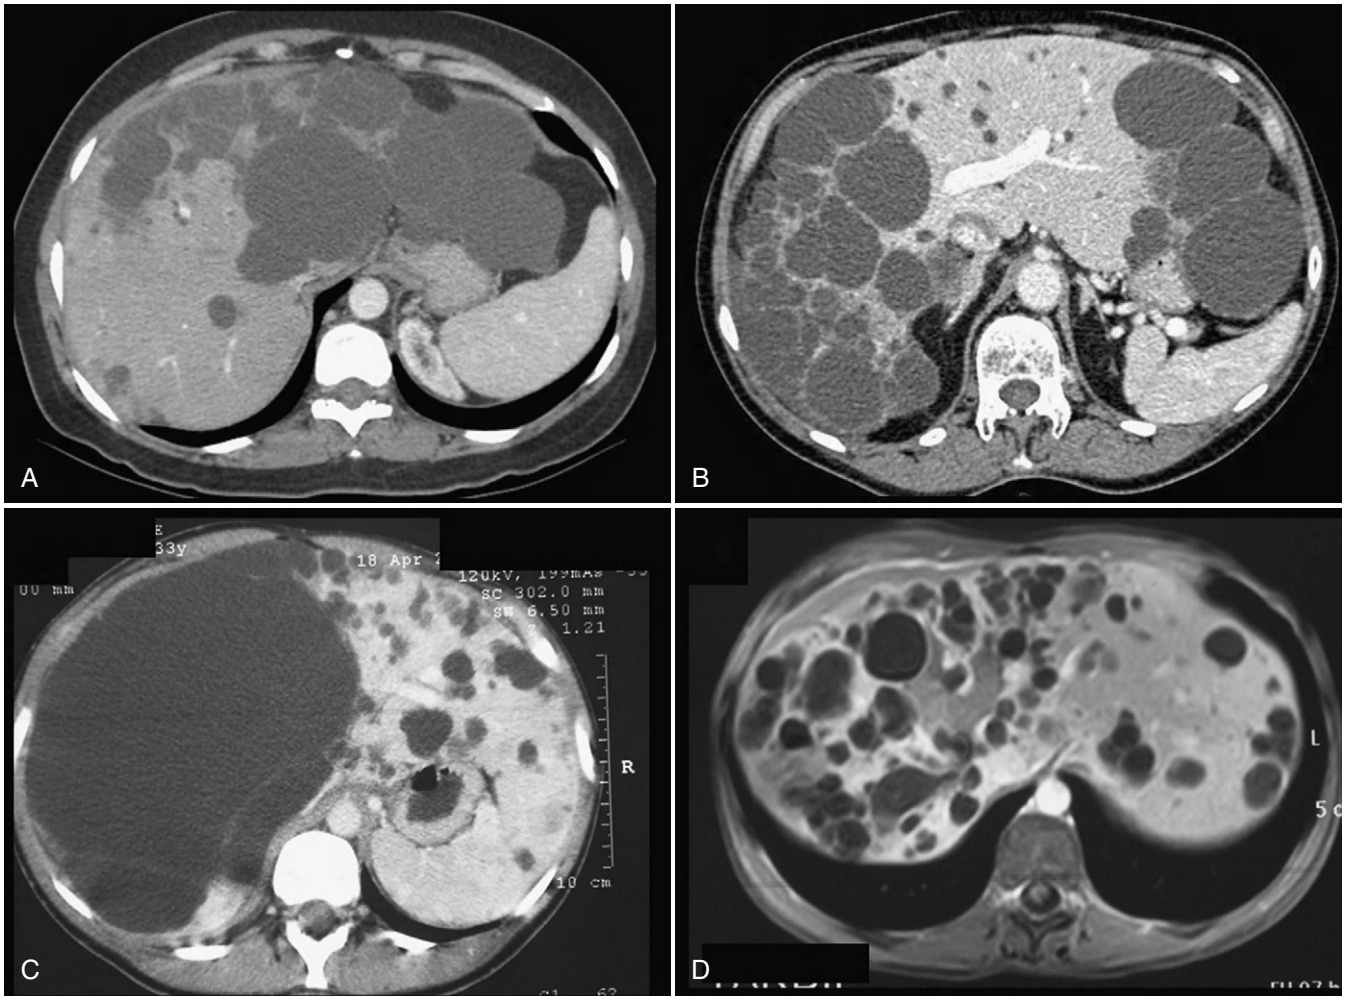

FIGURE 69B.5. Examples of patients with polycystic liver disease but with limited cyst involvement, in whom laparoscopic fenestration of the cysts could be considered. **A,** Cysts are mainly located in the left lateral section. **B,** Fenestration of the cysts in the left lateral section is likely to be effective, whereas fenestration of those in the right liver is not because the cysts are small and deeply located. **C** and **D,** The same patient before and after fenestration of a large cyst in the right liver. Note that the large cysts collapses, small cysts remain, and the obstruction of the termination of the hepatic vein persists, which can account for some persisting symptoms of congestion.

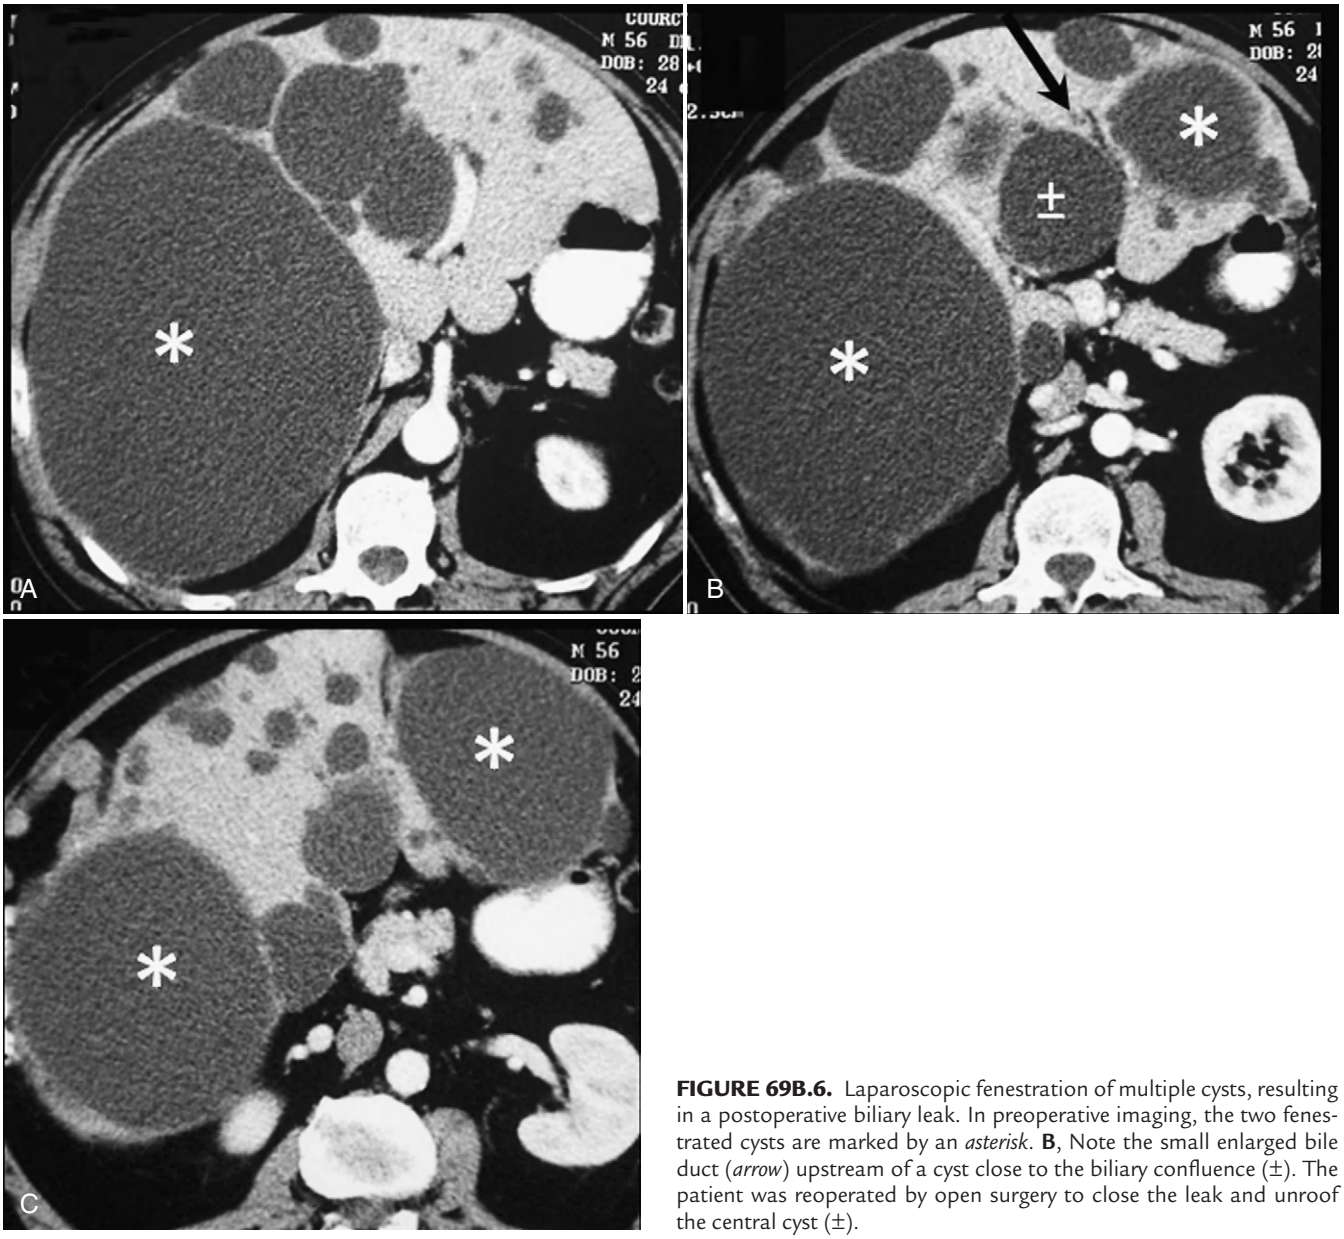

FIGURE 69B.6. Laparoscopic fenestration of multiple cysts, resulting in a postoperative biliary leak. In preoperative imaging, the two fenestrated cysts are marked by an *asterisk*. **B**, Note the small enlarged bile duct (*arrow*) upstream of a cyst close to the biliary confluence (±). The patient was reoperated by open surgery to close the leak and unroof the central cyst (±).

Complications

The main intraoperative hazard is inadvertent injury of vascular structures that are compressed at the periphery of the cysts. What looks like a simple membrane between two cysts may in fact be a large hepatic vein; therefore it may be wise to puncture it with a fine needle before widely opening it. Hemorrhage from hepatic vein injury can be massive in patients with PCLD because the termination of the hepatic vein is frequently compressed by cysts, resulting in outflow obstruction. Biliary injury may also occur when cysts located around the biliary confluence are approached. As for hepatic veins, the biliary confluence may be compressed between adjacent cysts, thus becoming unrecognizable. Most complications occur when deeper, localized cysts are treated.

Fenestration for PCLD is associated with a higher incidence of postoperative biliary leak compared with fenestration for simple cysts. This occurs particularly when cysts are left untreated around the biliary confluence (Fig. 69B.6). Performing intraoperative cholangiography to ensure that biliary drainage of both hemilivers is normal at the end of the procedure is advisable.

Postoperative ascites is also a frequent complication. It may result in delayed wound healing or in ascites superinfection. The mechanism is probably multifactorial and includes persistent secretion by the epithelial lining, relative outflow obstruction, or impaired kidney function.

Mortality, although at low rates, has been reported, and morbidity averages 31% (Table 69B.1).

Outcome

The incidence of symptomatic recurrence overall is 35% (see Table 69B.1). Results are largely influenced by morphologic aspects of the disease.

PCLD, polycystic liver disease; NA, not available

HEPATECTOMY

Partial liver resection has been proposed, in combination with fenestration of the remnant liver, to reduce liver volume and increase regeneration of the noncystic liver (Que et al, 1995). This is made possible by the frequently asymmetric distribution of the cysts, with some areas being relatively spared (Fig. 69B.7). Regeneration is associated with expansion of these areas, whereas the volume of the remaining small cysts remains unchanged or progresses very slowly. Although this technique is highly successful in some patients, it is technically demanding, associated with a high morbidity rate, and its indications are becoming more selective and restrictive.

Technique

The site and extent of resection are dictated by the location of the cysts, and surgery aims at removing as much cystic liver as possible. Care should be taken, however, to leave a sufficient amount of functional remnant liver. In particular, evidence of congestion related to outflow obstruction should be ruled out. This can be done on imaging by carefully analyzing the termination of the hepatic veins after reconstruction and looking for a collateral circulation between hepatic veins, usually running close to the liver surface. A biopsy may also be useful, although the interpretation of results is not standardized.

The liver resection is most often a left lateral sectionectomy, a left hepatectomy, or a right hepatectomy. The main hazard is injury of the hepatic vein or of the biliary confluence, a danger compounded by the fact that the usual landmarks are displaced by the cysts and are hardly recognizable. Intraoperative US is of little help because vascular and biliary structures are compressed, and the presence of cysts interferes with visualization. Extensive fenestration of the larger cysts is performed first to decompress the liver, gain access to its dome, and mobilize the right or left triangular ligaments. Transection is performed either in the noncystic parenchyma or proceeding stepwise between the cystic cavities. When approaching the biliary confluence, the surgeon should always bear in mind that glissonian pedicles are compressed between the cysts, and that no cyst wall should be cut before being sure that this is not the case. The same holds true for the hepatic veins close to their termination.

After hepatectomy, the remnant liver is widely fenestrated (see Fig. 69B.7). Intraoperative cholangiography may be advisable to ensure that no bile duct injury has occurred and that bile drains freely (i.e., that a deeply situated cyst does not compress the remnant right or left duct). Considering the high rate of biliary leak, a leakage test should also be performed; it is also wise to place running sutures along the transected cyst walls. After right-sided resections, care should be taken to secure the remnant liver in a stable position, resulting in adequate venous outflow. A suction drain is frequently left in the abdomen.

Morbidity and Mortality

Hepatectomy for PCLD, although a benign disease, is a demanding procedure with a definite risk of mortality and high morbidity rates, even when performed by highly experienced

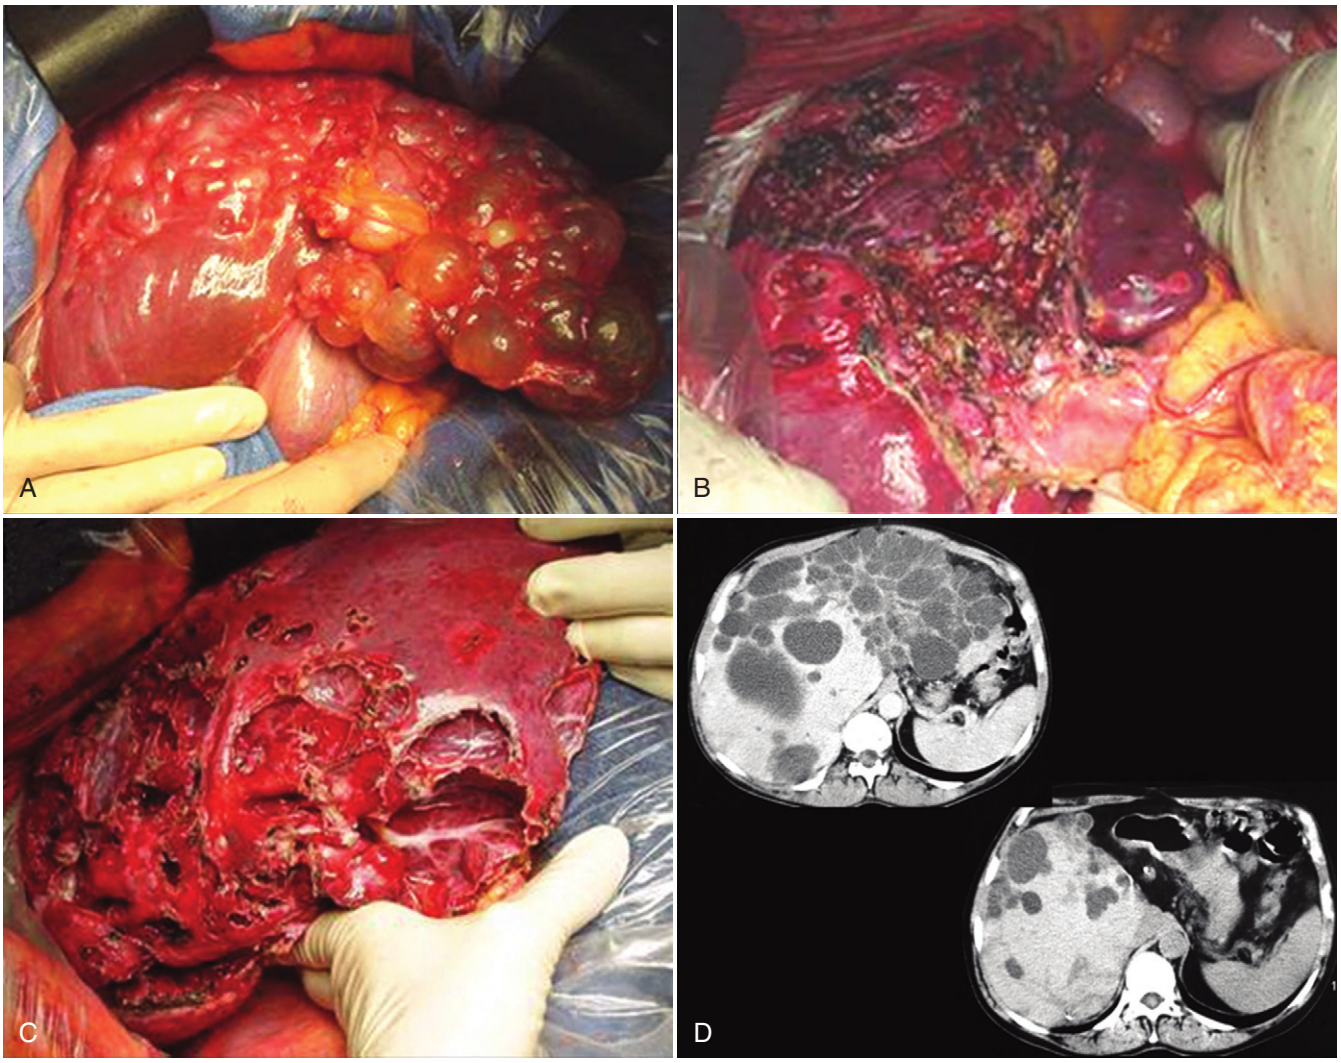

FIGURE 69B.7. Principle of liver resection for polycystic liver disease. **A,** The liver is massively enlarged, but some areas of noncystic liver remain. **B,** An extended left hepatectomy is performed. **C,** The remaining right liver is widely fenestrated. **D,** Preoperative and postoperative computed tomographic scan shows an expansion of the noncystic liver.

hepatopancreatobiliary surgeons. The main intraoperative risk is that of bleeding; and perioperative transfusions are required in 50% to 80% of the patients. Injury to the main bile duct within the liver remnant occurs in 5% (Aussilhou et al, 2010; Schnelldorfer et al, 2009).

Mortality rates in the literature average 4% (Table 69B.2) and has been related to abdominal sepsis, acute Budd-Chiari syndrome, and complications related to treatment of complications. Intracranial hemorrhage from ruptured aneurysms have also been described (see Chapter 69A).

Morbidity rates average 64% (see Table 69B.2), but some consider that it is virtually constant. The most frequent complications are ascites and pleural effusion, and the mechanism is likely the same as for fenestration: persistent fluid secretion by the remnant epithelial lining and relative outflow obstruction. However, increased portal pressure and lymphatic leakage associated with liver resection increase this risk. Furthermore, patients undergoing liver resection, rather than fenestration tend to have more severe PCLD with malnutrition. Although ascites resolves in most patients within 1 month, some have required stenting of the inferior vena cava or hepatic veins to resolve outflow obstruction (Grams et al, 2007; Schnelldorfer et al, 2009). The next most frequent complications are hemorrhage and biliary leak; approximately 10% of patients require reoperation for management of these. In contrast, liver failure is infrequent. Hepatectomy is usually not performed in patients with severe kidney failure. In those with moderate impairment, although a slight transient deterioration of kidney function may be observed, most patients have recovered their preoperative creatinine levels by the time of discharge.

Preoperative risk factors for complications include kidney dysfunction, ascites, and denutrition (Schnelldorfer et al, 2009). In the presence of these symptoms, liver transplantation is indicated.

Long-Term Outcome

Results are highly variable among series and among patients. This reflects the diversity of the clinical and morphologic situations as well as the extent of resection. The average reduction in hepatic volume achieved ranges between 50% and 75% (Aussilhou et al, 2010; Schnelldorfer et al, 2009), which results

PCLD, polycystic liver disease; NA, not available

in considerable objective and subjective improvement in more than 75% of the patients (Fig. 69B.8). Symptoms may recur because of the enlargement of some cysts that were left untreated, and such patients may benefit from targeted treatments, sclerotherapy in particular. In addition, other recurrences are related to the progressive reexpansion of the entire liver. It has recently been estimated that after 4 years of follow-up, the liver was on average 11% larger than the initial remnant volume after resection (Schnelldorfer et al, 2009). However, half of the patients have stable volumes, a difference that may also reflect the variable natural history of the disease.

TRANSPLANTATION

Because PCLD is a genetic disease, liver transplantation is the only curative treatment (see Chapter 97A). As for any benign disease, there is some reluctance to perform this high-risk procedure for this indication, considering that liver function is preserved. However, some patients with massive liver involvement have incapacitating symptoms that may be life threatening (ascites, denutrition); in this situation, and when liver resection is considered too high risk with little anticipated efficacy, liver transplantation is the only option (Fig. 69B.9). Quality of life is excellent after transplantation despite the need for long-term immunosuppression.

In countries where graft allocation is patient oriented, based on Model for End-Stage Liver Disease (MELD) criteria, exceptions have been implemented because patients with PCLD who do not have liver failure would otherwise have no chance to undergo transplantation (Arrazola et al, 2006).

Technique

Most transplantations have been performed with livers from brain-dead donors, although living donors have also been used (Mekeel et al, 2008). The technique is the same as that for other indications, but, as for hepatectomy, extensive fenestration is required first to gain access to the liver. The inferior vena cava can be preserved, which is important in the context of living donation, but transient clamping may be necessary to achieve this. A transient portocaval shunt is required in most instances because PCLD does not induce portal hypertension with spontaneous portosystemic shunts.

In patients with ADPKD (see Chapter 69A), simultaneous kidney transplantation is not necessary if the glomerular filtration rate is more than 60 mL/min (Martin et al, 2008) but is indicated if it is less than 30 mL/min. For values between 30 and 60 mL/min, single liver transplantation appears safe, provided renal-sparing immunosuppression is used. Secondary kidney transplantation may be required in half of the patients with the drawback of previous immunization through liver transplantation (Jeyarajah et al, 1998; Pirenne et al, 2001; Ueno et al, 2006).

Perioperative Risk

Liver transplant for PCLD is also technically demanding, particularly in patients who have undergone previous procedures. Virtually all patients require an intraoperative transfusion. Reported mortality rate is 16% overall (Table 69B.3) and is mainly related to sepsis. As for other indications of transplantation, perioperative mortality and morbidity, in particular from sepsis, are increased in patients with the most severe forms of the disease. Such severe forms are usually associated with malnutrition (Lang et al, 1997; Pirenne et al, 2001).

Long-Term Outcome

The 5-year survival rate in the registries is 80% to 84%, higher than for most other indications. Quality of life is excellent (Kirchner et al, 2006), and short- and long-term results are the same for liver transplantation as for combined transplantation of liver and kidney.

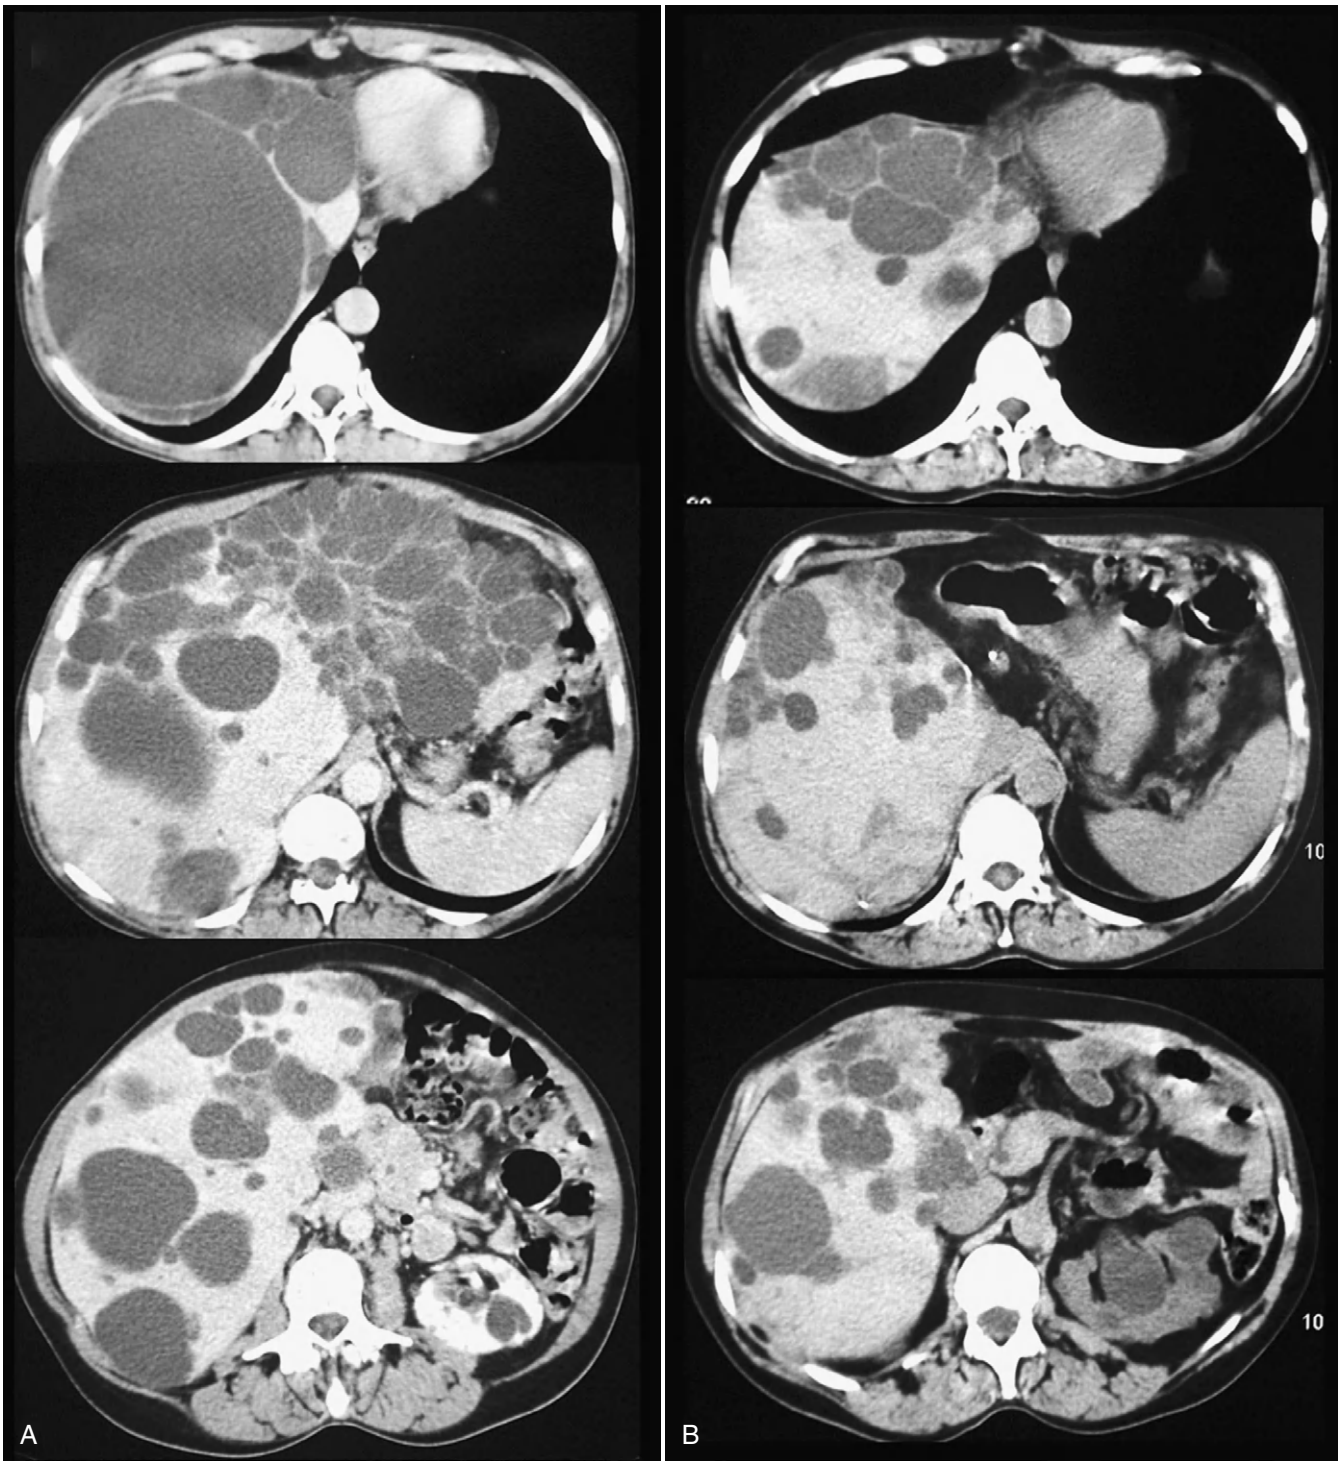

FIGURE 69B.8. Computed tomographic scan in a patient who had undergone left hepatectomy and fenestration of the right liver for polycystic liver disease. **A,** Preoperative view. **B,** View 24 months after surgery.

Choice of Surgical Treatment

PCLD covers a wide range of morphologic and clinical situations (see Chapter 69A), and three classifications have been proposed to help the clinician chose among the various treatment options. One classification was designed to identify under which circumstances fenestration of PCLD is indicated (Gigot et al, 1997). The two others have more recently aimed at defining the limits of resection (Li et al, 2008; Schnelldorfer et al, 2009), but all three classifications overlap to some degree (Fig. 69B.10).

Gigot's classification mainly relies on the number and size of the cysts. Type I is defined by a limited number (<10) of large cysts (>10 cm), in which each cyst can be treated as if it were a simple cyst. Laparoscopic fenestration is indicated in this

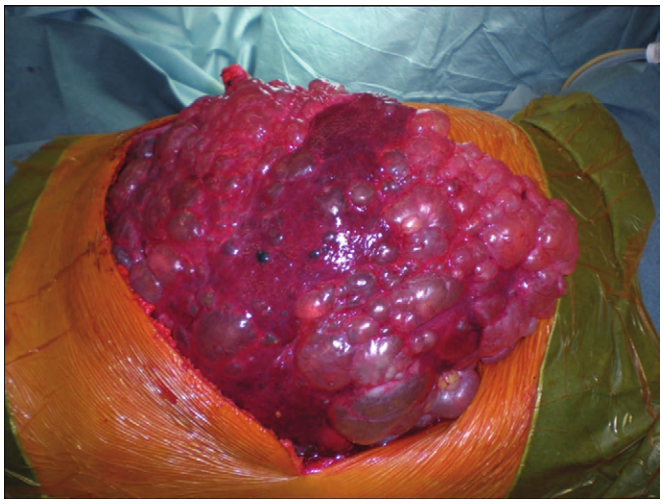

FIGURE 69B.9. Intraoperative view of a patient undergoing liver transplantation for polycystic liver disease. Note that the liver is massively enlarged, and there is hardly any spared area of noncystic liver.

PCLD, polycystic liver disease; LT, liver transplantation; KT, kidney transplantation

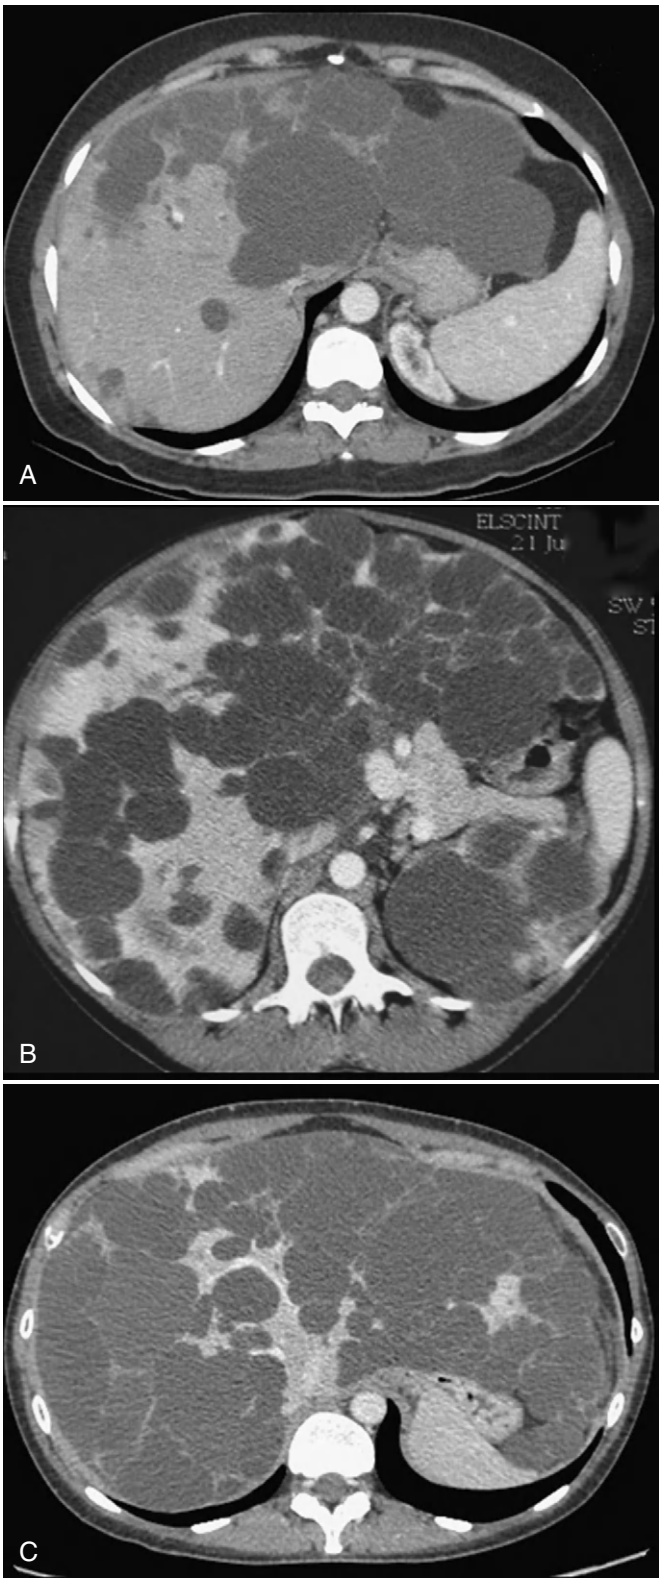

FIGURE 69B.10. Treatment according to severity of polycystic liver disease. **A,** A mild form can be treated by laparoscopic fenestration or hepatectomy. **B,** A moderate form in which fenestration is unlikely to be effective; left hepatectomy can be considered because the future remnant liver is large and has normal inflow and outflow. **C,** A severe form requiring liver transplantation.

situation, but these patients account for less than 10% of PCLD. Type II corresponds to diffuse involvement of liver parenchyma by multiple medium-sized cysts with remaining large areas of noncystic liver parenchyma; some patients with type II disease can benefit from open fenestration. Type III corresponds to the most severe form of adult polycystic liver disease with massive, diffuse involvement of liver parenchyma by small and medium-sized liver cysts, with only a few areas of remaining normal liver parenchyma between cysts; it is not an indication for fenestration.

Li's classification differs in that it also takes into account deeply located cysts that would be left in place in the remnant liver. Types A and B are defined as the presence of less than or more than 15 cysts, respectively. This classification is correlated with the outcome after resection.

Schnelldorfer's classification stratifies patients according to symptoms, number and size of the cysts, volume of relatively normal parenchyma, and whether this spared parenchyma has a normal vascular inflow and outflow. Fenestration is indicated in patients with moderate symptoms resulting from a limited number of large cysts, preserving more than two sectors with adequate inflow and outflow. Hepatectomy is indicated when symptoms are more severe and disease is more extensive, as long as the future remnant liver corresponds to more than one sector with normal vascularization. Highly symptomatic patients with insufficient remnant parenchyma in terms of volume of vascularization should undergo transplantation; patients with ascites or denutrition should undergo transplantation and not resection.

Although the natural history of PCLD is highly variable among patients, progression is fairly linear for any given patient (see Chapter 69A). Therefore age at the time of diagnosis, first symptoms, incapacitating symptoms, and kidney involvement are useful markers to predict the future need for transplantation. When transplantation will likely be indicated at some stage of the disease, fenestration and resection should be considered with caution to avoid increasing the risks of transplantation.

CONCLUSION

Treatment is only indicated when symptoms related to cysts are present. Single large cysts can be equally treated by sclerotherapy or laparoscopic fenestration. In patients with symptoms related to a limited number of large cysts, fenestration is the treatment of choice. In PCLD patients whose symptoms cannot be linked to one or a few large cysts, treatment may range from observation to transplantation, depending on the severity of symptoms and whether areas of noncystic parenchyma can be preserved. Liver resection, and to some extent fenestration, should be avoided if liver transplantation is anticipated, considering the likelihood of cyst progression and the added complexity of the liver transplant procedure, if prior cyst fenestration or resection has been performed.

CHAPTER 70B

Nonhepatic surgery in the cirrhotic patient

Amelia J. Hessheimer, Truman M. Earl, and William C. Chapman

OVERVIEW

Chronic liver disease and cirrhosis were the twelfth leading cause of death in the United States and resulted in more than 30,000 deaths in 2009 (Kochanek et al, 2011). Chronic viral infection and alcohol abuse account for the majority of the disease burden globally, but the incidence of obesity-associated nonalcoholic fatty liver disease accounts for an ever-increasing proportion of cases, especially in Western societies. Furthermore, clinicians continue to gain knowledge and skills to care for patients with cirrhosis in the end stages of their disease. These facts explain why a significant increase has been seen in the number of patients with comorbid liver disease and cirrhosis encountered in both general and specialty surgical practice.

Cirrhosis can have dramatic effects on multiple organ systems, making surgery on the cirrhotic patient a complex and difficult undertaking. A recent, large, population-based study demonstrated that people with cirrhosis, in particular those with portal hypertension, have significantly worse outcomes after elective operations than those without (Fig. 70B.1; Csikesz et al, 2009). The mere act of opening the abdominal wall in a cirrhotic patient with portal hypertension causes collateral blood vessels to dilate and may lead to systemic hypotension and hepatic decompensation secondary to ischemia (Haskal et al, 1994; Norton et al, 2003).

Extrahepatic surgery in the cirrhotic patient may be a formidable undertaking. The objective of this chapter is to provide practical knowledge on how to evaluate these patients before surgery as well as current information on some of the most commonly performed procedures in this unique population.

EVALUATION AND STRATIFICATION OF LIVER DISEASE

The decision regarding whether a cirrhotic patient is medically fit to undergo an operation can be difficult to make. Many factors must be considered, but the most important are the magnitude and necessity of the proposed operation, the nonhepatic comorbidities of the patient, and the severity of the liver disease. Numerous factors have been correlated with poor outcome in patients with cirrhosis—including low albumin levels, blood transfusion requirements, abnormal coagulation, and ascites—and various scoring systems to gauge these have evolved. The first, most widely used scoring system is the Child-Turcotte-Pugh (CTP) system, which incorporates several objective and subjective variables to stratify severity of liver disease. Historically, patients with CTP scores of A, B, or C have been shown to have operative mortality rates of 10%, 30%, and 80%, respectively (Garrison et al, 1984; Mansour et al, 1997).

The Model for End-Stage Liver Disease (MELD) score was developed to predict death after transjugular intrahepatic portosystemic shunt (TIPS) in an effort to determine who was likely to progress toward needing liver transplantation. In an effort to improve on the tripartite CTP system, researchers have recently evaluated to ability of MELD to predict morbidity and death after nonshunt abdominal surgery (Befeler et al, 2005; Farnsworth et al, 2004). As with CTP, MELD correlates with risk of postoperative death (Figs. 70B.1 and 70B.3). Several reports have found that MELD is superior to CTP in predicting postoperative problems, although these improvements generally are modest (Perkins et al, 2004). Interestingly, the survival rates from the more recent series indicate a fairly dramatic improvement in survival compared with older series (Fig. 70B.3).

In addition to factors considered in MELD and CTP scoring, other factors have been identified for risk stratification and prediction in cirrhotic patients undergoing major operations. These include elevated creatinine level, chronic obstructive pulmonary disease (COPD), male gender, and an American Society of Anesthesiologists (ASA) class of IV or V (Ziser et al, 1999). Teh and colleagues (2007) demonstrated ASA classification as a useful marker to further stratify the comorbid illness in cirrhotic patients preoperatively. This case-control study of cirrhotic patients who underwent major nontransplant operations identified MELD score, ASA class, and age as predictors of perioperative death. An ASA class of IV was equivalent to the addition of 5.5 MELD points in added risk, and age greater than 70 years was equivalent to three additional MELD points. A single point increase in MELD score was associated with a 15% increase in perioperative death. Emergency surgery predicted in-hospital death, although patients undergoing emergency operations had a higher median MELD score. ASA class V was the strongest predictor of 7-day mortality, and MELD score was the most robust predictor beyond 7 days. The median survival of patients in this series was 4.8 years for a MELD score of 0 to 7, 3.4 years for a score of 8 to 11, 1.6 years for 12 to 15, 64 days for 16 to 20, 23 days for 21 to 25, and 14 days for 26 or greater.

PERIOPERATIVE MANAGEMENT AND OPTIMIZATION

The perioperative management of patients with cirrhosis involves aggressive attempts to control the various manifestations of their underlying disease. Much of this is covered at length in other chapters (see Part 3, Anesthetic Management: Preoperative and Postoperative Care). Nonetheless, a few considerations are worth mentioning here.

Most cirrhotic patients have protein-energy malnutrition, placing them at an increased risk for developing a variety of postoperative complications, such as wound dehiscence,

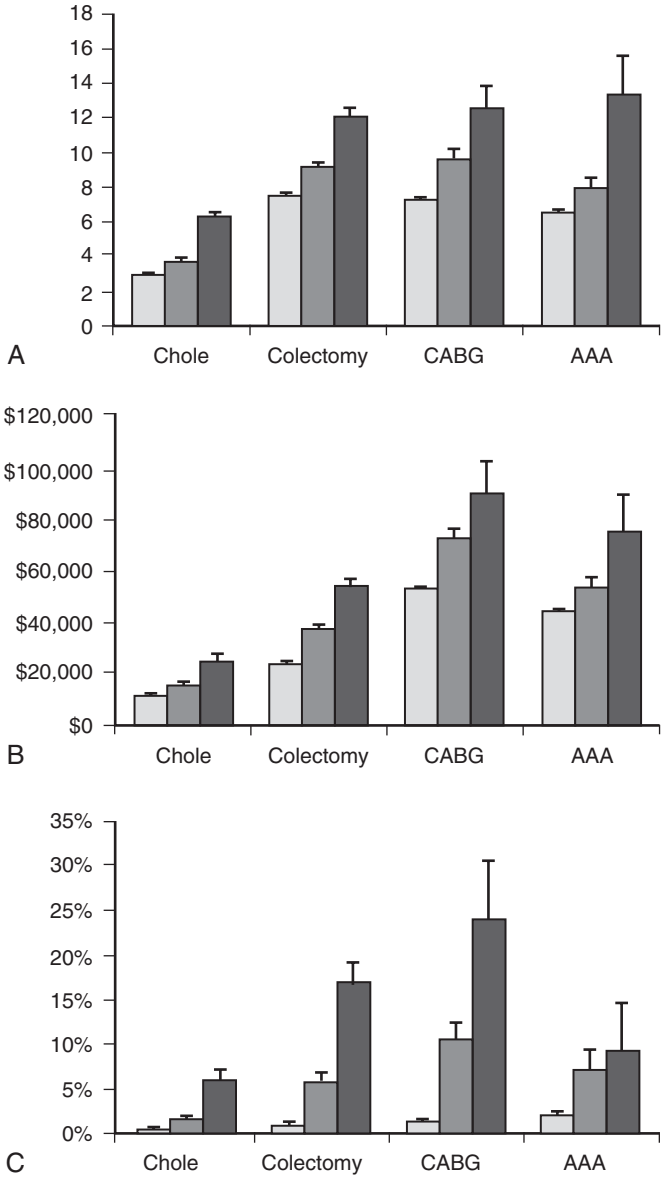

FIGURE 70B.1. Outcomes for patients who underwent four index operations (cholecystectomy [*Chole*], colectomy, coronary artery bypass grafting [*CABG*], and abdominal aortic aneurysm [*AAA*]). **A,** Length of stay. **B,** Total charges. **C,** Mortality rate. Normal, light gray; cirrhosis, medium gray; cirrhosis complicated by portal hypertension, dark gray. *(Modified from Csikesz NG, Nguyen LN, Tseng JF, 2009: Nationwide volume and mortality after elective surgery in cirrhotic patients. FIGURE 70B.2. Perioperative morbidity and mortality rates in a recent series of patients who underwent nonhepatic abdominal surgery. **A,** Stratified by Child-Turcotte-Pugh (*CTP*) class. **B,** Stratified by Model for End-Stage Liver Disease (*MELD*) score. *(Modified from Telem DA, Schiano T, Goldstone R, et al. 2010. Factors that predict outcome of abdominal operations in patients with advanced cirrhosis. Clin Gastroenterol Hepatol 8:451-457.)*

infections, reaccumulation of ascites, and death (Merli et al, 2002). Nutritional status should be evaluated preoperatively; when found to be deficient, efforts should be undertaken to improve it (see Chapter 24). Nasoenteric or parenteral feedings that use low-sodium formulas supplemented with trace elements and branched-chain amino acids are an option for patients who are unable to adequately nourish themselves.

Coagulopathy secondary to impaired hepatic synthesis of clotting factors and decreased vitamin K stores as a result of malnutrition and poor intestinal absorption may be present. Thrombocytopenia is also common in these patients secondary to splenic sequestration and bone marrow suppression. Preoperative transfusions of fresh frozen plasma and platelets lower the risk of bleeding. In the operating room, careful tissue handling and the maintenance of a low central venous pressure are other factors that can help to minimize blood loss (Alkozai et al, 2009). If significant bleeding arises, cryoprecipitate, diamino-8-D-arginine vasopressin, and recombinant factor VIIa are additional options to reverse coagulopathy and control hemorrhage (O'Leary et al, 2009).

In the perioperative period, altered mental status in a cirrhotic patient should be thoroughly evaluated. Only after all other potential causes have been ruled out can hepatic encephalopathy be diagnosed. With the acute onset of encephalopathy, protein intake may be briefly withheld. Lactulose should be administered and titrated for three soft bowel movements a day. Oral antibiotics, such as metronidazole or neomycin, may also be used to decrease the intestinal bacterial load (Muilenburg et al, 2009). Surgery should be postponed if encephalopathy arises preoperatively. Postoperatively, the administration of

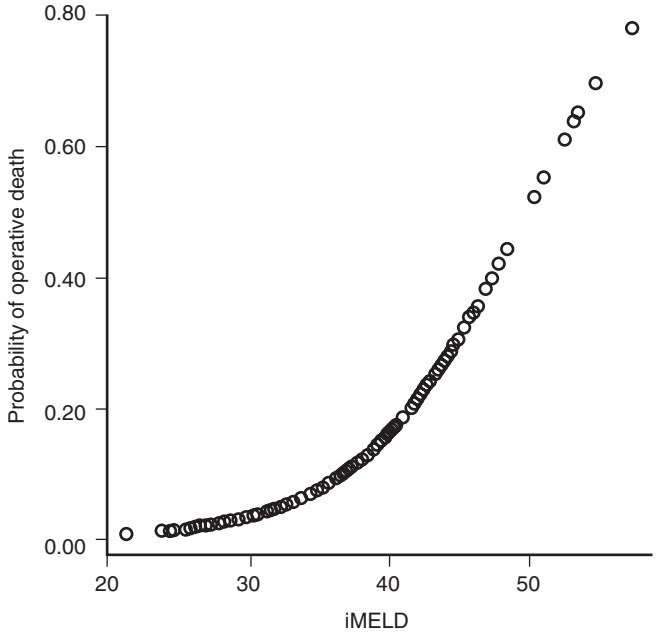

FIGURE 70B.3. Relationship between the predicted probability of operative death and Integrated Model for End-Stage Liver Disease (*iMELD*) in 190 patients with cirrhosis who underwent operation. *(Modified from Costa BP, 2009: Value of MELD and MELD-based indices in surgical risk evaluation of cirrhotic patients: retrospective analysis of 190 cases, World J Surg 33:1711.)*

narcotics and other sedating medications should be kept to a minimum. There is no role for prophylactic lactulose therapy for all cirrhotic patients undergoing surgery (O'Leary et al, 2009).

Perioperative fluid management in cirrhotic patients can be very difficult. Patients with cirrhosis should be adequately resuscitated to avoid hypotension and hepatic ischemia, but fluids should also be given judiciously to minimize the accumulation of ascites postoperatively. One center that performs a large volume of surgery on patients with end-stage liver disease limits the infusion of crystalloid solutions in the perioperative period (Telem et al, 2010b). Instead, all patients with advanced liver disease are placed on a postoperative sodium-poor albumin drip until they are able to resume oral intake.

Ascites increases the risk of postoperative renal failure, infections, and wound dehiscence. Even if ascites is drained at the time of surgery, it rapidly reaccumulates in the postoperative period. Medical therapy, which includes salt restriction and diuretics, is typically considered the first line of treatment. TIPS, however, may be considered a first-line treatment for refractory ascites and may be placed before elective surgery to help control ascites throughout the entire perioperative period (Azoulay et al, 2001; Gines et al, 2004; Schlenker et al, 2009). Moreover, TIPS may also reduce the risk of significant perioperative bleeding. In one of the largest series on the use of TIPS in patients undergoing major extrahepatic surgery, 25 cirrhotic patients with a mean MELD score of 15 ± 7.6 underwent TIPS at a median of 20 days before major abdominal and cardiothoracic operations. Blood transfusions were relatively minimal in the series, with a median of 3 units for abdominal operations (range, 0 to 21) and 4 units for cardiothoracic operations (range, 0 to 20). With a median follow-up of 33 months, actuarial 1-year patient survival was 74%, and the three postoperative deaths in the series occurred in patients with MELD scores higher than 24, all of whom underwent emergent surgery (Kim et al, 2009). Studies that compare outcomes after surgery with preoperative TIPS placement versus those with no TIPS, however, are lacking. Also, the optimal time interval between TIPS placement and elective surgery is unclear, but it is common for a period of several weeks to be required to see a clinical improvement in ascitic volume after TIPS; therefore shunts should probably be placed several weeks prior to planned operations.

SPECIFIC PROCEDURES

Cholecystectomy

The incidence of gallstones in patients with cirrhosis is twice that of the general population as a result of increased intravascular hemolysis and decreased gallbladder motility and emptying (Bouchier, 1969; Conte et al, 1991; Schwesinger et al, 1985). In the 1980s, rates of major morbidity and mortality in patients with cirrhosis undergoing cholecystectomy were as high as 35% and 25%, respectively (Aranha et al, 1982; Cryer et al, 1985; Garrison et al, 1984; Schwartz, 1981). Postoperative death occurred secondary to blood loss, sepsis, and liver failure. Almost invariably, these procedures were performed as open laparotomy. At that time, the presence of cirrhosis was considered a contraindication for the laparoscopic approach, based on the assumption that it would lead to increased rates bleeding and liver failure (Yerdel et al, 1993). However, as greater experience in laparoscopic surgery has been gained, this point of view has changed, and now many studies demonstrate favorable morbidity and minimal to no mortality in patients with early cirrhosis (CTP class A and B) undergoing laparoscopic cholecystectomy (Cucinotta et al, 2003; Fernandes et al, 2000; Ji et al, 2004; Morino et al, 2000; Poggio et al, 2000; Yeh et al, 2002). A recent meta-analysis comparing laparoscopic cholecystectomy in cirrhotic and noncirrhotic patients demonstrated significantly higher rates of morbidity (21% vs. 8%, respectively; $P < .001$), intraoperative bleeding (26% vs. 3%; $P < .001$), and open conversion (7% vs. 4%; $P < .05$), but no difference was reported in terms of wound infection and mortality rates between the two (Puggioni & Wong, 2003).

Laparoscopic cholecystectomy offers improved visualization for meticulous dissection and avoids the need for a large subcostal or upper midline incision. It is associated with less operative blood loss, shorter operative time, and decreased length of hospital stay versus the open procedure in cirrhotic patients (Puggioni & Wong, 2003). Furthermore, laparoscopic cholecystectomy leads to fewer adhesions in the right upper quadrant, which are associated with increased bleeding complications and longer operative times in patients who ultimately undergo liver transplant.

Some specific technical considerations must be considered when performing laparoscopic cholecystectomy in a cirrhotic patient. In placing the umbilical port, particular care must be taken to avoid venous collaterals and the umbilical vein. One approach may be to place one of the other ports first, such as the subxiphoid port, in order to then place the umbilical port under direct visualization. Transillumination of the abdominal wall helps the surgeon to avoid these and other venous collaterals during trocar placement. Furthermore, the subxiphoid port

should be placed off midline to avoid the falciform ligament and the recanalized umbilical vein. Careful traction on the gallbladder helps to avoid undue bleeding as it is dissected off the liver. Instruments such as the Harmonic Scalpel (Ethicon, Somerville, NJ) or LigaSure (Covidien, Mansfield, MA) may also be used to help control bleeding during the dissection (Curro et al, 2005; El-Awadi et al, 2009; Morino et al, 2000; Schiff et al, 2005; Tuech et al, 2002). A subtotal or supracystic cholecystectomy, leaving part of the gallbladder wall attached to the liver bed and ligating the cystic duct from within the gallbladder with a purse-string suture, is an option in patients with large pericholecystic venous collaterals (Bornman & Terblanche, 1985; see Chapter 33). Trocars should also be removed under direct visualization to ensure adequate abdominal wall hemostasis at the end of the procedure. Finally, if anatomy is unclear or any doubt exists as to the safety of continuing laparoscopically, the procedure should be converted to open.

In patients with advanced cirrhosis (CTP class C), cholecystectomy in general is associated with very poor outcomes. Despite the lack of controlled trials, the literature supports the use of alternatives to cholecystectomy, such as a percutaneous cholecystostomy, in this high-risk group (Cucinotta et al, 2003; Curro et al, 2005; Delis et al, 2010; Yeh et al, 2002). An endoscopically placed cystic duct stent is another option proposed by some (Gaglio et al, 1996; Shrestha et al, 1996, 1999).

In general, the CTP scoring system is used in the literature to stratify patients suitable for cholecystectomy. Although some evidence suggests that the MELD classification system may be more accurate in predicting postoperative complications, these data are inconsistent, and cutoff values vary among studies (Delis et al, 2010; Perkins et al, 2004). Therefore, until the MELD system has been further validated, CTP should be used for stratification. In CTP classes A and B patients with symptomatic cholelithiasis and/or acute cholecystitis, laparoscopic cholecystectomy should be performed by surgeons experienced in managing cirrhosis. In patients with class C cirrhosis, surgery should be deferred until liver disease is under better control, and alternate interventions, such as percutaneous cholecystostomy or endoscopic stenting, should be used.

Herniorrhaphy

Umbilical hernias occur in up to 20% of patients with cirrhosis. The pathogenesis of umbilical hernias in the setting of cirrhosis is multifactorial; ascites causes increased intraabdominal pressure, poor nutritional status leads to decreased abdominal muscle mass and fascial strength, and umbilical vein dilation results in enlargement of the preexisting supraumbilical fascial opening (Belghiti & Durand, 1997). In addition to the risks of bowel incarceration and strangulation that affect all patients with umbilical hernias, additional unique risks accompany having an umbilical hernia and cirrhosis. Skin ulceration over the hernia may be associated with the leakage of ascites, sac rupture, bacterial peritonitis, and even evisceration, with very high attendant rates of morbidity and mortality. Although rare, spontaneous umbilical rupture is associated with up to a 60% perioperative mortality rate and has been shown to correlate independently with an adverse outcome after emergent repair (Telem et al, 2010a).

Historically, mortality rates for umbilical hernia repair (UHR) in patients with cirrhosis were prohibitively high, and the prevailing opinion among surgeons was that uncomplicated hernias should be left untreated (Baron, 1960; O'Hara et al, 1975). UHR was only undertaken when complications, such as incarceration, strangulation, skin breakdown or impending rupture, or overt rupture, necessitated immediate intervention. In the present era, however, outcomes appear to be significantly improved for elective and even complicated UHR in patients with end-stage liver disease. Most series published in the literature since the early 1980s have reported little to no perioperative deaths and relatively low morbidity, although most of them have been relatively small retrospective studies (Belghiti et al, 1990; de la Pena et al, 2000; Ozden et al, 1998; Pescovitz, 1984; Runyon & Juler, 1985).

Marsman and colleagues (2007) looked at outcomes of elective UHR versus conservative management in patients with umbilical hernias, cirrhosis, and ascites. Seventeen patients with a median MELD score of 23 (range, 18 to 26) underwent elective UHR, and another 13 patients, also with a median MELD score of 23 (range, 18 to 27), were observed. In the elective UHR group, 3 patients (18%) had local wound complications, but there were no instances of hepatic decompensation or perioperative death. In contrast, in the group that was observed, 10 patients (77%) developed complications, including nine cases of incarceration and one spontaneous rupture with evisceration; these led to emergency UHR in six patients, and there were two perioperative deaths (15%). Although this was a retrospective study, and it is likely that some selection bias existed between the two groups, it is one of the few studies to compare early UHR versus watchful waiting in patients with comparable and relatively high MELD scores.

Another recent report, a retrospective review of the Veterans' Affairs National Surgical Quality Improvement Program (VA NSQIP) database, analyzed the results of UHR in 127 cirrhotic and 1294 noncirrhotic patients (Gray et al, 2008). It determined that UHR performed electively in patients with cirrhosis was associated with an outcome similar to that in patients without cirrhosis. When UHR was performed emergently, however, patients with cirrhosis had significantly worse outcomes than those without. One drawback of this study was that the authors were not able to classify the degree of hepatic impairment among the patients with cirrhosis.

In patients with ascites, UHR has been combined with peritoneovenous (PV) shunting, closed-system suction drainage, or temporary peritoneal dialysis catheters to help manage ascites as the repairs heal (Ammar, 2010; Belghiti et al, 1990; Leonetti et al, 1984; O'Connor et al, 1984). A meta-analysis compared UHR with concomitant interventions to control ascites, namely PV shunting, versus repair alone and determined that uncontrolled ascites was associated with a relative risk ratio of 8.51 (95% confidence interval, 2.69 to 26.9) for hernia recurrence (McKay et al, 2009). Although PV shunting cannot be recommended in the current era because of the associated complications and high incidence of shunt occlusion, TIPS has been used more recently to successfully reduce ascites in the period surrounding UHR (Fagan et al, 2004; Inturri et al, 1996; Telem et al, 2010a). No controlled studies have evaluated the perioperative use of TIPS in UHR in patients with ascites, and definitive recommendations regarding its use cannot be made. In addition, TIPS may lead to new onset of encephalopathy or worsening of existing encephalopathic symptoms. Nonetheless, it is an option to manage ascites in patients who are deemed suitable candidates.

Whether nonabsorbable mesh should be used for the repair in cirrhotic patients is another issue of debate. Traditionally,

the use of foreign material has been avoided in the repair of complicated hernias. However, some evidence suggests that nonabsorbable mesh may be used successfully, even when ascites is present (Ozden et al, 1998). A recent study prospectively randomized 80 CTP class A and B patients with cirrhosis and an umbilical hernia to either primary tissue repair with sutures or mesh repair with polypropylene onlay (Ammar, 2010). Surgical site infection occurred at a higher rate in the mesh group (16%) versus suture repair (9%), but the difference was not significant. Furthermore, all infections were successfully managed conservatively and did not require mesh removal. At a minimum of 6 months of follow-up, hernias recurred in 14% of patients in the suture repair group and in only 3% of patients in the mesh repair group ($P < .05$). Again, the dataset is small, but it does appear that mesh onlay may be used to lower the risk of recurrence in patients with cirrhosis who have umbilical hernias, in particular those with well-compensated disease.

In terms of inguinal hernia repair, results in this patient population are similar to those for umbilical herniorrhaphy (Inagaki et al, 2009; Lawson et al, 2009; Patti et al, 2008). Outcomes after elective repair do not vary between cirrhotic and noncirrhotic patients, although outcomes after emergent repair of an incarcerated or strangulated inguinal hernia are significantly worse in patients with cirrhosis (Carbonell et al, 2005). It appears that cirrhotic patients may safely undergo inguinal hernia repair with mesh; local wound complications, if they do arise, are usually easily treated (Inagaki et al, 2009; Lawson et al, 2009). In short, it is reasonable, and the data would suggest even advisable, to repair hernias electively in patients with cirrhosis. However, as with any elective operation, patients should be well compensated and medically optimized, and ascites should be controlled.

Colectomy

Compared with cholecystectomy and herniorrhaphy, considerably less data are available on colon resection in patients with chronic liver disease and cirrhosis. As in patients without cirrhosis, indications for colon resection include colon cancer, diverticular disease, and colonic ischemia. Colorectal surgery, which is associated with relatively high rates of morbidity and mortality when performed on the general population, is particularly high risk for those with cirrhosis. In fact, the mortality rate for patients with cirrhosis undergoing colectomy is around 20% to 25% (Metcalf et al, 1987; Meunier et al, 2008; Nguyen et al, 2009). Emergent colectomy is associated with an even higher mortality rate: up to 36% in patients with cirrhosis who have portal hypertension and 21% in those with portal hypertension who did not have cirrhosis (Nguyen et al, 2009). It is preferable to perform colorectal surgery in a cirrhotic patient on an elective basis whenever possible.

In a recent, large, population-based study, extraintestinal complications, such as pulmonary and wound complications, were increased in patients with cirrhosis and portal hypertension in particular. On multivariate analysis, total colectomy, malnutrition, and comorbid cardiac, pulmonary, and renal disease were the most significant predictors of postoperative morbidity (Nguyen et al, 2009). In another recent, retrospective, single-center study that included 41 cirrhotic patients undergoing colorectal surgery (CTP class A, 40%; class B, 49%; class C, 12%), the presence of preoperative ascites was significantly linked to postoperative morbidity (Meunier et al, 2008). When colectomy is performed on an elective basis, every effort should be made to optimize comorbid conditions and nutrition and to control ascites before surgery.

When feasible, the laparoscopic approach for colectomy may be advantageous in this patient population. Laparoscopy has significantly improved outcomes for gallbladder surgery in patients with cirrhosis, in particular in patients with well-compensated disease. Along these lines, a report on laparoscopic-assisted colectomy in 17 patients with compensated cirrhosis (CTP class A, 71%; class B, 29%) was notable for relatively minimal blood loss (mean, 245 mL; range, 100 to 250 mL), a 29% morbidity rate, and no operative deaths (Martinez et al, 2004). The study was small, and the group of patients was highly selected. Nonetheless, this research does offer some indication that laparoscopic colectomy, when performed at centers experienced in advanced laparoscopic surgery, may lead to improved outcomes in CTP class A and B patients versus the open approach.

Bariatric Surgery

Because of the high incidence of nonalcoholic fatty liver disease (NAFLD) and its association with the metabolic syndrome, chronic liver disease is not infrequent among patients being considered for bariatric procedures. The finding of overt cirrhosis is estimated to occur in 1.4% of patients undergoing these operations (Dallal et al, 2004). The majority of these patients are diagnosed with cirrhosis intraoperatively, and surgery is abandoned. Few reports exist as to the safety and efficacy of bariatric procedures in known cirrhotic patients. In the largest series to date, which includes 30 patients analyzed retrospectively, 27 were diagnosed intraoperatively (Dallal et al, 2004). All patients were classified as CTP class A, and there were no perioperative deaths.

Given the paucity of data, the decision of whether to proceed with operation in patients with well-compensated cirrhosis is unclear. Certainly, patients with more advanced disease and/or portal hypertension are at significant mortality risk. However, several reports document the reversal of even advanced liver disease after surgical weight loss (Dixon et al, 2004; Kral et al, 2004). Therefore it appears that bariatric surgery may be reasonable in patients with early fibrosis and possibly in those with well-compensated cirrhosis. As outlined earlier, the risk inherent to the procedure, severity of liver disease, and comorbid conditions must be considered individually along with the potential benefit of surgical weight loss.

The choice of weight loss procedure in those deemed candidates is also unclear (Baltasar, 2006; Sarr, 2006). Despite the histologic improvement in liver disease seen with biliopancreatic diversion, several case reports of hepatic failure after this procedure exist (Castillo et al, 2001; Grimm et al, 1992; Kral et al, 2004). The optimal procedure regarding weight loss remains under intense debate in the bariatric surgical community and is beyond the scope of this chapter. However, the suggestion has been made that sleeve gastrectomy may be the procedure of choice in patients with cirrhosis because of minimal bleeding complications, protection from malabsorption associated with other bariatric procedures, and potential improvement in transplant candidacy (Baltasar, 2006; Takata et al, 2008). No studies evaluating the use of adjustable gastric bands in cirrhotic patients are available.

Cardiac Procedures

Cardiovascular risk factors occur at greater rates among those with cirrhosis than among the general population (Hessheimer et al, 2010). Furthermore, although an uncommon cause, congestive heart failure may actually lead to hepatic congestion, fibrosis, and ultimately cirrhosis. Because of these and other factors, cardiac surgery is becoming increasingly more frequent in patients with end-stage liver disease, in particular those awaiting liver transplantation (Thielmann et al, 2010). Cardiac surgery, however, is extremely risky in patients with cirrhosis. Mortality rates are as high as 50% to 80% in patients with advanced liver disease undergoing cardiac surgery with cardiopulmonary bypass (CPB) because of high rates of infection, gastrointestinal complications, and bleeding (Bizouarn et al, 1999; Kaplan et al, 2002; Klemperer et al, 1998).

Outcomes for cirrhotic patients undergoing cardiac surgery have variably been associated with preoperative serum cholinesterase, serum bilirubin, and platelet count (An et al, 2007; Filsoufi et al, 2007; Hirata et al, 1999; Morisaki et al, 2010; Reinhartz et al, 1998). More consistently, however, outcomes have been linked to the preoperative CTP or MELD score. CTP class B and C and/or a MELD score greater than 13 to 15 have been shown to correlate with a significantly increased risk for postoperative complications and death in cirrhotic patients undergoing cardiac procedures, in particular those involving CPB (Ailawadi et al, 2009; An et al, 2007; Filsoufi et al, 2007; Hayashida et al, 2004; Klemperer et al, 1998; Morisaki et al, 2010; Thielmann et al, 2010).

CPB induces the production of inflammatory cytokines and other vasoactive substances and leads to further derangements in hemodynamics, coagulation, and immune function. Advanced cirrhosis (CTP class B and C) is considered a contraindication for CPB (An et al, 2007; Filsoufi et al, 2007; Hayashida et al, 2004). A few recent reports, however, have described successful on-pump valve procedures in patients with advanced liver disease (Iino et al, 2008; Nemati et al, 2008; Takahashi et al, 2006). By preoperative optimization of hepatic status, aggressive administration of platelets and fresh frozen plasma throughout the perioperative period, and dilutional ultrafiltration (DUF) during CPB, these investigators were able to curtail the negative effects of CPB in patients with decompensated disease. DUF in particular helps to minimize hemodilution and remove inflammatory mediators produced during CPB (Iino et al, 2008). Another option that has shown modest success in patients with moderate to severe cirrhosis in need of coronary artery bypass (CAB) is off-pump surgery (Ben Ari et al, 2006; Hayashida et al, 2004; Murashita et al, 2009). Off-pump CAB may reduce bleeding and transfusion requirements. Further investigations, however, are required to determine the true applicability of these techniques in this patient population.

Thoracic Procedures

The literature on thoracic surgery in patients with cirrhosis primarily describes thoracoscopic procedures for the treatment of refractory hepatic hydrothorax, a complication that occurs in approximately 5% of cirrhotic patients (Alberts et al, 1991). It is a symptomatic transudative pleural effusion that is believed to arise secondary to tiny defects in the diaphragm that allow ascites to flow from the high-pressure peritoneal cavity into the low-pressure pleural space (Huang et al, 2005; Nakamura et al, 1996; Zenda et al, 1998). Hepatic hydrothorax may result in significant respiratory compromise, and initial treatments include sodium restriction, diuretics, TIPS, and frequent thoracenteses. When these fail, video-assisted thoracoscopic surgery (VATS) with closure of obvious diaphragmatic defects and/or mechanical or chemical pleurodesis are options that may allow prolonged symptomatic relief (Assouad et al, 2003; Ferrante et al, 2002; Mouroux et al, 1996; Northup et al, 2009). Potential complications include empyema and persistent leakage of high volumes of ascites from the chest tube site. Nonetheless, the procedure is relatively well tolerated and is associated with success rates of up to 80%, even in patients with advanced cirrhosis (Cerfolio & Bryant, 2006).

Cirrhosis is present in approximately 4% to 7% of patients undergoing esophagectomy in some series (Fekete et al, 1987; Lu et al, 2005; Tachibana et al, 2000). Actual rates of cirrhosis in patients with esophageal neoplasms are likely higher than reported, based on the fact that alcohol plays an important role in the pathogenesis of both diseases; stage for stage, many more cirrhotics than noncirrhotics would be deemed unsuitable for surgery. Unlike gastric resection, esophagectomy in cirrhotic patients is actually associated with relatively few deaths as a result of postoperative liver failure, in theory because of the radical gastroesophageal devascularization and postoperative anorexia, which may lead to a significant reduction in alcohol consumption (Tachibana et al, 2000). Nonetheless, esophagectomy in cirrhotic patients is associated with much higher rates of surgical morbidity and mortality compared with noncirrhotics, in the range of 31% to 87% and 17% to 26%, respectively (Fekete et al, 1987; Lu et al, 2005; Tachibana et al, 2000). Perioperative bleeding, ascitic effusions, pneumonia, and sepsis are the most common complications and cause the majority of postoperative deaths. Significant preoperative coagulopathy, hyperbilirubinemia (>3 mg/dL), weight loss (>10% to 15% of body weight), and CTP classes B and C are associated with the highest rates of postoperative death and may be considered contraindications for surgery. For patients surviving the immediate postoperative period, however, overall survival appears to be similar to that of noncirrhotic patients undergoing the same procedures (Tachibana et al, 2000). Esophageal resection may play some role in well-selected patients with mild underlying liver disease.

Only four published reports from two centers have reported on pulmonary resection for non–small-cell lung cancer in patients with cirrhosis, the great majority of whom were CTP class A (Iwasaki et al, 2006; Iwata et al, 2007a, 2007b, 2008). Surgical morbidity rates were approximately 19% to 27%, and mortality rates were 5% to 13%. The most common complications were infection, bleeding, and acute liver failure. Based on the retrospective nature of the studies and the small number of patients they included, the authors were unable to conclude whether these operations had any impact on life expectancy in this patient population.

Trauma

Cirrhotic patients represent approximately 1% to 1.5% of the trauma population and an even greater proportion of those sustaining blunt trauma (Georgiou et al, 2009; Wutzler et al, 2009). In these patients, falls are the most common cause of injury (43%), followed by assault (Chen et al, 2007; Georgiou et al, 2009). Complications occur in up to 10% of patients and

primarily include acute respiratory distress syndrome, trauma-associated coagulopathy, pneumonia, and sepsis (Christmas et al, 2005; Georgiou et al, 2009). In-hospital mortality rates are high, in the range of 22% to 33%. The CTP classification appears to be associated with a stepwise increase in the risk of death: up to 15% in class A, 37% in class B, and 76% in class C (Christmas et al, 2005).

Cirrhotic trauma patients are significantly more likely than those without cirrhosis to undergo laparotomy, and splenectomy is one of the most common operations performed (Christmas et al, 2005; Georgiou et al, 2009). This is not surprising given the prevalence of portal hypertension and splenomegaly among these patients. Among cirrhotic patients, nonoperative management of splenic injury fails in up to 92% of patients (Fang et al, 2003). On the other hand, multivariate analyses from several studies have demonstrated that after laparotomy, 40% to 55% of cirrhotic patients ultimately die in the hospital, versus only 15% to 24% of those who avoid laparotomy (Christmas et al, 2005; Demetriades et al, 2004; Georgiou et al, 2009).

Obviously, management of these patients is highly complex. The American College of Surgeons recommends that trauma patients with a history of cirrhosis be transferred to a trauma center, if they are not at one already (Wahlstrom et al, 2000), and should be very carefully resuscitated and monitored in an intensive care setting. Bleeding complications are common, and coagulopathy and hypothermia should be aggressively corrected. Because these patients are almost routinely malnourished and hypoalbuminemia has been significantly linked with poor outcomes, nutritional support with solutions rich in branched-chain amino acids should be started early (Chiarla et al, 1997). It is imperative to promptly diagnose injuries in these patients, although interventions should be undertaken judiciously. Early consultation with hepatology and/or hepatobililary surgery, if possible, is strongly advised.

SUMMARY

In many instances, nonhepatic elective surgery may be safely performed in patients with cirrhosis. There is certainly almost always an increase in morbidity and mortality when compared with patients without chronic liver disease; however, often these are not prohibitive. The severity of liver failure as judged by the CTP or MELD scoring systems appears to be the most important factor in determining postoperative outcomes. CTP class A or B cirrhotic patients and those with a MELD score less than 15 are often suitable operative candidates, depending on the magnitude and necessity of the procedure. Emergency operations carry greater risk, as does comorbid illness and age. Perhaps most importantly, operations on cirrhotic patients should be performed only after medical optimization of liver disease and only by centers experienced in managing end-stage liver disease.

CHAPTER 75B

Esophageal varices: acute management of portal hypertension

Joseph Awad and Julia Wattacheril

OVERVIEW

The most important aspect of care in patients with suspected variceal or other portal hypertensive hemorrhage is adequate resuscitation while directed diagnostic maneuvers and therapies are being coordinated. Although this chapter focuses on acute esophageal variceal bleeding, many of the principles and therapies may apply to other sources of portal hypertensive bleeding. Acute variceal hemorrhage is associated with a 15% to 20% mortality rate at 6 weeks (Abraldes et al, 2008; Villanueva et al, 2006). Although evidence supports the use of endoscopy for diagnosis and treatment, insufficient resuscitation can lead to significant periprocedural complications. Appropriate pharmacotherapy has proven equally effective in controlling variceal hemorrhage in some studies. More importantly, pharmacotherapy can be started immediately in any hospital, regardless of endoscopic staff availability.

The morbidity of patients who present with acute variceal hemorrhage is strongly influenced by their reason for recent decompensation. In most instances, early resuscitative measures followed by pharmacotherapy and endoscopy allow improvement in hepatic synthetic function and provide time to address more definitively the overall management of the patient and any recurrent bleeding. In patients with life-threatening exsanguination, balloon tamponade is a useful maneuver until the patient is stable enough for endoscopy. In patients with bleeding refractory to pharmacotherapy and endoscopic intervention, transjugular intrahepatic portosystemic shunting (TIPS) generally is the next option for short- and mid-term stabilization (see Chapter 76E). Shunt operations (see Chapters 76A through 76D) have traditionally been reserved for individuals for whom transplantation and TIPS are not an option but who have a reasonable chance of operative survival.

EMERGENCY MANAGEMENT

Before any diagnostic maneuvers can be performed (e.g., endoscopy), support of the circulating blood volume with adequate resuscitation is imperative. Isotonic crystalloid is the first replacement fluid of choice, but typed and cross-matched blood products are needed for the majority of patients with variceal hemorrhage. Evidence supports the use of colloids over crystalloid and packed red blood cells with the end points of optimal hemodynamics and oxygen transport (Shoemaker, 1987). Maintenance of hemoglobin values of approximately 8 g/dL are recommended; higher blood volumes are associated with increased portal pressures, higher rebleeding rates, and higher mortality rates. Other measures of the adequacy of resuscitation include systolic blood pressures of 90 to 100 mm Hg, central venous pressures of 9 to 16 mm Hg, and adequate urine output; pulmonary artery occlusion catheters may be a useful adjunct in some patients. When the adjusted prothrombin time is prolonged by more than 3 to 4 seconds, fresh frozen plasma is likewise recommended. Recombinant Factor VIIa has not been shown to benefit patients with cirrhosis with gastrointestinal (GI) hemorrhage over standard therapy (Bosch et al, 2008). For patients with significant bleeding or decreased consciousness, endotracheal intubation should be expedited.

Complications from variceal bleeding contribute to overall morbidity and mortality related to chronic liver disease. Preventing these complications can therefore have a significant impact on the short-term mortality rate associated with variceal bleeding. Antibiotic prophylaxis has been shown to decrease variceal rebleeding and bacterial infection (Bernard et al, 1999; Fernandez et al, 2006). Systematic reviews have shown decreased mortality rates with antibiotic prophylaxis in the setting of GI bleeding (Soares-Weiser et al, 2002). Consensus agreement supports norfloxacin use for 7 days (400 mg bid) in patients with two or more of the following: malnutrition, ascites, encephalopathy, or serum bilirubin level greater than 3 mg/dL. Ceftriaxone had better outcomes than norfloxacin when given intravenously in areas with known quinolone resistance according to randomized, controlled data (Fernandez et al, 2006). It may be that other antibiotics with similar spectra of activity would provide satisfactory substitutes in the event of problems with patient tolerance, local antibiotic availability, or susceptibility issues.

Controlling Acute Hemorrhage: Pharmacologic Agents

Coupling pharmacologic measures and endoscopy with the initiation of preventative measures provides the most sustainable results when attempting to control acute GI hemorrhage in patients with advanced liver disease. The specific drugs are widely available, generally safe, and can be initiated as soon as variceal hemorrhage is suspected. Drugs such as somatostatin or its analogues, octreotide and vapreotide, work by constricting arterial and thus venous splanchnic blood flow, thereby reducing portal hypertension acutely. In randomized controlled trials comparing these vasoactive agents with others, including vasopressin and terlipressin, no significant differences in bleeding control were reported, although vasopressin was associated with more adverse events (Banares et al, 2002; Villaneuva et al, 2006). Currently, an initial bolus dose of octreotide 50 µg IV followed by 50 µg/h is recommended. Duration usually extends

from 72 hours to 5 days, and recurrent bleeding should be treated with an additional bolus dose. Only octreotide and vasopressin are currently available in the United States.

Controlling Acute Hemorrhage: Endoscopic Therapy

The two main endoscopic therapeutic choices are endoscopic variceal ligation (EVL) and sclerotherapy. The strong preference remains for EVL, given its superior control of bleeding and decreases reported in rebleeding rates, mortality rates, and esophageal complications. Both techniques require a skilled endoscopist; however, when both groups were treated with somatostatin concomitantly, failure rates of EVL were estimated at 10% compared with 24% of sclerotherapy patients. Failure to control acute bleeding is also significantly more frequent in the sclerotherapy group (Villanueva et al, 2006).

After adequate sedation and diagnostic endoscopy, EVL should commence. The decision regarding whether to start with a standard 2.8-mm gastroscope versus a therapeutic endoscope is practitioner dependent given the potential for clot removal by irrigation. Once a variceal source has been identified, the endoscope should be removed and a multibanding kit should be applied with a standard gastroscope. Bands should be applied to any vessels actively spurting blood or displaying stigmata of recent hemorrhage, such as red wale marks, white nipples, and/or adherent blood clots. Other vessels should then be ligated, starting as close as possible to the esophagogastric junction. The varix is drawn into the ligator by applying suction, and a band is then applied as shown in Figure 75B.1.

Two techniques of sclerosant injection are in use, and the choice of which to use is somewhat institutionally and regionally influenced. Sclerosants can be injected into the varix itself (intravariceally) or adjacent to it (paravariceally); both techniques appear to be effective. Often a paravariceal injection results inadvertently from an intravericeal injection attempt, given the technical challenges in an acutely bleeding patient. Sodium morrhuate and sodium tetradecyl sulfate are the two sclerosants most commonly used in the United States, and each varix should be injected with 1 to 2 mL of sclerosant just above the esophagogastric junction and 5 cm proximal. Some endoscopists find sclerotherapy effective when active bleeding impairs visualization for EVL. On occasion, application of sclerotherapy sufficiently impedes bleeding enough to allow band ligation.

Balloon Tamponade

A correctly placed balloon tube can temporarily control acute variceal bleeding. The balloon tube is primarily used when patients have continued, active bleeding despite attempted control by emergency endoscopic therapy, but a balloon tube may also be inserted when massive variceal bleeding obscures visibility during emergency endoscopy; both are relatively uncommon circumstances. Balloon tube tamponade has also proved to be lifesaving during the transfer of patients to a tertiary care center, to control a subsequent major bleed while awaiting emergency endoscopy, and to stop variceal bleeding while preparing for alternative therapy when endoscopic therapy fails (e.g., a further major, acute variceal bleed after two emergency endoscopic treatments during a single hospital admission).

The balloon tube should be inserted by a practitioner familiar with the technique (details presented below). The tube should be left in place for as short a time as needed for resuscitation, endoscopic treatment, or TIPS placement. Bleeding that continues after tube insertion warrants additional assessment regarding correct placement and potential for repeat endoscopy. In these cases, a bleeding lesion below the balloon in the distal stomach or duodenum that was missed at the first diagnostic endoscopy is usually the culprit (Terblanche et al, 1994).

