CHAPTER 25

Postoperative complications requiring intervention, diagnosis, and management

James J. Mezhir, Helmut Schoellnast, Stephen B. Solomon, and Peter J. Allen

OVERVIEW

The literature regarding postoperative adverse events is difficult to interpret, because most reports are retrospective in nature, and the definitions of adverse events vary among institutions. Complication rates may vary by how hard one looks and by what definition an individual surgeon uses to declare a postoperative event as a complication rather than normal postoperative recovery. This is particularly true for retrospective analyses, which likely overlook many events. Over the past decade these difficulties have been addressed through the development of more carefully defined systems for documenting and grading perioperative complications to improve reporting and provide more uniform methods for comparing outcomes across institutions and countries (Bassi et al, 2005a; Clavien et al, 2009; DeOliveira et al, 2006; Grobmyer et al, 2007; Vin et al, 2008). These systems of standardized grading and reporting of adverse events have become the norm in medical oncology trials and are becoming so in prospective surgical trials. Such standardization should improve our ability to define the morbidity of a procedure and to compare morbidity among approaches and institutions.

Over the last 15 years, major hepatic and pancreatic resections have been performed with increasing frequency (Allen, 2007; Brennan et al, 2004; Cameron et al, 2006; Jarnagin et al, 2002; Nguyen et al, 2009; Riediger et al, 2007; Balcom et al, 2001). This increase has been most apparent at high-volume institutions and may be secondary to a trend in specialization. Multiple reports have shown a link between high-volume surgeons and institutions and decreased postoperative mortality for both pancreatic and liver resection (Begg et al, 1998; Birkmeyer et al, 2003; Eppsteiner et al, 2008, 2009; Lieberman et al, 1995). Despite the observed decrease in postoperative mortality, morbidity remains statistically unchanged over time with most large series reporting a 35% to 45% major complication rate following either pancreatic or hepatic resection (Ho et al, 2005; Simons et al, 2009; Turaga et al, 2008).

This apparent improvement in postoperative mortality without an observed decrease in morbidity suggests an improved ability to successfully rescue patients who experience significant postoperative complications. Management of serious complications following pancreatectomy and liver resection has shifted from operative reexploration to interventional or endoscopic procedures (Vin et al, 2008). High-quality imaging and increasing familiarity with the specific perioperative events has led to earlier detection and intervention and a subsequent reduction in the need for reoperation. Percutaneous drainage procedures are now the typical approach to postpancreatectomy leak or abscess, and they can be performed with minimal sedation and low morbidity.

This chapter seeks to outline the most commonly reported postoperative events following pancreatic and hepatic resection and the trials designed to assess technical approaches to reduce these events. We review the current definitions and grading systems for the reporting of these events; outline the management of the most common events, pancreatic leak and perihepatic fluid collection; and provide a detailed discussion of interventional techniques.

PANCREATECTOMY

The mortality associated with pancreatectomy has significantly improved over the last 20 years; however, the morbidity has remained essentially unchanged. Operative mortality following pancreatic resection in large series reported since 2000 is presented in Table 25.1. The overall perioperative mortality has ranged from 2% to 9% for pancreaticoduodenectomy (PD), and reported morbidity rates are between 35% and 43% (Buchler et al, 2000; Mezhir et al, 2009, Muscari et al, 2006; Winter et al, 2006a). Recent studies show significantly improved mortality rates compared with reports from the 1980s and 1990s. This trend is illustrated in perioperative mortality data over a span of more than 25 years at Memorial Sloan-Kettering Cancer Center (MSKCC; Fig. 25.1). In a 5-year period between 1983 and 1990, the mortality rate was 10% in 125 pancreatic resections; between 2006 and 2009, the operative mortality rate was 1.7% in 694 pancreatic resections. The operative mortality rates presented in Table 25.1 are remarkably similar despite the fact that these data are from different institutions around the world.

Complications may occur at the operative site (hemorrhage, leak, obstruction) or remotely (deep venous thrombosis, cardiac arrhythmia, pneumonia). Despite efforts to optimally manage comorbid conditions preoperatively, cardiac and pulmonary events occur following major surgeries. In addition, the combination of prolonged operative time, fluid volume, and underlying malignancy may increase the risk of certain complications unrelated to technique, such as pulmonary embolus, atrial

dysrhythmia, and pneumonia. The most common severe complications following pancreatic and hepatic resection are directly related to the technical aspects of the operation itself. The frequency of the most commonly reported major complications following pancreatectomy are listed in Table 25.2. These include delayed gastric emptying (DGE), intraabdominal fluid collection or abscess, hemorrhage, wound infection, and anastomotic fistula. A comprehensive list of complications taken from a series of 204 consecutive pancreaticoduodenectomies at MSKCC from 2001 to 2003 is presented in Table 25.3 (Grobmyer et al, 2007).

Pancreatic leak/fistula continues to be one of the most common and most difficult complications following pancreatectomy. Multiple studies have reported pancreatic fistula to be more common following central or distal pancreatectomy compared with pancreaticoduodenectomy (Pratt et al, 2006; Goh et al, 2008; Kleeff et al, 2007; Kooby et al, 2008; Nathan et al, 2009; Ferrone et al, 2008; Reid-Lombardo et al, 2007). The series reported in Table 25.1 also demonstrate that central pancreatectomy (Adham et al, 2008; Crippa et al, 2007; Hirono et al, 2009; Ocuin et al, 2008; Roggin et al, 2006; Sauvanet et al, 2002) and total pancreatectomy (Billings et al, 2005; Karpoff et al, 2001; Muller et al, 2007; Reddy et al, 2009) are procedures associated with slightly higher overall morbidity than PD and distal pancreatectomy, and total pancreatectomy is associated with a slightly higher mortality rate than PD.

Defining and Grading Complications After Pancreatectomy

Accurate identification and reporting of perioperative complications are vital to improve quality of care and to compare outcomes among different institutions and time periods. Without a standardized system for complication recording, there is a significant risk of inaccuracy and underreporting. Recently, several institutions have implemented specific classification and grading systems for surgical complications (Clavien et al, 1992, 2009; DeOliveira et al, 2006; Grobmyer et al, 2007). These systems have developed simplified definitions of postoperative complications and a grading system for severity using therapy-oriented grading schema.

This approach to defining and grading adverse events has been well established in medical oncology. The Common Terminology Criteria for Adverse Events (CTCAE) developed by the National Institutes of Health Cancer Therapy Evaluation Program (CTEP) has been utilized in clinical trials since 1982 (National Cancer Institute's Cancer Therapy Evaluation Program). CTCAE is an example of a universally employed terminology system for complication reporting that has been utilized across medical disciplines. This system also includes a limited schema for postoperative complications. Table 25.4 demonstrates an example of the grading system for common complications following pancreatectomy. The grade of the complication increases with the invasiveness of the treatment required.

Among the complications listed, pancreatic fistula is one of the most severe that can occur after pancreatectomy. The reporting of this complication is arguably the most problematic, as definitions have varied. Pancreatic fistula often precedes other complications, such as abscess and hemorrhage. Inherent to its cause, complications from pancreatic leak, or any anastomotic leak for that matter, often overlap (see Management of Fistula, Leak, and Abscess below). When a postoperative patient

has fever, tachycardia, and leukocytosis and cross-sectional imaging reveals a perianastomotic fluid collection, the etiology of this collection is likely an anastomotic leak. When the collection is drained, if it is infected, it may be recorded or defined as an abscess. If the fluid is amylase rich, one investigator may report it as a pancreatic fistula and another may report it as a pancreatic leak. This ambiguity is reflected in reports that reflect rates of intraabdominal abscess for pancreatectomy ranging from 1% to 15%. Moreover, the incidence of fistula ranges from 2% to 27% for PD and 12% to 31% for distal pancreatectomy in part as a result of the inconsistent definitions utilized in studies from different institutions.

Toward a Unifying System for Reporting Pancreatic Fistula

Pancreatic fistula has been recently defined by the International Study Group of Pancreatic Fistula (ISGPF; Bassi et al, 2005a). This system has served as a foundation for defining and reporting pancreatic fistula among numerous studies and is an example of the efforts to unify complication reporting. The study group comprised an international panel of pancreatic surgeons working in high-volume centers, and it aimed to develop a simplified and universal definition of pancreatic fistula with a grading system based on clinical impact. *Fistula* was defined as "drain output of any measurable volume of fluid on or after postoperative day 3 with amylase content greater than three times that of normal serum amylase." Three grades were applied according to clinical impact, from grade A (none) to grade C (significant; Table 25.5). As demonstrated in Table 25.6, many institutions have implemented this system for reporting the rates and outcomes of pancreatic fistula.

Independent prospective validation of the ISGPF definition and grading system has been reported. Pratt and others (2006) prospectively analyzed postoperative complications in 176 consecutive patients after pancreaticoduodenectomy. There were 53 patients with confirmed fistulae (30% incidence), categorized in the various grades: 26 patients (15%) were grade A, 21 (12%) were grade B, and 6 (3%) were grade C. No deaths were related to fistula in this study. Patients with grade A fistulas had shorter hospital stays and fewer secondary complications than patients with grade B and C fistulas, although the overall rate of secondary complications between grade B and C fistulas was not significantly different (76% vs. 100%, respectively, $P = .2$). Patients with grade C fistulas had a higher frequency of intensive care unit (ICU) transfer and blood transfusions and longer hospital stays compared with those who had grade B fistulas, and five of the six patients with a grade C fistula were discharged to a rehabilitation facility, significantly more than patients with grade A and B fistulae.

In an economic assessment, the authors reported a correlation between increased health care costs and increase in fistula

Table 25.3

grade. This study validated the ISGPF classification scheme by demonstrating no clinical consequence of grade A fistulas, whereas grade B and C fistulas led to more complications, longer hospital stays, and higher health care costs.

Randomized Controlled Trials Aimed at Reducing Complications

Multiple prospective randomized controlled trials have been performed to evaluate technique and complications following pancreatic resection. Selected prospective trials published since 2000 are presented in Table 25.7. In general, these studies have reported conflicting outcomes with no specific technique demonstrating superiority. The interpretation of surgical technique trials is difficult, as most trials randomize patients between "the standard technique" at a given institution and a "new," perhaps less familiar technique. These studies are often underpowered, and it is therefore not surprising that equivalency is concluded. Fortunately, none of the reported techniques have been shown to be inferior from an oncologic standpoint, and therefore any of these reported techniques may be considered acceptable in the appropriately selected patient.

Routine preoperative biliary drainage (PBD) has been evaluated in multiple prospective randomized trials. These trials have evaluated both percutaneous external and endoscopic internal drainage (see Chapters 27 and 28). These studies, as well as multiple retrospective case-matched reports, have documented an increase in perioperative complications in patients undergoing PBD (Mezhir et al, 2009; Povoski et al, 1999). A recent prospective, controlled clinical trial randomized patients with serum bilirubin levels between 2.3 and 14.6 mg/dL to PBD or no PBD prior to pancreaticoduodenectomy (van der Gaag et al, 2010). The authors reported 39% significant complications in the no PBD group compared with 74% in the PBD group ($P < .001$). These data support previous prospective and retrospective studies and do not support routine PBD in patients with moderately elevated bilirubin.

Pylorus preservation has been evaluated as a technique to decrease the morbidity of PD (see Chapter 62A). Standard PD with partial gastrectomy versus pylorus-preserving PD (PPPD), with or without extended lymphadenectomy, has also been investigated in randomized trials. As demonstrated in Table 25.7, no benefit was demonstrated for either approach in regard to operative or long-term oncologic outcomes, but extended lymphadenectomy was associated with increased perioperative morbidity, including DGE and pancreatic fistula (Yeo et al, 2002; Seiler et al, 2005).

Pancreatic fistula rates have been assessed according to anastomotic technique in an attempt to reduce postoperative pancreatic fistula. Randomized comparisons have been made between pancreaticojejunal invagination to direct duct-mucosa anastomosis and pancreaticojejunostomy (PJ) to pancreaticogastrostomy (PG). Berger and colleagues (2009) performed a two-institution randomized controlled trial comparing pancreatic invagination to duct–mucosa anastomosis with patients stratified based on the texture of the pancreas. A significant reduction in fistula rates were seen when using the invagination technique (12%) compared with duct-mucosa anastomosis (24%), and leak rates were significantly higher overall in soft glands. Bassi and colleagues (2005b) showed a decrease in DGE, biliary fistula, and abdominal collections with PG; however, these findings have not been replicated by other groups (Duffas et al, 2005; Yeo et al, 1995). No study to date has demonstrated convincingly an optimal method for pancreatic stump closure following distal pancreatectomy (Knaebel et al, 2005); the results of an ongoing, large, multiinstitutional randomized trial may provide some guidance (Diener et al, 2008).

Other adjuncts to reduce pancreatic leak have included somatostatin analogs, stents, and tissue glues. The perioperative use of somatostatin analogs was found to reduce fistula rates in several European trials (Montorsi et al, 1995; Buchler et al, 1992; Friess et al, 1995). However, these findings have not been reproduced in recent large, single, and multiinstitutional studies performed in the United States (Sarr, 2003; Suc et al, 2004; Yeo et al, 2000). Fibrin glue has been applied in two settings to determine its role for reducing pancreatic fistula, applied in a perianastomotic fashion (Lillemoe et al, 2004) or as a plug into the pancreatic duct prior to anastomosis (Suc et al, 2003). Neither study showed a reduction in fistula rates. Two prospective trials evaluated pancreatic stent placement at the time of anastomosis; in one study, a pancreatic duct stent significantly reduced the rate of pancreatic fistula (Poon et al,

Table 25.4

Definitions and Grading of Complications According to CTCAE: Example

Adverse Event and Definition	Grade 1	Grade 2	Grade 3	Grade 4	Grade 5
Gastroparesis					
An incomplete paralysis of the muscles of the stomach wall, resulting in delayed gastric emptying into the small intestine	Mild nausea, early satiety, and bloating; able to maintain caloric intake on regular diet	Moderate symptoms; able to maintain nutrition with dietary and lifestyle modifications; may need pharmacologic intervention	Weight loss refractory to medical intervention; unable to maintain nutrition orally	—	—
Abdominal Infection					
An infectious process involving the abdominal cavity	—	—	IV antibiotic indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Intraabdominal Hemorrhage					
Bleeding in the abdominal cavity	—	Medical intervention or minor cauterization indicated	Transfusion, radiologic, endoscopic, or elective operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Wound Infection					
An infectious process involving the wound	—	Localized; local intervention indicated (e.g., topical antibiotic)	IV antibiotic indicated; radiologic or operative intervention indicated	Life-threatening consequences; urgent intervention indicated	Death
Pancreatic Fistula					
An abnormal communication between the pancreas and another organ or anatomic site	Asymptomatic; clinical or diagnostic observations only; intervention not indicated	Symptomatic; altered GI function	Severely altered GI function; tube feeding or TPN or hospitalization indicated; elective operative intervention indicated	Life-threatening consequences; urgent operative intervention indicated	Death

Antibiotic intervention includes antifungal and antiviral therapy.
CTCAE, Common Terminology Criteria for Adverse Events; IV, intravenous; GI, gastrointestinal; TPN, total parenteral nutrition

Table 25.5

International Study Group of Pancreatic Fistula Grading System

Clinical Variable	Grade A	Grade B	Grade C
Clinical condition	Well	Often well	Ill-appearing/ bad
Supportive treatment: PPN/ TPN/enteral nutrition; antibiotics; somatostatin analog	No	Yes/no	Yes
Imaging results (if obtained)	Negative	Negative/ positive	Positive
Persistent drainage ≥3 weeks (± drain in place)	No	Usually yes	Yes
Reoperation	No	No	Yes
Death related to fistula	No	No	Possibly yes
Clinical signs of infection	No	Yes	Yes
Sepsis	No	No	Yes
Readmission	No	Yes/no	Yes/no

Pancreatic fistula is defined as drain output of any measurable volume of fluid on or after postoperative day 3 with amylase content >3 times normal serum activity. Once this criterion has been met, the grading system is applied.
PPN, partial parenteral nutrition; TPN, total parenteral nutrition

Modified from Bassi C, et al, 2005: Postoperative pancreatic fistula: an international study group (ISGPF) definition. Surgery 138(1):8-13.

2007), but the other study did not demonstrate any difference in fistula rates or overall complications (Winter et al, 2006b).

The routine use of intraperitoneal drains following elective pancreatic surgery remains an area of debate. Conlon and colleagues (2001) randomized 179 patients after pancreatic resection (PD or distal pancreatectomy) to placement of intraperitoneal drains or no drains, demonstrating no benefit to routine drainage. Moreover, patients in the drainage group were more likely to have an intraabdominal abscess, collection, or fistula.

Management of Postpancreatectomy Complications

Pancreatic Leak, Fistula, and Abscess

Vin and colleagues (2008) reported a series of 908 pancreatic resections and the rate and management of pancreatic fistula, leak, and abscess. As demonstrated in Figure 25.2, a significant overlap was found among these three separately defined complications in the 158 patients in which they occurred. This further highlights the difficulty in defining discrete complications, the crossover between different definitions, and the clinical relevance of complication grading. In this study, a *pancreatic fistula*, defined as clinical signs or symptoms with amylase-rich drainage greater than 50 mL/day beyond postoperative day 10, was identified in 92 patients; however, in 63 of these (69%), the

fluid that was drained was culture positive. These patients could therefore have been defined as having either or both a pancreatic fistula and postoperative abscess. Regardless of the definition, patients who develop a pancreatic fistula, leak, or abscess will often evidence similar findings and be treated in a similar fashion. Importantly, the type of complication (fistula, leak, or abscess) was not associated with presentation (fever, leukocytosis) or overall morbidity (duration of drainage, length of stay, ICU admission); however, these factors were similar in patients who had a similar grade of complication.

Vin and colleagues (2008) reported a 90-day mortality rate of 5% in patients who developed fistula, leak, or abscess. These complications were more common in men and in patients undergoing treatment for bile duct, ampullary, and duodenal tumors (63 [31%] of 206) compared with pancreatic tumors (95 [14%] of 702; $P < .001$). Type of resection (PD vs. distal pancreatectomy), tumor histopathologic subtype, and PBD were not associated with occurrence of fistula, leak, or abscess. Surgical drains were placed in 88 patients with these complications. The surgical drain alone, without additional interventional radiologic management, was successful for treatment in 16 (18%) of 88 patients, and 133 patients were managed with percutaneous drainage alone.

Duration of drainage was defined as the time from initial drain placement when performed percutaneously, the date of operation for drains placed intraoperatively, or the date of reoperation for collections requiring operative drainage to the time of drain removal. Mean duration of drainage was 38 days (range, 3 to 228 days). Factors associated with drainage for more than 30 days on multivariate analysis included distal pancreatectomy (odds ratio [OR], 4.3; $P = .01$) and drain output greater than 200 mL during the first 48 hours (OR, 2.9; $P = .02$). In this study, PD patients more often had initial fever, culture-positive collections, and drainage more than 30 days compared with distal pancreatectomy patients. Those in the latter group, by contrast, were more often readmitted, had initial drainage on readmission, and were more likely to have prolonged drainage.

Delayed Gastric Emptying

Delayed gastric emptying (DGE) after PD is common (see Table 25.2) and is typically reported in 9% to 16% of patients. A review of randomized controlled trials for treatment of DGE has been recently published (Traverso & Hashimoro, 2008), examining the literature for level I evidence, and four trials were identified that focused on the prevention of DGE. The largest study from Yeo and others (1993) randomized patients to erythromycin or control and found no reduction in the incidence of DGE. In a separate study, erythromycin did significantly reduce postoperative DGE, but the study was very small, and DGE occurred in 57% of patients in the control arm (Ohwada et al, 2001). Tani and colleagues (2006) randomized patients to retrocolic or antecolic gastrojejunostomy and found a significantly lower rate of DGE with the antecolic approach.

Although DGE and pylorus preservation have been a concern, to date no study has found a difference in the

*Included patients treated with distal pancreatectomy and PD

†Included distal pancreatectomy, central pancreatectomy, and PD

PBD, preoperative biliary drainage; PPPD, pylorus-preserving pancreaticoduodenectomy; PD, pancreaticoduodenectomy; ELND, extended lymph node dissection; PG, pancreaticogastrostomy; PJ, pancreaticojejunostomy; DGE, delayed gastric emptying

incidence of DGE following conventional compared with pylorus-preserving procedures (Diener et al, 2007). As discussed earlier in this chapter, and as highlighted in Table 25.7, the reported incidence of DGE was lower in two studies analyzing anastomotic technique. Bassi and colleagues (2005b) found a statistically significant reduction in DGE in patients who had PG compared to PJ. In the study by Yeo and others (2002), comparing radical with standard PD, an increase in DGE was seen in the radical group. It is important to note, however, that neither study had DGE as the primary end point.