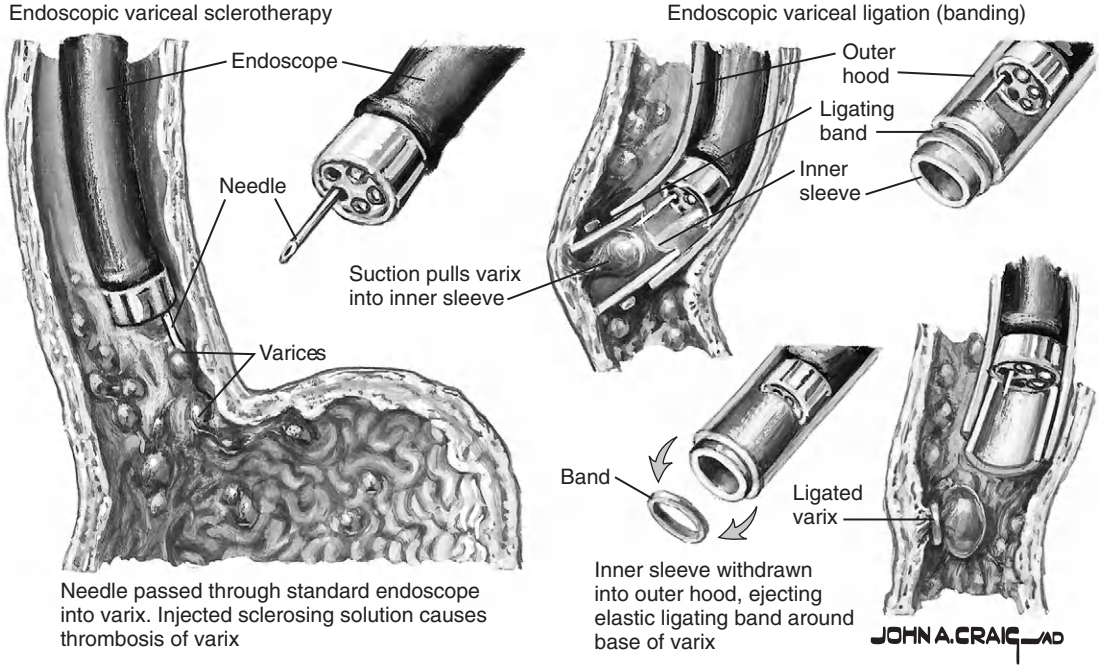

FIGURE 75B.1. Variceal bleeding ligation techniques. *(Netter illustration from www.netterimages.com. Copyright Elsevier, Inc. All rights reserved.)*

TECHNIQUE. After confirming a complete air seal underwater, the deflated lubricated tube is passed via the mouth through a bite guard placed between the teeth. The tube is inserted as far as possible. To confirm the balloon's position in the stomach, the epigastrium is auscultated while instilling air via the aspirating lumen of the gastric tube with a 50-mL syringe. Thereafter, the gastric balloon is cautiously inflated via its lumen with 50-mL increments of air until a total of 100 mL has been inserted. Air should be easy to insert; if the tube is curled in the esophagus, resistance is felt and the inflation must be stopped immediately; otherwise, the esophagus may be damaged. If the gastric balloon has been easily inflated, it is pulled up until it is seated firmly against the esophagogastric junction. Then the position of the tube is confirmed radiographically before another 150 to 200 mL of air is added to the balloon.

Tension on the tube is often maintained by taping it to the facemask of an American football helmet. Alternatively, a split tennis ball strapped to the tube at the mouth guard can be used to protect the patient's lips from the pressure of the tennis ball. Adequate tension on the gastric balloon can be checked regularly at the mouth. Inflation of the esophageal balloon is not usually necessary because traction on the gastric balloon is generally sufficient to compress gastric veins that feed esophageal varices. If esophageal balloon inflation is required, a three-way tap and a blood pressure manometer are used to inflate the esophageal balloon to 40 mm Hg before clamping the tube. This pressure needs to be checked regularly, and the balloon should be deflated hourly to prevent esophageal necrosis. The fourth lumen, which opens in the esophagus, is placed on constant suction; the gastric lumen is used for suction and to administer medication such as lactulose.

Patients with a balloon tube in place are monitored carefully in an intensive care unit (ICU). When the balloon tube has been inserted and fixed and bleeding has been arrested, resuscitation is continued, clotting abnormalities are corrected, and the patient is made as fit as possible for the necessary subsequent management. The balloon tube should usually be removed within 24 hours (Blumgart & Belghiti, 2007).

Gastric Varices

Approximately 20% of patients with cirrhosis have gastric varices, either in isolation or associated with esophageal varices. Bleeding from gastric varices carries greater risk and is associated with increased mortality rates (Ryan et al, 2004). In these cases, endoscopic variceal obturation (EVO) with cyanoacrylate has been demonstrated as superior to endoscopic variceal ligation in controlling initial hemorrhage as well as controlling rebleeding (Lo et al, 2001; Tan et al, 2006). TIPS is also effective in controlling acute hemorrhage from gastric varices. Decreased recurrent bleeding has recently been demonstrated in patients undergoing TIPS versus EVO (Lo et al, 2007). In the United States, where N-butyl-2-cyanoacrylate is not available and 2-octyl-cyanoacrylate has been used instead, adverse events have been noted. Its use requires specialized endoscopic training; in situations where this is not available, primary placement of TIPS is preferred (Garcia-Tsao & Lim, 2009).

Ectopic Varices

Ectopic varices are those in an atypical location (nonesophageal or nongastric). Bleeding from ectopic varices accounts for approximately 1% to 5% of variceal bleeding (Helmy et al, 2008). Most ectopic varices arise from global portal hypertension, but they may be related to regional thrombosis or prior surgery sites, where the healing process promotes venous connections between a high-pressure portal system and the lower pressure systemic circulation. Common sites include the duodenum, anorectal region, umbilicus, and ostomies. Patients typically bleed into the lumen of the GI tract, but peritoneal and retroperitoneal bleeding can occasionally occur. Given their relatively rare occurrence, treatment recommendations have been made on case reports, case series, and small reviews, not in randomized controlled trials.

Imaging and endoscopy techniques have allowed approximation of the prevalence of ectopic varices. Anorectal varices have been reported in 10% to 40% of patients with cirrhosis; duodenal varices have been reported in 40% of patients with portal hypertension as seen during angiography. Fortunately, bleeding from these lesions is quite rare.

Peristomal/stoma varices are seen in patients with ostomies who have, or later develop, portal hypertension such that alternatives to creating an ostomy should be considered in these patients. Although more common in those with significant intrahepatic portal hypertension, they are particularly insidious and can bleed at a hepatic venous pressure gradient (HVPG) of less than 12 mm Hg. Peristomal varices are most common on the skin near the stoma rather than deep within the stoma. Thus it is important to remove the skin covering around the stoma and apply direct pressure or local treatment to the bleeding vessel.

Initial management remains the same as in esophageal variceal bleeding, namely to provide adequate clinical assessment and resuscitative measures, hemodynamic support, and antibiotic prophylaxis. Vasoactive drugs are reasonable to use, and endoscopy should proceed with goals similar to those for therapy of variceal bleeding.

Band ligation of ectopic varices has been limited to a few reports and mainly involves varices in the rectum and duodenum. Banding can be performed when the diameter of the varix does not exceed the endoscope diameter. More studies have evaluated the role of sclerotherapy in ectopic varices, but the results were less than optimal. Colorectal varices respond less often to sclerotherapy, possibly as a result of the dilution of sclerosant to an ineffective concentration in these larger varices.

The argon-beam plasma coagulator (APC) has been used in the prevention and eradication of recurrent esophageal varices but should not be used in the acute management of variceal bleeding. It may be useful in bleeding ileocolonic varices, but evidence for its use in other ectopic variceal sites has not been sufficiently demonstrated.

Embolization with coils, gel foam, collagen, autologous blood clot, or thrombin has been effective in interventional radiology as an adjunct to band ligation or TIPS. Occlusion of the supplying vein decreases blood supply to the varix itself. Steel coils, placed via interventional techniques, are most effective in achieving total focal occlusion. Success rates for bleeding cessation are reported to be greater than 90%; however, the underlying portal hypertension is not treated.

Surgical treatment, including direct focal devascularization, is effective and usually performed in the presence of portal vein occlusion or advanced cirrhosis. Some of the direct approaches used are oversewing of varices via duodenotomy, duodenal dearterialization and stapling, circumferentially stapled anoplasty, and double-selective shunting. Nonselective portosystemic shunts (see Chapter 76D) are much more invasive and are therefore less commonly used (Helmy et al, 2008).

Portal Gastropathy and Gastric Antral Vascular Ectasia

Portal gastropathy is rarely a cause of rapid life-threatening bleeding, but it can be severe enough to require daily transfusion. This situation is most common in the presence of gastric antral vascular ectasia (GAVE), a condition well described by its name. GAVE can occur without portal hypertension but is especially difficult to manage in the presence of portal hypertension. The antrum often has a red, longitudinally striped appearance that gives this condition its alternative name, *watermelon stomach.* In the absence of portal hypertension, this cause of chronic blood loss and iron deficiency anemia can be treated with APC or antrectomy. However, APC in the setting of portal hypertension is much less effective and can even cause a worsening of bleeding. Unfortunately, TIPS shunting has also been of little benefit, and antrectomy is usually too risky to be considered.

Recently, banding of antral mucosa has been described as a treatment for this condition. Up to 12 bands can be placed per session with about three sessions required to complete the treatment course. Banded mucosa is sloughed and replaced by mucosa without ectatic blood vessels. Wider experience with this modality will help determine the place of banding in this difficult to manage condition (Wells et al, 2008).

RECURRENT BLEEDING

GI hemorrhage in patients with cirrhosis either recurs or cannot be controlled in approximately 10% to 20% of cases despite coordinated efforts with directed therapy. In these cases, shunt therapy is indicated. In Child-Turcotte-Pugh class A (compensated) cirrhotic patients, surgical shunts (see Chapters 76A through 76D) have proven efficacious. However, in most acute and later recurrences, TIPS is the preferred mechanism of portal decompression (see Chapter 76E). In addition to serving as a bridge to liver transplantation in patients not responding to pharmacologic and endoscopic therapy, TIPS is sometimes thought to be advantageous because of the lower portal pressures during transplantation. A TIPS functions as a nonselective shunt, and the development of encephalopathy or worsening of existing encephalopathy should be considered before implantation. Stenosis or occlusion may develop in up to 50% of patients within 1 year with bare metal stents; however, results appear to be improved when stents covered with polytetrafluoroethylene (PTFE) are used; both types of stents can be restored with angiographic interventions.

In the era of TIPS, an extensive gastric and lower esophageal devascularization together with transection of the lower esophagus is rarely required (see Chapter 75C). The extensive abdominothoracic Sugiura procedure popularized in Japan has been replaced by a transabdominal procedure in most institutions (Blumgart & Belghiti, 2007).

No Therapy: Observation Only

Patients with end-stage liver disease who are not candidates for transplantation and who present with major esophageal variceal bleeding complicated by multiorgan failure perhaps should not be subjected to the most invasive procedures described. Withholding treatment in these circumstances, in which the chances of meaningful survival is remote at best, is a difficult clinical and ethical decision but one that must be considered, discussed, and accepted in the appropriate clinical scenario.

CHAPTER 75C

Esophageal varices: operative devascularization and splenectomy

Chung-Bao Hsieh and Kuo-Feng Hsu

TREATMENT OF ESOPHAGEAL VARICES

With the development of advanced vasoactive agents (see Chapter 75B), endoscopic therapies (Chapter 75B), and transjugular intrahepatic portosystemic shunting (TIPS; see Chapter 76E), the need for surgical treatment for esophagogastric varices has decreased (Cello et al, 1984). Most patients with esophagogastric varices have cirrhosis and portal hypertension; for patients in advanced stages of liver failure, liver transplantation (see Chapter 97) is the optimal treatment, although shunting (see Chapter 78) or nonshunting operations can be considered for treatment of bleeding complications. Rikkers (1998) reported that portosystemic shunts and esophagogastric devascularization have an important role in selected patients with bleeding related to portal hypertension.

Compared with the risk of postoperative hepatic encephalopathy in surgical shunts and TIPS, nonshunting procedures maintain postoperative portal perfusion and long-term hepatic and systemic hemodynamics in patients with cirrhosis, which results in a low incidence of postoperative encephalopathy (Lin et al, 1993; Vons et al, 1996). The applications of shunting operations are limited in patients with extensive thrombosis of the mesenteric venous system, but nonshunting operations do not have such limitations. In addition, nonshunting operations do not alter vascular anatomy and complicate future liver transplant surgery, although they can cause significant upper abdominal adhesions, which are associated with increased bleeding at the time of transplantation.

In the era of multimodalities for bleeding esophagogastric varices, the role of nonshunting operations is redefined as 1) an emergency procedure when medical treatment, endoscopic ligation or sclerotherapy, and TIPS have failed; 2) a part of combined therapies to achieve better outcomes in selected patients (Burroughs et al, 1989); and 3) a long-term bridge to liver transplantation, particularly in patients with splanchnic thrombosis or in the absence of a facility capable of TIPS (Selzner et al, 2001).

In general, nonshunting operations include the devascularization procedure, splenectomy, and esophagus transection. The devascularization procedure has been described as obliteration of varices or disconnection of the esophagogastric veins from the hypertensive portal tributaries. These approaches, known as the Hassab (Hassab, 1998) and Sugiura procedures (Sugiura & Futagawa, 1973), and other modified procedures are discussed.

EFFECTS OF DEVASCULARIZATION AND SPLENECTOMY FOR ESOPHAGEAL VARICES

The principle of devascularization procedures for variceal bleeding is based on anatomic features. The coronary vein and gastric veins are anastomosed with tributaries of the superior vena cava by collateral channels in the submucosa of the esophagus, between the two muscular layers, and in the periesophageal region. In portal hypertension, the increased venous pressure can produce varices throughout the length of the esophagus and down into the upper stomach. In the region of the esophageal hiatus, periesophageal vein dilation does not usually occur, and the most blood flow goes through the esophageal submucosal varices. Hence, most bleeding occurs in the distal segment of the esophagus, in the last 5 cm, usually at the esophagogastric junction (Spence, 1984).

Spence and colleagues (1983) applied a computerized image analysis system to study the venous anatomy of the esophagus; serial sections have shown that the large vessels in the lamina propria communicate directly with dilated intraepithelial blood channels via the epithelial papillae. These intraepithelial channels seen histologically represent the cherry-red spots viewed endoscopically (Spence & Terblanche, 1987). An ideal technique of control for bleeding varices would be permanent obliteration of the varices in the lower periesophageal vessels and intraepithelial dilated vessels.

Portal hypertension, however, is not decreased even with the ideal devascularization procedures. Some methods to reduce the portal hypertension include medication with β_2-blockers, octreotide, and vasopressin (Dell'Era et al, 2008) and surgical treatment. Liver transplantation is the most effective treatment to reduce portal hypertension, but splenectomy may also have benefit in this regard. Zhang and colleagues (2009) found a decreased portal venous pressure gradient, decreased portal venous flow, and increased hepatic artery flow after splenectomy with periesophagogastric devascularization, which resulted in short-term improvement in hepatic functional reserve. De Cleva and colleagues (2007) compared esophagogastric devascularization plus splenectomy with distal splenorenal shunt in hemodynamic evaluation and found similar improved hyperdynamic circulation in schistosomal portal hypertension.

HISTORY OF ESOPHAGEAL TRANSECTION, DEVASCULARIZATION, AND SPLENECTOMY

Crile (1950) proposed transthoracic ligation of esophageal varices, and subsequently many modifications of his technique have been devised. Boerema (1949) and Vosschulte (1957) introduced the simple button technique for transabdominal esophageal transection, but unfortunately, this method was a major source of stricture formation (Johnston & Kelly, 1976). Walker (1964) used a vertical incision for the muscle layers of the esophagus and a transverse division of the mucosa and

submucosa to reduce the risk of posttransection leakage. About the same time, Tanner (1961) proposed a subcardiac portoazygos disconnection with gastric transection. Hassab (1967) found that in patients with bleeding esophageal varices secondary to schistosomiasis, an adequate gastroesophageal devascularization procedure via the abdomen was possible. This technique, known as the *Hassab procedure,* included splenectomy but not esophageal or gastric transection, and Hassab (1998) reported a remarkably low rate of rebleeding with this method.

Japanese surgeons devised an extensive transthoracic paraesophageal devascularization and esophageal transection combined with an abdominal component consisting of splenectomy, devascularization of the upper stomach, vagotomy, and pyloroplasty (Sugiura & Futagawa, 1973). Thereafter, some Japanese surgeons modified this *Sugiura procedure* with a sole abdominal approach and achieved similar survival (Inokuchi, 1985).

In 1974, Vankemmel published the first report of the use of a circular stapling gun for esophageal transection. This technique removes approximately 1 cm of full-thickness esophageal wall, provides a safe suture line, and reduces the risk of stricture formation. Jin and Rikkers (1996) reported the American experience with a modified Sugiura procedure without esophagus transection as an effective method for treating variceal hemorrhage. Johnson and colleagues (2006) proposed that the same results could be achieved with a transabdominal modified devascularization procedure without esophageal stapler transection. Nakamura and colleagues (1996) simultaneously used the Hassab procedure and endoscopic injection sclerotherapy for esophageal varices. Hashizume and colleagues (1998) first applied the laparoscopic technique to perform the Hassab procedure and splenectomy successfully in 10 patients with cirrhosis and varices. Jiang and colleagues (2009) compared open and laparoscopic splenectomy with azygoportal devascularization and concluded that the laparoscopic procedure was a safe and effective method in carefully selected patients.

HASSAB PROCEDURE

Hassab (1967) proposed a method of gastroesophageal decongestion and splenectomy (GEDS) for management of bleeding varices. In this approach, the patient is in a supine position; a 30-degree, head-up tilt improves the exposure of the operative field. A midline epigastric incision is generally used. Occasionally, an extended left subcostal incision or L-shaped incision of the left upper abdomen is used for extreme splenomegaly. The left lobe of the liver is retracted. In case of left lobe hypertrophy in cirrhotic patients, division of the left lobe ligaments may be useful. Splenectomy was initially performed, and the splenic artery could be suture ligated from the upper part of the pancreatic body if pancreatic tail oozing persisted. Next, the gastrohepatic ligament is divided in the area where it is thin and usually transparent, exposing the right crus of the esophageal hiatus. The incision is carried out superiorly over the anterior aspect of the esophagus, dividing the reflection of the parietal peritoneum at the junction between the esophagus and the diaphragm. The incision is pursued down the left side of the esophagus until the left crus of the esophageal hiatus is identified. The abdominal esophagus is isolated by circumferential dissection and looped with a tape (Fig. 75C.1).

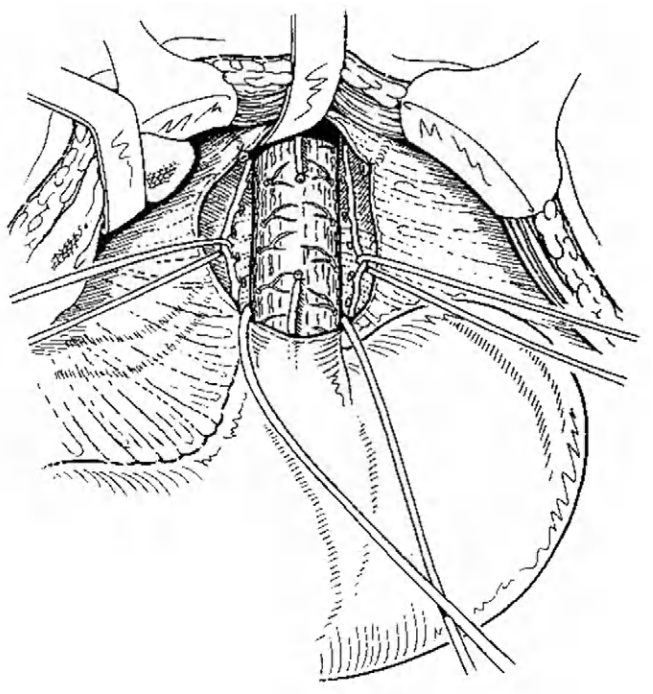

FIGURE 75C.1. Technique of esophageal exposure for devascularization. A tape has been placed around the esophagus, and the vagus nerves have been divided.

The Hassab procedure consists of splenectomy, perihiatal devascularization of the lower esophagus, ligation of the left gastric vessels, devascularization of the proximal half of the stomach, and separation of the stomach from its bed through the abdominal approach (Fig. 75C.2). The points of this technique are 1) perihiatal devascularization of the lower 3 to 4 inches of the esophagus with ligation of any vessels or vagus nerves ascending through the hiatus and diaphragm; 2) ligation of the left gastric artery branches to the stomach, taking care to avoid injury to any accessory left hepatic artery; 3) devascularization of the proximal half of the stomach, taking care to reperitonealize the greater curvature of the stomach to avoid rebleeding; and 4) aggressive pulmonary toilet, which is necessary to avoid basal collapse and chest infection. As an additional step, suction drainage of the splenic bed was suggested by Hassab (1998) to avoid subphrenic infection, although this is probably unnecessary.

Hassab (1998) suggested that combined sclerotherapy or endoscopic ligation could reduce rebleeding if there were missed obliterated esophageal perforators or if devascularization at operation was incomplete. Nakamura and colleagues (1992) applied endoscopic ultrasonography and reported that GEDS is effective for the extramural connections, but for the intramural connections, combination with sclerotherapy is necessary. Hassab (1998) reported that esophageal transection is unnecessary and instead disconnected the perigastroesophageal portoazygos connections; this is contrary to Sugiura and Futagawa (1973), who preserved them and interrupted gastroesophageal continuity with stapled transection and reanastomosis. Zhang (1991) compared treatment of variceal bleeding treated with GEDS or GEDS plus esophageal transection and found that the simple procedure without transection was effective in maintaining good quality of life with no encephalopathy. He reported maintenance of liver function and an upper gastrointestinal (GI)

bleeding rate of 3.1% within 2 years. The addition of esophageal transection did not change the bleeding rate and added more serious complications early after operation.

SUGIURA AND MODIFIED SUGIURA PROCEDURES

The Sugiura procedure is a nonshunting technique aimed at the eradication of esophageal varices. The operation consists of an extensive paraesophagogastric devascularization with esophageal transection and splenectomy through successive thoracic and abdominal incisions. The results obtained by Sugiura and Futagawa (1973, 1984) in Japan were impressive and led some authors to evaluate the efficacy of the operation in Western countries. In the West, the Sugiura procedure was believed to be technically complex and time consuming and was largely ignored or abandoned. Interest was renewed, however, when simplified procedures using an exclusive abdominal approach and stapled transection were described (Peracchia et al, 1980). The original procedure proposed by Sugiura and Futagawa (1973) and the modified procedure described by Ginsberg and colleagues (1982) and Umeyama and colleagues (1983), which is the procedure used routinely use today (Liao et al, 2009), are described.

Sugiura Procedure

The original Sugiura procedure (Fig. 75C.3) is performed in two steps; a thoracic approach is taken first, followed by an abdominal procedure 4 to 6 weeks later (Sugiura & Futagawa, 1973). The thoracic procedure is carried out through a left lateral thoracotomy using the sixth or seventh intercostal space. The mediastinal pleura over the esophagus is opened longitudinally. The lower part of the thoracic esophagus is surrounded by dilated (adventitial) veins that form a plexus. These adventitial veins run parallel to the esophageal wall and communicate with the submucosal veins (variceal channels) via large perforating veins. All these perforating veins must be completely and systematically ligated and divided to devascularize the esophagus; at the same time, great care must be taken not to damage the adventitial veins, which represent a spontaneous portacaval shunt. Usually, 30 to 50 perforating veins must be ligated over a 12- to 18-cm length of the thoracic esophagus. At the level of the hiatus, periesophageal channels are bulky and esophageal varices predominate. Thorough devascularization of this region is paramount because it prepares the area for esophageal transection. After completion of the devascularization, esophageal transection is performed at the level of the diaphragm. During this step, esophageal varices are electively occluded with sutures. A nasogastric tube is left in the stomach and the thorax is closed with appropriate drainage.

The abdominal procedure is subsequently performed through an upper midline or left subcostal laparotomy, and splenectomy is performed. The abdominal esophagus and the cardia are devascularized, as are the greater curvature and the posterior aspect of the stomach. The posterior vagus nerve is divided as in a selective vagotomy (Sugiura & Futagawa, 1973). Devascularization of the lesser curvature of the stomach follows, and the cardioesophageal branches of the left gastric vessels are ligated and divided. Devascularization is performed over more than 7 cm of gastric wall from the cardia (Sugiura & Futagawa,

1973), and the esophagus and the cardia are completely mobilized and freed from the adjacent anatomic structures. Devascularization is facilitated by the division of the anterior vagus nerve; because of this, pyloroplasty is performed, and the abdominal incision is closed. Both key steps of the abdominal procedure may be performed during the same operative session by using synchronous incisions. If such an option is elected, the abdominal procedure is carried out through a left subcostal incision.

Modified Sugiura Procedure

In this approach, the entire operation is performed through a one-stage transabdominal approach via a midline incision or extension of a left subcostal incision as an L-shaped incision. The patient is slightly rotated to the right, and strong mechanical retractors lift the costal margin cephalad to expose the left subphrenic space.

The procedure is initiated with splenectomy. Removal of the spleen, which is usually enlarged, dramatically improves the exposure of the abdominal esophagus and facilitates paraesophagogastric devascularization. Gastric devascularization is begun at the greater curvature of the stomach and continues along its upper part and is performed adjacent to the stomach wall. Completion of the greater curvature devascularization at the cardia is facilitated by placing a tape around the abdominal esophagus. This maneuver is not always easy in the presence of portal hypertension, especially when extrahepatic portal vein thrombosis is present, and it is difficult in patients who have undergone previous sclerotherapy. The posterior aspect of the upper part of the stomach is devascularized, including the esophagogastric branches of the left gastric vessels; devascularization is likewise pursued along the lesser curvature. The surgical technique used is similar to that of proximal gastric vagotomy. The heel of the crow's foot of the nerve of Latarjet nerve is divided, and devascularization is carried up to the esophagus.

To improve the exposure of the esophagus, the diaphragmatic orifice of the esophagus is opened. The pericardium is freed from the upper aspect of the diaphragm, which is divided sagittally. Esophageal devascularization is performed close to the esophageal wall by dividing only the vessels running transversely (perforating veins) and coursing to perforate the esophageal wall. Devascularization is pursued over a distance of 10 to 12 cm; this step of the operation is facilitated by using clips. In patients who have had previous sclerotherapy with periesophageal fibrosis, completely safe devascularization may be technically impossible; but at the very least, devascularization should be done within the limits of safety to avoid damaging the esophagus. The degree of difficulty during this step of the procedure most likely is linked to the type of sclerosant used and the number of sclerotherapy sessions carried out before surgery (Alam et al, 1996; Chaudhary & Aranya, 1991).

Esophageal transection is performed with a mechanical stapler introduced through a short gastrotomy (Fig 75C.4). In cases of previous sclerotherapy, thickness of the lower end of the esophagus and inflammatory changes preclude the use of a large stapler. A 29-mm circular stapler is optimal for this procedure; however, a smaller stapler (25 mm) may be required, especially in patients treated by previous sclerotherapy (Mariette et al, 1994).

In the postoperative period, it has been the tradition to start total parenteral nutrition for 7 days. On postoperative day 7, the patient is administered a meglumine diatrizoate meal or gastrografin swallow to check the patency of the transection line and confirm the lack of fistulae. Endoscopic examination of the esophagus is systematically performed 3 weeks postoperatively, and dilation of any stricture is performed as required.

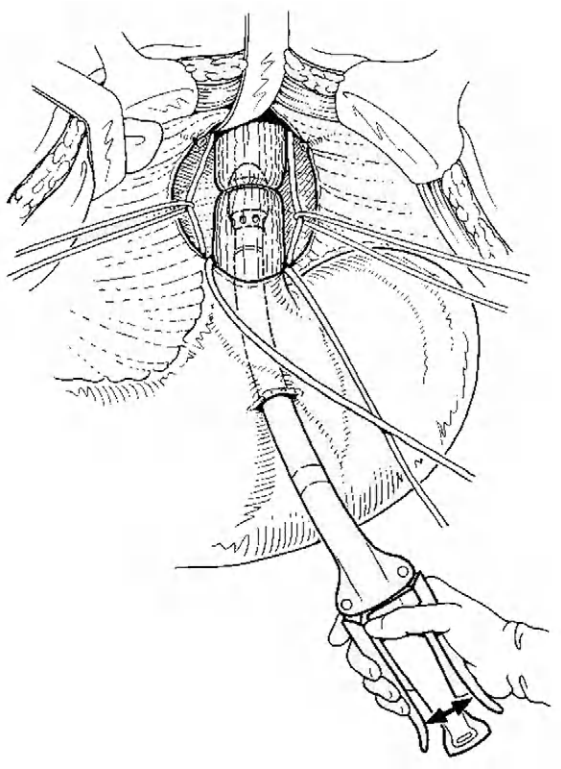

FIGURE 75C.4. Esophageal transection by a mechanical stapler. The head of the circular stapler has been closed, and the esophageal anastomosis has been completed.

The Sugiura operation includes five procedures, and only devascularization of the gastroesophagus remains in many versions of the modified Sugiura operation. Ginsberg and coworkers (1982) proposed that esophagogastric devascularization be performed without dividing the main vagus trunks; only a proximal gastric vagotomy is done, thereby avoiding a pyloroplasty. Hidalgo Huerta and colleagues (1983) proposed using a Nissen fundoplication to allow wrapping of the transection line, which may prevent reflux possibly caused by extensive dissection of the cardia. Johnson and colleagues (2006) reported that devascularization without esophageal transection has similar safety and outcome as devascularization with esophageal transection to control variceal bleeding. In a prospective, controlled, randomized trial that included 55 patients, Orozco and colleagues (1998) reported that splenectomy may be unnecessary in the Sugiura procedure for control of variceal bleeding; they showed that the no-splenectomy group had fewer blood transfusions and less postoperative portal vein thrombosis, and no difference was reported in rebleeding and encephalopathy rates compared with the splenectomy group.

LAPAROSCOPIC DEVASCULARIZATION

With the development of laparoscopic instrumentation and advanced surgical techniques, the gastroesophageal devascularization procedure can now be performed laparoscopically.

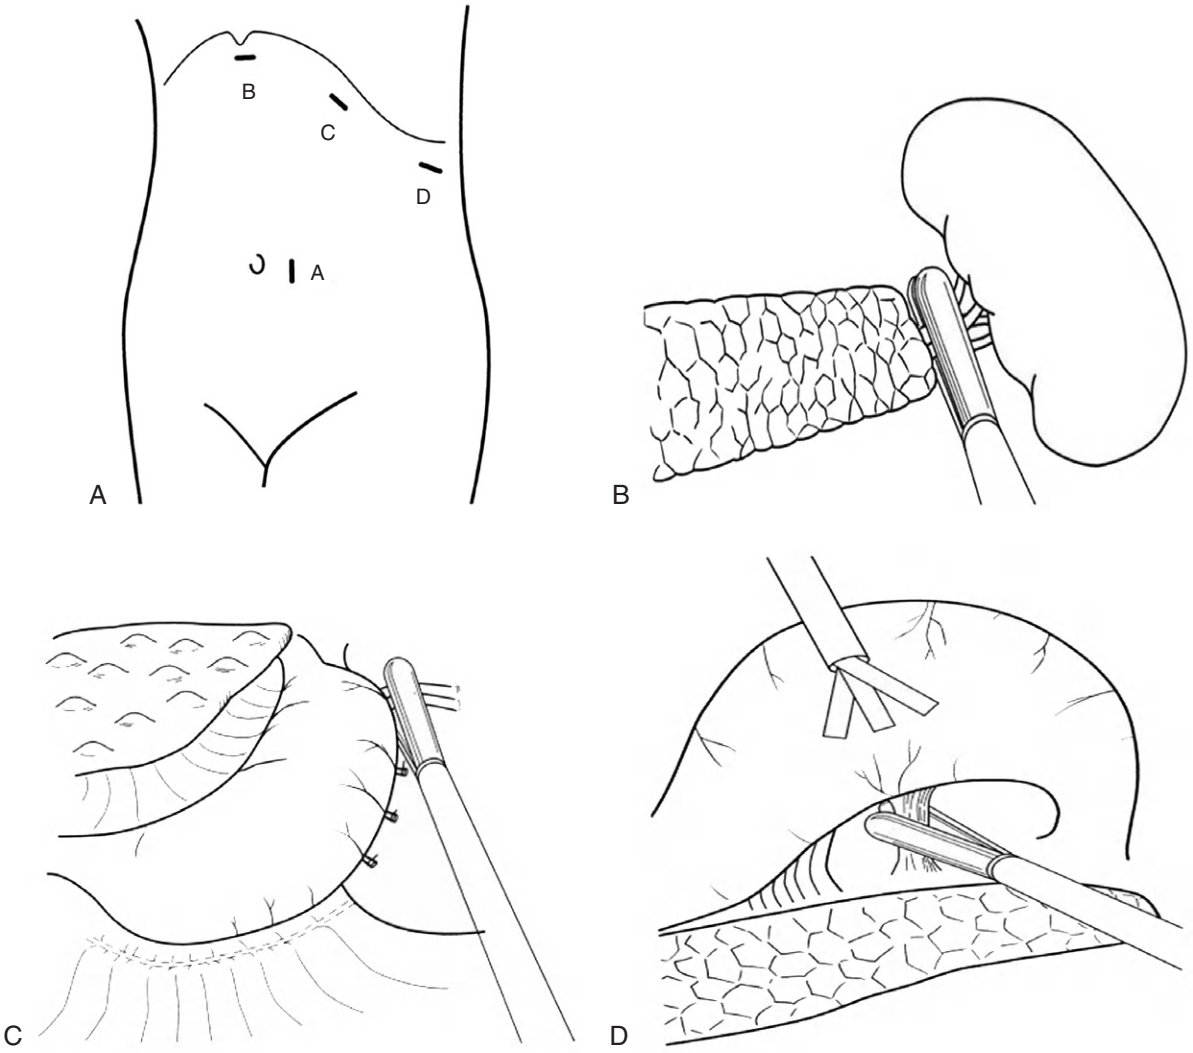

FIGURE 75C.5. Port sites. **A,** Close to the umbilicus, where a laparoscope is inserted (**B** to **D**), in the left upper abdomen along the subcostal line, is where 12-mm trocars are inserted. **B,** The splenectomy is completed with an autosuture device, and the splenic artery and vein are cut. **C,** Devascularization along the fundic area is done with the autosuture device after dissecting the posterior wall of the stomach. **D,** Devascularization along the lesser curvature, including the left gastric artery and vein, is done with the autosuture device, while the greater curvature of the stomach is lifted up. *(From Hashizume M, 1998: Laparoscopic gastric devascularization and splenectomy for sclerotherapy-resistant esophagogastric varices with hypersplenism. J Am Coll Surg 187:263-270.)*

The patient is placed in a right semidecubitus position; the trocar port sites are shown in Fig. 75C.5A. The laparoscope is introduced through the cannula close to the umbilicus, and three other 12-mm trocars are inserted into the left subcostal region. The splenocolic ligament is divided with the Harmonic Scalpel (Ethicon, Cincinnati, OH), and the spleen is mobilized from splenophrenic and splenorenal ligaments by both blunt dissection and coagulation. Exposure of the splenic hilum is completed by a division of the gastrosplenic ligament, and the short gastric vessels are divided with a Harmonic Scalpel or autosuture device (Linear Cutter; Ethicon); the autosuture device can also be useful for resecting the spleen at the splenic hilum (Fig. 75C.5B). A large, nylon surgical sack (Endo Catch II; U.S. Surgical, Norwalk, CT) is introduced into the abdominal cavity, and the spleen is maneuvered into the sack, where it is grasped by forceps and crushed with a Kelly clamp and removed.

Devascularization of the short gastric vessels is completed along the greater curvature of the upper stomach after splenectomy. First, the posterior wall of the fundus is dissected and devascularized with the autosuture device (Fig. 75C.5C). Next, the lesser omentum is opened with the Harmonic Scalpel, and the esophageal branches of the left gastric vessels are cut along the lower esophagus. The lesser curvature of the stomach is then dissected until the left gastric artery and vein are exposed, while the greater curvature is lifted up with a retractor (Fig. 75C.5D). Finally, the upper stomach is freed from its bed, and devascularization completed.

Kitano and associates (1994) first reported seven cirrhotic patients with bleeding esophagogastric varices treated by laparoscopic devascularization of the lower esophagus and upper stomach. Hashizume and colleagues (1998) successfully applied the laparoscopic Hassab procedure for sclerotherapy-resistant esophagogastric varices combined with hypersplenism. In

TIPS, transjugular intrahepatic portosystemic shunt; DSRS, distal splenorenal shunt

subsequent years, other authors (Danis et al, 2004; Jiang et al, 2009; Wang et al, 2008; Yamamoto et al, 2006) reported their experience with laparoscopic devascularization with splenectomy and concluded that this is a feasible, relatively safe, and minimally invasive surgical procedure in selected patients.

RESULTS

A number of treatment options exist for bleeding esophagogastric varices, including surgical shunting, nonshunt operations, and endoscopy with sclerotherapy or variceal ligation (Table 75C.1). The two kinds of devascularization of gastroesophageal varices are the Hassab and Sugiura procedures, and the reported rebleeding rates, respectively, are 6.2% to 8.3% and 10% to 26%. A concerning complication of the Hassab operation is gastric outlet obstruction as a result of vagus trunk transection without pyloroplasty. The specific complications of the Sugiura operation are esophageal leak and stenosis from the esophageal transection procedure. Compared with the rebleeding rate of 20% to 50% in endoscopic sclerotheapy, devascularization operations seem to be better for rebleeding control. The distal splenorenal shunt has a superior rebleeding control rate, but shunt occlusion and encephalopathy have limited its clinical application in some centers. Although the devascularization operation is complex, it can achieve rebleeding control.

Operative Mortality

The overall operative mortality rate of the Hassab procedure in Egypt (Hassab, 1967) is 12.4%, and the overall operative mortality rate is 8.5% for the Sugiura operation in Japan (Inokuchi, 1985). The rates compare favorably with the operative mortality rates of various other abdominal operations performed in cirrhotic patients (Franzetta et al, 2003; Sirinek et al, 1987). When the devascularization operation is used as an emergency procedure, the operative mortality rate increases dramatically to 38.4% in the Hassab and 20.6% in the Sugiura procedure (Table 75C.2). The overall and emergency operative mortality rates with the modified Sugiura operation from Japanese reports (Inokuchi, 1985) are 7.1% and 31%, respectively. A laparoscopic Hassab operation was recently developed, but experience is still limited and it has only been performed in highly select patients. Other variations of the Sugiura procedure have been proposed outside Japan; however, given the limited case experience, it is not possible to gauge surgical mortality rates accurately with the modified procedures.

Operative Morbidity

The rates of complications and 5-year survival in various devascularization operations are different (Table 75C.3). The correlative factors should be related to the severity of the liver cirrhosis (e.g., Child-Turcotte-Pugh class C), etiology of the liver disease (schistosomal or cirrhotic portal hypertension), and the surgical methods used (with or without esophageal transection). The rebleeding rates are 6.2% to 12%, 5% to 26%, and 3.9% to 31% with the Hassab, Sugiura, and modified Sugiura procedures, respectively. The range of the rebleeding rates may be attributable to the complete or incomplete devascularization procedure (Hassab, 1998). Most devascularization procedures do not result in deterioration of liver function, and chronic encephalopathy is generally not exacerbated. Complications of esophageal leakage and stenosis are related to esophageal transection. The rate of esophageal leakage and stenosis with the Sugiura operation are 6% to 14% and 2% to 28%, respectively. The incidence rates for the modified Sugiura operation are similar, and the risk of portal vein thrombosis after the Sugiura procedure has been emphasized by Sugiura and Futagawa (1984). Portal vein thrombosis may be linked to thrombocythemia or to a decrease in portal blood flow after splenectomy (Takenaka et al, 1990) and affects 1% to 6% of patients. The 5-year survival rate with the Hassab operation is 73% to 85%, seemingly better than other devascularization procedures. However, these improved results may be attributable to the frequent use of schistosomal portal hypertension with preserved liver function. The 5-year survival rate of the Sugiura and modified Sugiura operations is approximately 70% and dramatically decreases to about 30% in the emergency setting.

ROLE OF SPLENECTOMY AND DEVASCULARIZATION IN LIVER TRANSPLANTATION

Shunt and nonshunt operations cannot improve liver function in cirrhotic patients in the long term; this can only be accomplished with liver transplantation. Some shunt operations impair liver function and result in worsening of hepatic encephalopathy (Henderson et al, 2006). Nonshunt operations, such as the Hassab and Sugiura procedures, seem to preserve liver function and increase hepatic artery flow in the short term (Zhang et al, 2009). Technique and experience accumulation has improved the success rate of endoscopic variceal ligation for variceal bleeding; however, endoscopic variceal ligation and devascularization with splenectomy can occlude collateral veins both inside and outside the esophageal wall (Liu et al, 2006). Laparoscopic devascularization with splenectomy combined with endoscopic variceal ligation may be an ideal procedure for consideration as a bridge to liver transplantation in cirrhotic patients with variceal bleeding. This approach not only controls variceal bleeding, but also may maintain liver function and may be associated with decreased surgical adhesions when compared with open devascularization procedures.

CHAPTER 76B

Technique of portocaval shunting

Seaborn A. Roddenbery V and Alex S. Rosemurgy II

OVERVIEW

Surgical shunts for portal hypertension and variceal hemorrhage are rarely undertaken today, in large part as a result of the recent popularity gained by transjugular intrahepatic portosystemic shunting (TIPS) (see Chapter 76E), a general lack of interest by surgeons, and the rising number of liver transplant centers across the United States. As a result, the number of hepatobiliary surgeons who have expertise in surgical shunting is declining, which is not to imply that this is appropriate, but it is true. Although current data document that surgical shunting is superior to TIPS in regard to patency, survival, risk of rebleeding, and maintaining effective hepatic blood flow, TIPS now predominates current therapy for variceal bleeding, likely because of its less invasive nature. The scope of this chapter is to describe the technical aspects of performing a native side-to-side portacaval shunt and a small-diameter prosthetic H-graft portocaval shunt. Unlike an end-to-side portacaval shunt, these shunts potentially preserve effective hepatic blood flow and are not ascitogenic.

Variceal hemorrhage secondary to portal hypertension presents an enormous challenge and responsibility to surgeons. Varices that are actively bleeding should be treated pharmacologically and endoscopically, if possible, prior to surgical management (see Chapters 75A and 75B). In the opinion of most providers, it should be a priority to stabilize the patient with nonoperative measures rather than attempt an emergency surgical shunt. The primary goal of surgery is to control ongoing hemorrhage and to prevent future life-threatening hemorrhage without inducing hepatic dysfunction. Patients should not be candidates for imminent liver transplantation (i.e., within 6 months), and an optimal candidate should have a Model for End-Stage Liver Disease (MELD) score less than 14 or have a Child-Turcotte-Pugh (CTP) class of A or B. However, for patients with advanced liver disease without prospects for transplantation, shunting is advocated for resource conservation and control of hemorrhage, albeit with increased risk of hepatic decompensation. With a recent episode of hemorrhage, the total bilirubin may be elevated, which increases the MELD score at the time of hospitalization. In these circumstances, it is helpful to extrapolate the patient's MELD score or CTP class back to a time prior to the most recent hospitalization and/or hemorrhage.

A side-to-side portacaval shunt, as well as a small-diameter prosthetic H-graft portacaval shunt (HGPCS), is constructed for bleeding esophageal or gastric varices as a result of portal hypertension, most commonly caused by cirrhosis. Side-to-side portacaval shunts are placed electively or as an emergency in patients with a history of bleeding esophageal and/or gastric varices not amenable to or failing endoscopic therapy; prophylactic shunts are not recommended. In patients with acute bleeding, every effort is made to correct underlying coagulopathy and metabolic disorders, as well as to control active bleeding, using pharmacologic and endoscopic measures or balloon tamponade. An absolute contraindication to side-to-side portacaval shunt is the presence of portal vein (PV) thrombosis; therefore, PV patency is assessed preoperatively to document patency using color-flow Doppler ultrasound or other tests, such as magnetic resonance angiography (MRA) or computed tomography (CT). Side-to-side portacaval shunts are indicated for Budd-Chiari syndrome or other disorders that severely impair hepatic outflow. Contraindications to use include PV or inferior vena cava (IVC) thrombosis, multiple previous abdominal operations, morbid obesity, severe mitral regurgitation and/or aortic stenosis, and poor cardiopulmonary reserve. In contrast to large-diameter side-to-side portacaval shunts, a small-diameter (8 to 10 mm), calibrated, side-to-side portacaval shunt preferentially maintains hepatopetal flow and a normal (6 to 8 mm Hg) pressure gradient between the PV and IVC.

A focused preoperative investigation should include a determination of MELD score and CTP class; assessment of underlying cardiac dysfunction—such as mitral regurgitation or aortic stenosis—and cardiorespiratory reserve; evidence of current alcohol abuse; nutritional status; and presence of ascites and/or encephalopathy. If cardiac dysfunction is suspected, an echocardiogram should be obtained to avoid postoperative heart failure. A transabdominal color-flow Doppler ultrasound or other test is mandatory to assess portasplanchnic patency, directional flow, and patency of the vena cava.

SURGICAL SHUNTS IN THE AGE OF TIPS

TIPS is a "definitive" nonsurgical treatment option for portal hypertension, often coined a "bridge to transplantation," but with many critical issues. The most common causes of TIPS failure are shunt thrombosis and stenosis, both of which lead to variceal rehemorrhage. Numerous reports have shown that hepatic decompensation is unacceptably common after TIPS. In addition, the survival data after TIPS are not comparable to surgical shunts, most notably small-diameter prosthetic HGPCSs (Clark et al, 2010). Of concern is that TIPS excessively diverts nutrient effective hepatic blood flow (EHBF) from liver parenchyma that is already compromised by increased sinusoidal resistance to portal blood flow (Rosemurgy et al, 1995, 2003), thus potentially accelerating hepatic decompensation. Although TIPS does successfully partially decompress the PV and corrects the abnormal physiologic pressure gradient between the PV and IVC, its failures and shortcomings should be recognized, as this treatment option is undertaken frequently,

without thorough consideration of its consequences. Although TIPS is viable for portal pressure decompression and temporary relief from variceal bleeding, the "bridge" to transplantation built by this procedure is seldom crossed; less than 10% of patients who undergo TIPS undergo liver transplantation.

Both TIPS and surgical shunts decompress the portal system, but surgical shunts—notably small, calibrated, side-to-side portacaval shunts and HGPCSs—relatively preserve effective hepatic blood flow. With TIPS, a decompression of portal venous pressure, along with the ensuing decrease in sinusoidal pressure, results in a concomitant increase in arterialization of the liver. However, after TIPS, increases in arterial blood flow, or "arterialization of the liver," are not sufficient to compensate for relative excessive diversion of portal blood flow from the hepatocytes. Excessive decreases in total nutrient blood flow (EHBF) to hepatocytes result after TIPS relative to small-diameter calibrated and reinforced side-to-side portacaval shunts, such as an HGPCS (Rosemurgy et al, 2003). The critical, life-threatening issues of decreased EHBF and variceal rehemorrhage loom over an otherwise successful TIPS decompression.

Variceal hemorrhage after TIPS is relatively common and often results from shunt stenosis or thrombosis. Despite strict follow-up and assessment, TIPS patients experience more shunt occlusion and stenosis, although occlusion can usually be corrected by interventional radiology. The issue is that patients require multiple interventions to maintain shunt patency, whereas with an HGPCS, occlusion is less common. Vigilance with follow-up is necessary after TIPS; often the first sign of TIPS malfunction is variceal rehemorrhage (Rosemurgy et al, 2005).

The long-term complications of nonpatency, shunt stenosis, and thrombosis associated with TIPS are well documented. In 2005, a randomized controlled trial of 132 patients undergoing TIPS versus HGPCS was reported (Rosemurgy et al, 2005). The data demonstrated that stenosis and thrombosis after TIPS placement occurred in significantly more patients, and with greater frequency, compared with HGPCS. In the 32 patients who received TIPS, 66 interventions and/or revisions were required to maintain shunt patency during a 1-year follow-up period. In this study, only seven patients required intervention for patency after HGPCS, and five patients had irreversible TIPS occlusion. Most importantly, irreversible shunt occlusion often presented as major variceal hemorrhage. Of the 32 patients who underwent revisions for TIPS stenosis or thrombosis, 20 of these patients had major variceal rehemorrhage within 30 days, two patients rehemorrhaged after 30 days, and none of the patients had stenotic or thrombosed shunts following HGPCS (Rosemurgy et al, 2005). Also, TIPS has proven to be more expensive than pharmacologic, endoscopic, or surgical shunt treatments, owing to the number of interventions necessary to maintain patency (Kravetz, 2007). Indeed, the "Achilles heel" of TIPS is its lack of patency, and the success of TIPS as a portal decompression procedure is masked by continuing stenosis and thrombosis, requiring more cost for intervention and follow-up. Proponents of TIPS believe this has changed with the advent of covered stents.

A critical issue of TIPS is subsequent mortality. Median time to death after shunting was 29 months (41 ± 39.4 months) after TIPS compared with 56 months (53 ± 40.1 months) after H-graft shunts. Predicted survival was identical in both groups, and actual survival was significantly better for each shunt than predicted, using survival data at 3, 6, 12, and 24 months after shunting (Table 76B.1). However, actual survival with H-graft shunts was superior to survival after TIPS. Furthermore, the time to failure for patients undergoing TIPS or HGPCS was significantly different. For all patients of all CTP classes, TIPS had a median time to failure of 14 months (29 ± 33.2) compared with a median time to failure of HGPCS of 43 months (48 ± 41.9). In a patient with a severely impaired liver, a difference of nearly 30 months is critical, as that time could be utilized to undergo transplantation, if such were indicated and possible.

Table 76B.1

Predicted and Actual Survival for Patients Undergoing TIPS or Small-Diameter HGPCS

		3 mo (%)	6 mo (%)	12 mo (%)	24 mo (%)
TIPS	Predicted	67	59	52	41
	Actual*	77	71	64	53
HGPCS	Predicted	68	60	54	43
	Actual*†	79	79	74	68

Nearly identical predicted survival documents an unbiased randomization. Actual survival after each shunt was superior to predicted survival; differences in actual survival cannot be explained by poor outcomes after each shunt. Actual survival was superior after 8-mm prosthetic H-graft portacaval shunts.

*Better than predicted survival ($P < .001$, Mantel Henzel chi-squared test)

†Better than actual survivial after TIPS ($P < .001$, Mantel Henzel chi-squared test).

TIPS, transjugular intrahepatic portosystemic shunt; HGPCS, prosthetic H-graft portacaval shunts.

For patients with poor hepatic reserve, the implications of reduced EHBF to an already diseased liver parenchyma can be devastating. EHBF is nutrient-rich portal blood flow—carrying venous return from the spleen, small intestine, and colon—and oxygen- and nutrient-rich arterial blood flow. This venous inflow to the liver also carries protein products and toxins that need to be neutralized, reduced, detoxified, or broken down to some degree by the liver. Given the changes in portal blood flow associated with TIPS, hepatic "arterialization" after TIPS is inadequate to maintain EHBF (Rosemurgy et al, 2003), therefore hepatic decompensation is promoted after TIPS.

TECHNIQUE OF SIDE-TO-SIDE PORTACAVAL SHUNTS

For a side-to-side portacaval shunt, the patient is positioned in a 30-degree left lateral decubitus position with rolled sheets. A transverse incision is used to divide the right rectus abdominis muscle and a portion of the external oblique and transversus abdominis muscles. Variations in incisions have been described, but in any case, the midline usually does not need to be crossed. Well-padded self-retaining retractors are placed over the gallbladder and hepatic flexure to expose the hepatoduodenal ligament.

A limited Kocher maneuver is undertaken, utilizing electrocautery generously, beginning at the foramen of Winslow with division of the tissue caudally. The peritoneal membranes contain collateral vessels that can be controlled with cautery, and identification and ligation of lymphatics in this area seems unnecessary. The ventral surface of the vena cava is exposed, and dissection of the areolar tissue encasing the vena cava is carried out circumferentially to the level of the renal veins. Often small veins entering the cava must be ligated during the

course of the dissection. Once its mobilization is complete, a vessel loop or umbilical tape is placed around the vena cava, which should elevate toward the PV without difficulty.

The hepatoduodenal ligament is then incised posteriorly and laterally with electrocautery, and the PV is identified. If present, the common bile duct and replaced hepatic artery are retracted medially with a vein retractor. Whatever shunt is utilized, it is very important to identify and preserve an accessory or replaced right hepatic artery to avoid deficiencies in EHBF after shunting. The dissection is carried out along the axis of the PV in a cranial then caudal fashion. While grasping the vein with a Russian forceps, a Yankauer suction tip is utilized to gently lift the fibroareolar tissue away from the vein. A circumferential dissection ensues with placement of a vessel loop around the PV; the vessel loop is used to retract the vein laterally, as the PV is mobilized to its bifurcation distally and toward the pancreas proximally.

To determine whether the mobilizations of both vena cava and PV are adequate, the vena cava is raised ventrally, and the PV is retracted posterolaterally, each with their respective vessel loops. Although typically unnecessary, a small portion of pancreas may be divided to ensure an adequate length of PV; in addition, a portion of the caudate lobe may be resected to ensure adequate caval length and exposure. Prior to and upon completion of the shunt, venous pressures in the PV and IVC are measured with a 25-gauge needle and a pressure-transducing setup identical to that utilized with an arterial line.

A side-biting Satinsky clamp is placed over the ventral aspect of the vena cava, and two right-angled vascular clamps are placed approximately 5 cm apart on an overlying segment of PV. A 2.5-cm longitudinal strip of vena cava is excised following venotomy. Excision of this "window" is to ensure adequate outflow for the shunt. Similarly, a 2.5-cm strip of PV is excised along the posterolateral aspect of the vein. Heparinized saline is injected within the lumina of both vessels. Beginning in the middle of the left/back wall of the anastomosis, a 5-0 double-armed polypropylene is used in a running manner at the cephalad and caudal extents (Fig. 76B.1). The sutures are tied at each corner of the anastomosis, at the cephalad and caudad extents. The right side or front wall is completed with two 5-0 polypropylene sutures, beginning at each corner; these are tied to the free ends of the posterior layer, and the right side is run from each end toward the midportion of the anastomosis. Prior to tying the sutures together, the vascular clamps are partially released, beginning with the vena cava, to release thrombus that may have formed. Upon completion of the anastomosis, the clamps are sequentially released, beginning with the vena cava, followed by the distal PV clamp and finally the proximal vein clamp. Portal and caval pressures should be similar—that is, equal or near equal—following completion of the shunt. An elevated gradient above 4 to 5 mm Hg should alert the surgeon to a technical problem that must be addressed expediently to decrease the risk of PV or shunt thrombosis.

Postoperative care includes careful monitoring of vital signs and urine output as well as judicious usage of intravenous fluids. Central venous pressure measurement is useful as a guide to the end point of resuscitation. It is important to be attentive to mental status changes and development of ascites, as these may be signs of shunt dysfunction. If shunt failure is suspected, a transabdominal color-flow Doppler should be obtained for confirmation. The best way to study shunt function is through transfemoral cannulation of the shunt and portal system. Through this approach, the shunt can be imaged radiographically, pressures across the shunt can be measured (i.e., the PV-IVC pressure gradient), flow in the portal system can be graded, and large collaterals from the portal system to the gastroesophageal variceal complex can be embolized.

TECHNIQUE OF SMALL-DIAMETER (8 MM) H-GRAFT PORTACAVAL SHUNTS

For a small-diameter HGPCS, the patient is placed supine on the operating table and rolled into a 30-degree left lateral decubitus position by placing a rolled sheet beneath the patient's right side. A transverse incision is utilized from the midline, extending just beyond the lateral border of the rectus sheath. The incision is placed over the liver edge, if palpable. Because of collaterals that may be present, the falciform ligament is carefully divided if necessary. Our preference is to use the table-mounted Omni retractor in conjunction with wound protectors; once the wound is saturated with Clorpactin solution and well padded, a sternal blade is placed cranially (Rosemurgy, 2007).

A Kocher maneuver is initiated at the foramen of Winslow and carried caudad, using electrocautery liberally. The goal is to expose approximately 5 cm of IVC, including only about one half of the ventral circumference of the vessel, thus facilitating placement of a side-biting Satinsky vascular clamp (Fig. 76B.2). Because the patient is rotated to the left, a common error is to carry the dissection lateral to the vena cava into the renal hilum; this should be avoided.

Once the vena cava is adequately exposed, attention is then turned to the hepatoduodenal ligament. A splanchnic blade is placed over a well-padded gallbladder. This retraction should be toward the patient's left shoulder, effectively rotating the common bile duct and any replaced/accessory right hepatic artery ventrally and medially. The dissection is then carried parallel and dorsal to the common bile duct. Lymphatics are predominantly found in this area, overlying the PV, and these should be ligated to avoid postoperative ascites formation. Care should be taken to identify an accessory or replaced right hepatic artery and to avoid injuring it. A vein retractor is placed over the common bile duct, and it is retracted medially to facilitate exposure of the PV. As the PV becomes visible, a generous portion of the vein should be grasped with Russian forceps. The enveloping tissue of the posterior hepatoduodenal ligament may be similarly grasped, and the plane is developed with a Yankauer sucker. Gentle, small strokes will separate the enveloping tissue from the PV without injuring any small branches. The ventral and medial surface of the PV is exposed in a similar fashion, grasping the vein with Russian forceps, retracting laterally, and passing the Yankauer sucker along the ventral surface of the vein. A right-angle clamp is placed around the PV, followed by a vessel loop (Fig. 76B.3). The vessel loop may then be used to retract the vein laterally and expose a generous circumferential portion of the PV if necessary, although circumferential dissection of the PV is generally superfluous.

A segment of 8-mm externally reinforced polytetrafluoroethylene (PTFE) graft is used for the prosthetic small-diameter HGPCS. The graft is fashioned to measure 3 cm from toe to toe and 1.5 cm from heel to heel. Because the PV is naturally oriented approximately 60 degrees to the vena cava, the bevels of each end of the graft are at 90 degrees to each other. Once the graft is cut to size, it is placed in a syringe full of heparinized

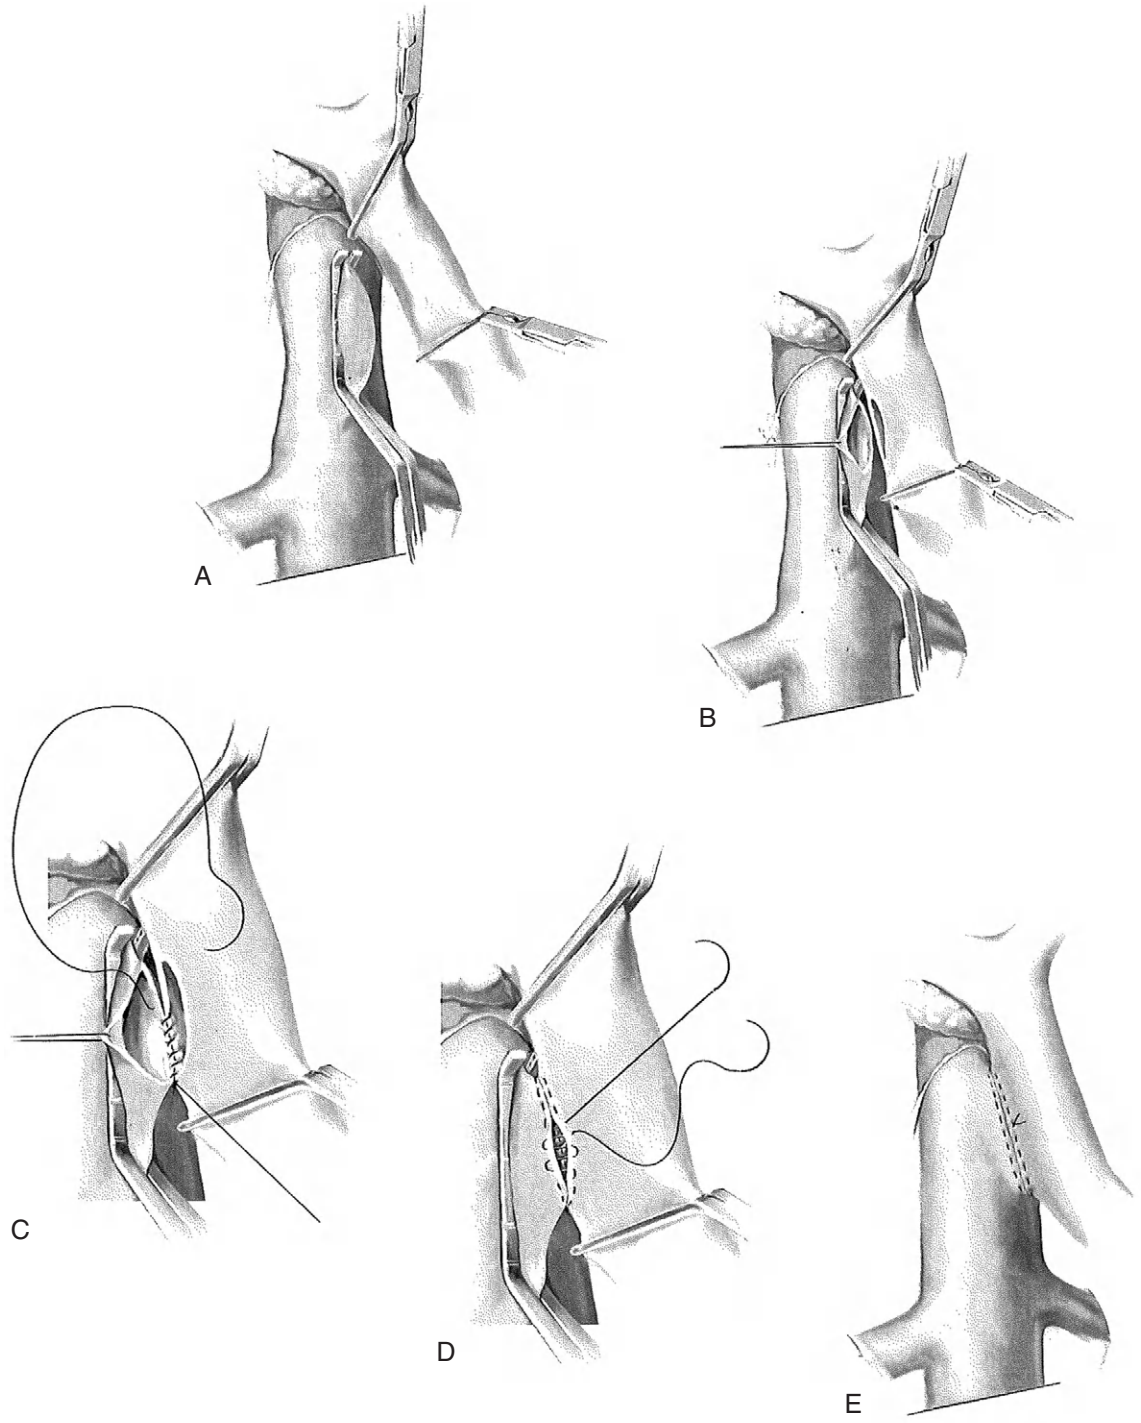

FIGURE 76B.1. Side-to-side portacaval anastomosis. *(From Orloff M, Orloff S, 2007: Portacaval shunts: side-to-side and end-to-side. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 687-702.)*

saline. With a finger over the tip of the syringe, suction is placed on the syringe. Dislodged air bubbles will emanate from the graft, and vigorous tapping on the side of the syringe will facilitate their dispersal. By removing air from the graft, heparin will completely bathe the prosthesis and facilitate Doppler ultrasound postoperatively, which may enhance patency.

A ringed forceps is used to grasp the anterior wall of the vena cava, retracting ventrally as a side-biting Satinsky clamp is placed upon the vein. The vascular clamp must be fully closed to prevent the wall of the IVC slipping from the clamp. A portion of the vena cava wall is then excised that should measure approximately 4 mm long and 2 mm wide ex vivo. The anastomosis to the vena cava is sewn with running 5-0 polypropylene suture, beginning at the cephalad apex of the anastomosis and progressing along the back, or left, medial wall (Fig. 76B.4). Begin by placing a horizontal mattress suture at the heel/

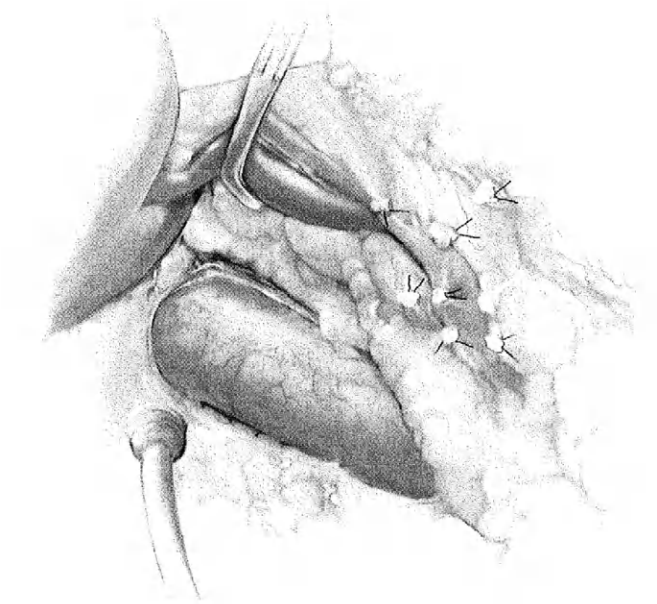

FIGURE 76B.2. Kocherization and preparation of the vena cava. *(From Rosemurgy A, et al, 2007: 8-mm Interposition Portacaval Shunt. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 675-685.)*

cephalad apex of the anastomosis, and run the suture in-to-out on the vein and out-to-in on the graft until beyond the toe of the graft. At that point, the other limb of the 5-0 polypropylene is utilized to complete the lateral front right wall of the anastomosis. The IVC-graft anastomosis can be assessed by occluding the graft with a right-angle clamp and releasing the occlusion of the Satinsky clamp (Fig. 76B.5). The Satinsky clamp is then replaced on the vena cava, and the graft is irrigated with heparinized saline to remove blood and clot.

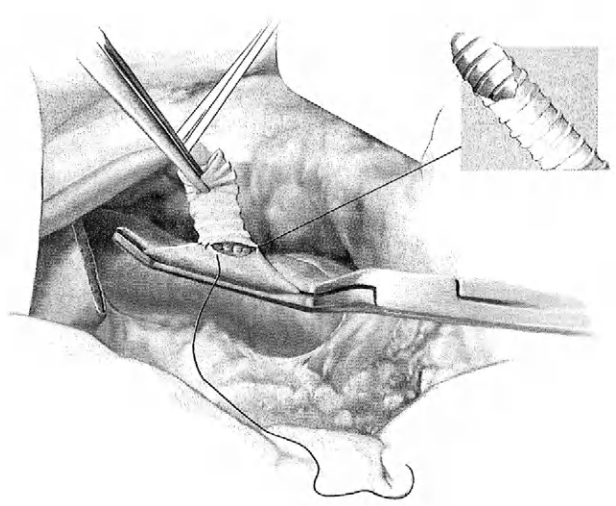

FIGURE 76B.4. Graft-caval anastomosis. *(From Rosemurgy A, et al, 2007: 8-mm Interposition Portacaval Shunt. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 675-685.)*

In constructing the PV-graft anastomosis, the posterolateral wall of the PV is grasped with a Russian forceps and retracted laterally. A right-angled side-biting clamp is then placed on the PV, although the PV need not be completely occluded to perform the anastomosis. An 11-blade scalpel is used to achieve a venotomy, which is then extended with Potts scissors. A retraction suture is placed in the mid-ventral venotomy to facilitate exposure (Fig. 76B.6). The anastomosis begins at the mid-dorsal/posterior aspect of the venotomy using a double-armed 5-0 polypropylene suture. Again, a horizontal mattress suture is placed, followed by a running suture (Fig. 76B.7), sewing in-to-out on the vein and out-to-in on the graft in a cephalad then caudal direction. Once the back row is complete, the suture is drawn tight with a nerve hook. The ventral layer is then sewn

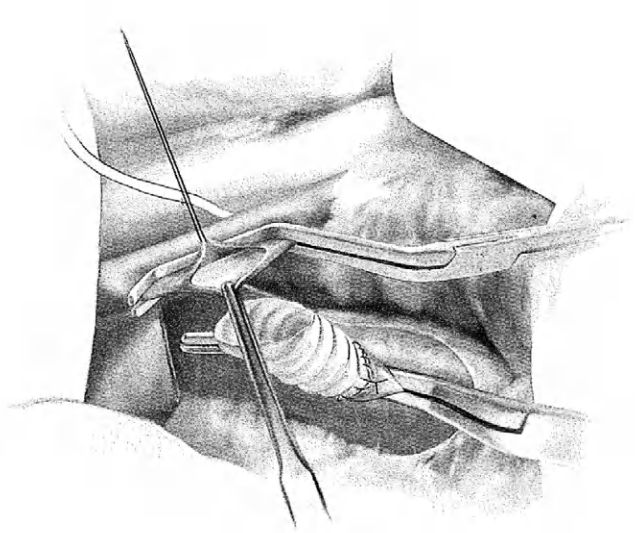

FIGURE 76B.6. Preparation of the portal vein–graft anastomosis. *(From Rosemurgy A, et al, 2007: 8-mm Interposition Portacaval Shunt. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 675-685.)*

with each free end of the double-armed suture, converging upon the midportion of the venotomy. Prior to closure, the PV clamp is partially released to blow clot and debris. Again, once the clamp is reapplied, vigorous irrigation of the graft and PV with heparinized saline is carried out.

Next, the sutures are tied along the anterior aspect of the anastomosis; this requires that arm of the suture be reversed to tie the sutures from opposing sides of the anastomosis (Fig. 76B.8). The clamp on the vena cava is removed prior to removing the clamp on the PV; a palpable thrill should be present in the vena cava cephalad to the anastomosis. Two metallic clips are preferentially placed cephalad and caudal to the caval

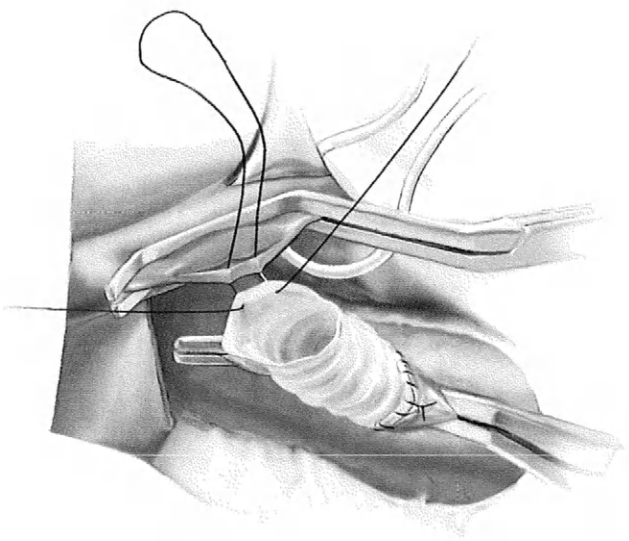

FIGURE 76B.7. Portal vein–graft anastomosis. *(From Rosemurgy A, et al, 2007: 8-mm Interposition Portacaval Shunt. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 675-685.)*

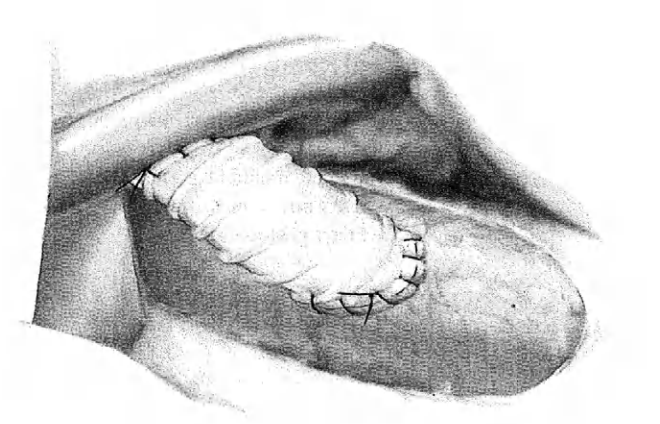

FIGURE 76B.8. The completed small-diameter prosthetic H-graft portacaval shunt. *(From Rosemurgy A, et al, 2007: 8-mm Interposition Portacaval Shunt. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 675-685.)*

anastomosis to allow radiologists to identify and cannulate the anastomosis (Fig. 76B.9).

Pressures within the PV and vena cava should be measured prior to beginning and immediately following attainment of the anastomosis. This may be accomplished using a 25-gauge needle and sterile pressure-transduction tubing identical to an arterial line. The tubing is connected to the needle and then passed to anesthesia to connect to the monitor. A near 20-mm Hg PV-IVC pressure gradient is generally observed prior to shunting, with an approximate pressure of 30 mm Hg present in the PV and a pressure of 10 mm Hg in the vena cava. Pressures are again measured after shunting, and we expect the gradient to fall by more than 10 mm Hg to less than 10 mm Hg; usually, a

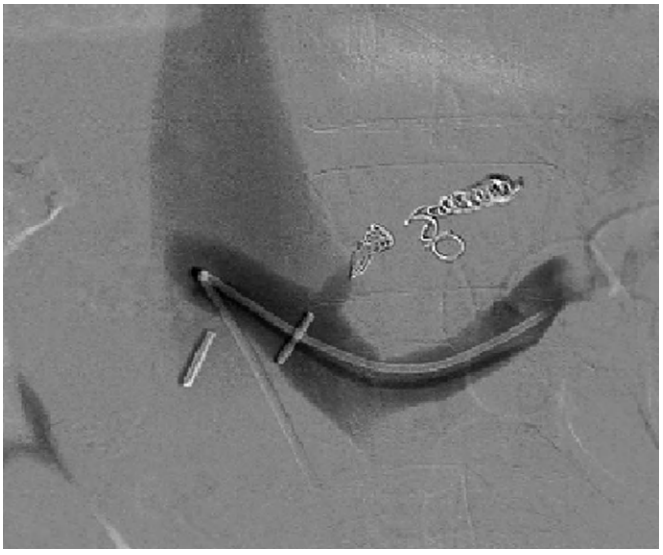

FIGURE 76B.9. Transfemoral portal venography after application of coils in the coronary vein following 8-mm H-graft portosystemic shunt. Note opacification of the inferior vena cava, documenting flow through the shunt. *(From Rosemurgy A, et al, 2007: 8-mm Interposition Portacaval Shunt. In Clavian P, Sarr M, Fong Y [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. New York, Springer, pp 675-685.)*

6- to 8-mm Hg gradient is observed. As expected, the caval pressure rises, and the portal pressure decreases. If the portal pressure and the PV-IVC pressure gradient fall by 10 mm Hg or more, and the PV-IVC pressure gradient is less than 10 mm Hg in the presence of a thrill on the IVC, long-term patency should be expected.

Postoperatively, the patient is placed in a monitored unit. We are judicious in regard to intravenous (IV) resuscitation after surgery, not exceeding a rate equal to the patient's maintenance requirements. IV therapy is discontinued as early as postoperative day 1, and we allow the patient to begin a trial of liquids, progressing the diet as tolerated. On the third or fourth postoperative day, a transfemoral shunt study is carried out by interventional radiology. As previously mentioned, metallic clips were placed at the vena cava–graft anastomosis to facilitate this procedure. Documentation of patency with venography and acceptable pressure measurements are necessary prior to discharge. Again, a gradient near 6 to 8 mm Hg is sought. New-onset encephalopathy and/or ascites following surgery should raise concern for PV or graft thrombosis. With concerns, a repeat transfemoral shunt study will confirm patency, or an intervention can be undertaken.

CONCLUSION

Variceal hemorrhage secondary to portal hypertension is a life-threatening condition that is most effectively treated by surgical management. Unfortunately, in the United States, most portal decompression procedures are implemented by nonsurgeons in the form of TIPS. Pharmacologic and endoscopic therapy should be first employed to address acute hemorrhage followed by a surgical shunt on an elective basis if possible. Small-diameter (8 mm) prosthetic H-graft portosystemic shunts have been studied in a prospective randomized trial and are superior to TIPS in regard to patency and survival. Additionally, effective hepatic blood flow is maintained at an acceptable level with the small-diameter HGPCS, unlike TIPS or other surgical shunts that divert an excessive amount of portal blood flow away from the hepatic parenchyma. Experience with side-to-side portacaval shunts is also promising and supportive, especially when undertaken in an emergency. Technical aspects of portacaval shunts are reproducible and should be within the armamentarium of hepatobiliary surgeons.

CHAPTER 76C

Distal splenorenal shunt

J. Michael Henderson

BACKGROUND

The distal splenorenal shunt (DSRS) was developed by Warren and colleagues in 1967 to achieve selective variceal decompression to prevent recurrent variceal bleeding. Selective variceal decompression combines the benefit of a decompressive shunt to control bleeding with maintenance of portal hypertension and portal flow to the cirrhotic liver to help maintain liver function. The original, classic article on selective variceal decompression described the animal work leading up to the initial clinical data on DSRS (Warren et al, 1967). Proof of concept was shown in the animal studies and in the results of the first six patients in whom DSRS was performed. The unique prior experiences of Warren and Zeppa led to the evolution of this concept: Warren had seen that total shunts control variceal bleeding, but at the cost of liver failure, whereas Zeppa had seen devascularization procedures maintain portal perfusion, but at a cost of significant risk of rebleeding.

Over the next 4 decades, DSRS became the most widely used operation to control variceal bleeding, with a worldwide following (Orozco et al, 2007). The technique continued to evolve, with greater degrees of portal azygos disconnection improving its effectiveness (Henderson et al, 1989). However, in the 1990s, the evolution of improved endoscopic therapy with banding (see Chapter 75B), introduction of transjugular intrahepatic portosystemic shunting (TIPS; see Chapter 76E), and coming of age of liver transplantation (see Chapter 97) left few indications for shunt surgery for variceal bleeding (see Chapter 76A).

INDICATIONS FOR DSRS

The indications for DSRS have markedly diminished in the last decade, as other options have improved, and the available expertise of surgeons facile at performing DSRS has diminished. That said, DSRS remains a good option for the following patients:

- Patients with variceal bleeding refractory to endoscopic and pharmacologic therapy who have well-preserved and stable liver function
- Patients with portal hypertension and normal livers, such as those with portal vein thrombosis, who have refractory bleeding and a patent splenic vein
- Patients in some geographic locations, where there is only one chance to control bleeding, and they cannot return for the multiple visits required for management with endoscopy or TIPS

PATIENT EVALUATION

Patients being considered for DSRS require full evaluation to define 1) gastroesophageal varices as the source of bleeding, 2) the cause of the portal hypertension, 3) status of liver function and damage, and 4) vascular anatomy. Evaluation for possible DSRS is only appropriate in patients on propranolol with documented recurrent variceal bleeding or persistent high-risk varices and who have had adequate endoscopic management. Accurate endoscopic evaluation is therefore the first step. In this context, these patients have had upper diagnostic and therapeutic endoscopy at the time of an acute variceal bleed, and follow-up endoscopy is aimed at therapeutic variceal obliteration. Prior to considering patients for DSRS, endoscopy should confirm persistent varices or portal hypertensive gastropathy.

The cause of portal hypertension for most patients in the United States and Europe with variceal bleeding is cirrhosis. In these patients, the first question to be addressed is whether the patient now or in the future is a candidate for liver transplantation. If the patient is likely to need a transplant in the next 1 to 2 years, surgical shunt is not indicated. If the patient has good liver function and is unlikely to need a transplant in the near future, DSRS may be a good option. Other etiologies of portal hypertension—portal vein thrombosis or noncirrhotic portal fibrosis, in which patients have normal liver function—need to be defined early in the evaluation, because the long-term prognosis depends on best prevention of variceal bleeding. Such patients may be candidates for DSRS earlier in their management.

Liver function is assessed from clinical findings and laboratory studies. Jaundice, ascites, and encephalopathy are the three clinical signs and symptoms of advanced liver disease and indicate that patients are not candidates for surgical decompression. Laboratory measurements of serum bilirubin, albumin, serum creatinine, and prothrombin time prolongation are the most useful studies to assess the status of cirrhosis. Combining the clinical and laboratory parameters to discern the Child-Turcotte-Pugh (CTP) class and/or Model for End-Stage Liver Disease (MELD) score gives an objective assessment of risk (Table 76C.1 and Box 76C.1).

Imaging for portal venous anatomy helps with diagnosis and treatment planning and should be performed as part of the evaluation of patients after their initial variceal hemorrhage. Doppler ultrasound can usually visualize the splenic, superior mesenteric, and portal veins as well as the hepatic veins for liver outflow. Early identification of thrombosis of the portal and/or splenic veins may alter the whole approach in the management of the patient. Ultrasound also should examine liver morphology, particularly for evidence of focal lesions suggestive of hepatocellular carcinoma. Computed tomography (CT) or magnetic resonance (MR) vascular imaging and morphologic assessment can augment ultrasound studies; usually these are sufficient to make clinical decisions.

Arteriography may sometimes be required for final definition of the veins before surgical intervention. The components of this evaluation can include the following:

Table 76C.1

Child-Turcotte-Pugh Classification

	NO. POINTS		
	1	2	2
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Increase in prothrombin time (sec)	1-3	4-6	>6
Ascites	None	Slight	Moderate
Encephalopathy	None	1-2	3-4

Grade A: 5-6 points
Grade B: 7-9 points
Grade C: 10-15 points

1. Hepatic venous pressure gradient (HVPG)
2. Left renal vein anatomy and drainage (this is abnormal in 20% of the population)
3. Superior mesenteric, portal, and splenic vein patency, flow direction, and venous anatomy on the venous phase of the arterial study
4. Major variceal inflow paths on the same study as in number 3 above

This combination of venous and arterial angiographic study can give information not available with ultrasound, CT, or magnetic resonance imaging (MRI).

Candidates for DSRS are CTP class A or B 7 or 8 patients (i.e., their CTP score is 7 or 8 points), usually without ascites, who are considered to have stable liver disease and are unlikely to need liver transplantation in the next 5 years.

TECHNIQUE FOR DISTAL SPLENORENAL SHUNT

Attention to detail in perioperative and postoperative monitoring and management of a patient undergoing DSRS improves outcome. Monitoring requires an arterial line, a central venous catheter, and a urinary catheter. Good venous access should be obtained in the event that rapid transfusion is required.

Blood and blood products should be available: packed red blood cells, fresh frozen plasma, and platelets may be required if there is major intraoperative blood loss or perioperative hemorrhage. A cell saver can be used in higher risk patients and may reduce blood bank requirements.

The patient is positioned on the operating table with the left arm at the side and the left side slightly elevated. Hyperextending the operating table to open the angle between the left lower ribs and iliac crest aids in exposure and access to the tail of the pancreas. The primary operating surgeon is on the patient's right. The operation is more easily completed when the first assistant (to the left of the table) also has experience with the procedure.

Model for End-Stage Liver Disease Score for Liver Disease Severity

Score = $0.957 \times \log_e$ creatinine (mg/dL) + $0.378 \times \log_e$ bilirubin (mg/dL) +1.120 $\log_e$ INR

INR, international normalized ratio

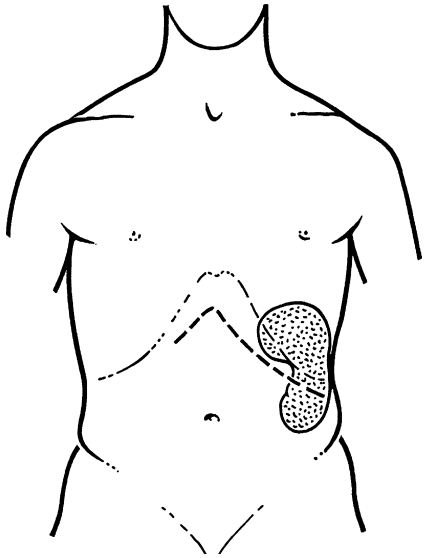

FIGURE 76C.1. The left subcostal incision extends across the midline and right rectus muscle.

The steps in DSRS are illustrated. The preferred incision is a long left subcostal incision, extended across the right rectus muscle (Fig. 76C.1). Coagulating diathermy should be used extensively in patients with portal hypertension to achieve hemostasis in dividing tissues. If present, ascites should be aspirated and cultured, and a liver biopsy specimen should be obtained to document the status of the liver at the time of the procedure.

Step 1: Exposure

The initial steps of this procedure provide access to the vessels. The pancreas is exposed by opening the lesser sac (Fig. 76C.2) and interrupting the gastroepiploic arcade from the pylorus to the first short gastric vessels. Exposure is greatly enhanced by taking down the splenic flexure of the colon from the lower pole of the spleen. This is done most easily by initially mobilizing the left side of the splenic flexure of the colon, then identifying the plane from there back into the lesser sac at the tail of the pancreas. The splenocolic ligament is divided, giving excellent exposure to the inferior margin of the pancreas from the mesenteric vessels to the splenic hilus. The pancreas is then fully mobilized along its inferior border over its entire length, so that it is turned completely on its side; this is achieved with a combination of Bovie coagulation and ligature of tissues (Fig. 76C.3). The inferior mesenteric vein is the first venous landmark identified: in 50% of patients, this vein enters the splenic vein; in the other 50%, it enters the superior mesenteric vein. The inferior mesenteric vein should be traced up to these vessels and then divided to aid further exposure.

Step 2: Isolation of the Splenic Vein

The superior mesenteric and splenic vein junction is identified, initially on its posterior surface; this is a safe plane for initial dissection. The splenic vein should be isolated along its inferior and posterior aspect with dissection occuring right on the vessel (Fig. 76C.4). At this point, the splenic, superior mesenteric, and posterior aspects of the portal vein all should be cleared (Fig. 76C.5).

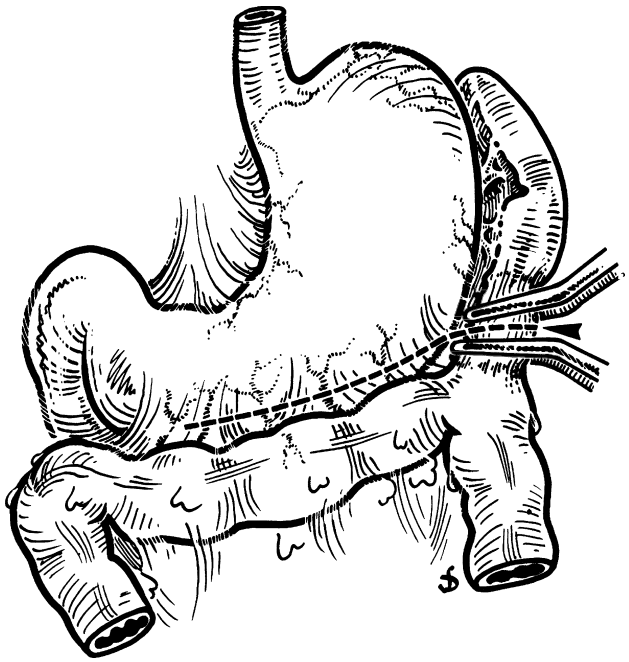

FIGURE 76C.2. Access to the pancreas is through the gastrocolic omentum. Dividing the splenocolic ligament improves exposure and divides collateral varices to the splenic hilus.

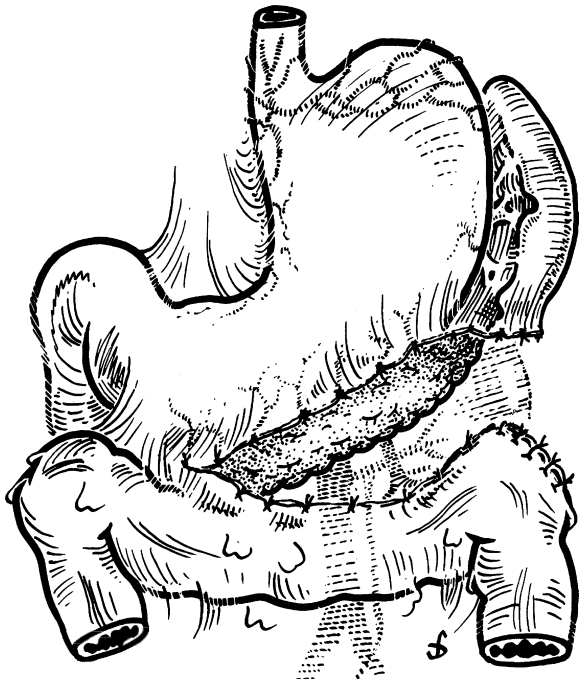

FIGURE 76C.3. The pancreas is mobilized from the superior mesenteric vein to the spleen by dividing the posterior parietal peritoneum along its inferior margin.

When the posterior plane is free, attention turns to the anterior and more difficult plane of dissection on the splenic vein. Tributaries rarely enter the anterior surface of the portal vein; so this plane between the neck of the pancreas and the portal vein should be opened first, then the pancreas should be cautiously separated and dissected from the anterior and superior surfaces of the splenic vein. The key is to dissect the pancreas

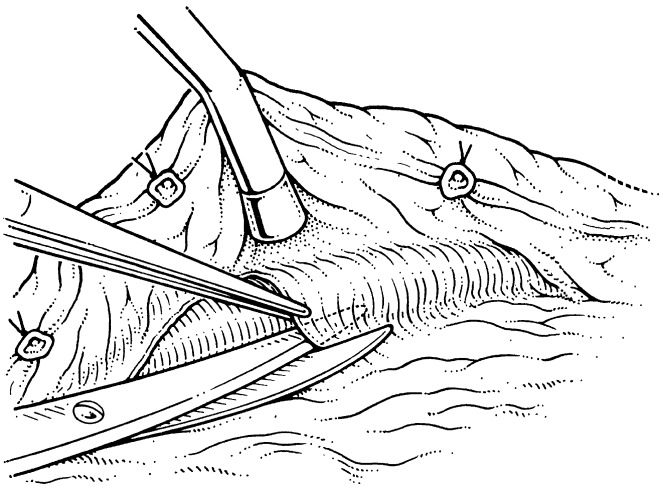

FIGURE 76C.4. The splenic vein is dissected initially along its inferior and posterior edge. This dissection must be directly on the vein.

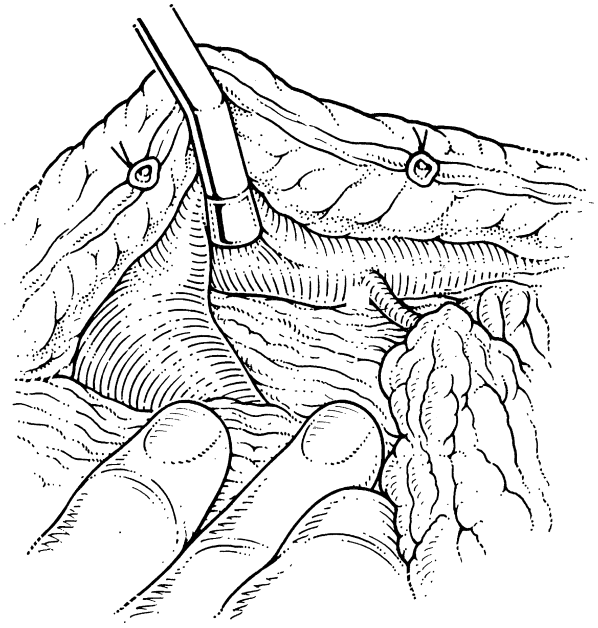

FIGURE 76C.5. The posterior plane behind the splenic vein should be developed first, and the plane behind the confluence of the splenic vein, superior mesenteric vein, and portal vein is opened.

off the splenic vein rather than the other way around. This requires a delicate touch and is best achieved by spreading the tissues gently in the line of the tributaries and at right angles to the splenic vein. This isolates the tributaries, and when identified, a fine right-angle clamp is passed around them, with a 3-0 tie on the vein side and a clip on the pancreatic side (Fig. 76C.6). As much of the splenic vein as possible should be dissected in this manner before dividing the splenic vein at the superior mesenteric vein junction.

Step 3: Isolation of the Left Renal Vein

The left renal vein is isolated and mobilized from the retroperitoneum; this is best done before dividing the splenic vein at the superior mesenteric junction. Preoperative renal venography

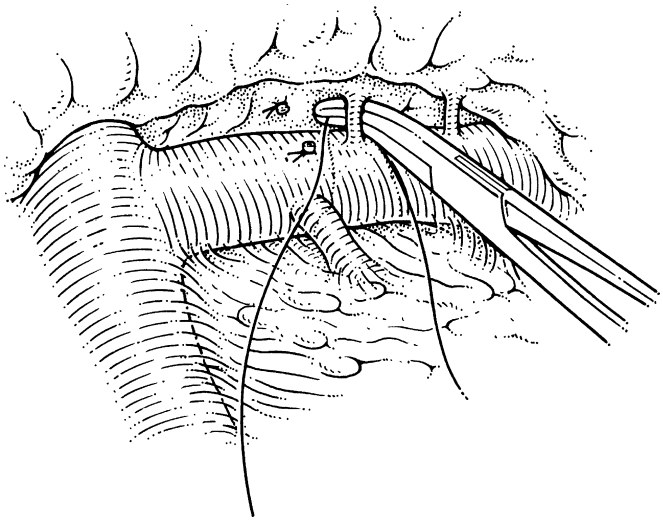

FIGURE 76C.6. Isolation of tributaries from the pancreas into the splenic vein requires their dissection at right angles to the splenic vein. These vessels have thin walls and require gentle dissection.

should have shown the anatomy and defined any abnormality: a circumaortic left renal vein is found in 16% of the population, and in 4%, the left renal vein is totally retroaortic; the latter may preclude performance of DSRS. In circumaortic anatomy, the anterior branch is usually larger and is adequate for outflow for DSRS.

The retroperitoneum is opened just to the left of the superior mesenteric artery and in front of the aorta; these landmarks are identified by palpation. The divided tissue in front of the left renal vein should be ligated, because there are many lymphatics in it, and ligation minimizes the risk of postoperative chylous ascites. Initial dissection should be minimal to identify the left renal vein, which should be mobilized over an adequate length to allow it to be brought up into a side-biting vascular clamp. The left adrenal vein should be divided, whereas the gonadal vessel is left intact, because it can serve as an outflow tract. The vein should be mobilized over approximately 3 cm, and as a guide, the anastomosis usually is made just anterior to the adrenal vein orifice.

Step 4: Division of the Splenic Vein

This is the step that lines up the splenic and left renal veins for anastomosis. The superior mesenteric end of the splenic vein is ligated with a 2-0 silk, and a large clip is placed flush with the vein behind that tie; this has led to the lowest incidence of thrombus within the portal vein at postoperative angiography. At this point the surgeon must judge whether enough splenic vein has been dissected free of the pancreas to allow it to come down to the left renal vein without kinking or tension. In the event that more dissection of the splenic vein is needed, this can now be performed more easily, because the vein can be manipulated downward, as shown in Figure 76C.7. The disadvantage of this maneuver is that the pressure in the splenic vein has increased with ligation, which leads to greater risk of tearing of the small tributaries.

In patients with alcoholic cirrhosis, data have shown that complete dissection of the splenic vein from the pancreas (*splenopancreatic disconnection*) is advantageous in leading to

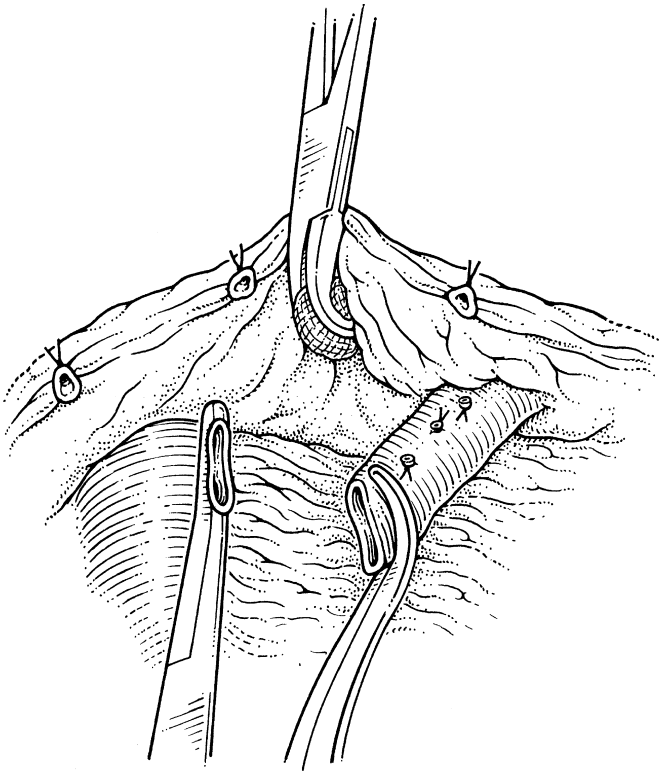

FIGURE 76C.7. Division of the splenic vein allows the angle between the pancreas and vein to be opened. This improves exposure for dissection of small tributaries to the splenic vein at the cost of increased pressure in the vein.

improved long-term maintenance of portal perfusion (Henderson et al, 1989). If this modification of DSRS is used, the complete dissection should be done at this time. Data do not support the need for entire splenopancreatic disconnection in patients with nonalcoholic liver disease.

Step 5: The Anastomosis

This is performed without tension, and usually the splenic vein needs to be trimmed so that when the clamps are removed, the vein is not redundant and lies without kinking. This alignment can be difficult to judge, particularly if the two veins are overlying each other. The position of the clamps and trimming of the splenic vein are shown in Figures 76C.8 and 76C.9. The left renal vein is opened over sufficient length without removing an ellipse. The posterior row of the anastomosis is completed with a running suture, with stay sutures placed at either end, and the suture is run on the inside; the anterior row is usually interrupted to avoid risk of a purse-string effect. The completed anastomosis is shown in Figure 76C.10.

Step 6: Portal Azygos Disconnection

The final step is interrupting the main paths by which the high-pressure portal vein attempts to connect to the now low-pressure splenic vein. These paths are by 1) transpancreatic collaterals, 2) collaterals along the mesocolon to the inferior ramus of the splenic vein, and 3) the left and right gastric venous systems (Henderson et al, 1985). The pancreatic siphon of large collaterals flowing through the pancreas can be prevented by

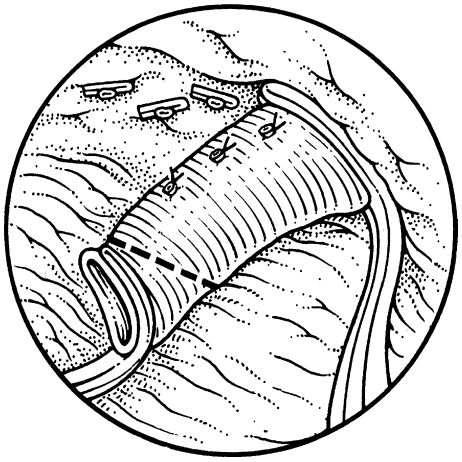

FIGURE 76C.8. Sufficient splenic vein must be dissected out of the pancreas for the vein to come down to the left renal vein without tension or kinking. An adequately dissected splenic vein usually needs to be trimmed.

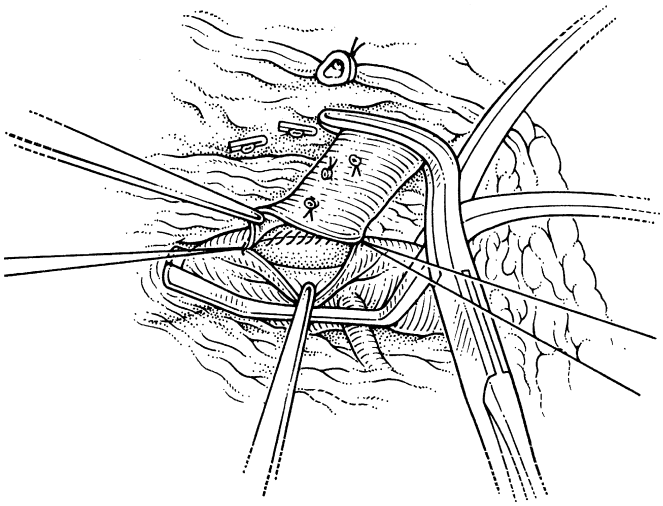

FIGURE 76C.9. The posterior anastomosis is made with a running suture. The clamps must be held for a tension-free anastomosis.

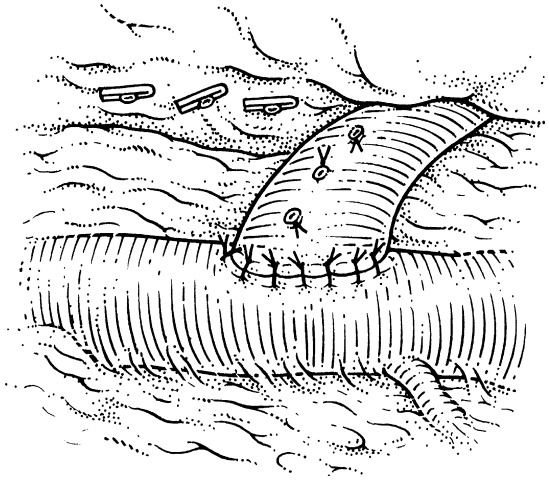

FIGURE 76C.10. The anterior row of the anastomosis is completed with interrupted sutures.

splenopancreatic disconnection as described earlier. The decision whether to do this is made on a benefit-risk basis, depending on the ease of full dissection. The collaterals that develop in the mesocolon have a final common pathway in the splenocolic ligament to the lower pole of the spleen and do not develop if the splenic flexure is taken down as described earlier. The transgastric collaterals are minimized by ligating the left and right gastric veins. The right gastric vein is usually small, but it should be interrupted just above the pylorus. The left gastric (coronary) vein may be very large, and it should be clipped or divided at its junction with the portal or splenic vein. It also should be isolated immediately above the pancreas and divided at this location.

Step 7: Closure

Abdominal closure should be in two layers with a running nonabsorbable suture. No drains are placed.

PATIENT MANAGEMENT

General Measures

Most patients who have a DSRS have cirrhosis. The perioperative risks are from liver failure, ascites, and infection, and these can be minimized by careful management. Risk factors should be defined before surgery, and patient selection is key to minimizing perioperative risk, as described in Patient Evaluation.

Ascites is the major risk factor postoperatively, but this risk can be reduced by careful fluid, diet, and diuretic management. Preoperatively, it is important that the patient maintain a low-sodium diet. If diuretics are necessary, adequate doses of an aldosterone antagonist diuretic to reduce renal sodium reabsorption are given. Perioperatively, the intravenous infusion of free sodium should be minimized, and if plasma volume expansion is required, 5% albumin or fresh frozen plasma should be used. Maintenance fluids should be 5% dextrose with half-normal saline. Postoperatively, when an oral diet has been started, the patient should be limited to 2 g of sodium per day, and dietary fat should be restricted to 30 g/day for the first month to reduce the risk of chylous ascites. In the early postoperative period, 100 mg/day spironolactone (Aldactone) should be given to minimize sodium retention and aid postoperative diuresis. Furosemide may be added to this regimen if significant postoperative ascites occurs. Rarely, paracentesis may be necessary. By following this management routine in CTP class A, B7, or B8 patients, the risk of ascites is minimized.

Infection is a further risk factor in patients with cirrhosis. Antibiotics should be given in the perioperative period. In the postoperative period, infection always should be considered as a possible explanation for patients who fail to progress.

Liver failure should not be a postoperative risk, if patients are appropriately selected for DSRS. CTP class A and B7 or B8 patients should not decompensate, unless they have an excessively difficult procedure with significant hypotension. Should liver decompensation develop, the only management is with liver transplantation.

Specific Measures

Before hospital discharge, the patient should have 1) stable liver function, 2) documented shunt patency, and 3) no increasing ascites. Shunt patency can be assessed indirectly with Doppler

ultrasound, but I advocate shunt catheterization at 1 week postoperatively to document patency and flow and to measure pressures. If the shunt is patent at this time, it is unlikely to undergo subsequent thrombosis or stenosis. The one exception is when DSRS is made with a recanalized splenic vein; this increases the risk of stenosis and requires further shunt catheterization at 3 to 6 weeks. Standard liver biochemistry should be measured on alternate days postoperatively. The bilirubin may increase by 1 to 2 points, but it rarely increases to greater than 5 mg/dL in appropriately selected patients. Fluid management was discussed earlier. Patients are usually ready for discharge from the hospital 6 to 8 days after surgery.

Follow-up

Patients undergoing DSRS should be maintained in long-term follow-up, primarily to follow the underlying liver disease. Cirrhosis is a chronic disease that tends to be progressive, and although data suggest DSRS does not accelerate the rate of progression of cirrhosis, patients may have to be considered for liver transplantation. Reevaluation every 6 to 12 months is recommended.

RESULTS

The goals of DSRS are to prevent recurrent variceal bleeding and, by maintaining portal perfusion, not to accelerate the course of the underlying liver disease. In the 1990s and 2000s, several series documented that these goals can be achieved. Most of these series are in good risk patients (CTP class A and B), and results have been excellent.

Bleeding control is equal to or greater than 90% (Henderson et al, 1992; Herman, 1995; Orozco et al, 1997; Rikkers, 1998; Livingstone et al, 2006; Elwood et al, 2006). The highest risk time for rebleeding after DSRS is in the first month (Richards et al, 1987). The technical failure rate should be less than 5%, and it should be defined before hospital discharge with direct shunt catheterization as described earlier. If a technical problem occurs with the anastomosis at that time, surgical reexploration should be undertaken; if it cannot be corrected, splenectomy and devascularization are indicated. Late thrombosis of DSRS is unusual, although patients with portal vein thrombosis undergoing DSRS have a higher rate of shunt stenosis requiring balloon dilation (Warren et al, 1988). Bleeding control is significantly better than that achieved with endoscopic therapy, which is approximately 25% to 30%.

Portal perfusion is maintained at late follow-up in 90% of patients with nonalcoholic liver disease. In patients with alcoholic cirrhosis, loss of portal perfusion occurs in 50% of patients (Henderson et al, 1985). Zeppa and colleagues (1978) documented poorer survival after DSRS in alcoholic patients than in nonalcoholic patients but never proved cause and effect. The mortality rate can be improved in the latter population by complete splenopancreatic disconnection (Henderson et al, 1989). In this modification, the entire splenic vein is dissected free of the pancreas before anastomosis. Splenopancreatic disconnection also has been documented to improve survival in nonalcoholic patients.

Hepatic function is maintained after DSRS in CTP class A and B patients as shown in the series in the 1990s. The rate of transplantation in these patients is currently less than 20%, but longer term follow-up may show an increase in this number at 10 to 20 years. Survival after DSRS is dictated by the severity of the underlying liver disease. The series from the 1990s and 2000s cited above documented 5-year survival of 80% to 90% for CTP class A and B patients.

Two major questions have arisen over the past 5 years: How often is variceal decompression needed, given improved pharmacologic and endoscopic treatment? (D'Amico et al, 2002) And is a surgical shunt ever needed in the era of TIPS? Current data show refractory bleeding through endoscopic and pharmacologic therapy in 15% to 20% of patients; most of these patients have poor liver function, and their only reasonable decompression option is liver transplantation.

The relative efficacy of surgical decompression versus TIPS has been studied in two randomized trials. One study assessed the 8-mm portacaval shunt versus TIPS, and although the surgical limb had better bleeding control, overall outcome was not significantly different (Rosemurgy et al, 2005). In a randomized trial (Henderson et al, 2006) of DSRS versus TIPS in CTP class A and B patients, the rebleeding rates were not significantly different, 6% and 11%, but 83% of TIPS patients required reintervention and dilation to achieve this outcome. Survival and encephalopathy rates were not significantly different in this study. Cost-effectiveness analysis showed a slight advantage to TIPS in this trial (Boyer et al, 2008), and it can be concluded that TIPS is equally effective as DSRS.

In summary, DSRS is an excellent operation for controlling refractory variceal bleeding in patients with portal hypertension and well-preserved liver function. Its current role is, however, minimal given the evolution of other therapeutic options, as succinctly summarized by Hector Orozco (Orozco et al, 2007): "What a pity. There have been many ideas to resolve a problem, many years of work, many patients treated, and one surgical solution that was approaching the ideal: low morbidity, low mortality, low recurrence of the hemorrhagic episodes, and long survival. Despite all of this, we threw it away because we did not know how, when, and to whom we might give it."

CHAPTER 76D

Mesocaval shunt

Matthew P. Landman and C. Wright Pinson

HISTORY OF THE MESOCAVAL SHUNT

Eck first described decompression of the portal system via the portacaval shunt in 1877. The first mesocaval shunt was developed primarily for children with portal vein thrombosis by Marion in 1953 (Marion et al, 1965) and Clatworthy in 1955. In the Marion-Clatworthy J-shunt, the inferior vena cava (IVC) is divided just proximal to the confluence of the iliac veins, and the proximal end is anastomosed to the lateral aspect of the superior mesenteric vein (Clatworthy, 1955). In 1954, Valdoni also described this procedure in a discussion regarding treatment options for portal hypertension. Because of the complications of venous stasis, including intractable lower extremity edema, this shunt never gained popularity in adults.

In 1970, Read and colleagues described the use of homologous vein graft as a conduit for the mesocaval shunt. In 1972, Drapanas reported good success with prosthetic mesocaval shunts by showing efficacy in 25 patients with acute exsanguinating variceal hemorrhage and popularized the procedure. Throughout the 1970s, several authors reported success with autologous, homologous, heterologous, and synthetic mesocaval shunts for the treatment of bleeding varices.

INDICATIONS FOR MESOCAVAL SHUNTS

With remarkable advances in endoscopic therapy, interventional radiology, and liver transplantation, the role of surgical shunts in the treatment of complications related to portal hypertension has been revised (see Chapter 76A). Although alternatives exist, surgical shunts remain an important intervention in some patients. The use of transjugular intrahepatic portosystemic shunts (TIPS; see Chapter 76E) has decreased the need for surgical shunts dramatically. TIPS provides only short-term treatment, however; it requires constant monitoring and frequent intervention, and such shunts are appropriate only in patients with advanced liver disease, as a "bridge" to transplantation, or in severely ill patients with a short life expectancy. In contrast, surgical shunt are best performed in patients who have bleeding varices refractory to endoscopic intervention with good hepatic reserve (i.e., Child-Turcotte-Pugh [CTP] classes A and B). Indications for surgical shunt procedures include variceal hemorrhage with good hepatic reserve, failed TIPS, portal vein thrombosis, Budd-Chiari syndrome, refractory ascites, portal hypertensive biliopathy, and small-for-size syndrome in liver transplantation; although more recently, portal decompression has emerged for the treatment of small-for-size syndrome in liver transplantation.

The most common indication for surgical shunt is bleeding varices refractory to medical and endoscopic therapy in patients who have good hepatic reserve and do not need liver transplantation in the near future. Henderson and colleagues (2000) showed excellent outcomes in CTP class A and B cirrhotic patients with refractory bleeding who received surgical shunts. In their series, the overall survival and rebleeding rates were 86% and 6.3%, respectively, with a median follow-up of 36 months. The choice between TIPS and surgical shunts depends on the patient's hepatic reserve and timing to possible transplantation. If transplantation is expected within 1 to 2 years, TIPS is likely to bridge the patient to transplantation without the need for surgical intervention. However, if transplantation is unlikely to occur within 1 to 2 years, surgical shunting is warranted; more than 50% of TIPS patients require intervention within this time period.

Orloff and coworkers (2002) reported the use of portosystemic shunts in the treatment of 200 children and adults with extrahepatic portal hypertension secondary to portal vein thrombosis. In contrast to patients with intrahepatic portal hypertension secondary to cirrhosis, this patient population is often younger and healthier and often has preserved liver function, making them excellent surgical candidates. In this large series by Orloff and colleagues (2002), 100% of patients had normal liver biopsies with normal liver function, and 66 patients (33%) underwent Marion-Clatworthy–type cavomesenteric shunts with no immediate postoperative mortality. Of note, six adult patients experienced postoperative lower extremity edema. The 15-year actuarial survival was noted to be 95% for all shunt types, with shunt patency at 97.5%. Liver function remained normal for 99% of these patients at 5 years. The authors concluded that portosystemic shunting is the most effective treatment for these patients and that these procedures should be performed early in the course of variceal bleeding episodes.

Although Budd-Chiari syndrome (see Chapter 77) with obstruction of the hepatic venous outflow was traditionally treated with portosystemic shunt procedures, other treatment options—including hepatic vein angioplasty, catheter-directed thrombolysis, TIPS, and liver transplantation—have been successfully introduced. After reviewing 54 Budd-Chiari syndrome patients treated at Johns Hopkins Hospital over 20 years, Slakey and colleagues (2001) concluded that shunting and transplantation result in 5-year survival rates of at least 75% in these patients. Fisher and associates (1999) advocated the use of hepatic vein angioplasty for Budd-Chiari syndrome patients with short-length hepatic vein stenosis or occlusion and surgical shunting for patients with diffuse hepatic vein occlusion or failed angioplasty; others recommend TIPS. However, recanalization of the hepatic veins is not always successful and may require a shunt procedure.

A study using the porcine transplant model suggested that mesocaval shunts may provide protective effects for small-for-size liver grafts by protecting them from portal flow–related injuries (Smyrniotis et al, 2003). Case reports are emerging that demonstrate successful use of this technique to alleviate portal

hypertension associated with small-for-size syndrome after living-donor liver transplantation (Boillot et al, 2002; Kokai et al, 2008). A porcine model has demonstrated retention of liver regenerative capabilities despite reduction of venous inflow after left hepatectomy with mesocaval shunt (Pouyet et al, 2007). Given the critical organ shortage and increasing use of segmental grafts, this approach may prove clinically useful in the future.

Because subsequent transplantation often is anticipated in patients receiving portosystemic shunts, the shunt procedure should minimize as much as possible any potential compromise of the technical aspects of the transplant operation. In contrast to portacaval shunts, the distal splenorenal and mesocaval interposition shunts do not alter the porta hepatis anatomy. In a case control study comparing decompressive procedures involving the hepatic hilum with both TIPS and other surgical shunts, Dell'Era and colleagues (2005) noted significantly higher operative times, higher transfusion requirements, increased hospital and intensive care unit (ICU) stays, and higher perioperative mortality in patients with procedures that affected the hepatic hilum. These findings have been reproduced by other authors as well (Menegaux et al, 1994; Mazzaferro et al, 1990; Brems et al, 1989), however, other studies have not found this association (Gonzalez et al, 2005; Abou Jaoude & Almawi, 2001; Boillot et al, 1991). The mesocaval interposition shunt is technically less challenging than the distal splenorenal shunt and requires minimal retroperitoneal dissection. It effectively relieves portal hypertension, and in contrast to the distal splenorenal shunt, it also relieves or prevents secondary ascites.

SHUNT MATERIALS AND MESOCAVAL SHUNT SIZE

Multiple variations of the mesocaval shunt procedure have been described in the literature, and significant debate has ensued regarding the ideal graft material and diameter for the mesocaval shunt. In 1970, Read and colleagues presented a series of eight mesocaval shunts with homologous vena cava. Also in 1970, Lord and associates published a report on seven mesocaval H-grafts with polytetrafluoroethylene (PTFE) prostheses, of which six remained patent for 20 months. Despite Lord's early success, many clinicians remained fearful of using prosthetic grafts in the venous system because of experimental failures in long-term patency. In 1972, Drapanas published data on 25 more mesocaval shunt procedures that used 19- to 22-mm Dacron interposition grafts and showed excellent patency rates. Drapanas cited a superiority of Dacron over PTFE for better incorporation into host tissues and continued to use Dacron in his studies.

Throughout the 1970s, several other groups reported success with large-diameter prosthetic grafts. In 1977, Filtzer and coworkers reviewed their institution's experience with 20 patients who underwent mesocaval shunt procedures using 18- to 22-mm Dacron grafts for bleeding esophageal varices. The long-term patency rate approached 90%. In 1975, Drapanas and associates published a follow-up study on the hemodynamics of 80 mesocaval shunts using large-diameter (18 to 22 mm) Dacron grafts. In this series, a decrease in mean portacaval pressure by 50% was noted, and 44% maintained hepatopetal portal flow. Only three graft thromboses occurred, and overall patency rate was 95%. One patient developed graft infection, however, with subsequent sepsis and death.

Although recurrent esophageal varices and hemorrhage were rare after these procedures, the large-diameter portacaval and mesocaval grafts (16 to 22 mm) often resulted in total portal shunting and loss of prograde portal flow, which many investigators thought led to progressive liver dysfunction and high rates of encephalopathy. Sarfeh and colleagues (1986) investigated the importance of maintaining hepatic portal perfusion for prevention of encephalopathy by systemically reducing the portacaval H-graft diameters. After reviewing 88 patients treated with portacaval shunting for bleeding esophageal varices, they reported maintenance of hepatopetal flow in 82% of patients with 8-mm PTFE H-grafts, 46% with 10 mm PTFE H-grafts, and only 3% with 14- to 20-mm Dacron grafts. Preserved prograde portal flow correlated with decreased rates of encephalopathy, which was observed in only 9% of patients with 8-mm PTFE H-grafts compared with 39% of those with large-diameter Dacron grafts. Although early graft thrombosis was more common in the small-diameter grafts (16%), the cumulative shunt patency rate was 97% for those grafts. One patient experienced graft infection with subsequent sepsis and death. In another study, Isaksson and colleagues (2005) noted that patients with a 14-mm mesocaval shunt had a steady, worsening performance in postoperative follow-up on several psychometric tests, and the rate of hepatofugal portal flow was 90% at 12 months in these patients.

Throughout the 1980s, most reports of small-diameter grafts focused on their use in the portacaval position as opposed to a mesocaval shunt. All studies showed a slightly increased rate of perioperative shunt thrombosis over the large-diameter shunts; this was mostly managed via angiographic revision (Collins et al, 1994; Rypins et al, 1988), and all small-diameter portacaval shunt procedures were coupled with aggressive portal vein collateral ablation.

More recent studies have shown the efficacy of small-diameter mesocaval shunts. Mercado and associates (2000) reviewed a 10-year experience with 10-mm PTFE mesocaval shunts for the treatment of bleeding esophageal varices in mostly low-risk patients with preserved hepatic function. Thirty-three patients underwent the procedure; 81% maintained long-term patency evaluated by angiography, but 15% developed episodes of rebleeding. Only 11% had encephalopathy, and 12-month survival was 81%. Mercado and colleagues (1996) also compared the distal splenorenal shunt with the 10-mm PTFE mesocaval shunt and showed decreased encephalopathy, decreased shunt thrombosis, and fewer changes in portal flow with the distal splenorenal shunt but no differences in mortality or rebleeding rates. They concluded that the mesocaval shunt continues to have a role in the surgical treatment of portal hypertension, when a selective shunt cannot be performed.

Despite considerable debate in the literature since the early 1970s, no definitive answer exists to the question of which graft material works best for the mesocaval shunt procedure. The small-diameter shunts provide preserved prograde portal flow in the early postoperative period but may still be associated with encephalopathy and loss of hepatopetal flow over time. In addition, postoperative encephalopathy rates vary considerably in the literature, from less than 10% to greater than 50%. Although rare, graft infection in the prosthetic grafts was uniformly fatal in the literature.

Reynolds and Southwick in 1951 first described the use of autologous vein graft for interposition between the portal vein and vena cava. Stipa and colleagues (1978) compared their

experience with the side-to-side portacaval shunt versus autologous internal jugular vein interposition mesocaval shunt in 79 patients with variceal hemorrhage and portal hypertension. Although no differences in survival were reported between the two groups, encephalopathy was greater in the portacaval shunt patients (54%) compared with the mesocaval shunt patients (35%), and 95% of the patients with mesocaval shunts maintained hepatopetal portal flow. Gonzalez and associates (1977) also reported the use of autologous vein graft in 26 patients; no graft infections were reported for patients undergoing mesocaval shunts with either homologous or autologous vein graft. These shunts require more time to harvest vein, however, and they may not be appropriate in an emergency or urgent setting.

The literature also shows favorable patency rates with mesocaval shunting. Ilkgul and coworkers (2005) reported an 89% overall patency rate over a median follow-up of 42 months in patients with autologous internal jugular vein grafts. Sigalet and colleagues (2001) found a 100% shunt patency at 4.3 years in 20 pediatric patients using autologous vein graft. It is important to note that all of the mesocaval shunts discussed in this review provided adequate portal decompression with low perioperative mortality and infrequent recurrence of variceal hemorrhage.

PREOPERATIVE EVALUATION AND MANAGEMENT

The patient should undergo an evaluation for encephalopathy, and if encephalopathy is present, the patient is not a good candidate for the procedure. Preoperative mesenteric angiography with late-phase portography, magnetic resonance angiography (MRA), or computed tomography (CT) angiography must be performed in all patients before the procedure. Additionally, venacavography and wedged hepatic venous pressure gradients can provide important anatomic and physiologic data. It is necessary to confirm the presence of an adequate-diameter superior mesenteric vein (SMV) and to show the direction of portal flow through the collateral vessels.

Before the operation, if possible, the patient should undergo diuresis with spironolactone and furosemide to minimize postoperative ascites. The patient should also receive standard antibiotic prophylaxis in the holding area immediately before surgery, but a formal mechanical bowel preparation is unnecessary.

Technique

Exposure

A transverse mid-abominal, right low subcostal, or midline incision may be used (Fig. 76D.1). Because of portal hypertension, a few large collateral vessels may be encountered in the subcutaneous tissue; these should be doubly ligated and divided instead of divided with electrocautery. When the peritoneum is opened, ascites is removed, and the abdomen is explored; a mechanical retractor is placed to provide maximal exposure. A liver biopsy often is performed and always should be done for any areas suspicious for hepatoma.

Exposure of the Superior Mesenteric Vein

The transverse mesocolon is retracted cephalad, and the small intestine is retracted caudad and to the left to expose the root of the mesentery and the ligament of Treitz. A transverse incision is made in the posterior parietal peritoneum to initiate

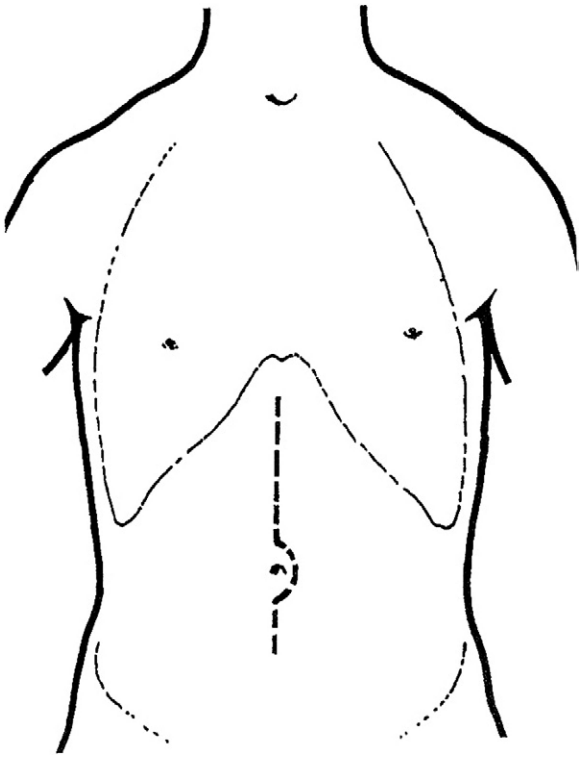

FIGURE 76D.1. The incision options for the mesocaval shunt procedure: transverse midabdominal, right low subcostal, or midline.

dissection of the SMV, which usually overlies the right lateral margin of the vertebral bodies. The superior mesenteric artery usually is located anterior and to the left of the SMV (Fig. 76D.2); however, these relationships are inconstant; Doppler may help identify the vascular structures.

During dissection of the SMV, multiple lymphatic channels and lymph nodes are encountered. Large, hypertrophied lymphatic channels should be ligated before division to prevent uncontrolled lymph flow during and after the procedure, which may contribute to postoperative ascites.

When the SMV is identified, it is mobilized and skeletonized from the inferior border of the pancreas to below the confluence of the ileocolic and jejunal veins, which form the SMV proper. Small branches are doubly ligated and divided, and large branches are controlled with vessel loops. The SMV is dissected bluntly on the anterior surface, and sharp dissection is limited, until the vein and all tributaries are identified. Usually, a large tributary vein enters the right posterior lateral border of the SMV between the ileocolic and middle colic veins, which should be controlled with a vessel loop. Occasionally, the inferior mesenteric vein, rather than the splenic vein, enters the side of the SMV directly. If so, the inferior mesenteric vein should also be controlled with a vessel loop before opening the SMV.

Ideally, a 6- to 7-cm length of large-diameter SMV should be exposed and mobilized to accommodate the graft. If necessary, the graft may extend onto the ileocolic vein. Alternatively, if the SMV is quite short, the ileocolic vein or middle colic vein or both may be sacrificed. In a patient with portal hypertension, the ileocolic vein may be quite large and could be mistaken for the SMV. A shunt between the ileocolic vein and cava is inadequate, however, for portal decompression.

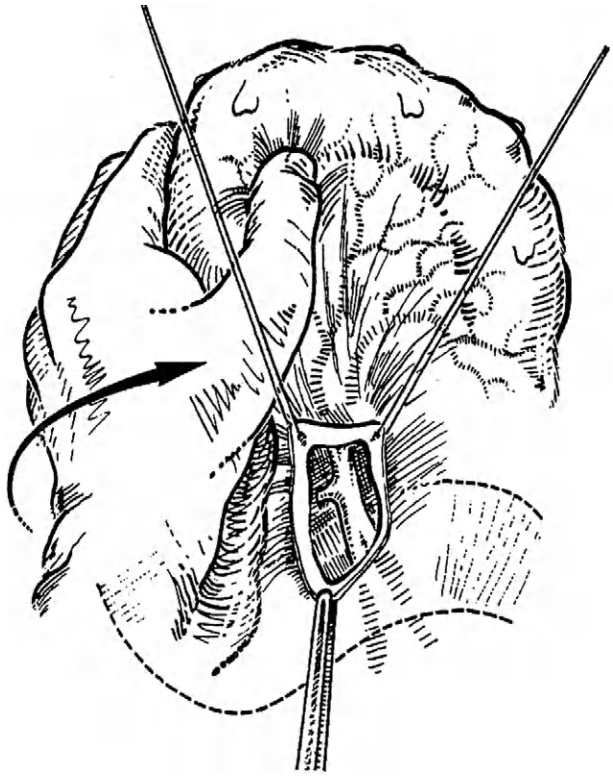

FIGURE 76D.2. Exposure of the superior mesenteric vein.

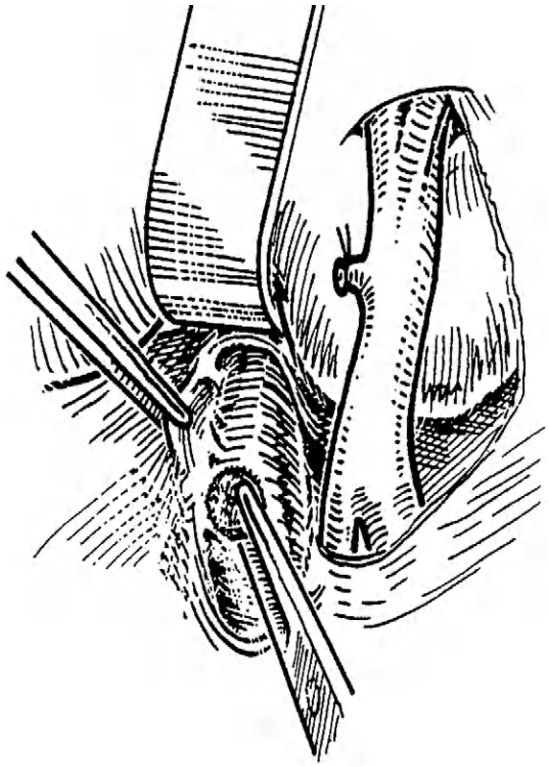

FIGURE 76D.3. Dissection of the anterior and lateral surfaces of the inferior vena cava and its relationship to the superior mesenteric vein.

Exposure of the Inferior Vena Cava

When an adequate length of the SMV is circumferentially mobilized, the IVC is identified by a direct approach through a window in the right colonic mesentery. Alternatively, the right colon and mesentery may be reflected to the midline, allowing access to the right retroperitoneum. The distal second portion and third portion of the duodenum are mobilized with a reverse Kocher maneuver. It is important to ligate and divide the large lymphatic channels in the retroperitoneum to avoid a significant lymphatic leak. A 6- to 7-cm length of IVC is dissected along the anterior and lateral borders (Fig. 76D.3). It is not necessary to mobilize the cava circumferentially but only enough to allow placement of a large Satinsky clamp for partial occlusion.

After mobilization of the SMV and IVC, soft tissue between these structures can be divided to allow graft to take the optimal route, but ligation of the large vessels should be avoided.

Preparation of the Vena Cava and Venotomy

The IVC-graft anastomosis is performed first, which eliminates the problems of diminished exposure for the caval anastomosis and prolonged SMV occlusion. A vascular suture can be placed in the anterior wall of the vena cava and used to tent it upward, while a large Satinsky clamp is placed to occlude the cava partially (Fig. 76D.4). It is important that the clamp occludes the superior and inferior ends of the vena cava segment to prevent bleeding during the anastomosis. The suture used to tent the cava is excised with an ellipse of anterior caval wall to form the venotomy (Fig. 76D.5). Using angled Pott scissors, the venotomy is enlarged to the same diameter, usually 8 to 12 mm, as the chosen ringed Gore-Tex or internal jugular vein graft. If the opening is too large, the graft does not assume a circular shape at the anastomosis.

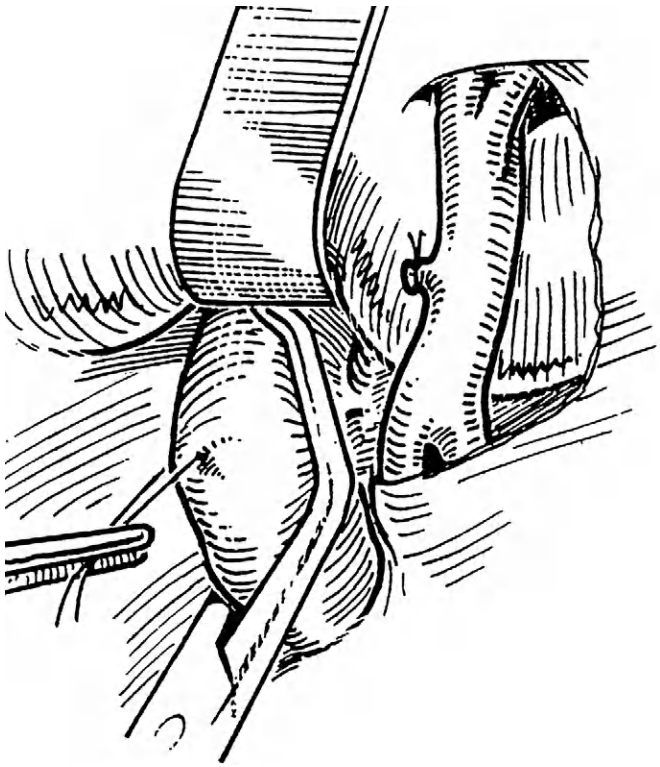

FIGURE 76D.4. Occlusion of the inferior vena cava with a Satinsky clamp and preparation of the vein for venotomy.

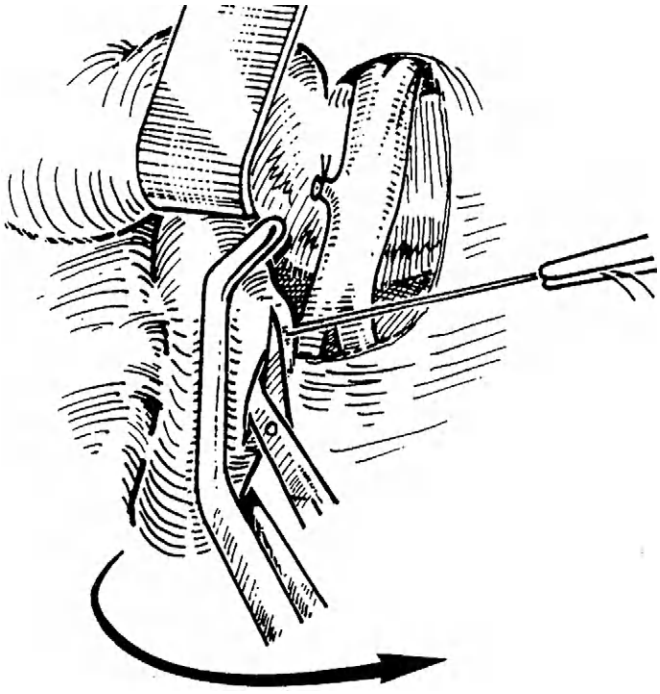

FIGURE 76D.5. Inferior vena cava venotomy.

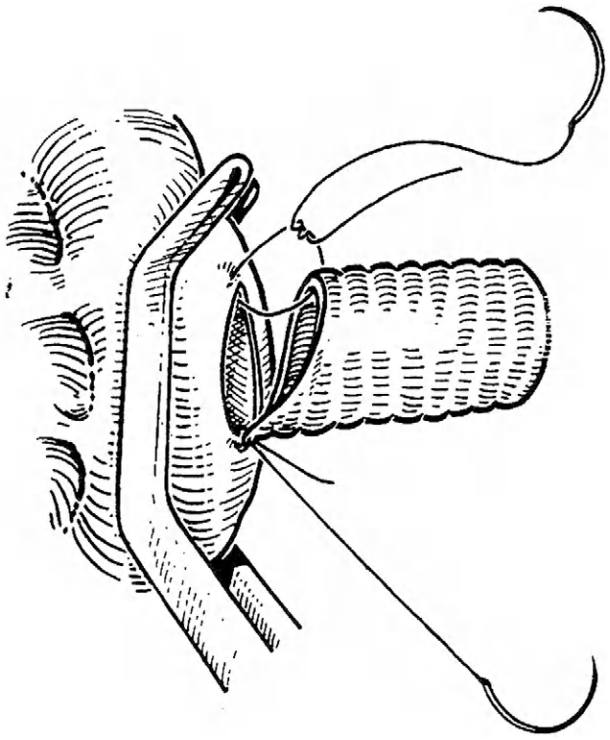

FIGURE 76D.6. Inferior vena cava–graft anastomosis.

Inferior Vena Cava–Graft Anastomosis

The caval anastomosis is located in the deepest and most dependent area of the wound, and good exposure is essential. The duodenum is retracted superiorly, and the rest of the viscera are retracted inferiorly. Two corner sutures are placed using 5-0 synthetic, nonabsorbable suture material at each end of the venotomy, and these are tied to position the graft over the venotomy (Fig. 76D.6). A stay suture also is placed midway along the medial caval venotomy lip for gentle traction to distract it away from the lateral suture line and to prevent incorporation into the opposite wall. The Satinsky clamp is rotated to the patient's left, and the right side of the anastomosis is completed first. It is started at the inferior margin using one end of the corner stitch and working upward, placing the continuous sutures outside-in on the graft and inside-out on the vein (Fig. 76D.7). At the superior margin, the suture is tied to one end of the superior corner stitch.

After completion of the right-side anastomosis, the Satinsky clamp is rotated to the patient's right, and the other end of the superior corner suture is run inferiorly to complete the left side of the anastomosis (Fig. 76D.8). Figure 76D.9 shows the completed anastomosis. A nerve hook may be used to ensure proper positioning of the cava or graft before each needle bite.

A vascular clamp is placed on the prosthesis, and the Satinsky clamp is released to ensure hemostasis of the anastomosis. Any anastomotic leaks are repaired, and the Satinsky clamp is reapplied to the vena cava. The vascular clamp is removed from the graft, and any remaining blood is suctioned from the graft lumen and irrigated with heparinized saline.

Superior Mesenteric Vein–Graft Anastomosis

In the SMV-graft anastomosis, the length of the graft is crucial. The graft assumes a C configuration as it passes inferiorly around the lower border of the third portion of the duodenum, then anterior to the third portion of the duodenum and uncinate process, before it is finally is anastomosed obliquely to the anterior-lateral surface of the SMV. If the graft is too short, undue tension is placed on the suture line, and the SMV is retracted and distorted. If the graft is too long, it becomes redundantly bowed and distorted when the clamps are removed.

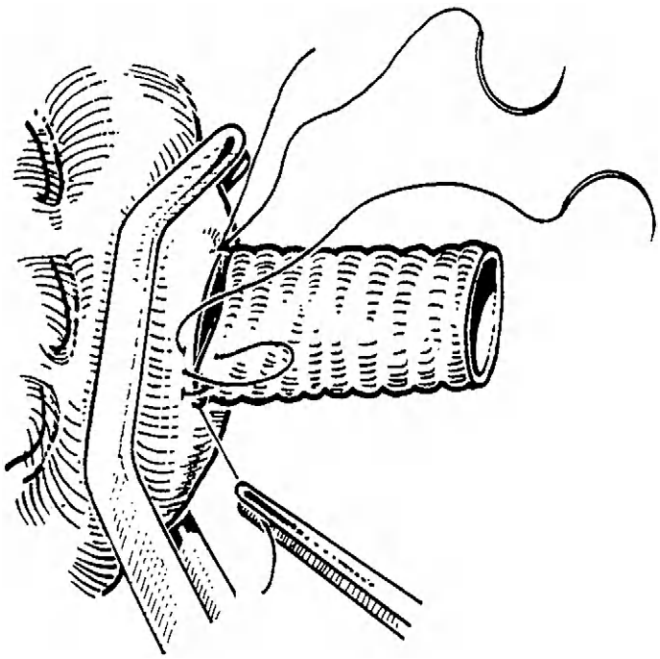

FIGURE 76D.7. The cava and graft are rotated medially, and the right lateral suture line is performed first.

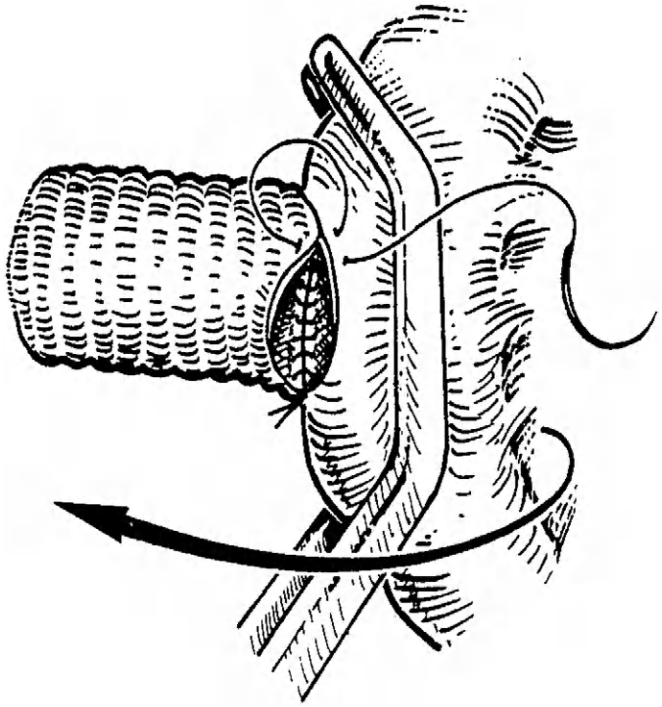

FIGURE 76D.8. The cava and graft are rotated laterally, and the left (medial) suture line is performed.

It also is helpful to mark the graft to maintain proper orientation. Alternatively, the graft may be short and relatively straight, assuming more of an H-graft appearance.

When the appropriate length is determined, the graft is cut obliquely to the angle at which it is to be anastomosed to the SMV. Two straight Cooley clamps are applied proximally and distally on the SMV, and the vein is partially rotated to allow the anastomosis to be performed on the anterior-lateral aspect of the vein. Retraction of the vessel loops placed on the tributaries provides adequate control of the tributaries during the anastomosis. Alternatively, vessel loops may be used to control all of the veins.

A small ellipse is excised from the anterior-lateral aspect of the SMV, and the venotomy is extended proximally and distally using angled Pott scissors to match the length of the obliquely cut graft. For H-shaped shunts, the venotomy is more right posterior-lateral on the vein. Sutures are placed at both ends of the venotomy and graft using 5-0 or 6-0 synthetic nonabsorbable suture material tied to approximate the vein and graft. The right lateral suture line is performed first in a continuous fashion from within the graft and vein, and is carried from the superior suture to the inferior suture (Fig. 76D.10). The left lateral suture line is created in a similar fashion by rotating the vein to the patient's right for better exposure (see Fig. 76D.10). The left lateral suture line also is started at the superior suture and carried down and tied to the inferior stay suture.

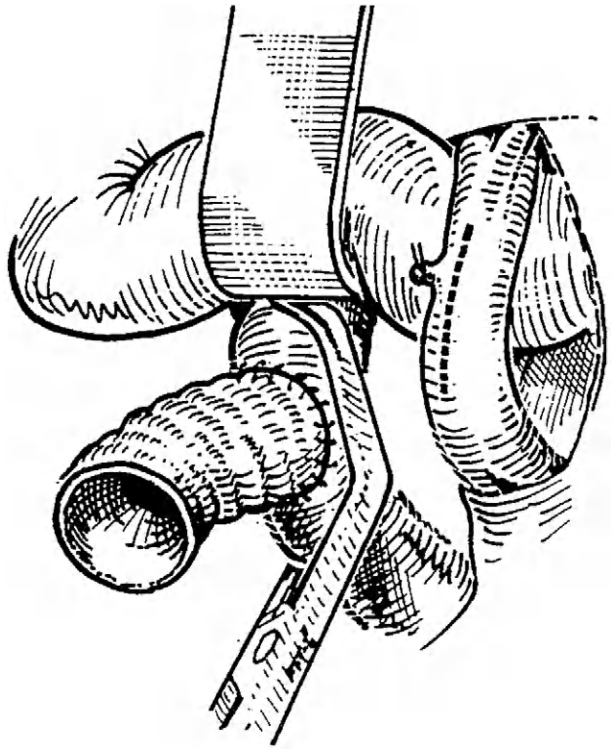

FIGURE 76D.9. The inferior vena cava–graft anastomosis is complete.

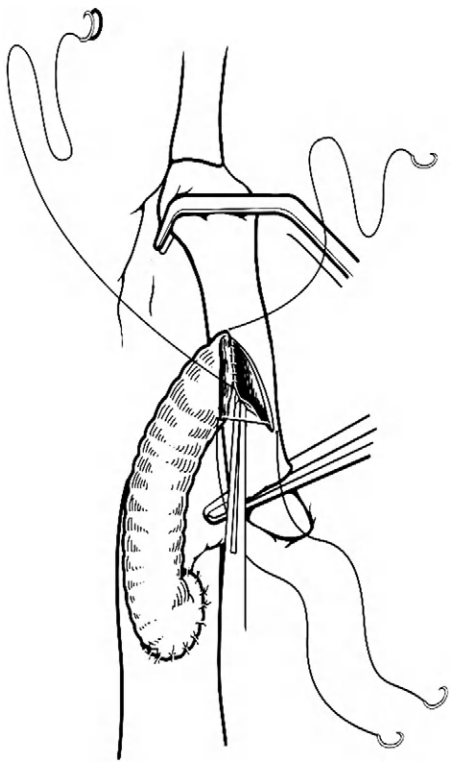

FIGURE 76D.10. After occlusion with vascular clamps, the superior mesenteric vein (SMV) venotomy is performed at the anterior-lateral aspect of the SMV, and the SMV-graft anastomosis is started. *(Illustration courtesy Dominic Doyle, Medical Arts Group, Vanderbilt University.)*

Evaluating the Anastomosis

The Satinsky clamp on the IVC is removed first, and all anastomotic leaks are repaired. The clamps are removed from the SMV, and flow is allowed through the shunt; gentle pressure may be applied to the anastomosis for hemostasis, and Doppler ultrasound may be used to interrogate the graft and anastomosis.

The pressures in the portal system are measured by positioning an 18 gauge needle connected to a water manometer into the SMV near the SMV-graft anastomosis (Fig. 76D.11). With the graft patent and mesenteric systemic flow intact, the pressure is measured as the decompressed portal pressure. The graft is clamped, and the pressure is rechecked to confirm that the system is indeed decompressed. A reduction in the pressure gradient by 12- to 18-cm H_2O should be expected. Also, a thrill may be palpated in the graft. When it is established that no technical problems exist with the graft, such as kinking or compression by surrounding tissues, the abdomen is irrigated, hemostasis is ensured, and the abdomen is closed.

Postoperative Evaluation and Management

Immediately after the procedure, shunt patency should be confirmed by duplex ultrasound, MRI, or CT angiography (Fig. 76D.12). If it is not possible to determine shunt patency via noninvasive techniques, an angiogram must be performed.

Postoperative care includes strict volume management. It is important to keep the central venous pressure as low as possible but to maintain appropriate cardiac output to preserve renal perfusion and function. Although most patients develop some postoperative ascites, it usually clears with a functioning shunt. Initially, patients should be cautious with their diet to minimize the risk of encephalopathy, but only rarely is it necessary to restrict patients to a meat-free diet and lactulose regimen.

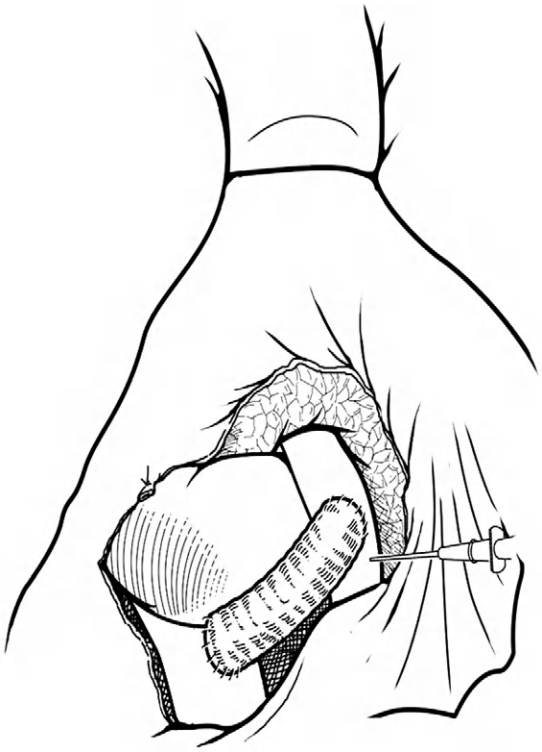

FIGURE 76D.11. After completion of the interposition mesocaval shunt, the portal system pressures are measured. *(Illustration courtesy Dominic Doyle, Medical Arts Group, Vanderbilt University.)*

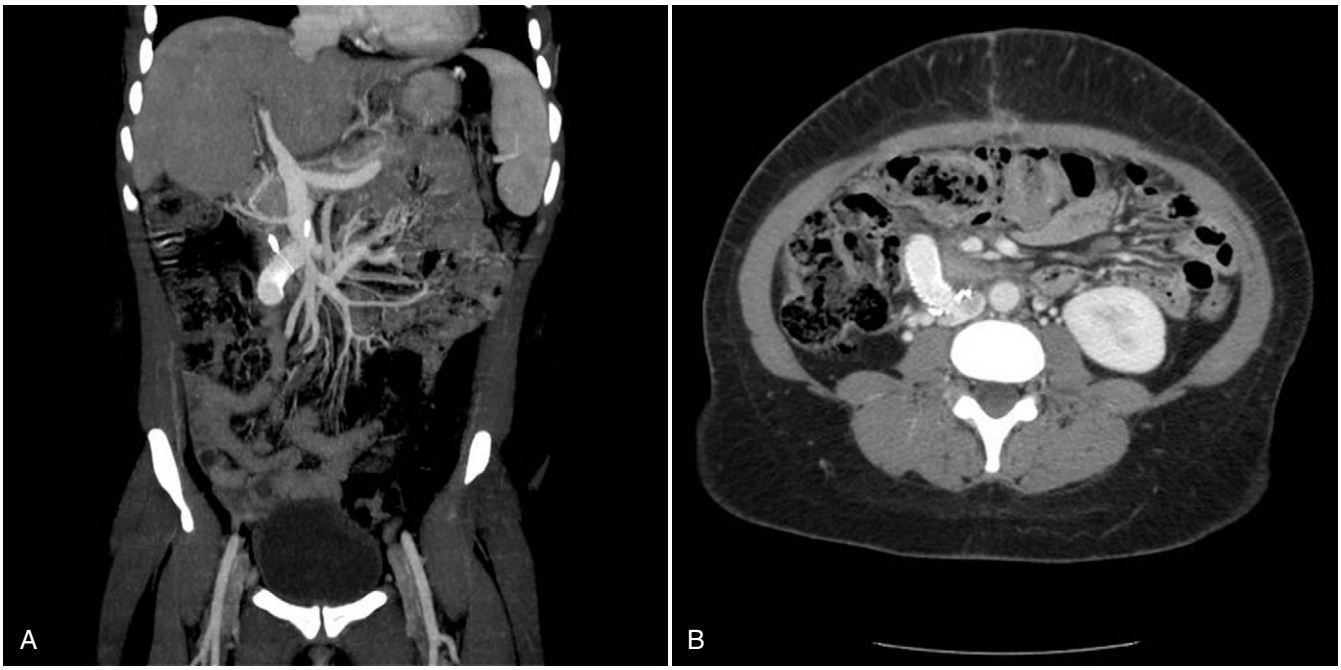

FIGURE 76D.12. Computed tomographic angiography of a patent interposition mesocaval shunt. **A,** Coronal image. **B,** Transverse image. *(Image courtesy Dr. Ravi Chari.)*

If gastrointestinal bleeding recurs, the patient should undergo shunt interrogation to determine shunt patency. Several studies also recommend routine shunt evaluation by either duplex ultrasound or angiography (Mercado et al, 1996; Orloff et al, 2002; Rypins et al, 1988). We perform follow-up duplex ultrasound every 3 to 6 months after the procedure for the lifetime of the shunt. Shunt stenosis is managed routinely with percutaneous transfemoral dilation and, rarely, stenting of the stenosis; operative revision is done only with failure of the less invasive interventional procedures. For early and late shunt thrombosis, most studies advocate shunt thrombectomy. After balloon catheter placement and dilation across any stenosis, an angiocatheter is placed at the SMV-graft anastomosis, and streptokinase is infused at a rate of 5000 U/hr for 24 hours (Rypins et al, 1988; Sarfeh et al, 1986).

SUMMARY

Despite advances in endoscopic therapy, interventional techniques, and liver transplantation, surgical shunts are important therapeutic tools in select patients. Because of its technical simplicity and low complication rate during subsequent liver transplantation, the mesocaval shunt is an ideal surgical shunt choice in some patients. It has been proven to effectively relieve portal hypertension and secondary ascites and to prevent recurrent variceal hemorrhage.

CHAPTER 76E

Transjugular intrahepatic portosystemic shunting: indications and technique

Michael Darcy

OVERVIEW

In the 20 years since its introduction, transjugular intrahepatic portosystemic shunting (TIPS) has gone from being a procedure reserved for desperate circumstances to one that is now routinely used to manage some complications of portal hypertension. The broader utilization of TIPS has been accompanied by changes in the indications and techniques, influenced by greater experience and better knowledge of outcomes.

INDICATIONS

Variceal Bleeding

Bleeding gastroesophageal varices not controlled by medical or endoscopic means was the original indication for which TIPS was devised, and this is still the primary indication. TIPS can routinely decompress the portal system to drop the portosystemic gradient (PSG) and will lead to immediate cessation of bleeding in 95% of patients (Fig. 76E.1). A number of randomized trials have compared TIPS to best medical management (Cabrera et al, 1996; Cello et al, 1997; Garcia-Villarreal et al, 1999; Gulberg et al, 2002b; Jalan et al, 1997; Merli et al, 1998; Pomier-Layrargues et al, 2001; Rössle et al, 1997; Sanyal et al, 1997; Sauer et al, 1997). These have demonstrated that TIPS provides better long-term control of variceal bleeding. In these studies, recurrent bleeding occurred in 18% to 56% of patients in the sclerotherapy cohorts versus only 9% to 23% of patients in the TIPS arms. Not only were these differences statistically significant for the primary outcome, the crossover rate from endoscopy to TIPS was 5% to 28%, but only 0% to 7% of the TIPS patients crossed over to endoscopic treatment.

Despite the improved control of bleeding, TIPS did not yield a survival benefit in most of these studies. One possible explanation for this is that by shunting portal blood flow from the liver, some deterioration in liver function occurs, and this might offset the improved survival related to control of hemorrhage. Alternatively, it is possible that the studies simply did not follow patients long enough to demonstrate the survival benefit. In most of the randomized trials, the survival in the TIPS group was longer than the medical therapy group but not long enough to achieve statistical significance; perhaps longer follow-up might have yielded a significant difference.

Better stratification of patients might also have yielded different results, as evidenced by one randomized trial (Monescillo et al, 2004) that stratified patients according to early measurement of their hepatic venous pressure gradient (HVPG) and then randomized high-risk patients (HVPG >20 mm Hg) to medical management or early TIPS placement. Not only did the TIPS group have fewer episodes of recurrent bleeding, both the in-hospital and 1 year mortality rates (11% and 38%) were significantly lower than in the non-TIPS cohort (38% and 65%).

One caveat regarding many of the randomized trials is that most were done using bare metal stents to create the shunt. Thus, within 6 to 12 months, the majority of the shunts in the TIPS group had stenosed. The current standard of care is to use stent grafts (polytetrafluoroethylene-covered stents) for TIPS procedures. These newer stent grafts have much improved patency and yield even better control of variceal bleeding than the bare metal TIPS (Angeloni et al, 2004; Angermayr et al, 2003; Bureau et al, 2007; Tripathi et al, 2006). Although more studies need to be done with stent grafts, at least one randomized trial (Garcia-Pagan et al, 2010) showed significantly better 1-year survival for TIPS performed with these improved stents compared with medical management (86% vs. 60%, $P < .01$).

The main downfall to TIPS is the development of new hepatic encephalopathy or exacerbation of existing encephalopathy, which occurs in 20% to 31% of cases (Boyer & Haskal, 2010). It is for this reason that TIPS is still recommended only after failure of medical management and not as front-line therapy for variceal bleeding. Interestingly, despite improved patency, the stent-graft TIPS has actually been associated with a lower incidence of encephalopathy compared with bare-stent TIPS (Bureau et al, 2007; Tripathi et al, 2006). This is another reason why the randomized trials comparing TIPS to medical management need to be repeated with the newer stent grafts.

Gastric Varices and Gastropathy

Gastric varices are also frequently seen in patients with portal hypertension and are actually associated with a higher rate of hemorrhage-related mortality compared with bleeding from esophageal varices (Garcia-Tsao & Bosch, 2010). TIPS can also provide good control of bleeding related to this condition, although the efficacy compared to endoscopic management is less clear. One large retrospective study comparing TIPS to endoscopic cyanoacrylate injection failed to demonstrate a benefit for TIPS in either control of bleeding or survival (Procaccini et al, 2009). However, another trial (Lo et al, 2007) that randomized patients to either TIPS or variceal obliteration with endoscopic cyanoacrylate injection showed that rebleeding was significantly less frequent in the TIPS group (11% vs. 38%, $P = .014$).

TIPS has also been used to treat portal hypertensive gastropathy, but data are sparse, and no randomized trials have evaluated the use of TIPS for this condition. Some investigators believe that TIPS is less effective for this condition, and several

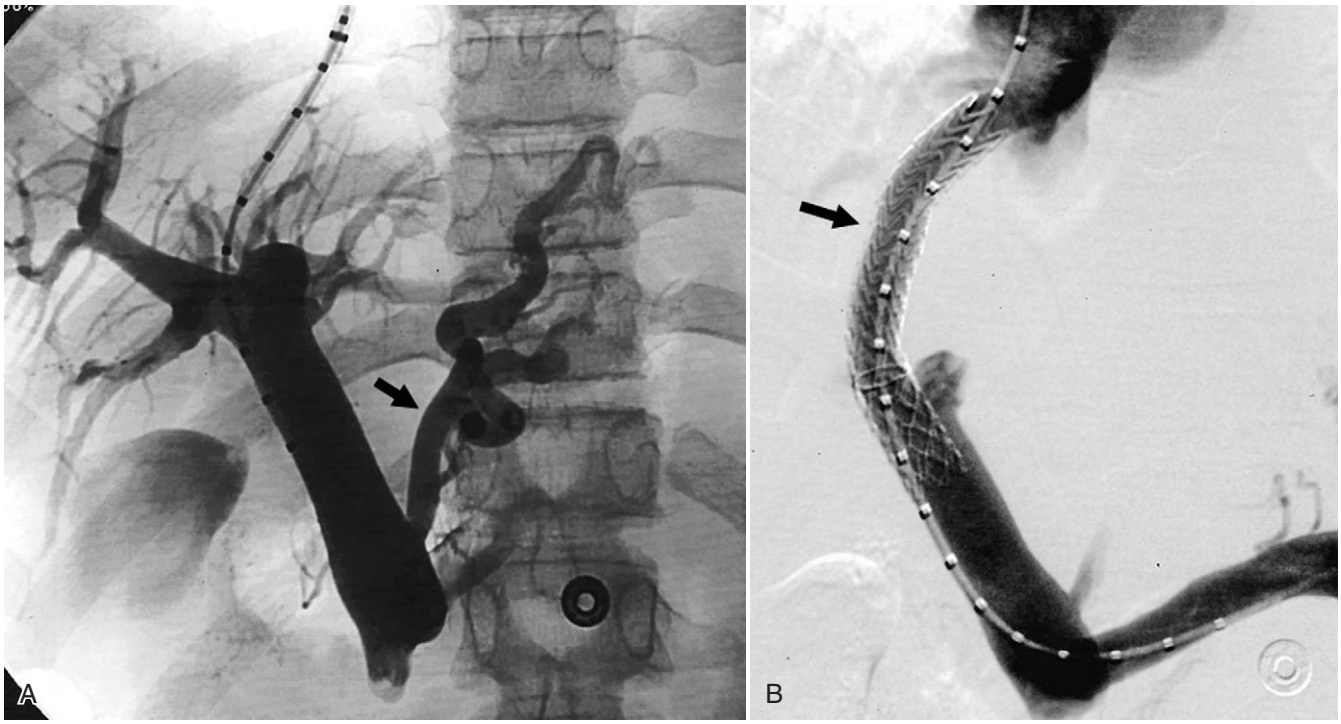

FIGURE 76E.1. A, Initial portal venogram shows a very large coronary vein (*arrow*) giving rise to gastroesophageal varices. **B,** Immediate post-TIPS portal venogram demonstrates good flow through the TIPS (*arrow*) and no further flow into the coronary vein.

studies have a shown a poor correlation between HVPG and the presence or severity of gastropathy (Bellis et al, 2007; Shimizu et al, 2002). Given that the function of TIPS is to reduce portal pressure, this lack of correlation between the severity of gastropathy and portal pressures may account for the more variable results seen with TIPS in this condition.

Ectopic Varices

The effective portal decompression achieved by TIPS has led to expansion of the indication to include bleeding from ectopic varices, which most often arise in enteric stomas and are caused by portal hypertension transmitted to the peripheral tributaries of the mesenteric veins. Several small series have described successful treatment of varices in these locations by decompression with TIPS (Spier et al, 2008; Kochar et al, 2008; Han et al, 2007; Vidal et al, 2006; Macedo et al, 2005; Alkari et al, 2005; Vangeli et al, 2004; Ryu et al, 2000). The rebleeding rate in this indication is higher than expected after decompression of the portal system, which has led several authors (Kochar et al, 2008; Vangeli et al, 2004) to suggest that the ectopic varices should also be embolized at the time of TIPS.

Ascites

Although TIPS was designed to treat variceal bleeding, early investigators recognized that the procedure also led to a reduction or resolution of ascites in many patients. A number of randomized controlled trials have compared TIPS to large-volume paracentesis (LVP) (Ginés et al, 2002; Lebrec et al, 1996; Rössle et al, 2000; Salerno et al, 2004; Sanyal et al, 2003). A meta-analysis of these trials (Deltenre et al, 2005) showed that at 4 and 12 months, ascites was controlled in 66% and 55% of the TIPS patients, respectively, compared with 24% and 19% for the LVP patients. Despite the improved control of ascites, survival was higher, but not statistically better, in the TIPS groups. Another meta-analysis of the data did show a slight survival benefit for the TIPS patients (Salerno et al, 2007). Again, these studies were all done with bare metallic stents, and because survival is better after TIPS with stent grafts, these studies bear repeating with the current technology. Data from trials of stent grafts show improved control of ascites compared to bare-stent TIPS. Jung and colleagues (2009) reported ascites control at 1 year in 64% of TIPS procedures performed with the Viatorr device (W.L. Gore, Flagstaff, AZ) versus only 33% in patients with bare metal stents.

Patients with intractable ascites tend to be a sicker population, and despite successful decompression of the portal system, survival in this cohort is likely to be lower compared with those who have had TIPS done for variceal hemorrhage (Wallace et al, 2004); however, TIPS can still lead to significant improvement in quality of life (Gulberg et al, 2002a). One caveat is that the physiologic effect is not always immediate, and some patients do not show resolution of ascites for 2 to 3 months after the TIPS; another is that the clinical response does not appear to be as good when TIPS is used to treat recurrent ascites in patients after liver transplantation. One small retrospective study (Saad et al, 2010) reported a clinical success rate of only 16% in patients after transplant.

Hepatic Hydrothorax

Based on the success with managing ascites, TIPS has also been applied to hepatic hydrothorax, which occurs in 5% to 10% of cirrhotic patients and can lead to significant shortness of breath and inability to perform normal daily activities. Similar

to ascites, TIPS is not used for primary therapy but instead is reserved for patients who are refractory to medical management. Patients requiring multiple thoracenteses or chest tubes can benefit from TIPS, with a beneficial response reported in 74% to 79% of patients undergoing the procedure (Dhanasekaran et al, 2010; Gordon et al, 1997; Spencer et al, 2002). Of those who respond, about two thirds have complete resolution of the hydrothorax, and the remainder experience partial resolution of the effusion but are symptomatically improved, with either decreased or resolved dyspnea. In our experience (Spencer et al, 2002), the patients who showed no clinical response to TIPS were all critically ill with elements of multiorgan failure, and 30-day mortality was 83%. Thus TIPS is unlikely to be helpful as a last-ditch effort to improve pulmonary function in severely ill patients on mechanical ventilation.

Budd-Chiari Syndrome

Since the early 1990s, TIPS has also been used to relieve the portal hypertension and hepatic congestion associated with Budd-Chiari syndrome (Ochs et al, 1993). The results obtained depend on the patient's physiologic status. Several studies (Khuroo et al, 2005; Blum et al, 1995) have shown that a more fulminant presentation correlates with decreased survival; however, patients with a more chronic form of Budd-Chiari syndrome have fairly good results with TIPS. The largest series of TIPS done for Budd-Chiari syndrome included 124 patients (Garcia-Pagan et al, 2008b). The 1- and 10-year transplant-free survival rates were 88% and 69%. This was significantly better than expected for this patient population and has led to a change in the guidelines so that TIPS is now a recommended treatment in patients who fail anticoagulation therapy (Boyer & Haskal, 2010). This study also demonstrated that patients with a greater degree of hepatic dysfunction did not benefit as much as those with better preserved hepatic function.

Portal Vein Occlusion

Portal vein (PV) occlusion is one indication for TIPS that sometimes arises even in patients without severe cirrhosis. The benefit of TIPS is that it provides a pathway into the portal system for introduction of mechanical thrombolytic devices (Fig. 76E.2) and also provides outflow to help maintain flow once portal patency is reestablished. TIPS has also been shown to be beneficial in treating portal hypertensive complications in patients with portal thrombosis who are awaiting liver transplantation (Bauer et al, 2006). The technical success rate for establishing a shunt and maintaining patency of the portal system is 70% to 100% (Bilbao et al, 2004; Radosevich et al, 1993), with the technical failures a result of the inability to traverse the portal occlusion. Clinical success—that is, termination of hemorrhage—was achieved in all patients in whom a TIPS was successfully created. This approach needs to be carefully considered in consult with a liver transplant surgeon and transplant hepatologist in transplant candidates, because TIPS placement in this setting can compromise access to the proximal PV, which has the potential to influence the outcome of liver replacement.

Preoperative Decompression

A relatively new application of TIPS has been for preoperative portal decompression in patients who need to undergo major intraabdominal, nonhepatic operations (see Chapter 70B; Azoulay et al, 2001; Gil et al, 2004; Schlenker et al, 2009). For patients with severe portal hypertension that requires colonic resection, the operative mortality can be quite high. Portal hypertension poses a risk in terms of dilated collateral veins, increased risk of operative bleeding, and the possibility of portal hypertension–related ascites, causing infectious complications or incisional ascites leakage postoperatively. In the reports of

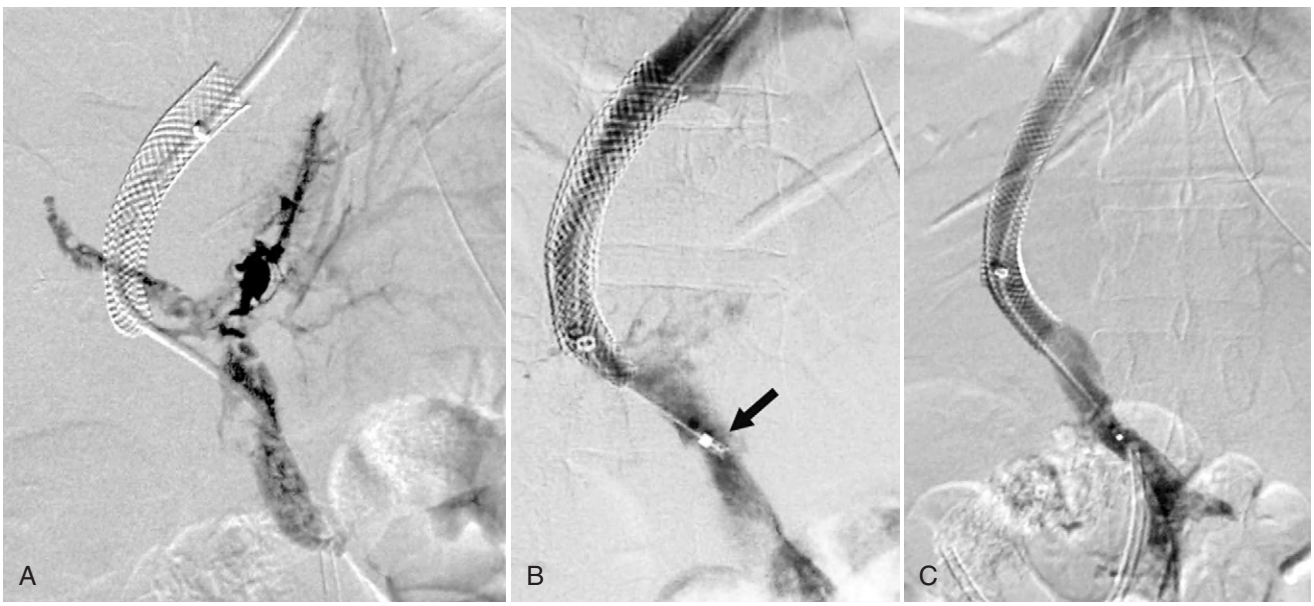

FIGURE 76E.2. A, Portal venogram after initial deployment of transjugular intrahepatic portosystemic shunting (TIPS) stent in a patient with preexisting portal thrombosis. Multiple filling defects are seen throughout the main portal vein and branches. **B,** Using a mechanical thrombectomy device (*arrow*) to lyse the portal thrombus. **C,** Final venogram with a patent portal vein and good flow through the TIPS.