Among these studies, significant variability was observed in the range of reported incidence of DGE. As with pancreatic fistula, part of the variability in incidence across studies was from the variation in definition. The ISGPF recently devised a formal grading system for DGE based on duration of nasogastric tube placement and the timing of patients' tolerance of solid food (Wente et al, 2007).

The authors' current management strategy for patients with significant DGE—that is, the inability to tolerate solid food or prolonged nasogastric tube requirement—is to perform cross-sectional imaging to exclude secondary causes, such as fistula, leak, or abscess. As initial treatment, intravenous metoclopramide is given with or without the addition of oral erythromycin. The possibility of an underlying structural abnormality should be investigated with upper gastrointestinal (GI) series or esophagojejunoscopy, which has the potential to evaluate and treat an anastomotic abnormality. In the setting of prolonged DGE, endoscopic placement of a feeding jejunostomy may be

required, but reoperation is reserved for patients who fail to progress after prolonged parenteral nutrition and medical therapy.

Hemorrhage

Postoperative hemorrhage is a potentially lethal complication after pancreatectomy, and it can occur in the immediate postoperative period (<7 days) or in a delayed fashion (>14 days). Management is often guided first by the patient's hemodynamic stability. Any unstable patient should be transfused and taken for reexploration. Patients who can be easily stabilized may be candidates for endoscopic or interventional radiologic management. Intraluminal bleeding is most commonly from the gastrojejunal anastomosis and can often be managed with endoscopic therapy. Extraluminal bleeding from arterial pseudoaneurysm (Fig. 25.3) or vascular erosion from a pancreatic fistula typically occur later, following operation, and these can be approached via angiographic embolization in stable patients. A high index of suspicion is critical, as mortality from late postoperative hemorrhage is significant (Brodsky & Turnbull, 1991).

Yekebas and others (2007) analyzed the treatment and outcome of 87 patients who had postoperative hemorrhage in a series of 1669 pancreatic resections in 1524 patients (overall hemorrhage rate, 6%). Hemorrhage was classified as mild in 36 patients (41%) and severe in 51 patients (59%); 29 patients (33%) had a sentinel bleed. The bleeding site was extraluminal in 51 (59%) and intraluminal in 36 (41%); 17 patients had what appeared to be extraluminal hemorrhage, but further evaluation confirmed bleeding from the transected pancreas or resection cavity; and 34 patients (39%) had pancreatic fistula that preceded hemorrhage.

Treatment included endoscopy, angiography with coil embolization, and reoperation. Endoscopic treatment was successful in three (20%) of 15 patients with intraluminal hemorrhage. Any patient with true extraluminal hemorrhage required reoperation, and 17 patients had bleeding from the pancreatic anastomosis and had a secondary anastomotic leak. Among 25 patients treated with coil embolization by angiography, coiling was successful in 20 (80%). Reoperation was performed in 60 patients; in 33, surgery was the first-line treatment of hemorrhage, and the remaining 27 were for failure of nonoperative measures. This included patients with pancreatic fistula (13 patients) and/or vascular abnormalities such as pseudoaneurysm and erosions (12 patients). Fourteen patients died from hemorrhage, for a mortality rate of 16%. All of the mortalities were in the group with delayed hemorrhage, which occurred after postoperative day 5.

This and other studies have demonstrated that significant morbidity and mortality are associated with postoperative hemorrhage, especially when delayed beyond postoperative day 5 (Choi et al, 2004). These patients often require reoperation or interventional radiology procedures to halt life-threatening hemorrhage. Furthermore, patients who experience a postoperative hemorrhage often have underlying complications that require treatment, such as pancreatic fistula. If angiographic embolization successfully treats hemorrhage, cross-sectional imaging should be performed to assess for the presence of leak, fistula, or abscess that would require drainage.

IMAGING AND INTERVENTIONAL THERAPY OF COMPLICATIONS AFTER PANCREATIC SURGERY

Imaging of Complications After Pancreatic Surgery

Imaging plays an important role in identifying complications and directing therapy in patients who have recently undergone pancreatic resection. The observation that 22% of patients undergoing a PD over a 12-year period required percutaneous interventions highlights the importance of imaging and image-guided interventions in the postoperative management of these patients (Zink et al, 2009). Transabdominal ultrasound (US) is a commonly available imaging tool that enables detection of focal, encapsulated, or free intraperitoneal fluid collections, but gastrointestinal gas and/or postoperative pneumoperitoneum superimposition represents the major disadvantage of US in the evaluation of the pancreas (see Chapter 13).

Computed tomography (CT) is the most effective imaging modality for evaluation of the pancreas after surgery (Johnson et al, 2002; see Chapter 16). It allows detection of the normal features as well as postoperative complications such as bleeding, anastomotic leakage, abscess, or fistula formation (Johnson et al, 2002; Scialpi et al, 2005). CT is performed when there is clinical or biochemical suspicion of complications in the early postoperative period (Scialpi et al, 2005). The data sets obtained with modern multidetector-row CT scanners provide voxels that are both submillimeter in dimension and isotropic, enabling reformations in any desired plane with spatial resolution similar to that in the transverse plane. Ideally the multiphase scan protocol includes good oral contrast with unenhanced CT as well as intravenous contrast-enhanced CT, including images acquired during the arterial phase and portal venous phase.

One potential advantage of MRI over CT imaging is the option to perform both contrast-enhanced MRI and magnetic resonance cholangiopancreatography (MRCP) using thick-slab and thin-slab, highly T2-weighted imaging (see Chapter 17). Ishizu and colleagues (1997) reported visualizing the pancreatic duct with MRCP in 91% of patients (69% complete duct visualization and 23% partial duct visualization) who had previous pancreatic surgery. This feature may enable improved

FIGURE 25.3. After Whipple procedure for pancreatic adenocarcinoma, a 63-year-old female patient had clinical evidence of bleeding 3 weeks after surgery. **A,** Abdominal computed tomography during the arterial phase revealed a large hematoma (*arrowheads*) centered in the subhepatic space with central highly enhancing components within this hematoma consistent with the lumen of a pseudoaneurysm at the origin of the gastroduodenal artery (*arrows*). **B,** Conventional angiography confirmed a pseudoaneurysm of the gastroduodenal artery (*arrow*), which was isolated by occluding the proper hepatic (outflow) and common hepatic artery (inflow) with multiple stainless steel coils. **C,** The angiogram after occlusion showed coils in the hepatic arteries (*arrows*) with lack of enhancement of the hepatic arteries and the pseudoaneurysm of the gastroduodenal artery. **D,** After placement of a covered stent (*between arrows*) into the hepatic artery in a 46-year-old male who had gastroduodenal artery stump bleeding after Whipple procedure. Covered stent placement is an alternate treatment to coils that allows preservation of hepatic artery flow.

management of leaks; however, the use of magnetic resonance imaging (MRI) must be balanced by its lower spatial resolution and reduced accessibility compared with CT.

On imaging studies, postoperative fluid collections are the most commonly seen complication of pancreatic surgery. An infected collection (abscess) is characterized by a complex fluid collection, representing pus and detritus, surrounded by a thick rim of contrast enhancement, representing inflammatory tissue (Fig. 25.4). Septations and gas inclusions may also be present. However, a clear differentiation between uninfected postoperative fluid collections with surrounding granulation tissue and abscess cannot be reliably done by imaging, and fine needle aspiration (FNA) is necessary when infection is suspected. Fluid collections after pancreatic surgery may occur in either retroperitoneal or intraperitoneal locations. The location of the fluid collection may suggest its origin. It has been observed that fluid collections around the PJ site were significantly more frequently associated with a pancreatic fistula. Fluid collections around the pancreas have shown elevated amylase values compatible with leakage in 82% of cases, in contrast to perihepatic collections, which have elevated fluid amylase values in only 46% of the collections (Zink et al, 2009; Hashimoto et al, 2007).

One of the most challenging imaging interpretations in the PD patient is distinguishing the jejunal anastomotic loop from a postsurgical fluid collection. The course of the normal loop can usually be followed from its origin to the pancreatic and biliary anastomoses in the right upper quadrant. Rarely, oral contrast refluxes into the loop, which can help identify its

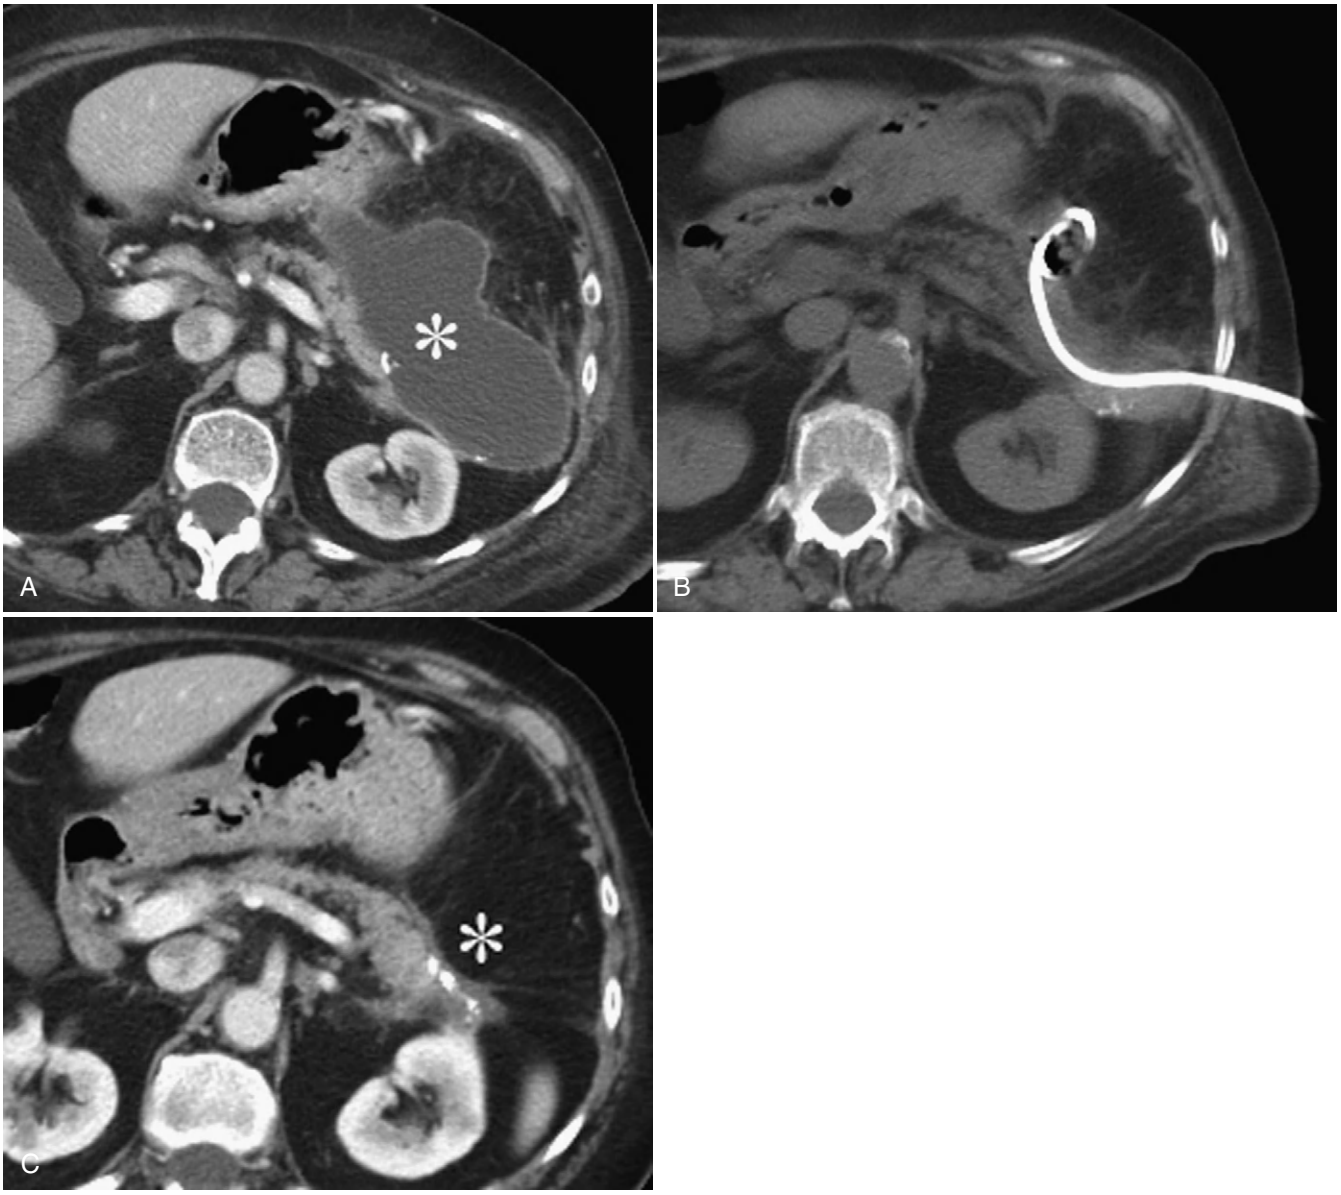

FIGURE 25.4. A 77-year-old female patient after distal pancreatectomy for resection of a neuroendocrine tumor of the pancreatic tail. **A,** Postoperative development of a 14 × 6 cm rim-enhancing fluid collection in the operative bed suspicious for abscess vs. postoperative seroma/pseudocyst (*asterisk*). **B,** Computed tomography (CT)-guided drainage of the fluid collection with a 10-Fr drainage catheter. Rust-colored fluid was aspirated and sent for analysis, which was suggestive of fistula. Culture was negative, and the catheter was removed after the output had diminished. **C,** CT follow-up 10 months after removal of the catheter showed resolution of the fluid collection (*asterisk*).

presence. In some cases, needle puncture of the possible collection with subsequent contrast injection may be necessary to differentiate a postsurgical fluid collection from the normal postsurgical jejunal loop (Gervais et al, 2001).

A fluid-containing pancreatic fistula presents as a tubular tract communicating with the main pancreatic duct, often surrounded by a rim of contrast enhancement. At MRCP, a fistula often shows a highly hyperintense T2 signal because of the pancreatic juice. Fistula can often be demonstrated with CT and MRI/MRCP. It has been reported that with CT, the site of pancreatic fistula, may be identified in 75% of patients compared with 93% with MRI and MRCP (O'Toole et al, 2007).

Finally, hematomas and pseudoaneurysms are important imaging findings after pancreatic surgery. Hematomas may appear as dense collections on CT, and active bleeding may be seen as contrast extravasation. Pseudoaneurysms may be the result of direct injury related to the dissection or to pancreatic fluid eroding a vessel; often they do not occur until several days to months after surgery (Sugimoto et al, 2001). Imaging with CT, Doppler ultrasound (US), or MRI may identify these pseudoaneurysms and help guide intervention (see Chapter 19; see Figure 25.3).

Interventional Radiology Techniques for the Postpancreatic Surgery Patient

Interventional radiology (IR) techniques have become the first-line management choice for many postpancreatectomy complications. Image-guided drainage of intraabdominal fluid collections, percutaneous biliary drainage (PBD), and angiography with vessel embolization permit a less invasive approach to postsurgical complications and frequently mitigate the need for reoperation. Sohn and colleagues (2003) reported the use of postoperative IR procedures in 12% of 1061 patients undergoing PD. And according to Baker and others (2008), these postoperative IR procedures were for intraabdominal abscess drainage (72%), PBD (18%), and angiography with or without embolization (10%).

Image-Guided Abdominal Drainage

One of the major advances in the management of postoperative fluid collections and abscesses over the past 2 decades has been the introduction of image-guided percutaneous drainage procedures, which have changed the management of patients previously requiring an urgent reexploration. Small fluid collections at the resection site are common in the immediate postprocedural period and usually resolve spontaneously. These collections generally do not require an interventional procedure, but they can be aspirated with a needle if there is clinical suspicion for infection (Gervais et al, 2001). Abscess drainage can be performed with US but is done more often with CT guidance (see Fig. 25.4). The technical success rate has been reported to be 96% to 100% (Betsch et al, 2002; Lagan et al, 2008; Zink et al, 2009). The complication rate of interventional drainage of fluid collections is low, however, bleeding and bowel perforation have been reported (Lambiase et al, 1992; Betsch et al, 2002; Lagan et al, 2008; Zink et al, 2009).

There are two widely used techniques of imaging-guided abscess drainage: the *trocar technique* and the *Seldinger technique*. The trocar technique is performed by direct puncture of the abscess using a trocar needle, which is covered by the catheter, and by removal of the trocar needle after the catheter is in position. The Seldinger technique is performed by puncture of the abscess using a coaxial needle, through which a guidewire is inserted into the fluid collection. The needle is then removed, leaving the guidewire in situ. The needle tract is serially dilated by exchange of dilators and guidewires. Finally, a drainage catheter is inserted into the abscess over the guidewire. The advantage of the Seldinger technique is that it is less traumatic to the surrounding tissue because of the initial use of small needles and the subsequent dilation with dilators, until the size of the catheter is reached. The advantage of the trocar technique is that this procedure is easier and faster to perform. Independent of the technique, a wide range of drainage catheters is available, ranging from 6 to 14 Fr in diameter (Gerzof et al, 1978; Goletti et al, 1993; vanSonnenberg et al, 1984). Although no difference has been seen comparing 7 and 14 Fr drainage (Roethlin et al, 1998), the diameter of the catheter may be chosen on the basis of viscosity of the content.

After catheter placement, the abscess is emptied, and specimens are sent for bacteriologic examination and culture and for evaluation of amylase levels. Postprocedural drain care includes local protection of the skin incision and flushing of the drain with gentle saline solution two to three times a day to prevent drain clogging. Documentation of the daily output volume is mandatory to evaluate drain function.

Percutaneous drainage of abdominal fluid collections has been reported to be as effective as operative drainage. No significant differences have been reported in mortality or morbidity, and the duration of hospital stay has been similar when patients were matched for age, sex, diagnosis, and abscess etiology and location (Hemming et al, 1991; Olak et al, 1986).

The earliest experiences with CT-guided percutaneous drainage of abdominal abscesses were reported in the late 1970s (Gerzof et al, 1978). Since then, the efficacy of the procedure has been confirmed in several studies, in which success rates of drainage of abdominal fluid collection or abscesses were 62% to 96% (Zink et al, 2009; Betsch et al, 2002; Lagan et al, 2008; Lambiase et al, 1992; Gerzof et al, 1978; vanSonnenberg et al, 1984; Cantasdemir et al, 2003; Cinat et al, 2002; Freeny et al, 1988). Multiple drainage procedures may be necessary in the same patient to achieve clinical success (Zink et al, 2009; Cinat et al, 2002).

A similar high rate of successful imaging-guided drainage can be achieved in patients with accompanying pancreatic fistula. The reported success rates in patients with accompanying fistulas have been 67% to 89% (Zink et al, 2009; Aassar et al, 1999; Kerlan et al, 1985; Singh et al, 2006). One important prognostic factor associated with decreased success of percutaneous drainage is the presence of yeast in the abscess fluid (Cinat et al, 2002).

Although studies have shown that fluid collections with pancreatic fistulae have similar drainage success compared with fluid collections without an active pancreatic leak, fluid collections with pancreatic fistulae require longer drainage. Zink and others (2009) reported the median duration of drainage in patients with abscess was 29 days compared with 11 days in patients with a sterile fluid collection. Patients with a pancreatic leak had median drain duration of 30 days (Zink et al, 2009).

Percutaneous Biliary Drainage

Biliary obstruction or leak is another example of a complication that can occur after pancreatic surgery that can be managed

using nonoperative techniques. Endoscopic management is possible but frequently difficult because of the alteration in the anatomy as a result of surgery. Malignant strictures can be palliated with a biliary drainage catheter, and metallic stents may be useful, but they frequently occlude in less than a year (Dahlstrand et al, 2009). Therefore, the decision to pursue metallic stenting often hinges upon a patient's life expectancy. Benign strictures can be relieved with balloon dilation but may also recur and require repeated dilations (Kocher et al, 2007). Bile leaks at the hepaticojejunostomy usually require both drainage of the bile fluid collection and PBD to divert bile and allow for the leak to heal (Gervais et al, 2001; Dorico et al, 2008).