TIPS for this indication, the operations were carried out without excessive bleeding or ascitic complications.

One unresolved question concerns how much time to allow between the TIPS and the operation to ensure optimal decompression of the dilated collateral veins. Although waiting a few weeks after portal decompression seems prudent, one group reported safely operating 2 days after TIPS (Theruvath & Adams, 2010). Given that TIPS can cause complications of its own, it should not be utilized casually for preoperative decompression.

CONTRAINDICATIONS

When medical and endoscopic methods have failed to control massive variceal hemorrhage, TIPS may be the only potentially lifesaving option. Thus most of the contraindications typically cited are only relative contraindications; however, if the indication for TIPS is nonemergent, these contraindications assume greater importance. Right heart failure is one of the most significant contraindications, because TIPS can precipitate acute death from total heart failure (Peron et al, 2000), but this complication has been reported so infrequently that it is impossible to define an absolute threshold for right heart pressures above which TIPS should not be performed.

Because TIPS diverts portal blood flow away from the liver, worsening of hepatic function can occur. This deterioration in hepatic function is often temporary, but if the patient already has preexisting hepatic dysfunction, TIPS may cause progression to more serious problems. The major problem is determining the threshold beyond which TIPS should not be performed. Multiple factors have been correlated with increased risk of post-TIPS liver failure, including less favorable Model for End-Stage Liver Disease (MELD) scores or Child-Turcotte-Pugh (CTP) class, increases in the serum bilirubin level, advanced age, a high serum creatinine level, the urgency for TIPS, and the presence of encephalopathy.

Various authors have proposed schemes to decide prospectively who should be treated with TIPS (Harrod-Kim et al, 2006; Malinchoc et al, 2000; Montgomery et al, 2005; Pan et al, 2008). Of these, the MELD score tends to correlate best with 1-year survival (Chalasani et al, 2000). Different MELD scores have been proposed as the cutoff above which patients should not undergo TIPS, but these figures must be weighed against the risk inherent in the patient's condition. In situations of life-threatening variceal hemorrhage, TIPS can often be life saving, even in a patient with a high MELD score.

Cavernous transformation is generally considered a contraindication, because it greatly increases the difficulty of gaining access to the portal system. Furthermore, even if a portal branch is accessed, it may be impossible to negotiate across the main PV occlusion to a portion of the portal system that is patent. Cases have been described in which a TIPS was created to a dilated periportal collateral with successful decompression of the portal hypertension (Brountzos et al, 2004; Wils, et al, 2009). Detailed preprocedure cross-sectional imaging can be useful to assess for the presence of a large, dominant collateral that can act as a target for the shunt.

Polycystic liver disease has been listed as an absolute contraindication because of potential intracystic hemorrhage, although successful TIPS in polycystic livers has been reported by us and others (Bahramipour et al, 2000; Shin & Darcy, 2001; Sze et al, 2006); some of these were even done with bare metallic stents without significant bleeding despite needle entry into the cyst cavity during creation of the parenchymal tract. The reason for the lack of intracystic hemorrhage would appear to be that the shunt provides a low-resistance pathway to the right atrium, and there is little reason for blood to flow into the contained space of a cyst. Although technically challenging, evidence is insufficient to suggest that polycystic liver disease should continue to be listed as a contraindication.

Active spontaneous bacterial peritonitis (SBP) is a potential risk for contamination of the stent graft being implanted. Thus if the indication for TIPS is nonemergent, the procedure is usually postponed until the SBP has cleared.

TECHNIQUE

TIPS can be performed with a high degree of technical success, usually over 95%. Despite this, the procedure remains technically challenging for many interventional radiologists, and careful attention to details is critical to ensure success.

Patient preparation is similar to other procedures that require heavy sedation or general anesthesia, and preprocedure imaging of the PV is helpful to ensure a patent PV. Although TIPS can be performed in the face of portal thrombosis that has not progressed to cavernous transformation, the procedure is more difficult in this setting and may require percutaneous transhepatic access. Puncture of the liver capsule can occur during TIPS, resulting in peritoneal hemorrhage; assessment and optimization of the patient's platelet count and coagulation parameters are therefore critical. Prophylactic antibiotics should be administered, because a permanent stent graft is being implanted, and cases of TIPS infection have been described (Mizrahi et al, 2009; Sanyal & Reddy, 1998; Suhocki et al, 2008). In patients with massive ascites, a peritoneal drain should be placed at the start of the case. As the ascites is drained, it helps with fluoroscopic visualization of the device being used, and it also gives the patient a head start at resolving the ascites. Additionally, drainage can be a useful intraprocedural way to monitor any intraperitoneal hemorrhage that may develop.

The procedure is started by accessing the jugular vein. The right internal jugular is the preferred access, because it provides a straight path into the inferior vena cava (Baijal et al, 1996) and hepatic veins. When the right internal jugular vein is occluded, the left internal jugular vein can be utilized. Despite the seemingly tortuous course from that access to the hepatic veins, use of stiff guidewires and long sheaths allows a high rate of technical success when starting from the left jugular (Hausegger et al, 1998). If both internal jugular veins are occluded, collateral veins or external jugular veins can sometimes be used for access. Alternatively, if the jugular vein is only partially thrombosed, the occlusion can be probed with a catheter and guidewire. If the obstruction can be traversed, a sheath may be placed to allow use of this access.

Next, a hepatic vein (HV) is catheterized, because this is the starting point for creating the transhepatic tract; typically the right HV is chosen because of its larger size. However, this is not always the best choice. If the patient has a small, shrunken liver and a large amount of ascites, the liver is often deviated in a cephalad direction. This causes an acute angulation of the right HV as it enters the inferior vena cava (IVC), which makes it very difficult to advance catheters and needles into the HV. In this setting, the middle HV is a better choice, because the pathway from the IVC into this vein is still relatively straight, even when ascites elevates the liver.

At this point, the angiographic catheter should be exchanged for a balloon occlusion catheter. Through this catheter, wedged venography can be done to localize the PV prior to making needle passes. Although a nonballoon endhole catheter can be used for wedged venography, all cases of hepatic capsular rupture during wedged venography have occurred with very peripherally positioned endhole catheters (Semba et al, 1996; Theuerkauf et al, 2001). A more centrally positioned balloon occlusion catheter allows the forceful injection to diffuse through a larger number of HV branches, thus decreasing the chance of rupture. Carbon dioxide (CO_2) gas is the preferred contrast agent for wedged venography. The lower viscosity compared with liquid iodinated contrast allows better flow through the sinusoids and better opacification of the PV (Krajina et al, 2002).

While the balloon catheter is in place, some recommend doing free and wedged HV pressures to determine the HVPG and confirm the presence of portal hypertension before creating the TIPS. Monescillo and colleagues (2004) have demonstrated that stratifying patients into low-risk (HVPG <20 mm Hg) and high-risk (>20 mm Hg) categories predicts the risk of recurrent bleeding and the chance of medical treatment failure. However, these pressures can be misleading; PV thrombosis may artifactually lower the wedged pressure, because it is a presinusoidal obstruction. Also, some patients who have gigantic varices decompressing the PV may actually have normal portal pressures (Fig. 76E.3) even when measured directly in the PV.

If the patient has a large umbilical vein collateral on the anterior abdominal wall, this can be punctured using ultrasound guidance and used as a pathway to feed a catheter into the portal system. Through this catheter, contrast can be injected to delineate the portal anatomy, plus the catheter can be positioned to act as a real-time target for the transhepatic needle passes (Fig. 76E.4). Unfortunately, such large umbilical collaterals are available in the minority of cases.

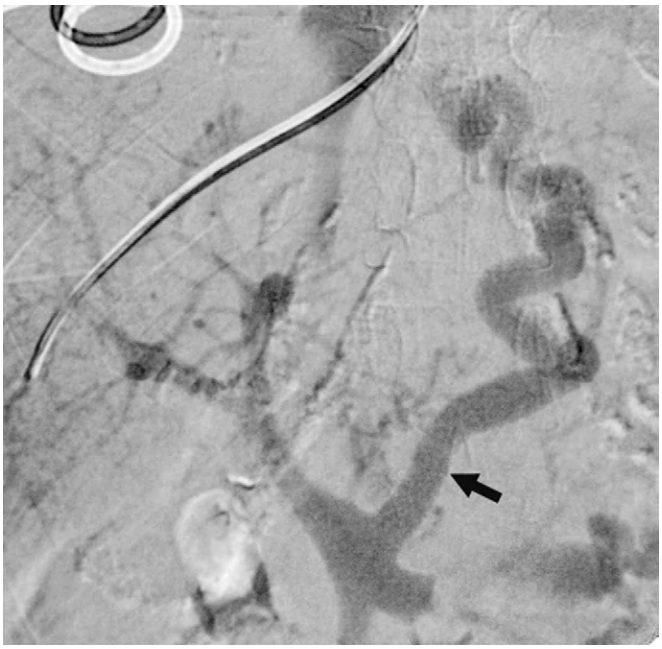

FIGURE 76E.3. Wedged hepatic venogram in a patient with long-standing portal hypertension who has a gigantic coronary vein (*arrow*), larger even than the main portal vein. In this patient, the coronary vein decompressed the portal system so well that the initial measured portal pressures were normal.

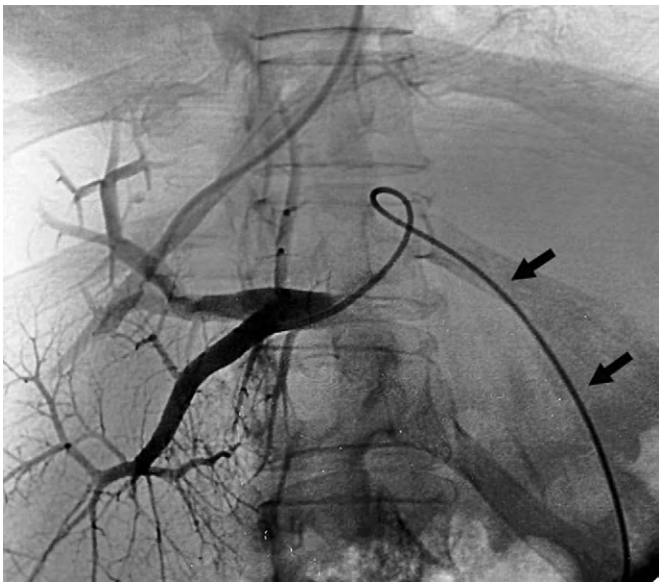

FIGURE 76E.4. A catheter has been introduced via the umbilical vein (*arrows*) through the left portal vein, and it is positioned in the right portal trunk, where contrast is injected to define the target for the transparenchymal puncture.

Next, a needle must be advanced into the portal system. Typically the preferred target is the trunk of the main right PV. Puncturing at the portal bifurcation is not recommended, because this is often extrahepatic, and access here increases the risk of intraabdominal hemorrhage. Access in more peripheral portal branches often leads to a tortuous tract that is more difficult to properly dilate and stent. Occasionally, the right portal trunk is a less optimal target than the left PV. This occurs when the right PV is thrombosed, or when the right lobe is shrunken and elevated, as can occur in patients with severe cirrhosis and massive ascites. In the later setting, the angle from the IVC to the right PV is often too acute to allow easy passage of the rigid transjugular needles. Middle HV to left PV tracts are often straighter and easier to create in this situation. A recent study (Chen et al, 2009) also found that TIPS created through the left PV were associated with a significantly lower rate of encephalopathy than right PV TIPS, but this has not been validated in larger studies.

An interesting variation on TIPS is the direct intrahepatic portosystemic shunt (DIPS) procedure (Hoppe et al, 2008). With this technique, intravascular ultrasound is used to guide a needle puncture directly from the IVC into the PV through the caudate lobe. The reported advantages of this are that the needle puncture is continuously monitored and guided into the IVC, in contrast to the relatively blind needle passes done during a TIPS procedure. In addition, the intrahepatic tract is relatively shorter than for a TIPS. This theoretically should lead to better patency, and in fact, primary patency at a mean of 256 days follow-up was 100% (Hoppe et al, 2008). Despite these potential advantages, DIPS has not been widely adopted.

Because accessing the PV is the most difficult part of a TIPS procedure, many investigators have tried to develop new

guidance mechanism that will aid this portion of the procedure. One promising approach is the use of magnetic resonance (MR) guidance (Arepally et al, 2006; Kee et al, 2005). Although MR guidance allowed the PV to be accessed with relatively few needle passes, it did seem to add to the complexity of the cases. In the study by Kee and colleagues (2005), the average procedure time was 2.5 hours, whereas in general practice, a TIPS can often be performed within 60 to 90 minutes.

Immediately after advancing a catheter into the PV, it is necessary to confirm its position with contrast venography. During the transhepatic puncture, it is possible to access a hepatic arterial branch instead of the PV. If this is not recognized, and the operator proceeds with the case, a hepatic artery to HV shunt may be created with disastrous results (Kerlan et al, 1994). Initial venography also serves to identify the point of entry into the portal system. This has implications for the safety of completing the procedure, because access into the main PV or the portal bifurcation is often an extrahepatic segment of the vein, and balloon dilating such a tract may lead to intraperitoneal hemorrhage (Kim et al, 2001).

Pressures should next be measured via the PV catheter and in the right atrium via the side arm of the access sheath. This is necessary to establish the baseline pressures and portosystemic gradient, not only to confirm portal hypertension but to provide a baseline value against which the TIPS results will be compared. However, as mentioned before, it is important to recognize that portal pressures may actually be normal in cases with clearly documented portal hypertension, if the varices or retroperitoneal collaterals are large enough to decompress the portal system completely. As long as the portal hypertensive complications are well documented—for example, endoscopic visualization of bleeding esophageal varices—TIPS is still indicated despite the low pressures, because this will redirect blood flow away from these large bleeding varices.

The next step is to measure the length of the tract to determine what size device to implant. This is done with a catheter with radiopaque markers on it. The tract is measured from the entry point in the PV back to the HV-IVC junction. It has been shown that patency is lower if the stent does not extend all the way to this point (Clark et al, 2004), because stenoses can form above a TIPS even in short segments of uncovered HV. Identification of the HV-IVC junction can be challenging, because the rapid inflow of unopacified IVC blood may hinder accurate localization of HV insertion. Positioning the sheath near the HV-IVC junction and injecting forcefully into the sheath to reflux contrast down the IVC is a useful maneuver to help define the HV-IVC junction (Fig. 76E.5).

The initial step for creating the shunt is to use a balloon catheter to dilate the parenchyma along the tract. This is typically done with an 8-mm low-profile balloon, because advancing larger, higher profile balloons into the PV can be very difficult initially. The dense periportal fibrosis can cause significant resistance to advancement of the catheter. A stiff guidewire, such as an Amplatz stiff wire (Cook, Bloomington, IN), is necessary to support the catheter.

Next, the tract has to be held open by deploying a stent. Although TIPS was first done with bare metal stents, restenosis became a significant problem. Primary patency decreased to 50% within 6 to 12 months, and many of the stenoses were due to pseudointimal hyperplasia in the shunt, as it coursed through the liver parenchyma (Saxon et al, 1998; Sterling & Darcy, 1997). Pathologic and histologic studies suggested that this

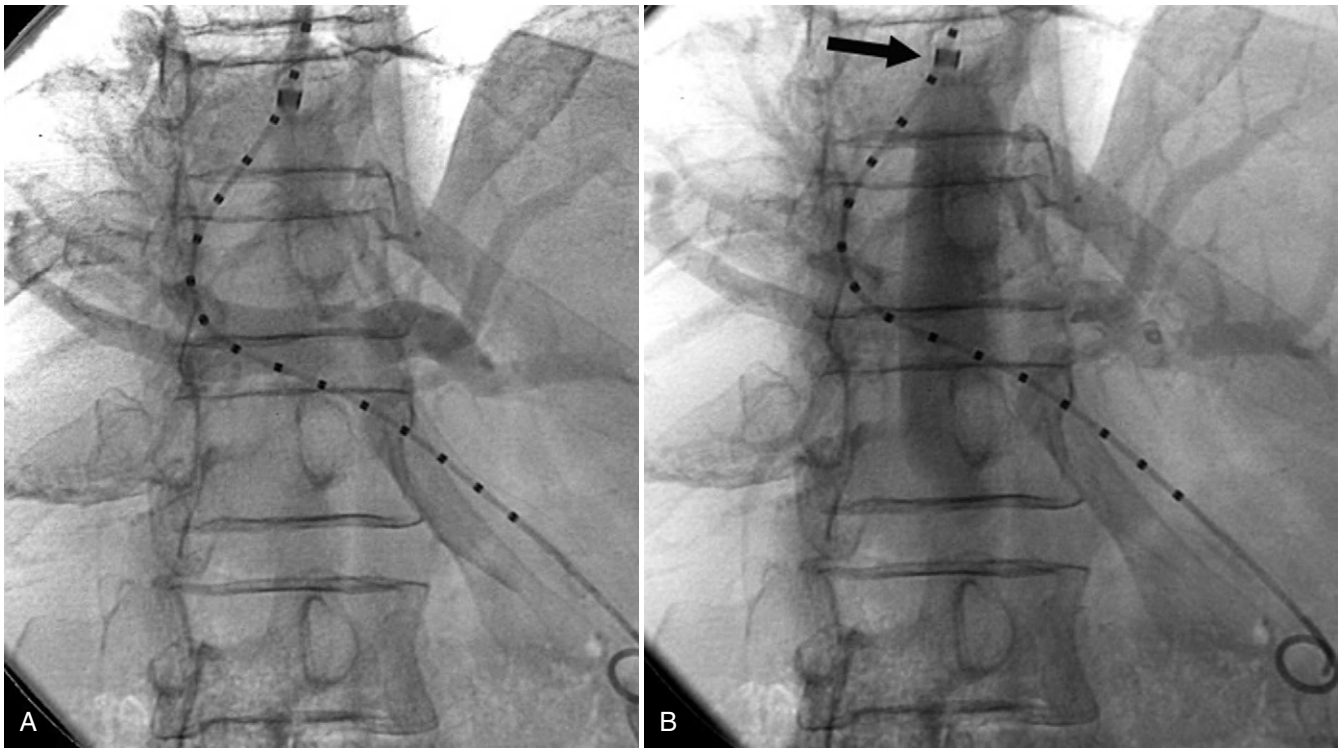

FIGURE 76E.5. A, Initial injection via the catheter in the portal vein does not define the hepatic vein–caval junction optimally. **B,** Injection via the sheath (*arrow*) positioned near the hepatic vein–caval junction better defines the location of the inferior vena cava.

FIGURE 76E.6. Transjugular intrahepatic portosystemic shunting created with a Viatorr device. The radiopaque band (*arrow*) defines the junction between the uncovered stent and the graft-covered portion, which lines the parenchymal tract.

pseudointimal hyperplasia was stimulated by communication with biliary epithelium, resulting from traumatic entry into the liver parenchyma during tract formation (LaBerge et al, 1993; Stout et al, 1995). To correct this problem, investigators started using stent grafts to exclude the liver parenchyma and bile from the shunt lumen.

One stent-graft device specifically designed for TIPS that has FDA approval for that application, the Viatorr device, has a 2-cm long, bare stent component that sits in the PV and a stent-graft segment—lengths vary from 4 to 8 cm—covering the parenchymal tract (Fig. 76E.6). Studies to date have shown significantly improved patency compared with stent grafts created with bare metal stents (Bureau et al, 2007; Tripathi et al, 2006; Vignali et al, 2005). An Italian multicenter study (Vignali et al, 2005) reported primary patency of TIPS created with Viatorr to be 76% at 2 years. Similarly, a randomized trial between Viatorr and bare-stent TIPS reported 2-year primary patency rates of 76% and 36% respectively (Bureau et al, 2007).

When stenoses do occur in patients with a Viatorr TIPS, they almost always develop in a short segment of uncovered HV above the shunt. For this reason, it is recommended to carry the stent graft right up to the HV-IVC junction. As radiologists gain more experience with proper placement of TIPS shunts, HV stenoses are likely to become even less of an issue. The improved patency of stent grafts now makes it feasible to use TIPS for long-term portal decompression rather than simply as a bridge to liver transplantation.

One concern that arose when stent grafts were first used was an increased potential for encephalopathy; however, for reasons that are not obvious, encephalopathy rates were actually lower with stent grafts than with bare metallic stents (Bureau et al, 2007; Tripathi et al, 2006). Along with the improved patency, a stent-graft TIPS provided better control of variceal hemorrhage in several studies (Angeloni et al, 2004; Bureau et al, 2007; Tripathi et al, 2006), although differences in survival did not reach statistical significance. Angermayr and colleagues (2003) did, however, show a significant improvement in survival: 76% at 3 years versus 62% for bare-stent TIPS.

Stent diameter is another variable that comes into play when choosing a device. Viatorr stents come in diameters of 8, 10, and 12 mm. Although 12 mm bare stents were often used, this was primarily to compensate for the pseudointimal hyperplasia that would develop. Because this is not really an issue with the Viatorr device, 12-mm diameter shunts are rarely utilized. The choice between an 8- and 10-mm Viatorr usually hinges on the patient's condition, although the 8 mm devices tend to be favored for patients with preexisting encephalopathy or borderline liver function to reduce the degree of diverted portal blood flow; however, this approach has not been validated.

In order to deploy a Viatorr, a delivery sheath must be advanced into the PV. This is because the bare portion of the stent, the caudal 2 cm of the Viatorr, is constrained only by the delivery sheath: as soon as it exits the sheath, that portion of the device expands. The need to have the sheath in the PV is occasionally a problem. If the tract is tightly curved, the sheath may kink once the inner dilator is removed. If the kink is significant, the sheath may not be able to pass across the Viatorr device. Switching to a self-constrained stent graft, such as the Fluency (Bard Peripheral Vascular, Tempe, AZ), allows passage of the device without needing to get the sheath through the tract into the PV (Fig. 76E.7). One theoretical disadvantage to this stent graft is the potential to occlude flow into the portal branches, because it is totally covered by PTFE, although this feature does not appear to increase the complication rate.

After stent-graft deployment, repeat portal venogram is performed, and pressure measurements are taken to confirm proper placement of the device, assess for complications related to stent placement, and ensure that the portal system has been adequately decompressed. The venogram should show good flow through the shunt and no further flow in varices or collateral pathways. Generally, the flow in the portal branches will also become hepatofugal toward the shunt, even if good hepatopetal flow was present prior to shunt creation. Pressure measurements should show a successful reduction in the portosystemic gradient. Typically, the target is to get the portosystemic gradient below 12 mm Hg, the commonly accepted threshold below which variceal bleeding is unlikely. Some speculate that resolution of ascites may require a slightly lower portosystemic gradient (PSG), down around 8 mm Hg (Boyer & Haskal, 2010). If the PSG is too high, careful venography and a pull-back pressure measurement are necessary to ensure that the tract is fully stented and that there are no kinks or thrombi that might be limiting flow through the shunt.

In some patients, the gastroesophageal varices may still fill on the post-TIPS venography despite adequate lowering of the PSG. This occurs in patients whose variceal channels are grossly enlarged. These pathways may be so large that the resistance to flow through them is the same or less than the resistance to flow through the TIPS; therefore embolization of these vessels may be needed to eliminate flow through them and redirect flow through the shunt.

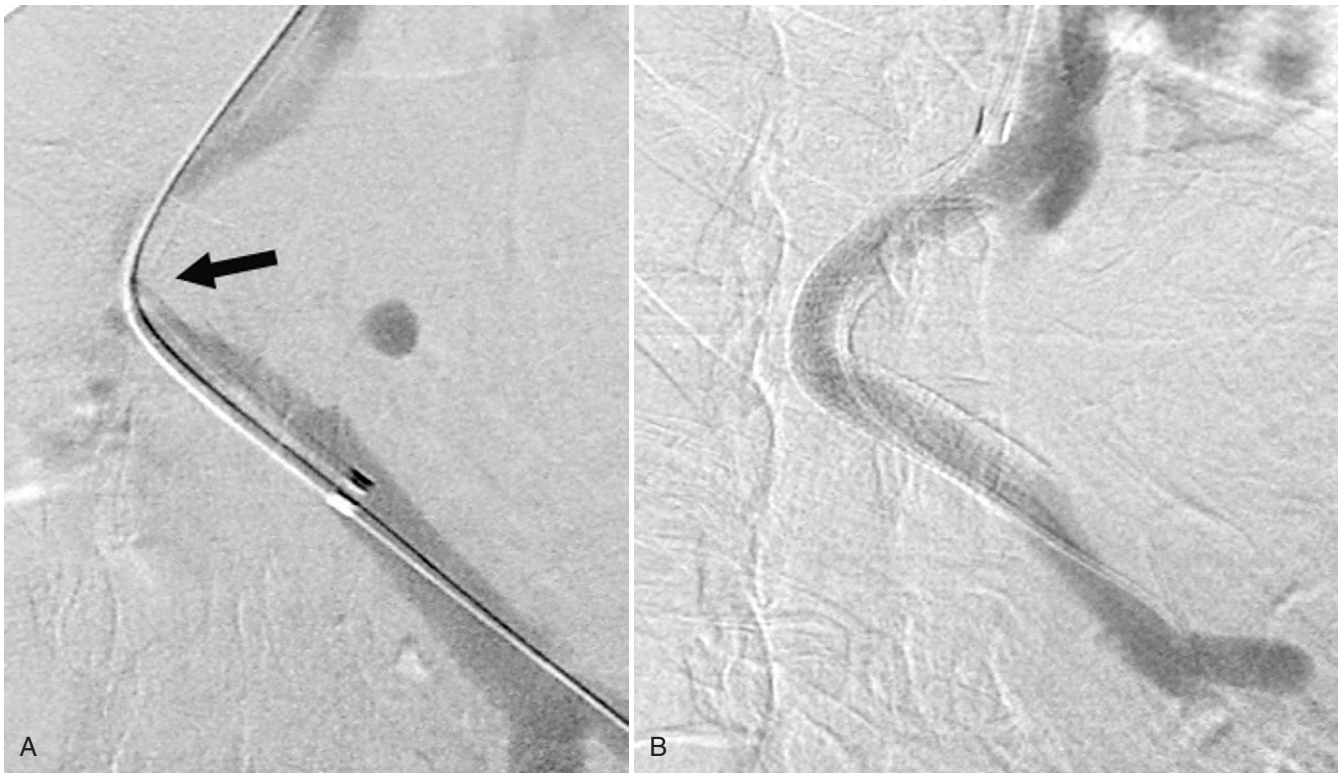

FIGURE 76E.7. A, Venogram done after advancing the sheath into the portal vein shows a kink (*arrow*) in the sheath; the Viatorr device could not be advanced past it. **B,** Final portal venogram after completing transjugular intrahepatic portosystemic shunting with a Bard Fluency stent graft.

SPECIAL TECHNICAL CONSIDERATIONS

Budd-Chiari Syndrome

When TIPS is being considered in patients with Budd-Chiari syndrome, the hepatic veins may be extensively thrombosed such that catheterization is not possible. In this situation, the needle that passes across the liver parenchyma may need to start from the HV stump, if it can be engaged, or directly from the IVC itself (Gasparini et al, 2002). The retrohepatic segment of the IVC is approximately 5 to 6 cm in length; to avoid creating a tract with a greater chance of hemorrhage, the needle passes should start from within this segment of the vein. Whereas a normal puncture from the right HV involves anterior and medial direction of the needle, a needle pass directly from the IVC must be directed more laterally. As with other indications, use of graft-covered stents improves outcomes. In a recent study looking specifically at Budd-Chiari patients (Murad et al, 2008), the 2-year primary patency was 12% for bare stents versus 56% for stent grafts.

Portal Thrombus

Performing TIPS in patients with portal thrombosis requires a moderate level of expertise. One of the major technical challenges is accessing the PV. Although this can often still be accomplished from a transjugular route, use of a percutaneous transhepatic tract is sometimes needed to initially recanalize the PV (Radosevich et al, 1993). Once access is established, it is usually beneficial to deploy the stents across the parenchymal tract even before attempting lysis of the portal thrombus. TIPS provides a great conduit for using mechanical thrombolytic devices in the PV. Often, the thrombus is more chronic in nature and does not easily lyse, thus extending stents down the main PV to a patent segment below the thrombus is frequently necessary to establish good flow through the shunt. Because these stents can complicate a subsequent liver transplant operation, it is important to discuss the likelihood and timing of transplantation prior to placing a stent in the main PV. When the patient is close to receiving a new liver, we have elected to not perform TIPS rather than risk increasing the complexity of the transplant operation.

Polycystic Liver

A polycystic liver presents additional challenges, both from the presence of the cysts and because of the liver's expanded size. Preprocedure CT scans can be used to analyze the distribution of cysts and their position relative to the right hepatic and PVs. The planned tract may be adjusted based on this analysis. If aspiration is done while passing the needle across the liver parenchyma, entry into a cyst is recognized by aspiration of clear fluid; the needle can then be redirected around the cyst. Because polycystic livers are usually expanded by the cysts, the parenchymal tract will tend to be longer than a TIPS in nonpolycystic livers. Thus multiple stents may be needed to fully cover the parenchymal tract.

CHAPTER 79B

Cystic hepatobiliary neoplasia

Olivier Farges and Valérie Paradis

OVERVIEW

The vast majority of nonparasitic cystic lesions of the liver are simple cysts. They are unilocular, do not communicate with the biliary tree, have a serous content, and although the epithelium does divide to account for volume expansion, they are not considered a tumor and have no malignant potential. Furthermore, they do not tend to recur following partial resection. These lesions are described in detail elsewhere in this textbook (see Chapter 69A). Although primary or secondary solid hepatic malignancies may become cystic as a result of tumor necrosis, it is extremely rare for them to be totally cystic, although this has been described in case reports for embryonic liver sarcoma, malignant fibrous histiocytoma, or metastases from a variety of primaries, most including neuroendocrine tumors or even colorectal primaries (Yang et al, 2009; Kim et al, 2009; Ding et al, 2006; Sugawara et al, 2000).

Primarily cystic hepatobiliary neoplasms that constitute another group of cystic tumors are extremely rare. They are of biliary origin and comprise both benign (with malignant potential) and malignant tumors that have initially been given the names of *cystadenoma* and *cystadenocarcinoma* (Ishak & Kamal, 1994); however, increasing evidence, in particular from Asian authors, suggests that biliary cystic neoplasia comprises a wider group of entities that resemble those described in the pancreas as being either mucinous cystic neoplasms (MCNs) or intraductal papillary mucinous neoplasm (IPMNs) (Zen et al, 2006a, 2006b). The main difference relates to the presence or absence of an ovarian stroma (OS) and whether a luminal communication exists between the tumor and the bile ducts.

No international consensus has been reached, and detailed characteristics of these tumors are not always described in the literature, casting some confusion on previous descriptions and reports of cystadenoma. Although the same confusion has been observed for cystic tumors of the pancreas, the clinical and pathologic differentiations of these two tumors are now accepted worldwide, now that a consensus on the definition of *pancreatic* MCNs has been reached (Kloppel et al, 2000; Suzuki et al, 2004). A second problem in analyzing the literature is that because of the rarity of the tumor, the number of large series is very limited, and most references are case reports.

DEFINITION

The initial definitions of cystadenoma by Edmondson in 1958 and by Wheeler and Edmondson in 1985 were strict and included three distinctive features: the lesion should be 1) multilocular (composed of multiloculated cysts) 2) lined by a columnar epithelium, and 3) accompanied by a densely cellular ovarian-like stroma.

This definition was revisited in 1994 by Devaney and colleagues following retrospective analysis of a larger series of 70 patients. Although most fulfilled the criteria set out by Edmondson and Wheeler, that definition was considered too restrictive, as the presence of an OS was inconsistently observed. Furthermore, not all cystadenoma-like lesions they saw were multilocular, and the epithelium lining was not exclusively of the columnar type; it was associated in one third with a cuboidal epithelium. This led the authors to suggest that lesions diagnosed as cystadenoma (or cystadenocarcinoma) should include cystic tumors both with and without OS as well as those having a unilocular gross appearance. More precisely, only 14% of the tumors they observed lacked OS, and only a single patient had a unilocular tumor, which actually was a cystadenocarcinoma.

Although being a landmark study by showing that cystadenoma-like lesions encompass different entities, those with OS exclusively observed in women and those without observed in both genders, with potentially different courses, which will be discussed below; this revision might have introduced some confusion, as detailed pathologic description of tumors subsequently reported as being cystadenoma (cystadenocarcinoma) has not always been provided, and some occasionally resemble atypical benign cysts or cystic forms of intrahepatic cholangiocarcinoma, rather than genuine cystadenoma (or cystadenocarcinoma), on the imaging or pathologic pictures illustrating these series and case reports.

Recently it has been suggested that by differentiating biliary cystic tumors based on their stroma and communication between the tumor and the bile duct, two groups of biliary tumors could be identified that are the counterparts of pancreatic cystic neoplasms. The first group has OS, typically does not communicate with the bile duct, and is the biliary counterpart of pancreatic mucinous cystadenoma. The second group lacks OS, communicates with the biliary ducts, and is sometimes referred to as *intraductal papillary mucinous neoplasm of the bile duct* (IPMN-B), similar to the intraductal papillary neoplasm of the pancreas. A consensus has not been reached yet on a naming convention, but in any case, most agree that only those tumors with OS should be termed *cystadenoma*.

HEPATOBILIARY CYSTADENOMA WITH OVARIAN STROMA

The most classic primary cystic tumors of the liver are hepatobiliary cystadenoma. Being of biliary origin, these tumors may occur anywhere along the biliary tree, including the common hepatic duct, cystic duct, or gallbladder; but the most frequent location, found in 83% to 94% of the patients, is the liver (Devaney et al, 1994; Buetow et al, 1995). These tumors are well known because of their inherent risk of malignant transformation, common to all adenomatous lesions, although this risk has not been precisely quantified.

Incidence

Cystadenomas are exceedingly rare. No accurate incidence estimates are available, but the largest series included 52 patients (Devaney et al, 1994), and most studies since then have comprised fewer than 10 patients; in the early 2000s, it was estimated that fewer than 200 patients had been reported (Duchini, 2001). It is frequently quoted that intrahepatic cystadenomas constitute fewer than 5% of cystic lesions of the liver based on an old report (Ishak et al, 1977), but this figure is likely overestimated; it has since become obvious that the prevalence of simple cysts of the liver in the adult population is higher than previously thought.

Pathology (See Chapter 78)

Cystadenomas are almost always solitary, and they may range in size from less than 1 to 40 cm; they are generally large, with a mean diameter of 15 cm (Buetow et al, 1995). Cystadenomas have been reported to develop equally in the right and left liver or to involve both lobes (approximately 33% each) (Devaney et al, 1994; Akwari et al, 1990); however, a striking feature in our experience, as well as in recent series, is the very high proportion of tumors occurring in the left paramedian section (segment IV) (Daniels et al, 2006; Lewin et al, 2006; Seo et al, 2010). Pictures of cystadenoma provided in the literature also show tumors in this location almost exclusively; an example is shown in Figure 79B.1.

Cystadenomas are grossly lobulated and multiloculated and usually contain clear to mucinous fluid (Buetow et al, 1995). Hemorrhagic fluid may be present (Lewin et al, 2006), but this is very rare and should raise the suspicion of malignancy (Buetow et al, 1995). A bilious content is similarly very unusual (Buetow et al, 1995), as lack of communication with the biliary tree is a distinctive feature; however, fistulization of cystadenoma in the biliary tree has been reported (Hanazaki, 1996; Yi et al, 2009), the same as for pancreatic mucinous cystadenoma, which may explain the bilious content.

The internal lining is generally smooth but may contain microscopic, or more rarely macroscopic, polypoid lesions projecting into the lumen (Fig. 79B.2). This internal lining has three distinct layers: 1) an epithelial layer, 2) a mesenchymal stroma, and 3) an outer layer of collagen connective tissue that separates it from the adjacent parenchyma (Fig. 79B.3).

The epithelial lining, as for pancreatic cystadenoma, consists of glandular, nonciliated cells arranged in a single, flat row with occasional papillary or polypoid projections, pseudostratifications, and cryptlike invaginations. In two thirds of the patients, the epithelium is columnar, but in one third, it consists of a combination of columnar and cuboidal epithelium. The epithelial lining may show denuded areas with chronic inflammation and hemorrhage. The columnar cells contain histologically benign appearing, basally located nuclei and intracellular mucin. The lining epithelium occasionally shows papillary infoldings, and mild epithelial atypia with a slight increase in the size of the basally located nuclei has been reported to be at least focally present in most patients. More severe dysplasia consisting of a multilayer appearance of hyperchromatic cells with loss of polarity appears much less frequently. Foci of intestinal metaplasia are also rare, seen in the form of numerous goblet cells. Atypia and metaplasia are suggestive of a high risk of malignant transformation (Devaney et al, 1994).

Phenotype has been further characterized in a limited number of patients. The epithelium shows strong and diffuse cytoplasmin staining with antibodies against CEA and CA19-9, whereas CA-125 staining is focal or absent (Subramony et al, 1993; Logroño et al, 2002). It also stains positive for CK-7, CK-19, CK-8, and CK-18 (Abdul Al et al, 2007), which supports a biliary origin, and it is negative for inhibin-α (Owono et al, 2001; Abdul Al et al, 2007), vimentin (Owono et al, 2001), and estrogen or progesterone receptors (Daniels, 2006), and CD56 is only expressed focally (Gütgemann et al, 2006).

The *stroma* consists of a compact arrangement of bland, spindle-shaped cells with round to oval nuclei. This appearance is reminiscent of OS, hence the name given to these tumors; but it has also been found to resemble the primitive mesenchymal elements associated with the developing biliary system in the fetus. This stroma may be abundant in some patients and focal in others, but mitotic activity is not prominent. It expresses estrogen and progesterone receptors, as does the stroma of pancreatic cystadenoma (Daniels et al, 2006; Weihing et al, 1997); α-inhibin, a gonadal protein that has a more limited expression

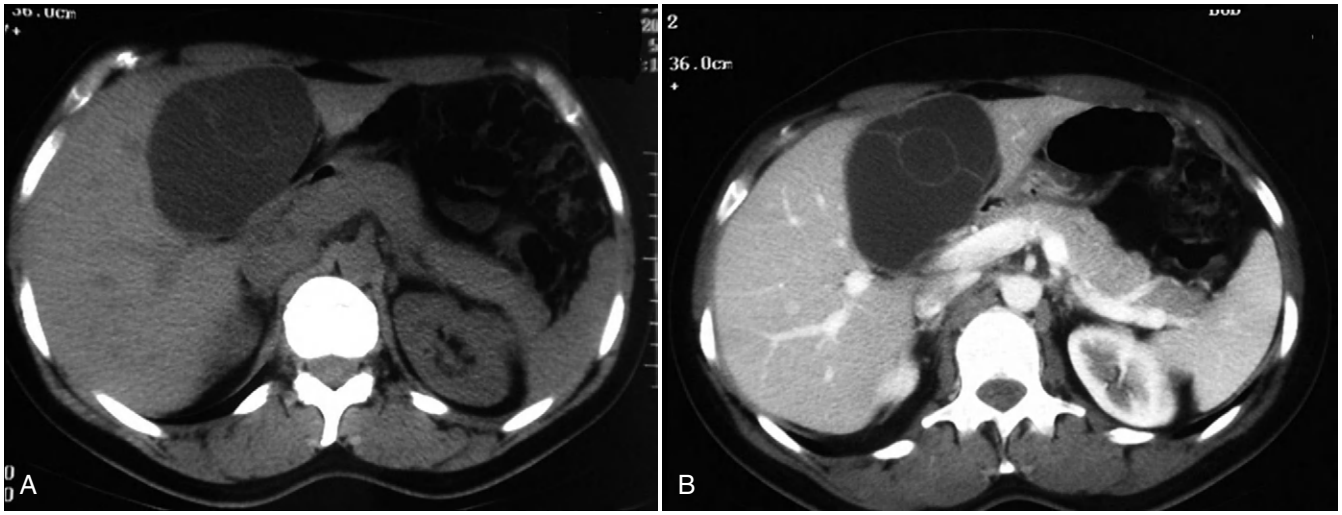

FIGURE 79B.1. Cystadenoma with ovarian-like stroma. The cyst has a thin wall and septa that enhance after injection of contrast agent (**B**). Note that the tumor is in segment IV, which occurs frequently.

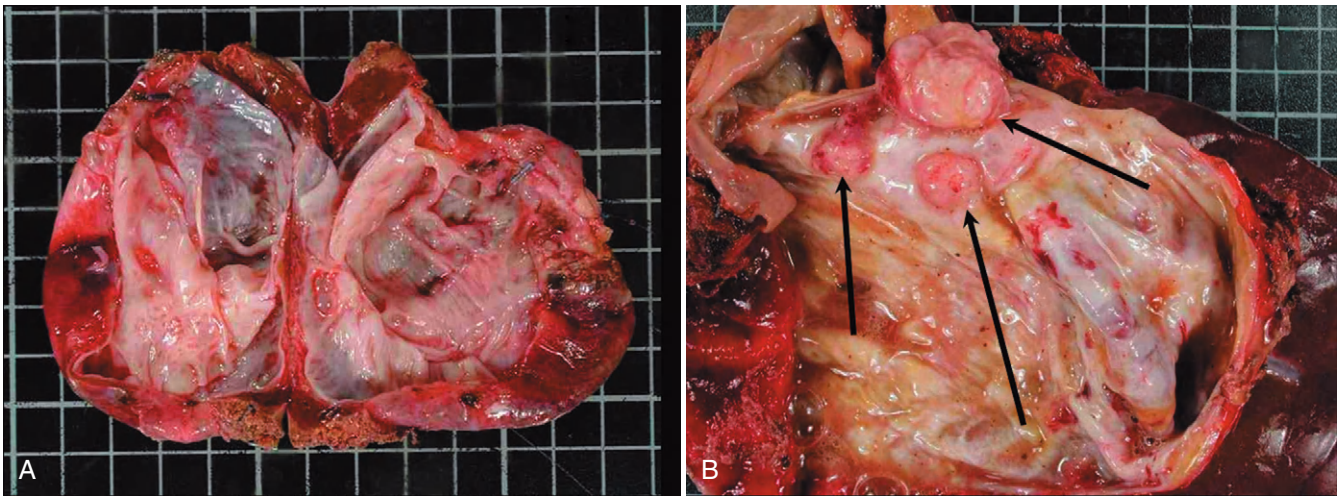

FIGURE 79B.2. Cystadenoma with ovarian-like stroma. The internal lining is smooth but may contain microscopic (**A**) or macroscopic (**B**) polypoid lesions.

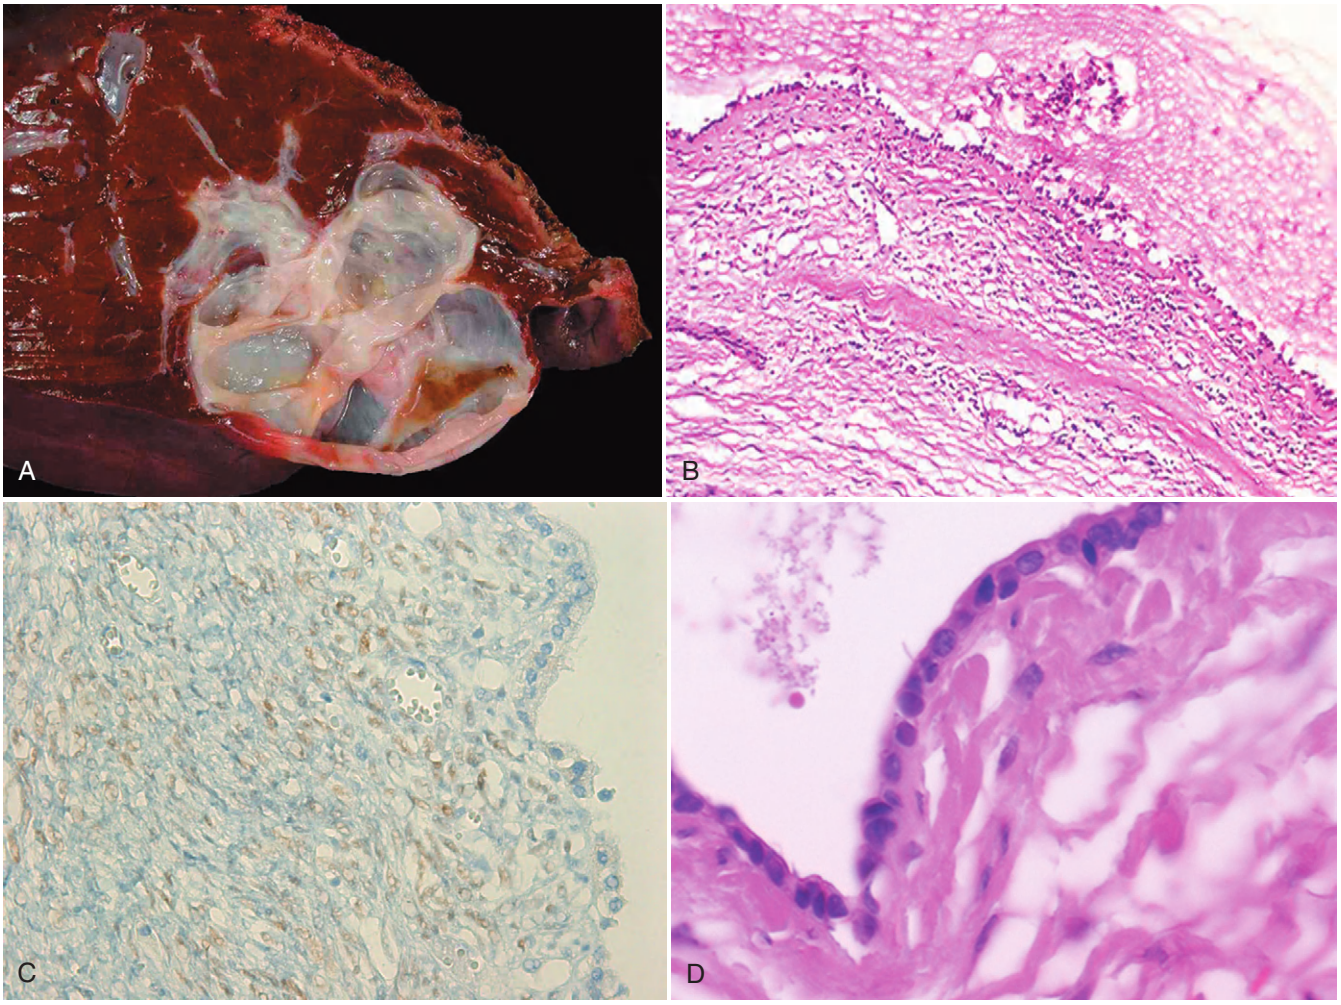

FIGURE 79B.3. Cystadenoma with ovarian-like stroma. **A,** Macroscopic view showing a multilocular cyst. **B,** Hematoxylin and eosin staining demonstrates a regular epithelial lining covering a densely packed, ovarian-like stroma and a hyalinized fibrous band that separates the cyst from the adjacent liver. **C,** Presence of progesterone-receptor–positive cells in the stroma. **D,** Histology of a simple biliary cyst composed of an unstratified epithelium of small cuboidal cells lining a fibrous wall is shown for comparison.

in the sex cord–stromal tissue, is also expressed in both hepatic and pancreatic mucinous cystadenoma (Ridder et al, 1998; Lam et al, 2008) and in sex cord–stromal tumors. They are immunoreactive with α–smooth muscle actin, vimentin, but also desmin. There is no immune reaction with CEA, CA19-9, or CA-125 (Devaney et al, 1994; Logroño et al, 2002).

A *densely hyalinized pseudocapsule* surrounds the tumor and separates it from the adjacent liver tissue, which explains how these tumors can be enucleated.

Despite the similarities between hepatic and pancreatic mucinous cystadenomas, few studies have compared the phenotypes of both lesions. One reported denser and more abundant stroma, more intense estrogen or progesterone receptors, and more α-inhibin in hepatic than in pancreatic cystadenomas, but the significance of this is unclear (Lam et al, 2008).

Risk Factors and Origin

There are no clearly identified risk factors apart from gender, as cystadenomas with OS are exclusively observed in women. However, a history of previous oral contraceptive use does not appear to be a distinctive feature (Devaney et al, 1994). Several hypotheses have been raised based on some pathologic features of the tumor, most notably the presence of an ovarian-like stroma or the occasional presence of eosinophilic or endocrine cells. It is still unclear whether cystadenomas are of congenital origin or are acquired neoplastic lesions.

The resemblance is striking among cystadenomas with OS located in the liver, pancreas, retroperitoneum, and ovary (Bakker et al, 2007; Nelson et al, 1988; Turbiner et al, 2007). The particular OS common to these locations contains estrogen and progesterone receptors and α-inhibin (Lam et al, 2008). These similarities suggest a common pathway of tumor development, although simultaneous occurrences of hepatic cystadenoma with pancreatic (Brachet et al, 2007) or ovarian cystadenoma (Skopelitou et al, 1996) are exceedingly rare.

One hypothesis is that during embryonic development, ectopic ovarian cells would have migrated to the liver or pancreas, released hormones and growth factors, and caused endodermally derived epithelium to proliferate and finally to form a tumor (Zamboni et al, 1999). The right and left primordial gonads are indeed located directly under the diaphragm prior to their descent, at the level of the dorsocranial side of the liver and the tail of the pancreas respectively. Furthermore, the cells covering the gonads show an activated morphology in contrast to the peritoneal epithelium elsewhere (Erdogan et al, 2006), which suggests that they have the ability to detach from the gonadal surface, cross the peritoneal cleft, and attach to the peritoneal surface of nearby organs. This hypothesis would explain the predominance of cystadenoma in the body or tail of the pancreas, rather than in the head, as well as the apparent predominance of liver cystadenoma in segment IV. Splenogonadal fusion has also been documented (Duncan & Barraza, 2005), and demonstration of endocrine cells in about 50% of cystadenomas is a distinctive feature (Terada et al, 1997) compatible with the hypothesis of these tumors developing from peribiliary glands.

The OS resembles the primitive embryonic mesenchyma of embryonic gallbladder and large bile ducts that contribute to the connective tissue surrounding the bile ducts (Subramony et al, 1993), and it has therefore also been suggested that these tumors could derive from ectopic embryonal tissue destined to form the gallbladder (Subramony et al, 1993) or from ectopic embryonic rests of primitive foregut sequestered within the liver (Wheeler & Edmondson, 1985).

Presentation

Intrahepatic biliary cystadenoma with an OS is exclusively observed in women. Age at diagnosis is highly variable, between 1 (Beasley et al, 1986) and 70 years, but it peaks in the fourth or early fifth decade. In most patients, the tumor is discovered during the workup of epigastric or right upper quadrant pain or vague abdominal complaints that include abdominal discomfort or swelling. Palpation of an abdominal mass that moves freely with respiration is also a classic circumstance of diagnosis. As the tumor may grow to a considerable size, a gradual increase in abdominal girth and/or compression of the stomach or duodenum may also occur; however, because of the slow progression of the neoplasm, the onset of symptoms tends to be insidious and to have evolved for a prolonged period of time before treatment (Akwari et al, 1990; Thomas et al, 2005). This may explain why most reported cystadenomas are large tumors. With the increasingly liberal use of imaging to investigate even the most minor symptoms, cystadenomas are often discovered incidentally, and it is possible that a significant proportion are not identified or are mistaken for simple cysts (Hara et al, 2001).

More acute episodes of pain have been reported in up to 35% of the patients, and most of these are related to biliary obstruction (Akwari et al, 1990; Erdogan et al, 2010). This is biologically witnessed by concomitant cytolysis or cholestasis. Jaundice or itching (Siriwardana & Pathirana, 2009) may also be present, whereas cholangitis is rare. Typically, such episodes are transient, and any jaundice tends to resolve spontaneously, which is compatible with the migration of mucous material or tumor embolus from the cyst into the bile duct (Fig. 79B.4). Such tumor protrusion in the bile duct lumen has been reported even for small cystadenomas less than 4 cm in diameter (Erdogan et al, 2006). An alternative mechanism of obstruction is simple compression of the biliary confluence by the cystadenoma. Other causes of acute presentation have included tumor rupture (Lempinen et al, 2005), superinfection, bleeding (Lewis et al, 1988), and caval compression (Catto et al, 1999), but these are rare.

Diagnosis

Differential Diagnosis

Apart from the other cystic tumors addressed in this chapter, most notably cystadenocarcinoma, the main differential diagnosis of cystadenoma is simple cysts that have become atypical on imaging studies as a result of intracystic bleeding (Kitajima et al, 2003) or previous sclerotherapy (Takayasu et al, 2003; see Chapter 69A). The risk of mistaking a cystadenoma for a benign cyst is that this lesion may be treated by simple unroofing, which is an inappropriate treatment associated with a high risk of recurrence (see Management below); to mistake a simple or atypical cyst for a cystadenoma is to perform an occasionally risky and unwarranted resection, because simple cysts do not require complete resection. Considering the very high incidence of simple cysts, the latter is probably much more common, and it has been shown that a cystadenoma-like lesion is almost as likely to be a simple cyst as to be a cystadenoma (Shimada et al, 1998; Teoh et al, 2006; Koea et al, 2008; Seo et al, 2010). Clinical history is totally unreliable in the diagnosis of hemorrhagic

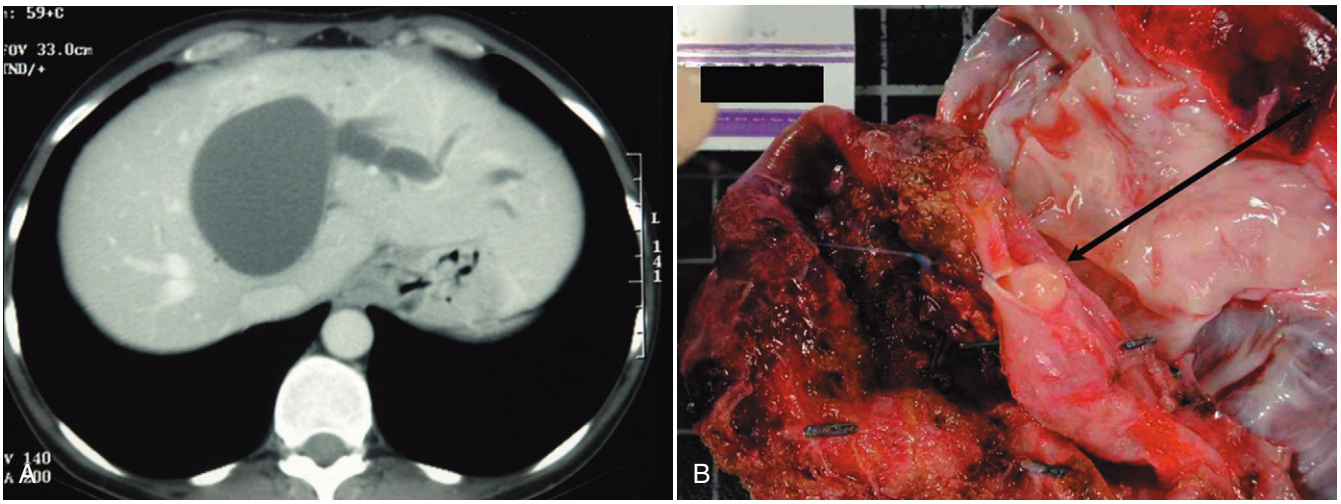

FIGURE 79B.4. Cystadenoma with ovarian-like stroma with tumor protrusion in the bile duct. **A,** Note the presence of dilated bile ducts upstream of the cyst located in segment IV. **B,** Tumor protruding into the left bile duct on the resected specimen.

cysts, as intracystic hemorrhage can occur in the absence of any symptoms (Kitajima et al, 2003), and the diagnosis mainly relies on imaging.

Alternative differential diagnosis must include nonsuppurative granulomatous infection of a simple cyst (Kawashita et al, 2006), hepatic abscess (Yamamoto et al, 2009), echinococcal cysts (Ramacciato et al, 2006), mesenchymal hamartoma (Mori et al, 2008), ciliated hepatic foregut cysts, intrahepatic lymphangioma, cystic hemangioma, cystic forms of hepatocellular carcinoma (HCC) or intrahepatic cholangiocarcinoma, mucin-producing metastases from thyroid or colon carcinoma and cystic metastases of the ovary, of melanoma, and of kidney and neuroendocrine tumors (Del Poggio & Buonocore, 2008). They have also been occasionally confused with pancreatic cysts (Logroño et al, 2002).

Imaging

The characteristic ultrasonographic (US) finding for biliary cystadenoma is an anechoic mass with echogenic internal septations (Fig. 79B.5). Papillary projections into the cystic space may also be seen. On CT scans, the lesions appear as multiloculated hypodense masses with a well-defined wall. The content demonstrates fluid attenuation because of the presence of mucin, blood, or bile. Fine septal calcifications may occasionally be seen, and both the wall and the septations enhance following administration of contrast material (see Fig. 79B.1).

With magnetic resonance imaging (MRI), cyastadenoma is typically seen as a fluid-containing multilocular cyst with homogeneous high signal intensity on T2-weighted images and homogeneous low or isosignal intensity on T1-weighted images (Lewin et al, 2006). These signals may vary depending on the content of the cystic fluid. Mucinous fluid will appear with an isosignal, serous fluid with a hyposignal, and hemorrhagic fluid with an hyperintense signal that can only be seen in the lower part of a fluid-fluid level. Thin internal septal structures separate fluid-filled spaces. These, along with the wall of the lesion, are contrast enhanced (Fig. 79B.6).

Contrast US is a promising exploration that allows analysis of the vascularization of the cyst wall and septa, but it has been used infrequently. An intracystic structure of complicated simple cysts corresponds to clots and is not enhanced (Akiyama et al, 2008). Although the periphery of the cyst may show enhancement, this corresponds to compressed adjacent liver, and this should be differentiated from enhancement of the cyst wall of cystadenoma (see Fig. 79B.5).

As for other cystic lesions, CT scan is less reliable and accurate than US or MRI. Cystadenoma in particular may wrongly appear unilocular on CT scan, whereas US (Korobkin et al, 1989) and MRI (Lewin et al, 2006; Williams et al, 2001) will visualize the internal septa. Two additional features besides multilocularity may help in the differential diagnosis of simple cysts: they are frequently multiple (Vuillemin-Bodaghi et al, 1997), whereas cystadenomas are single lesions; and although biliary dilation has been considered uncommon, a mild enlargement upstream of the tumor is probably more frequent than previously thought—using higher resolution imaging, enlargement was observed in one to two thirds of the patients in recent series (Lim et al, 2007; Seo et al, 2010). Along the same line, an increase in serum alkaline phosphatase levels has recently been shown to be a feature distinctive from simple cysts (Seo et al, 2010).

Cytology and Tumor Markers

CYTOLOGY. Aspiration cytology is either nonspecific or it shows chronic inflammatory exudates with large numbers of neutrophils, lymphocytes, and macrophages. A few groups of nonatypical bland cuboidal to columnar epithelial cells, occasionally arranged in papillary clusters, may be seen (Logroño et al, 2002).

TUMOR MARKERS. Unlike for the pancreas, measurement of tumor markers in hepatobiliary cystic lesions has been infrequently performed, and results are confusing. Early case reports have pointed to a link between cystadenoma and CA19-9 by showing its expression by epithelial lining and by revealing increased intracystic and serum concentrations (Thomas et al, 1992; Lee et al, 1996). However, CA19-9 is also expressed by normal biliary epithelial cells, and very high levels have occasionally been measured in the bile of patients with various nontumoral conditions (Horsmans et al, 1997; Shimada et al, 1998; Ker et al, 1991). It is also expressed by the epithelium lining

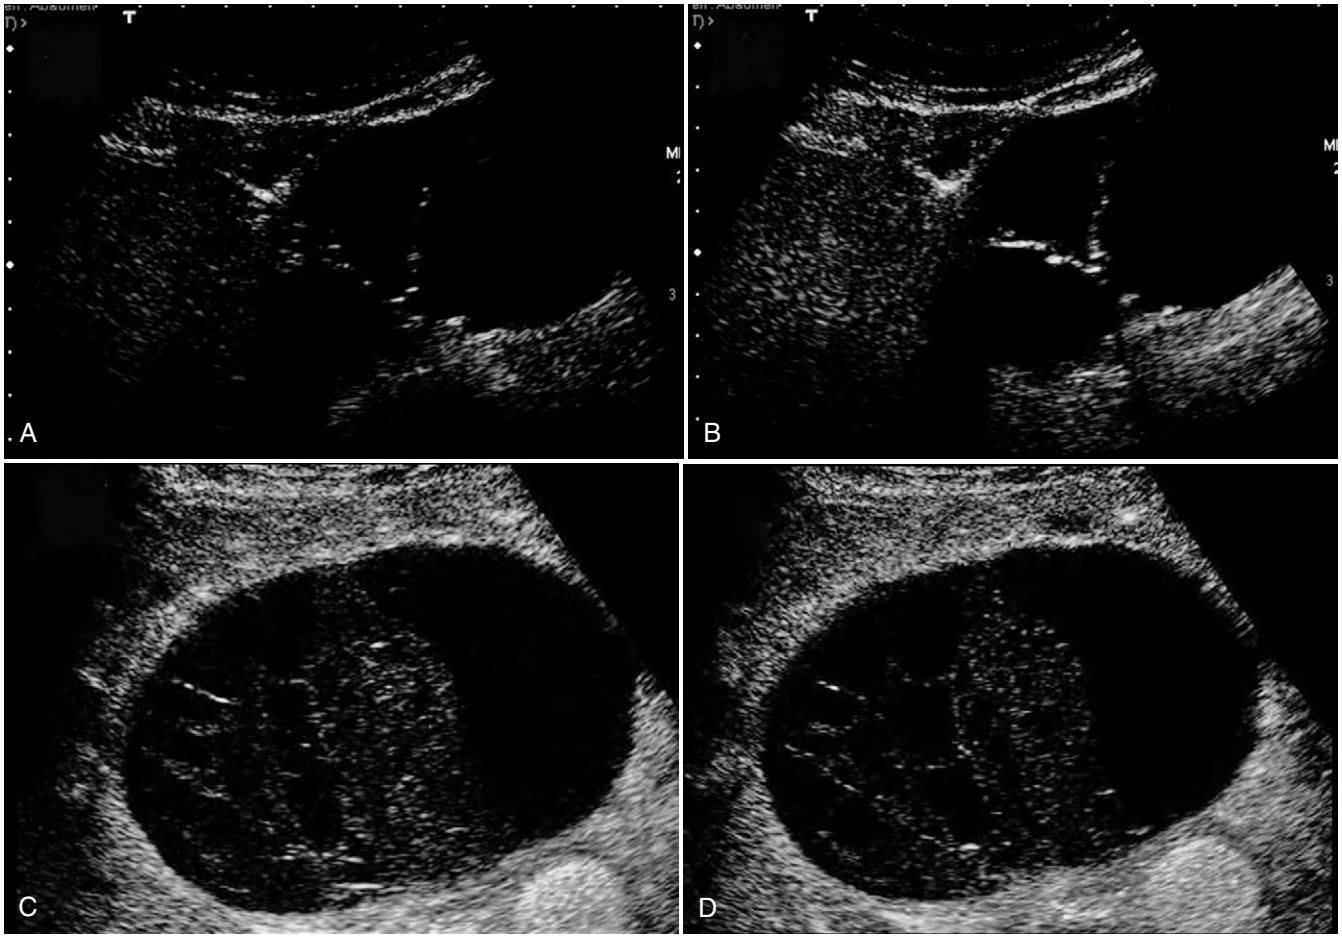

FIGURE 79B.5. Ultrasound (US) and contrast US of a cystadenoma with ovarian-like stroma (**A** and **B**) and of a hemorrhagic simple cyst (**C** and **D**). Normal US (**A** and **C**) and contrast US (**B** and **D**) are shown. The septa are enhanced in the cystadenoma, but in hemorrhagic cysts, the intracystic material corresponds to clots and does not enhance.

simple cysts of the liver (Park et al, 2006) and in the cystic fluid of simple cysts (Park et al, 2006; Choi et al, 2010). An increased serum concentration of CA19-9 in these patients has even been reported and can occasionally be very high, probably as a result of communication of the cyst with the circulation. Three studies have shown that cyst concentration (Choi et al, 2010; Seo et al, 2010) and serum concentration of CA19-9 (Park et al, 2006; Choi et al, 2010) are comparable in patients with cystadenoma and simple cysts. As will be discussed below, CA19-9 is also inaccurate in differentiating cystadenoma from cystadenocarcinoma (Horsmans et al, 1997).

It has also been suggested that a CEA concentration greater than 600 ng/mL in the supernatant of cystic liver lesions could accurately differentiate cystadenoma or cystadenocarcinoma from benign, nonmucinous cysts (Pinto & Kaye, 1989). The epithelial lining of cystadenoma indeed stains positive for CEA (Logroño et al, 2002); however, this has not been confirmed in subsequent studies, in which concentrations in cystadenoma and simple cysts were comparable (Shimada et al, 1998; Choi et al, 2010; Seo et al, 2010).

Complications

Cystadenoma with an OS is considered a precancerous lesion, as will be detailed below. Malignancy arises in most cases from the epithelium lining (cystadenocarcinoma), but sarcomatous transformation of the OS has also been reported (Akwari et al, 1990). No specific feature has been clearly linked to a higher risk of malignancy, apart from the presence of epithelial atypia (dysplasia) or intestinal metaplasia. The odds ratio for their association with malignancy has been calculated to be 8 (95% confidence interval [CI], 2.4 to 27.0) and 2.4 (95% CI, 1.2 to 3.5), respectively (Devaney et al, 1994).

Although cystadenoma with an OS by definition does not communicate with the biliary tree, fistulization in the bile duct may occur. Ensuing symptoms probably only occur in patients with a mucinous cystic content. Incidence of this complication is unknown, as it is only documented by endoscopic retrograde cholangiopancreatography (ERCP) and intraoperative cholangiography (IOC), which are not routinely performed. Other complications have included rupture in the peritoneal cavity, superinfection, bleeding, and caval compression, as previously mentioned.

Management

Cystadenomas require complete excision to prevent recurrence of symptoms and malignant transformation. Evidence that partial excision, aspiration, and external or internal drainage are ineffective is that recurrence has been noted very early on (Ishak et al, 1977; Wheeler & Edmondson, 1985; Lewis et al, 1988; Devaney et al, 1994) and that 40% to 50% of the patients

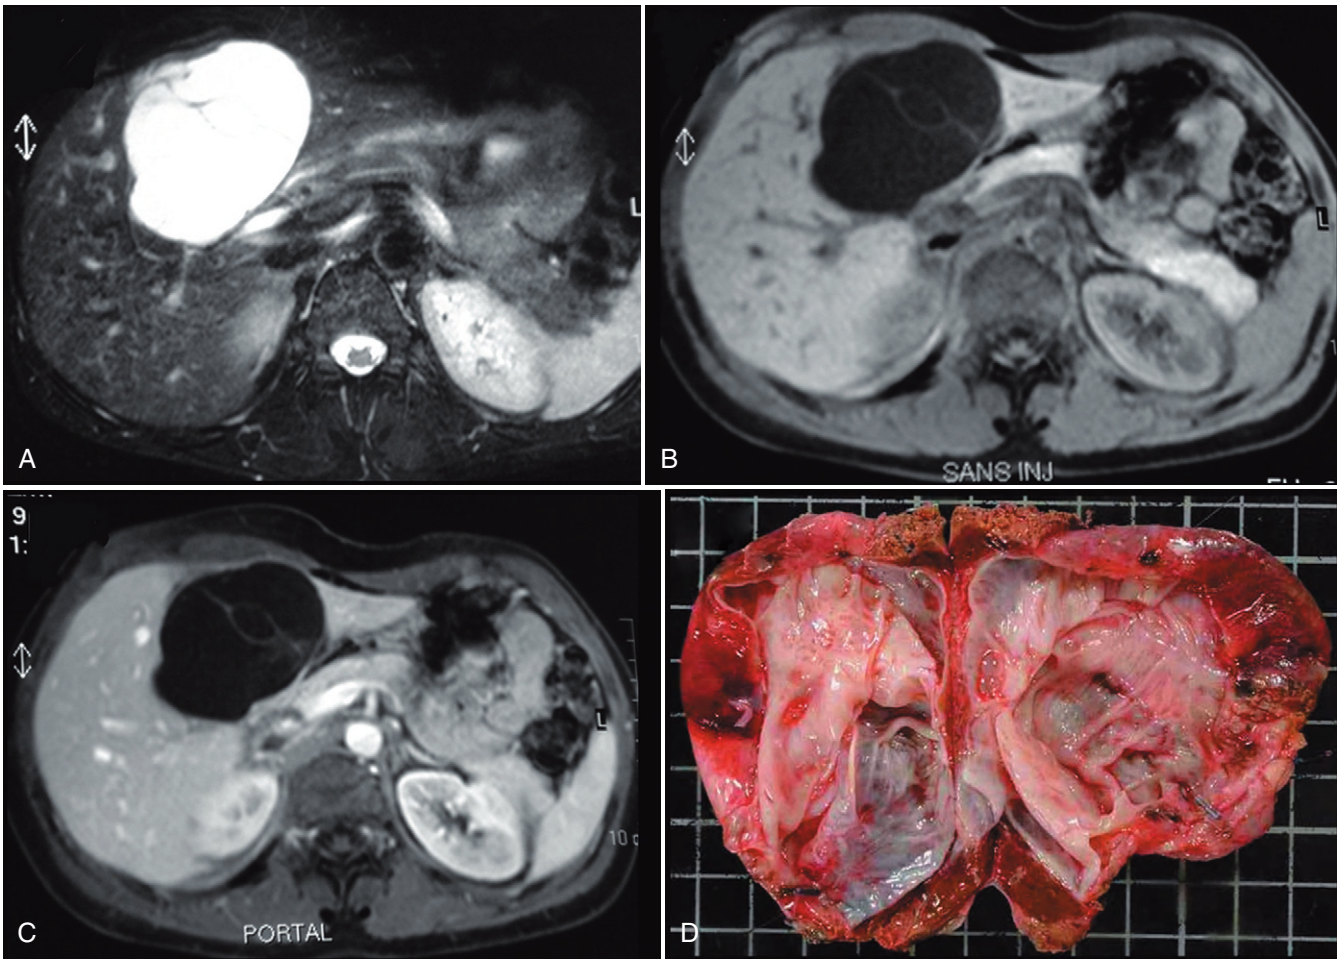

FIGURE 79B.6. Magnetic resonance imaging of a cystadenoma with ovarian-like stroma (**A**-**C**) and macroscopic view (**D**). culled by tertiary referral centers had undergone such previous treatments prior to referral (Hansman et al, 2001; Thomas et al, 2005; Vogt et al, 2005; Daniels et al, 2006; Delis et al, 2008). Updated evidence is shown in Table 79B.1. Recurrence occurs at a mean of 21 months but may be delayed up to 4 years (Vogt et al, 2005). This may explain why recurrence following incomplete resection has not been systematically observed, as most studies only have short-term follow-up (Barabino et al, 2004; Lewis et al, 1988; Manouras et al, 2008). Development of a cystadenoma following partial resection of a cystadenocarcinoma has also been documented (Woods, 1981; Devine et al, 1985; Lei & Howard, 1992; Akwari et al, 1990).

Fenestration of the cystadenoma with fulguration of the internal cystic lining has been attempted with occasionally adequate long-term success (Thomas et al, 2005), but experience is too limited to recommend this strategy. Although not documented, it is likely that some small cystadenomas mistaken for simple cysts have also been successfully treated with percutaneous ethanol injection. Ethanol is indeed effective in the management of simple cysts, hydatid disease, and hepatocellular carcinoma; however, this cannot be currently recommended, especially as most cystadenomas are large, and ethanol injection induces morphologic changes that prevent accurate follow-up of the cyst wall. In any case, the clinician should not rely on intraoperative frozen-section biopsies to differentiate simple cysts and cystadenoma, as these can be falsely negative even when repeated (Vogt et al, 2005; Manouras et al, 2008).

Surgery can consist of partial hepatectomy or enucleation, as there is a dissection plane between the cystadenoma and the adjacent parenchyma. Care should be taken when the cyst lies in segment IV so as not to injure the biliary bifurcation. IOC should be performed to document a potential biliary communication and exclude the presence of mucus or tumor material in the bile duct. Treatment of extrahepatic cystadenoma should include bile duct resection and bilioenteric reconstruction rather than simple enucleation from the bile duct wall. As for other tumors, laparoscopic resection can be an option for trained surgeons (Koffron et al, 2004; Veroux et al, 2005). A single case of recurrence following complete resection has been reported (Wheeler & Edmondson 1985).

HEPATOBILIARY CYSTADENOMA WITHOUT OVARIAN STROMA

Some cystadenomas have been reported that do not have OS. Before considering this diagnosis, several samples of the specimen should be analyzed, as in some patients, the OS may be only focally present (Devaney et al, 1994). Although cystadenoma with and without an OS have very similar clinical and morphologic features, a distinctive characteristic is that the

former only develops in women, whereas the latter may develop in both genders. It is unclear, however, whether cystadenoma without an OS is a discrete entity, or whether it comprises a heterogeneous group of cystic tumors. For this reason, some pathologists would not retain the diagnosis of cystadenoma if the OS were lacking.

Incidence

The largest surgical series of cystadenoma, with or without an OS, published over the past 15 years have, as a rule, included a higher number of tumors with OS than without in a proportion of 5 to 10 to 1 (Table 79B.2; Buetow et al, 1995; Devaney et al, 1994; Erdogan et al, 2010; Regev et al, 2001); however, others have reported equal numbers (Owono et al, 2001; Vogt et al, 2005), and in one study, virtually all cystadenoma lacked OS (Koffron et al, 2004). This discordance is puzzling but probably speaks to the lack of strict pathologic definition of this entity. It is likely that a number of tumors previously diagnosed as cystadenoma without an OS were in fact simple cysts of the liver that had a multilocular appearance as a result of intracystic bleeding, or because several cysts were juxtaposed. They might also have included cystic forms of IPMN-B, which is addressed separately in this chapter.

Pathology

Cystadenomas without OS are typically multilocular and have a mucinous content (Fig. 79B.7). The epithelium is phenotypically similar to the classic cystadenoma (see above). Devaney and colleagues (1994) did not observe areas of atypia or dysplasia in this variant, but others have (Owono et al, 2001). These tumors also tend to more frequently communicate with the biliary tree than cystadenoma with an OS. In particular, a higher proportion of patients are seen with bilious fluid within their cyst (Buetow et al, 1995); however, data are scarce, and ERCP and IOC have not been routinely performed. If confirmed this feature would strengthen the parallel between some, at least cystadenoma without an OS and IPMN-B.

The phenotype of the epithelium lining cystadenoma without an OS has been very inconsistently characterized but has been reported to stain positive for CK-7, CK-8, CK-18, CK-19, MUC1, MUC5, and MUC6 but not for CEA, CA 19-9, or MUC3 (Kazama et al, 2005; Qu et al, 2009). This phenotype is close to that of large bile ducts (see Chapter 78).

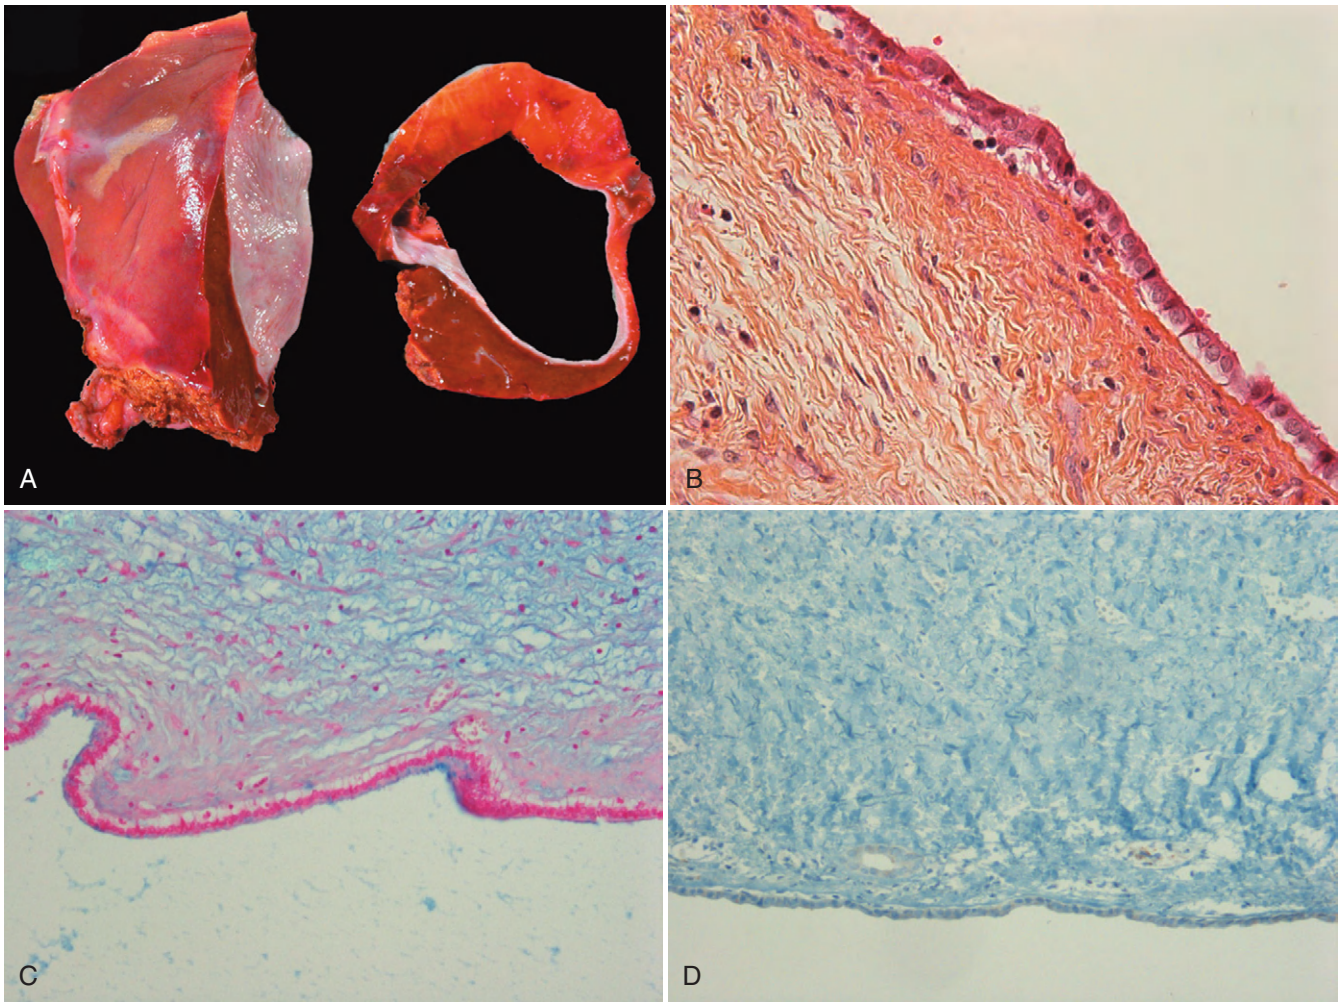

FIGURE 79B.7. Cystic mucinous tumor without ovarian-like stroma. **A,** Macroscopic view showing a unilocular cyst. **B,** Hematoxylin and eosin staining demonstrates cyst lining by an unstratified epithelium of regular cuboidal cells lying on a fibrous wall without ovarian-like stroma. **C,** Mucin production is observed in epithelial lining cells. **D,** No progesterone receptor immunostaining was observed in the fibrous wall.

Presentation and Diagnosis

Unlike those with OS, cystadenomas without OS have been described in both genders, and the sex ratio is actually close to 1 based on the rare available data (Owono et al, 2001; Buetow et al, 1995; Devaney et al, 1994). Otherwise, age (peaking between 40 and 60 years), symptoms, and size of the cyst are comparable (Buetow et al, 1995). Imaging studies have up to now been unable to differentiate between cystadenoma with and without an OS (Buetow et al, 1995; Owono et al, 2001; Lewin et al, 2006). In the cystic fluid, CA19-9 appears always increased, and CEA levels are also increased in most patients (Dixon et al, 2001; Koffron et al, 2004).

Natural History and Management

Very little data are available on the natural history of cystadenoma without an OS. Case reports suggest that it may undergo morphologic changes with a progressive increase in diameter, mural thickening, development of papillary nodules, and subsequent malignant transformation (Akiyoshi et al, 2003; Fukunaga et al, 2008). These changes have been observed over a prolonged period of time (10 years). Whether cystadenoma with and without an OS have the same malignant potential is unclear. It is accepted, however, that both require complete resection. IOC should be performed to document a potential biliary communication. If present, the diagnosis of IPMN-B should be considered and ruled out by frozen-section analysis.