Angiography and Embolization (See Chapter 19)

Postoperative bleeding pseudoaneurysms usually occur relatively late after surgery and are associated with a high mortality rate (Rumstadt et al, 1998). In a report by Otah and colleagues (2002), the average presentation was 19 days after surgery, and the majority of patients were already discharged home. All patients in this report first had a sentinel bleed with minimal blood seen in drains or in the GI tract. *Sentinel bleeds* were defined as the appearance or paradoxical increase in the amount of blood from the abdominal drains or GI tract combined with a decrease in hemoglobin of 2 g/dL at least 3 days after surgery (Tien et al, 2008). This has led some to take a very aggressive approach to the presence of even minimal bleeding beyond 3 days after resection. CT angiography can sometimes identify the vessel of interest, however, this potential benefit must be weighed with the additional contrast dose needed to perform CT. Given that the likely bleeding source will be identified on angiography, the CT may not be beneficial, especially in patients with borderline renal function. Many believe angiography with possible embolization should be pursued in the presence of a sentinel bleed, with reoperation reserved only for the presence of active, massive bleeding or failed embolization (Otah et al, 2002; Blanc et al, 2007). The success rate is approximately 85% (Tsai et al, 2007).

Pseudoaneurysms after pancreatic surgery occur in the gastroduodenal artery most commonly, followed by the hepatic artery, superior mesenteric artery, and splenic artery (Tien et al, 2008). Selective coil embolization across the pseudoaneurysm is successful in approximately 85% of patients (Tsai et al, 2007). More recently, however, some have reported the use of covered stents, instead of coils, to exclude the pseudoaneurysm while preserving flow to distal structures supplied by the injured vessel (Narumi et al, 2007; Suzuki et al, 2009; Wallace et al, 2007). A demonstration of these images and techniques is shown in Figure 25.3.

Drain Management

After catheterization of the abscess, a specimen is obtained for microbiology and chemistry studies (amylase, bilirubin). The collection is drained before gentle contrast injection to limit possible bacteremia that might occur in a distended collection during injection. Contrast injection can identify fistulae and may show additional pockets of drainable fluid. Once drainage is complete, imaging should be obtained to document a collapsed cavity. The catheter should be marked at the skin site as an indicator of possible migration during the patient's follow-up management. Saline flushes should be used two to three times daily to maintain a patent tube.

After patients have defervesced and otherwise improved clinically, they may be eligible for discharge with their catheters for home management. Whether the patient is in the hospital or at home, the catheter output should be carefully monitored. If the daily net output remains high (>50 mL) for several days, an ongoing fistula or leak may be present. If the daily net output diminishes to fewer than 10 mL, consideration should be given for a tube study to evaluate for a functional tube, particularly if any systemic signs of recurrent infection are evident. A saline flush should be easily injected into the tube with the complete volume returned upon aspiration. If the tube is functional and has not been dislodged, and the patient is not having pain or fever, then it may be removed. On the other hand, if the saline flush cannot be completely aspirated, the tube has been moved from its skin marking, or the patient's clinical condition has changed, then the tube should be imaged.

Imaging method depends on physician preference: some prefer a fluoroscopic tube injection; others prefer a CT scan, and others still prefer both studies. The fluoroscopic contrast injection will show the remaining cavity size and the presence of fistula. The CT can also show the cavity size but not necessarily a fistula. If the CT shows a collection remaining around the catheter, a malfunctioning tube must be suspected, as functional tubes should have no collection around the tube. If imaging demonstrates nondraining locules, some prefer to try an intracavitary tissue-type plasminogen activator (TPA). One report showed an 89% success rate using TPA to drain abscess refractory to simple catheter drainage (Beland et al, 2008). The risk of bleeding should be carefully considered prior to the use of TPA in a postpancreatectomy patient, and this should be utilized only in carefully selected patients.

Postpancreatic drains may be present for several weeks. The study by Vin and colleagues (2008) demonstrated a mean duration of 38 days (range, 3 to 228 days). Pancreatic drains ideally require an active participation by the patient or patient's caregivers.

Supportive Management of Pancreatic Fistula

Patients with infected fluid collections are typically treated with broad-spectrum antibiotic therapy until clinical signs and symptoms of infection resolve. To date, no strong clinical evidence is available to show that somatostatin analogs enhance fistula closure (Stojadinovic et al, 2003). A recent prospective trial randomized patients with pancreatic or enterocutaneous fistulae to intramuscular injection of 30 mg of a sustained-release somatostatin analog, lanreotide, or placebo (Gayral et al, 2009). The investigators found a significant reduction in fistula output within 72 hours of injection (primary end point), however, no difference was found in fistula closure rates (secondary end point).

To date, no evidence of any benefit has been shown for supplemental parenteral or enteral nutrition in patients with pancreatic leak who can tolerate oral intake. It is our general practice to allow patients ad libitum feeding as tolerated. More aggressive supportive care, such as total parenteral nutrition, is reserved for patients with secondary complications precluding oral intake or extremely high output that is responsive to initial bowel rest. Patients are managed in the hospital until they have return of oral intake and bowel function and can reliably manage their drain with or without nursing assistance.

Reoperation

Improvements in interventional and endoscopic techniques have reduced the need for reoperation in many patients after

pancreatic resection. Reoperation is still necessary, however, in 3% to 5% of patients following pancreatic or liver resection, and it should be considered in patients with clinical deterioration from hemorrhage, abscess, leak/fistula, or intestinal ischemia. Reoperation rates, as seen in Table 25.2, range from 4% to 15% and vary according to type of pancreatic resection. Standop and others (2009) reported their series of 31 patients (11% of 285 consecutive PDs) who required reoperation. The most common indications for reoperation were hemorrhage (29%) and intraabdominal abscess (23%). Among patients who required reoperation, 45% required a second operative procedure. The mortality rate among patients requiring reoperation was 13% compared with 2% for the cohort of patients that did not require reoperation. Significant mortality in patients requiring reoperation is as high as 60% in some series, indicating the critically ill nature of these patients (Hoshal et al, 2004).

HEPATECTOMY

A large series of hepatic resection reveals that the morbidity associated with open resection ranges from 14% to 45%, and the reported mortality ranges from 0% to 3% (Table 25.8; Jarnagin et al, 2002; Adam et al, 2006; Cescon et al, 2009; Huang et al, 2009; Imamura et al, 2003, Palavecino et al, 2010; Poon et al, 2004; Rees et al, 2008; Koffron et al, 2007). The outcome following hepatic resection has significantly improved over the last 20 years. In 1977, Foster and Berman first reported a multicenter analysis of 621 hepatic resections. In this report, the overall mortality was 13%, and it was more than 20% in patients who had major hepatic resection. The most common cause of operative mortality was hemorrhage. Large series from high-volume centers published in the late 1990s have reported mortality rates of less than 5% (Fan et al, 1999; Gayowski et al, 1994). The significant improvements are multifactorial and include a better understanding of hepatic anatomy, modern cross-sectional imaging, improved anesthetic techniques, improved patient selection, and the use of parenchymal-sparing resections. These innovations have significantly reduced the incidence of massive hemorrhage, which is no longer the dominant cause of death after hepatic resection. The perioperative mortality rate over the last 20 years at MSKCC reflects this trend, with operative mortality rate decreasing from 4.3% from 1996 to 1997 to 1.3% in 2000 to 2001 ($P < .001$). From September 2001 to September 2009, we performed 1877 hepatic resections, and the 90-day mortality rae remained at 2.1%. Over the past 8 years, median estimated blood loss was slightly lower (300 mL), but mean hospital stay remained the same (9 days). With this reduction in hemorrhage, a shift has been seen toward hepatic failure and infectious complications being the leading causes of death after hepatic resection.

The most commonly reported complications following hepatectomy are presented in Table 25.8. In the series of 1803 patients reported by Jarnagin and others (2002), the most common complications arose from the liver and biliary tract that included perihepatic abscess, hepatic failure, sterile perihepatic fluid collection, and bile leak or biloma. Pulmonary complications were the second most frequent complication and included symptomatic pleural effusion, pneumonia, and atelectasis. These findings are similar to other large series that have carefully documented complications by system; these are presented in Table 25.9 (Cescon et al, 2009; Imamura et al, 2003; Jarnagin et al, 2002; Poon et al, 2004).

Factors associated with the development of perioperative complications after hepatectomy have been examined in large series. In the series reported by Jarnagin and colleagues (2002), one of the patterns noted over time was a significant increase in parenchymal-sparing segmental resections and a decrease in the number of hepatic segments resected. This corresponded to a decrease in blood loss, decreased use of blood products, and shortened hospital stay (Table 25.10). On multivariate analysis,

two factors predictive of morbidity and mortality included the number of hepatic segments resected (Fig. 25.5) and operative blood loss. Retrospective data from MSKCC, as well as those from other institutions, have shown that a parenchymal-sparing approach is associated with less perioperative morbidity without compromising oncologic outcome in appropriately selected patients (Gold et al, 2008; de Haas et al, 2008). Independent predictors of morbidity following hepatic resection in the series from Jarnagin and colleagues (2002) included major concomitant biliary procedure or vascular resection, lower preoperative albumin, and elevated preoperative creatinine. Additional factors associated with increased mortality included elevated preoperative bilirubin, complex hepatic resection, a lower preoperative platelet count, and increased age.

Attempts to reduce complications following hepatic resection have been aimed at techniques to reduce blood loss, operative time, and the requirement for transfusion (see Chapter 22). One major advance in liver surgery has been the concept of low central venous pressure (CVP) anesthesia during resection. It has been demonstrated from retrospective (Melendez et al, 1998) and prospective randomized controlled trials (Wang et al, 2006) that maintaining a low CVP (<5 mm Hg) results in reduced blood loss, lower morbidity, and increased preservation of renal function after hepatic resection.

Techniques for parenchymal transection and their association with postoperative complications have been extensively studied (Pamecha et al, 2009; Poon, 2007). Techniques for parenchymal division include crush clamping, stapling, vessel sealing systems (i.e., LigaSure, Covidien, Boulder, CO), and multiple options for ultrasonic dissection with or without intermittent inflow occlusion. Among the numerous techniques studied in randomized trials, there does not appear to be a single "best" option. Since most studies are performed by high-volume, experienced liver surgeons, it may be difficult to show small differences among techniques (Palavecino et al, 2010; Arita et al, 2005; Ikeda et al, 2009; Patrlj et al, 2010). A recent Cochrane review analyzed seven randomized controlled trials comparing methods for parenchymal division, which included

Modified from Jarnagin WR, et al, 2002: Improvement in perioperative outcome after hepatic resection: analysis of 1,803 consecutive cases over the past decade. Ann Surg 236(4):397-406.

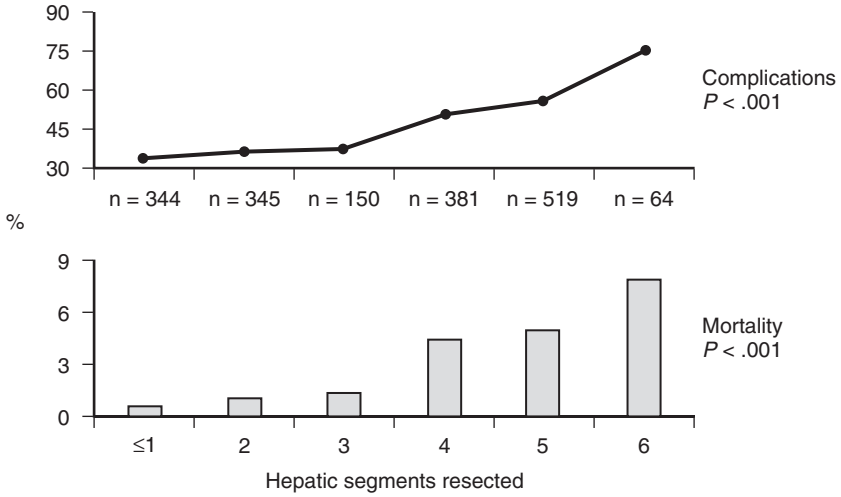

FIGURE 25.5. Perioperative complications and mortality rate stratified by the number of hepatic segments resected. *(Reproduced from Jarnagin WR, et al, 2002: Improvement in perioperative outcome after hepatic resection: analysis of 1,803 consecutive cases over the past decade. Ann Surg 236[4]:397-406.)*

556 patients (Pamecha et al, 2009). The authors concluded that the crush-clamp technique was the procedure of choice, because the parenchymal transection devices offered no improvement in time or reduction in blood loss compared with crush clamping. In addition, the crush-clamp technique was faster in many of the studies examined. In one positive randomized controlled trial, Lesurtel and colleagues (2005) found that the crush-clamp technique with intermittent vascular inflow occlusion was more effective in terms of reduced time and blood loss and more cost efficient than ultrasonic dissection devices.

An additional technique to potentially reduce the need for perioperative blood and plasma transfusion is intraoperative acute normovolemic hemodilution (ANH), which has recently been studied in a prospective randomized trial at MSKCC (Jarnagin et al, 2008), where 136 patients undergoing major hepatectomy (three or more segments) were randomized to ANH or standard low-CVP anesthesia techniques. Patients randomized to the hemodilution arm had a reduction in the overall perioperative transfusion rate, but this did not reach statistical significance (50% vs. 25% in the standard arm; $P = .067$). ANH patients did have a statistically significant decrease in intraoperative transfusions and had higher postoperative hemoglobin levels compared with the control arm. Furthermore, where intraoperative blood loss was 800 mL or greater, hemodilution patients had a statistically significant decrease in both red cell and plasma transfusion rates. Hemodilution was safe and effective, yet the ideal patients for routine use are currently not defined.

In an effort to better predict the need for intraoperative transfusion, Sima and colleagues (2009) developed a nomogram for perioperative transfusion risk. Factors such as number of segments in the planned resection, malignant versus benign diagnosis, anticipation of extrahepatic resection, and decreased preoperative hemoglobin and platelet count predict the risk for potential transfusion, and blood conservation techniques such as acute normovolemic hemodilution may be planned preoperatively.

The need for routine intraperitoneal drains following hepatic resection has been studied in a prospective manner. Fong and colleagues (1996) randomized 120 patients to drain or no drain following hepatic resection; patients were stratified based on extent of resection, and no difference was found in overall morbidity, perioperative mortality, or requirement for percutaneous drainage between groups. The authors reported that in the 50 subsequent hepatic resections following completion of the trial, only four patients (8%) required percutaneous drainage. These results were concordant with a recent Cochrane review, which demonstrated no evidence for routine placement of intraperitoneal drains following elective hepatectomy (Gurusamy et al, 2007). Currently, it is our practice to drain selectively, and we consider routine drainage only in those patients who have ongoing biliary leakage from the hepatic transection surface and/or a bilioenteric anastomosis created at the time of resection.

Imaging and Interventional Therapy of Bile Leaks and Abscesses After Hepatectomy

Imaging

US, helical CT, and MRI/MRCP are the noninvasive diagnostic procedures widely applied to the liver and biliary system. Ordinary postoperative fluid collections, bilomas, hematomas, and abscesses can be detected with these modalities. Acute and subacute hemorrhage usually shows a typical high density in CT and can therefore be reliably diagnosed with this modality. In addition, active bleeding can be demonstrated by contrast media extravasation on contrast-enhanced CT. In particular, the typical appearance of biloma on imaging is that of an encapsulated mass with space-occupying and space-conforming characteristics contiguous with the liver resection plane or biliary structure (Vujic & Brock, 1982). Repeated imaging may be necessary to clearly differentiate between uninfected postoperative fluid collections and abscesses because of overlapping. In addition, an ordinary postoperative fluid collection may progress to become an abscess. FNA may be necessary to rule out infection when a patient's condition is suspicious for infection and imaging shows an equivocal fluid collection.

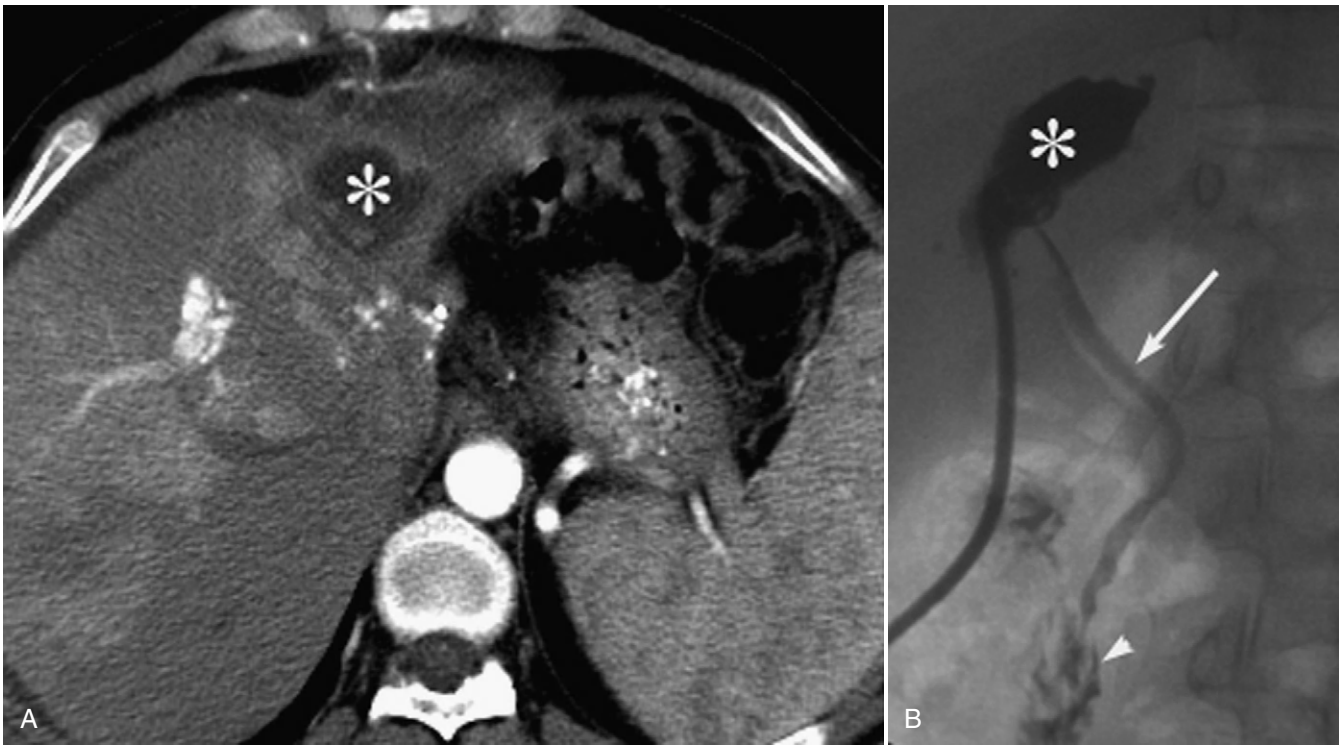

FIGURE 25.6. A 46-year-old male patient with HIV and hepatitis B infection after partial left hepatectomy as a result of hepatocellular carcinoma. **A,** Postoperative follow-up computed tomography revealed a fluid collection at the liver resection site (*asterisk*); it was treated with percutaneous catheter placement. **B,** Contrast injection into the cavity under fluoroscopy revealed the small cavity (*asterisk*) communicating with the common hepatic bile duct (*arrow*). Contrast media is noted in the duodenum (*arrowhead*). Endoscopic retrograde cholangiopancreatography was performed, and a plastic stent was placed into the common bile duct to decrease the output of the fistula.

Interventional Procedures for Treating Posthepatectomy Patients

Hepatic Abscess Drainage

Percutaneous drainage of a hepatic abscess is a minimally invasive, image-guided procedure that carries lower morbidity and is less expensive compared with surgical treatment (Ferraioli et al, 2008). Preparation for the procedure includes evaluation for coagulopathy, choosing the imaging modality for guidance during the procedure (US or CT), and choosing the appropriate route of access. Single abscesses may be drained with US guidance, whereas multiple abscesses may require CT guidance and placement of multiple catheters (vanSonnenberg et al, 2001).

The technical success rate of US- and CT-guided hepatic catheter drainage has been reported to be 94% to 96% (Liu et al, 2009). Abscesses located near the dome of the diaphragm may be technically more difficult to drain without transgressing the pleura, but clinical success rates for percutaneous drainage of intrahepatic abscesses of 70% to 100% have been reported (Akinci et al, 2005; Attar et al, 1986; Dondelinger et al, 1990; Gerzof et al, 1985; Giorgio et al, 2006; Rajak et al, 1998; Mezhir et al, 2010). We reported that yeast in culture and the presence of an obstructed biliary tree were independent predictors of failure of percutaneous drainage of pyogenic hepatic abscess (Mezhir et al, 2010). When biliary obstruction is present, relief of the obstructed biliary tree is mandatory for successful abscess treatment (Fig. 25.6). Size and the presence of loculations did not preclude successful percutaneous drainage in this study.

Although single, small abscesses are generally adequately treated by percutaneous drainage, debate continues on the optimal treatment of large, multiloculated abscesses. Nonetheless, similar clinical success rates of 82% to 92% have been reported for single and multiple abscesses and for single multiloculated and multiple multiloculated abscesses (Liu et al, 2009; Ogawa et al, 1999). Other authors have reported higher success rates for unilocular abscesses and have proposed a treatment algorithm, with small abscesses being treated with antibiotics alone; large, unilocular abscess with percutaneous drainage plus antibiotics; and large, multiloculated abscessed treated with surgical therapy (Hope et al, 2008). It has been reported that repeated catheter drainage improves the success rate (Hope et al, 2008). The clinical success rate for treatment of unilocular abscesses was 83% if a single drainage was performed and 100% if repeated drainages were performed. The success rate for treatment of multilocular abscesses was 33% for single drainage and 50% if repeated drainages were performed (Hope et al, 2008). Some suggest use of intracavitary TPA to aid with multiloculated collections refractory to simple percutaneous drainage (Beland et al, 2008).

Several studies have shown the superiority of percutaneous catheter drainage over needle aspiration. For abscesses, needle aspiration was successful in 60% to 92% of patients, whereas percutaneous catheter drainage was successful in 97% to 100% of patients (Giorgio et al, 2006; Rajak et al, 1998; Singh et al, 2009; Zerem & Hadzic, 2007). Among the successfully treated patients, the average times for clinical improvement, hospital stay, and total resolution of the abscess were similar in the two

treatment groups (Giorgio et al, 2006; Rajak et al, 1998; Singh et al, 2009; Zerem & Hadzic, 2007). In one study no significant difference in the success rate between aspiration and drainage was reported, but multiple aspirations were required in the aspiration group to achieve success (Yu et al, 2004).

Interventional Management of Bilomas and Bile Leaks

Hepatic tumor surgery may also be complicated by biliary leak. It is known that a large number of ordinary postsurgical bile leaks heal spontaneously (Czerniak et al, 1988), but many perihepatic bilomas require percutaneous drainage, particularly those that become infected (Christoforidis et al, 2007). In cases of persistence of a fistula, patients may have prolonged hospital stays (Czerniak et al, 1988). Endoscopic transpapillary drainage or PBD may serve to decompress the biliary system and divert bile flow from the defect in the bile ducts, which may lead to healing of the fistula without need for repeat surgery.

Percutaneous transhepatic biliary drainage has been proven as a low-risk procedure that provides a considerable reduction in repeat laparotomy (Cozzi et al, 2006; Funaki et al, 1999; Kaufman et al, 1985; Vaccaro et al, 1991). It has been reported that percutaneous transhepatic bile drainage was successful in patients with bile leaks in 81% to 90% (Cozzi et al, 2006, Funaki et al, 1999, Ernst et al, 1999) and that technical success was achieved in 90% to 100% when the bile ducts were not dilated (Cozzi et al, 2006; Funaki et al, 1999). Several authors have reported that the success rate of percutaneous or endoscopic treatment depends on bile leak location: success rates are higher when bile leaks are located at the resection plane of the liver, and they are lower when bile leaks occur in the area of the main bile ducts (Fragulidis et al, 2008; Lo et al, 1998).

Supportive Management

Patients are managed using pathway constructs following hepatectomy at MSKCC. This includes daily measurement of white blood cell count, hemoglobin, platelets, and electrolytes including phosphate levels, liver function tests, and international normalized ratio. Especially after major hepatectomy, there can be significant phosphate depletion in the early postoperative period. In addition, aggressive pulmonary toilet and early mobilization is critical to prevent pulmonary complications in patients following hepatic resection.

Supportive management after intervention for bile leak or perihepatic abscess is similar to that for complications after pancreatectomy. Patients who tolerate adequate oral intake and who are able to manage their abscess drain independently or with nursing care can be sent home.

CHAPTER 26

Quality of life and hepatopancreatobiliary tumors

Piera Robson, Sofija Pitka, and Steven D. Passik

QUALITY OF LIFE

Quality of life (QoL) is a clinically and biologically meaningful outcome for the oncologic patient. Historically, surgical, procedural, and interventional outcomes have been measured in clinical and objective terms using end points such as morbidity, mortality, and disease-free survival. In the 1990s, there was increased recognition of the need to evaluate the patient's subjective experiences, how they felt and functioned. Measurement of a patient's QoL throughout the clinical course should be standard practice. A surgeon often manages the care of a hepatopancreatobiliary cancer patient beyond the surgical procedure alone. Management includes orchestrating diagnostic tests, biliary interventions, and percutaneous ablative therapies. For any of these procedures, the goal of the physician is to minimize the impact on a patient's function and to improve overall QoL (Langenhoff et al, 2001; Miner et al, 2002; Blazeby & Vickery, 2001; Sajid et al, 2008; Pallis & Mouzas, 2004; Sun et al, 2008).

Surgical resection of malignant tumors of the liver, bile ducts, gallbladder, and pancreas is performed for both curative and palliative reasons. Hepatopancreatobiliary surgical outcomes have continued to improve, because advancements in presurgical imaging and surgical techniques have resulted in better patient outcomes, fewer complications, and higher survival rates. After recovery from surgery, while a patient remains disease free, QoL is usually excellent. For those patients who are not candidates for a curative resection, palliation is the major treatment goal (Sun et al, 2008; Abraham et al, 2002; Singhal et al, 2005). Indications for palliative surgical resection include locoregional disease control and surgical bypass to relieve biliary or gastrointestinal obstruction (Nakakura & Warren, 2007; Koninger et al, 2007). Resolution of symptoms such as pruritus, anorexia, fatigue, and pain and improvement of QoL are the major treatment goals.

In the past 10 years, QoL data in the literature have grown significantly. These data can facilitate physician-patient conversations regarding treatment options, especially in the palliative setting. Most of the reports in the literature provide insight into procedural outcomes and their effect on symptoms and QoL. The end result is a more robust clinical understanding of the trajectory of the disease process and of the differing effectiveness of the treatment options. Even though the importance of QoL and symptom assessment is increasingly recognized, much research has yet to be done. Current literature does not delineate well between outcomes in different subgroups; for many procedures, it is not clear what patient characteristics predict a better outcome versus no significant gain or a decline in QoL. As more information becomes available, our understanding of clinical QoL assessment outside of a research setting will be better, with a more direct application to patient care.

This chapter defines and describes QoL as it pertains to patients with hepatopancreatobiliary cancers. Questionnaires commonly used to assess QoL are reviewed, and guidelines for designing QoL studies in this population are presented. An overview of currently available QoL studies is presented to allow for more focused discussions by disease type and procedure. Finally, the future of QoL investigations in hepatopancreatobiliary patients is discussed.

Definition of Quality of Life

In 1947, the World Health Organization (WHO) broadened the definition of health to include not only the absence of disease but also "the complete physical, mental, and social well-being of a person" (WHO, 1947). Karnofsky and Burchenal (1949) subsequently outlined basic criteria for evaluation of new chemotherapeutic agents, describing a simple scale to measure the effect of nitrogen mustard on patients with lung cancer. In the years following, numerous anticancer therapies emerged that increased survival, but toxicities were significant. Izsak and Medalie (1971) sought to identify the "costs of survival" among cancer patients. Noting that a growing number of patients with cancer were surviving longer, they began looking at the lives of the survivors from multiple angles, namely the psychological, behavioral, and environmental aspects. This new insight into patient health care caused a dramatic increase in interest in the new field of QoL research (Aaronson, 1988). One event that placed QoL end points in the spotlight was the controversial approval of gemcitabine for the treatment of pancreatic cancer on the basis of a beneficial clinical response. The "surrogate end point" of clinical benefit was likened to improvement in QoL based on the parameters of pain intensity, analgesic consumption, performance status, and weight gain (Burris et al, 1997). The concept of clinical benefit has increased dialogue about pancreatic cancer and QoL and undoubtedly has raised awareness of the importance of QoL assessment in palliative care settings.

In an effort to better describe clinical benefit, the term *health-related quality of life* emerged and has come to include the aspects of QoL that are most influenced by health and health care interventions (Kassa & Loge, 2002). The terms *quality of life* and *health-related quality of life* are often used interchangeably, but no single definition of either exists. There is consensus, however, that QoL is multidimensional and at a minimum encompasses physical symptoms, treatments, functional ability, family factors, emotional well-being, intimacy, and social aspects (Cella, 1998).

The broad overuse of the term *quality of life* has led to the misleading notion that measurements of performance status (e.g., Karnofsky and Eastern Cooperative Oncology Group, 1949), clinical indicators (e.g., bilirubin level), or symptom checklists adequately reflect QoL (Blazeby & Vickery, 2001). Other clinical factors—including laboratory values, postoperative complications, and time spent in the hospital—also have been translated into QoL results. Although these assessments have value in clinical care and research, care must be taken not to mistake or substitute them for proper QoL measurement.

Applications of Quality of Life Assessments in Surgery

In the past, informal feedback from patients regarding symptoms and functional status combined with the clinician's objective assessment was considered sufficient for making judgments about patients' QoL. Over the past few decades, a demand for more information about the broader effects of treatment and illness has required more formal definitions and evaluations of QoL (Blazeby & Vickery, 2001; Gouma et al, 1999; Barbarisi et al, 2001). In addition to defining the patient's physical, psychological, and functional problems, QoL assessments also evaluate surgical outcomes, compare treatment options, aid preoperative selection of patients, predict prognosis, and monitor quality of care. In the case of neurosurgical measurements of QoL, the standard remains the Karnofsky Performance Status (KPS) set by Karnofsky and Burchenal (1949), which only addresses three variables of QoL: 1) work, 2) activity, and 3) self-care (Meyers & Weitzner, 1995).

Quality of Life as an Outcome

Outcomes research is a new and interesting field in clinical research and in daily clinical practice. In 1996, the American Society of Clinical Oncology published a special article to clarify effectiveness of cancer treatments (ASCO, 1996). Outcomes were divided into cancer outcomes (response rate) and patient outcomes (survival and QoL). As a surgical outcome, QoL has become an issue of increasing importance. The American College of Surgeons has dedicated a section of its Surgical Forum to QoL and outcome studies since 1996 (Tassinari et al, 2003; Velanovich, 2001). More holistic patient outcomes can be given priority over cancer outcomes in several situations. Examples of surgical trials in which consideration should be given to QoL data are 1) adjuvant trials in which a moderate risk of disease recurrence is present; 2) trials in which survival is not expected to differ between treatment arms, but QoL might be affected; 3) trials in which the primary intent is palliative; and 4) equivalency trials in which lesser surgical procedures are done with the expectation that survival and tumor control will be equal (Whalen & Ferrans, 2001).

Comparing Treatment Options

Along with the morbidity and mortality statistics given to patients during discussion of treatment options, QoL data should be included to provide concrete information about severity and duration of side effects and possible functional limitations. This information may be particularly helpful when presenting the option of adjuvant therapy. Considering the multiple factors that must be weighed when recommending appropriate palliation, QoL results may help or even be the deciding factor in treatment decisions. Frank discussions between physicians and patients about what to expect could lead to more informed decision making.

Psychological Screening

For many patients with newly diagnosed cancer, the psychological trauma can be quite intense. This is particularly true for patients with hepatopancreatobiliary cancer, most of whom face an uncertain future, with much of their remaining time consumed by oncologic treatment. The psychological impact of receiving such a diagnosis and living with the disease is profound. Depression and anxiety have been reported in 50% of patients with pancreatic cancer before their diagnosis, and several studies have suggested hormonal and neuropsychiatric links to explain this phenomenon (Holland et al, 1986; Passik & Breitbart, 1996; Passik & Roth, 1999). Attention to the emotional sequelae of hepatopancreatobiliary cancer may improve QoL and treatment adherence significantly. QoL questionnaires and/or psychological questionnaires may be used early in the diagnosis to identify problems that may not otherwise be detected during routine evaluation. Linden and colleagues (2005) found the Psychological Screen for Cancer to be an important tool in screening and for "following changes in patient distress throughout the cancer care trajectory." Early identification of depression or anxiety allows for prompt evaluation by a mental health professional. Subsequent intervention with psychotherapy and/or medication may result in better psychological outcome for many patients.

Prognostic Indicators

QoL data have been shown to have prognostic value in several chemotherapeutic trials in patients with advanced metastatic colorectal cancer. Earlam and colleagues (1996) reported physical symptom scores were better predictors of survival than tumor size. In three large studies, QoL scores were independent predictors of survival; QoL was a stronger predictor of survival than clinician-rated performance status in two of these studies (Earlam et al, 1996; Schoffski et al, 1996; Maisey et al, 2001). One author concluded that QoL measurement may help stratify patients in clinical trials and may facilitate comparisons between studies (Blazeby & Vickery, 2001; Conroy & Blazeby, 2003). Pretreatment QoL was found by de Graeff and others (2001) to be a strong predictive indicator in the assessment of cancer survival in which performance status, physical functioning, and well-being were the QoL variables. For many patients with primary liver cancer or metastatic neuroendocrine cancer in the liver, treatment is often palliative and multimodal in nature, consisting of surgical, hormonal, ablative, and chemotherapeutic approaches. QoL assessment as a prognostic indicator and stratification tool may be useful for treatment algorithms and may help patients with poor performance status avoid futile treatments.

Physician-Patient Communication and Decision Making

The surgical oncologist is responsible for explaining surgical and ablative treatment options and for discussing treatment side effects, potential for cure, and impact of treatment on QoL. Physicians should have open discussions with patients as they advise them in these important treatment decisions. The physician opens the door for better communication by first trying to understand the value each patient places on issues such as survival, toxicity, disease-free interval, and impact on functional status; by matching treatment options to the patient's value

system, the physician can become more effective. Research has shown that patients differ greatly in how they view risk/benefit ratios. A study evaluating treatment options for elderly patients found that meetings with a facilitator along with written information allowed the patient and the family to make decisions better suited to their QoL needs (Matulonis, 2004). Knowledge of and effective communication of QoL results may lead to better informed, shared decision making and ultimately may improve the physician–patient relationship and the outcome (D'Angelica et al, 1998).

QUALITY OF LIFE AFTER HEPATOPANCREATOBILIARY SURGERY

Over the past 10 years, hepatopancreatobiliary operations have moved from high morbidity and high mortality procedures to procedures that are safe and effective in an experienced surgeon's hands. When procedures are performed with the intent to cure, patients are usually accepting of a short-term decline in QoL as a part of recovery from surgery or as a surgical or procedural complication (Perez et al, 1997). When consenting for a procedure, patients usually assume the risks of the surgery willingly as the price of a cure. In this setting, assessment of QoL improves understanding of the impact of a surgery. On the other hand, for both procedural and surgical palliative interventions, patients are less forgiving of postprocedure complications that cause a decline in QoL in the face of an imminently diminishing life span. Therefore QoL becomes an important outcome to include when evaluating a palliative intervention.

Miner and others (2002) offer insight into outcomes after palliative surgeries for advanced malignancy. Their study, limited by a small number of subjects (n = 36) and early mortality (median survival, 108 days), found that 54% of the patients who underwent palliative operations for unresectable disease experienced no clinical improvement after surgery, and these patients died significantly sooner than those who experienced a benefit. For those who did experience an improvement in QoL, duration of improvement was a median of 3.4 months. The surgeon's preprocedure predictions regarding ability to relieve symptoms were correct 78% of the time for those with positive outcomes, while he or she only mistakenly thought they could ameliorate 1 (7%) of the 14 patients who did not improve. The reasons for the surgeon proceeding with the surgery in the belief of a poor clinical outcome were not discussed. Prior to surgery, 26% of patients expressed fear that they did not expect to survive the surgery; patients also reported a strong relationship with their surgeon before the surgery, and this did not change significantly afterward.

Unfortunately, the study found that 46% of patients undergoing palliative surgery expressed hope that their physician would find no evidence of disease at the time of surgery (Miner et al, 2002). This belief cannot simply be attributed to optimism, hope, or a delusional process; however, it is likely that these patients harbored misconceptions regarding the procedure that were not corrected during the consenting process. It is critical that patients understand that a palliative procedure is being done *only* to improve QoL; a cure cannot be achieved, and there will still be evidence of disease. Furthermore, patients should have a realistic expectation as to whether the goal of palliation is achievable. Surgeons should trust their clinical judgment regarding their ability to bring about a favorable clinical outcome as well as the potential for futility. These opinions should be discussed with patients, and such discussions are likely to be in depth and difficult; but the end goal of more realistic patient expectations should not be undervalued, and this is an important topic in palliative medicine that should be further explored.

Existing research is deficient in taking QoL analysis to the next step, in which data are used to identify subsets of patients who are more likely to experience a QoL benefit from various procedures. Currently, QoL data offer insight into the patient experiences at one moment in time, or if collected at more that one time point, how their perspective changes over time. This information fills in the clinical picture, but in a clinical trial, the data are often presented as a stand-alone component, not linked to other outcomes. If QoL analysis is considered to be equivalent to a clinical parameter, such as decline in serum bilirubin, it will provide a more balanced view of surgical outcomes. This information can then be correlated with preprocedural characteristics to provide clinicians with information for evidence-driven decisions regarding clinical recommendations.

Measurement and Interpretation of Quality of Life End Points

It has been established that QoL is an important outcome that should be incorporated into surgical oncology, but the problem remains: How should it be measured? Specifically, what should be measured? First, the concept needs to be clearly defined, because a great deal of variability surrounds the way QoL might be measured in a clinical trial. In a review of QoL studies in six major surgical journals, Velanovich (2001) found that many studies made errors in conceptually defining QoL and in choosing QoL questionnaires. Passik and Kirsch (2000) suggested a "levels of evidence" approach to understanding QoL end points in clinical trials. Such an approach is based on the type and sophistication of the questionnaire chosen for the trial and the conclusions one can make from the resulting data. This approach may be helpful in interpreting QoL conclusions made by authors and in aiding investigators in trial design (Table 26.1). The European Organization for the Research and Treatment of Cancer (EORTC) has placed the evaluation of QoL on questionnaires such as the QLQ-C30, SF-36, and the Rotterdam Symptom Checklist and on modules specific to the disease and treatment (Giannakopoulos et al, 2005). Better understanding of the QoL concept would help the investigator design a study, and it would help to make the published results more meaningful (Koller & Lorenz, 2002; Sprangers, 2002).

Types of Quality of Life Instruments

QoL instruments can be broken down into three general categories: 1) generic, 2) cancer specific or symptom specific, or 3) modular. Generic instruments are multiitem scales designed for use in a wide range of chronic diseases. Examples include the Nottingham Health Profile (NHP), Medical Outcomes Short Form Health Survey (SF-36), and the Sickness Impact Profile (SIP). These are well-validated instruments best suited for comparisons of QoL results across different chronic health conditions. They are generally not sensitive enough to detect changes after interventions for cancer. Cancer-specific or symptom-specific instruments address problems specific to cancer patients. Examples of these are the Spitzer QoL Index (QLI), the Functional Living Index-Cancer (FLIC), and the

Table 26.1

Levels of Evidence for the Determination of QoL in Clinical Trials

Level of Evidence	Approach Taken	Explanation
Low	Single items	This approach includes the use of face-valid items only. Typically, these are designed by researchers for a particular study and have not been piloted or validated by any formal psychometric means.
Middle (A)	Conversion of existing tools	This approach is highlighted by the adaptation of tools from traditional psychology and psychiatry to oncology and assuming that they will be valid and reliable indicators for cancer patients (e.g., Ways of Coping population questionnaire).
Middle (B)	Assessment of a singular domain of QoL	The middle level of evidence also may focus on measuring a single domain of QoL. Typically, the focus is placed on physical well-being and measurement of side effects of treatment (e.g., toxicity ratings of treatments).
High	Multidimensional assessment of QoL	The highest level of evidence requires a multidimensional approach. This should cover the domains of physical, psychological, social, and functional well-being (e.g., FACT, FLIC, CARES).