CYSTADENOCARCINOMA

Definition and Incidence

Cystadenocarcinomas are very rare primary cystic tumors that do not primarily communicate with the biliary tree; they are lined by a tubulopapillary malignant epithelium (Fig. 79B.8). Single case reports exist in which malignancy was an adenosquamous carcinoma (Devaney et al, 1994) or it developed in the stroma (Akwari et al, 1990). Cystadenocarcinoma was first described in 1943 by Willis, but by 2000, only 100 had been reported in the literature (Lauffer et al, 1998; Bardin et al, 2004), and they were considered to account for only 0.4% of hepatic malignancies (Takayasu et al, 1988). Most have been

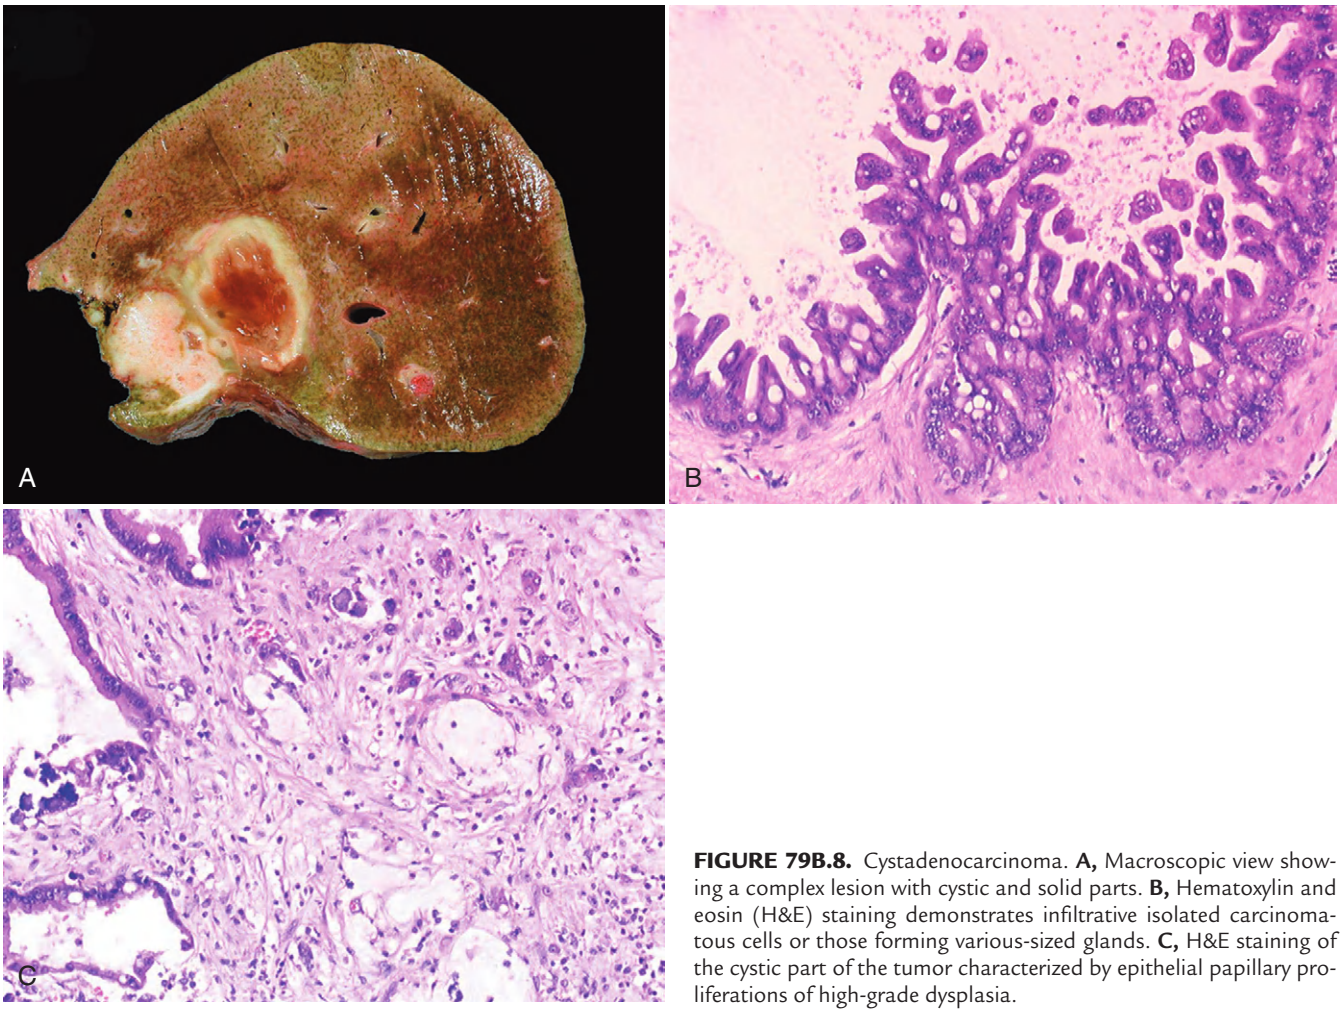

FIGURE 79B.8. Cystadenocarcinoma. **A,** Macroscopic view showing a complex lesion with cystic and solid parts. **B,** Hematoxylin and eosin (H&E) staining demonstrates infiltrative isolated carcinomatous cells or those forming various-sized glands. **C,** H&E staining of the cystic part of the tumor characterized by epithelial papillary proliferations of high-grade dysplasia.

found in the liver, with only anecdotal reports of locations in the extrahepatic bile duct and the gallbladder in particular (Waldmann et al, 2006). As for cystadenomas, these are usually stratified in two groups depending on the presence or absence of an OS (Ishak et al, 1977; Lee et al, 2009); however, some pathologists are reluctant to consider the diagnosis of cystadenocarcinoma when the OS is lacking, as these may correspond to cystic variants of mass-forming intrahepatic cholangiocarcinoma or to malignant IPMN-B (Zen et al, 2006). The distinction is not purely academic, as these tumors have distinct modes of spread and prognoses that could influence management. This should be taken into account when analyzing the literature, and even when reading this section.

Epidemiology and Presentation

Overall female to male ratio is 2:1, but cystadenocarcinomas with OS are exclusively observed in women, whereas those without OS are twice as frequent in men (Bardin et al, 2004). Although the age range is wide—from 18 to 88 years—it peaks in the late 50s and 60s (Lauffer et al, 1998; Seo et al, 2010), approximately 15 to 20 years later than cystadenomas. This difference is in especially obvious for those lesions with OS (Akwari et al, 1990; Buetow et al, 1995; Devaney et al, 1994; Wheeler & Edmondson, 1985).

Although usually nonspecific, symptoms are virtually always present and are initially rather indolent. They are common to cystadenoma and include abdominal swelling, discomfort, pain, or palpation of an abdominal mass. Biliary obstruction with jaundice is reported in 20% of the patients, related to biliary compression or migration of mucus or tumor material. Acute symptoms may otherwise occur as a result of intracystic hemorrhage or tumor rupture. As a rule, diagnosis is delayed, and the mean time interval between first symptoms and treatment is 29 months (Lauffer et al, 1998); one case was reported of a cystadenocarcinoma being discovered 1 year after bone metastasis (Berjian et al, 1981).

Origin and the Cystadenoma-Cystadenocarcinoma Sequence

Cystadenocarcinomas have no identified risk factors, and their origin is unknown, but it is usually assumed that they are the malignant counterpart of cystadenoma. The proliferating epithelial cells indeed resemble those observed in cystadenoma, both express a biliary-type phenotype, and typical areas of cystadenoma (benign columnar epithelium) coexist with malignant papillary epithelium in most patients (up to 90%; Lauffer et al, 1998). Longitudinal morphologic studies of single patients whose cystic lesions were followed for more than a decade

have also shown the progressive development of typical cystadenocarcinoma (Akiyoshi et al, 2003; Kubota et al, 2003). As a whole, cystadenocarcinomas also tend to be larger and to be discovered 5 to 10 years later than cystadenoma (Lauffer et al, 1998). The transition from one to the other is thought to occur through dysplasia or metaplasia that may be observed within cystadenoma (see Pathology above). This applies to both intrahepatic (Ishak et al, 1977; Akiyoshi et al, 2003) and extrahepatic cystadenoma (Davies et al, 1995; Coulter & Baxter, 1989) as well to cystadenomas both with and without OS (Ishibashi et al, 2007).

The risk of malignant transformation of cystadenoma into cystadenocarcinoma is unknown, as the tumor is rare, and limited data are available. A rough estimate can be made by comparing the relative proportion of "cystadenoma" and cystadenocarcinoma in published series (see Table 79B.2). Among resected patients, 15% of tumors with OS were malignant. Although biased, this estimate is consistent with that reported for choledochal cysts, also premalignant lesions. In contrast, the proportion of cystadenocarcinoma is apparently much higher among tumors without OS or an undefined stroma (see Table 79B.2). The reason for this discrepancy is unclear, which does not necessarily imply that cystadenomas without OS are at greater risk of malignant transformation. These could also include intrahepatic cholangiocarcinoma mistaken for cystadenocarcinoma or malignant IPMN-B (papillary cholangiocarcinoma; see Cystic Variants section below).

The time necessary for a cystadenoma, with or without OS, to undergo malignant change and subsequently become invasive in the cyst wall, the adjacent parenchyma, or neighboring organs is unknown. Case reports have shown that a lesion may remain morphologically unchanged for years, but that once mural nodules appear, these may progress within a few months (Akiyoshi et al, 2003). The propensity of, and time necessary for, the malignant epithelial proliferation to become invasive is also unknown. It has been reported that in approximately one third (Devaney et al, 1994) to one half (Lauffer et al, 1998; Nakajima et al, 1992) of the patients who had been operated, the tumor was confined to the cyst, which may explain the very high survival rates reported after complete resection. However, parenchymal extension appearing as satellite nodules or perineural and lymphatic invasion for tumors located close to a glissonian pedicle does exist, and distant metastases are present at the time of diagnosis in 20% of the patients (Lauffer et al, 1998).

Diagnosis

Cystadenocarcinoma could theoretically be mistaken for metastases from cystadenocarcinoma of the ovary or pancreas, but these are usually multiple, whereas cystadenocarcinomas are, as a rule, single lesions. The main difficulty lies in how best to differentiate them from cystadenoma on the one side and from cystic variants of mass-forming intrahepatic cholangiocarcinoma or malignant IPMN-B on the other side. It could be argued that these distinctions are of little practical importance, as all require resection; however, the extent of resection may differ.

Gross Morphology and Imaging

Cystadenocarcinoma shares most of the morphologic and radiologic features of cystadenoma. The lesions are solitary (Seo et al, 2010) and usually large, with an average diameter of 12 cm but growing up to 40 cm (Lauffer et al, 1998); they can also be small, and cystadenocarcinoma of less than 5 cm have been reported, including one of 2 cm (Lauffer et al, 1998; Williams et al, 2001; Lewin et al, 2006). Therefore a small tumor is not evidence that a lesion is benign. Macroscopically, they more frequently have a hemorrhagic or bilious content (Buetow et al, 1995), and hemorrhage or nodularity within the cyst wall is evident (Buetow et al, 1995; Lewin et al, 2006; Seo et al, 2010).

On imaging, cystadenocarcinomas are also more frequently associated with larger septa; intrahepatic cysts debris; bile duct dilation (Seo et al, 2010); enhancement of mural nodules on CT scan, MRI, or contrast US (Korobkin et al, 1989; Pojchamarnwiputh et al, 2008; Ren et al, 2010); and coarse calcifications along the wall or septa (Buetow et al, 1995; Korobkin et al, 1989; Fig. 79B.9). However, all of these features can also be observed in nonmalignant cystadenoma (Fukunaga et al, 2008; Choi et al, 2010), and differentiating both tumors on macroscopy or imaging alone has up to now proven very

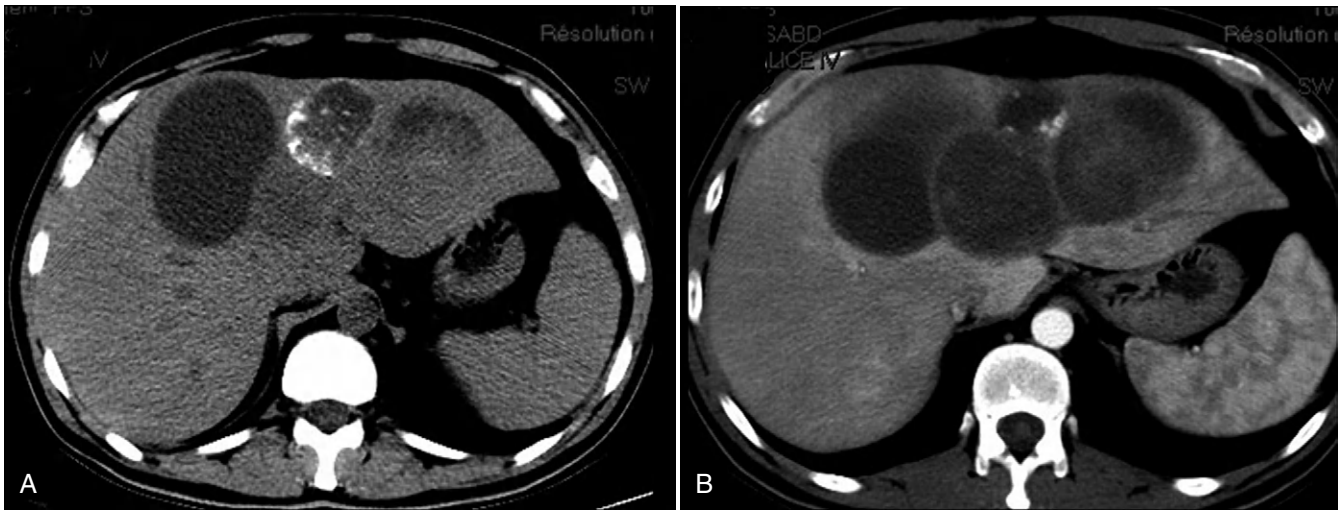

FIGURE 79B.9. Computed tomographic appearance of a cystadenocarcinoma. **A,** Gross calcifications are present along the cyst wall. **B,** Heterogeneous tissue material enhances within the cyst lumen after injection of contrast agent.

difficult (Buetow et al, 1995; Hai et al, 2003). Case reports exist of fluorodeoxyglucose positron emission tomography (FDG-PET) CT positivity (Takanami et al, 2009), but the accuracy of this exploration has not been evaluated.

Biology

An increase in serum tumor markers CEA and CA19-9 is very rare and, when present, is usually mild (Lauffer et al, 1998; Hai et al, 2003). This has also been described, in particular for CA19-9, in cystadenoma both with and without an OS (Hai et al, 2003; Horsmans et al, 1996; Kim et al, 1998; Thomas et al, 1992), and serum levels greater than 50,000 have been reported (Scoggins et al, 2004).

Cyst Content

Cystic fluid analysis does not provide discriminant information. The content is usually hemorrhagic, bilious, or mixed. Although in earlier case reports, fine needle aspiration cytology was found to be useful (Wee et al, 1993; Iemoto et al, 1983), more recent studies have shown that malignant or even atypical cells are very infrequently retrieved (Hai et al, 2003; Seo et al, 2010).

Although inconsistently measured, CA19-9 and CEA concentrations are usually increased in the cystic fluid; but this increase is comparable to that observed in cystadenomas, and CA19-9 is present at very high concentrations in most patients (Hai et al, 2003; Seo et al, 2010), although it has been reported to be normal in a patient whose cystadenocarcinoma did not stain positive for this tumor marker (Horsmans et al, 1997). Although some patients may have CEA levels higher than those observed in cystadenoma or simple cysts, most have normal or mildly elevated concentrations that are therefore not discriminant (Seo et al, 2010). This is consistent with the observation that the epithelium of both cystadenoma and cystadenocarcinoma stain positive for CEA (Tomioka et al, 1986).

Cyst sampling should in any case be performed with caution, as cystadenocarcinomas—and biliary tumors in general—have a high propensity for peritoneal seeding that has been observed following this procedure (Iemoto et al, 1981; Nakajima et al, 1992). Pleural effusion, presumed to be related to aspiration cytology, has also been reported (Hai et al, 2003).

Treatment

Surgery should consist of complete resection, and IOC should be considered, as some of these tumors may communicate with the biliary tree. As tumor extension cannot be reliably assessed on preoperative imaging, it is advisable to perform a formal resection with a wide margin rather than an enucleation. Resection of the biliary confluence followed by a hepaticojejunostomy may be required if the tumor lies close to the biliary confluence. Every effort should be made not to open the cyst, as peritoneal carcinomatosis has been observed after accidental cyst rupture despite negative cytology for tumor cells in cystic fluid (Kosuge et al, 1992). Partial resection of cystadenocarcinoma with an OS is associated with a dismal prognosis.

Following complete resection, the prognosis appears better overall than that of patients with hepatocellular carcinoma (see Chapter 80) or cholangiocarcinoma (see Chapter 50A). Cystadenocarcinomas associated with OS tend to have a more favorable course than those not associated with OS (Devaney et al, 1994; Asahara et al, 1999) with less frequent parenchymal, vascular, and lymphatic invasion (Hai et al, 2003). It is unclear, however, whether this relates directly to the presence of an OS; to gender (cystadenocarcinomas with an OS are exclusively observed in women), as shown for other malignancies; or to tumor invasiveness.

CYSTIC VARIANTS OF INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM OF THE BILE DUCT

IPMN-B is a relatively new, distinct pathology characterized by intraluminal papillary proliferation in the bile ducts that produce mucin (Nakanuma et al, 2002). They almost exclusively occur in the intrahepatic bile ducts or the left or right bile ducts, do not have an OS, and probably correspond to entities previously described using the terms *biliary papilloma, mucin-producing ICC, intraductal mucosal-spreading mucin-producing peripheral cholangiocarcinoma, intraductal growth-type peripheral cholangiocarcinoma,* and *intraductal variant of peripheral cholangiocarcinoma.* These tumors have striking clinical, histologic, and phenotypic similarities with IPMN of the pancreas (IPMN-P; Kim et al, 2000; Zen et al, 2006a; Fukushima & Mukia, 2000; Kloppel & Kosmahl, 2006), and both may occasionally coexist in the same patient (Ishida et al, 2002; Zalinski et al, 2007; see Chapters 56 and 57).

They may macroscopically be divided into two types: the *ductectatic type* evidences diffusely dilated bile ducts; the *cystic type* appears as a large cystic mass (Sakamoto et al, 1997). A parallel has therefore been drawn between branch duct cystic IPMN-P and cystic variants of IPMN-B that are thought to develop from small bile ducts. Because these variants of IPMN-B have both cystic (mucin) and solid (papillary projection) compartments, they may resemble cystadenoma or cystadenocarcinoma (Terada & Taniguchi, 2004; Aoki et al, 2005; Lim et al, 2007) and might have been mistaken for them in the past.

Definition and Etiology

IPMN-B, including its cystic variants, has mainly been described in the East, initially in patients with hepatolithiasis or *Clonorchiasis* infection (Chen et al, 2001). It develops in the bile duct lumen and is characterized by innumerable frondlike papillary infoldings, which consist of columnar epithelial cells surrounding slender fibrovascular stalks supported by connective tissue from the lamina propria. Further stratification is based on the presence and severity of atypia of the biliary epithelia: *type 1* is low-grade dysplasia, *type 2* is high-grade dysplasia, *type 3* is in situ and microinvasive adenocarcinoma, and *type 4* is invasive adenocarcinoma. Types 3 and 4 are associated with papillary tumor tissue and mucobilia in the large, dilated ducts containing stones; whereas this is frequently absent in type 1 lesions, intraductal spreading is virtually constant. This description was somewhat confusing, as these tumors had been observed in a specific context of chronic biliary inflammation; however, it has subsequently been described in the absence of such conditions (Shibahara et al, 2004; Zen et al, 2006a; Hayashi et al, 2008), although etiology remains unknown.

Pathology

Cystic IPMN-B morphologically is multilocular and frequently contains mucinous fluid (Fig. 79B.10). It may also occasionally

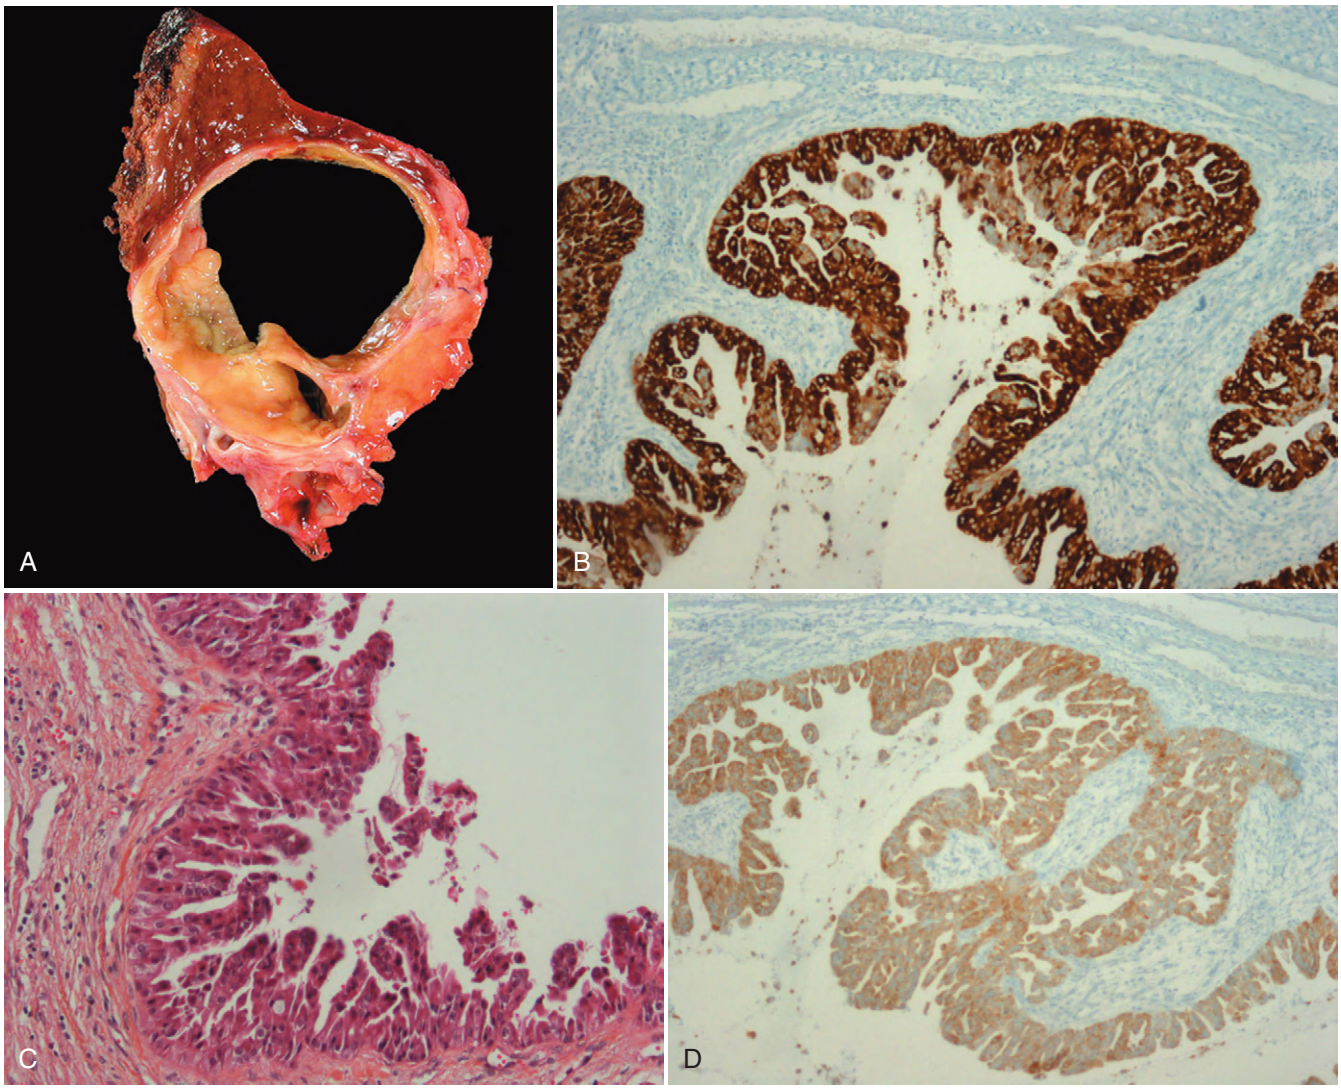

FIGURE 79B.10. Intraductal papillary mucinous neoplasia of the bile ducts (IPMN-B). **A,** Macroscopic view showing a multilocular cyst characterized by papillary mural nodules within a smooth wall. **B,** The lining epithelium is composed of papillary projections made of several layers of atypical cells. No features of mural invasion are present. **C,** Epithelial proliferation is strongly positive for MUC5. **D,** Cell proliferation displays slight MUC1 staining.

be hemorrhagic (Zen et al, 2006a). Papillary mural nodules within an otherwise smooth or finely granular wall are virtually constant except in totally benign lesions (Paik et al, 2008). In situ or invasive adenocarcinomas are particularly prevalent in IPMN-B and are present overall in up to 60% to 70% of the patients, and even higher rates have been found in the cystic variant (Yeh et al, 2006; Paik et al, 2008). This may either be a mucinous carcinoma, associated with profuse mucous secretion; a tubular adenocarcinoma, invading the bile duct wall with abundant fibrous stroma at the base of the papillary lesions and commonly associated with vascular, lymphatic, and perineural invasion; or a combination of these (Zen et al, 2006a, 2006b).

As for IPMN-P, the lining epithelia of IPMN-B has been classified into a *pancreatobiliary type*, *intestinal type*, *gastric type*, and *oncocytic type* (Zen et al, 2006b). More simply it can be categorized as a *columnar type*, which resembles the intestinal type of IPMN-P, and a *cuboidal type*, which resembles the pancreatobiliary type or oncocytic variant of IPMN-P (Shibahara et al, 2004). In one study, both were observed in the cystic form of IPMN-B, whereas only the columnar type was observed in the ductectatic form (see Chapter 78).

A parallel has been established between the cell type and the incidence of malignant changes. Cuboidal pancreatobiliary oncocytic-type epithelium is more frequently—actually, almost always—associated with the presence of carcinoma than the columnar type, but this is more frequently a superficial (in situ) tumor than an invasive one (Shibahara et al, 2004; Zen et al, 2006a).

The epithelium stains positive for CK-7 (biliary phenotype) and occasionally and inconsistently for CK-20 (intestinal phenotype). CA19-9 is observed diffusely, and CEA is restricted to areas of high-grade dysplasia and sometimes carcinoma (Zen et al, 2006a, 2006b).

Although MUC5AC is expressed in virtually all patients (gastric phenotype), MUC2 (intestinal phenotype) is more frequent in the columnar type, and MUC6 is more often seen in the cuboidal type (Shibahara et al, 2004; Zen et al, 2006a, 2006b). MUC1 is in contrast not expressed except in some invasive areas of tubular cholangiocarcinomas, in which MUC2 expression may disappear (Shibahara et al, 2004; Zen et al, 2006a, 2006b).

Diagnosis

Cystic variants of IPMN-B develop almost equally in both genders and peak in the sixth decade, which is 10 to 20 years older than for cystadenoma with an OS (Shibahara et al, 2004; Zen et al, 2006a). Many patients are asymptomatic, with their tumor discovered during a general health examination, but epigastralgia, jaundice, and cholangitis may occur. Cystic variants cannot be differentiated from cystadenoma or cystadenocarcinoma by their diameter, which may range between 2 and 17 cm (Lim et al, 2007; Yamashita et al, 2007), nor can it be discerned by thickness of septa or presence of calcifications (Lim et al, 2007); however, cystic variants are more frequently associated with prominent or large (>1 cm) mural nodules and bile duct dilation distal to the tumor. The latter is due to the issue of mucus from the cyst in the bile ducts. Communication with the biliary lumen is indeed a key feature (Kazama et al, 2005), but CT and MRI are insufficient to show the luminal communication (Lim et al, 2007; Yamashita et al, 2007), probably because it is too narrow. Preoperative ERCP or IOC is more reliable; in contrast, macroscopic examination of the specimen is inaccurate (Zen et al, 2006a).

Complications

The two main complications of cystic variants of IPMN-B relate to the migration of mucus or tumor material in the bile ducts and to malignant transformation. Mucobilia may result in transient symptoms of biliary obstruction, and biliary obstruction by mucus has occasionally resulted in bile duct rupture (Lim et al, 2004). Malignant transformation is particularly frequent, although the stage of malignancy is less advanced than for other biliary tumors (Zen et al, 2006b). As most of these tumors show malignant changes at the time of diagnosis, they are likely slow growing.

Management and Prognosis

Cystic IPMN-B requires resection, and an IOC should be performed to document the biliary communication and rule out the presence of mucus in the bile duct. As IPMN-B may spread superficially along the lumen of the bile ducts or be present in adjacent ducts, simple enucleation of the cyst may be insufficient. Formal hepatectomy should be performed, occasionally with extrahepatic bile duct resection and lymph node sampling. Even in patients with associated carcinoma, the prognosis is better than after resection of intrahepatic or hilar cholangiocarcinoma (Shibahara et al, 2004; Zen et al, 2006a, 2006b; Paik et al, 2008). Five-year survival is 61% and may be as high as 80% for those patients with the cuboidal cell type. Survival following resection of malignant IPMN-B is adversely impacted by the presence of the columnar cell type (Shibahara et al, 2004) and MUC1 expression (Higashi et al, 1999; Shibahara et al, 2004).

CONCLUSION

Cystic tumors of the liver are rare and comprise different entities that should be stratified with regard to content (mucinous or nonmucinous), tumor stroma (presence or absence of an OS), and relation to the bile ducts (communicating with the lumen or not). Cystic tumors with an OS (cystadenoma) occur in women, do not typically communicate with the bile duct, and in most cases are adenomas, although no reliable criterion differentiates them from cystadenocarcinoma. Malignant transformation may occur in up to 15%. IPMN-B may have a cystic appearance, occurs in both genders, and communicates with the biliary lumen, although this may be difficult to document; it may spread beyond the cystic mass in the adjacent bile ducts and frequently harbors severe dysplasia or malignancy, which may be either invasive or superficial. These lesions share several features and are currently considered to be the counterparts of the same lesions occurring in the pancreas; in any event, they require complete resection. Cystadenoma without an OS is an ill-defined entity that is not accepted by all pathologists worldwide, as they may include some IPMN-B or atypical cysts.

CHAPTER 81B

Metastatic malignant liver tumors: neuroendocrine

Saboor Khan, David M. Nagorney, and Florencia G. Que

OVERVIEW

The liver is second only to regional lymph nodes as the dominant site of metastases from all gastrointestinal (GI) tract malignancies. Because progression of hepatic metastases is the predominant cause of death in patients with GI cancers, hepatic metastases have been the focus of a multimodal treatment approach. Importantly, the accumulated experience documenting the survival potential of hepatic resection for selected patients with colorectal metastases (see Chapter 81A) has prompted evaluation of this approach for other malignancies metastatic to the liver. Whether similar approaches will prove effective for neuroendocrine metastases remains unclear.

Evidence supporting hepatic resection for metastatic GI neuroendocrine tumors (NETs) continues to emerge. Hepatic resection of metastatic NET to the liver is appealing because gastrointestinal NET has a similar route of metastatic dispersal through the portal venous system, as do colorectal cancers. Moreover, their natural history is typically prolonged compared with other GI tract cancers and, in fact, with other solid tumors. Initial experience with hepatic resection for metastatic NET (Foster & Berman, 1977) suggested that patients might benefit in terms of survival and symptom relief from clinical endocrinopathies when antihormonal and antineoplastic therapies were ineffective. Consequently, interest in hepatic resection for metastatic NET has grown. In addition to the prolonged natural history of NET and the clinically significant endocrinopathies, several other observations have supported further assessment of hepatic resection: 1) the prolonged presence of intrahepatic disease before evidence of extrahepatic progression, 2) the impression that the severity of clinical endocrinopathy correlates with the intrahepatic volume of metastatic disease, 3) the resectability of the primary and regional NET despite metastatic disease, and 4) the presence of normal, nonmetastatic liver. This chapter details the clinical data supporting hepatic resection for metastatic NET; presents the current outcomes for hepatic resection, hepatic transplantation, and ablative therapy for metastatic NET; and presents an algorithm for long-term management of patients with metastatic NET in the liver.

CLASSIFICATION OF GASTROENTEROPANCREATIC NEUROENDOCRINE TUMORS

Most neuroendocrine metastases to the liver are of GI or pancreatic origin, so-called *gastroenteropancreatic* (GEP) tumors (Rindi et al, 1998). GEP neuroendocrine tumors have historically been divided into two broad types, *carcinoid* and *noncarcinoid,* either of which may or may not be associated with hormone production that causes a clinical endocrinopathy (functional or nonfunctional, respectively). Traditionally, GI carcinoids (GICs) have been classified by their site of origin—*foregut* (lung, thymus, stomach, duodenum, pancreas, bile duct, gallbladder, and liver), *midgut* (small intestine, appendix, and proximal colon), and *hindgut* (distal colon and rectum)—because biologic and biochemical features within these groups vary. In contrast, pancreatic neuroendocrine tumors have been classified simply by whether they are functional (see Chapter 61). Regardless of origin, neuroendocrine tumors are similar histopathologically. Many histologic and morphologic features are shared by both benign and malignant tumors. Importantly, only the confirmed presence of metastases confers an unequivocal diagnosis of malignancy.

Clinical behavior for NET has ranged from an indolent to an aggressive clinical course with rapid cancer progression and death. For GEP neuroendocrine tumors, two schemes have been employed (Capella et al, 1995; Solcia et al, 2000). Broadly these classifications stratify patients with malignant GEP into *low-grade* (well-differentiated) or *high-grade* (poorly differentiated) NET (World Health Organization [WHO] classification) and subtype each as either *functioning* or *nonfunctioning*. In general, only patients with liver metastases from well-differentiated (low-grade) but not poorly differentiated (high-grade) NET are approached surgically. The TNM (tumor-node-metastases) staging has also been proposed (Rindi et al, 2006, 2007) and correlated with survival (Fischer et al, 2008; Pape et al, 2008a, 2008b; Skov et al, 2008). Some classifications tend to limit patients based on the number and extent of hepatic metastases on the radiologic imaging: a single metastasis (type I), isolated metastatic bulk accompanied by smaller deposits (type II), and disseminated metastatic spread throughout the liver (type III). These three groups differed significantly in regard to tumor-related characteristics, but this classification correlated with therapeutic approach and long-term survival (Frilling et al, 2009). The recently published guidelines by the North American Neuroendocrine Tumors Society (NANETs) highlight the importance of a uniform approach to pathologic reporting. This is especially relevant regarding differentiation and grade of individual tumors, which have a major impact on prognostication and choice of therapy (Klimstra et al, 2010).

GIC cancers produce a variety of proteins and peptide hormones (Onaitis et al, 2000; Schnirer et al, 2003). Almost all NETs are positive for neuroendocrine markers chromogranin A and neuron-specific enolase, but serum levels have correlated poorly with prognosis (Tomassetti et al, 2001); however, they are useful for treatment follow-up (Jensen et al, 2007; Nikou et al, 2008). Pancreatic NETs produce a wide variety of one or more peptides: gastrin, insulin, glucagon, and vasoinhibitory

peptide, among others (Gumbs et al, 2002; Mansour & Chen, 2004). Nonfunctional pancreatic NET implies either the production of an inactive peptide, subclinical hormone production, or no peptide production. Reviews for the specific endocrinopathies from pancreatic neuroendocrine tumors are cited for reference to recognize their implications in clinical management (Gumbs et al, 2002; Mansour & Chen, 2004).

Epidemiology

A brief overview of the most commonly encountered primary GEP NETs is presented because combined resection of the primary and regional extent of disease and hepatic metastases is frequently undertaken. GICs comprise nearly 75% of all carcinoids with the remainder primarily of bronchopulmonary origin. The distribution of GIC is composed of the small intestine (35%), rectum (23%), appendix (19%), colon (12%), stomach (6%), duodenum (4%), and hepatobiliary-pancreatic region (2%) (Modlin et al, 2003). The relative incidence of gastric and rectal carcinoids has increased over the last 3 decades but has decreased in the appendix. GICs are frequently associated with noncarcinoid tumors in the small intestine (29%), stomach (21%), and appendix (18%). Overall, localized disease characterizes the presentation of rectal (80%) and gastric (70%) carcinoids, and nonlocalized disease is represented in colonic (80%) and small intestinal (67%) carcinoids. Although GICs are often considered to behave benignly, 13% of patients have metastatic disease at presentation, and overall 5-year survival for GIC is only 67% (Kulke & Mayer, 1999).

Nonfunctional NETs of the pancreas have an equal sex distribution (Hochwald et al, 2001). NET of the pancreas occurs in 0.5 to 1 person per 100,000 population. Nonfunctional NET accounts for more than 50% of pancreatic NET in most series, and wide variations in incidence between types of NET are likely related to the definition of "nonfunctional." Multicentricity is not infrequent (15%). The epidemiology of functional pancreatic neuroendocrine tumors varies widely, with or without the multiple endocrine neoplasia (MEN) 1 syndrome, and is beyond the scope of this chapter; however, references are provided.

Small Intestinal Carcinoids

Small intestinal carcinoids are the most common GIC (Kulke & Mayer, 1999; Modlin et al, 2003). Patients usually present with abdominal pain, diarrhea, GI obstruction, and bleeding. Small intestinal carcinoids account for 90% of patients with the carcinoid syndrome. Approximately 20% of patients with the syndrome will have clinically evident carcinoid heart disease, and an even larger proportion will have occult heart disease detectable by echocardiography (Bernheim et al, 2007). Small intestinal carcinoids are often associated with dense mesenteric fibrosis, intestinal obstruction, hemorrhage, and intestinal ischemia secondary to vessel compression by metastatic regional lymph nodes and local release of vasoactive hormones (mesenteric angiopathy) (Eckhauser et al, 1981). Nearly 20% to 30% of patients have multiple GI carcinoids, and more than a third of patients have concurrent noncarcinoid cancers. Besides regional lymph node metastases, these carcinoids frequently metastasize to the liver, peritoneum, retroperitoneal nodes, and ovaries.

Resection is the only potentially curative treatment for small intestinal carcinoids (Hellman et al, 2002a; Loftus & van Heerden, 1995; Soreide et al, 1992; Woodside et al, 2004). Because of the frequency of the associated syndrome, careful preoperative evaluation and preparation are necessary. When suspected clinically, baseline urinary 5-hydroxyindole acetic acid (5-HIAA) levels should be obtained. The extent and site of the primary small intestinal carcinoid can be defined by barium contrast GI series, enteric computed tomographic (CT) scan, enteric magnetic resonance imaging (MRI), or by small bowel enteroclysis. Further imaging of the abdomen and chest for metastatic disease is best defined by contrast-enhanced CT. Often CT will identify mesenteric adenopathy and stranding characteristic of regionally advanced small bowel carcinoids even without identification of the site of the primary carcinoid on small bowel contrast studies.

Assessment of the relationship of the regional lymphatic metastases to the vessels of the small bowel is important in planning resection of the primary and regional extent of disease (Mullen et al, 2005). Despite the typical desmoplastic reaction adjacent to the involved regional lymph nodes, resection is feasible, except with extensive invasion of the third portion of the duodenum and the uncinate process of the pancreas, circumferential arterial and venous encasement without patent proximal arterial collaterals, or distal mesenteric arteries not large enough for reconstruction (Ohrvall et al, 2000; Schindl et al, 2002).

Various imaging methods may be helpful. Although not anatomically useful in operative planning, somatostatin receptor scintigraphy and octreoscanning are useful is evaluating the overall disease extent and the site of the primary, when not recognized by other studies; these are also helpful in modifying treatment strategies (Slooter et al, 2001). The role of MRI is increasing, primarily in assessing the extent of hepatic metastases. MRI is particularly sensitive in detecting small metastases within the liver and often will detect disease not seen by other imaging techniques inclusive of CT; however, MRI has limited applicability for defining the site of the primary carcinoid.

The recognition of carcinoid heart disease demands a thorough cardiac evaluation (Fox & Khattar, 2004). The major implication of carcinoid heart disease is the presence of right heart failure and the consequently elevated systemic venous pressures that can cause a pulsatile liver (implying hepatic vein pressures >25 mm Hg), which precludes hepatic resection. The presence of clinical significant carcinoid heart disease dictates medical treatment, and occasionally even valve replacement, prior to resection of the primary small intestinal carcinoid and the hepatic metastases (Moller et al, 2005). Survival after surgical repair of carcinoid heart disease is improved compared with medical treatment, even without surgical treatment of hepatic metastases (Connolly et al, 1995). Some patients may be candidates for hepatic resection after repair of carcinoid heart disease, depending upon objective decreases in systemic venous hypertension and the degree of functional cardiac improvement (Connolly et al, 2002; McDonald et al, 1999). Conversely, hepatic resection has been shown to be associated with decreased cardiac progression of the carcinoid heart disease and improved prognosis (Bernheim et al, 2008).

Any patient with the carcinoid syndrome requires preoperative and intraoperative somatostatin analogue therapy to prevent a *carcinoid crisis* (Oberg et al, 2004), a clinical syndrome of life-threatening intraoperative hypotension or hypertension and severe flushing with or without concurrent bronchospasm or arrhythmias. To date, the frequency and factors predictive of this perianesthetic complication remain unknown. Prevention is essential, and appropriate treatment should be prescribed in all patients undergoing intervention for metastatic carcinoid tumors (Kinny et al, 2001). Short-acting analogues

are preferred, even if the patient has received the long-acting analogue within 30 days. Management should consist of subcutaneous short-acting somatostatin analogue on call to operation and intravenous infusion of the analogue throughout the operation and in recovery. Additional intraoperative increases in infusion rates are appropriate for unexplained intraoperative hemodynamic instability.

Resection of small intestinal carcinoids should encompass the primary tumor, any multicentric tumors, and the regional lymph nodes. When intestinal ischemia is present, resection of the thickened, chronically ischemic bowel is indicated; resection of the regional lymph nodes is often possible by keeping the dissection immediately adjacent to the nodes and retracting the visceral vessels away from the involved nodes (Hellman et al, 2002a). Preservation of the blood supply to the GI tract is essential to prevent short-bowel syndrome. As mentioned previously, preoperative CT with intravenous contrast will define those patients with resectable nodal disease, which is very difficult to assess intraoperatively. Resection of hepatic metastases is generally indicated only if complete resection of the primary and regional disease is feasible. Resection of hepatic metastases should be performed concurrently, if all gross metastases can be excised. If nearly all of the hepatic disease can be resected (or ablated), cytoreductive resection should be considered, because both survival and symptom-free quality of life may be improved (Knox et al, 2004; Sarmiento et al, 2003; Chambers et al, 2008). Staged resections can be performed with similar expectations in outcomes. Overall 5-year survival for small intestinal carcinoid ranges from 50% to 67%.

Pancreatic Neuroendocrine Tumors (See Chapter 61)

An aggressive operative approach generally is warranted for NET of the pancreas (Fendrich et al, 2006; Hochwald et al, 2001; Matthews et al, 2002; Phan et al, 1998; Schurr et al, 2007; Solorzano et al, 2001). Resection remains the treatment of choice for patients with localized NET of the pancreas and for selected patients with hepatic metastases (Oberg & Jelic, 2008). Resection of the primary NET and the regional lymph nodes is generally possible despite their often large size. The extent and type of pancreatectomy is dictated by the site of the primary NET; pancreatoduodenectomy is used for NET of the head of the pancreas, and distal pancreatectomy/splenectomy is best for body or tail NET (see Chapter 62). In some cases, enucleation may be an alternative approach. For patients with locally invasive NET of adjacent structures or the GI tract, resection should be en bloc. Laparoscopic pancreatectomy is currently applicable for resection of most pancreatic NET (Fernandez-Cruz et al, 2002, 2008). Whether concurrent laparoscopic resection of the primary pancreatic NET and hepatic metastases is feasible has not been proven. Concurrent resection of primary pancreatic NET and hepatic metastases can be performed safely, although staged resections may be preferable, particularly in patients with involvement of the head of the pancreas (Sarmiento et al, 2002). Overall actuarial 5-year survival rates for NET of the pancreas range from 45% to 63% with a median survival of about 4 years.

Natural History

Regardless of whether NETs are classified as carcinoid or noncarcinoid, the natural history of patients with unresected or unresectable hepatic metastases has been similar. Overall, patients with unresected hepatic metastases from NETs have a 5-year survival of approximately 30% (Proye, 2001) and a median survival of 17 months (House et al, 2006).

Several factors affect the natural history of both carcinoid and noncarcinoid cancers (Durante et al, 2009). Clearly, liver metastases are the most significant factor adversely affecting outcome (Moertel, 1987; Pape et al, 2008a). With or without liver metastases from NET, 5-year survival is approximately 30% to 40% and 90% to 100%, respectively. Poorly differentiated NET and progressive neuroendocrine metastases in the liver (>25% volume increase on two CT scans within 3 months) further adversely affects survival among patients with hepatic metastasis (Madeira et al, 1998). Progression in size or number of hepatic neuroendocrine metastases can be expected in 90% after a median follow-up of 11.5 months (Skinazi et al, 1996). Carcinoid heart disease occurs only in the presence of metastatic carcinoid tumor to the liver independently and predicts poor survival. The survival of patients with clinically severe carcinoid heart disease is approximately 1.6 years; the survival rate is only 31% at 3 years, unless cardiac surgery is undertaken successfully (Connolly et al, 1995; Fox & Khattar, 2004). Patients with carcinoid heart disease should be considered for hepatic surgery, as stated before, because cardiac disease progression is reduced, and prognosis is improved (Bernheim et al, 2008).

Although uncontrolled functioning endocrinopathies from metastatic neuroendocrine tumors can be life threatening—for example, severe hypoglycemia from insulinoma and GI perforation from gastrinoma—the impact of such events on the natural history of these patients is unknown. Conversely, it is likely that clinical control of endocrinopathies can affect natural history of NET; however, specific studies to document clinical control of endocrinopathies by antihormonal therapy with objective tumor responses have not been well documented, except for gastrinoma before and after the use of H_2 blockers or proton pump inhibitors (Norton et al, 2003a).

Similar to carcinoid tumors, the 5-year survival of patients with pancreatic NET ranges from 30% to 40% with a median survival of approximately 40 months (Chen et al, 1998; Thompson et al, 1985). Whether the presence or absence of clinical endocrinopathies affects the natural history of patients with metastatic pancreatic NET is unclear; however, the specific NET likely affects overall natural history. Up to 75% of patients who present with midgut or hindgut tumors are likely to have liver metastases, in particular the nonfunctioning group, and those with a pancreatic primary (likely to be high grade) have the highest rate of liver involvement (Steinmuller et al, 2008). In a series of 35 patients with hepatic metastases, 60% of which were from gastrinomas, the 5-year survival was approximately 70%. The prognosis also is affected by the extent of metastatic NET in the liver (Chamberlain et al, 2000; Phan et al, 1998); the 5-year survival was only 24% with more than 75% tumor replacement of the liver, whereas 5-year survival approached 80% for less than 50% tumor replacement.

SURGICAL AND ABLATIVE TREATMENT OF HEPATIC NEUROENDOCRINE METASTASES

Hepatic Resection for Neuroendocrine Metastases

The current mainstay of treatment for metastatic GI neuroendocrine tumors to the liver is resection (see Chapter 90E);

however, no randomized controlled data support improved survival from hepatic resection of metastatic NET. Although hepatic resection of malignancy is employed most often with curative intent, the tumor biology of these typically indolent and slow-growing cancers renders them less responsive to more commonly employed palliative therapies, such as chemotherapy and radiation; thus, resection with palliative intent (cytoreduction) may afford patients a real and significant advantage in palliation and may prolong survival. Importantly, the focus on palliation and extension of life, rather than on complete remission, is conceptually a paradigm shift, because most hepatic resections are undertaken for cure in patients with metastatic solid cancers.

The treatment of hepatic metastases from NET is aimed at reduction of the mass of malignant tissue (cytoreduction) chiefly for two reasons: first and foremost, metastatic gastrointestinal NET is usually indolent and slow growing, with a well-differentiated histopathologic grade (WHO classification) (Solcia et al, 2000); thus chemotherapy and radiotherapy regimens targeted toward rapidly dividing cells are relatively ineffective; second, symptoms secondary to expression and secretion of biologically active peptides by these tumors is directly related to overall mass of tumor, although production of peptides may be heterogeneous among individual metastases. Similarly, pain and decreased performance status may negatively impact on quality of life for patients with nonfunctional NET metastatic to the liver. In patients who do respond to medical treatment, debulking surgery—cytoreduction of more than 90% of the liver tumors—is a valid and direct method of providing relief from symptoms. These reasons, coupled with improved safety for hepatic resection, have prompted some to advocate hepatic resection as a primary therapeutic option for patients with both functional and nonfunctional metastatic NET (Chambers et al, 2008). Based on these premises, hepatic cytoreduction, whether by hepatic resection or transplantation, should address clinical endocrinopathies and improve survival; as a corollary, the duration of response should be in proportion to the extent of the debulking or cytoreduction of the metastatic NET and the growth rate of the residual NET (House et al, 2006).

Currently, hepatic resection of metastatic NET is recommended if the primary tumor and regional disease are resectable or resected, and a minimum of 90% of the volume of hepatic metastases is resectable or ablatable (Steinmuller et al, 2008). Our initial results showed that debulking hepatic resection could be performed safely, and overall survival was about 75% at 4 years (Que et al, 1995). No significant difference in survival was found between patients undergoing complete (R0) or incomplete (R1 to R2) resections. Mean duration of symptom response was nearly 2 years. Subsequently, our findings in 170 patients undergoing hepatic resections showed that symptoms resolve in 98% of patients. Median time to symptom recurrence was 45 months, and 59% of patients experienced recurrent symptoms at 5 years. Overall survival was 61% and 35% at 5 and 10 years, respectively, and perioperative mortality rate was 1.2%. Recurrence, however, was 84% at 5 years and 94% at 10 years (Fig. 81B.1; Sarmiento et al, 2003). Examples of results obtained from cytoreductive hepatic resection for neuroendocrine tumors are shown in Figure 81B.2.

A review of the current literature on hepatic resection for metastatic NET is summarized in Table 81B.1. The cumulative findings from these reports support an aggressive operative approach for metastatic NET. Overall 5-year survival has ranged from 41% to 82% with a median 5-year survival of up to 100%. Only four perioperative deaths have been reported among the tabulated patients (n = 556). When addressed, resolution of endocrine symptoms exceeded 90% in most series, although duration of response was not routinely reported.

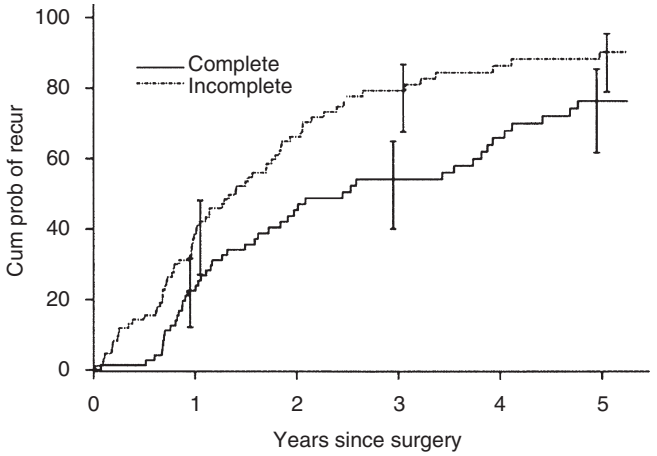

FIGURE 81B.1. Recurrence rate was lower for patients with complete resection of the tumor compared with incomplete resection. Cum Prob of Recur, cumulative probability of recurrence. *(From Sarmiento JM, et al, 2003: Surgical treatment of neuroendocrine metastases to the liver: a plea for resection to increase survival. J Am Coll Surg 197:29-37, with permission from the American College of Surgeons.)*

Although the majority of patients reported to date have had metastatic carcinoid cancer to the liver, survival has not differed appreciably among patients with carcinoid and noncarcinoid (primarily islet cell) cancers. Current data do not show that survival is affected by the presence or absence of clinical endocrinopathy. Interestingly, although complete macroscopic resection of hepatic metastases (R0/R1) has been undertaken more frequently, survival has not significantly differed among patients with complete or incomplete hepatic resection of metastatic NET, provided cytoreduction exceeds 90% of the estimated hepatic cancer volume (Que et al, 1995; Sartori et al, 2005). Significant improvement in quality of life with prolonged survival also has been confirmed for patients undergoing adequate (>90%) cytoreduction (Knox et al, 2004). These data suggest that hepatic resection of metastatic NET is safe and clinically effective, and overall operative survival is nearly double that of patients with unresected metastases. Few other factors related to the primary NET, metastatic disease, or patients appear to correlate with survival.

A major challenge is providing treatment for bilobar synchronous hepatic metastases, which are relatively common. Although one-step surgery may be feasible, it might require right portal vein embolization (see Chapter 93) to enhance the size of the future liver remnant. Compared with two-step surgical procedures that include resection of the primary and clearance of left liver, followed by right portal vein occlusion and a second step consisting of right or extended right hepatectomy, it seems that with or without preoperative portal vein embolization, one-step surgery is associated with a higher rate of R2 resection and more postoperative complications (Elias et al, 2003; Kianmanesh et al, 2008; Steinmuller et al, 2008). This

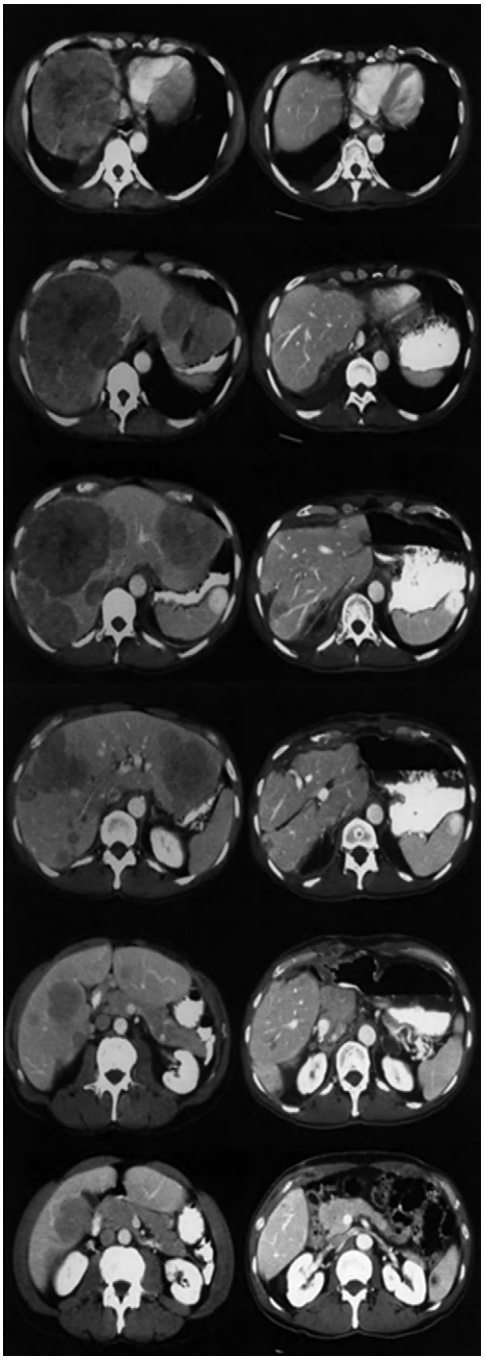

FIGURE 81B.2. Computed tomographic images for a patient with metastatic carcinoid tumor before (*left*) and 18 months after (*right*) cytoreductive hepatic resection. Intrahepatic recurrences were ablated by percutaneous radiofrequency ablation.

might in part be due to preoperative intensive selection of patients in two-step procedures and dissociation of major liver and abdominal surgery; however, compared with liver transplantation, the two-step procedures represent a valid alternative by pushing the limit of respectability in type III patients, especially those with bilobar, synchronous liver metastases (Kianmanesh et al, 2008; Steinmuller et al, 2008).

Complete resection remains the goal of cytoreductive hepatic resection, because both progression rate and median time to clinical recurrence are significantly reduced. The theoretic impact of minimizing residual metastatic NET in the liver on outcome is depicted in Figure 81B.3. Resection of more than 90% of the volume of hepatic metastases can result in significantly different residual cancer volumes based on variations of the incident metastatic volume. Figure 81B.3 shows the projected outcomes of three different residual tumor volumes on symptom recurrence and survival, assuming a greater than 90% resection and a cancer doubling time of 6 months. Both time to recurrence of symptoms and survival are related to residual metastatic cancer volume. The clinical impact of cytoreductive hepatic resection is not more than 90% resection of metastatic NET in the liver but the minimization of residual metastatic volume, that is, not resected volume but rather residual liver volume.

The overall frequency of recurrence or progression after hepatic resection is approximately 80% at 5 years. Intrahepatic progression of residual metastases after R1 or R2 resection or recurrence after R0 resection dictates subsequent liver-directed therapy, unless the risk of liver failure or extrahepatic disease spread override this issue. Although cure of patients with metastatic NET to the liver is infrequent, prolonged palliation is possible. Patterns of intrahepatic recurrence have not been well studied, but intrahepatic recurrence is typically multicentric in our experience. The extent and distribution of hepatic recurrence dictates the choice of therapy. For solitary recurrences, either resection or ablation is appropriate. Given that serial imaging usually identifies small recurrences after hepatic resection, percutaneous ablative approaches are preferable, because morbidity associated with percutaneous RFA is less than that after repeat resection, which is advised for lesions in sites that preclude safe RFA. Sequential ablation or resection is undertaken as recurrence is recognized, until precluded by extent of recurrence within the liver. Metastatic NET that precludes ablation or resection is treated by embolization or chemoembolization, with or without systemic chemotherapy in the absence of extrahepatic disease and with chemotherapy in the presence of extrahepatic disease. A schema for management of neuroendocrine metastases to the liver is outlined in Figure 81B.4.

Hepatic Transplantation for Neuroendocrine Metastases (See Chapters 97A and 97E)

Orthotopic liver transplantation (OLT) has been frequently employed for the treatment of metastatic NET (Table 81B.2). The rationale for OLT is similar to that for resection, with the caveat that adequate cytoreduction by resection is precluded by extensive intrahepatic disease and the absence of extrahepatic metastases. OLT during the time period of intrahepatic disease may be curative or at least significantly palliative. Unlike resection, OLT addresses all hepatic metastases and should provide similar, if not greater, duration of palliation of symptoms and survival. The attractiveness of R0 resection afforded by OLT and the high recurrence rate of NET associated with resection has fostered ongoing evaluation of OLT for metastatic NET (Mazzaferro et al, 2007).

As with resection, OLT was undertaken if the primary and regional NET had been resected, and distal metastases were excluded by octreotide scintigraphy and dynamic CT or MR imaging. Outcomes have been reported for 239 patients. Results and selection criteria have varied, and actual duration of follow-up has been limited, but 1-year survival has ranged from

*Curative
†Cytoreductive

50% to 100% (mean, 82%), and 5-year survival from 36% to 89% (mean, 57%), with a mean overall follow-up of 36 months. Interestingly, only 23 patients have reportedly reached actual 5-year disease-free survival. Symptomatic relief from clinical endocrinopathies, when present, has been uniformly complete, but duration of symptom relief after OLT has not been clearly documented. Rates of recurrence are generally similar to those after resection, and criteria of patient selection for OLT likely account for this finding.

Several studies have attempted to correlate clinicopathologic factors to survival. Age, location of the primary NET, extent of the primary operation, extent of hepatic metastases, Ki67 index, E-cadherin expression, genetic instability (TP53), and histologic features have been assessed. Age less than 50 years, limited hepatic metastases, low Ki67 index, regular E-cadherin staining, and R0 resection of the primary NET with no evidence of locoregional progression for 1 or more years has correlated with prolonged survival (Fernandez et al, 2003). Current data preclude routine use of these factors as selection criteria for OLT until further confirmed.

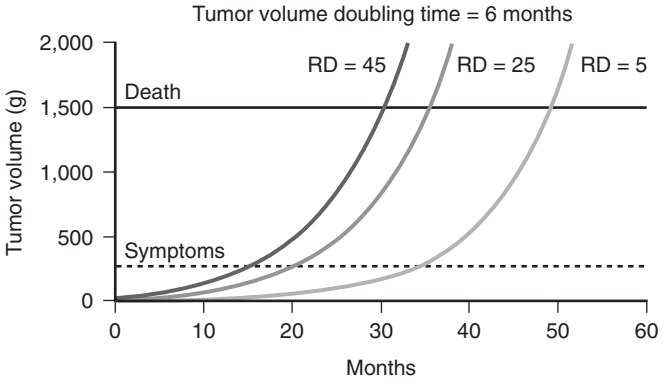

FIGURE 81B.3. Projected tumor doubling time as a function of residual tumor volume after cytoreductive resection and its impact on symptom recurrence and survival over time. RD, residual disease.

Current data do not support OLT as a primary treatment modality for metastatic NET (Clark et al, 2006; Fernandez et al, 2003; Mazzaferro et al, 2007; Steinmuller et al, 2008), but it should be considered an investigative treatment alternative in specialty centers. OLT should probably be considered only in patients with resected primary NET, after a period of disease stability, with exclusion of any extrahepatic disease, and only for selected NET. Whether other biologic or genetic markers will improve the reliability for selection remains unclear.

Radiofrequency Ablation of Neuroendocrine Hepatic Metastases

Multiple minimally invasive ablative modalities exist for the treatment of liver tumors, including cryotherapy, percutaneous ethanol injection (PEI), and thermal techniques such as radiofrequency ablation (RFA), microwave ablation, and interstitial laser thermotherapy (ILT) (see Chapters 83, 84, and 85). Currently, RFA is the most widely used ablative technique for hepatic tumors in general because of its versatility, ease of use, and relatively low risk of complications (Bleicher et al, 2003;

*Multicenter collective review

Giovannini & Seitz, 1994; Livraghi et al, 2003; Pearson et al, 1999; Wong et al, 2001); however, its utility for NET metastases will be limited by disease extent in most patients.

The application of RFA for metastatic NET arose after its efficacy was established in the treatment of hepatocellular carcinoma and metastatic colorectal cancer (Curley et al, 1999; Pawlik et al, 2003; Solbiati et al, 2001a; Wood et al, 2000). Local tumor control was achieved in 82% to 98% of treated metastases, although duration of follow-up varied (Bleicher et al, 2003; Bowles et al, 2001; Curley et al, 2000; de Baere et al, 2000; Pawlik et al, 2003, Pearson et al, 1999; Rhim & Dodd, 1999; Solbiati et al, 2001a). Local recurrence rates were higher in patients with colorectal metastases and lower in those with neuroendocrine hepatic metastases (Bleicher et al, 2003; Solbiati et al, 2001b), which is likely related to differences in disease biology and length of follow-up. Successful ablation typically occurred in the treatment of metastases smaller than 3 cm (de Baere et al, 2000; Kettenbach et al, 2003; Solbiati et al, 2001b; Wood et al, 2000); only 50% of tumors greater than 5 cm were ablated completely, even with repeated ablation (Goldberg & Ahmed, 2002).

Published experience with RFA for neuroendocrine hepatic metastases has been limited. RFA has been employed both primarily and as an adjunct to resection. Objective tumor destruction has been well documented and has been shown highly effective in local tumor control, with local recurrence in 3% to 5% of treated metastases (Berber et al, 2002; Hellman et al, 2002b). Improved survival with RFA of metastatic NET has been suggested for selected patients (Elias et al, 2003, 2009).

Duration of follow-up is insufficient to determine actual durability of local control given the protracted natural history of neuroendocrine cancers. Progression of hepatic metastases occurs in about 30% of patients within 2 years (Berber et al, 2002; Hellman et al, 2002b). Specific factors of the hepatic metastases—such as site, degree of necrosis or fibrosis, and hormonal markers—have not yet been correlated to RFA response.

RFA effectively relieves clinical endocrinopathies related to neuroendocrine hepatic metastases; nearly 90% of patients report some degree of symptom relief following ablation (Berber et al, 2002; Hellman et al, 2002b; Henn et al, 2003; Siperstein et al, 1997; Siperstein & Berber, 2001), and duration of relief from symptoms usually is 10 months or longer (Berber et al, 2002; Henn et al, 2003). These findings approach those reported after hepatic resection of metastatic NET (Chamberlain et al, 2000; Sarmiento et al, 2003). For limited hepatic metastases, RFA can achieve similar results percutaneously; however, it must be emphasized that the proportion of patients with disease that is amenable to percutaneous ablation is small. In the setting of extrahepatic disease, isolated hepatic ablation will have a limited effect on symptoms (Henn et al, 2003); however, clinical efficacy will depend upon the volume and site of extrahepatic tumor and the specific hormone expression.

Serum and urine neuroendocrine tumor markers are generally proportional to tumor burden (Jensen et al, 2007; Moertel, 1987). The response of such markers to RFA has been variable. In a study of 34 patients treated with intraoperative RFA, only 65% had a decrease in serum tumor markers afterward (Berber et al, 2002). Persistently elevated tumor markers after RFA likely reflect patient selection, completeness of ablation, and occult or overt neuroendocrine cancer within the abdomen or elsewhere. A favorable response in reduction of serum tumor markers following ablation may predict the durability of symptomatic response and may be associated with improved survival and decreased incidence of disease progression (Berber et al, 2002).

Ethanol Ablation of Hepatic Neuroendocrine Metastases (See Chapter 85)

Ethanol ablation has also been incorporated into the treatment of primary and secondary hepatic neoplasms, including metastases from neuroendocrine malignancies in selected patients (Castells et al, 1993; Giovannini, 2002; Giovannini & Seitz, 1994; Lencioni et al, 1995; Livraghi et al, 1995, 1999; Shiina et al, 1993). Several studies have documented a complete intrahepatic response in patients with hepatic neuroendocrine metastases treated with percutaneous ethanol injection (PEI) (Livraghi et al, 1991), which permits ablation of metastases adjacent to structures at risk of damage by RFA.

Highly selective ethanol ablation can be performed on metastases adjacent to vital structures, such as the hepatic flexure of the colon; those adjacent to large vessels vulnerable to the heat-sink effect; and those adjacent to central bile ducts, where subsequent biliary stricture may occur (Fig. 81B.5). Moreover, metastases of very small size can also be ablated successfully with ethanol, with limited collateral injury to adjacent liver.

Cryoablation of Hepatic Neuroendocrine Metastases (See Chapter 85)

Intraoperative cryoablation is effective in the treatment of primary and secondary tumors of the liver (Finlay et al, 2000; Mahvi & Lee, 1999; Neeleman et al, 2001; Seifert et al, 1998b; Sheen et al, 2002; Zhou & Tang, 1998). Based on a collective review of 1990s literature, local recurrence develops in about 30% of cryoablated tumors (Seifert et al, 1998b). In a direct comparison of cryoablation and RFA in the treatment of both primary and secondary hepatic tumors, RFA was shown to be more effective in local control (2% vs. 14% local recurrence) with fewer complications (3% vs. 41% complication rate) (Chung et al, 2001; Pearson et al, 1999).

Current experience with cryoablation for hepatic neuroendocrine metastases reflects ablations performed intraoperatively (Bilchik et al, 1997; Cozzi et al, 1995; Goering et al, 2002; Seifert et al, 1998a). Most often, the intraoperative cryoablation is performed in conjunction with resection of the primary tumor and hepatic metastases (Cozzi et al, 1995; Seifert et al, 1998a). Local control of neuroendocrine hepatic metastases has occurred in 95% of treated tumors (Chung et al, 2001; Cozzi et al, 1995; Seifert et al, 1998a), which is similar to other ablative techniques. Some relief of symptoms has been shown in all patients, even with recognized subtotal ablative debulking (Bilchik et al, 1997; Cozzi et al, 1995; Seifert et al, 1998b), and postoperative ablative adjuvant therapy with a long-acting somatostatin analogue can prolong symptom-free survival (Chung et al, 2001).

Guidelines for Ablation

General guidelines for the ablation of liver metastases are analogous to the treatment of hepatocellular carcinoma and colorectal metastases. Recognizing the prolonged survival and clinical endocrinopathies associated with metastatic NET, broader application of ablation as a component of multimodal treatment

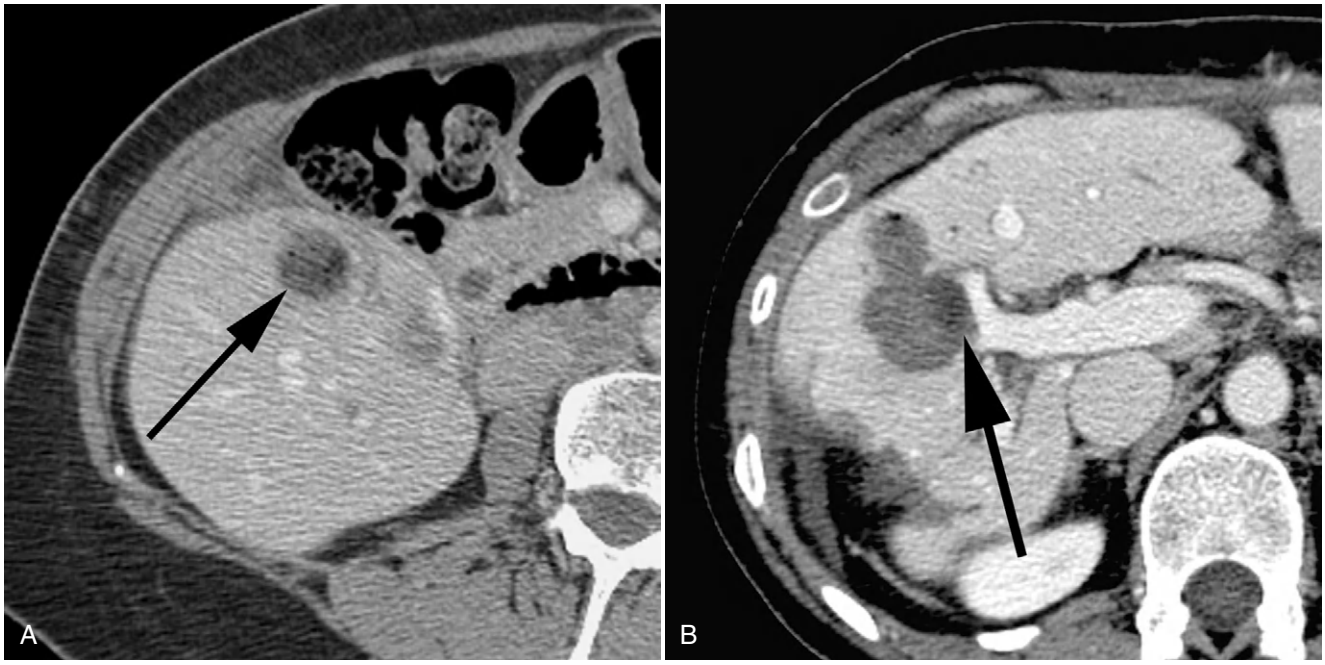

FIGURE 81B.5. Ethanol ablation of critically located neuroendocrine hepatic metastases. **A,** Computed tomography (CT) with intravenous contrast shows nonenhancing, low-density, post–ethanol ablation changes within treated 2 cm carcinoid hepatic metastasis (*arrow*), located near the hepatic flexure of the colon. Radiofrequency ablation (RFA) was deferred due to risk of thermal injury to the colon. **B,** CT with intravenous contrast shows combined RFA and ethanol ablation changes in a carcinoid metastasis located adjacent the right anterior portal vein. Subtle low-density ethanol changes medially in the treated tumor are noted by the *arrow*. Ethanol was selectively used because of the relative cooling of the ablation zone by adjacent blood flow, which could result in inadequate ablation ("heat-sink effect").

is warranted. Indeed, because reports of surgical experience have shown that cytoreduction of NET can considerably improve both patient symptoms and survival, the corollary of an aggressive ablation of progressive hepatic neuroendocrine metastases should provide similar patient benefit.

Three clinical scenarios exist for ablation of neuroendocrine hepatic metastases: 1) as an adjunct to concurrent surgical resection of hepatic metastases; 2) as treatment of limited hepatic metastases in patients unfit for operation; and 3) as the primary hepatic therapy when clinical expertise or intraoperative circumstances preclude safe resection. Palliation of symptoms is an inherent aim for all patients with functional neuroendocrine symptoms.

RFA complements intraoperative resection of hepatic neuroendocrine metastases. Given the extensive hepatic tumor burden typically encountered, ablation affords selective treatment of metastases located deep in the liver or in sites not further resectable after partial hepatectomy. Adjunctive RFA optimizes debulking of hepatic metastases, reduces the extent of resection, and increases overall candidacy for surgical treatment.

Resection is precluded in many patients with neuroendocrine metastases to the liver because of the extent of tumor burden, comorbid disease, or prior hepatic resection. In such patients, percutaneous ablation allows for less invasive tumor debulking and may have some advantage over chemotherapy alone, as shown by Ruers and colleagues (2007).

In contrast to nonneuroendocrine metastases, surgical experience justifies subtotal debulking of significant hepatic tumor by the ablation of multiple metastases (Fig. 81B.6). Generally speaking, if the metastasis is visible with imaging, it can usually be treated in some manner with percutaneous ablation, using either RFA or ethanol, provided sufficient liver parenchyma has been preserved to prevent hepatic decompensation.

This large-volume ablation contrasts with the ablation of limited disease. Such a patient might have one or two very small hepatic metastases such that surgical resection might be considered overly aggressive given the effectiveness of percutaneous RFA in treating such tumors (Fig. 81B.7). Percutaneous treatment is typically performed on an outpatient basis and obviates the longer hospitalization after resection. Moreover, given the invariable recurrence of metastases following surgical resection (Sarmiento et al, 2003), percutaneous ablation is well suited for the patient who has undergone prior liver surgery. Unlike surgical resection, ablation can easily be performed on multiple occasions based on occurrence of new metastases.

RFA of neuroendocrine hepatic metastases allows a relatively noninvasive mechanism to treat patient symptoms, similar to the role of hepatic resection. In our experience, less than 5% of patients are treated solely for tumor-related symptoms. The focus of such ablative treatment is usually twofold, with both debulking of the patient's hepatic tumor and secondary symptom management (Fig. 81B.8).

Microwave (MW) ablation therapy is a local treatment by which tumors are destroyed by coagulation from the passage of MWs into tissue. MW therapy is emerging as a reliable technique under a variety of clinical situations. Two main zones are described after ablative therapy: central and transitional. No viable cells were demonstrated in 93% of lesions after treatment, even up to 6 cm in diameter (Gravante et al, 2008).

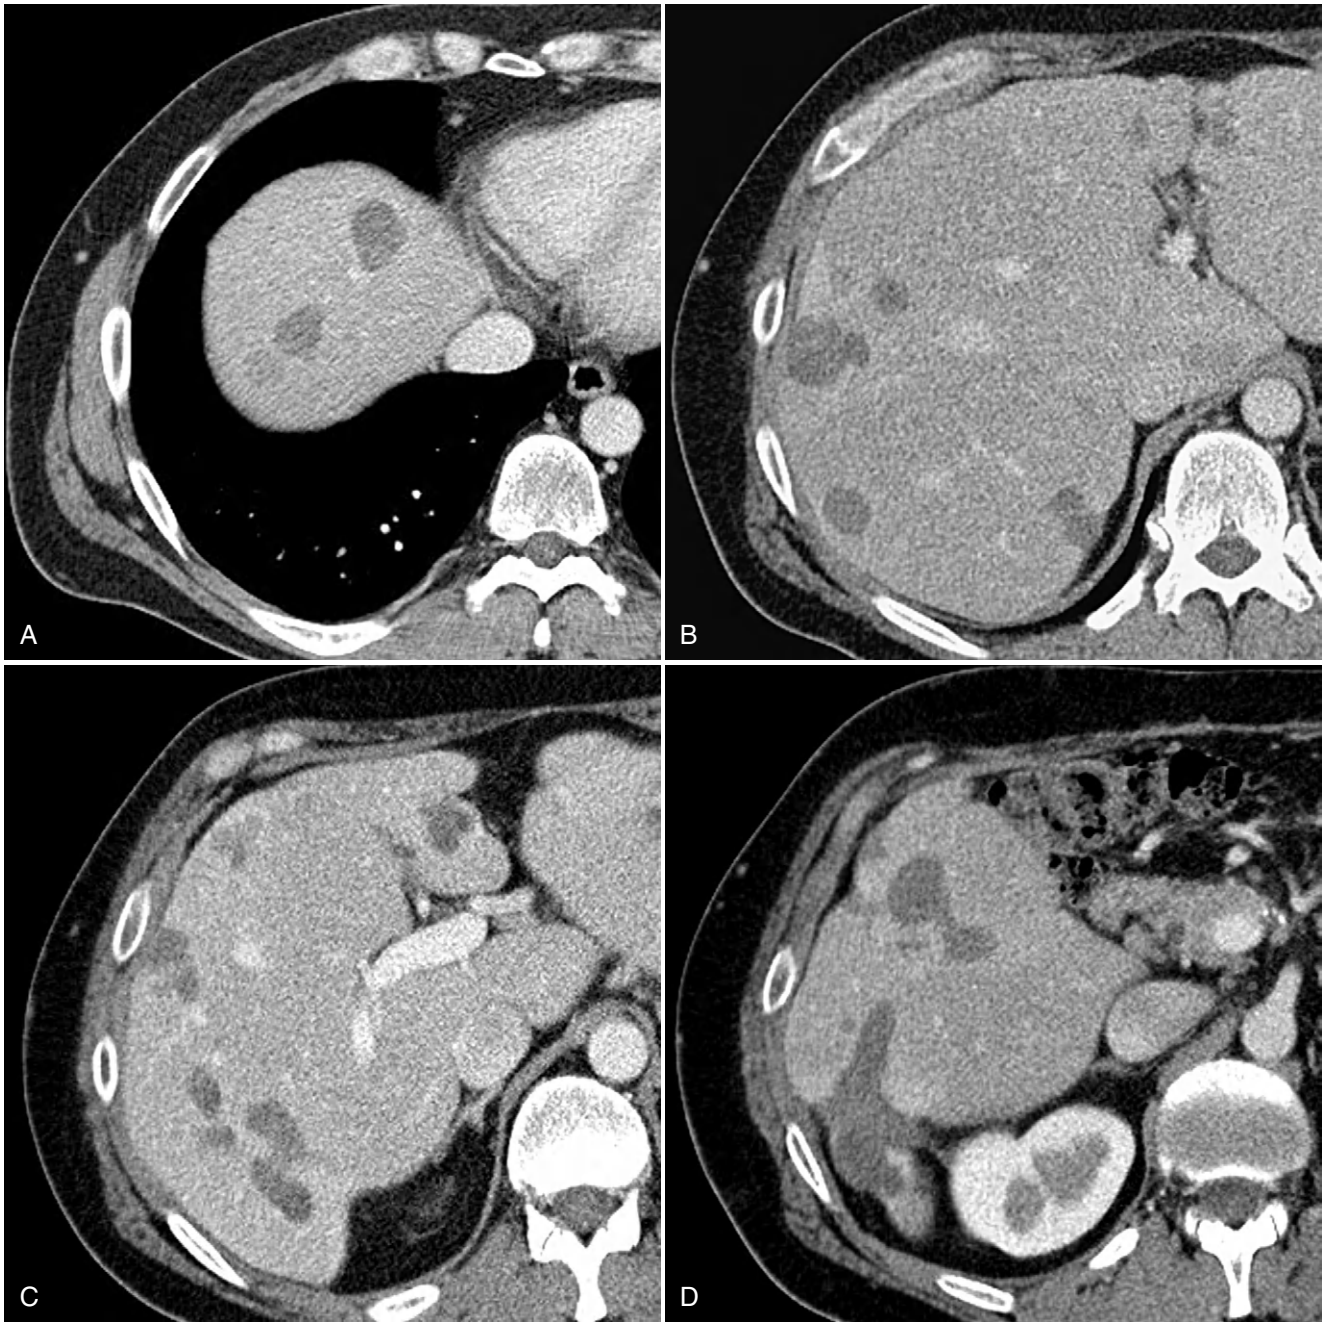

FIGURE 81B.6. Radiofrequency ablation (RFA) of multiple neuroendocrine hepatic metastases. Patient with metastatic islet cell carcinoma has undergone four RFA procedures with the treatment of 50 metastases, including the treatment of 19 metastases in a single percutaneous ablation session. **A** to **D,** CT images following intravenous contrast shows the extensive nonenhancing ablation defects throughout the liver.

Although data comparing RFA with MW are awaited, the results reported in observational studies indicate that MW may have a role when larger ablation zones are required (Boutros et al, 2010).

MEDICAL TREATMENT OF HEPATIC NEUROENDOCRINE METASTASES

The several approaches for the medical treatment of metastatic NET include somatostatin analogues, chemotherapy, immunotherapy, embolization or chemoembolization, and internal irradiation with iridium 131 conjugates (de Vries et al, 2002; Van Essen et al, 2009).

Somatostatin Analogues

Octreotide is a synthetic somatostatin analogue with a significantly longer half-life and duration of action than native somatostatin (Lamberts et al, 1996). It is primarily cytostatic but can also be cytotoxic. The effect of somatostatin analogues is mediated through type 2 and type 5 somatostatin receptors, inhibiting the cellular release of hormone. Response may correlate to

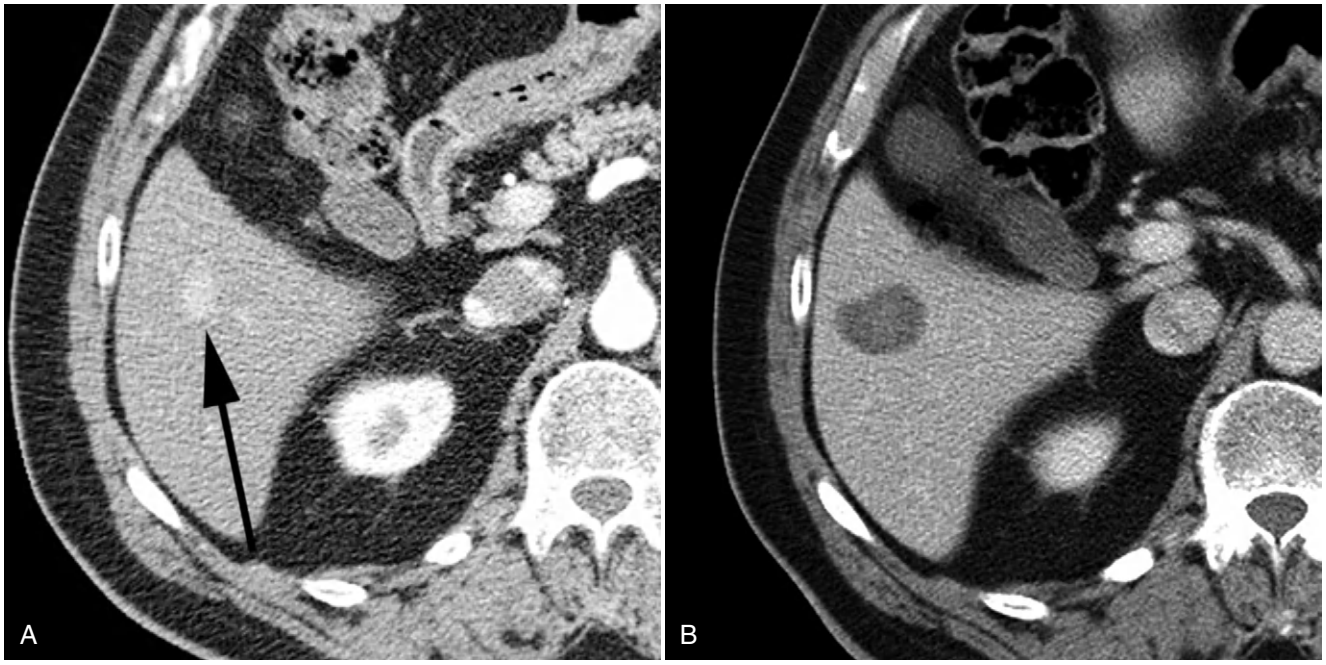

FIGURE 81B.7. Percutaneous radiofrequency ablation (RFA) of metastatic carcinoid in a nonsurgical patient. **A,** Computed tomography (CT) with intravenous contrast shows a subtle, hyperenhancing, solitary 2.3-cm metastasis in the right lobe of the liver (*arrow*). Given limited disease and surgical risk in this 115-kg patient, the metastasis was treated with RFA. **B,** CT obtained 3 months following ablation shows no recurrent tumor.

somatostatin receptor scintigraphy (Janson et al, 1994); the analogues also can affect cell-cycle arrest in G_1 phase, induce apoptosis, and inhibit angiogenesis. Lantreotide is currently the longest acting or slowest release analogue. Octreotide dose ranges from 100 to 500 μg three times daily, and lantreotide is given 60 to 120 mg every 4 weeks.