QoL, Quality of life; FACT, Functional Assessment of Cancer Therapy; FLIC, Functional Living Index-Cancer; CARES, Cancer Rehabilitation Evaluation System

From Passik S, Kirsch K, 2000: The importance of quality-of-life endpoints in clinical trials to the practicing oncologist. Hematol Oncol Clin North Am 14:877-886.

Gastrointestinal Quality of Life Index (GQLI). These scales assess QoL issues common to cancer patients in general but usually lack disease or treatment specificity. Many single-symptom scales abound and include the McGill Pain Questionnaire, the Constipation Assessment Scale, the Piper Fatigue Scale, and numerous others.

Perhaps the gold standard of QoL instruments for cancer patients is the modular questionnaire. Two examples are the Functional Assessment of Cancer Therapy (FACT), also known as the Functional Assessment of Chronic Illness Therapy (FACIT), and the EORTC QLQ-C30. They combine assessment of overall QoL domains—physical, social, functional, and emotional well-being—with disease-specific subscales or "modules." This approach often eliminates the need for multiple instruments yet results in general and disease-specific or treatment-specific QoL information. The FACT and QLQ-C30 are multilingual and are widely used around the world. They are considered by many experts to be the most valid and standardized instruments for QoL assessment in cancer patients, and each has disease-specific subscales developed for use in patients with hepatopancreatobiliary cancer, such as the FACT-HEP (Blazeby et al, 2004; Fitzsimmons et al, 1999; Heffernan et al, 2002; Kavadas et al, 2003; Pallis & Mouzas, 2004). The FACT-HEP is shown in Figure 26.1, and the QLQ-C30 is shown in Figure 26.2. Disease-specific subscales for the QLQ-C30 include the QLQ-LMC21 (metastatic colorectal cancer), PAN-26 (pancreatic cancer), and HCC-18 (hepatocellular carcinoma).

Questionnaire Selection

Since the inception of QoL research in the 1970s, there has been a proliferation of questionnaires, also known as *instruments* or *measures.* Many studies in the past experienced pitfalls with instrument selection and in some cases used instruments designed by the investigator for the purpose of the study without proper validation. In some published studies, the questionnaire is not well described or is simply left unidentified. Other studies report that QoL was improved or worsened based on performance status ratings such as Karnofsky or Eastern Cooperative Oncology Group. These functional performance scores are clinician rated and are not considered to be QoL scores.

Several points must be taken into consideration when deciding which QoL instrument to choose for a particular study. It is generally accepted that QoL is best measured from the patient's perspective, and instruments designed for self-completion are considered to be the most accurate. The instrument should have proven psychometric properties, such as validity (measuring what the user believes it is measuring), reliability (eliciting the same responses from the same patients the second time it is administered when no change would be expected), and sensitivity to changes over time (how likely a change in scores is going to reflect a change in the patient's condition). The instrument should be multidimensional, covering at least four domains of well-being: 1) physical, 2) functional, 3) emotional, and 4) social. The test should be able to elicit a total or global QoL score from the four domains being measured, and a disease-specific or treatment-specific dimension also is useful to obtain information about side effects that are unique to a specific disease or treatment.

The length of an instrument is an important consideration, because although it is important to be thorough, the burden on the patient and staff is a practical concern. Missing data would be more common if the patient were handed a thick packet of papers, and the time required to complete paperwork may affect a patient's willingness to continue in the study. These are crucial considerations if longitudinal assessments are in the study design, or if the patient's condition is expected to deteriorate.

Methodology is important to consider during the design stage of a study. Will the patient complete the questionnaire in the outpatient clinic, or will a research nurse or study assistant complete it over the phone with the patient? Will it be completed at home and mailed back? Will proxy completion be allowed? Was the questionnaire validated for the form of administration the physician plans to use? A multilingual instrument should be considered, depending on the population to be studied. The QLQ-C30 and the FACT have been translated into multiple languages using a rigorous, well-described translation and revalidation method. Selecting the right QoL questionnaire for a study can be a challenge given the enormous number of available QoL questionnaires. Some are more reliable or more valid than others, and some are more sensitive. Some questionnaires have been developed for a certain population of patients or for assessment of a specific condition.

The first step is to decide if QoL is an end point and if changes in QoL are expected. Groenvold (1999) presented four criteria that can be used in the evaluation of QoL as an end point in clinical trials: 1) inclusion of "relevant QoL issues in the questionnaire," 2) large sample size "to detect meaningful differences," 3) timing, and 4) the questionnaire must be free of missing data. A trial meeting these four criteria produces

high-quality data, otherwise the results of that trial may be invalid (Groenvold, 1999).

Questionnaire selection and study design depend on the research question being asked. An excellent resource that is dedicated to helping investigators with QoL research is the Mapi Research Institute. This institute has developed a patient-reported outcome and QoL instruments database, which contains valuable information regarding patient-reported outcomes research and an index of QoL questionnaires (www.PROQOLID.org).

Table 26.2 lists basic issues to consider or questions to ask when designing a study with QoL as an outcome, modified

Table 26.2

Questions to Consider when Designing a QoL Study

Conceptual

Is QoL defined?
Is there a predefined QoL end point?
What domains of QoL will be measured?
Are there expected changes from specific treatment?

Questionnaire Selection

Is there a rationale for using a specific questionnaire?
Is the questionnaire valid, reliable, and sensitive to change?
Was it validated for the study population you intend to use it for?
Does it cover at least the main dimensions relevant for cancer patients?
Is it relatively short and simple?
Is it completed by the patient?
Is it available in other languages relevant to the study population?
Are there disease-specific or treatment-specific questions?
Can a global QoL score be obtained from the results?

Methodology

In what setting will the study be conducted (inpatient, outpatient, home)?
Is a baseline assessment included?
Will timing of assessments reflect change in health-related QoL owing to disease or treatment?
How will it be administered (self-completion with/without research staff's assistance, mailed questionnaires, or phone completion)?
Will proxy completion be allowed?
Is there a research nurse or research assistant responsible for collecting data?
Will reasons for missed data be recorded?

Interpretation of Results

How will missing data be handled?
What clinical factors will be considered (e.g., type of operation, complications, laboratory results, length of hospital stay, preoperative and postoperative treatment)?
Are results likely to be clinically and statistically significant?
How will the results be used?

QoL, quality of lift

Modified from Efficace F, et al, 2003: Beyond the development of health-related quality-of-life (HRQOL) measures: a checklist for evaluating HRQOL outcomes in cancer clinical trials—does HRQOL evaluation in prostate cancer research inform clinical decision making? J Clin Oncol 21(18):3502-3511.

from a combination of two sources: the minimum standard checklist from Efficace and colleagues (2003) and the Gill and Feinstein Criteria for Assessment of Quality of Life studies (Gill & Feinstein, 1994). Table 26.3 lists questionnaires that are relevant for use in hepatopancreatobiliary patients, limited to QoL and symptom questionnaires for patients with cancer or those that address the symptoms associated with diseases of the hepatopancreatobiliary tract. The list is not exhaustive, and questionnaire selection depends on study design and the research question being asked (Mapi Research Trust, QoL Instrument Database; www.PROQOLID.org).

Quality of Life Studies in Hepatopancreatobiliary Cancer

The literature of QoL studies in hepatopancreatobiliary cancer, and particularly pancreatic cancer, has grown significantly since the turn of the century. In the past, authors of research articles discussed QoL in terms of a practitioner's subjective observations, but these conclusions were not grounded in evidence supported by a validated instrument. The discussion of QoL studies in specific disease states that follows is limited to those studies that utilized a validated instrument. The results of these studies are summarized in Table 26.4.

Pancreas Resection

It is commonly known that patients with pancreatic cancer, who experience symptoms of pain and fatigue among others, have impaired QoL compared with the norms in a population (Muller-Nordhorn et al, 2006; see Chapter 58B). Crippa and others (2008) demonstrated that surgical intervention for pancreatic cancer has a favorable impact on QoL. The literature on QoL after pancreatic resection is the most robust collection of all the subgroup analyses, and the group of studies in Table 26.4 include two randomized pancreatic cancer studies, which is comparatively more than for any of the other disease subsets discussed in this chapter (Van Heek et al, 2003; Nguyen et al, 2003). For many other studies in this group, comparisons were made in a nonrandomized setting, which minimizes the scientific rigor of the comparison (Scheingraber et al, 2005).

Many studies have compared the various surgical approaches to pancreatoduodenectomy (PD) including the pylorus-preserving PD (PPPD), Whipple procedure, standard PD (SPD), classical partial PD (CPPD), and total PD (TPD; see Chapter 62A). For patients undergoing surgical resection with a curative intent, an initial decline from baseline was seen in the first 3 postoperative months (Schniewind et al, 2006; Nieveen van Dijkum et al, 2005). Various surgical approaches were compared, but only Nguyen and colleagues (2003) evaluated randomized patients postoperatively. The authors found no differences in QoL and gastrointestinal function between PD and radical PD at a mean of 2.2 years after resection. In related cross-sectional studies, similar global QoL scores were found in patients who had PD with pancreatogastrostomy or pancreatojejunostomy reconstruction and those who underwent PD for multiple endocrine neoplasia type 1, compared with the general population (You et al, 2007; Schmidt et al, 2005).

Total pancreatectomy (TP) generally has been avoided, because it creates an iatrogenic chronic disease process in which patients are dependent on pancreatic enzymes and high doses of insulin. Billings and colleagues (2005) compared 27 TP patients at a mean of 7.5 years after resection with a national database. TP patients experienced an impact on their QoL and health status compared with the general population (Billings et al, 2005). Prior to undergoing a TP, it is advised that patients be thoroughly advised regarding not only the procedure but the expected outcomes, as well as being meticulously educated, prudently selected, and ascertained of adequate medical support in the future.

Palliation of unresectable pancreatic cancer is a worthwhile area of QoL exploration, because the goal of palliation is impacted by a major surgical procedure (see Chapter 63B). Van Heek and colleagues (2003) found in a randomized study that double bypass—hepaticojejunostomy and a retrocolic gastrojejunostomy—reduced the need for reoperation and creation of a gastrojejunostomy by 18%, and it significantly lowered the risk of postoperative gastric outlet obstruction over a single bypass (hepaticojejunostomy; Van Heek et al, 2003). No difference in postoperative QoL was reported between the groups. These QoL results were similar to the results of Shaw and others (2005), who compared PD to open cholecystectomy and found no difference in global QoL between the two groups, although differences were seen in subscales and item analysis (see Table 26.4; Shaw et al, 2005). In a different area of palliative care,

Table 26.3

Quality of Life Questionnaires

Questionnaire	First Author	Type	Description	Mode of Administration	No. Items	Translation	Comments
Edmonton Symptom Assessment System (ESAS)	Bruera, 1991	Symptom/general oncology	Visual analog scale that assesses common symptoms in terminal cancer patients	S, P, C	9	Yes	Useful in hospice/ palliative care settings
Functional Assessment of Chronic Illness Therapy Measurement System or Functional Assessment of Cancer Therapy (FACIT-G, FACT-G) Version 4	Cella, 1993	QoL, general oncology, and chronic illnesses	Assesses four domains of health-related QoL, five domains when disease-, treatment-, or symptom-specific module is used; used worldwide	S, I, T	27 in FACT-G (core or general)	Yes	40 disease-specific subscales available (e.g., hepatopan-creatobiliary [FACT-HEP]); computer scoring programs available
Functional Assessment of Cancer Therapy Hepatoobiliary Symptom Index–8-item (FHSI-8)	Yount, 2002	Brief symptom scale	Assesses common symptoms in patients with advanced hepatopancreatobiliary cancer	S, I, T	8	Yes	Derived from the FACT-HEP
Quality of Life Questionnaire Core 30 Item (QLQ-C30)	Aaronson, 1993	QoL, general oncology with disease-specific modules	Used worldwide in a wide range of cancer patient populations; may be supplemented by disease-specific modules	S	30	Yes	Disease-specific modules available for pancreatic (PAN-26), metastatic colorectal (QLQ-LMC21), and primary liver (HCC-18) cancers
Functional Living Index: Cancer (FLIC)	Schipper, 1984	QoL, general oncology	Assesses the effect of disease and treatment-related symptoms of cancer on patient's function	S	22	Yes	
M.D. Anderson Symptom Inventory (MDASI)	Cleeland, 2000	Symptoms, functioning, general oncology	Assesses the severity and impact of cancer-related symptoms	S, I	19	Yes	
Memorial Symptom Assessment Scale (MSAS)	Portenoy, 1994	Symptoms, general oncology	Provides multidi-mensional information about a diverse group of common symptoms	S	32	No	Short form available (MSAS-SF)
Quality of Life Index (QLI)	Spitzer, 1981	QoL, general oncology	Assesses health outcomes in patients with cancer and other chronic diseases	P, S	5	Yes	
Ferrans and Powers Quality of Life Index (QLI)	Ferrans, 1992	QoL, general population, satisfaction	Measures QoL in terms of satisfaction with life	S	66	Yes	

Table 26.3

Quality of Life Questionnaires—cont'd

Questionnaire	First Author	Type	Description	Mode of Administration	No. Items	Translation	Comments
Quality of Life Scale–Cancer 2 (QOL-CA)	Padilla, 1983	QoL, general oncology	Measures health-related well-being of patients with cancer	S	30	No	
Rotterdam Symptom Checklist (RSCL)	de Haes, 1998	QoL	Measures psychological and physical distress in cancer patients	S, P, I	30, plus 8 items on ADLs	Yes	
Symptom Distress Scale (SDS)	McCorkle, 1978	Symptoms, functioning	Assesses symptom distress in cancer patients	S	13	Yes	
Gastrointestinal Quality of Life Index (GIQLI)	Eypasch, 1993	QoL, general gastroenterology	Assesses QoL in patients with gastroenterologic, hepatic, and pancreatic diseases	S	36	Yes, original in German	Not cancer specific

C, caregiver; I, interviewer; P, proxy; S, self; T, telephone; ADLs, activities of daily living; QoL, quality of life

Wehrmann and colleagues (2005) found that pancreatic duct stenting for obstruction relieved pain symptoms by 4 weeks, lasting for 12 weeks, and improved QoL at the 4-week time point before returning to baseline levels at 12 weeks.

Hepatic Resection

QoL after hepatic resection has been understudied and underreported in the literature despite the frequency that hepatic resections are performed and the improved outcomes (see Chapters 80 and 81 and Part 7, Subsection). Available studies do demonstrate consistent findings among the population. For those who have a survival duration beyond several months, an improvement is seen in QoL. Poon and colleagues (2001) reported on 66 patients who underwent surgical resection of hepatocellular carcinoma (HCC). Although 33 patients had recurrence, mean QoL scores were higher for all patients at 3 months after surgery than at baseline. For those who remained free of recurrence over the 2-year study, QoL measures demonstrated a sustained improvement. This finding was echoed by Chen and others (2004), who demonstrated that after a surgical resection for a primary liver cancer, an initial decline in QoL was seen for the first 10 weeks. After that, an improvement over baseline scores was noted among survivors. The patients who underwent a major hepatectomy experienced a greater decline in QoL immediately following the surgery. Similarly, other studies have reported the return to baseline physical and functional well-being after surgical resection to be 6 weeks for a minor hepatectomy (two segments or less) and 3 months for a major hepatectomy (Martin et al, 2007; Eid et al, 2006). Banz and colleagues (2009) compared those who underwent hepatectomy for benign and malignant disease and found no difference in general and global QoL. Unlike many other populations discussed in this chapter, the surgical procedure, not the disease burden, has the most significant impact on QoL.

Hepatic Artery–Directed Therapies

Regardless of the population treated or the method—transarterial chemoembolization (TACE), bland embolization, or use of yttrium 90 microspheres (^{90}Y)—hepatic artery–directed treatments (see Chapters 83 and 84A) have not been well investigated from a QoL standpoint. Since 2000, only four studies have been published investigating QoL in patients undergoing hepatic artery embolization (HAE) (Gray et al, 2001; Steel et al, 2004, 2006; Kalinowski et al, 2009). All of these studies involve the use of ^{90}Y, they had limited subjects, and the conclusions were divergent. In overlapping populations, Steel and colleagues (2004, 2006) found a decline in QoL for those undergoing TACE or ^{90}Y at 3 months postprocedure, but the directionality diverged at 6 months between the two studies. Gray and colleagues (2001) used a little-researched tool, and Kalinowski and colleagues (2009) reported on only nine patients, so their findings of improvement of QoL postprocedure at 18 and 6 weeks, respectively, are limited.

Although not a traditional QoL assessment, symptom assessment offers value in understanding the impact of a treatment on a population. The Carcinoid Symptom Severity Score (CSSS) was developed to quantify symptoms of patients with neuroendocrine tumors. Neuroendocrine cancer patients have slowly progressing disease, but the symptoms caused by their tumor can negatively impact their QoL. The CSSS categorizes symptom presence, frequency, and effects on lifestyle into five different levels of symptoms (Schell et al, 2002; Wessels & Schell, 2001). Schell and others (2002) demonstrated an improvement in symptoms after HAE with lipiodol/Gelfoam utilizing the CSSS. Current clinical practice and research endeavors would benefit from use of this CSSS tool to consistently and succinctly summarize the impact of symptoms on this population.

Treatment of Gastric Outlet Obstruction

Gastric outlet obstruction (GOO) is a debilitating problem for those with advanced malignancies, particularly pancreatic and gastric cancers. Palliative interventions that relieve the symptoms of dysphagia, nausea, emesis, reflux, abdominal pain, and impaired eating stand to improve QoL for this population. Currently, the palliative treatment options are surgical bypass—gastrojejunostomy or laproscopic gastrojejunostomy (LGJ)—percutaneous gastrostomy, percutaneous jejunostomy, or duodenal stenting (DS). Only three reports include a QoL component, and study populations are small, but the initial results are promising for minimally invasive techniques. DS was shown to improve QoL and to decrease nausea and emesis for

Table 26.4

Quality of Life Studies in Hepatopancreatobiliary Cancer Patients

Study	Patient Population (N)	Study Purpose/QoL End Point	Study Design and Assessment Points	QoL Instrument	QoL Results	Comments
Palliation of Obstructive Jaundice						
Abraham et al, 2002	MBO without liver metastasis who were not surgical candidates (N = 50)	Document change in QoL 1 month after ERCP with endoscopic stent placement	Prospective cohort design	SF-36 Health Survey Questionnaire	Improvement in total bilirubin was significantly associated with improvements in QoL, particularly social function and mental health. Bilirubin level >14 at baseline was associated with lack of improvement in social function at 1 month and a 25% mortality rate at 1 month.	Completion rates: baseline, 100%; 1 month, 52% (26/50)
Artifon et al, 2006	MBO from metastatic pancreatic cancer with liver metastasis but without gastric outlet obstruction (N = 30)	Primary outcome was comparison of cost of care Secondary outcome was comparison of QoL after surgical drainage (choledochojejunostomy) and endoscopic drainage with stent placement	Prospective randomized design comparing surgical drainage against endoscopic drainage; assessed at baseline, 30, 60, and 120 days after drainage	SF-36 Health Survey Questionnaire	QoL scores improved postprocedure at 30 and 60 days and returned to preprocedure levels at 120 days. Endoscopic stent patients had a significantly higher QoL than those with surgical drainage at 30 and 60 days. No difference was found in survival or complication rates between the groups.	SF-36 data not presented. Instrument completion rates not presented.
Berr et al, 2000	Nonresectable bile duct cancer, Bismuth III and IV (N = 23)	Investigate survival impact of photodynamic therapy on survival; secondary outcome was to explore change in QoL	Prospective, phase II trial, single-arm study design; assessed every 3 months after procedure	Spitzer QLI Score	QoL scores improved by 15% and stabilized for 15 months. Time frame improvement first noted, not documented.	QoL score secondary end point and details described in text were limited.
Chan et al, 2005	Patients with obstructive jaundice secondary to unresectable malignancy without having a previous drainage procedure (N = 94)	Primary end point was to evaluate stent patency; secondary end points were morbidity, mortality, and QoL assessment	Randomized, double-blind study comparing ciprofloxacin vs. placebo used for and after stent placement for malignant biliary obstruction; assessed at baseline and 1 month	SF-36 Health Survey Questionnaire	No difference in QoL between groups was found except for significant improvement in social functioning in ciprofloxacin group. Lack of differences in groups was found in the setting of no difference in stent patency but significant improvement in cholangitis frequency with ciprofloxacin group: 10 vs. 21 episodes in placebo ($P = .17$).	Completion rates: ciprofloxacin group 15/44 (34%) and placebo group 16/50 (32%) completed both baseline and 1-month assessment. Only patients who completed both assessments were evaluated.
Ortner et al, 2003	Unresectable cholangiocarcinoma with a >3 cm tumor (N = 39)	Compare survival impact of endoscopic stenting plus PDT with stenting alone on survival; explore change in QoL and cholestasis	Prospective, unblinded, randomized, multicenter study with a group sequential design (block size of 4); group A: PDT after plastic stenting; group B: plastic stenting alone	EORTC QLQ-C30	Post PDT, group A scores significantly improved in physical functioning and emotional and global QoL. Compared with group B, significant difference was noted in physical function, cognitive function, role, and global QoL. Group A had a significantly prolonged survival compared with group B. Only 21% of patients in both groups had successful drainage.	Completion rates were 100% at two reported time points. Length of time between drainage and second time point not clearly defined. Study limited by the possibility of inadequate stenting, creating a bias in favor of the PDT group.
Robson et al, 2010	Malignant biliary obstruction (N = 109)	Evaluate QoL, symptoms, and outcomes PBD	Prospective, longitudinal, cohort study; assessed at baseline, 1 week, and 4 weeks after drainage	FACT-HEP and VASP	Mean FACT-HEP scores declined significantly at 1 and 4 weeks after drainage. VASP scores improved significantly over time. Mortality rates were high: 28% by 8 weeks, 4.74-month median survival.	Completion rates: baseline, 100%; 1 week, 59% (64) of survivors; 4 weeks, 40% (43) of survivors.

Saluja et al, 2008	Gallbladder carcinoma with hilar obstruction (N = 54)	Comparison of endoscopic plastic stent placement with percutaneous plastic stent placement; primary outcome measures were QoL and successful drainage	Prospective, randomized design; assessed at baseline, 1 month, and 3 months after procedure (27 patients per study arm)	WHO-QOL BREF-26 and EORTC QLQ-C30	Neither arm demonstrated a significantly improved QoL 1 month after procedure. Symptoms of insomnia, fatigue, constipation, and appetite improved at 1 month in the PBD group. The endoscopic arm demonstrated improvement in the symptoms of pain, fatigue, and constipation. Mortality rates were high: PBD group, 60 days (range, 43-77); endoscopic stent group, 60 days (range, 28-92).	Completion rates: baseline, 100%; 1 month, 89% (48/54); 3 month, 33% (18/54). Small group. Pruritus was not assessed.
Wiedmann et al, 2004	Unresectable hilar cholangiocarcinoma (N = 23)	Examine survival after PDT with assessment of QoL as secondary end point	Prospective longitudinal cohort study; assessed at baseline and every 6 months until 42 months	Spitzer QLI Score	All patients except one reported an improved QoL over baseline that continued through the 42-month assessment point. Estimated 1-year survival for those with M0 disease: 47%; 4-year estimate: 5%.	Completion rates: baseline, 100%; 6 months, 74% (n = 17) of survivors; 12 months, 39% (n = 9); 18 months, 26% (n = 6); 42 months, 9% (n = 2).
Hepatic Artery–Directed Therapy						
Gray et al, 2001	Unresectable liver metastases from resected large bowel adenocarcinoma randomized to HAC with floxuridine or HAC with ^{90}Y microspheres (N = 74)	Assess tumor response parameters and treatment toxicity; QoL and survival were secondary end points	Phase III randomized clinical trial; QoL assessed before treatment and at 3-month intervals	Priestman and Baum's 11-question linear self-assessment scale	QoL between groups equivalent. Only sexual interest/ability reportedly deteriorated over 18-month posttreatment period. Patient-reported treatment regimens tended to improve, not deteriorate, QoL.	QoL data or statistics not reported.
Kalinowski et al, 2009	Unresectable neuroendocrine cancer with liver metastases undergoing ^{90}Y microsphere embolization (N = 9)	Assess safety and efficacy of ^{90}Y microsphere embolization; assessment of QoL in this population was a secondary end point	Prospective, longitudinal, cohort design; assessed QoL before procedure and at 3, 6, 9, and 12 months after procedure	EORTC QLQ-C30 and QLQ-LMC21	Postprocedure scores decreased in 6 of 9 patients. At 6 months, 6 of 7 experienced significant improvement in QoL scores.	It does not appear in the graphs that QoL score improved over initial assessments. Completion rates of instruments unknown. QoL methods and results not clearly defined.
Steel et al, 2006	Patients with biopsy-proven hepatopancreatobiliary carcinoma who underwent treatment with transarterial chemoembolization or ^{90}Y microsphere infusion (N = 158)	Confirm reliability of FACT-HEP in this heterogeneous population, test sensitivity of FACT-HEP to selected biomarkers, and determine MID estimates	Prospectively assessed QoL at baseline (before embolization), 3 months, and 6 months	FACT-HEP	Reliability of FACT-HEP confirmed. Decline in QoL scores from baseline to 3 months seen in all subscales and general scores. Slight improvement observed at 6 months, with only functional well-being returning to baseline level.	MID estimates established by study provide benchmark scores useful in interpreting changes in QoL. Completion rates: baseline, 100%; 3 months, 35% (n = 55); 6 months, 17% (n = 27).
Steel et al, 2004	Patients diagnosed with HCC undergoing treatment with hepatic arterial infusion of cisplatin (HAI) or ^{90}Y microspheres (N = 28)	Examine the difference between health-related QoL and survival in patients diagnosed with HCC	Nonrandomized, parallel cohort study; QoL assessed at baseline, 3, 6, and 12 months	FACT-HEP	Overall decline in QoL scores in all categories from baseline to 6 months; 3-month FWB scores and overall QoL scores were higher with ^{90}Y compared with HAI. Difference in FWB scores in groups continued to 6 months.	Instrument completion rates: baseline, 100% (n = 28); 3 months, 100% (n = 28); 6 months, 50% (n = 14); data from 12 months not presented.

Table 26.4

Quality of Life Studies in Hepatopancreatobiliary Cancer Patients—cont'd

Study	Patient Population (N)	Study Purpose/QoL End Point	Study Design and Assessment Points	QoL Instrument	QoL Results	Comments
Gastric Outlet Obstruction						
Mehta et al, 2006	Malignant gastric outlet obstruction randomized to DS or LGJ (N = 25) Predominant diagnosis was pancreatic cancer (n = 15)	Evaluate complications, pain, and QoL after minimally invasive techniques used for palliation of gastric outlet obstruction	Randomized, nonblinded design; pain assessed at baseline and 1 day after procedure; QoL assessed at baseline and 1 month after procedure	SF-36 Health Survey Questionnaire	A significant increase in pain was reported at day 1 after the procedure in the LGJ group ($P = .05$); no difference was noted in the DS group. Only significant change in QoL was an increase in the mean physical health score in the DS group 1 month after procedure.	Completion rates of QoL instruments: baseline, 100%; 1 month, 24% in LGJ group (6 patients); 7% in DS group (7 of those successfully stented).
Miner et al, 2002	Advanced malignancies undergoing palliative surgeries with general anesthesia for palliation of disease related symptoms (N = 26)	Identify items associated with improved outcomes after surgical palliation	Mixed-method, prospective, cohort study with monthly postprocedure assessments until death	FACT-general; Memorial Pain Assessment Card	Of the 26 patients, 8 had indications of gastric outlet obstruction. Surgeries performed were gastrostomy (n = 1), gastrojejunostomy (n = 6), and subtotal gastrectomy (n = 1). Of these patients, 3 had an improvement in symptoms and QoL and 5 did not.	Completion rates: 18 (69%) were assessed monthly until death. Interesting analysis of the patient, family, physician interactions when discussing palliation.
Schmidt et al, 2005	Gastric outlet obstruction secondary to metastatic cancer or unresectable primary cancer (N = 47)	Investigated outcomes after palliative interventions, including surgical bypass, PEG, PEJ, or endoscopic stent	Prospective, longitudinal cohort study; QoL assessed at baseline, 1 month, and 3 months after intervention	EORTC QLQ-C30 and QLQ-STO22	Despite high mortality rates (median survival, 64 days), stent and surgical bypass patients reported improvements in QoL after procedure and at 3 months with a decline in nausea and vomiting.	Completion rates: 1 month, 26/41 (63%) patients living; 3 months, 12/19 (63%) patients living.
RFA						
Ruers et al, 2007	Colorectal cancer with liver metastasis; only patients who underwent an attempt at curative laparotomy, divided into three groups based on outcome: (1) radical resection of metastasis, (2) candidates for local ablative therapy with or without resection, (3) candidates for chemotherapy (N = 201)	Evaluate survival and QoL of the three groups with a specific interest in the value of ablative therapies over chemotherapy	Comparative, prospective, consecutive cohort study: 117 had surgical resection, 45 had ablation, and 39 had chemotherapy; QoL evaluated at baseline and every 3 months for randomly selected members of the cohort (n = 109)	EuroQoL-5D and EORTC QLC-C30	The resection group had a significant increase in survival over the other two groups. All groups experienced a decline in QoL and physical function 3 months after procedure. The surgical group and the RFA group returned to baseline at 1 year. QoL for the chemotherapy group remained below baseline.	QoL assessment was not completed by all members of the cohort. Method for randomly selecting those to compete instruments was not discussed. Instrument completion rates were not included in report.
Wang et al, 2007	HCC patients undergoing TACE alone or TACE followed by RFA (N = 83)	Evaluate outcomes and QoL after TACE and TACE + RFA	Prospective, nonrandomized cohort, longitudinal design; 43 received TACE, 40 received TACE + RFA; QoL assessed at baseline and 3 months	FACT-general, translated into Chinese	The TACE + RFA group had higher overall general FACT scores as well as higher social well-being and FWB scores 3 months after treatment. Predictors of QoL scores were the Child-Pugh class scores and incidence of tumor recurrence.	Completion rates of instruments were not included.

Hepatic Resection

Banz et al, 2009	Patients having undergone hepatic resection for benign or malignant disease >6 months before analysis (N = 135)	Evaluate whether a postoperative diagnosis was associated with differences in long-term QoL	Cross-sectional study; 89 (66%) had malignant disease, 46 (34%) had benign disease	EORTC QLQ-C30 and EORTC LMC21	QoL was assessed a mean of 26.5 months after surgery. Patients who underwent liver resection for malignant disease had similar general, global, and self-assessed QoL to those who had benign disease. Physical function, pain, and social function scores were worse in the malignant group.	Time points for assessment of QoL were inconsistent. Preprocedure QoL scores were not available for comparison. Results were biased in favor of patients undergoing resection for malignancy with better survival.
Chen et al, 2004	Primary liver cancer (predominately HCC) treated with surgical resection (segmentectomies, lobectomies, combined segmentectomies) (N = 36)	Assess QoL after liver resection	Longitudinal, prospective cohort study; QoL assessed before procedure and at weeks 2, 5, and 10; months 4, 6, and 9; and years 1, 1.5, and 2	GQLI	Initial significant decrease postoperatively between baseline and 2- and 10-week time points. Patients undergoing lobectomy and combined segmentectomy had significantly greater declines in reported QoL than those with segmentectomies alone at 2 weeks. At 9 months, the 19 survivors (53%) reported significantly higher QoL scores than baseline ($P < .05$).	100% of patients completed the baseline and 2-week QoL assessments, with a subsequent decline at all points to 36% (13/36) completing 2-year assessment.
Martin et al, 2007	Cholangiocarcinoma, HCC, or metastatic colorectal cancer undergoing major (>2 segments) or minor hepatectomy (N = 32)	Evaluate the time to return to baseline QoL after resection	Prospective, longitudinal design; assessed at consent, discharge, first postoperative visit (2-3 weeks), 6 weeks, and 3, 6, and 12 months; total of 24 had major hepatectomy; 8 had minor hepatectomy	FACT-HEP, FACT-FHSI-8, EORTC, Profile of Mood scale (brief POMS), EORTC QLQ PAN26, Global rating scale	Patients undergoing major resection had a return to baseline QoL (physical well-being, FWB) after initial decline at 3 months with progressive improvement at 6 months. Those undergoing minor resection had a return to baseline functioning at 6 weeks.	Completion rates: 100% for all time points. FACT-HEP instrument was predominately evaluated, with supportive data provided from other instruments.
Poon et al, 2001	HCC patients undergoing resection who met the criteria of no extrahepatic disease, no main portal vein thrombosis, Child-Pugh class A or B liver function, and anatomically resectable disease (N = 66)	Measure QoL outcomes after curative resection for HCC	Prospective, longitudinal design; QoL assessed at 3, 6, 9, 12, 18, and 24 months	FACT-general, translated into Chinese	Postoperative QoL scores (general, physical, social, emotional well-being) were significantly higher at 3 months ($P < .001$). In the 2-year period, 20 of 66 patients died from recurrence; these patients maintained mean QoL scores that were higher than baseline up to 18 months. All 46 patients who completed all time points had mean QoL scores higher than before the procedure at all time points. Thirteen of these 46 had recurrence and a significant decline in QoL over time ($P < .001$). No significant change was seen in QoL over time in the recurrence-free group.	Instrument completion rates were 100% at baseline and 3 months. All time points were completed by 100% of survivors. An analysis of 10 patients who were unresectable and went on to chemoembolization was included as a control group, but considering the small number, this group was not included in this discussion.

Pancreatic Cancer

Billings et al, 2005	Disease requiring TP matched by age and gender with national database and insulin-dependent patients with diabetes	Evaluate QoL after TP	Cross-sectional matched-design; 99 patients who underwent TP were identified, 34 survived; of these, 27 completed questionnaires	SF-36 Health Survey Questionnaire, ADD QoL, EORTC PAN26	Mean follow-up time: 7.5 years after surgery. Pancreatic patients had SF-36 role physical and general health scores ($P < .5$) and ADD-QoL scores ($P < .1$) significantly lower than the national controls. The ADD-QoL scores were not significantly different from other insulin-dependent patients with diabetes.

Table 26.4

Quality of Life Studies in Hepatopancreatobiliary Cancer Patients—cont'd

Study	Patient Population (N)	Study Purpose/QoL End Point	Study Design and Assessment Points	QoL Instrument	QoL Results	Comments
Crippa et al, 2008	Newly diagnosed pancreatic adenocarcinoma at various stages (N = 92)	Evaluate QoL and survival in this population	Prospective, longitudinal design; divided into groups: (1) apparently localized cancer treated surgically (n = 28, 30.5%); (2) locally advanced cancer (n = 34, 37%); (3) metastatic cancer (n = 30, 32.5%). QoL assessed at baseline, 3, and 6 months	FACT-HEP	Group 1, all of whom underwent surgical resection, had improved QoL. Group 2 experienced no change, and group 3 experienced a decline. Median survival was 9.8 months after diagnosis with a significant difference in survival among the groups.	Groups 2 and 3 were heterogeneous treatment groups and were treated with chemotherapy ± radiation or no treatment. Completion rates were 56% (63% of survivors) at 3 months and 48% (59% of survivors) at 6 months.
Han et al, 2007	Pancreatic mass that survived >3 years with no clinical evidence of recurrence after SPD or PPPD (N = 67)	Evaluate nutritional status, gastrointestinal symptoms, pancreatic function, and QoL postoperatively	Retrospective chart review with cross-sectional analysis of symptoms and QoL (23 had SPD and 44 had PPPD)	EORTC QLQ-C30	QoL was higher in the PPPD group ($P < .05$). SPD patients reported fewer steatorrhea and diabetic symptoms but more flatus, diarrhea, and fatigue then did the PPPD patients.	This study excluded those who underwent pancreaticogastrostomy and combined liver resection.
Kostro et al, 2008	Pancreatic cancer undergoing surgical resection including PD, DBP, and laparotomy (N = 54)	Assess QoL postoperatively	Comparative, longitudinal, prospective, cohort study; 26 had PD,17 had DBP,11 had laparotomy; assessed at baseline and postoperatively at 1, 2, 3, and 6 months	EORTC QLQ-C30 and EORTC PAN26	No significant differences in were found in global health status among the groups. Palliative options (DBP and laparotomy) controlled symptoms with acceptable QoL, but 8 weeks before death QoL rapidly declined.	Completion rates were baseline, 100%; 1 month, 85% (n = 46); 2 months, 78% (n = 42); 3 months, 57% (n = 31); and 6 months, 41% (n = 2).
Muller-Nordhorn et al, 2006	Pancreatic cancer (various stages) admitted to hospital (N = 45)	Compare QoL with established population norms	Cross-sectional evaluation	EORTC and EuroQol (EQ-5D)	QoL was significantly impaired compared with population norms. Fatigue and pain were significantly associated with impaired QoL.	
Nguyen et al, 2003	Periampullary adenocarcinoma undergoing PD (n = 55) or radical PD (n = 50)	Assess QoL of patients postoperatively	Cross-sectional evaluation of 105 randomized patients	FACT-HEP	Assessments were completed a mean 2.1 years after surgery. No differences at long-term follow-up in QoL and gastrointestinal functional status between PD and radical PD. Radical PD patients had significantly higher postoperative complication rates (43% vs. 29%, $P = .01$). No survival differences were noted between the groups.	
Nieveen van Dijkum et al, 2005	Pancreatic or periampullary surgery undergoing PD or DBP (N = 114)	Evaluate QoL postoperatively	Prospective, longitudinal study with 72 undergoing PD and 42 undergoing DBP; assessed at baseline; 2, and 6 weeks; and 3, 6, 9, and 12 months after surgery (with 59 patients completing weekly assessments)	MSO-24 and GIQLI	QoL scores returned to baseline for both groups 3 months postoperatively. The return for the DBP group was only brief before a decline began again. Rapid decline in QoL was seen 8 weeks before death.	Compliance varied: baseline compliance was 91% in the PD group, 92% in the DBP group. At 6 weeks, both groups had compliance at the low end of 50%. The response recovered to 83% and 89% at 12 months for PD and DBP, respectively.

Schmidt et al, 2005	Benign and malignant disease undergoing PD with PG or PJ for reconstruction (N = 104)	Explore effects on QoL and long-term morbidity	Cross-sectional analysis of QoL before and after surgery	EORTC QLQ-PAN26	Mean assessment was 6.4 years after surgery. Global QoL was the same in both groups. PG group had significant reduction in gastric acid reflux, gastrointestinal ulcers, and pain compared with preoperative state but an increase in steatorrhea, early satiety, and food aversion. PJ patients only reported a difference in jaundice postoperatively.	
Schniewind et al, 2006	Adenocarcinoma of pancreatic head undergoing classic partial PD or PPPD (N = 91)	Examined effects of QoL postoperatively	Prospective, longitudinal design with 34 undergoing PD, 57 undergoing PPPD; assessed at baseline, 3, 6, 12, and 24 months	EORTC QLQ-C30	The 5-year survival was 18% for all patients. QoL was impaired for 3 to 6 months postoperatively. No difference was reported in global QoL between groups. Patients who had a lymphatic resection reported increased diarrhea and pain.	Response rates: 56% preoperatively, peaked at 72% of survivors at 3 months, and fell to 56% of survivors at 24 months.
Shaw et al, 2005	Pancreatic tumors undergoing PD (Whipple and total) matched with patients undergoing a benign open cholecystectomy (N = 49)	Examine long-term QoL between groups	Cross-sectional matched design on age and gender studied over a 9-year period	EORTC QLQ30 and PAN26	Mean assessment at 42 months after procedure. Global health status between groups was similar. The malignant group had deficits in physical and role functioning, expressed concern for future health, and had a greater incidence of fatigue, muscle weakness, and failure to gain weight.	Matched design is a worthwhile study design for comparisons.
Van Heek et al, 2003	Periampullary cancer found to be unresectable during exploration randomized to undergo a DBP or SBP (N = 65)	Primary end point was to assess the development of GOO with secondary end points of morbidity, mortality, length of hospital stay, survival, and QoL	Randomized study design; assessed at baseline, discharge, and monthly thereafter for 6 months (36 in DBP group, 29 in SBP group)	EORTC-C30 and PAN26	Two of 36 DBP and 12 of 29 SBP patients developed GOO ($P = .001$). No difference was reported in length of hospital stay, survival, or change in QoL between the groups. QoL returned to baseline by 4 months after procedure.	Completion rates were >90% in both groups for the first 4 months postoperatively and 75% in the last 2 months.
Wehrmann et al, 2005	Unresectable cancer, pancreatic duct obstruction, and postprandial epigastric pain (N = 20)	Evaluate pain and QoL before and after treatment	Prospective longitudinal cohort; assessed at baseline, 4 weeks, and 12 weeks	Spitzer QLI Score	Successful procedure in 19 patients. Patients reported a significant improvement in pain and QoL at 4 weeks, but scores decreased again at 12 weeks to a level closer to preprocedure.	Total of 100% of patients completed the baseline and 4-week QoL assessments; 16 (84%) of 19 completed the 12-week assessment.
You et al, 2007	Patients with a diagnosis of MEN-1 who underwent surgical treatment of pancreatoduodenal neoplasms (N = 28)	Evaluate the effect of PD resection on perioperative complications, function, and QoL	Retrospective chart review with a cross-sectional evaluation of postoperative QoL	EORTC QLQ-C30 and a unique symptom index	Assessed QoL a mean 5.4 years postoperatively. Patients reported QoL no different than those of the general population. Insulin-dependent diabetes developed in 20% of patients.	