Somatostatin analogues have been associated with a biochemical response in about 70% of patients, and symptomatic relief is seen in 60% to 90% (Oberg et al, 2004). Objective reduction in tumor size, or more than 50% of the largest diameter, has occurred in less than 10% of patients. Stabilization of NET has been observed in 36% to 70% of patients for a median duration of 12 months (Oberg et al, 2004). As expected, symptomatic response has been correlated with improved quality of life, although response to somatostatin analogue therapy varies by type of NET. As noted previously, short-acting somatostatin analogue therapy is used to prevent or to treat the carcinoid crisis periprocedurally for any intervention such as resection, transplantation, ablation, or embolization. In general, somatostatin analogue treatment is well tolerated. Steatorrhea, diarrhea, abdominal discomfort, and biliary sludge or gallstones can develop but rarely preclude continued use (Kaltsas et al, 2004; Kvols et al, 1987; Trendle et al, 1997). More recently, the long-acting analogues of somatostatin, such as lanreotide and long-acting octreotide, have become available and are the mainstay of symptomatic treatment (Modlin et al, 2008).

Chemotherapy

Systemic chemotherapy is generally reserved for patients with advanced or progressive disease, where other treatment efforts have failed (Brentijens & Saltz, 2001; Kaltsas et al, 2001; Rivera & Ajani, 1998). Recent results of randomized trials have established the role of sunitinib in the management of pancreatic NETs. It has been shown to increase progression-free and overall survival (Raymond et al, 2011). Data from previous trials are also presented. Patients with pancreatic NET have been more responsive to chemotherapy than those with carcinoid tumors (Rivera & Ajani, 1998), and streptozocin-based combinations with 5-fluorouracil (5-FU) and doxorubicin have resulted in objective responses in 45% to 69% of patients (Oberg, 2001; Moertel et al, 1992); however, a more recent study reported disappointing results using a 5-FU and streptozocin combination (Maire et al, 2009). Median duration of response for high-grade NET is about 8 to 9 months. Carcinoid tumors may be less sensitive to cytotoxic agents because of the preponderance of low-grade malignant (well-differentiated) histology and low proliferation index (Bajetta et al, 2002). Dacarbazine, 5-FU, and epirubicin combination therapy has achieved objective tumor response in about 30% of patients with carcinoid tumors (Bajetta et al, 2002; Oberg et al, 2004), and median duration of response for carcinoid tumors is about 6 months. Some success has been achieved with hepatic artery infusional cisplatin in pancreatic NET metastases (Igarashi et al, 2007).

α-Interferon

Systemic α-interferon (α-IFN) may be used to treat advanced NET. The mechanism of α-IFN is mediated through direct inhibition of the cell cycle (G_1/S phase), protein and hormone production, and antiangiogenesis; it is mediated indirectly by increased immune stimulation (Oberg et al, 2004). Although an objective tumor response is seen in only 10% to 15%, both symptomatic and biochemical responses have been observed in about 40% to 60% of patients (Biesma et al, 1992; Fjällskog et al, 2002; Jacobsen et al, 1995; Moertel et al, 1989; Oberg et al, 1986, 2004). Disease stabilization has occurred in 40% to 60% of patients. Adverse reactions to α-IFN are common and may dictate its discontinuation; chronic fatigue and hematologic cytopenias are the most common side effects.

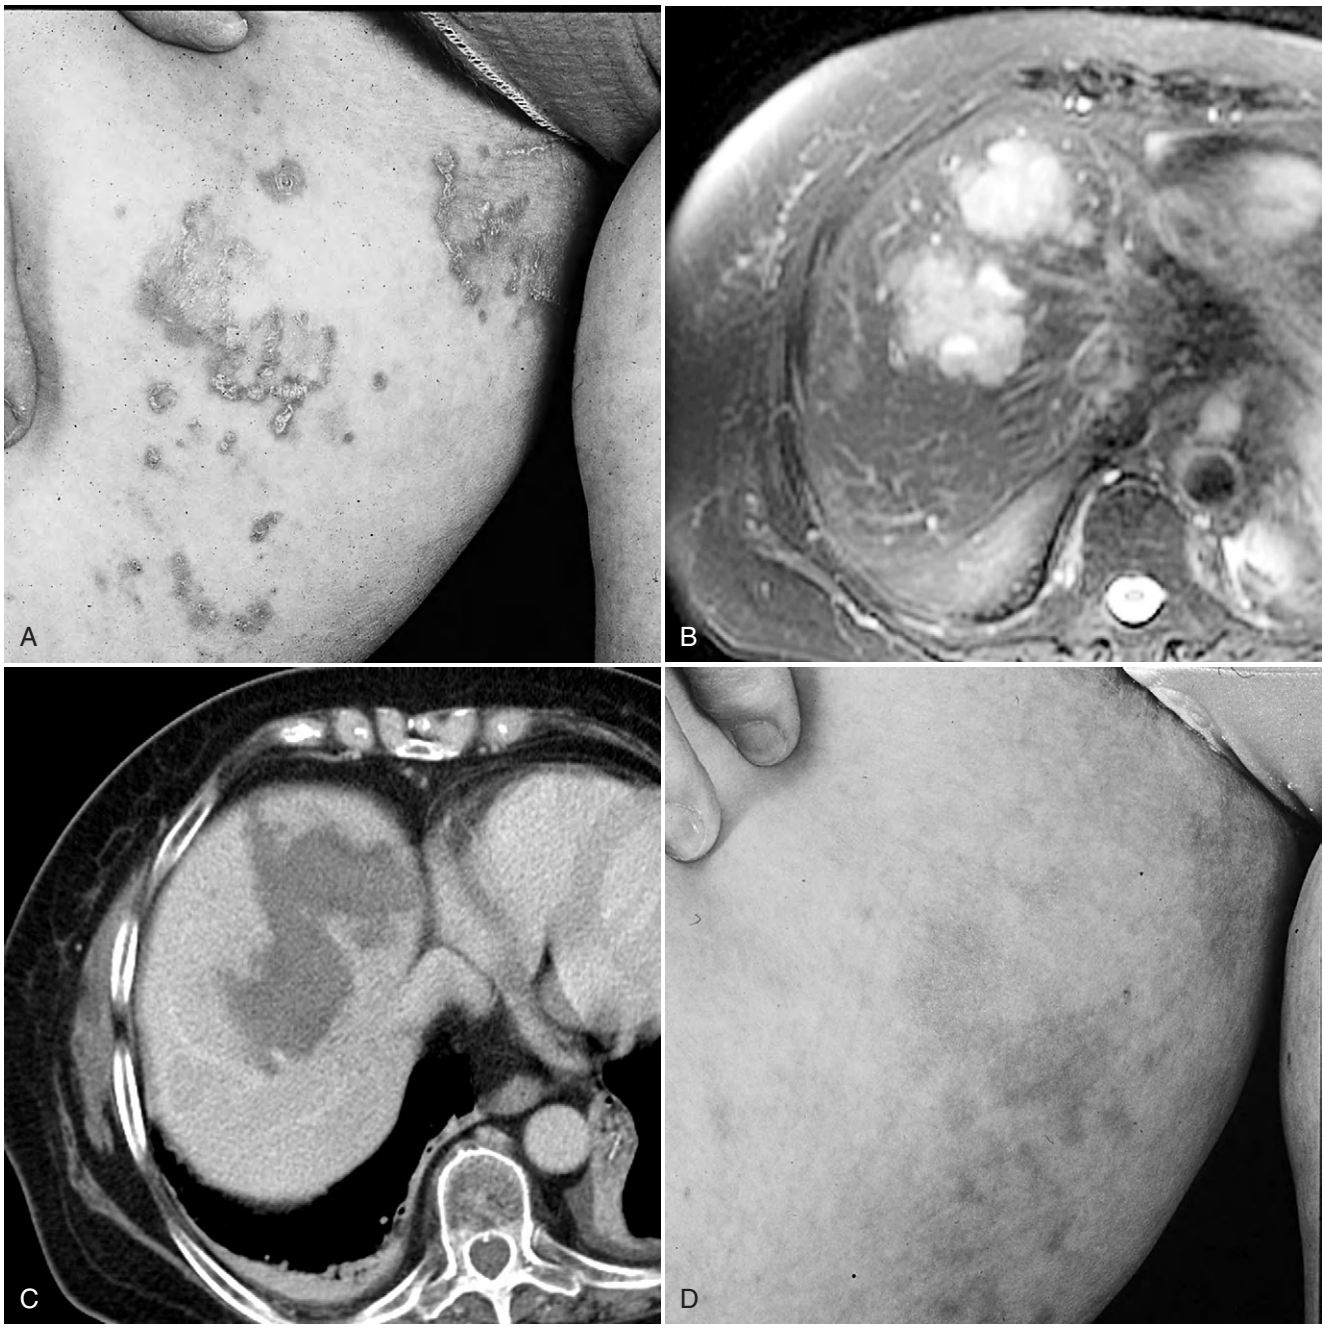

FIGURE 81B.8. Percutaneous radiofrequency ablation (RFA) for relief of symptoms from metastatic glucagonoma (serum glucagon, 16,000 pg/mL). **A,** Symptomatic necrolytic migratory erythema days before ablation session. **B,** Magnetic resonance imaging shows multiple hyperintense hepatic metastases. **C,** CT performed hours after the RFA shows large, corresponding nonenhancing ablation defect in the liver parenchyma. Patient's rash resolved within days of the RFA. **D,** At 2-month follow-up, patient was asymptomatic with healed rash, and serum glucagon was 3700 pg/mL. *(From Atwell TD, et al, 2005: Radiofrequency ablation of neuroendocrine metastases. In vanSonnenberg E, et al, [eds]: Tumor Ablation: Principles and Practice. New York, Springer Business + Science Media, pp 332-340.)*

Embolization or Chemoembolization of Hepatic Neuroendocrine Metastases (See Chapter 83)

Neuroendocrine metastases are intensely hypervascular. Embolization of the hepatic arteries results in ischemia of the metastases and causes variable degrees of tumor necrosis, which can alleviate symptoms or endocrinopathies (Perry et al, 1994). Embolization alone or in combination with intraarterial chemotherapy (chemoembolization) has been employed for relief of symptoms. Repeated embolization is possible depending upon the interventional vascular technique used, selective or nonselective. Objective tumor responses to embolization alone have ranged from 30% to 70% with similar symptomatic response rates (Brown et al, 1999; Oberg et al, 2004). Intermittent or temporary dearterialization with the use of an implantable hepatic artery occluder provides similar symptomatic relief for 6 to 12 months (Bengmark et al, 1982). Duration of response has ranged from 15 to 30 months, and chemotherapy following embolization has prolonged duration of response (Moertel et al, 1994). These findings, coupled with the theoretical advantages

of high intrahepatic concentration afforded by arterial infusion of chemotherapeutic agents, have prompted evaluation of chemoembolization. Although chemoembolization has been used for metastatic NET, range and duration of response has been similar to embolization alone (Fiorentini et al, 2004). To date, no randomized trial comparing embolization with and without chemotherapy have confirmed a significant difference in outcomes or response, and observational data have shown no statistical difference between the two groups (Pitt et al, 2008; Ruutiainen et al, 2007). A combination of chemoembolization with hepatic artery chemoinfusion for patients with unresectable hepatic disease has achieved better than 3-year survival for the majority of patients (Christante et al, 2008).

Complications are generally tolerable, although not insignificant. A postembolization syndrome consisting of nausea, right upper quadrant abdominal pain, fever, and elevation of serum transaminases usually lasting for 3 to 7 days is common. Parenteral analgesias, intravenous hydration, and antipyrexics are often necessary. Antibiotic prophylaxis is recommended for embolization. Other side effects include gallbladder necrosis, hepatic abscess, and renal failure. Patients with large (>5 to 10 cm) metastases and those with more than 50% to 70% hepatic replacement are at greater risk of complications. Sequential lobar embolization may reduce the severity of the postembolization syndrome and may lower the risk of complications. Mortality after embolization has ranged from 2% to 7%.

New Drugs and Targets

Recent randomized trials assessing the utility of sunitinib maleate notwithstanding (Raymond et al, 2011) the crucial issue with rigorous assessment of medical treatment is that most studies are retrospective, assess heterogeneous tumors, commonly lack standardized entry criteria, reflect single-center experience, and are underpowered. As previously discussed, the tyrosine kinase inhibitor sunitinib malate has shown proven efficacy in the management of metastatic pancreatic NETs (Raymond et al, 2011). It has recently been approved by the FDA and has been adopted by several European countries.

Traditional DNA-damaging cytotoxic drugs are of limited efficacy in GEP NETs for reasons outlined above. Several proangiogenic molecules are overexpressed in NETs, such as vascular endothelial growth factor (VEGF) and its receptors and related signaling-pathway components: epithelial growth factor receptor, insulin-like growth factor-1 receptor, phosphoinositide-3-kinase, RAC-α serine/threonine-protein kinase (AKT), and mammalian target of rapamycin (mTOR). New drugs that target some of these molecules are under assessment in early clinical trials, such as bevacizumab (monoclonal antibody against VEGF). Angiogenesis and mTOR inhibitors (temsirolimus, everolimus) may have potential, but less than 20% of patients show a radiologic response (Konings et al, 2009; Yao et al, 2008). Although strategies that use these biologic agents might advance the management of GEP NETs, they were first developed for other tumor types. The development of more effective drugs for GEP NETs will need improved understanding of GEP NET biology and perhaps the discovery of a molecular target specific to all or some subtypes of GEP NETs. Use of somatostatin receptors to target so-called *passenger drugs*—that is, active cytotoxic drugs that are physically linked to agents that bind to somatostatin receptors—might hold promise.

Recently, the combination of two oral cytotoxic agents, capecitabine and temozolomide, has been shown to have significant activity in patients with advanced pancreatic endocrine tumors. A response rate of 70%, combined with a progression-free survival of 18 months, was recently reported (Strosberg et al, 2010).

Peptide Receptor Radionuclide Therapy

GEP NETs overexpress peptide receptors, mainly subtype 2, which become internalized after ligand binding; therefore they are targets for cytotoxic drugs coupled to somatostatin, such as radiolabeled somatostatin analogues. Using indium 111 diagnostic scintigraphy for these receptors can identify tumors that express somatostatin receptors (Nasir et al, 2008; de Jong et al, 2009). This new treatment is proving to be safe and effective and might become an important treatment strategy for lesions that express adequate densities of somatostatin receptors (Kwekkeboom et al, 2008).

Primary Hepatic Neuroendocrine Tumors

Albeit rare, neuroendocrine tumors may arise primarily within the liver. Hepatobiliary neuroendocrine tumors accounted for only 2% of all GI carcinoids in the Surveillance Epidemiology and End Results (SEER) database over a 30-year period, and primary hepatic carcinoids accounted for less than half of these tumors (Modlin et al, 2003). Most reports of primary hepatic carcinoids are single-case experiences, and case series are usually limited to less than 6 patients (Knox et al, 2003). Primary hepatic carcinoids have similar histopathologic and immunohistochemical findings as extrahepatic carcinoids. Most primary hepatic carcinoids are nonfunctional and are rarely associated with the carcinoid syndrome; however, because they can be functional and may be associated with a specific endocrinopathy, and not limited only to the carcinoid syndrome, they should probably be termed *primary hepatic neuroendocrine tumors* and not *hepatic carcinoids.*

The diagnosis presumes a thorough search and exclusion of an extrahepatic neuroendocrine tumor. The cell of origin is unknown. Pancreatic heterotopia has been postulated as a source of these tumors. Some may arise from intrahepatic biliary tract radicles, because carcinoids of the extrahepatic biliary tract are more common. Moreover, most primary hepatic neuroendocrine tumors arise centrally or in the perihilar area within the liver (Hwang et al, 2008). Finally, some primary hepatic neuroendocrine tumors may in fact be metastases from an occult primary NET or a primary NET that had spontaneously regressed. A history of prior GEP resections warrants careful pathologic review of the resected specimen to exclude a missed primary NET. Conversely the absence of an identifiable extrahepatic site of NET after resection is posited as evidence supporting the liver as a primary site.

NET shows a female predominance (65%), and mean age at presentation is 50 years. Typical symptoms and signs at presentation include abdominal pain, jaundice, weight loss, and rarely a specific endocrinopathy. The imaging features are similar to other neuroendocrine tumors (Fig. 81B.9). The criteria for resectability of primary hepatic NET are similar for other hepatic malignancies. Because of the central location within the liver, extended lobar hepatic resections are frequently required for resection of these tumors. Hepatic transplantation has also been employed.

A review of the literature reveals an overall 5- and 10-year survival of 78% and 59%, respectively (Knox et al, 2003).

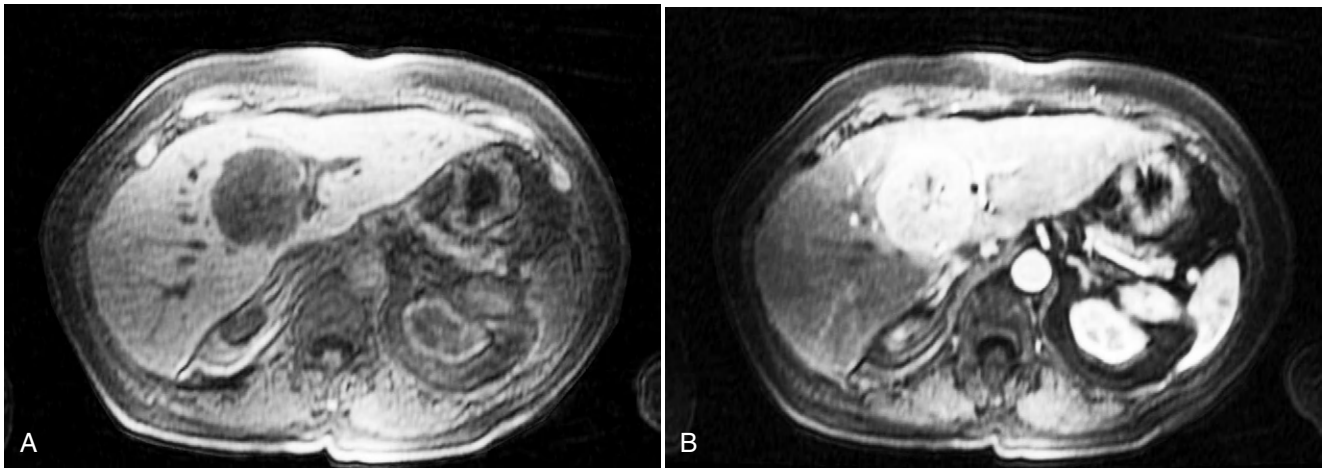

FIGURE 81B.9. T1-weighted **(A)** and T2-weighted **(B)** magnetic resonance images of a primary hepatic neuroendocrine tumor depicting the expected features of discrete hypervascular solitary mass residing centrally within the liver.

Among the 44 patients reported to have had hepatic resections for treatment, 5- and 10-year survival were 80% and 68% respectively (Knox et al, 2003). Predictors of long-term survival have been few, and analysis of such factors is limited by the low prevalence of primary hepatic NET. In fact, hepatic multicentricity and bilaterality, extrahepatic metastases at the time of resection, advanced age, and gender have not correlated adversely with survival. Recurrence within the liver has not been uncommon, and repeat resections have been reported and are associated with further prolongation of survival. Hepatic transplantation has also proven effective for primary hepatic NET deemed unresectable otherwise by standard techniques (Fenwick et al, 2004). The overall and disease-free survival after hepatic transplantation are similar to those of standard resection, albeit limited in duration of follow-up and number of patients reported. Current data preclude assessment of antihormonal therapy and chemotherapy, although anecdotal reports suggest responses are similar to those in patients with extrahepatic NET.

CHAPTER 81C

Noncolorectal nonneuroendocrine metastases

Jürgen Weitz and Ronald P. DeMatteo

OVERVIEW

Hepatic resection is a well-established therapy for patients with liver metastases from colorectal or neuroendocrine carcinoma. Resection of liver metastases from colorectal cancer (CRC) results in a 3-year survival rate of 30% to 61% and a 5-year survival rate of 16% to 51%, depending on patient selection (Choti et al, 2002; Fong et al, 1997, 1999; Scheele et al, 1995; Schlag et al, 1990; Tomlinson et al, 2007; see Chapter 81A). In patients with hepatic neuroendocrine metastases, 5-year survival rates of 76% have been achieved with surgical resection, and some surgeons occasionally employ liver transplantation (Chamberlain et al, 2000; Lehnert, 1998; see Chapter 81B). In contrast, the role of hepatectomy in patients with liver metastases from noncolorectal, nonneuroendocrine (NCNN) tumors is not well defined, but the number of reports on this topic is increasing.

SERIES SUMMARIZING MULTIPLE PRIMARY TUMOR TYPES

Most current reports regarding hepatectomy for metastases of NCNN tumors combine multiple primary tumor types in order to have a sufficient number of patients to analyze. Despite this approach, most series are still limited by small numbers or inclusion of patients with neuroendocrine metastases (Benevento et al, 2000; Buell et al, 2000; Elias et al, 1998; Goering et al, 2002; Hamy et al, 2000; Hemming et al, 2000; Karavias et al, 2002; Laurent et al, 2001; Schwartz, 1995; Takada et al, 2001; van Ruth et al, 2001; Yamada et al, 2001).

Goering and colleagues (2002) reported the outcome of 48 patients who had undergone liver resection or ablation for liver metastases from noncolorectal tumors. With a median follow-up of 48 months, the 5-year survival rate was 39%, and the median overall survival was 45 months. No difference was found in survival between patients treated with liver resection versus those treated with cryotherapy. The 3-year survival for patients with primary neuroendocrine (n = 13), genitourinary (n = 16), and soft tissue tumors (n = 15) was 91%, 52%, and 34%, respectively ($P = .26$).

Elias and colleagues (1998) performed hepatectomy in 147 patients with liver metastases from a noncolorectal primary. Operative mortality was 2%. The overall 5-year survival rate was 36% with the following results for various primary tumors: breast cancer 20% (n = 35), neuroendocrine tumor 74% (n = 27), testicular cancer 46% (n = 20), sarcoma 18% (n = 13), and gastric cancer 20% (n = 11). The authors pointed out that the overall survival was similar to results they obtained in 270 patients who underwent liver resection for metastases of CRC.

Hemming and associates (2000) performed liver resections in 37 patients with NCNN primaries. After a median follow-up of 22 months, the overall 5-year survival rate was 45%. Curative resection and primary tumor type were independent prognostic markers of overall survival in this series. In the subgroup with nongastrointestinal primary tumors (n = 30), the overall 5-year survival rate was 60% compared with 0% for patients with gastrointestinal primary tumors (n = 7; $P = .01$).

Laurent and coworkers (2001) analyzed the outcome of 39 patients who underwent potentially curative resection of NCNN liver metastases. Patients had primary gastrointestinal (n = 15), genitourinary (n = 12), or miscellaneous (n = 12) tumors. The 5-year survival for the entire group was 35%. Notably, 5-year survival was 100% for patients with a disease-free interval that exceeded 24 months from removal of the primary versus 10% otherwise ($P = .01$). No other prognostic parameters were identified.

The Memorial Sloan-Kettering Cancer Center (MSKCC) experience of hepatic resection for metastases from NCNN carcinoma was analyzed by Weitz and associates (2004). The objectives of this study were to define perioperative and long-term outcome and to define prognostic factors for survival in 141 patients who underwent resection for liver metastases from NCNN carcinoma during the period from April 1981 through April 2002. Table 81C.1 depicts the primary tumor types. The median operative time was 238 minutes (interquartile range, 180 to 321 minutes), and the median blood loss was 600 mL (interquartile range, 250 to 1420 mL). The median length of hospital stay was 9 days (interquartile range, 7 to 12 days). Of 141 patients, 46 (33%) developed postoperative complications, but the 30-day mortality rate was 0%. The median follow-up was 26 months, with a median follow-up of 35 months. The 3-year relapse-free survival rate was 30% (median, 17 months), and the 3-year cancer-specific survival rate was 57% (median, 42 months). Primary tumor type and length of disease-free interval from the primary tumor were significant independent prognostic factors for relapse-free and cancer-specific survival (Figs. 81C.1 to 81C.3; Table 81C.2).

Margin status was significant for cancer-specific survival and showed a strong trend in relapse-free survival. Patients with a primary reproductive tract tumor who underwent R0 resection had the best outcome, with a 3-year cancer-specific survival of 78%. In the group of patients with primary non–reproductive tract tumors, survival after R0 resection was influenced largely by the length of the disease-free interval. Patients with a disease-free interval of 24 months or less achieved a 3-year survival of 36%, but only 5% were free of relapse after 3 years. Patients with a non–reproductive tract primary and a disease-free interval of more than 24 months had a 3-year cancer-specific

Data from Weitz J, et al, 2004: Partial hepatectomy for metastases from non-colorectal, nonneuroendocrine carcinoma. Ann Surg 241:269-276.

survival of 72% and a 3-year relapse-free survival of 30%, with 14 5-year survivors in this group.

Laparoscopy might be a reasonable staging tool for patients with NCNN liver metastases. D'Angelica and coworkers (2002) examined 30 patients with potentially resectable NCNN tumors based on preoperative imaging. Nine of these patients had unresectable disease, six of whom were identified by laparoscopy.

Adam and colleagues (2006) reported the results of 1452 patients undergoing hepatic resection for NCNN liver metastases. The primary tumors were most commonly located in the breast (32%) and the gastrointestinal (GI) tract (16%) or were urologic tumors (14%). Operative mortality rate was 2.3%, with a surgical morbidity of 21.5%. Overall 5- and 10-year survival rates were 36% and 23%, respectively. On multivariate analysis, patient age (>60 years), type of primary tumor (non-breast, melanoma, or squamous cell histology), extrahepatic disease, R2 resection, and major hepatectomy were independent adverse prognostic factors. Using these factors, patients could be classified into low risk (0 to 3 risk factors, 5-year survival: 46%), medium risk (4 to 6 risk factors, 5-year survival: 33%), and high risk (>6 risk factors, 5-year survival: <10%; $P = .0001$).

The retrospective nature of all of these studies and the consequent bias related to patient selection represent major limitations. Nevertheless, the general theme is one of potential benefit in selected patients with limited disease, specific primary tumor types, and a prolonged disease-free interval.

SERIES FOCUSED ON ONE PRIMARY TUMOR TYPE

Sarcoma

One of the largest surgical series of patients with sarcoma metastatic to the liver was composed of 56 patients who underwent liver resection (DeMatteo et al, 2001). These patients were selected from 331 patients with liver metastases from sarcomas who had been admitted to MSKCC during the years 1982

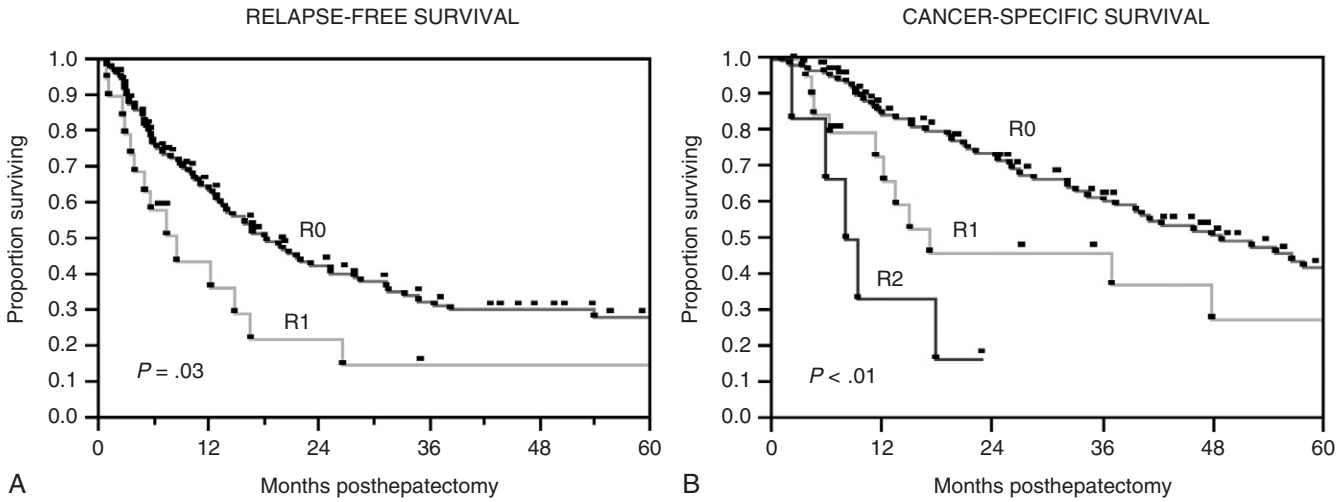

FIGURE 81C.1. Survival after resection of hepatic metastases stratified according to margin status (R0, n = 116; R1, n = 19; R2, n = 6). **A,** Relapse-free survival. **B,** Cancer-specific survival. *(From Weitz J, et al, 2004: Partial hepatectomy for metastases from non-colorectal, non-neuroendocrine carcinoma. Ann Surg 241:269-276.)*

through 2000. Gastrointestinal stromal tumors (GISTs; Fig. 81C.4) and leiomyosarcomas were the most common histology; no perioperative deaths were reported in patients undergoing complete resection of the tumor, and the 5-year overall survival rate was 30% with a median of 39 months in completely resected patients. Patients who did not undergo complete resection had a 5-year survival of only 4% (Fig. 81C.5). A disease-free interval of less than 24 months was a significant adverse prognostic parameter for survival on univariate and multivariate analysis (Fig. 81C.6).

In a report from Pawlik and colleagues (2006b), 66 patients undergoing liver resection and/or ablation were included; the 5-year disease-free and overall survival rates were 16.4% and 27.1%, respectively. Patients in whom RFA was part of the treatment and patients who did not receive chemotherapy, mostly imatinib mesylate for metastatic GISTs, showed a significantly reduced survival.

The treatment strategy for patients with liver metastases from GISTs has changed since the development of the targeted agent imatinib mesylate, which achieves dramatic tumor response rates (Corless et al, 2004; DeMatteo, 2002) such that imatinib is now the first-line treatment. Resection is considered for patients when they reach the maximal response to imatinib, if all gross tumor can be removed and for those who have immediate or limited acquired resistance to the drug (Antonescu et al, 2005). Patients with mulitfocal resistance to imatinib seem not to beneftit from surgical intervention (DeMatteo et al, 2007).

Breast Cancer

In a small proportion (4% to 5%) of patients with breast cancer, liver metastases are the only sign of disseminated disease (Fig. 81C.7; Elias et al, 2003). Although it has not been formally proven that liver resection prolongs survival for selected patients with liver metastases of breast cancer, 5-year survival was 33% to 61% in more recently published series (Caralt et al, 2008; Elias et al, 2003; Vlastos et al, 2004). Patients with liver

Data from Weitz J, et al, 2004: Partial hepatectomy for metastases from non-colorectal, non-neuroendocrine carcinoma. Ann Surg 241:269-276.

metastases from breast cancer receiving chemotherapy only rarely, if ever, survive 5 years (Wyld et al, 2003). Even with aggressive systemic chemotherapy, the median survival for patients with isolated liver metastases of breast cancer was only 23 to 27 months, with time to progression of 8 to 10 months in two more recent trials (Atalay et al, 2003). Resection for liver metastases in this setting may prolong survival for a subset of highly selected patients (Singletary et al, 2003).

Table 81C.3 summarizes the published studies of liver resection for metastatic breast cancer. Meaningful comparisons between these studies cannot be made, because they are heterogeneous studies reporting small patient numbers with different inclusion criteria and treatment strategies. Valid criteria for selecting patients who might benefit from hepatic resection for metastases of breast cancer cannot be defined at this time.

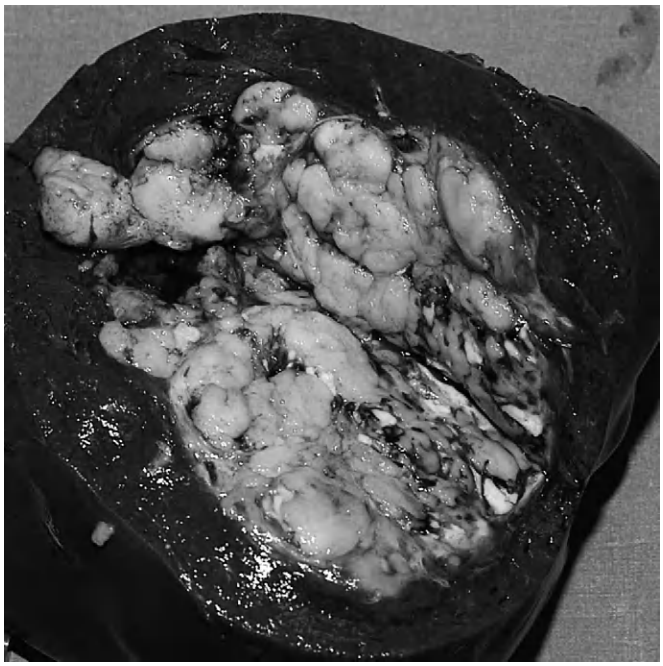

FIGURE 81C.4. Right hepatectomy for a liver metastasis from gastrointestinal stromal tumor.

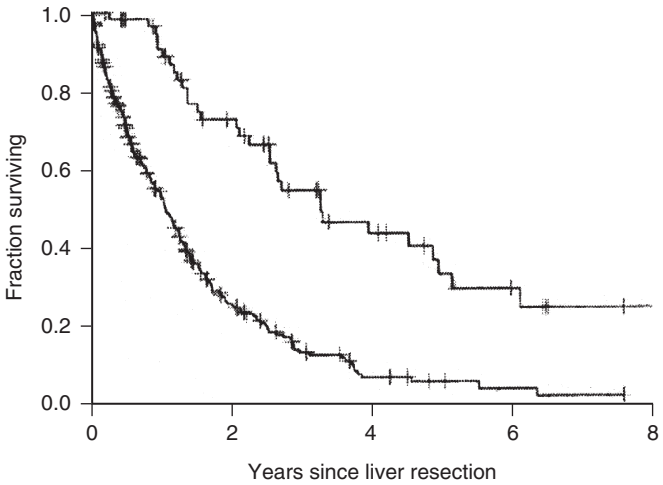

FIGURE 81C.5. Disease-specific survival of patients with liver metastases from sarcoma who underwent complete resection (*upper line,* n = 56) versus other treatment (*lower line,* n = 275; *P* = .0001). *(From DeMatteo RP, et al, 2001: Results of hepatic resection for sarcoma metastatic to the liver. Ann Surg 234:540-548.)*

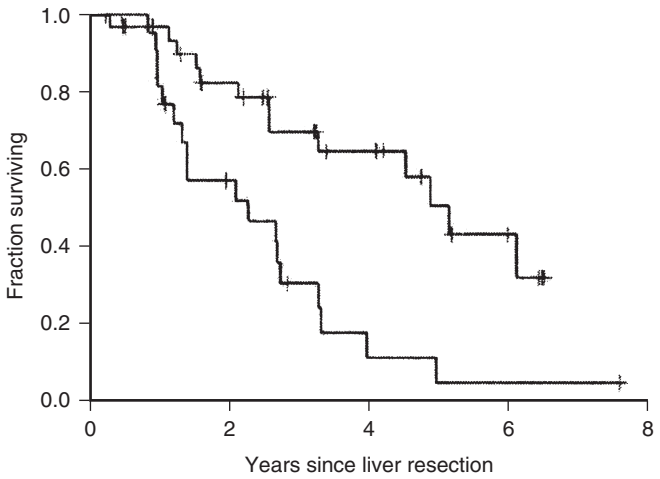

FIGURE 81C.6. Disease-specific survival of patients after complete resection of liver metastases from sarcoma with a disease-free interval of more than 2 years (*upper line,* n = 32) versus less than 2 years (*lower line,* n = 24; *P* = .002). *(From DeMatteo RP, et al, 2001: Results of hepatic resection for sarcoma metastatic to the liver. Ann Surg 234:540-548.)*

A common recommendation is that patients with extrahepatic disease should not undergo liver resection, even though some studies did not find a worse prognosis for such patients. Some authors also suggest that patients should first undergo systemic chemotherapy, and that only patients who do not progress should undergo liver resection. Formal randomized trials confirming this strategy have not been performed. Recently, a report regarding radiofrequency ablation (RFA) has been published; median survival for included patients was 30 months, but the follow-up time was only 19 months, and the local tumor progression rate was 25% (Meloni et al, 2009).

Melanoma

Melanoma recurs after potentially curative resection in approximately one third of patients, with almost every organ being at risk (Allen & Coit, 2002). Hepatic metastases are diagnosed in about 10% to 20% of patients with stage IV melanoma, even though it is well documented that most patients have liver metastases on postmortem examination. Patients with liver metastases as the initial site of metastatic disease have a very poor prognosis, with a median survival of 4.4 months (Rose et al, 2001). Most patients have unresectable disease, owing to extrahepatic disease or disseminated hepatic metastases. This point was shown by a study from the John Wayne Cancer Institute and the Sydney Melanoma Unit (Rose et al, 2001). During the years 1971 through 1999, 26,204 patients with melanoma were seen in these institutions, and 1750 patients (6.7%) had liver metastases. Only 34 patients underwent surgical exploration for attempted liver resection, and hepatectomy was performed in 24 patients. Of these 24 patients, 12 had synchronous extrahepatic disease, and 18 patients could be rendered disease free surgically. The 10 patients who underwent exploration only had a median survival of 4 months; the overall survival of all patients with liver metastases treated nonoperatively was 6 months. Overall survival in the patients who underwent complete resection was 28 months, with a median disease-free survival of 12 months. One patient achieved 10-year survival, and the 5-year overall survival was 29%. Complete gross resection and histologically negative margins were associated with an improved disease-free survival, and complete gross resection showed a trend for improved overall survival (*P* = .06).

From this experience, one might conclude that extrahepatic disease per se is not a contraindication for resection, as long as all disease is resectable. Selection of patients is crucial, which is well documented in this study. Only 1.4% of all patients with liver metastases underwent hepatic resection, and these patients had a median disease-free interval of 58 months before presenting with hepatic metastases. Several other small series in the literature mostly comprise fewer than 10 patients undergoing liver resection for metastatic melanoma, with median survival times of 10 to 51 months (Herman et al, 2007; Rose et al, 2001). Repeat hepatic resection might be beneficial for some patients who can be rendered disease-free surgically (Mondragon-Sanches et al, 1999).

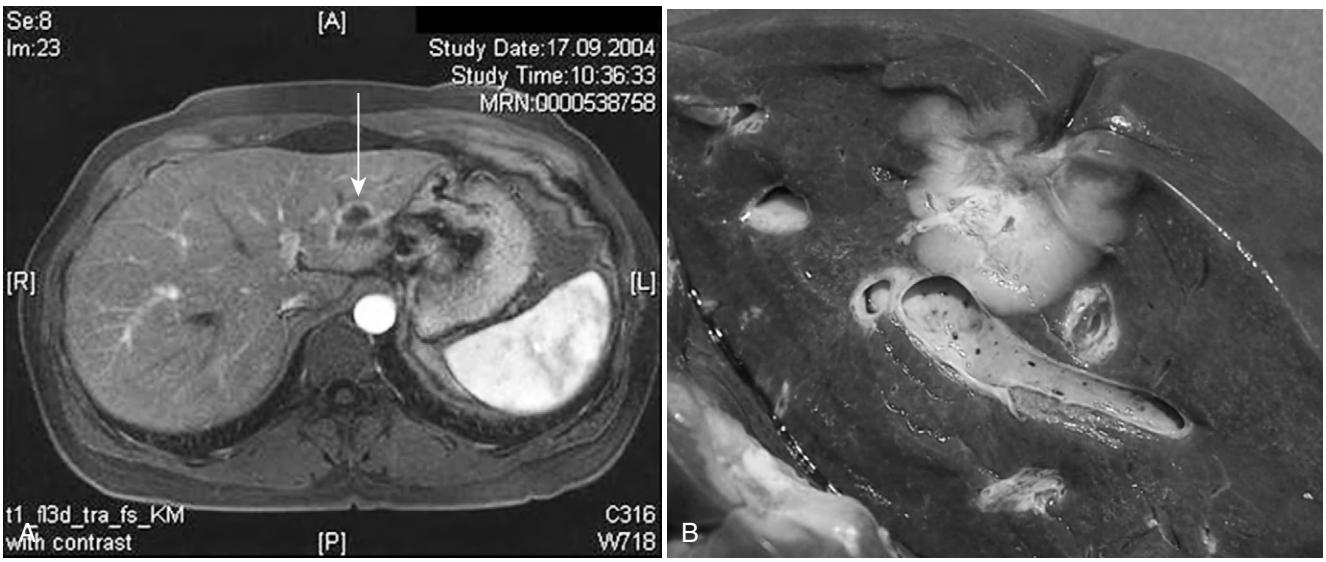

FIGURE 81C.7. Liver metastasis of breast cancer. **A,** Computed tomographic scan shows the lesion (*arrow*) to have early peripheral contrast enhancement. **B,** The patient underwent resection of segments II and III; a gross photograph of the sectioned specimen is shown.

Table 81C.3

Results of Liver Resection for Metastatic Breast Cancer*

Reference	No. Patients	Median Survival (mo)†	Adverse Prognostic Factors	Comments
Caralt et al, 2008	12	36	Disease-free interval <24 mo	Seven patients developed hepatic recurrence
Vlastos et al, 2004	31	63	None	Inclusion criteria: no extrahepatic disease
Elias et al, 2003	54	34	Negative receptor status (odds ratio, 3.5)	Inclusion criteria: no extrahepatic disease, no disease progression on chemotherapy
Carlini et al, 2002	17	53	None	Inclusion criteria: no extrahepatic disease
Pocard et al, 2000	49	42	Short disease-free interval; node-positive primary	Inclusion criteria: good performance status, objective response on chemotherapy, 1 to 3 liver metastases
Selzner et al, 2000	17	27	Short disease-free interval	6041 patients with breast cancer treated during study interval
Yoshimoto et al, 2000	25	34	None	67% of patients developed recurrence in the liver
Seifert et al, 1999	15	57	None	Inclusion criteria: no extrahepatic disease
Raab et al, 1998	34	41.5‡	R1 resection; local recurrence of primary tumor	59% of patients had isolated metastasis

Uveal Melanoma

Uveal melanoma is a distinct entity that seems to have a different tumor biology, and it commonly spreads to the liver. About 50% to 80% of patients with uveal melanoma who develop distant metastases have liver involvement. Hsueh and colleagues (2004) reported 112 patients with metastatic uveal melanoma, and 78 patients had liver metastases. A total of 24 patients underwent surgical resection for metastatic disease, five with liver metastases. A multivariate analysis showed resection, but not site of metastasis, to be a significant predictor of survival. The median survival for patients undergoing resection was 38 months in this series, with a 5-year survival of 39%. Aoyama and colleagues (2000) presented a series of 12 patients with metastatic uveal melanoma, nine with liver metastases. Median recurrence-free survival after complete resection was 19 months, with a median overall survival exceeding 27 months, emphasizing that selected patients with metastatic melanoma may benefit from resection. In a report from Pawlik and colleagues (2006a), 16 patients with liver metastases from ocular melanoma underwent resection; the median time to recurrence was 8.8 months. Compared with patients undergoing liver resection for metastatic cutaneous melanoma, more patients developed recurrent disease in the liver (53% vs. 17%); however, the 5-year survival was significantly better for metastatic ocular melanoma (21% vs. 0%; $P = .015$). Despite these data, most patients with liver metastases from uveal melanoma are not candidates for a complete resection. For these patients, regional chemotherapy might offer increased response rates, and probably increased overall survival, compared with other treatment options (Feldman et al, 2004).

Gastric and Pancreatic Cancer

Most reports on liver resection for NCNN metastases of gastrointestinal origin are based on patients with gastric cancer. Patients undergoing hepatic resection for metastatic gastric cancer are highly selected, which is apparent in the report of Ochiai and colleagues (1994), who treated 6540 patients with gastric cancer. Liver resection for metastases was performed in only 30 of these patients (0.46%). Table 81C.4 summarizes more recently published data; there have been few long-term survivors.

Only a handful of long-term survivors have been reported after the resection of liver metastases from pancreatic ductal adenocarcinoma (Detry et al, 2003). In a report from Shrikhande and colleagues (2007), 11 patients underwent combined pancreatic and liver resection for metastatic pancreatic cancer, with a median survival of 11.4 months. A recent review on this topic summarized 103 patients who underwent liver resection for metastatic pancreatic cancer; median survival ranged from 5.8 to 11.3 months (Michalski et al, 2008). Consequently, surgery remains highly controversial and unlikely to benefit most of these patients. For other primary malignant tumors of the pancreas that show a less aggressive tumor biology, such as solid pseudopapillary tumor of the pancreas, resection of liver metastases might be justified (Martin et al, 2002).

Renal Carcinoma

About 10% of patients with renal tumors develop liver metastases, and they have a dismal prognosis: fewer than 10% survive beyond 1 year, and only about 2% to 4% develop hepatic disease that is amenable to complete resection. Several series in the literature report fewer than 10 patients undergoing liver resection for metastatic renal tumors, with survival exceeding 5 years in about 13% of patients (Alves et al, 2003). In one series, 14 patients with liver metastases from primary renal tumors underwent partial hepatectomy (Alves et al, 2003). Median survival was 26 months, with a 3-year survival of 26%. Patients with a disease-free interval less than 24 months and patients with a diameter of the metastases exceeding 5 cm showed a worse prognosis. In patients with recurrence after hepatic resection, survival was better for patients who could undergo a repeat hepatectomy. In a more recent report on 31 patients, 5-year overall survival was 39% for the whole patient group and 50% for margin-negative patients (Thelen et al, 2007). In patients with hepatic metastases from renal tumors who are candidates

for a complete resection, surgical exploration may be justified. Other therapies should also be considered, such as hepatic artery embolization and targeted molecular therapy, such as with sunitinib.

Reproductive Tract Tumors

Effective chemotherapeutic regimens are available for most reproductive tumors. Resection is only one component of a multimodal approach to the treatment of liver metastases from these tumors. The development of liver metastases is a well-defined adverse prognostic factor for patients with germ cell tumors (Gholam et al, 2003). Rivoire and associates (2001) attempted to define guidelines for the resection of liver metastases from germ cell tumors. These authors examined 37 patients who had undergone liver resection for metastatic germ cell tumors. All patients had received cisplatin-based chemotherapy before surgery. Median survival was 54 months with an overall 5-year survival rate of 62%. The authors defined three prognostic factors associated with a worse outcome: 1) pure embryonal carcinoma in the primary tumor, 2) liver metastasis greater than 3 cm, and 3) presence of viable residual disease after chemotherapy. Because no patient with liver tumors less than 1 cm had viable disease, the authors recommended a nonsurgical approach for these patients. Men with liver tumors greater than 3 cm in diameter represent a high-risk group that may not benefit from partial hepatectomy, but resection was recommended for the other subgroups.

Hahn and coworkers (1999) presented data regarding 57 patients undergoing liver resection for metastatic testicular cancer after systemic chemotherapy. In 48 patients, concomitant cytoreductive procedures for extrahepatic disease were performed. The overall 2-year survival rate was 97.1%. Pathologic analysis of resected specimens showed either a benign lesion or only necrotic tumor in 58% of specimens. Three of five patients with active disease and persistently elevated serum markers died during follow-up, underlining the importance of response to chemotherapy as a predictor of outcome.

Patients with metastatic ovarian or fallopian tube carcinoma usually do not present with isolated liver metastases, because the disease is generally diffuse within the abdomen and pelvis. Cytoreductive surgery that reduces disease to less than 1 cm when combined with chemotherapy is an accepted treatment approach. For these diseases, liver resection may be necessary because of true liver metastases or secondary liver involvement by peritoneal disease. A median overall survival of 62 months after hepatic resection has been described with this approach in 24 patients, with 18 patients having extrahepatic disease at the time of hepatectomy (Yoon et al, 2003). In this study, complete resection of all gross disease was possible in 21 patients, whereas in three patients, tumor debulking to less than 1 cm was performed. Merideth and colleagues (2003) reported 26 patients who underwent liver resection for metachronous metastases from ovarian carcinoma; cytoreduction was suboptimal (residual tumor = 1 cm) in five patients. Median disease-related survival was 26.3 months, and a disease-free interval exceeding 12 months and optimal cytoreduction were associated with improved outcome. Other reports also justify hepatic resection in metastatic ovarian carcinoma (Bristow et al, 1999; Chi et al, 1997; Lim et al, 2009). Unlike most other tumors, ovarian cancer is usually confined to the liver surface, and although extensive involvement can be seen, intraparenchymal hepatic metastases are uncommon (Fig. 81C.8).

Liver resection for metastases from cervical and endometrial cancer have been reported in the literature with an overall survival of 7 to 50 months (Kollmar et al, 2008; Tangjitgamol et al, 2004). Selected patients may benefit from hepatectomy; however, because of the small number of published cases, no general conclusions can be drawn from the available data.

Other Primary Tumors

Resection of liver metastases of lung cancer has been reported, and in selected patients, long-term survival has been achieved. Di Carlo and associates (2003) summarized the available data from the literature. Liver resection was performed in 14 patients with liver metastases from lung cancer, and two patients lived longer than 5 years.

A recent report summarized the results of hepatic resection for metastatic squamous cell carcinoma from various primary sites (anus, head/neck, lung, esophagus, and others) (Pawlik et al, 2007). The median overall survival was 22 months, with

FIGURE 81C.8. Axial computed tomographic image of a large ovarian metastasis to the left liver. Note that the tumor is extending into the liver from without, with no penetration is evident through the liver capsule.

synchronous disease, metastasis size greater than 5 cm, and positive surgical margins being adverse prognostic parameters.

Patients presenting with liver metastases from an unknown primary tumor are a challenge to manage, because median overall survival is approximately 5 months. Liver resection or ablative therapy might be appropriate for some patients, in whom all disease can be destroyed or removed, but a median disease-free survival of only 6.5 months has been reported (Hawksworth et al, 2004).

CRITICAL EVALUATION OF LIVER RESECTION FOR METASTATIC NONCOLORECTAL NONNEUROENDOCRINE TUMORS

Before discussing the rationale of liver resection for metastatic NCNN tumors, it is helpful to consider the reasons for the relative success of liver resection for metastatic CRC. As a result of the favorable long-term outcome after resection and the improved safety of liver resection, the treatment strategy for patients with liver metastases arising from primary CRCs has changed in the past 2 decades. Liver metastases from CRC are no longer viewed as indicators of untreatable, widespread, systemic disease, and cure is still possible with surgery in some patients.

Two different concepts explain the relatively favorable outcome of patients undergoing hepatectomy for liver metastases from CRC: First, the tumor biology of metastatic CRC may be different from that of other solid tumors. Tumor cell dissemination of CRC via the bloodstream may be inefficient and could lead to death of most of the tumor cells shed into the bloodstream before the development of clinically significant metastases. Implantation of circulating colorectal tumor cells in the liver may be particularly effective owing to the expression of particular adhesion molecules (Mizuno et al, 1998; Sugarbaker, 1993; Weiss, 1990). The second reason may be the venous drainage of the large intestine via the portal vein to the liver. Tumor cells that reach the liver through the portal vein may be effectively entrapped by the liver, preventing systemic spread. If this concept is correct, tumor cells must overcome hepatic filtration to reach the systemic circulation and cause distant metastases (Sugarbaker, 1993).

Both notions are substantiated by clinical and experimental findings. It could be shown that the liver is an effective filter for CRC cells, because these cells can be found more frequently in blood samples obtained from the portal vein compared with blood samples from the vena cava (Koch et al, 2001). Tumor biology is also important, however, because the most relevant prognostic factors after resection of colorectal liver metastases, such as length of disease-free interval and nodal status of primary tumor, are at least in part surrogates for tumor biology (Fong et al, 1999).

These concepts are crucial when trying to define the value of surgical resection of noncolorectal liver metastases. Except for gastrointestinal primaries, the liver is not the primary filter for venous blood from the organs being discussed in this chapter. Liver metastases from nongastrointestinal cancers indicate systemic tumor spread; this makes selection of patients with good tumor biology a crucial factor to offer hepatic resection to patients who may benefit the most. Tumor biology depends mainly on the primary tumor type, which is shown by the fact that relapse-free and cancer-specific survival for patients with reproductive tract primary tumors is significantly longer compared with that of patients with non–reproductive tract primary tumors in most studies.

When selecting patients for liver resection, it also is important to select patients with more favorable tumor biology within a particular histology. Disease-free interval, or the time between the treatment of the primary tumor and the development of liver metastasis, may be a valid surrogate marker in this respect, with a longer disease-free interval being associated with less aggressive tumor biology. Most studies support this concept, because patients with a longer disease-free interval show a longer relapse-free and cancer-specific survival after hepatectomy.

The biologic behavior of liver metastases also is most likely linked to the behavior of the primary tumor, because positive lymph node status or venous invasion of the primary tumor predicts worse outcome after hepatectomy for liver metastases in some studies. Tumor biology also appears to determine whether a patient would respond to systemic chemotherapy, which might be an important component when managing these patients, as has been shown for hepatic metastases of reproductive tract primary tumors.

Another important point that should be considered when contemplating hepatic resection for a patient with NCNN metastases is the likelihood of achieving a microscopically complete tumor resection. In most studies, long-term survival can be achieved only if the tumor can be removed completely, which depends on tumor-related factors and surgical expertise. When summarizing the published data, primary tumor type, length of disease-free interval, and pathologic features of the primary tumor may be valid criteria to assess the potential outcome after a planned hepatic resection for patients with metastatic NCNN tumors. By applying these criteria, long-term survival after potentially curative resection of liver metastases can be achieved. The use of systemic chemotherapy to assess the biologic behavior of the tumor also should be considered, although randomized trials validating this approach are lacking.

CONCLUSION

Hepatic resection for metastatic NCNN tumors is safe and is associated with a favorable outcome in highly selected patients. Primary tumor type and disease-free interval seem to be valid selection parameters. Because hepatic resection is often the only modality offering a potential cure, it should be considered in some patients with metastases from NCNN tumors.

CHAPTER 84B

External-beam radiotherapy for liver tumors

Alice Ho and Karyn A. Goodman

OVERVIEW

The advancement of radiation therapy (RT) for hepatobiliary tumors over the last decade has been a remarkable achievement that has improved delivery, outcomes, and quality of care for patients with primary liver and biliary tumors. Whereas RT for tumors in or near the liver has been limited by the tolerance doses for the liver, as well as for the surrounding normal organs, more conformal techniques and sophisticated treatment-planning software have made focal treatment fields possible. Accurate delivery of targeted treatment, which is hampered by the significant degree of organ motion in the abdomen, has historically been problematic for clinicians; however, the emergence of novel imaging and motion-management techniques are allowing for more targeted therapy of these tumors and new attempts to escalate the dose of RT. Classic approaches to portals and fractionation have been abandoned in favor of more focal techniques of irradiating liver tumors. These techniques typically consist of innovations designed to minimize normal hepatic irradiation and enhance target conformality, such as intensity-modulated radiation therapy (IMRT), image-guided radiation therapy (IGRT), and the use of motion management. The role of all of these new approaches in the radiotherapeutic management of primary liver and biliary tumors will be discussed. In addition, the role of new alternative fractionation protocols and the use of radioisotopes in the management of primary liver tumors will also be highlighted.

TECHNICAL INNOVATIONS

Intensity-Modulated Radiotherapy

Over the last decade, more sophisticated imaging and treatment-planning techniques have allowed for more focal delivery of RT. Now routine is computed tomography (CT)-assisted three-dimensional conformal radiation therapy (3D-CRT), which uses diagnostic CT or magnetic resonance imaging (MRI) to define normal and target structures. IMRT is a further technical innovation, now frequently used in hepatobiliary radiation. As opposed to conventional radiation that uses large, fixed radiation portals and field borders based on correlations between the bony anatomy and the soft-tissue target, IMRT uses CT-based planning, and the target volumes and normal structures are delineated individually on axial CT imaging. With conventional RT, normal tissues adjacent to target structures cannot be spared and receive the prescribed radiotherapy dose, limiting the radiation dose that can be delivered safely. When planning treatment using IMRT, the radiation dose is prescribed to the target volume, and strict dose constraints are placed on normal tissues. The IMRT plan is then developed using a computer-optimized algorithm to deliver radiation of varying intensity to the target volume via multiple beams to meet the requirements for the target volume coverage and normal tissue constraints. The overall result is a highly conformal dose distribution customized to the shape of the tumor (Fig. 84B.1). This minimizes exposure of surrounding normal tissues and organs to high-dose radiation.

Image-Guided Radiotherapy and Motion Management

The development of 3D-CRT and IMRT, which allow for delivery of more conformal radiotherapy to the tumor, has made more accurate localization of the tumor at the time of treatment necessary to avoid missing the target. The need to improve targeting in radiation treatment has led to the development of image-guided radiation therapy to reduce the uncertainties of tumor positioning. On-board 3D CT imaging, known as *cone-beam CT* (CBCT), has been developed to allow real-time assessment of tumor positioning on the linear accelerator, while the patient is on the table prior to treatment delivery; however, CBCT scans may not show the target lesion in the liver because of limitations in resolution and contrast (Fig. 84B.2). Because liver tumors are not well visualized on standard megavoltage portal images or even on CBCT, surrogates for tumor location have been used to help verify tumor positioning prior to treatment. Fiducial markers (see Fig. 84B.2) have been introduced to help identify the tumor and allow for better visualization and improved setup for both conventionally fractionated treatments and, more importantly, for focal RT. Gold fiducial markers can be percutaneously inserted in or around the liver tumor, or postoperative clips can be used to help evaluate the postoperative bed on kilovoltage images. These fiducial markers are essential to allow for both tumor localization and assessment of tumor motion during treatment, and they are used in conjunction with many of the motion-management techniques described below.

Although 3D-CRT and IMRT offer the ability to tighten the margin around the target volume, the motion of the liver is complex because of organ deformation and rotation with respiration. Some series have found that the liver moves from 1 to 8 cm in the superior-inferior direction with respiration, and smaller shifts are noted in the anterior-posterior and left-right directions with breathing (Shirato et al, 2004). Because of this significant displacement over time, standard treatment techniques require large margins on the gross tumor volume to ensure a full dose to the tumor throughout the respiratory cycle.

Novel methods of accounting for target motion have been developed to improve the accuracy of treatment delivery. Motion management is often combined with IGRT for targeted, focal liver irradiation, as the bony landmarks do not precisely represent tumor location as a result of organ motion. The

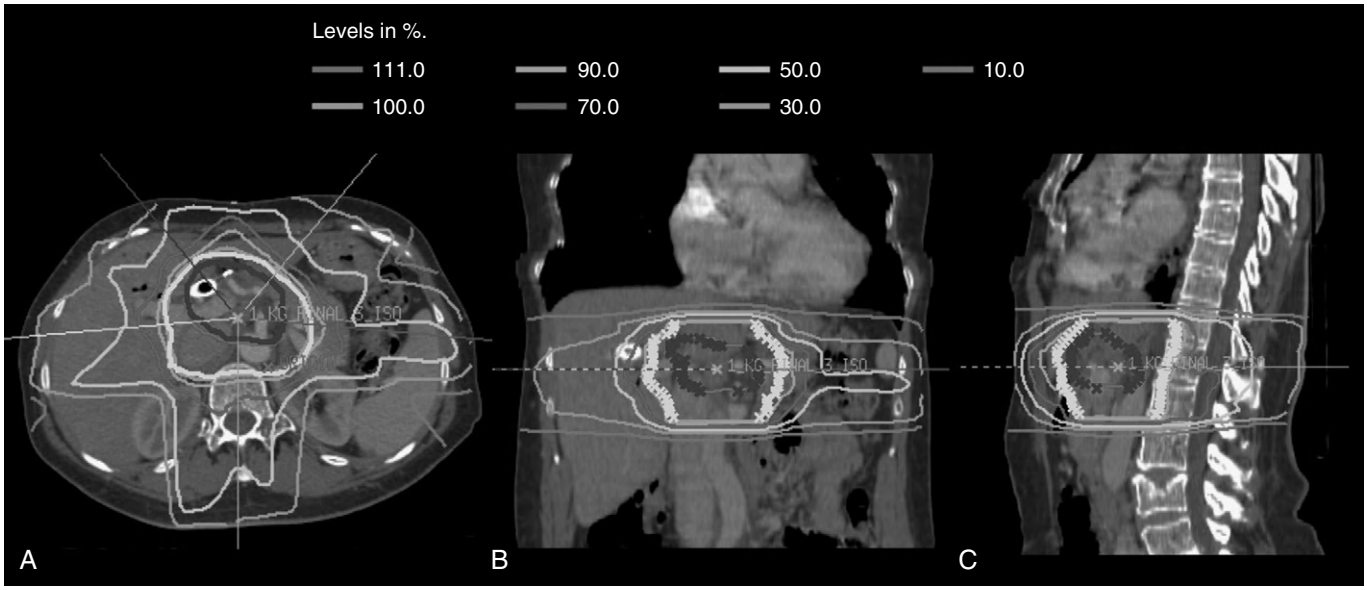

FIGURE 84B.1. Axial (**A**), coronal (**B**), and sagittal (**C**) views of an intensity-modulated radiotherapy plan for an unresectable hilar cholangiocarcinoma. *Hash marks* delineate the planning target volume, which encompasses the tumor and subclinical regions of spread (nodal regions). *Thick lines* delineate the gross tumor volume receiving a higher dose per day using a dose-painting technique. *Thin lines* represent the radiation isodose lines as described.

many approaches to motion management can be broadly categorized as *motion compensating*, such as respiratory gating and tumor tracking, or *motion restricting*, such as abdominal compression and active breathing control. *Respiratory gating* is a technique in which the radiation beam is turned on and off, depending on where the tumor is with respect to the respiratory cycle. The beam is generally turned on during expiration, when there is the least amount of motion. Respiratory gating is achieved using software to correlate the motion of the chest wall to the phase of respiration; however, the chest wall motion may not reflect the motion of the internal organs, thus this technique requires the ability to evaluate the motion of the tumor on a daily basis to evaluate the degree of respiratory motion of the tumor versus the chest wall motion. One option is to place high-density gold fiducial markers in or around the tumor to allow for radiographic tumor localization. With fluoroscopy, the radiopaque gold fiducial markers can be followed throughout the respiratory cycle to confirm that the treatment beam will be turned on at the appropriate time. For patients treated with the CyberKnife (Accuray, Sunnyvale, CA), the accompanying Synchrony tumor tracking system is used for real-time targeting of tumors. A series of light-emitting diodes (LEDs) are placed on the chest wall, and movement is detected by wall-mounted cameras in the treatment room. Using motion-tracking software, the Synchrony system (Colorado Cyberknife, Lafayette, CO) identifies, updates, and then correlates external body surface movement with movement of the internal tumor fiducials. Throughout the procedure, the Synchrony system monitors the target and modifies the correlation model as needed to follow changes in tumor motion. Abdominal compression uses a belt that is inflated to compress the abdominal cavity and limit the degree of respiratory excursion of the abdominal contents. Active breathing control is a method of breath holding that also limits the ventilatory motion while the beam is on.

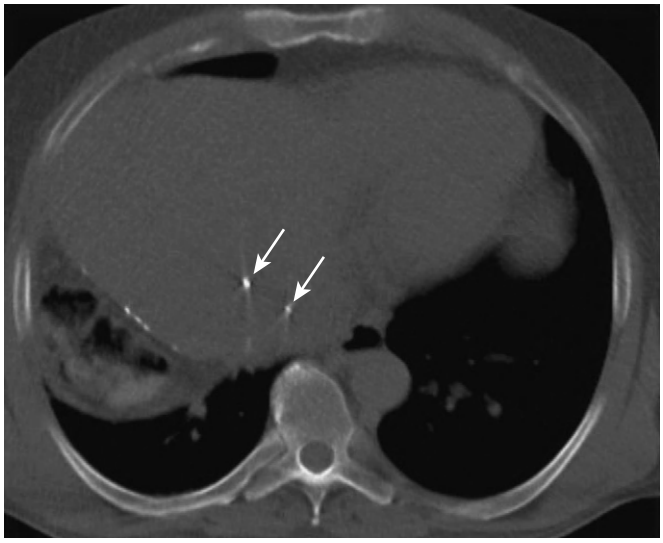

FIGURE 84B.2. Cone-beam computed tomographic image acquired on linear accelerator prior to treatment delivery. Low resolution limits identification of the tumor volume, but radiopaque gold fiducial markers (*arrows*) are visible and can be used for localization purposes.

HEPATOCELLULAR CARCINOMA

Early on, researchers determined that low doses of large-field hepatic irradiation were ineffective in controlling gross hepatocellular carcinoma (HCC) and that higher doses of whole-liver irradiation resulted in high rates of radiation hepatitis. Stevens (1994) states that 75% of patients treated with 40 Gy or greater radiation to the whole liver will develop liver dysfunction, and an early study of adjuvant liver irradiation for HCC (Fugitt et al, 1973) demonstrated that 4 of 52 patients treated with

more than 55 Gy had fatal hepatitis. These widely quoted early results have resulted in RT being placed on the list of potential palliative therapies for HCC.

With the development of 3D-CRT, high-dose, partial liver irradiation was also attempted for patients with unresectable liver tumors (Dawson et al, 2000; Lawrence et al, 1993; Robertson et al, 1997). Investigators at the University of Michigan have reported a Phase II study of 3D-CRT and concurrent intraarterial floxuridine chemotherapy for unresectable hepatobiliary disease. They treated 128 patients with unresectable HCC (n = 35), intrahepatic cholangiocarcinoma (n = 46), or colorectal hepatic metastases (n = 47). Doses ranged from 40 to 90 Gy (median, 60.75 Gy) and were based on the amount of normal liver tissue, evaluated by dose-volume histograms, that could be effectively excluded from the fields to a maximum risk of radiation-induced liver disease (RILD) of 10% to 15%. At a median follow-up time of 16 months (26 months in patients who were alive) the median survival was 15.8 months, and the 3-year survival was 17%; in addition, 38 patients (30%) developed grade 3 or greater toxicity, and 5 patients developed RILD, one of whom died.

More recently, studies of external-beam radiotherapy (EBRT) using IMRT have been reported. A dose-escalation trial of conformal radiotherapy using 3D-CRT (n = 24) or IMRT (n = 16) was performed at Fudan University in Shanghai (Ren et al, 2010). The median tumor dose was 51 Gy (range, 40 to 62 Gy), and the median dose to normal liver was 17 Gy (range, 9 to 22 Gy). None of the patients experienced grade 3 or greater toxicity. The acute hepatic toxicities were mainly elevated liver enzymes; in-field progression-free rates at 1 and 2 years were 100% and 93%, respectively; overall survival at 1 and 2 years was 72% and 62%, respectively.

Investigators from the University of Virginia reported their experience treating 20 patients with HCC using IMRT to deliver 50 Gy in 20 fractions with concurrent capecitabine (McIntosh et al, 2009). The median tumor size was 9 cm, and 45% of patients had Child-Turcotte-Pugh (CTP) class B cirrhosis. The average volume of liver that received greater than 30 Gy was 27%. None of the patients experienced grade 3 or greater acute or late toxicity, and no cases of RILD were reported. The median survival for patients who had class A and B disease was 22.5 months and 8 months, respectively. These numbers exceed those quoted for radiation or regional chemotherapy alone and match most surgical series, they should therefore serve as the basis for future studies using dose escalation and radiation sensitizers.

Alternative fractionation schemes have also been introduced in the treatment of HCC. Both hyperfractionation (lower dose per fraction, twice-daily treatments) and hypofractionation (high dose per fraction in fewer fractions) have been applied to improve response rates in liver malignancies. The rationale for hyperfractionation is the rapid doubling time of HCC tumors (estimated at 41 days) and the shortened treatment times. Hyperfractionation was used in the University of Michigan series (Ben-Josef et al, 2005; Dawson et al, 2000; Lawrence et al, 1993; Robertson et al, 1997). In a nonrandomized study by the Radiation Therapy Oncology Group (RTOG) (Stillwagon et al, 1989), 194 patients with advanced HCC—70% to 80% of whom had metastases or had failed prior treatment—received treatment to the whole liver. Conventional fractionation (3 Gy four times per week to 21 Gy) was used in 135 patients, whereas 59 received 24 Gy in 1.2 Gy fractions twice a day. Concurrent doxorubicin and fluorouracil were given intravenously every other day to both groups. The response rate for both was dismally low (approximately 20%) and unaffected by fractionation scheme. Both acute esophagitis and thrombocytopenia occurred significantly more often in the group that received twice-daily radiation.

With improved tumor localization techniques and motion-management modalities, hypofractionation using IGRT has been evaluated in the treatment of primary liver tumors. Focal, high-dose stereotactic body RT (SBRT) was evaluated in a Phase I study of 41 patients with primary liver tumors, the majority of which were HCC. Dawson and colleagues (2000) prescribed a variable dose of 24 to 54 Gy given over six fractions; the dose was dependent on the volume of liver irradiated and the estimated risk of liver toxicity using a normal tissue complication model. Grade 3 elevation of liver enzymes was seen in five patients (12%). No RILD or treatment-related grade 4 or 5 toxicity was seen within 3 months of SBRT, and overall clinical outcomes were better than expected for this high-risk population. This study was limited to patients with class A cirrhosis or better; however, the majority of patients with unresectable HCC have more advanced cirrhosis, and the underlying liver dysfunction must be considered when delivering any type of liver irradiation.

Emerging data show that dose-volume constraints may be used in cirrhotic patients receiving conformal RT for HCC (McGinn et al, 1998; Mornex et al, 2006). Such guidelines have been shown to allow safe delivery of relatively high doses of conformal RT for HCC (McGinn et al, 1998). These guidelines were used in a Phase II study that confirmed 3D-CRT could be used safely and effectively for patients with tumors less than 5 cm and class A or B cirrhosis (Mornex et al, 2006). SBRT appears to be a promising alternative for patients with unresectable primary liver tumors. This modality may prove to be an option not only for definitive treatment of primary liver tumors but also as a bridge to transplant for HCC patients.

Hypofractionated, focal RT using charged particles has also been studied, particularly in Asia. In small, nonrandomized studies, high-dose RT delivered with protons has been shown to result in acceptable local control and survival rates for unresectable primary liver tumors (Chiba et al, 2005; Fukumitsu et al, 2009; Matsuzaki et al, 1994). A recent prospective study evaluated 51 patients treated with proton RT to deliver 66 Gy equivalents in 10 fractions to those with one to three HCCs 10 cm or smaller (Fukumitsu et al, 2009); of these, 20% were CTP class B. The 5-year local control and survival were 88% and 39%, respectively, and 5-year survival was 46% among patients with solitary tumors and class A liver function. These results are similar to those obtained after surgery; liver function remained stable or improved in 84% of patients, and no RILD was observed. Investigators at Loma Linda Hospital reported the results of their Phase II study in which 34 HCC patients were treated with cobalt-60 Gy equivalents (CoGyEq) in 15 fractions using protons, resulting in a 2-year local control rate of 75% (Bush et al, 2004). Six patients underwent liver transplantation between 6 and 16 months after completion of RT, two of whom had no residual tumor. These newer modalities may be able to minimize normal tissue effects via precise dose localization and should be investigated further.

Selective internal RT (SIRT) or radioembolization using yttrium-90–labeled microspheres for the treatment of HCC has

gained interest in recent years (see Chapter 84A). The ^{90}Y microspheres have several advantages as a potential therapy for liver lesions, including the selective delivery of radiolabeled microspheres via the hepatic artery and the short-depth dose afforded by ^{90}Y, a β-emitter. A meta-analysis of SIRT using either resin or glass microspheres demonstrated that for HCC, a treatment response—complete response, partial response, and/or stable disease—was seen in 89% for resin microspheres and 78% for glass microspheres (Vente et al, 2009). In a large, multiinstitutional, retrospective review of 515 patients who received 680 treatments of SIRT, stable disease was seen in 76.8%, a partial response in 9.5%, a complete response in 4.5%, and progressive liver disease in 9% (Salem et al, 2010). The treatment was well tolerated, with an incidence of RILD of only 4% and nonliver grade 3 or greater toxicity in 6% (gastritis or gastric ulceration) (Kennedy et al, 2009). Salem and colleagues (2010) recently reported long-term outcomes for 291 HCC patients treated with intraarterial ^{90}Y microspheres. The median dose was 103 Gy per treatment, and the mean number of treatments per patient was 1.8. The overall time to progression was 7.9 months, and overall median survival was significantly longer among patients with class A disease (17.2 months) versus those with class B disease (7.7 months).

Recent data suggest that the use of combined RT and chemoembolization may give promising results. Seong and colleagues (2000) from South Korea evaluated 27 patients who had not responded to transarterial chemoembolization (TACE); failure was judged by incomplete tumor filling of Lipiodol adriamycin on angiogram/CT), and patients went on to receive RT (51.8 ± 7.9 Gy). They found objective responses in 67% of patients, a median survival of 14 months from the start of RT, and 1-year overall survival of 85% (Seong et al, 2000). In a separate review, Seong and colleagues (1999) evaluated 30 patients treated with TACE followed by planned RT and noted a 63% objective response rate and a median survival of 17 months. Cheng and colleagues (2000) reported similar results, with a median survival of 19.2 months in patients treated with combination radiation and TACE.

The role of radiotherapy for HCC tumor thrombosis has also been investigated. Vascular invasion is a relatively common and potentially lethal complication of advanced HCC, potentially leading to pulmonary metastases or infarction, Budd-Chiari syndrome, and cardiac and hepatic dysfunction. Portal vein or inferior vena cava (IVC) involvement by tumor thrombus is associated with an extremely poor prognosis and limits the ability to deliver therapy such as TACE. Radiotherapy has been used in many Asian centers to address portal vein or IVC thrombosis to reduce the thrombus size to minimize the risk of clot dissemination, alleviate portal hypertension, and allow for surgical resection or TACE (Koo et al, 2009; Zeng et al, 2005). Zeng and colleagues (2005) retrospectively reviewed the outcomes for 158 patients with HCC who had portal vein and/or IVC tumor thrombus diagnosed and treated at the Zhongshan hospital in Shanghai, China, from 1998 to 2003. Forty-four patients received EBRT (median dose of 50 Gy in 2-Gy fractions), and 144 did not receive EBRT. Approximately 80% in each group were also treated with TACE or resection. The 1-year survival was 0% for patients receiving no therapy, 10.7% for TACE alone, 27.8% for resection alone, and 34.8% for patients receiving any EBRT as part of their therapy. No deterioration of liver function was observed, and only seven patients developed additional elevations of alanine aminotransferase (ALT; less than twice upper limit of normal), and all returned to normal range within 1 month.

BILIARY TUMORS

Intrahepatic Cholangiocarcinoma (See Chapter 50A)

Complete resection remains the gold standard and best chance of cure for patients with intrahepatic cholangiocarcinoma (IHCC); however, even with a complete resection, the 5-year overall survival rates range from 21% to 63% (Carpizo & D'Angelica, 2009). Local recurrence is most common, thus adjuvant therapy has been investigated. A recent analysis of outcomes of patients with IHCC obtained from the Surveillance, Epidemiology, and End Results (SEER) database demonstrated an improvement in overall survival for patients undergoing adjuvant radiotherapy versus surgery alone (Shinohara et al, 2008). The median overall survival was 11 months for surgery and adjuvant RT versus 6 months for surgery alone.

Although patients with IHCC are somewhat less likely to have underlying liver disease than those with HCC, their tumors are often unresectable because of other limitations to curative surgical excision that include lymphadenopathy, vascular involvement, metastases, and multilobar or adjacent organ involvement (Chen et al, 1989).

EXTRAHEPATIC CHOLANGIOCARCINOMA (SEE CHAPTER 50B)

Historically, the use of EBRT for extrahepatic hepatocellular carcinoma (EHCC), including hilar and distal bile duct tumors, was largely limited to unresectable, recurrent, or gross residual disease treated in the pre-CT era, and this led to the conclusion that extrahepatic bile duct carcinomas were radioresistant; however, no evidence supports the idea that bile duct tumor cells have an inherent radioresistance, rather the doses of radiation generally administered have been limited by the surrounding structures. Indeed, some recent reports indicate that radiation limited to relatively small fields, but reaching higher dose levels, combined with more modern surgical approaches and techniques may have a positive effect on outcome (Cameron et al, 1990; Gonzalez Gonzalez et al, 1990; Schoenthaler et al, 1993). In general, this improvement has been found to be most marked in the setting of minimal residual disease (Schoenthaler et al, 1993), although occasionally an advantage is seen in unresectable patients treated with stents and radiation (Cameron et al, 1990).

The indications for postoperative RT are not yet clear. Patients with negative resection margins are rarely referred for consideration of RT, although the available data suggest isolated locoregional recurrence rates of up to 60% after curative resection. Investigators at the University of Michigan published their retrospective experience with adjuvant RT after a potentially curative resection in 81 patients with localized EHCC (Ben-David et al, 2006). With a median follow-up of 1.2 years, the median overall survival and progression-free survival were 14.7 and 11 months, respectively. Complete resection (R0) was the only predictive factor significantly associated with increases in both overall and progression-free survival, and no difference in outcomes was reported between R1 and R2 resections. The first site of failure was locoregional in over two thirds of patients.

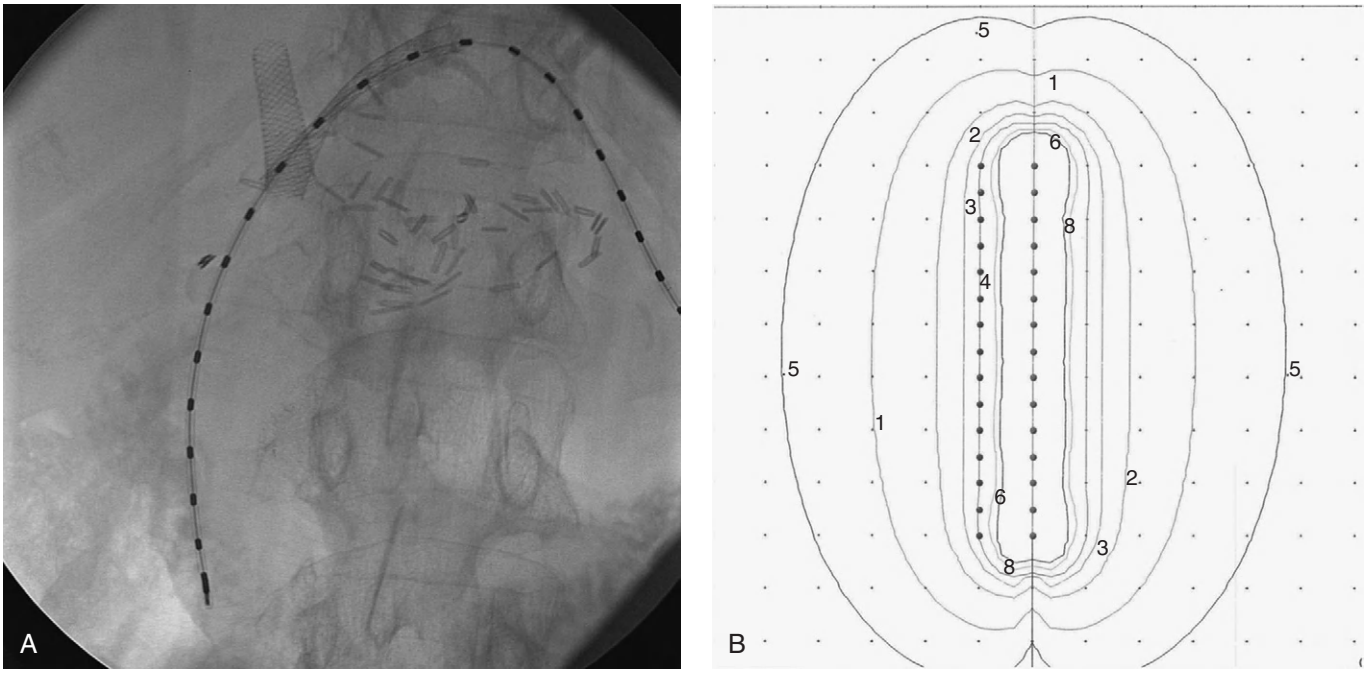

FIGURE 84B.3. Iridium-191 brachytherapy treatment for a hilar cholangiocarcinoma. **A,** Dummy wire in percutaneously placed catheter used to identify treatment area across the stent. **B,** Dose distribution to deliver 4 Gy to 1 cm from the source.

Clearly, local failure plays a significant role in many EHCC deaths, and this is a persistent problem after surgery with or without irradiation and after irradiation alone (Gonzalez Gonzalez et al, 1990; Schoenthaler et al, 1993).

Prognostic factors that may help determine which patients might benefit from adjuvant therapy include age younger than 65 years and small tumor size (Schoenthaler et al, 1994). The degree of differentiation, lymph node involvement, local invasiveness, and papillary characteristics may also serve as prognosticators. All of these factors must be weighed with the demands of upper quadrant irradiation, the patient's overall medical status, and the significant quality of life issues raised by this disease. As always, by far the most important prognosticator for survival is the extent of resection.

An ongoing intergroup study led by the Southwest Oncology Group (SWOG) is evaluating the use of adjuvant chemotherapy (gemcitabine and capecitabine) followed by chemoradiation (concurrent RT and capecitabine) for resected EHCC or gallbladder tumors. This Phase II study will help to establish the role of adjuvant therapy for EHCC.

Short-term morbidity associated with RT includes nausea, vomiting, malaise, fatigue, or weight loss, and many patients with indwelling catheters have intermittent fevers. Long-term post-RT complications, particularly duodenal, have been reported in the literature at rates that seem to vary with survival times; these are discussed in greater detail in later sections. Efforts to minimize the dose to nearby radiosensitive structures, and hence to minimize complications, may include brachytherapy in combination with EBRT, potentially using the new technology of high-dose-rate brachytherapy; intraoperative RT; higher linear energy transfer modalities; radioprotectors; and the increasing use of CT-based conformal planning systems.

Brachytherapy has been used at numerous institutions. Overall, a slight trend has been observed toward improved survival with its use as a boost (Jarnagin, 2000). The potential advantages are clear: the area is reasonably accessible via stents placed during surgery or by the interventional radiologist; a high dose can be limited to a few surrounding centimeters; and the risk of serious short-term toxicity is low, although most series report rates of cholangitis of 30% to 50%. Dose distributions can be quite satisfactory with the use of iridium-192 catheters. Ideally, an external-beam dose designed to eradicate microscopic disease (i.e., 45 to 50 Gy) is given first, followed by seed placement designed to give an additional high dose to the site of gross or highly suspect disease. Doses ranging from 15 to 100 Gy have been administered using ^{192}Ir, ^{131}I, and gold-198. Dose is usually prescribed at 0.5 to 1.0 cm from the radiation sources (Fig. 84B.3).

Long-term complications secondary to the high doses and use of stents are common and include stricture, bowel obstruction, and bleeding. In addition, the rapid dose falloff means that some of the high-risk area may well lie outside the high-dose area, so brachytherapy should only be used in conjunction with EBRT. No study has shown that brachytherapy alone has anything but the briefest of palliative effects, although reports of high-dose-rate brachytherapy are just beginning to appear in the literature (Kurisu et al, 1991).

Intraoperative RT has been used for EHCCs at several institutions. After promising preliminary work in Japan, an RTOG protocol (85-06) gave 14 to 22 Gy as intraoperative RT before 45 to 50 Gy external beam to eight evaluable patients with unresectable, unresected, or recurrent tumors. Two patients were alive, one with no evidence of disease, at the time of publication, with a median follow-up of 10.5 months (Wolkov et al, 1992), In their study of 15 patients, Busse and colleagues (1989) had a median survival of 14 months with a 50% local control rate using 5 to 20 Gy. In a study by Buskirk and colleagues (1992), the only long-term survivors had either

intraoperative RT or a brachytherapy boost. All of these reports involve the use of both intraoperative RT and EBRT, as the use of the intraoperative RT alone and brachytherapy alone have not been shown to have a durable impact. Intraoperative electron doses of 15 to 25 Gy have been given, again before external-beam treatments of approximately 45 to 50 Gy. Buskirk and colleagues (1992) leave transhepatic catheters in place after this procedure.

The role of liver transplantation for unresectable hilar cholangiocarcinoma is under active investigation (see Chapter 97E). Results from the Mayo Clinic are encouraging; they have been using 4500 cGy neoadjuvant chemoradiation, concurrent fluorouracil, and a brachytherapy boost, followed by liver transplantation (Rea et al, 2005). Of 71 patients enrolled, 38 underwent liver transplantation. The 3- and 5-year survival rates for this group were 82% and 82%. These results compared favorably with another group of patients who underwent resection, whose 3- and 5-year survival rates were 48% and 21%, respectively. It must be emphasized that transplantation is reserved for highly selected patients, and selection criteria are quite stringent, favoring those at earlier stages of disease compared with patients undergoing resection.

SUMMARY

Innovations in target delineation, liver imaging, focal radiation delivery, and motion management have led to a significantly more comprehensive understanding of the treatment of primary liver and biliary tumors with radiation therapy over the past decade. As radiation oncologists continue to explore new technologies that allow safe dose escalation to liver and biliary lesions, the outlook for improved outcomes for patients with hepatobiliary tumors appears promising.

CHAPTER 85B

Cryoablation for liver tumors

T. Peter Kingham and Michael I. D'Angelica

OVERVIEW

Hepatic resection is the standard of care for the majority of resectable primary and metastatic liver tumors confined to the liver (Cha et al, 2002; Fong et al, 1999; Scheele et al, 1995; Wei et al, 2006; see Chapters 80 and 81A). In patients with impaired liver function or small hepatocellular tumors, ablation is sometimes employed as first-line treatment (Chen et al, 2006; Livraghi et al, 2008); however, most patients with malignant liver tumors are not amenable to potentially curative resection because of anatomic, functional, or prognostic factors (see Chapter 2). Even when the malignancy is considered unresectable, local control of primary and isolated metastatic hepatic malignancy may change the natural history of these diseases. Several prospective and retrospective analyses have shown liver failure to be a common cause of death in patients with unresected liver tumors (Couto et al, 2007; Nagorney & Gigot, 1996). Ablative techniques can be combined with surgical resections to decrease hepatic tumor load and possibly eliminate it. They also expand the treatment options for disease recurrence in patients whose liver remnant is not optimized or amenable to surgical resection. With ablation, it is possible to prolong survival and increase the disease-free interval in patients. Cryotherapy was one of the original ablative techniques, but it has increasingly been replaced by radiofrequency ablation (RFA) and more recently microwave ablation (MWA) because of high complication rates and high local recurrence rates, somewhat cumbersome technology, and higher complication rates with cryoablation, although its use continues to be described for treating close or positive margins after resection.

PATIENT POPULATION

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is one of the most common malignancies in the world with more than 1 million cases occurring each year worldwide (see Chapter 80; Nordenstedt et al, 2010). It is well known that HCC is the most common malignancy in Southeast Asia and in sub-Saharan Africa owing to endemic viral hepatitis, especially hepatitis B. Since the 1990s the incidence of HCC has increased significantly in the United States and other Western countries as hepatitis C rates have risen. In the United States, the mortality rate for HCC has improved over the past 2 decades, as screening programs have identified patients with tumors at earlier stages. Of patients presenting with HCC, only 15% to 25% are operable, and less than 10% are resectable with curative intent (Bolondi et al, 2001; Farmer et al, 1994); however, most patients with unresectable disease have tumor confined to the liver. At a regional referral center for liver cancer, curative treatments can be applied to 30% to 40% of patients (Bruix & Llovet, 2002). More than half of patients presenting with primary liver cancer are potential candidates for hepatic regional therapy, of which a significant number may be amenable to ablative techniques.

Metastatic Disease

The liver is one of the most common sites of metastatic spread, particularly from gastrointestinal malignancies (see Chapter 81A). Most malignancies that recur in the liver do so in combination with extrahepatic metastases, making resection or ablative regional therapies unsuitable management strategies. In contrast, recurrences from colorectal primary tumors are localized to the liver in approximately one third of patients, allowing use of potentially curative regional interventions. Only a small proportion of patients with metastases confined to the liver are operable, and an even smaller fraction are resectable, owing to technical and prognostic factors. By evaluating all patients with hepatic colorectal metastases at a single center, Scheele and colleagues (1995) found 21% of patients with synchronous disease and 51% of patients with metachronous disease to be potentially resectable.

Most patients with metastatic disease confined to the liver are not candidates for resection therapies but are potentially eligible for regional ablative treatments. Systemic and regional chemotherapy for metastatic colorectal cancer has improved dramatically, with median survivals of greater than 20 months now commonly reported (see Chapters 86 and 87). Additionally, response rates for systemic chemotherapy are generally greater than 50%, and combined with regional chemotherapy, they approach 90%. Survival at 5 years for patients after resection of colorectal liver metastases in modern series ranges from 46% to 58% (Karanjia et al, 2009; Pawlik et al, 2005). Resectional and ablative therapies now must be interpreted in the context of effective chemotherapy, opening the door for downstaging of unresectable tumors and adjuvant therapy for borderline resectable tumors.

GENERAL INDICATIONS FOR NONRESECTIONAL THERAPY OF LIVER TUMORS

Numerous patient- and tumor-related factors conspire to make liver tumors "inoperable" or "unresectable." General and liver-related comorbidities are common contraindications to hepatic resection and are often independent of the extent of disease or proposed operation. Most patients with HCC have limited hepatic reserve secondary to cirrhosis or portal hypertension or both, which often precludes a safe liver resection (see Chapters 2 and 70A). Many technical factors make a hepatic malignancy

unresectable. Insufficient future liver remnant, involvement of all three hepatic veins, and involvement of portal inflow to both lobes of the liver are examples of such technical issues. Many techniques to deal with technically unresectable tumors have been developed, such as portal vein embolization, parenchymal-sparing segmental resections, and two-stage operations (see Chapters 92, 93A, and 93B); nonetheless, most liver tumors are still unresectable.

Cryotherapy has been used to treat many primary and metastatic liver tumors; however, extensive experience exists only for hepatic metastases from colorectal and neuroendocrine primary tumors and for primary liver cancer. Ablation should be considered a second-line alternative to liver resection in patients with resectable disease, except in patients with small HCCs, where the choice between resection and ablation is controversial; however, in the situations enumerated previously, in which resection is not possible or safe, ablation can provide a relatively effective alternative therapy with less morbidity than open hepatic resection. The most pronounced benefits of ablation in these situations are that it can be done laparoscopically, percutaneously, or with a small laparotomy; it can also preserve maximal parenchyma and minimize the overall surgical insult to the patient.

The choice of ablative device is surgeon dependent, and no absolute indications and contraindications apply to cryoablation specifically. Ablation often is employed in combination with resection to treat contralateral tumors in a small remnant.

PATHOPHYSIOLOGY OF CRYOABLATION

The methods by which subzero temperatures destroy tumors are not tissue specific, and both normal and neoplastic tissues are sensitive to extreme cold. Cryotherapy causes cell death by a variety of physical and chemical mechanisms that depend on the rate of cooling, absolute depth of hypothermia, rate of thawing, number of freeze-thaw cycles used, and delayed effects of ischemia after thawing. When a cryoprobe is inserted into the liver, three overlapping zones of injury develop within the ice ball. Rapid tissue freezing occurs closest to the cryoprobe, and the rate of freezing decreases in proportion to the distance from the probe, creating zones of intermediate and slow cooling. Similarly, a gradient of temperature develops in the ice ball, decreasing 3° C/mm to 10° C/mm from –170° C near the probe to just below 0° C at the periphery of the cryolesion. The dynamics of the freezing process cause different mechanisms of injury in these three idealized zones (Gage & Baust, 1998; Mascarenhas & Ravikumar, 1998).

Cooling Rate

The rate at which tissue cools affects the proportion of cells killed by a single freeze cycle. Maximal cell death is achieved at slow and rapid cooling rates, although from different mechanisms, whereas greatest cell survival is seen with intermediate cooling rates. Cellular dehydration causes lethal injury at slow cooling rates, whereas rapidly cooled cells are destroyed by the mechanical action of ice crystallization and expansion.

Slow Cooling Rates

Intracellular and extracellular fluids are complex solutions containing varying amounts of protein, macromolecules, and electrolytes. The presence of solutes in water depresses its freezing point and allows it to supercool, rather than crystallize, below 0° C. Because the composition of the intracellular and extracellular compartments differs markedly, the extracellular fluid freezes before the intracellular fluid. As ice forms in the extracellular space, solutes are excluded, making the remaining fluid hyperosmolar. Cellular dehydration occurs as the unfrozen intracellular water flows out of the cell along the osmotic gradient. At a critical level of dehydration, no further fluid can be extracted from the cell, because the intracellular macromolecules become concentrated enough to equalize the osmotic gradient across the cell membrane. The ion concentration across the membrane becomes deranged, however, allowing ions to flow into the cell from the hypertonic extracellular fluid to reestablish the Gibbs-Donnon equilibrium. As a consequence of cellular dehydration, the intracellular pH and ion concentrations are altered, proteins denature, and membranes and membrane-bound enzyme systems are disrupted. Some cells die as a direct result of dehydration, whereas others require the added insult provided during isotonic rehydration, which occurs during the thaw cycle. When the cryolesion thaws, the extracellular fluid melts first, briefly creating a relatively hypotonic environment. Water flows into the hyperosmolar and hypertonic cells causing them to swell, burst, or die. This type of injury predominates in the slowly cooled zone at the periphery of the cryolesion.

Intermediate Cooling Rates

With intermediate cooling rates (1° C to 10° C/min), the cells dehydrate as the extracellular fluid turns to ice; however, the temperature falls fast enough to freeze the intracellular water before cellular dehydration reaches the critical level to produce irreversible cell injury. Intracellular ice formation excludes solutes, increasing the intracellular osmotic concentrations, equalizing the osmotic gradient across the cell membrane, and stopping further cellular dehydration. As a result, the critical level of dehydration to allow influx of solutes is not reached, protecting the cell from the lethal injury caused by water influx secondary to isotonic rehydration during the thaw cycle. Cells in the zone of intermediate cooling do not suffer the consequences of the cellular dehydration, and their survival is improved.

Rapid Cooling Rates

Rapidly frozen tissue is destroyed by an altogether different mechanism. Cooling rates on the order of 50° C/min, found only in close proximity to the cryoprobe, cause intracellular fluid to freeze before cellular dehydration occurs. Intracellular ice is particularly lethal. Small ice crystals coalesce, causing a physical grinding action that disrupts organelles and cellular membranes leading to reproducible and certain cell death.

Depth of Hypothermia

Independent of the cooling rate, extensive tissue injury occurs at temperatures below –20° C, and temperatures below –40° C are lethal for almost all tumor cells. The mechanism of cell injury at these temperatures is the formation of intracellular ice. At higher temperatures, the rate of cooling influences the rate of ice formation and the mechanism of cell death; however, when the temperature is below –40° C, almost all of the water within the cell is frozen, ensuring complete tissue ablation. For cryotherapy to be reliable, all targeted tissue must reach these levels of hypothermia to achieve reproducible and certain cell death, the theoretic goal of cryotherapy. This level of hypothermia is

not consistently reached at the periphery of the ice ball, where temperatures may be 0° C.

The sensitivity of different tissues to hypothermia varies considerably. Most normal hepatocytes die at –15° C to –20° C, whereas at –10° C most hepatocytes survive. Bile ducts, connective tissue, and vascular structures tolerate slightly lower temperatures than hepatocytes. In contrast, liver tumors tend to require deeper hypothermia to –40° C for complete and reliable cell death. As a general rule, the –40° C isotherm is located approximately three quarters of the distance from the probe to the edge of the ice ball as seen at intraoperative sonography. To reach this level of hypothermia and obtain reliable ablation at the tumor margin, the ice ball is extended 1 cm beyond the peripheral edge of the tumor.

Thawing Process

Further damage to tissue occurs during the thawing process and varies according to the rate of the thaw. Rapid thawing of frozen tissue tends to increase cell survival, whereas slow thawing is more destructive than either rapid or slow cooling. In slowly thawed tissue, the extracellular ice melts before the intracellular ice, briefly making the extracellular fluid relatively hypoosmolar compared with the intracellular fluid. Free water flows down this osmotic gradient into the cells, causing them to swell and ultimately burst. Simultaneously, the ice within the cell undergoes recrystallization, especially in the temperature range of –20° C to –25° C. Recrystallization is a process by which ice crystals reform, coalesce, and enlarge, mechanically disrupting the cellular membranes. The effects of thawing are potentiated by allowing the entire lesion to reach ambient temperature slowly and passively.

Repeated Freeze-Thaw Cycles

Repeated freeze-thaw cycles in animal models have been shown to move the margin of reliable complete cell kill outward by producing larger ice balls more rapidly (Poppendiek, 1967). This movement is due to increased thermoconductivity of the previously frozen liver. Tissue near the cryoprobe is ablated adequately with one freeze-thaw cycle, because low enough temperatures are achieved to ensure complete cellular destruction. The added benefit of multiple cycles occurs in the periphery of the tumor, where the depth of hypothermia is unpredictable, and the cell kill is unreliable. Early histologic signs of cellular damage in lesions undergoing multiple freeze-thaw cycles are more dramatic, confirming the added benefit of such cycles.

Microvascular Effects

In addition to the acute physicochemical and structural damage to the cell and its environment, the lethal effects of cryoablation are potentiated by disruption of vascular structures, which causes delayed hypoxia and necrosis (Rubinsky et al, 1990). The vascular effects are acute and chronic. Freezing at slow cooling rates causes the radius of the sinusoids to increase by a factor of 2, which is equivalent to increasing the volume in the intravascular space by a factor of 4. The expansion of the vascular space tears the endothelium, exposing and disrupting the underlying basement membrane. Platelet thrombi develop, and permeability increases, leading to swelling and microcirculatory failure. The tissues supplied by these damaged vessels become ischemic and necrotic. This mechanism of injury is more important in the intermediate and slow cooling zones, where direct cellular injury by intracellular ice formation or dehydration is not reliable. For maximal benefit, cryosurgery should be performed so that there is rapid freeze, slow thaw, and repeated freeze-thaw cycles; however, experimental evidence has shown that high-flow venules at the periphery of an ice ball are crucial in shutting down the microcirculation of the tumor, and repeated cycles do not seem to improve this effect (Richter et al, 2005). It also has been shown in experimental models that the serine protease inhibitor aprotinin decreases platelet trapping and improves tissue destruction in cryolesions (Kollmar et al, 2004). The effects of cryosurgery on tissues are a result of direct cellular damage secondary to physicochemical effects and indirect cell damage secondary to loss of cellular integrity and destruction of vascular channels.

Morphologic and Histologic Changes After Cryotherapy

Immediately after thawing, the area of liver treated with cryoablative techniques appears dark red, swollen, and usually well demarcated. Histologic examination reveals congestion of the hepatic sinusoids associated with hemorrhage, decreased levels of cellular glycogen, and an absolute reduction in the number of mitochondria. With time, the lesion takes on a light gray color and slowly resorbs over the ensuing weeks. Microscopically, this period correlates with polymorphonuclear cell and macrophage infiltration of the tissue. The cryolesion is progressively replaced with fibrous tissue, usually with a persistent area of necrosis and fibrosis, but occasionally the lesion is completely resorbed.

Immunologic Effects of Cryoablation

In early studies of cryotherapy, anecdotal reports of regression of untreated tumor sites suggested a generalized, tumor-specific immunologic response to the cryoablated lesion (Faraci et al, 1975). These effects have not been substantiated in animal or human models, although it is unlikely that an antitumor immune response enhances the effect of cryotherapy.

OPERATIVE TECHNIQUE

Hepatic cryotherapy can be performed via a variety of approaches, including percutaneous, laparoscopic, and open methods, but the open approach allows the most flexibility and accuracy. Cryotherapy at laparotomy also is less anatomically limiting than minimally invasive approaches and permits treatment of lesions in areas difficult to access by other methods. The difficulty with the open approach is the morbidity that accompanies a major abdominal incision; however, minimally invasive cryotherapy techniques have been developed and are increasingly popular. The technology of laparoscopic instrumentation and percutaneous localization continues to improve for all types of ablation, and the role of these techniques continues to increase.

Preoperative Preparation

The extent, location, and proximity of the liver tumor to the hepatic vascular and biliary structures should be defined by careful review of preoperative imaging studies. Patients with more than 40% of the liver replaced with tumor are not

candidates for cryoablative techniques, because it is difficult to ablate this volume of tumor, and the perioperative morbidity is prohibitive. In general, the same preoperative preparations are required before cryosurgery as for liver resection, because a small percentage of patients may be converted to resection owing to unexpected resectability or intraoperative complications.

Two devastating complications associated with hepatic cryotherapy are the cryoshock syndrome, a complex of coagulopathy and renal and pulmonary failure, and intraoperative hypothermia (Seifert & Morris 1998); preoperative hydration is important to decrease the incidence of renal dysfunction (Bagia et al, 1998). Hypothermia is another significant complication that can be alleviated using heated fluid and airway circuits and a Bair Hugger (Arizant Healthcare, Eden Prairie, MN) warming system (Onik et al, 1993). Blood and blood products should be made available for the infrequent cases of intraoperative bleeding.

Cryotherapy at Laparotomy: Open Cryotherapy

The abdomen is approached through a right subcostal or bilateral subcostal incision with vertical extension in the midline. The peritoneal cavity is explored thoroughly to detect extrahepatic metastatic disease. Enlarged lymph nodes, particularly those in the porta hepatis, are evaluated by frozen section. The liver is mobilized from its ligamentous attachments and examined bimanually. Using a 5-mHz intraoperative ultrasound (US) transducer, each Couinaud segment of the liver is systematically scanned to determine the extent of disease and its relationship to the hepatic vascular and biliary structures. Suspicious lesions undergo US-directed core biopsies for histologic confirmation, but all lesions seen on preoperative studies should be confirmed by intraoperative US, biopsy, or both.

When an operative strategy is defined, the porta hepatis is encircled for the possibility of needing a Pringle maneuver during the procedure. The cryoprobe is introduced into the center of each lesion under US guidance. The placement is confirmed sonographically by viewing the probe in two or three perpendicular planes. In general, it is preferable to introduce the cryoprobe through the anterior surface of the liver, while monitoring the introduction of the probe and formation of the ice ball with the US transducer placed on the posterior side of the liver. Intraoperative US allows safe placement of the probe, avoiding injury to major intrahepatic vascular and biliary structures. To minimize tumor spillage and to avoid "cracking" the surface of the tumor, the cryoprobe is optimally inserted through normal liver before entering the tumor.

Depending on the depth of the lesion, direct introduction of the probe into the tumor or wire-guided, Seldinger-style localization may be used. The Seldinger technique is best used for deep intraparenchymal and nonpalpable tumors. First, the tumor is identified by intraoperative US. An echogenic needle is passed into the center of the lesion under US guidance and subsequently is exchanged for a J-wire (Fig. 85B.1A). When the J-wire is in place, the tract of the wire is dilated with a coaxial dilator and peel-away sheath. The dilator is withdrawn, and the cryoprobe is inserted through the sheath into the center of the tumor. The position of the cryoprobe is evaluated again using US in two or three different axes. The probe must be placed through the center of the tumor with the tip near the opposite margin to encompass the tumor completely within the cryolesion.

It is crucial to tailor the type of cryoprobe and freezing technique to the size and location of the tumor. The temperature gradient within the ice ball significantly affects the efficacy of the procedure. The temperature near the probe approximates that of liquid nitrogen, whereas at the periphery of the ice ball,

the tissue may be only a few degrees below 0° C. In addition, the rate of cooling is determined by the size of the probe, the flux of refrigerant, and the thermoconductivity of the uninsulated portion of the probe. To achieve maximum tumor ablation, the operator must understand the physical properties of the cryotherapy system. The system we use employs vacuum insulated probes and supercooled liquid nitrogen refrigerant. It permits the use of four simultaneous and completely independent probe placements. Two probes are available with this system, accommodating different size tumors. The 3-mm blunted probe creates a cryolesion 4 cm in diameter, whereas the 8-mm trocar point probe creates a 6-cm freeze zone. Two 8-mm probes, used in tandem, create a 10-cm cryolesion (Ravikumar et al, 1991b). Other systems have flat-faced probes that can be applied to a flat surface to create a hemispheric cryolesion of 3 to 4 cm, which can be helpful to treat close margins (Gruenberger et al, 2001).

When the trajectory is chosen, and appropriate placement of the probes is accomplished, the liver is insulated from surrounding tissues using laparotomy pads, towels, or rubber mats. After the probe is placed, and the surrounding tissue is protected, the freezing process is started. At −100° C, the probe sticks to the tissue, allowing placement of additional probes safely without dislodging the first probe; two or three probes can be placed in the liver at the same time, but we do not recommend treating more than three lesions simultaneously, because it is difficult to monitor concurrent cryoablations adequately, and the incidence of intraoperative hypothermia is higher.

Maximal cooling is started, and real-time US monitoring of the freezing process is carried out. The freeze front is seen as a hyperechoic rim with posterior acoustic shadowing (Fig. 85B.1B). Cooling continues until the freeze front extends 1 cm beyond the US margin of the tumor. Typically, the freezing process takes 8 to 15 minutes to complete, depending on the efficiency of the cryotherapy system and the size of the tumor. The freeze zone shown by intraoperative US closely approximates the pathologic and histologic volume of cryonecrosis.

After completion of the first freeze cycle, the tissue is allowed to thaw passively. Active rewarming is unnecessary and may adversely influence results. Complete thawing of the tumor may take 20 to 30 minutes, extending the overall operative time. Because cryotherapy failure usually occurs at the periphery of the ice ball, it is necessary only to thaw the most peripheral centimeter of the ice ball before initiating the second freeze cycle; this reduces operative time without compromising clinical efficacy. The second freeze-thaw cycle is accomplished in a similar fashion.

After completion of the second freeze-thaw cycle, the probe is actively rewarmed, allowing it to disengage before the tumor completely thaws. The probe tract is packed with absorbable knitted fabric, such as Surgicel or another hemostatic material, and gentle pressure is applied to the liver, preventing delayed hemorrhage from the probe tract. Rough handling of the thawing ice ball may cause a cleavage plane to develop at the interface of the ice ball and the normal liver parenchyma, which can cause massive bleeding. Generally, the probe insertion tract stops bleeding promptly, as the coagulation cascade activates at body temperature. After the two freeze-thaw cycles, the treated volume usually remains hyperechoic on US, whereas the surrounding normal liver becomes hypoechoic owing to edema; this gives the treated tumor a "halo" appearance on imaging studies (Fig. 85B.1C).

POSTOPERATIVE CARE

Drains are not used, and the abdomen is closed in the routine fashion. Postoperative care is usually unremarkable. Fluid shifts tend to be minimal, and patients usually can be fed on postoperative day 2. A transient elevation of the liver enzymes is usually seen, along with leukocytosis, a decrease in platelet count, and fairly high fevers in the early postoperative period. The increase in the liver transaminases is related directly to the volume of liver treated and usually resolves within 1 week. The platelet count falls for the first few days, then it stabilizes, only to return to normal or supranormal levels in 7 to 10 days. Less commonly, the coagulation profile deteriorates with increased partial thromboplastin and prothrombin times and elevation of serum levels of fibrin split products and D-dimers. Clinically significant disseminated intravascular coagulopathy (DIC) is rare, but pleural effusions are common as a result of liver mobilization and treatment of areas adjacent to the diaphragm. Most of the early consequences of the surgery resolve spontaneously, and the hospital stay is generally less than 6 days.

LAPAROSCOPIC CRYOTHERAPY

The introduction of videolaparoscopy and refinement of cryoprobe and US technology have allowed the development of laparoscopic cryoablative therapy. The laparoscopic cryoprobes are 40 cm long and can pass through a 5-mm port. Because the probes are not malleable, expertise in laparoscopic hepatic US and accurate placement of the working trocars are essential. Patients with lesions in segments VI and VII can be placed in the right side up position to maximize exposure. The wire-guided Seldinger technique described earlier has been adapted to facilitate accurate placement of the laparoscopic cryoprobe, and the dilators have been modified to make them stiffer than the dilators used in the open procedure. The probe is passed into the sheath, and the sheath is retracted to the liver edge during the freeze-thaw cycles. The cryoablation is completed under laparoscopic vision and US monitoring. A split-screen image allows simultaneous viewing of the probe and the US image of the developing ice ball.

The reported experience with laparoscopic cryotherapy is scant, and the patients are highly selected. With the expansion of RFA and its laparoscopic application, laparoscopic cryoablation has become less popular, and further publications have not been forthcoming. Reports have been limited to small case series, generally fewer than 10 patients, but the technique seems to be safe and effective in these highly selected patients (Seifert & Junginger, 2004). Despite current technologic limitations, the laparoscopic approach offers several advantages: it is minimally invasive, it eliminates the morbidity associated with a laparotomy incision, and it decreases the length of hospitalization and overall recovery.

PERCUTANEOUS CRYOTHERAPY APPROACHES

Percutaneous approaches for cryotherapy are established, although they have been relatively slow to develop; this is likely related to the explosion in popularity of percutaneous RFA. This approach originally was limited by the large diameter of current cryoprobes, location of the tumors, and accurate radiologic localization. Despite these problems, several moderate-sized

series have been published, which confirm the feasibility and safety of this approach. Guidance most typically was performed with CT or with US, but more recently, techniques using magnetic resonance imaging (MRI) have been developed (Wu et al, 2010).

FOLLOW-UP OF PATIENTS TREATED BY CRYOTHERAPY

Although cryotherapy is an accepted procedure for HCC and liver metastases, prospective and comparative data supporting its efficacy are limited. It is important for a reasonably standardized follow-up to be collected on all patients that includes careful documentation of recurrence patterns and disease-specific outcome. Follow-up of patients after cryotherapy comprises history and physical examination, contrast-enhanced CT scans, and tumor marker determinations. The patient should undergo clinical evaluation, serial liver tests, and tumor marker determinations every 3 to 4 months for 2 years and then every 6 months. carcinoembryonic antigen (CEA) and α-fetoprotein (AFP) levels usually reach their nadir at 4 to 8 weeks after ablation (Steele et al, 1990).

CT scans of the liver should be obtained at 4- to 6-month intervals for the first 2 years. It is important to obtain an early CT scan within a few weeks after treatment to be used as a baseline. Successfully treated tumors initially appear larger than the original lesion because of swelling and because of the margin of normal tissue also treated (Fig. 85B.2). Subsequently, the lesion decreases in size and may disappear completely. Gas bubbles may be seen within the necrotic tumor and may be a result of the packed probe tract. These bubbles rarely indicate hepatic abscess and should not be acted on unless other signs of sepsis are evident. In 3 to 6 months, the lesions shrink and leave behind a persistent area of fibrosis and architectural distortion.

TECHNICAL CONSIDERATIONS

Inflow Occlusion

The flow of warm blood through vessels adjacent to the tumor may act as a heat sink that changes the conformation of the ice ball and alter tumor ablation near the vessel. Some groups have used inflow occlusion with a Pringle maneuver to diminish these effects. Experimental studies have not confirmed these assertions in the porcine model, in which clamping the hepatoduodenal ligament did not alter the size of the ice ball that formed, the amount of liver necrosis, or the incidence of large vessel infarction (Kahlenberg et al, 1998). The relative contraindication to cryoablation near vessels may be only theoretic, and further evaluation of this problem is necessary.

Monitoring the Ice Ball

Most investigators use US to monitor the ice ball, because the pathologic size of liver necrosis closely correlates with the US size of the ice ball. Others have used thermocouples to monitor the temperature at the margin of the ice ball; however, this is an unnecessarily invasive procedure that provides no important additional information. Electrical impedance through the cryolesion is not as accurate as US in defining adequate ablation; but MRI is a promising technology, because it can accurately evaluate temperature gradients within the ice ball in real time. Spectroscopic information obtained by MRI also may provide accurate information on cellular necrosis. MRI is generally unavailable in most operating and interventional radiology suites and remains an investigational tool.

Bile Duct Warming

To protect the major bile ducts from the adverse effects of cryotherapy, some surgeons cannulate the bile ducts to circulate warmed fluids during the cryoablation. At present, there is not enough evidence of benefit to support this invasive procedure.

COMPLICATIONS OF CRYOTHERAPY

The complications of hepatic cryotherapy can be broadly classified into three types of problems: 1) operative, 2) technical, and 3) late onset. The operative complications include complications that are not specific to cryotherapy, whereas the technical and late-onset complications are directly related to the procedure (Table 85B.1). The overall morbidity rate ranges from

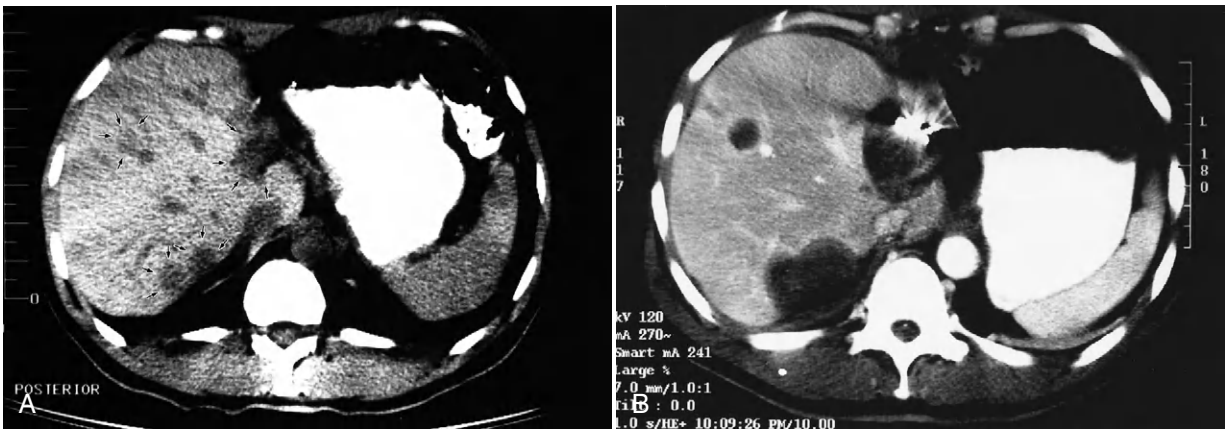

FIGURE 85B.2. A, Pretreatment computed tomographic (CT) scan shows multiple liver metastases (*arrows*) in a patient who had previously undergone resection of segments II and III for metastatic disease. **B,** CT scan 7 days after cryotherapy of five metastatic tumors. The area of necrosis is larger than the original lesions.

Table 85B.1

Complications After Hepatic Cryotherapy: Summary of 869 Patients in 20 Series

Complication	Incidence (%)	Range (%)
Cracking of ice ball	19*	1-25
Hemorrhage	3.7	0-13
Coagulopathy	3.8	0-8
Acute renal failure	1.4	0-17
Bile fistula/biloma	2.9	0-10
Intraabdominal abscess	1.7	0-9
Pleural effusion	6.3	4-18
Death	1.6	0-8

*Reported in only 5 of 20 studies

Modified from Seifert JK, et al, 1998: A collective review of the world literature on hepatic cryotherapy. J R Coll Surg Edinb 43:141-154.

10% to 40%, and the mortality rate ranges from 0% to 5% (Seifert & Junginger, 2004).

Generalized Hypothermia

Generalized hypothermia, a potentially serious adverse event, is generally rare, but it depends on the number of lesions treated and their proximity to blood vessels, especially the vena cava and hepatic veins. The consequences of intraoperative hypothermia are multiple and include cardiac depression, arrhythmias, and coagulopathy. These effects can be ameliorated by warming parenteral fluids and using closed-circulation body warmers and heating blankets. Perhaps most importantly, treatment of multiple large lesions simultaneously should be avoided.

Hemorrhage

After removal of the cryoprobe, hemorrhage through the probe tract is common. The blood does not clot, because the activity of the enzymes that activate the coagulation factors is depressed by the localized hypothermia. Pressure and hemostatic materials usually control the probe tract bleeding. More significantly, the tumor can crack at the interface with the normal uncryoablated tissue, and massive hemorrhage can ensue that requires transfusion, packing, or even conversion to resection. Careful handling of the frozen tissue and gentle extraction of the cryoprobe can minimize this complication, which has been reported in 0% to 25% of treated patients. Diligent use of intraoperative US to avoid moderate-sized vessels during probe placement minimizes this problem.

Bile Fistula and Bile Collections

Bile collections are reported after cryotherapy, affecting approximately 3% of patients in collected series (Seifert & Morris, 1998). Bile collections and fistulae are most common when superficial lesions are treated. Late strictures of the major bile ducts owing to injury during the freezing process may occur and predispose patients to cholangitis. The risk is increased for cryoablated tumors located near the hepatic hilum or the bifurcation of the major biliary ducts, although no long-term studies have confirmed this risk of bile duct injury and late stricture (see Chapters 42A and 42B).

Cryoshock

Cryoshock is a complex of multisystem organ failure, renal failure, and DIC after cryotherapy, and it is potentially lethal. The cause of this symptom complex is unknown, but it is responsible for 18% of deaths after hepatic cryotherapy. In a survey of all groups using cryotherapy, cryoshock was reported in only 21 of 2173 patients undergoing hepatic cryotherapy for tumor (Seifert & Morris, 1998). The cause of this phenomenon is likely related to systemic release of proinflammatory cytokines, such as tumor necrosis factor, interleukin (IL)-1, IL-2, and IL-6. Experimental studies have correlated the risk of this syndrome with larger ablations and with higher systemic levels of these cytokines (Ng et al, 2004; Seifert et al, 2002).

Mortality

The overall early mortality rate for cryotherapy is low at 1.5% (range, 0% to 8%) (Seifert & Junginger, 2004). In expert hands, the operative mortality for major hepatic resection is similar. The most common causes of death after hepatic cryotherapy are not specific to the cryotherapy but rather to cardiac and pulmonary comorbidities. The more common treatment-specific causes of death include cryoshock, liver failure, and hemorrhage.

LONG-TERM RESULTS OF CRYOABLATION

Cryoablation of Hepatocellular Carcinoma

Cryoablation of primary liver cancer has been reported in more than 200 patients. The outcome of these reported series is difficult to interpret, however, because many patients were treated with cryotherapy in combination with resection, chemotherapy, or hepatic artery ligation. There is about a 60% reduction (range, 40% to 82%) in AFP levels after cryotherapy in patients in whom AFP was elevated preoperatively. Reduction of AFP serum levels after cryotherapy does not clearly translate into a survival benefit.

For primary liver cancer patients treated with cryotherapy alone, the 5-year survival is approximately 30%. As expected, survival correlates well with the biologic characteristics of the tumor, of which size seems to be the most important factor. Zhou and colleagues (1996) showed that 5-year survival was 48% for tumors less than 5 cm, whereas it was only 25% for larger tumors (Zhou et al, 1996). The pattern of recurrence is predominantly in the liver after cryotherapy, but the reports typically do not describe whether the cryotherapy was complete, or what the intended margin was. In addition, it is often not reported whether the tumor recurred in the treated area, or whether these recurrences were a separate, intrahepatic, distant tumor resulting from intrahepatic metastases or new primaries. Few studies contain longitudinal survival information, and these results must be corroborated by larger multicenter studies controlling for tumor size, number of lesions treated, and adequacy of treatment.

It is difficult to compare the results of resection with cryotherapy, because the reported series generally are not comparable in terms of tumor characteristics. The operative mortality

for resection of HCC historically has been 6% to 8% in most series, but now with better selection criteria and improved techniques, mortality is generally less than 5%. The median survival is approximately 30 months, with 5-year survivals of 30% to 40%. Similar survivals are reported in selected patients who undergo percutaneous ethanol injection (PEI); however, these are performed in highly selected patients (see Chapter 85A). Livraghi and colleagues (1995) reported a multicenter trial of PEI for HCC that included 746 patients (Livraghi et al, 1995). Survival was related to the size of the lesion, number of tumors, and Child-Turcotte-Pugh (CTP) class of the associated cirrhosis. For unifocal tumors less than 5 cm, the 5-year survival rates were 47%, 29%, and 0% for class A, B, and C cirrhosis, respectively. Even in the presence of multifocal disease, 36% of patients with class A cirrhosis survived 5 years after PEI. Similar results have been reported by Castells and associates (1993) in a comparative study of resection and PEI for HCC less than 4 cm. At 4 years, survival was equivalent for the two modalities.

Hepatic artery infusion chemotherapy, hepatic artery ligation, and systemic chemotherapy all have 25% response rates for HCC. These responses have not led to improved survival, however, and these approaches remain investigational.

Because of patient selection and the combination of therapies used with cryotherapy, for the most part, comparisons with other modalities are meaningless. The development of RFA has generally replaced cryotherapy in the treatment of HCC. Future directions may include hepatic artery infusional chemotherapy after ablative therapies for unresectable tumors.

Cryoablation of Liver Metastases

Liver metastases arising from colorectal, lung, pancreas, and stomach primary tumors constitute the most common malignant tumors of the liver (see Chapter 81A). Most cancers that metastasize to the liver do so in combination with extrahepatic dissemination. The natural history and pattern of recurrence for colorectal cancer is different. Of the approximately 160,000 new cases each year, half develop liver metastases within 5 years of diagnosis. Approximately 20% of these patients (16,000) develop metastatic disease confined to the liver. Only a quarter (4000 to 5000 patients) are amenable to hepatic resection with curative intent; the remaining 12,000 patients with liver-only colorectal metastases are candidates for regional therapies to the liver. The number of patients being considered for liver resection is now increasing because of improved resection techniques and dramatic improvements in adjuvant chemotherapy.

The ultimate goal of regional treatment of liver metastases is increased survival, but long-term follow-up of patients after cryotherapy for liver metastases is inadequate. Most published studies do not have follow-up exceeding 2 years, and few groups have treated enough patients to draw valid conclusions regarding the efficacy of cryotherapy in this setting. Series with adequate follow-up reporting 3- and 5-year survival have been published, albeit with relatively small numbers. In addition, cryotherapy has been used primarily as a salvage procedure or in combination with other treatment modalities, including resection or hepatic artery ligation or infusion, which obscures the results for cryotherapy alone. Ravikumar and associates (1991a) reported overall and disease-free survivals of 78% and 39% at 5 years for 18 patients undergoing complete cryoablation of liver metastases. These encouraging results have not been duplicated in more recent studies, probably because of less stringent selection criteria. Most series (Table 85B.2) report median overall survival of about 2 years after cryoablation of liver metastases. In 24 patients treated with cryotherapy, regardless of whether the ablation was complete or not, Ravikumar and associates (1991b) reported disease-free and overall survival rates of 24% and 63%, respectively. Similarly, Weaver and colleagues (1995) found that 11% of patients were disease-free at a mean follow-up of 30 months, and 62% of treated patients were alive 24 months after cryoablation. Seifert and Morris (1998), in a series of 116 patients with colorectal metastases, showed a median survival of 26 months, and 13% of patients were alive at 5 years. More recent publications have reported 4- and 5-year actuarial survival ranging from 22% to 36% (Kerkar et al, 2004; Rivoire et al, 2002; Seifert & Junginger, 2004). Despite the wide variation in outcome with cryotherapy, some patients in each of the series achieved durable survival with this treatment. Actual follow-up is greater than 5 years for individual patients, suggesting that cryotherapy can be curative in some cases. Based on the worldwide data, it seems that durable local control is achieved in about 20% of patients treated with cryotherapy.

Because the series reporting survival are generally small and include patients treated with cryotherapy, in combination with resection for control of inadequate margins, and patients receiving hepatic artery infusion chemotherapy (see Chapter 86), the results cannot be combined for a proper meta-analysis. Because there are no randomized trials of cryotherapy, Tandan and coworkers (1997) undertook a critical comparative review of resection and cryoablation of colorectal liver metastases. This analysis reviewed 178 studies published from 1973 to 1995. Only studies with survival data exceeding 2 years and data for liver resection if the series included more than 60 patients were included; four cryotherapy and nine resection studies met these minimum inclusion criteria. The median follow-up times for the two procedures were 12 to 28.8 months for cryotherapy and 21 to 69 months for liver resection. The data on liver resection were found to be more valid and consistent, but this review supported a role for cryotherapy in the management of liver metastases. Based on this evaluation, the authors concluded that cryosurgery offers potential advantages in the treatment of liver metastases, it should not be used in cases of resectable disease outside of a clinical trial, and randomized trials comparing the two modalities are needed. Survival seems to be related to the size of the lesions, the volume of liver replaced by tumor, a low pretreatment serum CEA level, absence of extrahepatic metastases, and whether the lesion underwent complete ablation. Normalization of an elevated precryotherapy CEA has been a favorable prognostic factor. Failure to achieve this normalization of CEA probably results from residual unrecognized micrometastatic disease.

Complete response at the treated site ranges from 60% to 90%, and most recurrences are at sites away from the cryolesion. The pattern of recurrence in these patients is primarily in the liver, with or without synchronous extrahepatic disease. This finding underscores the need for additional therapy to further reduce the incidence of hepatic recurrence. With the improvements in regional and systemic chemotherapy, the utility of cryotherapy combined with chemotherapy has been shown even in grossly unresectable patients (Kemeny et al, 2001). An additional use for cryoablation is in the treatment of close or inadequate margins. Edge cryotherapy in these

situations has resulted in good local tumor control (Gruenberger et al, 2001; Hou et al, 2007; Yan et al, 2006). Survival after hepatic resection of liver metastases is substantially better (20% to 58%) than after cryotherapy, but the patient populations are not comparable. Cryotherapy generally has been reserved for patients who are unable to undergo resection and who might have a poorer prognosis.

COMPARISON WITH RADIOFREQUENCY ABLATION

Over the past 10 years, RFA has replaced cryotherapy in many centers (see Chapter 85C). Pearson and colleagues (1999) prospectively studied the complication rates and early local recurrence rates in patients with primary or metastatic liver tumors who were treated with cryotherapy or RFA. With a total of 54 patients treated with cryotherapy and 92 patients treated with RFA, a 41% complication rate was reported in the cryotherapy group compared with a 3% complication rate in the RFA group ($P < .001$). The majority of complications in the cryotherapy group were symptomatic pleural effusions and intrahepatic abscesses. Recurrence rates with a median follow-up of 15 months also favored RFA, with a 2% recurrence rate compared to 14% in the cryoablation group ($P < .01$). Percutaneous cryotherapy and RFA were compared in a retrospective study by Adam and colleagues (2002) with a group of 64 patients. They reported complication rates of 29% for cryotherapy patients and 24% for those who underwent RFA ($P = .66$), but local recurrence rates were 53% in the cryotherapy group, compared with 18% in the RFA group ($P = .003$).

SUMMARY

Because most patients who present with hepatic tumors are unresectable, ablation has a role in the treatment of primary and metastatic liver tumors. With improving chemotherapy for metastases, ablative techniques may play a larger role in the management of bilobar tumors and technically unresectable tumors. The availability of ablative treatment options expands the possible treatments for unresectable disease and allows resection in combination with ablation for more marginal candidates. Ablations can be performed safely in patients with significant comorbidity. Given high recurrence rates in many series that have examined results after ablation of primary or metastatic liver tumors, innovative approaches combining systemic or regional chemotherapy or both are needed to control micrometastatic disease. For now, ablation expands the possible treatments of these diseases and may alter the natural history of the tumor recurrence while also having an impact on survival. Due to higher complication rates and higher local recurrence rates in several series, cryotherapy has been replaced by radiofrequency ablation in most centers. It is relevant in centers where it is the only available ablative modality and for a historic understanding of the development of ablative techniques.

CHAPTER 85C

Radiofrequency ablation for liver tumors

Anton J. Bilchik, Robert M. Krasny, and David Allegra

OVERVIEW

Hepatic resection and transplantation are the only curative options for patients with liver metastases or primary liver tumors (see Chapters 80, 81, and 97). Unfortunately, resection is possible in only about 20% of patients; most hepatic malignancies are surgically inaccessible or are associated with a large tumor burden or inadequate hepatic reserve. Liver transplantation for hepatocellular carcinoma (HCC) is limited by a shortage of donor organs (see Chapter 97D). Patients with unresectable disease may be candidates for systemic therapy (see Chapter 88), local ablative techniques (percutaneous ethanol injection, microwave tumor coagulation, interstitial laser photocoagulation, cryosurgical ablation, or radiofrequency ablation [RFA]; see Chapter 85), or hepatic-directed therapy (hepatic artery ligation, chemoembolization, hepatic artery perfusion; see Chapters 83, 86, and 89).

Over the past decade, multiple clinical trials have evaluated RFA for the treatment of primary liver tumors and liver metastases. Animal experiments in the early 1990s determined the size and shape of ablations that could be achieved in the liver (Rossi et al, 1990). Rossi and colleagues (1996) then demonstrated the effectiveness of RFA for the treatment of HCC in humans. The Food and Drug Administration (FDA) approved RFA for generic tissue ablation in 1996 and for ablation of unresectable hepatic metastases in 2000. Since then, randomized trials have been performed in early HCC that demonstrate equivalent survival to resection (Lu et al, 2006), but prospective data in colorectal liver metastases are limited.

RFA destroys tumor by generating heat within a lesion. During RFA, a high-frequency alternating current changes the direction of ions around an alternating electrode charge. This creates frictional energy and heat conduction. As tissue temperature increases above 45° C, loss of cellular structure and protein denaturing result in tumor cell death. RFA can be performed in the operating room via celiotomy or laparoscopy, or it may be done in the radiology suite by a percutaneous approach. It can be used with other modalities of liver-directed therapy, such as resection and hepatic artery perfusion, and it can be used in conjunction with systemic therapy for other sites of metastatic disease. RFA continues to evolve with the introduction of new technology that increases the field of ablation and simplifies the technique. Long-term survival data have been reported in both HCC and colorectal hepatic metastases (Table 85C.1). A recently published position statement by the Society of Interventional Radiology (Gervais et al, 2009) describes four categories of patients that are preferred candidates for RFA: those with 1) inadequate liver function, 2) comorbid conditions, 3) anatomic distribution, and 4) for local tumor control as a bridge to transplantation.

RADIOFREQUENCY ABLATION TECHNOLOGY

RFA destroys tissue by generating enough heat to denature cell protein and cause cell death (Fig. 85C.1), which can occur instantaneously at 60° C, a temperature achieved by all RFA devices. During RFA an electrical generator produces a current that alternates directions rapidly. Charged molecules in the tissue follow the direction of the changing current: this results in friction, which produces heat. The current around the ablation electrode creates a relatively uniform zone of conductive heat that radiates out from the electrode. If tissue impedance is low, an expanding spherical zone of ablated tissue is created. As the temperature rises, tissue charring and desiccation occur. Also, nitrogen gas forms that can be seen on ultrasound (US) as air bubbles in the tissue. Both of these events raise tissue impedance and inhibit heat conduction, thereby inhibiting further tissue ablation. The spherical size of the ablated tissue is proportional to the square of the RF current (RF power density). It is also dependent on the size of the electrode and the duration of the applied energy. The RF power density decreases in proportion to the square of the distance from the electrode, resulting in a rapid decrease in tissue temperature with increasing distance from the electrode (Strasberg & Linehan, 2003). Changing technology strives to improve ablation zones by limiting impedance and increasing the RF power density.

Early RFA electrodes were unipolar. Because they produced a 1.5- to 2.0-cm cylindrical zone of ablated tissue, only tumors less than 2 cm in diameter could be ablated. These electrodes were eventually replaced by single electrodes that deployed multiarray tines (multiarray electrodes) to create a larger, more spherical zone of ablation. The current multiarray electrodes described below can ablate fields of 4 to 5 cm in diameter. Technologic developments to reduce tissue impedance and increase the zone of ablation will allow progressively larger tumors to be treated with single ablations.

Three different RF electrodes and generators are commercially available. The Radiofrequency Interstitial Tissue Ablation (RITA; AngioDynamics, Latham, NY) and RadioTherapeutics (Boston Scientific, Natick, MA) systems use multiarray electrodes (Fig. 85C.2). The RITA system has a single electrode through which multiple tines are deployed. The ablation is performed at sequential steps of electrode deployment. Thermoprobes measure temperature in the ablation zone, and an automated adjustment is then made to maintain a steady temperature during the ablation. The electrode/generator system measures temperature and time as end points of ablation. This system was recently modified by the addition of saline perfusion to reduce impedance and increase the diameter of the ablation field to 7 cm. The RadioTherapeutics system automatically

CRC, colorectal carcinoma; HCC, hepatocellular carcinoma; RFA, radiofrequency ablation

adjusts current according to tissue impedance; temperature is not measured. The multiarray umbrella-shaped electrode can ablate fields of about 4 cm. The Cool Tip Cluster Electrode, a single or three-pronged electrode, is manufactured by Covidien (Mansfield, MA); each electrode is internally perfused with cold saline, the current is sent in pulses, and the system measures impedance and temperature. Ablation zones can reach 5 cm in diameter with the three-pronged device.

Technical Aspects of Radiofrequency Ablation

Patients who come to medical attention with liver tumors should be evaluated for curative resection or transplantation for HCC. Those whose performance status or disease location or distribution prohibits resection may be candidates for RFA. Prior to RFA, all patients should undergo computed tomography (CT), magnetic resonance imaging (MRI), and/or fluorodeoxyglucose (FDG) positron-emission tomography (PET). If these whole-body imaging techniques reveal extrahepatic sites of metastatic disease, systemic therapy may be a preferred option instead of resection or RFA. Patients with physiologically active neuroendocrine tumors are an exception in that debulking may reduce debilitating symptoms. Baseline hepatic function should be assessed through laboratory indicators of synthetic function and Child-Turcotte-Pugh (CTP) classification of liver dysfunction. A thorough history and physical examination are essential to determine patient performance and prior treatment history.

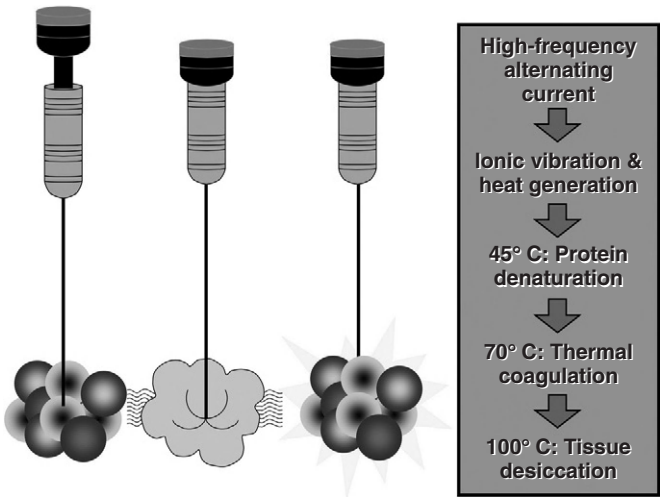

FIGURE 85C.1. Schematic of radiofrequency ablation.

If a surgical approach is undertaken, laparoscopy can reveal extrahepatic disease, and intraoperative US can identify intrahepatic disease not detected by preoperative imaging. A 30-degree angled laparoscope can be used to examine all parietal and visceral peritoneal surfaces, the lesser sac, omentum, and viscera. If extrahepatic disease is found, RFA should not be done, and systemic treatment should be considered. A flexible 7.5-MHz ultrasonic probe is used to evaluate the liver and determine the proximity of liver lesions to major vascular and biliary structures. The exact location of hepatic metastases will affect the technical approach for RFA.

If extrahepatic and/or extensive intrahepatic disease has been detected, ablation is unlikely to be of any benefit. US during surgical or percutaneous RFA or CT during percutaneous RFA is used to guide the probe into the lesion, and the ablation is monitored by real-time US imaging of an expanding hyperechogenic zone (Fig. 85C.3). Depending on the maximal ablation size achievable by the probe, multiple overlapping ablations may be needed to destroy a tumor and produce a surrounding rim of necrosis (Fig. 85C.4). This can be technically challenging. US cannot reliably distinguish between ablated and normal tissue, so ablation should begin at the most posterior portion of the tumor. The probe then can be withdrawn in approximately 2-cm increments to create sequential overlapping zones of ablated tissue. If target temperatures are not reached, as may be the case for lesions near major vascular

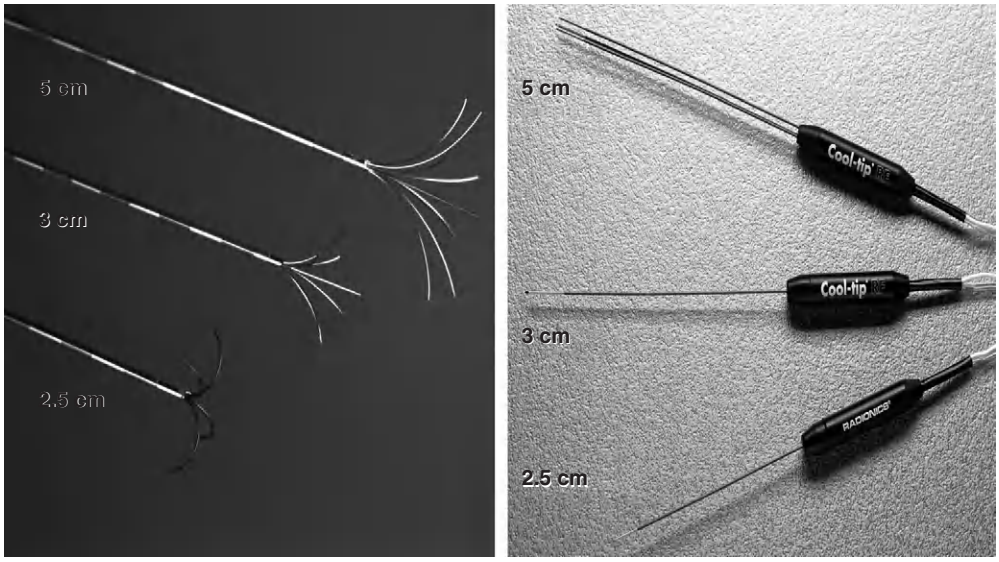

FIGURE 85C.2. RITA (*left*) and Radionics (*right*) probes used for radiofrequency ablation.

structures because of a heat-sink effect, the tines are withdrawn slightly or rotated approximately 45 degrees to increase the temperature in the region of ablation. Each ablation should create a 1-cm margin of treated normal parenchyma to ensure complete tumor destruction and reduce the risk of local recurrence. After ablation, as the RFA needle is withdrawn, the probe tract is cauterized to prevent hemorrhage and tumor seeding of the needle tract.

RFA can be performed by celiotomy (open), laparoscopy, or a percutaneous approach. The choice of technique depends on the patient's condition, the number and location of liver tumors, and the skill of the physician performing the ablation. Each approach offers certain advantages and disadvantages that must be weighed to determine the best approach for the individual patient.

Percutaneous Radiofrequency Ablation

A skilled interventional radiologist typically performs percutaneous RFA as an inpatient or outpatient procedure under US, CT, or combined guidance. The patient is sedated and/or given a local anesthetic. CT guidance provides several advantages: it allows precise placement of the electrode despite the generation of gas within the ablation, and it is possible to assess the adequacy of the ablation during the procedure by performing a contrast-enhanced scan. If areas of inadequate ablation are identified, additional targeted ablations can be performed during the initial procedure.

The percutaneous approach is somewhat limited, as some liver lesions can only be accessed by a surgical approach. Tumors near the periphery of the liver may be problematic because of the risk of thermal injury to other visceral structures such as the small bowel, stomach, or transverse colon; with an open technique, these structures can be retracted away from the liver. Other lesions can be approached percutaneously but raise technical challenges. For example, ablation of lesions at the dome of the liver might result in thermal injury to the diaphragm. Introduction of an air pocket can be used to separate the diaphragm and liver to avoid diaphragmatic thermal injury (Raman et al, 2004); this requires skill and may result in complications such as diaphragmatic injury or pneumothorax. Injection of saline or use of a balloon catheter has also been reported to separate structures from the liver to avoid thermal

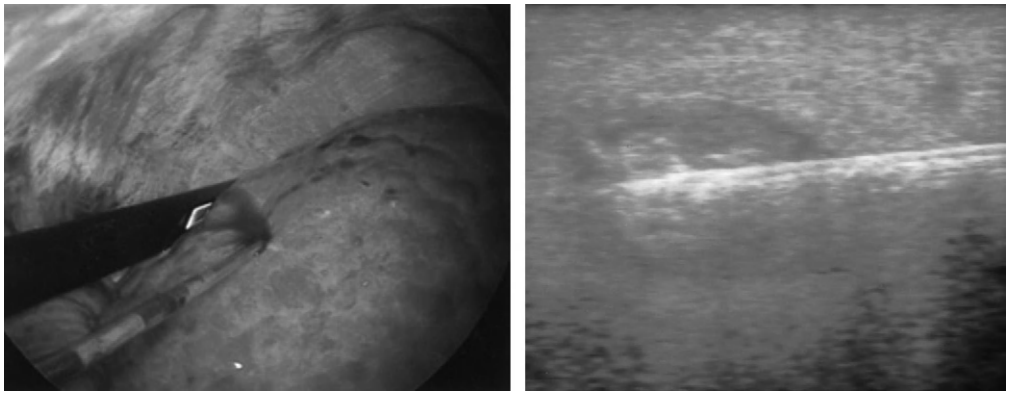

FIGURE 85C.3. Ultrasound-guided radiofrequency ablation.

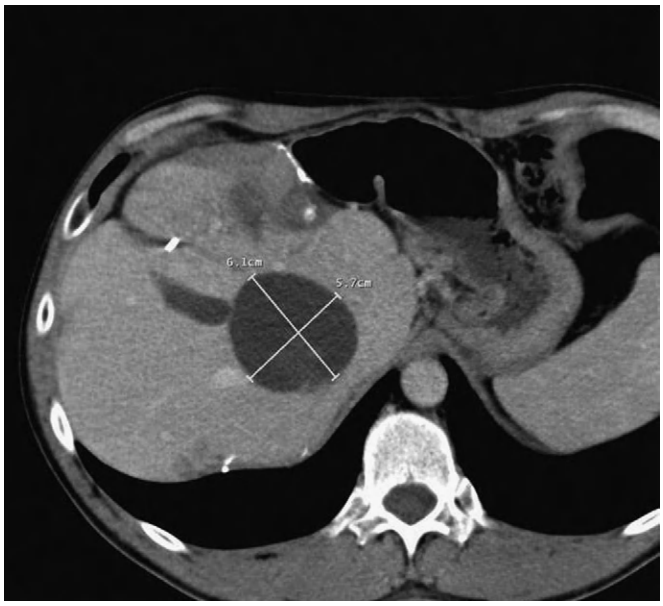

FIGURE 85C.4. Computed tomographic scan demonstrating large-volume ablation achieved with multiple overlapping ablation technique.

injury; however, clinically relevant diaphragmatic injuries are rare in our experience (Fig. 85C.5). Because a percutaneous approach is less invasive than a surgical approach, it may also be preferable in patients with comorbid conditions or poor medical status.

Open or Laparoscopic Radiofrequency Ablation

RFA via celiotomy or laparoscopy is performed in the operating room by a surgeon, while the patient is under general anesthesia. Unlike the percutaneous approach, a surgical approach allows visual inspection of the intraabdominal cavity for extrahepatic disease. Intraoperative US is used to evaluate the liver for intrahepatic lesions not seen on preoperative imaging. In a study of 308 patients undergoing laparoscopic RFA with intraoperative hepatic US, preoperative imaging failed to identify extrahepatic disease in 12% of patients and additional hepatic lesions in 33% of patients (Bilchik et al, 2000). Similarly, Siperstein and colleagues (2000) found that 30% of patients who underwent laparoscopic US of the liver prior to RFA had additional metastatic nodules not apparent on the preoperative CT scan. Larger liver lesions (>5 cm) are more easily treated with an operative approach than percutaneously. These lesions may require multiple overlapping ablations. Intraoperative occlusion of the portal triad can increase the ablation zone by decreasing the heat-sink effect created by nearby vessels. Furthermore, a surgical approach is sometimes necessary when other treatments are used in combination with RFA. For example, a surgical approach is ideal for patients who have bilobar liver metastases, who may benefit from concomitant liver resection. Larger liver lesions may be resected, and smaller lesions in the opposite lobe may be treated by RFA.

Laparoscopy is less invasive than celiotomy, and patients often require slightly shorter hospital stays. In some cases, a celiotomy is needed because of decreased access to the liver and limited position of the US and RFA probe under laparoscopy; However, in the presence of multiple adhesions in the abdomen from prior operations, or if the tumor cannot be approached safely, laparoscopy may not be possible. In this case, a celiotomy is warranted.

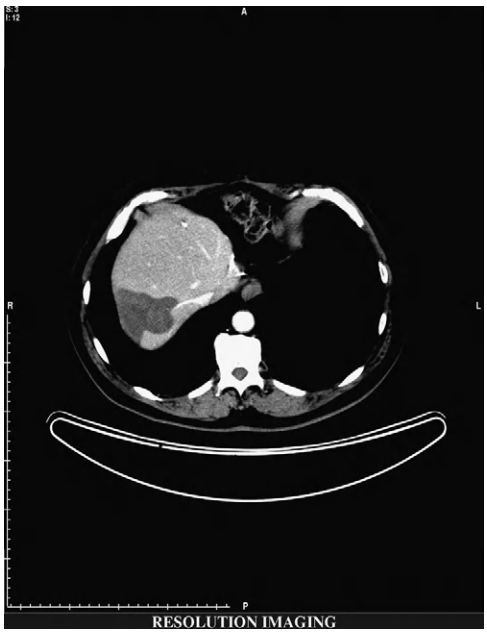

FIGURE 85C.5. Percutaneous ablation performed adjacent to the diaphragm.

Monitoring and Follow-up

After laparoscopic or percutaneous RFA, patients are usually admitted to the hospital for 23 hours or are discharged home the same day; after open RFA (celiotomy), patients are usually hospitalized for 3 to 5 days. In all cases, red blood cell and leukocyte counts, liver function tests, and temperature are closely monitored. RFA typically causes a mild transient elevation of liver function tests, core temperature, and leukocyte count. These should normalize within about 3 days. Continued elevation, especially 5 or more days after RFA, may be an indicator of a potential complication and should prompt further clinical investigation. Tumor markers such as carcinoembryonic antigen (CEA) for colorectal cancer metastasis and α-fetoprotein (AFP) for HCC can also be used to monitor patients as appropriate.

Contrast-enhanced CT scans obtained within a month and then at 3-month intervals after RFA should be compared with preprocedure CT scans. Liver necrosis from RFA can be seen as a nonenhancing hypodense region. When complete necrosis of the tumor is achieved, the resulting necrotic zone exceeds the original tumor size. Postprocedure CT scans are important to determine the success of RFA and to monitor the liver for evidence of recurrence. PET scans may also be particularly sensitive in the assessment of the adequacy of ablation and presence of marginal recurrence (Fig. 85C.6) or to distinguish viable tumor from areas of previous surgical or ablative therapy (Fig. 85C.7).

Current Practice

RFA has mainly been used for unresectable HCC or metastatic disease confined to the liver (see Chapters 80, 81A, and 81B).

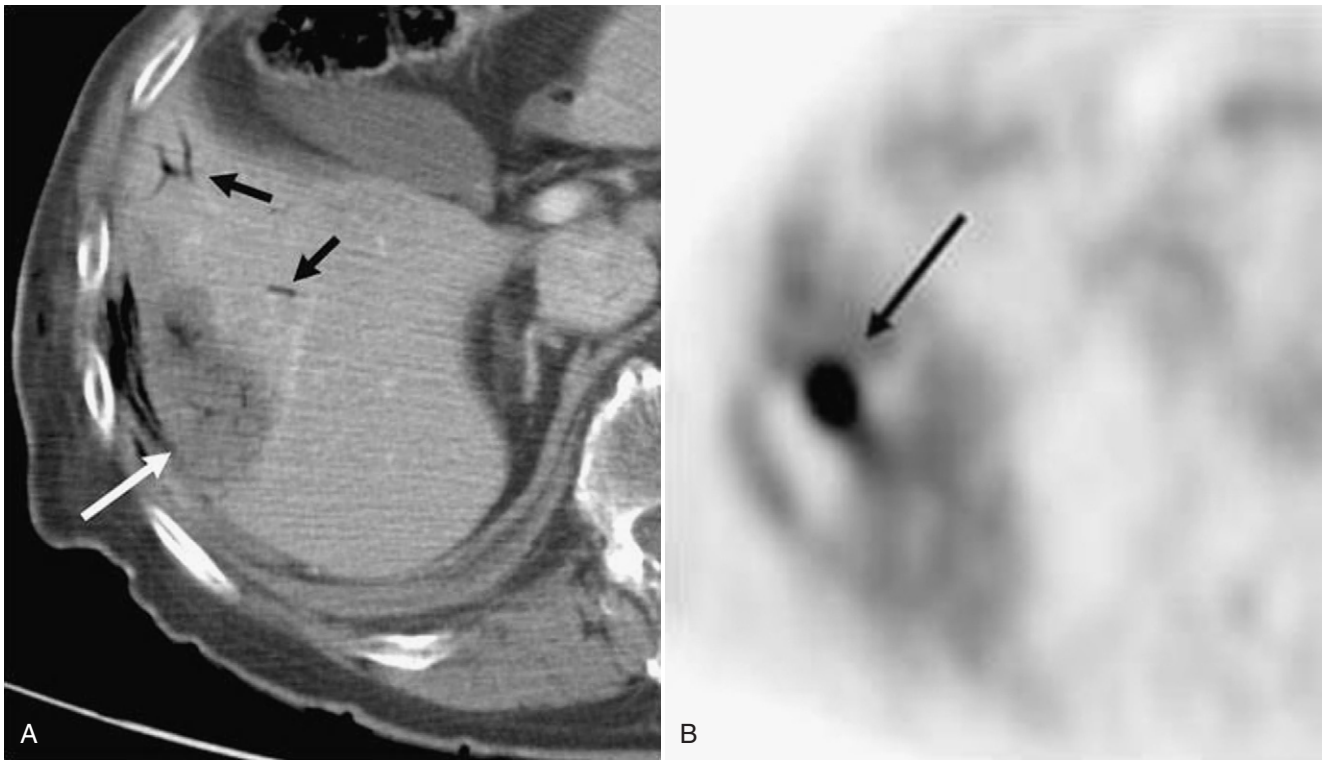

FIGURE 85C.6. A, Marginal recurrence not clearly visualized by computed tomography. **B,** Recurrence is clearly identified by positron emission tomographic scan.

Tumors may be deemed unresectable based on size, number, location, or doubling time. Therefore, selection of patients is based initially on a thorough preoperative workup that includes imaging to evaluate for other sites of disease, prior response to systemic therapy, and the biology of the disease. If systemic therapy eliminates extrahepatic metastases, and if its effects prove durable over several months, RFA of hepatic metastases may be considered; however, this applies to a small subset of unique patients. Some patients will have resectable disease but limited hepatic reserve. For example, a patient with cirrhosis and HCC might not have enough hepatic reserve for tumor resection but would be able to tolerate RFA. In other patients, resection of larger lesions and RFA of smaller lesions can completely eradicate tumor while maintaining hepatic reserve. Finally, patients who have multiple comorbid factors may not be good candidates for an operation and may be best treated by a less invasive approach such as percutaneous RFA.

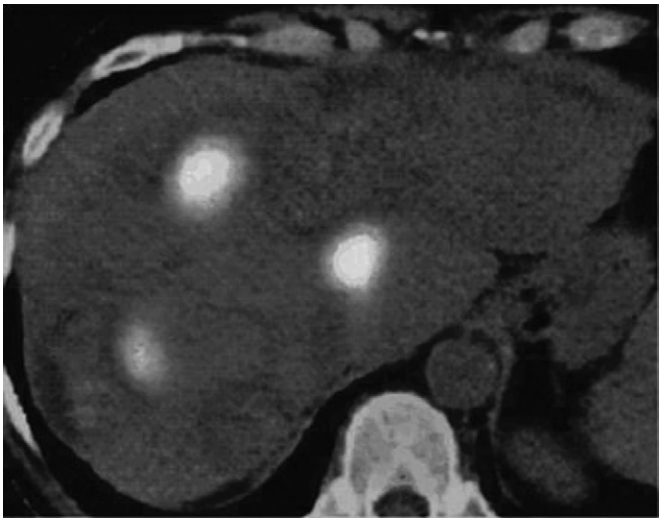

FIGURE 85C.7. Positron emission tomography scan demonstrating areas of viable tumor distinguished from areas of successful ablation.

Radiofrequency Ablation of Colorectal Hepatic Metastases (See Chapter 81A)

Resection offers the only curative option in patients with colorectal hepatic metastases, with 5-year survival approaching 60% (Ahmad et al, 2007; Pawlik et al, 2008; Tomlinson et al, 2007). The improvement in survival is attributed to more effective systemic therapy and expanded criteria for defining resectability. Despite these, many patients are poor candidates for resection, and RFA provides a locoregional alternative. In a recent review of 21 studies (Stang et al, 2009), the median progression-free survival after RFA ranged between 6 and 13 months; the median and 5-year survival ranged between 24 and 59 months and 18% to 40%, respectively.

No randomized trials have compared RFA to resection in patients with colorectal hepatic metastases. One retrospective study of 358 patients compared resection, RFA plus resection, RFA alone, and laparotomy with biopsy (Abdalla et al, 2004); RFA was used for cure when complete resection was not possible. All patient-related and tumor-related factors known to influence outcome were similar among the groups. The rate of recurrence was 84% after RFA alone, 63% after RFA plus resection, and 52% after resection alone. Local recurrence in the area treated was more common after RFA plus resection (9%) than after RFA alone (5%) or resection alone (2%). The

Table 85C.2

Radiofrequency Ablation vs. Resection for Hepatic Colorectal Metastases (Nonrandomized)

First Author, Year	No. Patients	Follow-up Median (mo)	Local Recurrence (%)	Overall Survival (%)
Oshow, 2003	20 resection	18	0	3 years (55)
	25 RFA		12	3 years (53)
Aloia, 2006	150 resection	31	5	5 years (71)
	30 RFA		37	5 years (27)
White, 2007	30 resection	68	0	5 years (65)

Park, 2008	59 resection	49	1.7	5 years (48)
	30 RFA		23	5 years (19)
Hur, 2009	42 resection	42	9.5	5 years (50)
	25 RFA		28	5 years (25)

RFA, radiofrequency ablation

3-year rate of overall survival was 73% after resection, 43% after RFA plus resection, and 37% after RFA alone. Patients who underwent RFA had a survival advantage over patients who underwent biopsy with or without chemotherapy. Four recent nonrandomized retrospective studies (Aloia et al, 2006; Hur et al, 2009; Park et al, 2008; White et al, 2007) demonstrated a survival benefit in patients undergoing resection versus RFA; the 5-year survival was between 48% and 71% for resection and between 19% and 27% for RFA (Table 85C.2). The survival analyses in these studies are limited by differences in patient selection, follow-up time, tumor type, and RFA approach, which make them difficult to compare.

Radiofrequency Ablation of Hepatocellular Carcinoma (See Chapter 80)

Locoregional methods for ablation of HCC include percutaneous ethanol ablation (PEI), chemoembolization, cryosurgery, and RFA, although RFA offers many advantages over PEI and cryoablation. In general, PEI requires multiple treatments and needle insertions to treat a single lesion, whereas RFA can treat the entire tumor with one or two probe insertions. Two randomized trials (Lencioni et al, 2003; Lin et al, 2005) have demonstrated superiority over PEI. The 2-year disease-free survival (DFS) was 96% in patients treated with RFA compared with 62% in patients treated with PEI (Lencioni et al, 2003). Similarly, Lin and colleagues (2005) demonstrated that in patients with HCC less than 3 cm in size, the 3-year DFS was superior in those treated with RFA. When compared with cryoablation, RFA is associated with less blood loss, less thrombocytopenia, and a shorter hospital stay (Bilchik et al, 2000). Cryoablation also carries the risk of a systemic inflammatory response, which can result in renal insufficiency, coagulopathy, hypotension, and death. This type of systemic response has not been reported with RFA.

Clinical trials of RFA for HCC have shown promising results (see Table 85C.1). Livraghi and colleagues (2008) demonstrated a local recurrence rate of only 2.8% at a median follow-up of 31 months for tumors smaller than 2 cm. Poon and colleagues (2004a) achieved a complete response rate of 91% for RFA of large (>3 cm) HCC and rates of local recurrence, distant intrahepatic recurrence, and extrahepatic metastasis were independent of tumor size.

Radiofrequency Ablation Versus Resection for Hepatocellular Carcinoma

Only two prospective randomized controlled trials have been done of RFA versus resection for the treatment of primary liver carcinoma (see Chapter 80). Chen and colleagues (2006) randomized 180 patients with a solitary HCC smaller than 5 cm to either resection or percutaneous RFA. The 4-year overall survival was 68% in the RFA group and 64% in the resection group. Local recurrence rates were also similar, with less morbidity in the RFA group. Lu and colleagues (2006) randomized 105 patients with either a solitary HCC tumor smaller than 5 cm or fewer than three tumors less than 3 cm in size to either a partial hepatectomy or percutaneous RFA and found that 3-year survival rates were similar in both groups (Table 85C.3),

Table 85C.3

Radiofrequency Ablation vs. Resection for Hepatocellular Carcinoma

Study	Patients	Morbidity (%)	Disease-Free Survival (%)	Overall Survival (%)
Chen et al, 2006*†	RFA: 71	4.2	46.4	67.9
	Resection: 90	55.6	51.6	64.0

but hospital stay and blood transfusions were significantly reduced in the RFA group.

Conflicting result have been reported in several nonrandomized studies (Hong et al, 2005; Lupo et al, 2007; Montorsi et al, 2005) that demonstrate therapeutic equivalence; others report a higher local recurrence rate and reduced survival in the RFA group (Vivarelli et al, 2004). This study was performed at two different centers; RFA was performed at one center and resection at the other. Overall and disease-free survivals were significantly better after resection; however, patients treated with RFA had more liver lesions and a higher CTP classification, both of which may have influenced outcome.

Guglielmi and colleagues (2008) also demonstrated that in HCC larger than 3 cm, significant improvement in survival was seen in patients undergoing surgical resection, but this did not translate to tumors smaller than 3 cm, nor did it apply to patients with multiple tumors.

Radiofrequency Ablation for Recurrent Hepatocellular Carcinoma

After resection or ablative therapies, most patients with HCC will succumb to progressive or recurrent liver disease. Hepatic resection is rarely feasible because of inadequate hepatic reserve, making RFA an effective therapeutic alternative. Taura and colleagues (2006) compared 610 patients who underwent a liver resection before and after 1990. The improved 5-year survival in the latter group (22% vs. 12%) was attributed to percutaneous RFA for intrahepatic recurrence. Similarly, Yang and colleagues (2006) demonstrated a survival benefit in 41 patients with recurrent HCC treated with percutaneous RFA. These studies suggest that RFA is effective in the management of recurrent HCC after resection, and RFA may be the treatment of choice for carefully selected patients with recurrent hepatic disease (Fig. 85C.8).

Radiofrequency Ablation as a Bridge to Transplantation (See Chapter 97D)

Many patients with HCC will succumb to liver failure because of a shortage of donors or will be removed from the transplant waiting list because of tumor progression; indeed, the dropout rate within a year has been reported as high as 38% (Yao et al, 2004). RFA has effectively been used as a bridge to transplantation. At a mean follow-up of 12.7 months, Lu and colleagues (2005) reported a dropout rate of only 5.8 months and 14% at a follow-up of 11.9 months (Brillet et al, 2006).

These encouraging data suggest that RFA is one modality that may be considered for prolonged waiting times. The impact on overall survival is less clear; however, one prospective study of patients with HCC awaiting transplantation undergoing RFA showed no survival benefit compared with the observation group (Porrett et al, 2006).

Tumor Response and Recurrence

CT or MRI is typically used to evaluate response rates (see Chapters 16 and 17); US does not accurately predict the extent of necrosis following RFA and should not be used to determine response. CT with contrast enhancement reveals a hypovascular ablated field with a rim of hypervascular inflammatory tissue; the rim enhancement area should disappear over several months time as inflammation resolves, and the treatment area should encompass the tumor and at least a 1-cm rim of normal tissue. Comparing preoperative imaging to postoperative imaging is important to determine that the tumor was adequately treated. Patients should receive serial CT scans after RFA to identify recurrences, which appear as irregular, nonenhancing areas on contrast CT.

Complete and Incomplete Response to Radiofrequency Ablation

Response rates vary from 48% to 98% across studies, in part because of differences in the size of treated lesions. Livraghi and colleagues (1999, 2000) evaluated percutaneous RFA in patients with HCC. The rate of complete response was 48% for tumors larger than 3 cm (2000), but it jumped to 90% for smaller tumors (1999), and the success rate was lower for infiltrating versus noninfiltrating HCCs. Similarly, Lencioni and colleagues (1998) found a statistically significant difference in response rates to percutaneous RFA for metastatic liver lesions larger than 3 cm (53%) versus those smaller than 3 cm (87%). Larger lesions typically require overlapping ablations, and areas of treated tumor may obscure US imaging of untreated tumor and result in higher treatment failures and recurrences.

The approach to RFA will also influence response rates (see Table 85C.1). Curley and colleagues (2000) reported that 6 of 76 patients who underwent percutaneous RFA had an incomplete response, whereas all 34 patients who underwent laparoscopic or open RFA had a complete response. This difference might be explained by better hepatic imaging with intraoperative US during laparoscopy or celiotomy than with transabdominal US during percutaneous RFA. Another possibility is that intraoperative probe positioning may be more accurate than percutaneous placement of the probe.

Tumor location adjacent to large vessels also influences response rates. Blood flow from large vessels will create a heat-sink effect that cools surrounding tissue and increases the temperature necessary for complete ablation. Large vessels are resistant to high temperatures that can damage surrounding tissue. Lu and colleagues (2002) found that porcine vessels smaller than 3 mm thrombosed or necrosed during RFA, but those larger than 5 mm were not affected. In another porcine model, vascular occlusion during RFA increased the volume of necrosis and prolonged the exposure of tissue to high temperatures (Chinn et al, 2001). De Baere and colleagues (2002) evaluated vascular inflow occlusion in patients undergoing RFA of tumors that were large (>35 mm) or near large blood vessels and found that balloon inflow occlusion significantly increased the area of ablation. These studies support the use of a Pringle maneuver to more effectively ablate tumors near major blood vessels and improve response rates. The use of RFA combined with hepatic artery embolization or chemoembolization is discussed in Chapter 83.

Rates of Recurrence at the Ablation Site

Recurrence rates are difficult to interpret across studies (Table 85C.4). Some authors report recurrences after complete ablation as determined by early postoperative CT or MRI, whereas others do not confirm complete response by postoperative imaging and report recurrences based on follow-up imaging. Investigators may report recurrence rates within the whole liver, rather than recurrence rates at the site of ablation, and the length of follow-up also impacts the recurrence rate. Bowles and colleagues (2001) evaluated 76 patients undergoing RFA of 328 tumors. Sixteen patients underwent repeated ablation for

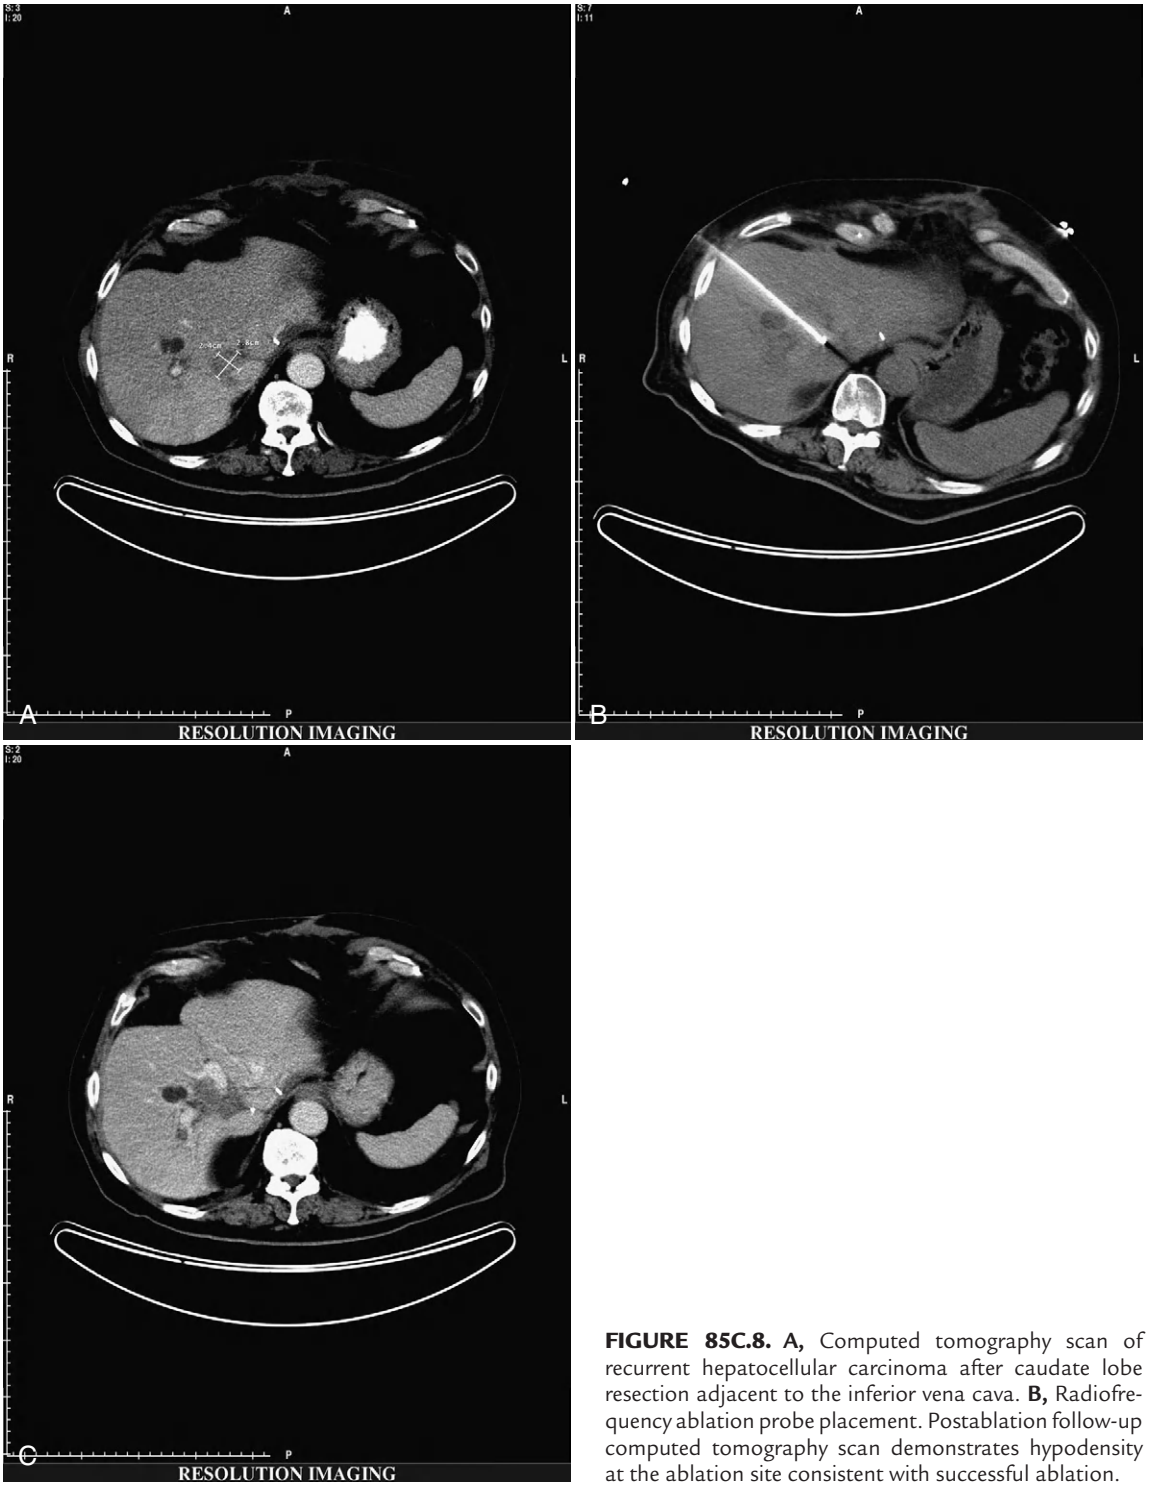

FIGURE 85C.8. A, Computed tomography scan of recurrent hepatocellular carcinoma after caudate lobe resection adjacent to the inferior vena cava. **B,** Radiofrequency ablation probe placement. Postablation follow-up computed tomography scan demonstrates hypodensity at the ablation site consistent with successful ablation.

recurrences or new lesions, and 30 recurrences were reported at the site of a prior ablation. Patients with large tumors, tumor vascular invasion, and hepatic dysfunction had a statistically higher recurrence rate. Solbiati et al (2001) evaluated 117 patients undergoing percutaneous RFA of colorectal metastases; time to local recurrence and frequency of recurrences were influenced by lesion size. Similarly, we found that tumor size significantly influenced local recurrence of metastatic disease, independent of RFA technique (Wood et al, 2000; Bleicher et al, 2003). No study has shown that differences in technique influence the rate of recurrence after a complete response.