DBP, double-bypass procedure; DS, duodenal stenting; ERCP, endoscopic retrograde cholangiopancreatography; EORTC QLQ-C30, European Organization for Research and Treatment of Cancer Core Questionnaire; FACT-HEP, Functional Assessment of Cancer Therapy Hepatobiliary Subscale; FWB, functional well-being; GIQLI, Gastrointestinal QoL Index; GOO, gastric outlet obstruction; HAC, hepatic artery chemotherapy; HCC, hepatocellular carcinoma; LGJ, laparoscopic gastrojejunostomy; ADD-QOL, Audit of Diabetes-Dependent QoL; MBO, malignant biliary obstruction; MEN-1, multiple endocrine neoplasia type 1; MID, minimally important difference; MSO-24, Medical Outcomes Study; PBD, post percutaneous biliary drainage; PD, pancreatoduodenectomy; PDT, photodynamic therapy; PEG, percutaneous gastrostomy; PEJ, percutaneous jejunostomy; PG, pancreatogastrostomy; PJ, pancreatojejunostomy; PPPD, pylorus-preserving pancreatoduodenectomy; QLI, Quality of Life Index; QoL, quality of life; RF, radiofrequency ablation; SBP single-bypass procedure; SPD, standard pancreatoduodenectomy; TACE, transcatheter arterial chemoembolization; TP, total pancreatectomy; VASP, Visual Analog Scale for Pruritus Assessment; WHO-QOL BREF-26, World Health Organization Quality of Life BREF-26; 90Y, yttrium-90

up to 3 months afterward, although success rates varied from 71% to 90% among the groups (Schmidt et al, 2005; Mehta et al, 2006; Kim et al, 2001). Schmidt and colleagues (2005) reported an improvement in QoL in their surgical bypass group as well. Miner and others (2002) presented data for a heterogenous group of patients undergoing surgical palliations; eight in that group underwent a palliative surgery for GOO, and three of eight patients experienced an improvement in all measured parameters; five did not. LGJ was not shown to be superior to DS in one small, randomized study (Mehta et al, 2006).

The value of DS in relieving symptoms related to GOO and improving QoL seems to be an emerging theme in the literature, but current sample sizes are too small, and the groups are too heterogenous to indicate one procedure's superiority over another at this time.

Palliation of Malignant Biliary Obstruction

In most cases, relief of malignant biliary obstruction (MBO) is a palliative intervention (see Chapters 18, 27, 28, 29, 49, 50A, 50B, 50C, 50D, 63A, and 63B). Endoscopic stenting (ES), surgical bypass, and percutaneous biliary drainage (PBD) are all capable of relieving jaundice; however, the topic has not been sufficiently explored to offer clear direction regarding which procedure is best suited for the spectrum of diseases and presentations. Advances have been made, and today palliative surgical bypass is infrequently performed because of the availability and technical successes of the less invasive ES and PBD.

Current literature is restricted to a handful of articles discussing QoL in patients with MBO who have undergone ES, PBD, surgical bypass, or photodynamic therapy (Berr et al, 2000; Abraham et al, 2002; Ortner et al, 2003; Wiedmann et al, 2004; Chan et al, 2005; Artifon et al, 2006; Saluja et al, 2008; Robson et al, 2010). Saluja and colleagues (2008) investigated QoL as a primary end point; the other authors assessed QoL secondarily. Beyond the common indication of relief of MBO, the populations in these studies varied, from those with specific cancers—pancreatic, gallbladder, and bile duct carcinomas—to more general malignant populations with MBO. For that reason it is difficult to make generalized conclusions from these studies. In addition, all of the discussed studies struggle with confounding variables from advancing disease and low response rates as a result of morbidity and mortality, which limit the ability to draw meaningful conclusions.

Patients were evaluated either longitudinally, to assess change in QoL after an intervention, or they were randomized for treatment comparisons. In one longitudinal study, Abraham and others (2002) found that hyperbilirubinemia and weight loss were predictive of poor QoL prior to ES, and ES was found to bring about an improved QoL in this population 1 month after ES placement, especially for those whose initial bilirubin was less than 13 mg/dL. Artifon and colleagues (2006) took evaluation of ES a step further and compared patients who had ES to those who underwent surgical resection. Both groups experienced an improvement in QoL scores at 30 and 60 days postprocedure with a decrease to below preprocedure levels at 120 days. The improvement at 30 and 60 days was significantly greater in the endoscopic group when compared with the surgical group ($P = .05$).

In another longitudinal study, Robson and colleagues (2010) studied the largest cohort in this subset (n = 109), looking at patients with MBO who presented for PBD who were not ES candidates. The patients reported a significant decline in QoL in the overall FACT-HEP scale over the 4-week assessment period but noted a significant improvement in pruritus during this time. The authors concluded that PBD did not improve QoL in the population in the face of a high rate of mortality (28% at 8 weeks postdrainage) (Robson et al, 2010). Saluja and colleagues (2008) randomized gallbladder carcinoma with hilar obstruction patients to either a percutaneously placed plastic stent or an endoscopically placed plastic stent. Neither group had a significant improvement in QoL, but PBD offered better technical success, and the ES group had a lower incidence of cholangitis over the PBD group. In light of these studies, the role of drainage, either ES or PBD, in decreasing the rate of clinical decline in these populations should be considered.

Improvement of QoL after photodynamic therapy (PDT) with ES placement is an emerging theme in the literature. In both prospective and randomized trials, patients experienced an improved QoL after undergoing PDT (Berr et al, 2000; Ortner et al, 2003; Wiedmann et al, 2004). Ortner and colleagues (2003) reported an associated improvement in survival over the stenting group. These reports offer the most positive outcomes from the prospective of improving QoL in a population.

The literature, as expanded on above, is more robust in clarifying which populations benefit from drainage of MBO. How each of these procedures independently alters QoL in the face of progressive disease needs to be clarified further to offer guidance on how to best palliate MBO in a patient whose clinical condition is already in decline.

Radiofrequency Ablation

Radiofrequency ablation (RFA) can be done intraoperatively and percutaneously (see Chapter 85C). Percutaneous RFA programs have expanded dramatically over the past 10 years. The percutaneous approach avoids complications related to an open or laparoscopic surgical procedure while still treating the disease and its symptoms, but these benefits have not been fully evaluated from a QoL perspective in the literature (Cho et al, 2010). Current literature on RFA is limited to two studies evaluating QoL in the setting of HCC or colorectal cancer with liver metastasis, the former utilizing percutaneous RFA, the latter operative RFA (Wang et al, 2007; Ruers et al, 2007). In the HCC study, Wang and others (2007) found a higher sustained QoL after transcatheter arterial embolization (TACE) with RFA than with TACE alone. They also found Child-Pugh class and rates of tumor recurrence were predictors of higher QoL scores.

Ruers and colleagues (2007) evaluated QoL after laparotomy for attempted resection of colorectal liver metastases. Expectedly, those patients who had successful resection of the metastasis had a better survival than those who could not be resected and instead had an intraoperative RFA or were closed and given postoperative chemotherapy. After an initial decline in all groups, QoL returned to baseline at 1 year for the resection and RFA groups, but the chemotherapy group's QoL remained low. This study design was complex and compared heterogenous populations. These results will be clarified better when the Belgium CLOCC trial (EORTC 40004, chemotherapy and local ablation versus chemotherapy) is published. That trial compares RFA with chemotherapy and chemotherapy alone in patients with liver metastases from colorectal cancer. These studies offer promising results: that percutaneous RFA may have the potential to improve QoL over standard treatment options. As minimally invasive RFA applications expand, it is

essential that QoL outcomes be evaluated along with clinical outcomes to further substantiate this procedure as a valid therapeutic option in palliative and curative settings.

CHALLENGES IN QUALITY OF LIFE RESEARCH

QoL has become a field of research unto itself and has drawn attention to the human side of cancer (Passik & Kirsh, 2000). It is far from a perfect science and comes with its own unique set of challenges. Aside from methodologic issues such as proxy completion, missing data, and attrition in terminal or very sick populations of cancer patients, many obstacles exist in the interpretation and applicability of QoL data. One problem faced by QoL researchers and clinicians is the translation of statistically significant changes in QoL scores to clinically meaningful changes. Many tests for QOL assessment have come under harsh criticism, as they tend to rely on mathematical data that "offer such narrow insights into a complex disease and into life when facing cancer" (Corner, 1999). A recently described dilemma that can complicate data integrity is the *response-shift phenomenon.* This occurs when a patient reports stable QoL over time, when clinically they are sicker, because the patient's internal standard adapts to the illness (Sprangers, 2002). The new "surrogate end points" in which clinical benefit is claimed from certain cancer therapies without the use of properly validated instruments poses yet another challenge.

CONCLUSION

The evaluation of QoL reported in the literature has increased dramatically in recent years. As more is learned about QoL, study designs are becoming more robust, and commonly used instruments are more easily recognized by clinicians. These steps are critical for integration of routine QoL assessment into clinical practice, and this chapter has sought to demonstrate the value of assessing QoL and the information that can be obtained through such studies.

There is still more work to be done. As Levine and Ganz (2002) reported, despite the fact that thousands of patients have had QoL measured by multiple instruments in clinical trials, there are only a few examples of outcomes that have influenced individual patients' decision-making or treatment policies. The bridge across the gap between QoL research and clinical practice is the challenge of the future. The conversion of a number into a true understanding of a patient experience is not realistic, but there are merits to utilizing scores to evaluate a patient against established population norms or to deepen the understanding of a person's clinical presentation.

The studies presented here, with their strengths and limitations, provide invaluable information for planning future work. Combine this with the growing interest and clarification of the concept of QoL in procedural settings, and it will undoubtedly lead to more formal evaluations and comparisons utilizing well-designed studies. An increase of current knowledge in this field will lead to a more grounded, realistic, and transparent understanding of the patient's experience of life.

CHAPTER 27

Interventional endoscopy: technical aspects

William R. Brugge

OVERVIEW

The field of therapeutic biliary and pancreatic endoscopy has evolved rapidly since the first reports of endoscopic sphincterotomy in 1974. A spectrum of interventional procedures has gained widespread acceptance as therapeutic alternatives to operative management (Table 27.1; Brugge & Van Dam, 1999). The minimally invasive nature of endoscopic retrograde cholangiopancreatography (ERCP) coupled with its ability to be performed under conscious sedation have resulted in its rapid dissemination around the world. Refinements in procedural technique and improvements in accessory equipment have improved results and safety. This chapter focuses on these technical advances. The indications, contraindications, and complications of interventional biliary and pancreatic endoscopy are presented elsewhere (see Chapters 14, 18, 36, 37, 50D, 54, and 63B) and are not directly addressed here.

CANNULATION

Selective cannulation of the bile and pancreatic ducts is a prerequisite for interventional procedures. Cannulation usually can be achieved with a standard cannulating catheter, using contrast injection to confirm successful cannulation. Use of a sphincterotome for cannulation has the advantage of enabling immediate sphincterotomy after cannulation. The sphincterotome also enables upward bowing in a caudocranial axis to assist in selective cannulation of the bile duct (Fig. 27.1). Wire-guided sphincterotome cannulation is associated with a lower rate of pancreatitis (Lee et al, 2009).

If free cannulation with a cannulating catheter fails, guidewire cannulation can be attempted. Hydrophilic guidewires with a special slippery coating are ideal for cannulation, because they minimize trauma to the papilla and more effectively seek out the path to the desired duct. The guidewire is extended several millimeters from the tip of the cannula or sphincterotome, and the papillary orifice is cautiously probed with the wire, until it slips into the duct (Fig. 27.2). When deep cannulation is achieved, the cannulating catheter can be advanced over the wire into the duct.

Precutting

Precutting is a useful technique to achieve selective bile duct cannulation when free or wire-guided approaches fail. The objective of precutting is to incise the roof of the papilla to expose the underlying opening of the bile and pancreatic ducts for selective cannulation. The widely used term *precut papillotomy* is misleading, because the term *papillotomy* has been used interchangeably with the term *sphincterotomy*. The term *papillary roof incision* more accurately describes the procedure of precutting.

Precutting is performed with either a needle-knife catheter (Fig. 27.3, top) or Erlangen-type precut papillotome (Fig. 27.3, bottom). Most of the published experience has been with the needle-knife catheter, which consists of a retractable bare diathermy wire that extends 5 mm from the tip of the catheter; the needle is inserted at or just above the papillary orifice, and the cut is directed upward in the 11 to 12 o'clock position (Fig. 27.4). Biliary cannulation success rates exceeding 90% have been reported (Misra, 2009). The needle knife can also be used to create a supraampullary fistula in patients with biliary obstruction as a result of an ampullary malignancy. Another application is to free an impacted stone at the papilla; an incision is made directly into the most bulging portion of the papilla against the surface of the impacted stone. Higher complication rates with precut sphincterotomy for stone extraction have been reported (Pereira-Lima et al, 2001).

Precutting is not without risk, but some series suggest that in expert hands, it does not increase the risks of pancreatitis (Lawrence et al, 2009). Two large multicenter studies identified precutting as a significant risk factor for postsphincterotomy pancreatitis, and there have been isolated reports of perforation. Practice guidelines have established that precutting requires appropriate training and expertise and should be reserved for patients with a strong indication for sphincterotomy (Carr-Locke, 2004).

Rendezvous Procedure

Biliary cannulation can be aided by a combined percutaneous and endoscopic approach, known as a *rendezvous procedure*. A guidewire is inserted via the percutaneous transhepatic route into the duodenum and is subsequently grasped at the endoscopic end. The guidewire is pulled through the working channel of the endoscope and serves as a guide rail to enable retrograde biliary cannulation, sphincterotomy, and further endoscopic intervention (Calvo et al, 2001).

A rendezvous approach also can be used to accomplish biliary or pancreatic duct cannulation under endoscopic ultrasound guidance (Mallery et al, 2004). The bile or pancreatic duct is punctured transduodenally or transgastrically with a standard fine aspiration needle loaded with a guidewire. The wire is advanced anterogradely across the stricture into the

duodenum (Fig. 27.5), and the stent is placed over the wire in the standard retrograde fashion.

A further variation of the rendezvous approach can be used to achieve cannulation of the pancreatic duct (Bataille & Deprez, 2002). The minor papilla is used to pass a wire from the duct of Santorini into the duct of Wirsung and then across the major papilla. When cannulation of the major papilla is achieved, the wire is rerouted from the minor papilla to the main pancreatic duct (Fig. 27.6).

Juxtapapillary Diverticula

Frequently found in elderly patients, juxtapapillary duodenal diverticula alter the position and anatomic boundaries of the papilla and displace the course of the bile and pancreatic ducts, making cannulation more difficult (Panteris et al, 2008). Accessing the papilla is a problem when it is located within the diverticulum, but various ancillary maneuvers may improve access. Aspirating air from the diverticulum may help "evert" the diverticulum, bringing the papilla into a more favorable position for cannulation. Altering the patient's position and applying abdominal pressure may also be helpful. Failing these, a small depot of normal saline can be injected into the submucosal plane of the mucosa adjacent to the papilla. The injection should be made on the diverticular side of the papilla in an attempt to "tilt" it toward the endoscopist (Fig. 27.7). The use of two accessories, forceps and cannula, inserted together through the working channel to enable the endoscopist to pull the papilla out of the diverticulum and cannulate the papilla simultaneously also has been described (Fujita et al, 1998).

Deep cannulation of the bile duct adjacent to a large juxtapapillary diverticulum may be difficult, because the diverticulum distorts the course of the distal common bile duct. It is helpful to alter the direction of cannulation after entering the biliary orifice according to the anatomy of the diverticulum (Fig. 27.8). The direction of cannulation may be caudal rather than cranial; a guidewire tends to straighten the course of bile and pancreatic ducts and may facilitate deep cannulation (Draganov et al, 2005).

Billroth II Gastrectomy

A patient who has undergone a Billroth II gastrectomy poses a special challenge to the endoscopist. Accessing the papilla is the first obstacle. When the afferent loop is long, it can be difficult to intubate, and the papilla can be difficult to reach. Cannulation of the Billroth II papilla is the second obstacle. Because the endoscope approaches the papilla from below rather than above, the papillary anatomy in a Billroth II patient appears reversed. The bile duct is cannulated by orienting the catheter downward, toward the 5 to 6 o'clock position, rather

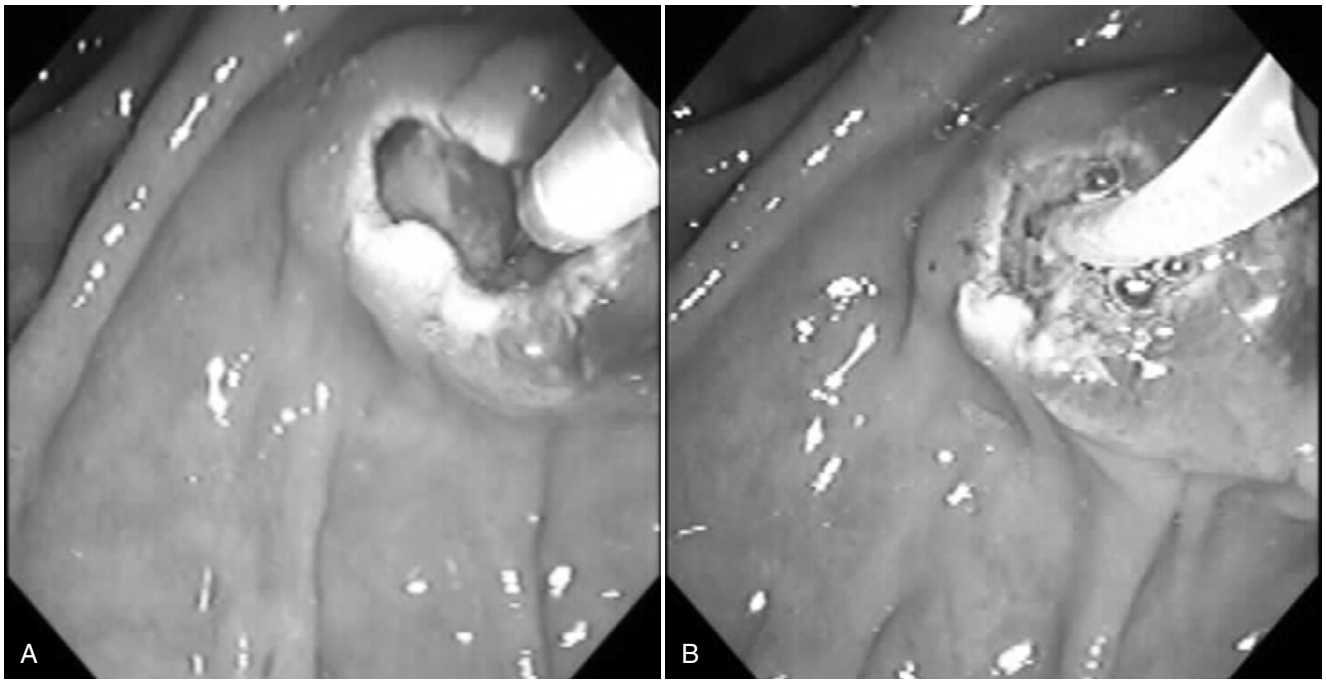

FIGURE 27.4. Precutting technique using a needle-knife catheter. **A,** Insertion of the tip of the precut catheter in the papillary orifice followed by cephalad incision of the papillary roof at the 12 o'clock position with pure-cut current. **B,** The incised roof retracts, exposing the underlying biliary duct orifice. The bile duct is selectively cannulated.