Complications of Radiofrequency Ablation

Reported morbidity and mortality rates associated with RFA (Table 85C.5) can be difficult to interpret, in part because

Table 85C.4

Local Recurrence After Radiofrequency Ablation of Hepatic Tumors

Gillams, 2008	38	Colorectal	Percutaneous	40 (42)

technical approaches vary. Some investigators combine RFA with other treatments, such as liver resection, but addition of a second procedure may inflate the complication rate. Ablation of multiple tumors also increases the risk of complications such as bleeding or bile leak. Early studies often used multiple sequential RFAs for treatment of a single hepatic tumor, because the monopolar electrode gave a smaller thermal ablation field than the current cluster electrodes. The multiple ablations required to destroy larger tumors increased the potential for complications.

Unfortunately, the reporting of morbidities is not standardized. Some authors regard low-grade fevers, transient liver function test elevations, small pleural effusions, and right upper quadrant pain as minor complications, whereas others believe these are expected events that should not be reported. As expected, studies undertaken at institutions with skilled interventionalists or surgeons report fewer complications. Variations in patient selection and disease type also confound interpretation of results: for example, patients with HCC have different comorbid factors than those with colorectal metastases, and a patient's preprocedural state may influence the outcome of RFA.

Direct complications of RFA include biloma, biliary fistula, ascites, hepatic insufficiency, arteriovenous fistula, symptomatic pleural effusion, abscess, pain, hemorrhage, hydropneumothorax, pneumothorax, and thermal injury to surrounding structures. Burns related to grounding pads have also been reported, but these can be avoided by proper positioning of the pads, by using more pads for longer ablations, and by carefully following the manufacturer's directions. Other potential complications are those related to an operative procedure, such as myocardial infarction, cardiac arrhythmias, and pneumonia.

As illustrated by the following two cases, RFA should be undertaken only by skilled physicians able to identify and manage its complications and only at centers equipped with appropriate staff and equipment for acute care. Figure 85C.9 shows a bile duct injury caused by RFA of a colorectal cancer metastasis near the porta hepatis. The injury was treated with endoscopic retrograde cholangiopancreatography (ERCP) and biliary stenting. Figure 85C.10 shows a hepatic artery pseudoaneurysm attributed to RFA of liver metastases. This was successfully treated with embolization by a skilled interventionalist.

The best way to avoid potential complications of percutaneous RFA is to understand its technical limitations. A large multicenter study reported morbidity and mortality rates of 0.3% and 2.2%, respectively (Livraghi, 2003b). In this study, about 33% of all deaths and 10% of morbidities were associated with gastrointestinal thermal injury and perforation. Patients with prior abdominal surgeries resulting in adhesions and those with peripheral liver tumors had an increased risk for gastrointestinal injury during percutaneous ablation. The authors recommended consideration of open or laparoscopic RFA, instead of percutaneous RFA, for tumors within 1 cm of the liver edge adjacent to bowel.

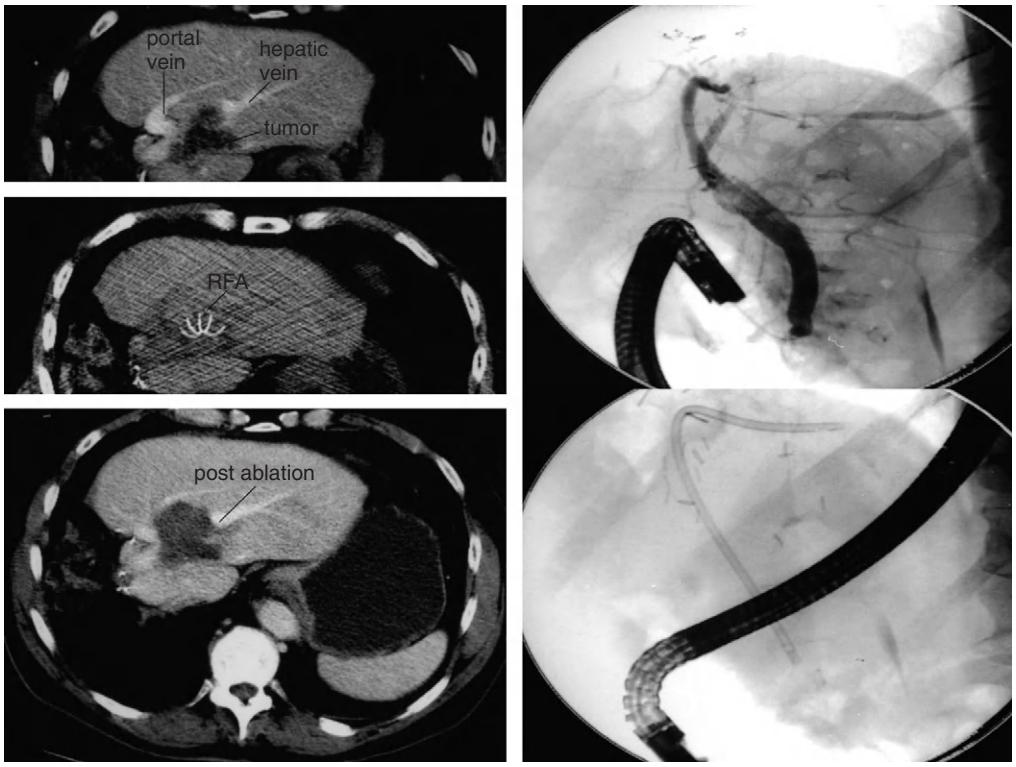

FIGURE 85C.9. Biliary injury following radiofrequency ablation treated with stent placement. RFA, radiofrequency ablation.

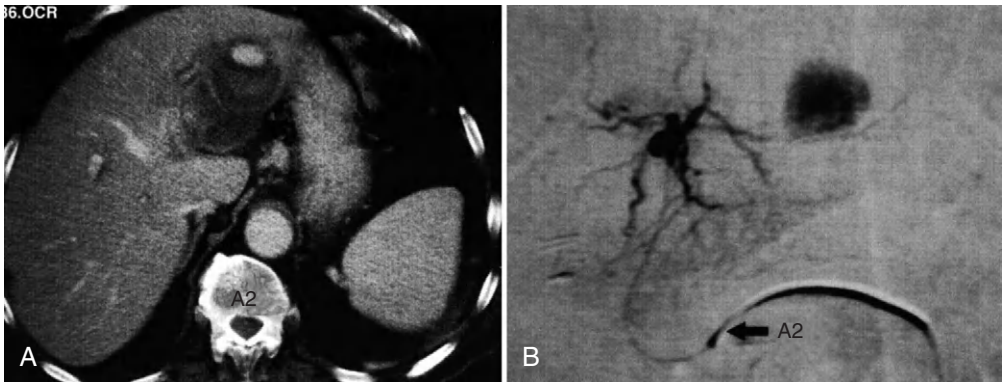

FIGURE 85C.10. Hepatic artery pseudoaneurysm following radiofrequency ablation.

Injury to the diaphragm is also a potential complication during percutaneous RFA, especially when tumors at the dome of the liver are treated. In an animal model, carbon monoxide was introduced into the peritoneal cavity to separate the diaphragm and the liver; although this reduced severe diaphragmatic injury during superficial hepatic RFA (Raman et al, 2004), the technique needs further clinical testing.

Abscess, one of the most frequent complications of RFA, typically occurs 1 week after ablation and requires percutaneous or surgical drainage (de Baere et al, 2003; Wood et al, 2000). Patients with bilioenteric anastomosis or biliary stenting appear to have a higher rate of abscess formation. All patients undergoing RFA should receive periprocedural antibiotics that cover coliforms as well as skin flora, and temperature and leukocyte counts should be followed after the procedure. Normally, low-grade fever and fatigue may occur immediately after RFA for up to 7 to 10 days, a so-called *postablation syndrome*; however, any persistent significant fever or elevation of white blood cell count should prompt CT imaging for possible hepatic abscess.

Reports of tumor seeding vary from 0.5% to 12% (de Baere et al, 2003; de Sio et al, 2001; Llovet et al, 2001), possibly reflecting differences in follow-up. Llovet and colleagues (2001) found that tumor seeding during RFA was related to subcapsular tumor location and poor tumor differentiation. Recent tumor biopsy, multiple needle insertions, and tumor hemorrhage during treatment may also increase the risk of needle-tract seeding. This complication can be avoided by limiting the number of needle insertions, angling the needle to traverse normal hepatic parenchyma prior to entering the tumor, and cauterizing the tract upon withdrawal of the needle. Nicoli and colleagues (2004) reported rapid diffusion of neoplastic cells after the creation of an arteriovenous fistula following RFA. The authors attributed seeding of tumor cells to the pressure gradient between the high-pressure tumor arteries and the low-pressure portal system; however, this is the only report of this complication in several thousand RFAs to date.

Injury to bile ducts during RFA can result in stenosis and proximal biliary dilation (see Chapter 42). Most physicians agree that tumors within 15 to 20 mm of a major bile duct should not be treated by RFA (Mulier et al, 2002); however, Elias and colleagues (2001) introduced intraductal cooling to prevent RFA-associated biliary stenosis. They infused cooled (4° C) Ringer's lactate through a catheter after choledochotomy. Intraductal cooling was undertaken in 13 patients undergoing RFA of tumors within 6 mm of a central bile duct; one patient had a local recurrence, and one developed biliary stenosis (Elias et al, 2004). Biliary stenting also can prevent biliary injury during ablation of tumors near the bile ducts (Wood et al, 2000).

SUMMARY

RFA can treat primary or metastatic liver tumors with success rates of 90% and little morbidity or mortality. It can be applied via an operative or percutaneous approach. An operative approach allows accurate assessment for the presence of extrahepatic disease and a better evaluation of intrahepatic disease. An operative approach also can isolate the liver from adjacent organs that could be injured during ablation, and it allows placement of the RFA probe in lesions that could not be reached by a percutaneous approach. A percutaneous approach allows the use of CT guidance, contrast-enhanced CT assessment of the ablation, shorter hospital stay, and it can also be performed as an outpatient procedure. Although the proximity of a tumor to certain structures may limit feasibility of percutaneous ablation, several techniques are available to separate adjacent structures from the ablation site. Percutaneous ablation may also be preferred in high-risk patients, those with limited hepatic reserve, or those with recurrent disease.

Two recent randomized trials demonstrate therapeutic equivalence compared with resection in small HCC tumors, but until more prospective studies have been performed, resection remains the initial choice for patients whose disease is confined to the liver. RFA may be an alternative for those unable to undergo resection because of limited hepatic reserve, bilobar disease, or poor medical status; in these cases, RFA can be very successful, and its results may be durable. Although RFA provides local control of metastatic colorectal liver metastases, its impact on survival is unclear. Systemic therapy should be used to treat or prevent other sites of metastatic disease.

As the field of RFA continues to evolve, further improvements in probe technology will allow larger zones of ablation and higher rates of complete response. Newer probes are now able to treat larger lesions with a single ablation, and this new technology will reduce limitations of tumor size on adequate response and recurrence rates. A multidisciplinary team is essential in the selection of appropriate patients for treatment.

CHAPTER 85D

Microwave ablation and emerging technologies for liver tumors

Kwan N. Lau and David A. Iannitti

OVERVIEW

Hepatic malignancies are common, with more than 1 million diagnosed each year worldwide. Tumors can be primary, as with hepatocellular carcinoma (HCC) or intrahepatic cholangiocarcinoma (IHC), or they can be secondary, as with colorectal liver metastases (CLM), neuroendocrine malignancy, or metastases from other primary cancers, such as those of the breast or lung. Many patients come to medical attention with advanced disease that is not amenable to surgical therapy. Unresectable disease carries a poor prognosis, because systemic chemotherapeutic agents and radiation therapy have limited efficacy in treating many of these diseases. As a result of the limited treatment options in this particular patient population, liver-directed regional therapies have evolved that include selective internal radiation therapy (Cianni et al, 2009), transarterial chemoembolization (TACE) (Rathore et al, 2010), portal vein embolization (PVE) (Manizate et al, 2010), and ablative technologies.

Ablation is not a new concept; it has been used in medicine for more than 100 years, initially as a therapy designed for patients with unresectable lesions (Halsted, 1894); however, advancements in medicine have transformed ablation into an effective locoregional therapy with an improved perioperative profile for morbidity and mortality and options of performing the procedure using an open, laparoscopic, or percutaneous approach. It has evolved from injecting ethanol (Uflacker et al, 1986) to employing different energy sources, such as cryoablation (Iannitti et al, 1998), radiofrequency ablation (RFA) (Iannitti et al, 2002), and microwave ablation (MWA) (Simon et al, 2006) to achieve tumor destruction (see Chapters 85A through 85C). Current ablation therapies also provide the flexibility to perform procedures in an ambulatory setting to allow treatment of patients whose disease is not amenable to resection. The application of ablative technology does not necessarily preclude patients from future operations, nor does it compromise their chance for transplantation (Casaccia et al, 2009); however, complications resulting from ill-advised ablative procedures may complicate subsequent attempts at resection.

The most common thermoablative technologies used clinically are RFA and MWA. Both modalities produce tissue destruction, but the physical properties of the energy sources are different. MWA is a relatively new modality compared with RFA, and it provides important physical advantages over RFA.

Thermoablation is an effective modality, because irreversible thermal destruction of tissue occurs when temperatures above 50° C are maintained for an interval of 4 to 6 minutes (Larson et al, 1996). Vaporization and carbonization occur when tissue temperature is raised rapidly to over 100° C. Effective ablation relies on an adequate margin around the lesion, ideally 1 cm, to ensure complete eradication of microscopic foci. Large ablation volume may require multiple applications of thermal energy.

PHYSICS OF MICROWAVE ENERGY

MWA that achieves heat destruction of tissue involves both active and passive heating. The active heating process of microwave energy requires the presence of dielectric molecules, such as water, to function. MWA is an excellent option for thermal ablation of solid organs, such as the liver (Brace, 2009a, 2009b). Clinical microwave energy operates at a frequency of 900 MHz to 10 GHz (Fig. 85D.1), which is much higher than radiofrequency (460 to 480 kHz). As a dipole molecule, water is affected by the applied electromagnetic field broadcasted by the microwave antenna. This property is called *dielectric permittivity* (ε). Water molecules orient themselves to the rapidly changing polarity of the electromagnetic field, and vibratory energy generates heat production. This process is called *dielectric hysteresis*. Microwaves emit nonionizing radiation for heating, and this produces homogeneous heating within the field regardless of the tissue types; this distinguishes MWA from monopolar RFA in terms of mechanism of heating and makes it a clinically superior method for ablation. The passive phase of microwave heating is by conduction of heat beyond the active heating zone and is susceptible to local tissue factors, such as heat and current sinking, which will be discussed later in this chapter.

The MWA systems used in the United States today are 915 MHz, 2.45 GHz, and 9.2 GHz; however, only the 915-MHz and 2.45-GHz systems are commercially available for tumor ablation. The 915-MHz and 2.45-GHz systems are more effective for large tissue destruction than monopolar RFA, and the 915-GHz system is currently under investigation for ablating lesions in the breast. Microwave energy can be generated through a magnetron or solid-state amplifier (Brace, 2009a, 2009b), and the antenna broadcasts the electromagnetic energy to the target tissue. The coaxial cable consists of an inner and outer conductor, and dielectric material is placed between the two layers. At its tip, the outer conductor is stopped to expose the inner conductor for broadcasting the microwave energy (Fig. 85D.2). This inner conductor is covered in a ceramic pointed tip for insertion into the tissue, and microwave energy can pass freely through the ceramic. The power loss is influenced by power output, cable diameter, and antenna design. Given its broadcasting characteristic, the microwave system does not require a grounding pad.

Large ablative volume can be created by increasing the power and duration of the application. Several factors influence the final ablative size, including water content of the tissue, power output at the generator, power loss at the cable, antenna

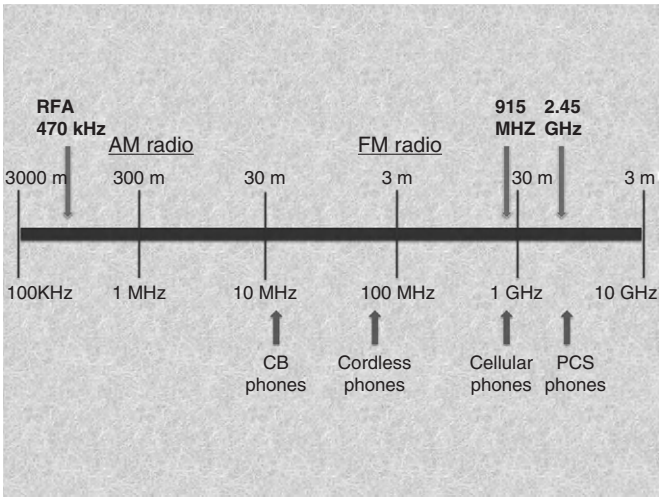

FIGURE 85D.1. Electromagnetic spectrum.

design, formation of clustered antennae, and the number of applications. Various tissue types exhibit different responses to microwave energy, and liver tissue usually exhibits a noticeable response to MWA (Hines-Peralta et al, 2006). Surgeons must understand the relationship between the different properties of tissue and the energy modality used to achieve successful ablation.

LOCAL TISSUE FACTORS THAT AFFECT THERMOABLATION

Local tissue factors play an important role in the final ablation volume and shape. The tissue's electric conductivity (σ) and dielectric permittivity (ε) influence the deposition of energy for radiofrequency and microwave, respectively, which explains why MWA is more effective than RFA in depositing energy across vessels and liver parenchyma.

Modalities using radiofrequency rely heavily on the tissue's electric conductivity, and heat is generated from ionic agitation of the molecules in the tissue. The tip of the monopolar RFA probe and the grounding pad forms a closed circuit, and alternate current passes between them. The current density is higher in the tip, compared with that of the grounding pad, because of the difference in surface area. The transfer of heat to the surrounding tissue is through conduction and is proportional to the amount of current deposited; however, the rate of perfusion to the target tissue could significantly affect the final heat transfer.

Coagulation necrosis of tissue is proportional to energy deposition minus heat loss (Goldberg et al, 2000). Hence, local tissue factors such as blood flow and tissue temperature affect energy deposition. Close proximity to blood vessels causes diversion of the current and decreases the amount of energy generated from the current; this is termed *current sinking*. The final ablative size is affected, because radiofrequency relies on heat transfer from the tip of the applicator, and the cooling from the vessel shunts the heat energy away; this phenomenon is termed *heat sinking*. Microwave technology also encounters such limitations but to a much lesser extent (Stauffer et al, 2003), because the propagation of microwave energy relies on the dielectric permittivity of the tissue, and it stays fairly constant along the broadcasted electromagnetic field (Table 85D.1). It can overcome the effect of current and heat sinking within its field and result in deeper heat penetration and more uniform ablative size. Outside the active heating zone, heat is propagated by conduction and is therefore susceptible to local factors such as heat sinking.

Another consideration is tissue desiccation and charring by the applicator during the heating process. Both conditions can significantly decrease the final ablative volume for RFA, because it requires a complete electric circuit to function. Acting as electric insulators, the resultant increase of impedance decreases the amount of current deposition and thereby decreases heat

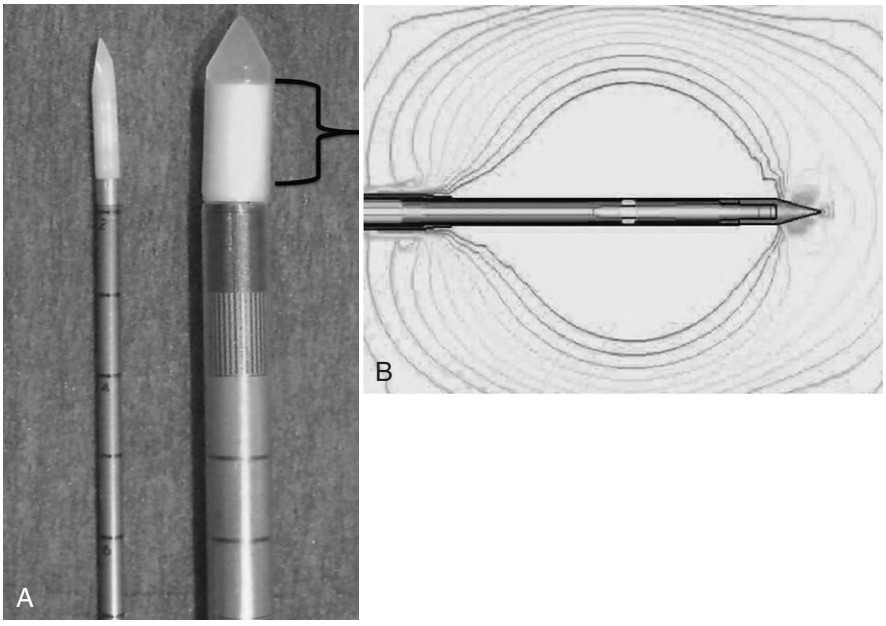

FIGURE 85D.2. A, *Left*, Microwave antenna as shown; *the bracket* points to the area from which microwave energy is broadcasted at the ceramic shield just beyond the termination of the outer conductor. **B,** Computer illustration of the projected microwave field from the microwave antenna.

Table 85D.1

Conductivity and Permittivity Among Various Tissues Compared with Liver Tissue

	Conductivity 470 KHz	Permittivity at 915 MHz	Permittivity at 2.45 GHz
Air	NA	0.02	0.02
Blood	5.14	1.79	1.51
Gallbladder	6.22	1.46	1.22
Bile	9.67	2.14	1.66
Liver	1	1	1

production. Moreover, if the target temperature is reached rapidly, above 100° C, the intracellular content vaporizes and carbonizes. The gas formation acts as an electric insulator that increases the impedance and hinders the heat diffusion (Dadd et al, 1996); both decrease the amount of current deposition and result in a less uniform ablative zone. Unlike radiofrequency, microwaves broadcast energy throughout the electromagnetic field and can achieve high power density uniformly, which results in deeper heat penetration and a more consistent ablative size.

915 MHz Versus 2.45 GHz

MWA, like RFA, can be carried out via three approaches: 1) open, 2) laparoscopic, and 3) percutaneous. The first clinical microwave system, Microtaze (Heiwa Electronics Industry, Tokyo), was developed in the 1990s. Clinical use was limited because of its 1.5-cm ablation zone (Saitsu et al, 1991, 1993), but 915-MHz and 2.45-GHz systems are currently available (Fig. 85D.3). Both systems were introduced to the United States market in 2008: the Viva Wave system (Valleylab, Boulder, CO) and the MTA microwave system (Microsulis Medical, Denmead, UK). Advancements in microwave technology and better antenna design have significantly improved ablative capabilities, and large-volume ablation can be reliably achieved.

The Viva Wave system uses a 915-MHz generator, and its power output can reach up to 45 W. It carries two different sized antennae for open and laparoscopic/percutaneous use and usually employs a three-antennae cluster design for achieving a 5-cm zone of ablation; it requires three generators firing in a nonsynchronized fashion. A saline-infused cool-shaft antenna is also available to reduce the incidence of skin burn during transcutaneous antenna placement. Another system was approved by the Food and Drug Administration (FDA) in 2008, the Micro-Therm X-100 (BSD Medical, Salt Lake City, UT). This is the only system with synchronized power output that uses multiple antennae.

The Acculis MTA (Microsulis Medical) is a 2.45-GHz system that uses a 5-mm antenna for its open application. It produces a 5-cm ablation zone reliably in 4 minutes and up to 8 cm in 8 minutes, with one application by a single antenna at 100 W. Currently under consideration by the FDA for approval is a 1.8-mm cool-shaft antenna for the laparoscopic/percutaneous approach.

The 2.45-GHz system is used more often in Europe and Asia, whereas the 915-mHz system is used in the United States; both are capable of producing an adequate ablation volume. The 2.45-GHz system uses a single antenna, and the 915-mHz employs a multiantenna array powered by separate generators. An advantage of using multiple antennae in different formations is to achieve various shapes and sizes of ablations (Simon et al, 2006). The microwave antenna is not composed of alloy but is coated with polytetrafluoroethylene (PTFE). It is not as rigid as the RFA metal applicator, and care should be taken during manipulation of the microwave antenna to prevent breakage at the tip of the antenna.

TECHNICAL CONSIDERATION FOR PERFORMING MICROWAVE ABLATION

Three approaches can be used for MWA: 1) open, 2) laparoscopic, and 3) percutaneous. The underlying principles to achieve successful ablation are the same. Each patient represents a unique circumstance, and the chosen approach should be tailored to the patient's need and the skill level of the practitioner. Lesions that are located anteriorly and not adjacent to a major pedicle can be ablated percutaneously using ultrasound (US), magnetic resonance imaging (MRI), or computed tomographic (CT) guidance. If the lesion is located deep in the liver, at the dome, next to a major pedicle, or adjacent to other structures such as the diaphragm and colon, ablation of these lesions should be performed surgically. The choice of an open or laparoscopic MWA is determined by the patient's history of celiotomy and the surgeon's level of advanced laparoscopic skill. If an open approach is used, it is best done through a subcostal or midline laparotomy.

Regardless of the approach, the patient is usually positioned supine on the table. The key of a successful ablative session is adequate exposure of the liver by taking down the suspensory attachments and performing a methodic evaluation of the liver by intraoperative US. All eight segments of the liver must be evaluated to ensure no lesions are missed, and it is helpful to review the preoperative imaging and formulate a table with information regarding the location and size of each lesion.

Once all lesions are identified, the plane of the needle tract should be evaluated to ensure that it does not cross a portal or major hepatic vein pedicle. The antenna is then deployed to treat the lesion. Close attention is paid to ensure no other structure is in the vicinity of the microwave field. Usually, the power and duration of each application is based on the size of the lesion and its proximity to major vessels, and 915 MHz can reliably reproduce a 5-cm ablative zone at 45 W for 10 minutes, and 2.45 GHz can achieve the same result with one antenna at 100 W for 5 minutes. The deepest lesion is usually treated first; in a staged procedure, the most difficult lesion is treated first.

Another consideration for ablating large lesions is how to overlap the zone of ablation. This is clinically challenging, given that the final ablative area is three-dimensional (3D), and the intraoperative US provides two-dimensional (2D) information in real time. Hence, a disciplined approach is needed to achieve adequate overlapping. Usually, the ablation is started at the most central medial portion of the lesion and progresses with the repeat ablations in an upward and outward fashion.

CLINICAL RESULTS OF MICROWAVE ABLATION FOR HEPATOCELLULAR CARCINOMA (SEE CHAPTER 80)

The first open microwave application for tumor destruction was reported in the early 1990s in Japan, when Seki and colleagues (1994) reported a series of 24 patients with HCC with a 92% survival at 3 years. The application of microwave technology has since expanded to treat colorectal liver metastases and metastases from other primary tumors; this will be discussed later in this chapter.

Clinical trials have evaluated the efficacy of MWA for treating HCC. In a Phase I trial that evaluated the safety of MWA, 11 patients underwent hepatoma ablation followed by resection (Simon et al, 2006). The complete destruction of viable tumor cells was confirmed by immunohistochemistry in the ablation zone. The average volume of ablation was 5.5 cm in diameter using three clustered antennae at 45 W for 10 minutes. The Phase II trial enrolled 87 patients for whom MWA was the primary treatment (Iannitti et al, 2007). In 94 ablation sessions, 224 lesions with a mean diameter of 3.6 cm were treated (Fig. 85D.4). The local recurrence rate was 2.7%, and regional recurrence was 43% during 19 months of follow-up; overall mortality rate was 2.3% with no procedure-related deaths. Major complications included two patients with postoperative fluid collections that required a drainage procedure and five patients with minor skin burn at the needle tract. This clinical trial proved that using MWA for hepatic tumors is a safe, effective treatment option with a low complication rate. Multiple series were subsequently published reaffirming the role of MWA in treating liver lesions (Table 85D.2; Kawamoto et al, 2005; Martin et al, 2009).

Clinical Results of Colorectal Liver Metastases (See Chapter 81A)

The most common hepatic lesions result from metastatic colorectal cancer (CRC). More than 50,000 patients die from diseases related to CRC yearly, and up to 60% of patients with CRC have metastasis to other organs. Despite advances in neoadjuvant therapy, roughly 60% of the patients are not candidates for hepatic resection, which remains the single most effective therapy. The 3-year survival rate is 30% for patients undergoing open resection, and the recurrence rate at 3 years is 54% (Wagner et al, 1984; Scheele et al, 1990). The low survival rate and high recurrence rate are due to the multicentricity of the disease and the presence of systemic microscopic foci.

The clinical results of MWA for colorectal liver metastasis are encouraging. The 3-year survival and local recurrence rate from multiple clinical series are comparable with published data from open resection (Liang et al, 2006; Shibata et al, 2000; Simon et al, 2006). In a small randomized controlled trial (RCT) with 30 patients, the overall survival was similar between the hepatectomy and MWA arms (Shibata et al, 2000). The lack of a large RCT makes a direct comparison of open resection with MWA difficult, and it may be difficult to obtain institutional review board approval for such a study in the United States on ethnical grounds.

The availability of MWA for patients with metastatic CRC and improvements in chemotherapy may improve overall survival. Patient management should involve a multidisciplinary team to determine the best treatment plan.

Clinical Results for Neuroendocrine Tumors and Metastasis from Other Primary Tumors (See Chapter 81B)

Lesions arising from neuroendocrine or other primary tumors should be evaluated for resection when clinically appropriate; however, curative resection is not possible in about 90% of the cases (Knigge et al, 2008). The focus of treatment should be palliative, and symptom relief can usually be achieved. Cytoreduction of the tumor can improve survival, with 5-year survival ranging from 40% to 60%. Most patients can be symptom free for 2 years (Weitz et al, 2005). Careful selection of therapeutic options combining different liver-directed modalities such as

Published Series Reporting Microwave Ablation Outcomes

First Author	Year	No. Patients	Frequency	Type of Study	Morbidity (%)	Mortality (%)	Local Recurrence (%)	Follow-up (mo)
Martin	2010	n = 100 HCC = 17 CLM = 50 Other = 33	915 MHz	Nonrandomized control trial	29	0	2	36
Liang	2009	n = 1136 HCC = 854 CLM = 86 Other = 196	2.45 GHz	Clinical case series	2.6	0.2	NA	NA
Iannitti	2007	n = 87 HCC = 23 CLM = 33 Other = 31	915 MHz	Nonrandomized control trial	16	2.3	2.7	19
Kawamoto	2005	n = 69 HCC = 69	2.45 GHz	Nonrandomized control trial	2.8	0	17.4	54

HCC, hepatocellular carcinoma; CLM, colorectal liver metastases; NA, not applicable

ablation, chemoembolization, selective internal radiation therapy (SIRT), and embolization may reduce the tumor burden and improve overall survival.

MICROWAVE ABLATION: SPECIFIC COMPLICATIONS AND FUTURE APPLICATIONS

MWA heats the entire electromagnetic field, and several potential complications may arise from this modality. Technical advances have made ablation near large vessels possible, which increases the potential for thrombus in the hepatic vein. The true incidence of hepatic vein thrombus (HVT) related to MWA is unknown. We identified three such cases in 122 MWA applications, all without symptoms, and the thrombus resolved after anticoagulation. We have used a porcine model to reproduce HVT, and it appears that puncturing the hepatic vein during MWA is a risk factor (Sindram, 2011). Surprisingly, the proximity of MWA to the hepatic vein is only associated with minimal endothelial damage.

Skin burn at the needle tract during laparoscopic/percutaneous application is an MWA-specific injury that has been reported in the literature (Iannitti et al, 2007). It can occur when the power output is increased, and the outer conductor does not sufficiently shield the microwave energy (Liang et al, 2009). The risk of skin burn can be minimized by reducing the inward angulation of clustered antennae, spacing antennae 1.5 cm apart, and applying an internal cooling tip with running saline to reduce the temperature (Sindram, 2011).

All structures within the microwave field are heated, so it is essential to be aware of critical structures within the field, such as the diaphragm and heart. Further research is ongoing for development of a microwave shield to potentially decrease risks to vital organs.

Another logical extension of microwave technology, similar to radiofrequency, is using the microwave energy to coagulate liver parenchyma before resection. Radiofrequency devices are commercially available for this purpose but require a longer application time.

Microwave technology offers superior physical properties compared with radiofrequency, and it makes ablating larger lesions in the liver possible. One series reported that large-volume ablation can be effectively and safely done with a recurrence rate of 22% for HCC lesions in sizes ranging from 3 to 7 cm (Yin et al, 2009).

EMERGING TECHNOLOGIES

The ideal ablation system should be safe, cost effective, and have reproducible ablation results and a tissue-specific applicator design with real-time feedback for dedicated algorithms to achieve optimal ablation size. Although no current system fits these criteria perfectly, new technologies that show great promise are on the horizon.

Evaluation of Surgical Device Innovation

Surgical innovation is rapid, and new technologies are developed so quickly that clinical validation is sparse. Traditionally, many surgical procedures were developed on a trial and error basis, which raised concern for patient safety during product development (Ergina et al, 2009). A framework to evaluate the safety of new devices is necessary to protect patients, but the framework must be flexible, so that regulatory bodies do not obstruct innovation. Surgeons involved in product development must have a thorough understanding of how the device works to minimize patient risk. The rapid emergence of different ablation modalities has made comparison among various technologies challenging. The introduction of a new device is usually based on case series to establish safety, followed by an RCT to prove its efficacy, before it is eventually approved by the FDA.

To critically evaluate ablation, a standardized evaluation of patient demographics that include preoperative chemotherapy, TACE, or other therapy should be recorded for a matched comparison (Barkun et al, 2009). The outcomes of ablation should be defined (local and regional recurrence, etc.) and the follow-up protocol outlined so results of different trials can be compared. Moreover, the complication profile should be uniform and based on a system similar to the Clavien-Dindo

classification for surgical complications (Clavien et al, 2009). An online database should be created with dedicated personnel to report data. These measures would facilitate collaboration of different institutions and provide more reliable data for patient safety and product development.

Real-Time Three-Dimensional Virtual Reality–Guided Targeting

The advancement in ablation technology has proved that large-volume ablation is a reality, but this capacity is useless if the targeting of a lesion is inaccurate. The complete destruction of a lesion requires an adequate margin, and achievement of this margin often requires multiple applications for adequate overlap of the ablation zone. The use of 2D ultrasound has greatly enhanced the ability to identify a target lesion, but deploying the microwave requires complex coordination between interpreting the information on the monitor and positioning the applicator to track the course from the parenchyma into the tumors. This complicated process has a learning curve, and even in the hands of an expert, improper applicator position can occur. So achieving an adequate 3D overlap of the ablative zone is challenging, especially when only 2D information is available. To aid the surgeon in this process, a real-time 3D system was developed by InnerOptic (Hillsborough, NC). Using either an electromagnetic field generator with sensors or stereoscopic infrared cameras with reflectors, real-time 3D information is generated into virtual reality images and projected on a true 3D stereoscopic screen (Fig. 85D.5). This provides valuable information for targeting lesions, especially from an angle that is out of the plane of the US probe. The safety and accuracy of various procedures such as biopsy, venous catheter placement, and percutaneous ablation might be improved once this system is available commercially.

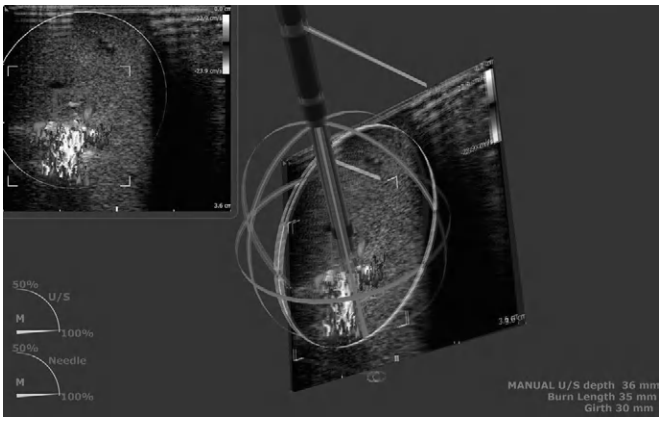

FIGURE 85D.5. Three-dimensional virtual reality image guidance system. Note the computer-generated ablation zone at the tip of the needle.

Other Ablation Modalities

Other modalities are currently under development to provide options for tumor ablation. The use of lasers, US, and pulsed electromagnetic waves are in various stages of development. We will briefly discuss laser interstitial thermotherapy (LITT), high-frequency focused US (HIFU), and irreversible electroporation here.

Laser Interstitial Thermotherapy

The application of lasers as a source of heat is not a new concept. Unlike laser therapy used in other industries, LITT uses a slow heating source, the neodymium:yttrium aluminum garnet (Nd:YAG) diode laser. It induces thermal coagulation by emitting laser light at a wavelength of 1064 nm from a low energy source of 3 to 20 W. After insertion of the laser fiber, LITT uses a slow heating process to prevent tissue coagulation, which reduces the penetration of the laser and limits the size of the ablation. LITT requires the photon of the laser to interact with the chromophores in the tissue to generate heat; hence conditions such as carbonization and vaporization, which decrease optimum penetration, significantly decrease the size of the ablation zone (Izzo, 2003; Sturesson, 1998).

Despite changes in the technology, LITT usually produces a relatively small lesion of 1 to 1.5 cm. Alterations of tip design have included using sapphire-tipped laser fibers, cool-tip applicators, and applications of different quartz diffusers; however, no significant improvement in ablative volume was observed with any of these (Castren-Persons et al, 1992; Heisterkamp et al, 1997). To overcome this deficit, a multifiber system was developed that is capable of producing lesions as large as 7 cm (Izzo, 2003); however, clinical use of this system is not widespread. Case series have reported favorable survival rates of 74% and 30% at 2 and 5 years, respectively (Mack et al, 2001), but no randomized trial has compared LITT with other ablative modalities, and further investigation is needed.

High-Intensity Focused Ultrasound

The application of US for diagnostic purposes is common, and regular transducers usually deliver time-averaged intensities of 0.1 to 100 W/cm^2 with compression and rarefaction pressure of 0.001 to 0.003 MPa, depending on the imaging mode used. US is a noninvasive modality, which makes it an attractive option for thermal ablation. In HIFU, the US beam can be focused to increase its intensity to 100 to 10,000 W/cm^2 to a focal region, with peak compression and rarefaction pressures up to 30 MPa and 10 MPa, respectively. Coagulation necrosis results in a few seconds with focal application of acoustic energy, which is converted to heat energy and is confined to a small volume of only 1 mm in diameter. The advantage of such a focused area is to decrease the undesired effect of thermal spread to adjacent tissue.

HIFU was first used to treat the eye, prostate, and kidney, but further investigation in ablating liver lesions has shown some promising results. A randomized trial compared TACE with HIFU, and a combination HIFU/TACE group showed a survival benefit of 6 months over a TACE-alone group (Wu et al, 2005). Research is ongoing for the treatment of liver lesions using HIFU, and clinical series have shown HIFU to be safe and effective, even near large blood vessels (Li et al, 2007; Zhang et al, 2009).

Irreversible Electroporation

A change in cell permeability caused by pulsed electrical energy, a phenomenon called *electroporation*, has been known for centuries and has been studied extensively in gene therapy and electrochemotherapy. Initially regarded as an undesired side effect, irreversible electroporation (IRE) is now under active

investigation for hepatic tumor ablation (Miller, 2005). IRE works by inducing cell necrosis after application of 1000 to 3000 V for a duration of milliseconds to microseconds (Padma et al, 2009). IRE is in its own class, because it does not involve thermal ablation; hence, local tissue factors such as heat or current sinking do not apply. Currently, no data for human use are available (Lencioni et al, 2010). An IRE system is commercially available now, and clinical investigation is ongoing to evaluate its safety and efficiency.

FUTURE DIRECTIONS

The future of ablation is exciting, and MWA will likely play a more prominent role in thermoablation. The theoretic advantages of its physical properties make it a reliable choice for ablation of liver lesions, especially for lesions larger than 3 cm or those near blood vessels. The addition of other modalities, such as high-intensity focused US and irreversible electroporation, complements MWA and allows practitioners more treatment choices for liver lesions. The emerging technologies, such as a real-time lesion-guidance systems, will increase the accuracy of ablation and may help define niche applications for various ablative modalities.

The continuing evolution of technologies for tumor destruction and the addition of accurate targeting systems will doubtless allow more surgeons to treat unresectable liver cancers with low morbidity and mortality. It is imperative to create a curriculum for upcoming hepatopancreatobiliary surgeons that will help them master ablative therapy and incorporate similar new technologies into practice.

CHAPTER 90B

Hepatic resection for benign disease and for liver and biliary tumors

Shishir K. Maithel, William R. Jarnagin, and Jacques Belghiti

OVERVIEW

Hepatic resection for removal of lesions of the liver may be necessary for a wide variety of conditions (Box 90B.1). Indications for partial hepatectomy include the treatment of primary benign or malignant growths of the liver and biliary tract or metastatic tumors, with the latter being the most common. Hepatic resection also may be necessary in the management of complex or symptomatic cystic disease involving the liver (see Chapters 68 and 69) and to allow access for repair of selected benign biliary strictures (see Chapter 42). Liver resection occasionally is necessary in the management of hepatic trauma. More recently, liver resection in living donors has been used in liver transplantation (see Chapter 98B).

The principles of segmental and subsegmental resection are not new (Nagasue et al, 1985), and they have been developed and refined through the years. Utilization of intraoperative ultrasound (IOUS) (Bismuth & Castaing, 1984; Castaing et al, 1985; Scheele, 1989) to identify intrahepatic structures (see Chapter 21) and a mastery of intrahepatic anatomy are paramount to performing safe resections. This chapter focuses on major resections, including right hepatectomy, left hepatectomy, and extended right (including segment IV) and left hepatectomy (including the right anterior sector). Commonly performed segmental resections, including caudate lobe resection, are briefly described. A more detailed description of segment-oriented resection of the liver is provided in Chapter 92.

Hepatic resection in patients with cirrhosis is further complicated by the presence of portal hypertension and a concomitant functional deficit of the future liver remnant (FLR) (see Chapter 90F). Liver resection for the removal of gallbladder carcinoma and cholangiocarcinoma at the confluence of the bile ducts can be especially troublesome in the postoperative period, because resection is frequently performed in the presence of biliary obstruction, bacterial contamination, and infection.

GENERAL PRINCIPLES

Benign Disease

Partial hepatectomy for the removal of benign tumors or cysts of the liver generally should be performed only for symptomatic patients, in the presence of doubt as to the diagnosis, or for tumors with known malignant potential (see Chapter 79). Removal of normal liver tissue should be kept to a minimum, thus when intervening for benign lesions, use of techniques for enucleation should be considered. Such enucleative methods may be utilized in the management of hemangioma, adenoma, and fibronodular hyperplasia. Enucleation also may be appropriate for tumor debulking of metastatic neuroendocrine tumors. The technique and principles of enucleation are described in the operation of pericystectomy for the removal of hydatid cysts of the liver (see Chapter 68).

Liver resection may be necessary in the management of some complex benign biliary strictures, especially when associated with ipsilateral liver atrophy (see Chapter 42). Some benign biliary conditions that sometimes necessitate resection include intrahepatic stones associated with recurrent pyogenic cholangitis (see Chapter 44) and Caroli disease, a congenital cystic disease of the liver (see Chapters 46 and 69). In these situations, the amount of normal hepatic parenchyma removed should be kept to a minimum in accomplishing the goal of the resection. Liver resection for hydatid disease is discussed in Chapter 68, and resection for hepatic trauma is discussed in Chapter 102.

Malignant Disease

When performing partial hepatectomy for malignant tumors, the guiding principle is to obtain negative margins of resection while maintaining patient safety. Ideally, the closest margin distance from the tumor edge should be approximately 1 cm (Are et al, 2007); however, the margin distance must often be sacrificed, both for patient safety and for preservation of major vascular structures in close proximity to the tumor that are required to sustain the future liver remnant. That said, complete resection with a close margin is still associated with improved survival, and thus the inability to obtain a wide margin based on preoperative imaging should not necessarily be a deterrent to resection (Pawlik et al, 2005; Poultsides et al, 2010). Furthermore, an effort should always be made to perform parenchyma-sparing resections without sacrificing oncologic efficacy.

The difficulty of achieving an adequate margin of clearance when performing wedge resections for peripherally situated tumors should not be underestimated. The deep margin is the most difficult to judge for adequate tumor clearance. Consequently, it has been shown that wedge resections can carry an unacceptable local recurrence rate (DeMatteo et al, 2000; Gall & Scheele, 1986), although this has not been universally observed (Zorzi et al, 2006). Another factor that may compromise wedge resections is the fact that the liver has a tendency to fracture at the interface between tumor and normal parenchyma. This is particularly a problem for hard tumors in a soft liver, as is often the case with metastatic colorectal carcinoma; thus the surgeon must maintain extreme caution during parenchymal transection for wedge resections to avoid a close margin, a problem best averted by transecting along anatomic planes defined by inflow and outflow structures.

Box 90B.1

Most Common Conditions for Which Liver Resection May Be Used

Benign Liver Tumors

Hemangioma
Adenoma
Focal nodular hyperplasia
Cystadenoma

Malignant Liver Tumors

Primary

Hepatocellular carcinoma
Cholangiocarcinoma

Metastatic, arising from

Colorectal cancer
Noncolorectal cancers and neuroendocrine tumors
Tumors directly invading the liver
- Adrenal tumors
- Renal carcinoma
- Gastric cancer
- Colonic cancer
- Retroperitoneal and inferior vena cava sarcoma

Gallbladder Cancer

Hilar Cholangiocarcinoma

Benign Conditions

Intrahepatic biliary strictures/fistulae
Intrahepatic biliary stones
Recurrent pyogenic cholangitis
Caroli disease
Liver cysts/polycystic liver disease
Parasitic cysts

Liver Trauma

Liver Resection in Liver Donors for Transplantation

Patients undergoing palliative resections for metastatic neuroendocrine tumors that are not amenable to complete resection may be good candidates for enucleation, as is often done for benign lesions (see Chapter 81B). Gallbladder carcinoma and cholangiocarcinoma situated at the confluence of the hepatic bile ducts frequently occlude biliary flow, and resection may be compromised not only by the adverse pathophysiology of obstructive jaundice, but also by infection that may have been introduced before operation as a result of either percutaneous or endoscopic stent placement. In addition, perioperative outcome is complicated by the concomitant partial hepatectomy and resection of the extrahepatic biliary apparatus and subsequent biliary reconstruction (see Chapter 50B).

The presence of cirrhosis also introduces unique challenges for performing liver resection. Preoperatively, appropriate patient selection is paramount to ensure that the FLR is adequate and that the patient will be able to tolerate the procedure. Intraoperatively, a firm, nodular, and enlarged liver poses technical difficulties in mobilization and parenchymal transection that may also contribute to increased blood loss secondary to portal hypertension. Postoperatively, the increased risk of liver insufficiency, hepatic failure, and increased susceptibility to infection are major concerns. Thus, resection should be reserved for patients with cirrhosis who have relatively preserved liver function, and the principles of parenchyma-sparing resection should be strictly followed (see Chapter 90F).

Principal Hazards

The main hazards of hepatic resection are biliary leakage and bleeding (see Chapter 25). Biliary leakage is a particular problem in patients in whom biliary reconstruction is necessary, for example, as in the removal of a hilar cholangiocarcinoma. Bleeding from the hepatic veins and the inferior vena cava (IVC) during parenchymal transection is a major concern. Bleeding is more likely to occur during major resection of superiorly and posteriorly placed tumors, where clearance is minimal between the tumor margin and the passage of the hepatic veins into the vena cava, or when tumors are closely adherent or adjacent to the IVC (Fig. 90B.1).

Future Liver Remnant

A healthy, noncirrhotic liver may tolerate a resection of up to 80% of its volume because the liver's enormous regenerative capacity enables functional compensation within a few weeks (see Chapter 5; Blumgart et al, 1971); however, such a favorable response cannot be taken for granted for extended hepatic resections. Only if reduction of the functional liver parenchyma is less than 50% can the risk of clinically significant liver insufficiency be virtually disregarded. Postoperative hepatic reserve is of particular concern after an extended left hepatectomy and when all of the parenchyma to the right of the falciform ligament is removed (extended right hepatectomy, which will be discussed later). Minimal to no risk of postoperative liver failure is present if most of the specimen volume has been replaced by an extensive tumor mass. In such patients, compensatory hypertrophy of the unaffected residual liver already has occurred preoperatively, and the loss of functional parenchyma is limited; however, a comparable volume of resection performed for multiple or unfavorably located smaller lesions carries a much greater risk of postoperative liver failure. Small tumors located adjacent to the inflow or outflow vessels of multiple segments may mandate removal of large amounts of functioning parenchyma.

Recently, some have advocated the liberal use of portal vein embolization (PVE) in this situation (see Chapter 93; Abdalla et al, 2002; Makuuchi et al, 1990; Palavecino et al, 2009); however, evidence is insufficient to suggest that PVE is associated with improved postoperative results in patients with normal parenchyma (Farges et al, 2003). In a series of 1800 liver resections performed at Memorial Sloan-Kettering Cancer Center (MSKCC), significant postoperative liver dysfunction and associated death occurred in only six patients (Jarnagin et al, 2002). In this series, PVE was utilized sparingly, and preoperative measures of liver function were not used routinely, such as the indocyanine green retention test; however, in patients with a damaged or steatotic liver—more common in obese patients, those with diabetes, and patients who have received substantial chemotherapy—the risk of postoperative liver insufficiency and failure is increased (Behrns et al, 1998; Kooby et al, 2003a). PVE may prove to be justified in this group of patients undergoing major resections. Biliary obstruction with jaundice is common in patients with hilar cholangiocarcinoma, who also are at increased risk. PVE in these patients also may be justified in select cases (see Chapters 50B and 93; Seyama et al, 2003).

In the cirrhotic liver, liver regeneration is much less effective; impairment of liver function after resection is greater, may last longer, and may result in terminal liver failure. Liver failure is

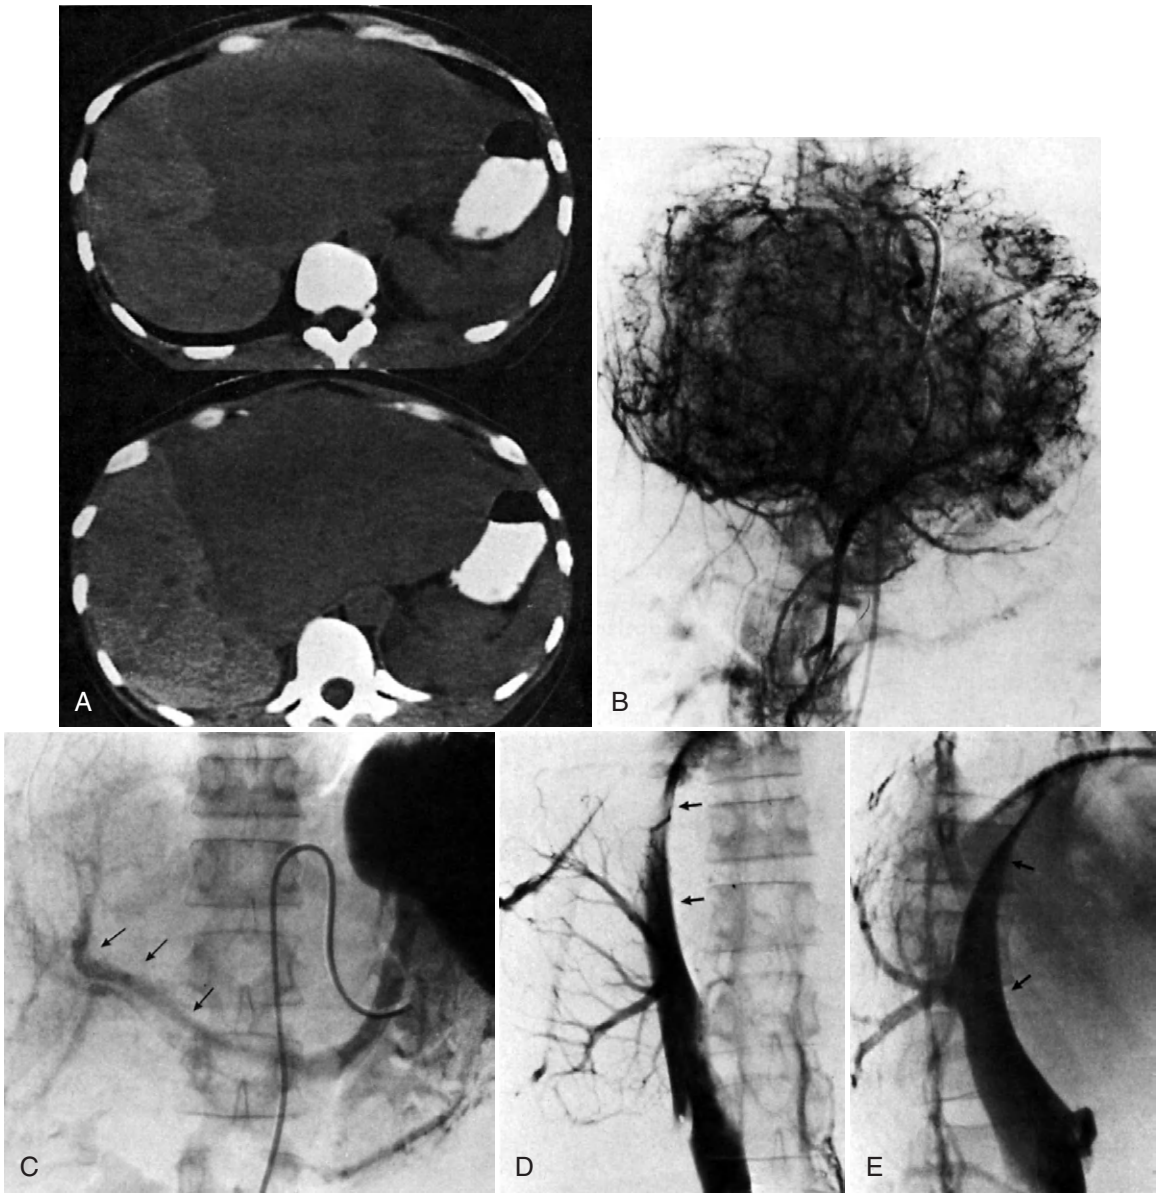

FIGURE 90B.1. **A,** Computed tomographic scan shows an enormous tumor occupying the left liver and extending beyond the principal plane into the right liver. Involvement of the vena cava and of the hilar structures is apparent. **B,** Selective hepatic artery angiogram reveals the gross size of the tumor within the left liver. **C,** Late-phase portogram shows gross displacement of the main trunk of the portal vein and its right branch (*arrows*). There is no filling of the left branch of the portal vein. Anteroposterior (**D**) and lateral (**E**) views of the inferior vena cava reveal severe compression but no tumor invasion; however, a collateral circulation has developed. The tumor proved to be a fibrolamellar hepatocellular carcinoma; it was treated by extended left hepatectomy. *Note:* Direct angiographic techniques have been supplanted by dynamic computed tomography and magnetic resonance imaging.

the most common cause of postoperative death after liver resection in patients with cirrhosis. Postoperative liver failure and postoperative mortality are related to the degree of preoperative liver decompensation and to the extent of nontumorous liver parenchyma removed. Liver failure may be precipitated by intraoperative bleeding, and a significant relationship has been found to exist between intraoperative blood loss, postoperative increase in serum bilirubin, and postoperative mortality. The occurrence of other postoperative surgical complications, such as abdominal infection, may also trigger postoperative liver failure. In addition, cirrhosis predisposes to multiorgan failure after hepatectomy. Although evidence supports the safety of major hepatic resection in cirrhotic patients with Child-Turcotte-Pugh (CTP) class A liver function (Fong et al, 1999a; Franco et al, 1990), it also suggests that PVE may improve perioperative outcomes by optimizing the FLR (Palavecino et al, 2009).

Portal Hypertension and Ascites

Liver resection leads to only a small increase in portal pressure in patients with a normal liver, but in patients with cirrhosis, a further augmentation of portal hypertension occurs, related to the amount of parenchyma removed and to an incapacity of the remaining liver to drain the splanchnic vascular bed. This increase in portal pressures may be the inciting factor that leads

to an increased risk of variceal bleeding after liver resection, observed more often in patients with cirrhosis.

The formation of ascites is one of the most frequent complications seen after liver resection in cirrhotic patients, occurring in 80% of patients. The etiology is likely twofold, the result of an increase in portal hypertension and of the ligation and division of lymphatics in the hepatic pedicle and liver ligaments. Postoperative ascites is a serious complication. Gross abdominal distension can interfere with ventilatory function and may result in leakage and disruption of the abdominal incision. Leakage of large-volume ascites may also lead to major fluid, protein, and electrolyte losses. In addition, ascitic fluid may become infected, and this may be an irreversible complication that leads to patient demise. Incidentally, ascites formation can also occur after liver resection and after fenestration in patients with polycystic liver disease (see Chapter 69B).

Infection

Despite the nearly universal formation of fluid collections after liver resections, particularly in the resection bed, infection of this fluid is relatively infrequent in most patients; however, a serious risk of infection follows liver resection in patients with biliary obstruction, especially in the presence of preoperative radiologic or endoscopic manipulation, and in cirrhotic patients. Alterations of humoral and cellular immunity are thought to predispose to infection after abdominal surgery in patients with cirrhosis. This risk is particularly high in patients with ascites or jaundice (Rimola et al, 1986). We also have empirically observed a slightly increased rate of infected fluid collections in patients undergoing simultaneous resections of a colorectal primary along with the liver metastases. In these combined resections, we now often leave an intraabdominal drain near the liver resection bed.

Selection of Patients for Liver Resection

When selecting patients for liver resection, the oncologic appropriateness of the resection must be considered first and foremost, followed closely thereafter by the general condition of the patient. Once resection is determined to be reasonable, and the patient appears to be a candidate from a general health perspective, the technical aspects of the resection must then be considered, including the extent of resection and the quantity and quality of the FLR. If the tumor can be completely resected without compromising hepatic arterial and portal venous inflow, biliary drainage, and venous outflow of the remnant, and if the FLR is of sufficient size in a well-functioning liver, nearly all patients are candidates for hepatic resection. Careful consideration must be taken when deciding to perform a major resection to remove multiple or centrally situated small lesions in patients in whom compensatory hypertrophy of the residual liver has not yet occurred. The selection of patients with a benign biliary stricture for hepatic resection is described in Chapter 42A, and the role of liver resection in specific situations, such as for hilar cholangiocarcinoma and hemangioma, are described below.

When considering patients with compromised liver function or cirrhosis for hepatic resection, it is important to understand that, in addition to the disease extent and the general condition of the patient, the degree of hepatic dysfunction is a major prognostic factor. The CTP classification system (Child & Turcotte, 1964; Pugh et al, 1973) is a simple means of assessing liver function preoperatively. Although more sophisticated tests can be used (see Chapter 2), the CTP classification is sufficient for most situations. Also, a low preoperative platelet count is a good surrogate marker for portal hypertension and underlying liver disease that otherwise may not be detectable (Bruix et al, 1996; Maithel et al, 2010). Operative mortality is much higher in CTP class B or C patients compared with those with class A liver function. Liver resection is particularly hazardous in a patient with a Pugh score greater than 8 (CTP class B). Serum bilirubin concentration is also an important prognostic factor, as liver resection is ill advised in patients with a serum bilirubin greater than 2 mg/dL or in the presence of clinically detectable ascites.

The extent of hepatectomy is guided by tumor size and location, but in general, the ideal is to remove as little parenchyma as possible. Small tumors located deep in the right liver are challenging, as it is preferable to avoid performing a right hepatectomy in such cases. If right hepatectomy is necessary, preoperative PVE of the affected lobe may allow hypertrophy of the contralateral side (see Chapter 93); however, the utilization of alternative methods for liver-directed therapy to obtain tumor control in a cirrhotic patient should be considered, especially in patients with multifocal disease. Alcohol injection, transarterial chemoembolization—bland, conventional, and using drug-eluting beads—cryoablation, radiofrequency ablation, microwave ablation, yttrium-90 therapy, and liver transplantation for managing tumors of the liver are discussed in detail in Chapters 84 through 86 and in Chapter 98.

ANATOMY AND CLASSIFICATION

Precise knowledge and mastery of the surgical anatomy of the liver, blood vessels, and biliary channels is essential for performing partial hepatectomy; this is described in detail in Chapter 1B. The liver is divided into sectors that comprise liver segments, each supplied by branches of the portal triads and drained by hepatic veins. Partial hepatectomy involves removal of one or more segments by isolation of the relevant portal pedicle, severance of the relevant hepatic veins and biliary drainage channels, and removal of the associated liver tissue.

The anatomic division between the right and left liver is not at the falciform ligament, but rather follows a line projected through a plane—the principal plane or Cantlie's line—running from the medial margin of the gallbladder bed to the left of the IVC posteriorly (Fig. 90B.2; Couinaud, 1954, 1957; Goldsmith & Woodburne, 1957; Healey & Schroy, 1953; McIndoe & Counseller, 1927). Each of these major right and left portions of the liver is divided into sectors and segments.

The Brisbane terminology dictates that the hepatic veins form the boundaries between the various sectors of the liver (Strasberg et al, 2000). Specifically, the medial margin of the right posterior sector is the right hepatic vein and comprises segments VI and VII. The right anterior sector is bordered by the right hepatic vein and middle hepatic vein, coursing along the principal plane, and it comprises segments V and VIII. Based on the Brisbane terminology, the area of liver that comprises segments IVa, IVb, and III forms the left medial sector; segment II forms the left lateral sector, because the left hepatic vein actually divides segment II from III. From a clinical perspective, resections of segments III, IVa, and IVb are rarely performed; furthermore, segment IVa/b is often referred to as the *left medial sector,* or the *left medial section* in Brisbane

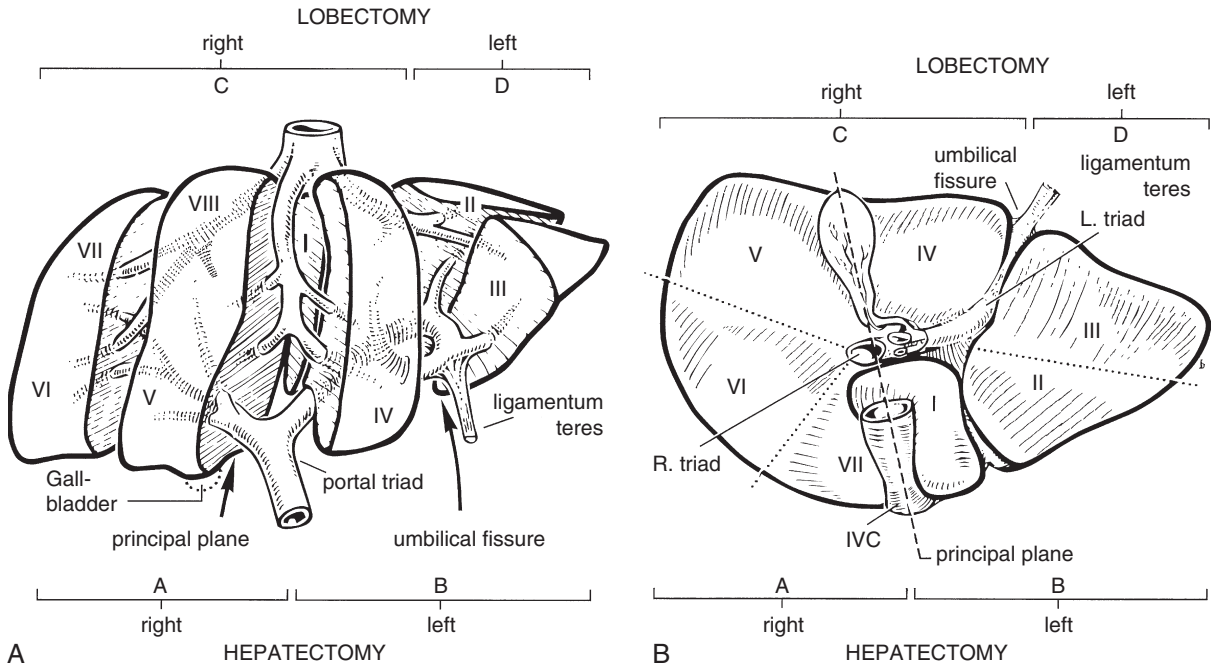

FIGURE 90B.2. **A,** Enlarged view to show the sectors (separated by the major hepatic veins) and the segmental structure of the liver. Each segment is supplied by a portal triad; the left portal pedicle traverses beneath segment IV to the umbilical fissure; the umbilical portion of the pedicle curves ventrally and caudally in the umbilical fissure. The blood supply to segment IV is recurrent as feedback vessels. **B,** Inferior surface of the liver; segment VIII is not seen because it lies superiorly. The anatomic division into right and left lobes by the umbilical fissure and into a right and left liver in the principal plane, along the principal scissura, is evident. IVC, inferior vena cava.

terminology, and it is bordered by the middle hepatic vein and umbilical fissure. The left lateral sector, or section, is comprised of segments II and III and represents the portion of liver to the left of the ligamentum teres and falciform ligament; thus in essence, the left liver is divided into a medial and lateral sector along the line of insertion of the ligamentum teres and the falciform ligament. This is the terminology that will be utilized for the remainder of this chapter. The portal venous and hepatic arterial branches conform to the segmental organization and run within the segments, and the draining hepatic veins converge posteriorly toward the inferior vena cava and mark the main scissurae of the liver (see Fig. 90B.2), within which they run (Couinaud, 1954, 1957).

Practically speaking, five types of major anatomic resections are practiced (Fig. 90B.3; see also Fig. 90B.2). The nomenclature of these operations is based on the anatomic descriptions of Couinaud (1954, 1957) and of Bismuth (1982; Table 90B.1). This classification emphasizes the importance of the scissurae of the liver and the umbilical fissure. The alternative, more commonly used terminology of Goldsmith and Woodburne (1957) is also listed in Table 90B.1. A newer terminology proposed by the International Hepato-Pancreatico-Biliary Association in Brisbane (Strasberg et al, 2000) is also referred to in Chapter 1 and is discussed above. The five different resections depicted in Figure 90B.3 can also be referred to as 1) right hepatectomy, 2) left hepatectomy, 3) extended right hepatectomy, 4) left lateral sectorectomy, and 5) extended left hepatectomy.

The portal vein and hepatic artery divide into major right and left branches outside the liver substance below the hilus (see Fig. 90B.2A). Here, when the overlying peritoneum is incised, it is possible to dissect each major branch beyond its bifurcation. The confluence of the right and left hepatic ducts

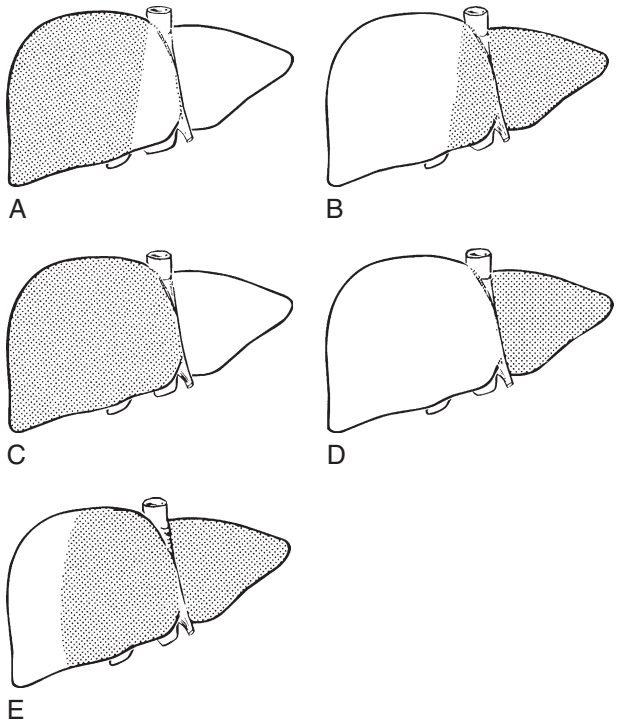

FIGURE 90B.3. Commonly performed major hepatic resections are indicated by shaded areas. **A,** Right hepatectomy. **B,** Left hepatectomy. **C,** Right lobectomy. **D,** Left lobectomy. **E,** Extended left hepatectomy. For the nomenclature of Goldsmith and Woodburne (1957), see Table 90B-1.

Table 90B.1

Nomenclature of Hepatic Resection

Couinaud (1957)	Goldsmith & Woodburne (1957)
Right hepatectomy (segments V, VI, VII, VIII; see Fig. 90B.3A)	Right hepatic lobectomy
Left hepatectomy (segments II, III, IV; see Fig. 90B.3B)	Left hepatic lobectomy
Right lobectomy (segments IV, V, VI, VII, VIII; sometimes includes segment I; see Fig. 90B.3C)	Extended right hepatic lobectomy*
Left lobectomy (segments II and III; see Fig. 90B.3D)	Left lateral segmentectomy
Extended left hepatectomy (segments II, III, IV, V, VIII; sometimes also segment I†; see Fig. 90B.3E)	Extended left lobectomy†

*Right lobectomy (extended right hepatic lobectomy) represents right hepatectomy extended to segment IV and has been referred to by Starzl and colleagues (1975, 1980) as *right trisegmentectomy;* this term is commonly found in the literature.
†Also referred to as *left trisegmentectomy* (Starzl et al, 1982).

also occurs outside the liver. At the hilum of the portal vein, the right branch is short, and its first branch often arises posteroinferiorly, close to the bifurcation, where it is easily damaged during dissection. By contrast, the left branch of the portal vein and the left hepatic duct pursue a longer, more horizontal extrahepatic course beneath segment IV and are more easily dissected free along their length.

The ligamentum teres (round ligament) runs sharply into the umbilical fissure of the liver, at the base of which the main vascular and biliary pedicle branches to the segments of the left liver (II, III, IVa, IVb). After entering the umbilical fissure, the left branch of the portal vein curves caudally and gives branches not only to the left lateral sector, segments II and III, but together with branches of the left hepatic artery, it gives rise to feedback vessels to the left medial sector—segment IVa and IVb of the left liver, also known as the *quadrate lobe* (see Fig. 90B.2A; Goldsmith & Woodburne, 1957; Starzl et al, 1975).

Outside of the liver substance, there is not a distinct sheath around the portal triad structures, and they must be dissected independently. The structures of the portal triad—the portal vein, hepatic artery, and bile duct—are covered with the Glisson capsule as they enter the liver parenchyma such that within the liver, they are contained in well-formed branching fibrous sheaths often referred to as *pedicles*. Thus, dissection outside of the liver substance mandates individual isolation of each portal triad structure, where there is considerable variation in anatomy. Pedicles are strong structures that contain the constituents of the portal triad, and intrahepatic dissection of these pedicles enables isolation and control of vascular and biliary elements without the need to individually expose each structure (Launois & Jamieson, 1992b).

The liver straddles the IVC immediately below the diaphragm, and the hepatic veins have a short extrahepatic course to empty into the vena cava (see Fig. 90B.2). This superior portion of the vena cava with the draining hepatic veins is masked behind a fold of peritoneum that extends from the cephalad aspect of the falciform ligament to the right and left triangular ligaments. The right hepatic vein emerges from the right scissura and usually enters the vena cava separately. By contrast, the left hepatic vein, which runs in the left scissura between segments II and III, is often joined by the middle hepatic vein, which occupies the principal scissura, before entering the vena cava. Several smaller veins from the posterior surface of the liver and the caudate lobe drain directly into the IVC.

An additional but important hepatic vein, the umbilical vein, runs beneath the falciform ligament and empties into the left hepatic vein. This vein is important in resections that remove segment IVa, because it provides drainage of segment IVb in the presence of ligation of the middle hepatic vein (see Chapter 92).

PREOPERATIVE CONSIDERATIONS

Preoperative Investigations

Preoperative investigations should seek to determine the nature of the lesion and give an index of resectability and the ideal surgical approach. Preoperative transcutaneous needle biopsy of liver tumor masses is not routinely necessary and is not always advisable (see Chapter 20). Preoperative biopsy should be pursued only if the information gained will alter the treatment plan. In the presence of a strong presumptive and clinical diagnosis of a potentially resectable liver tumor, we prefer to avoid the possibility of tumor dissemination, rupture, or hemorrhage, which may occur using percutaneous methods (Thompson et al, 1985). Laparoscopic exploration and visualization, particularly when used in combination with laparoscopic US, may provide valuable information regarding the presence of additional lesions not appreciated on preoperative imaging, and it may also reveal the presence of extrahepatic disease. By minimizing unnecessary laparotomy, this approach has been shown to increase the resectability rate of patients submitted to laparotomy (Jarnagin et al, 2000; John et al, 1994; Li Destri et al, 2008).

There are three major risks of hepatic resection: 1) hemorrhage, which may arise at the porta hepatis from branches of the hepatic artery or portal vein or posteriorly from hepatic venous radicles or the IVC; 2) biliary fistula or stricture as a result of damage to the biliary apparatus; and 3) postoperative liver insufficiency or failure. Intraoperative bleeding complications are most likely to occur when resecting tumors or other lesions that are large and in close proximity to the IVC and/or major hepatic veins (Hawkins et al, 2005). Similarly, tumors near the hilus at the confluence of the hepatic ducts and division of major vessels as they enter the liver substance can be challenging to remove. Given the numerous anatomic variations in the vascular and biliary anatomy of the liver, preoperative cross-sectional imaging should be routinely obtained and evaluated for important spatial relationships between tumor and these structures.

One such modality that provides valuable information in this regard is computed tomography (CT) (see Chapter 16). Peripherally placed lesions, unless substantially large, rarely involve the hilar structures or vena cava; however, more centrally situated lesions may involve major vessels close to the hilus, and appropriate CT scanning (see Chapter 16) can be most helpful in creating an image of the extent of disease and degree of vascular compromise by the tumor (Fig. 90B.4). Liver tumors can sometimes respect intersegmental planes and push structures away rather than invade them directly. This can be demonstrated not only by CT scan (Figs. 90B.5 and 90B.6), but also

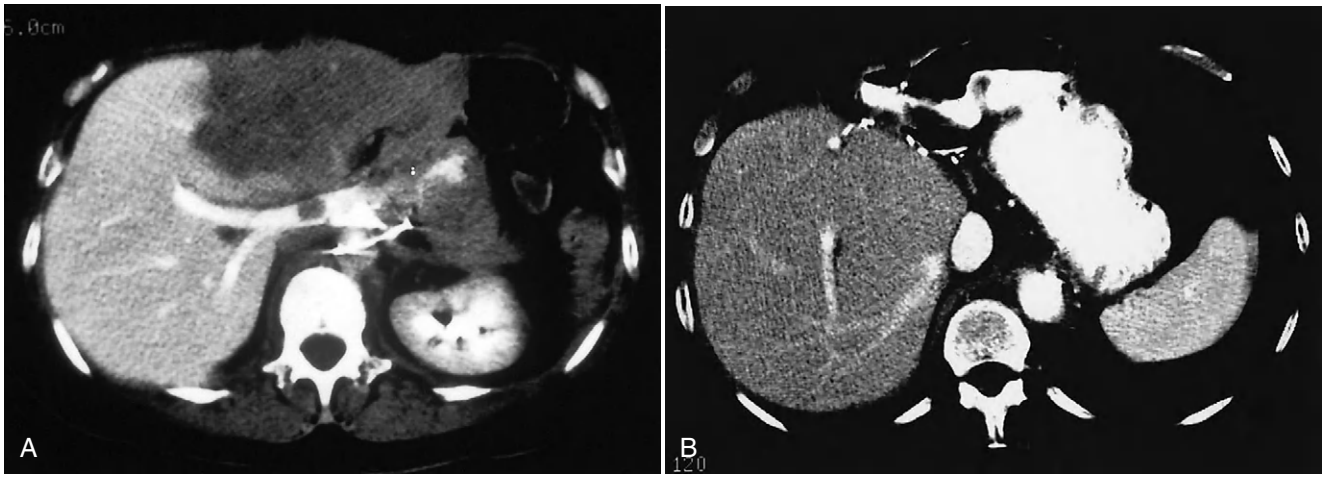

FIGURE 90B.4. Computed tomographic portography illustrates metastatic melanoma to the liver. **A,** A large metastatic deposit of melanoma occupies segments II, III, and IV and extends into segments V and VIII. The left portal vein contains an extension of tumor that protrudes into the main portal venous trunk. **B,** Extended left hepatectomy was performed together with resection of the affected portion of the portal vein and subsequent portal vein reconstruction. Recurrent tumor in the right buttock was excised 1 year after hepatectomy. The patient was alive and well without evidence of further recurrence in the liver 10 years postoperatively.

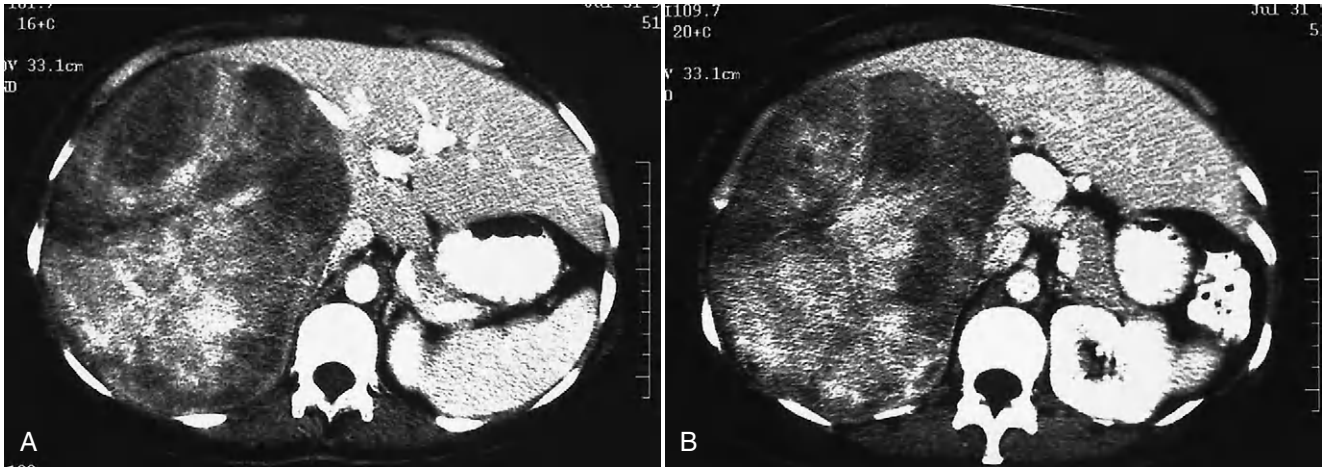

FIGURE 90B.5. A large, well-circumscribed tumor in the right liver has expanded and is adjacent to the inferior vena cava. **A,** Tumor has pushed the middle hepatic vein medially. **B,** Tumor protrudes by pressure effect into segment IV. Final histology revealed that this lesion was a benign fibrous tumor of the liver. Extended right hepatic lobectomy (right lobectomy) was performed without incident.

FIGURE 90B.6. Computed tomographic scan shows a large metastatic deposit from a hypernephroma occupying segments II, III, IV, V, and VIII of the liver. The tumor is pushing the posterior sectoral triad posteriorly. A thin rim of liver tissue separates the tumor from the vessels. In this instance, the plane of transection is dictated by the tumor. Hepatic resection by extended left hepatectomy was successfully carried out, and the patient was alive and well for more than 7 years.

can be confirmed by angiographic methods (see Fig. 90B.1) or by duplex ultrasound (US). However, with the advancement in technology and the high-quality images obtained with cross-sectional imaging, direct angiography is rarely necessary. Other tumors may hang from the liver in a pedunculated fashion (Baer et al, 1989), and they may be attached to the liver by a relatively small base, even when very large. Such "hanging" tumors are readily depicted on CT scan (Fig. 90B.7). Tumor involvement of the diaphragm also may be suggested by CT, but likewise, this should not deter the surgeon from attempted resection, because such apparent diaphragmatic involvement from metastatic tumors is frequently secondary to an adhesion to a site of previous necrosis of the tumor and not actually from direct tumor invasion (Weinbren & Blumgart, 1986). Primary tumors may still be approached for resection as well, even if they involve the diaphragm (Foster & Berman, 1977).