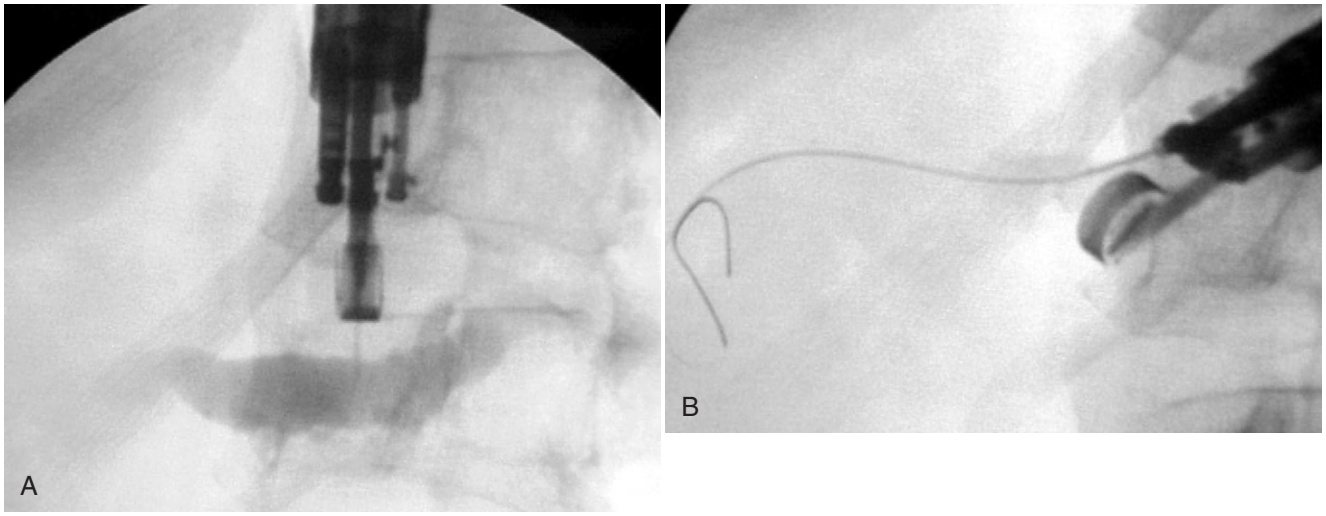

FIGURE 27.5. Radiographs showing transgastric endosonography-guided puncture and injection of the pancreatic duct (**A**) followed by antegrade passage of a wire across the stricture into the duodenum (**B**).

than toward the standard 11 to 12 o'clock position. It is helpful to use a new, straight catheter or mold a downward bow into the catheter to achieve this (Fig. 27.9). A rotatable sphincterotome can also aid in the cannulation of the bile duct (Kim et al, 2008). Cannulation of the pancreatic duct is achieved by inserting the catheter at the 11 o'clock position and aiming it upward in a right-to-left orientation. The bile duct is usually easier to cannulate than the pancreatic duct, because the catheter is automatically directed in the axis of the bile duct. The placement of a guidewire into the bile duct aids in the placement and performance of the sphincterotomy (Dolay & Soylu, 2008).

SPHINCTEROTOMY

Endoscopic sphincterotomy aims at opening the terminal part of the common bile duct or pancreatic duct by cutting the papilla and sphincter muscles. Although not always mandatory for interventional procedures, it greatly facilitates duct access and manipulation.

FIGURE 27.6. Endoscopic image showing a pancreatic rendezvous procedure using the minor papilla to pass a wire anterogradely across the major papilla into the duodenum.

FIGURE 27.9. Cannulation of the bile duct with reversed anatomy after Billroth II gastrectomy.

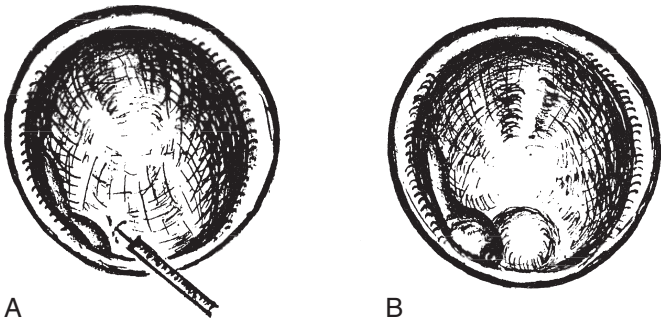

FIGURE 27.7. Technique to improve access to a papilla located on the inner surface of a diverticulum. **A,** With a standard injection catheter, 1 to 2 mL of saline is injected adjacent to the papilla on the diverticular side. **B,** Raised submucosal tissue "tilts" the papilla into view.

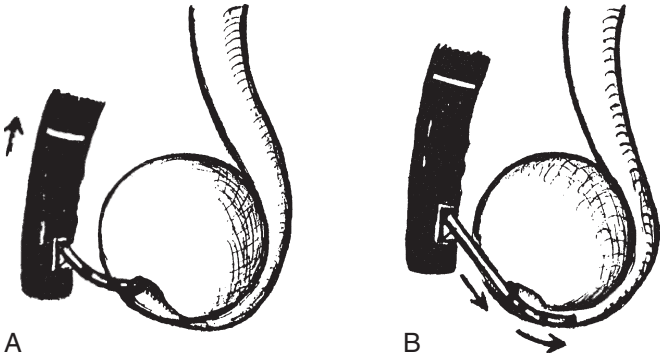

FIGURE 27.8. Technique for deep cannulation of the bile duct in the setting of a large juxtapapillary diverticulum. **A,** Slight withdrawal of the endoscope shifts the angle of cannulation more caudad. **B,** The catheter is advanced while gradually straightening the cannulation angle.

The basic technique of sphincterotomy has changed little since its initial description. The standard sphincterotome, the Erlangen "pull-type" model, consists of a catheter containing a cautery wire exposed 20 to 25 mm near the tip of the instrument. The leading tip distal to the wire, the "nose," is 5 to 10 mm in diameter. After deep bile duct cannulation, the sphincterotome is retracted slowly, until one fourth to one half of the wire length is exposed outside the papilla. The sphincterotome is slightly bowed so that the wire is in contact with the roof, but not excessively, to avoid a "zipper" incision. The incision is made by gently lifting the sphincterotome against the papillary roof using the elevator and up–down controls while applying short bursts of current. The power settings vary according to the type of diathermy unit used. It is debated whether blended or pure-cut current should be used. Theoretically, pure-cut current would be associated with less edema of the ampulla and may decrease the risk of pancreatitis, but the risk of postsphincterotomy hemorrhage might be greater. In a prospective randomized study, the use of pure-cut current was associated with a lower incidence of pancreatitis than with blended-current sphincterotomy (Elta et al, 1998). In addition, the use of blended current after pure cutting reduced the risk of bleeding without increasing the risk of pancreatitis (Gorelick et al, 2001). Another randomized study found that pure-cut current did not reduce the frequency of pancreatitis and was associated with a significantly increased risk of minor bleeding (Macintosh et al, 2004). If blended current is used, the cut should be monitored for excessive tissue blanching and edema, because this is likely to increase the risk of pancreatitis.

The length of a bile duct sphincterotomy should be tailored to the indication. A small incision (≤1 cm) is adequate for stent insertion, whereas stone extraction usually requires a larger incision, depending on the size of the stone to be extracted

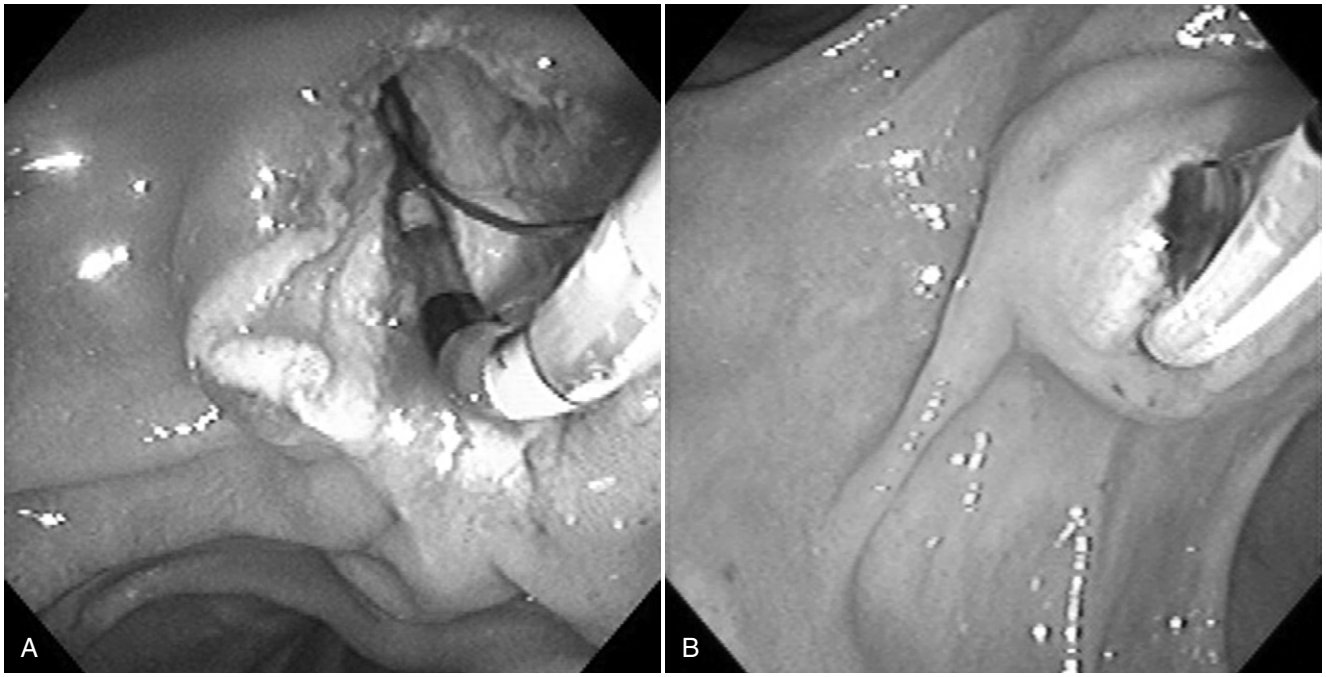

FIGURE 27.10. Biliary (**A**) and pancreatic (**B**) sphincterotomy using a standard sphincterotome.

(Fig. 27.10A). The extent of the sphincterotomy is limited by the length of the intraduodenal portion of the common bile duct. The length of a pancreatic duct sphincterotomy should not exceed 1 cm because of the perpendicular insertion at the ampulla (Fig. 27.10B). In rare cases, a biliary sphincterotomy can be performed with a sphincterotome placed through a percutaneously placed choledochoscope (Itoi et al, 2004). The adequacy of a sphincterotomy can be gauged by the ability to move the bowed sphincterotome across the opening. In the presence of a juxtapapillary diverticulum, the incision should be performed in millimeter increments, paying close attention to the boundaries of the incision and the course of the intraduodenal segment of the bile duct. Late stenosis has been reported to be more common after pancreatic sphincterotomy than after biliary sphincterotomy and is easily treated with repeat endoscopic sphincterotomy (Veldkamp et al, 2007).

In a Billroth II patient, the standard pull-type sphincterotome is unsuited for sphincterotomy because of the difficult approach to the papilla. Special sphincterotomes and techniques have been developed to accommodate this anatomic variation (Dolay & Soylu, 2008). As an alternative to the sphincterotome, a needle knife can be used to perform the sphincterotomy over a previously inserted stent that serves as a guide rail for the incision (Nakahara et al, 2009; Fig. 27.11).

Sphincterotomy of the minor papilla in a patient with pancreas divisum requires greater caution because of the smaller size of the papilla. Wire-guided cannulation will aid in the performance of a minor ampulla sphincterotomy (Maple et al, 2009). The incision length is generally 3 to 5 mm, but it may be larger if the minor papilla is very prominent. The incision is made at the 12 o'clock position. A needle knife can also be used to perform the sphincterotomy over a 5- or 7-Fr stent (Fig. 27.12; Kwan et al, 2008), and balloon dilation sphincteroplasty can be used to aid in the extraction of pancreatic duct stones (Maydeo et al, 2009). A reduction in symptoms and episodes of pancreatitis is often reported after sphincterotomy in older patients with a history of recurrent pancreatitis and a dilated pancreatic duct (Fukumori et al, 2007; Borak et al, 2009).

SPHINCTEROPLASTY

Balloon dilation of the sphincter muscle using high-pressure hydrostatic balloons 6 or 8 mm in diameter has been employed as an alternative to sphincterotomy (Fig. 27.13; MacMathuna et al, 1994). The theoretical advantage of this approach is the preservation of the sphincter function. The drawback of balloon dilation is a more limited size of the papillary opening, which may limit the size of the stone that can be extracted using the balloon or a basket catheter. Stones measuring greater than 8 mm often require mechanical lithotripsy to enable transpapillary extraction. The risk of pancreatitis seems to be higher after a sphincteroplasty compared with a sphincterotomy, but balloon dilation after a limited sphincterotomy does not increase the risk of pancreatitis (Kowalski et al, 2009).

STONE EXTRACTION

Several series have shown that 85% to 90% of bile duct stones can be removed effectively after endoscopic sphincterotomy with a basket and/or balloon catheter (see Chapters 36 and 37). The choice of basket or balloon is largely dictated by stone size: baskets are sturdier and provide better traction for removal of a larger stone (Fig. 27.14); a balloon catheter occludes the lumen and is ideal for removing small stones or sludge (Fig. 27.15).

Several technical points may increase the success rate of stone extraction. The sphincterotomy should be generous enough to enable extraction of the stone. The adequacy of the incision can be assessed by passing an inflated balloon catheter

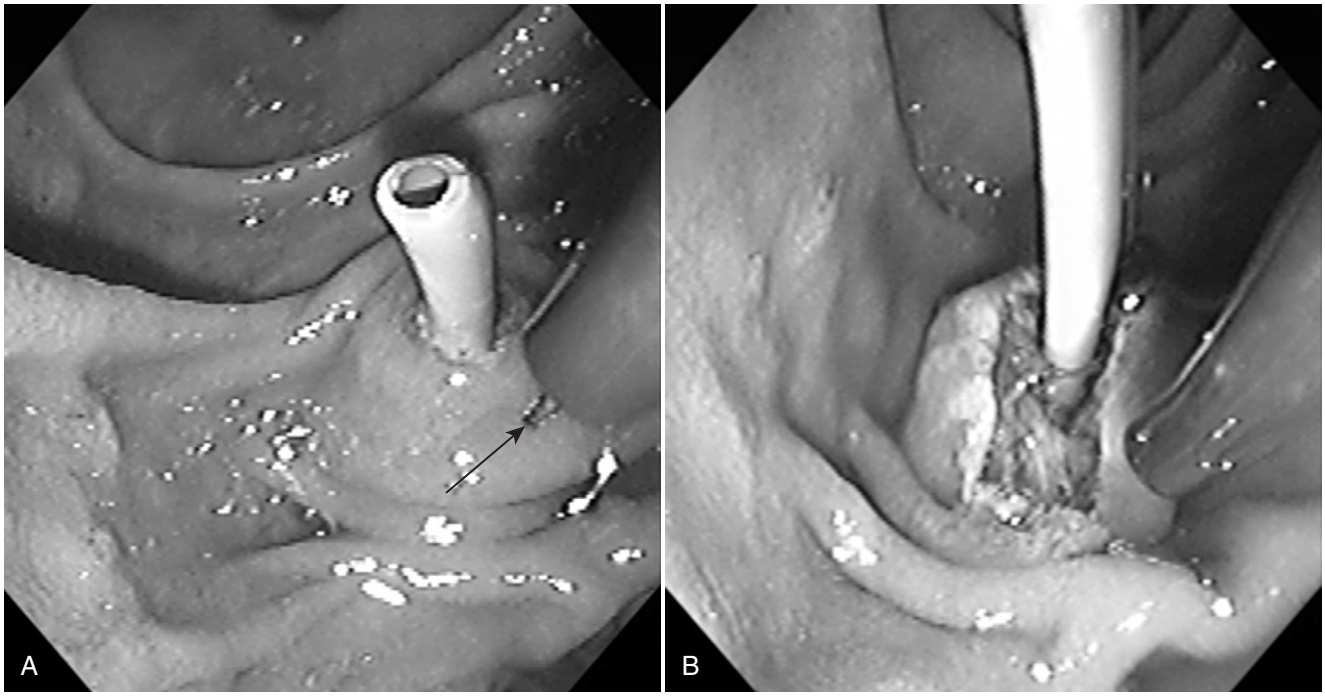

FIGURE 27.11. Sphincterotomy over an indwelling stent in a Billroth II patient. **A,** Needle-knife (*arrow*) positioned for sphincterotomy after stent insertion. **B,** Appearance after completed sphincterotomy.

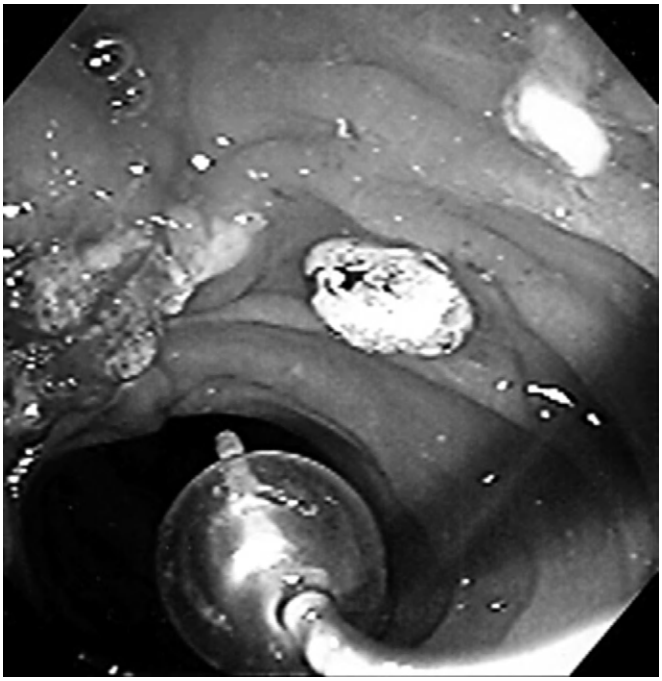

FIGURE 27.15. Extraction of small stones with a balloon catheter.

through the sphincterotomy opening. If multiple medium or large stones are present, it is important to remove stones individually, beginning with the lowermost stone, to avoid stone impaction. If a stone is mistakenly captured, it can be dislodged from the basket by pushing it upward into the hepatic duct confluence, where the basket tends to fold over or advance into the hepatic duct, thereby releasing the stone. When extracting a stone, the direction of traction should be in the axis of the bile duct, which can be verified on fluoroscopy. The success rate of stone extraction after balloon sphincteroplasty is very high (Garcia-Cano et al, 2009). Lithotripsy is indicated for the extraction of stones too large for extraction through the sphincteroplasty (Attasaranya et al, 2008).

Intrahepatic stones pose a special challenge, because they are difficult to access via the retrograde transpapillary route (see Chapters 39 and 44). These stones usually form above strictures and are tightly impacted, and a wire-guided basket may be helpful to gain access to such stones. Intrahepatic stones also can be removed by the percutaneous transhepatic route (see Chapters 28 and 44).

Pancreatic duct stones are a common finding in obstructive chronic pancreatitis. Pancreatic duct stones tend to be firmly impacted or form proximal to a stricture, requiring preliminary fragmentation using lithotripsy techniques. Stone fragments and debris are extracted with a basket or balloon (Fig. 27.16). A recent study comparing surgical and endoscopic treatment of benign pancreatic disease suggests surgery provides a superior long-term outcome (Cahen et al, 2007).

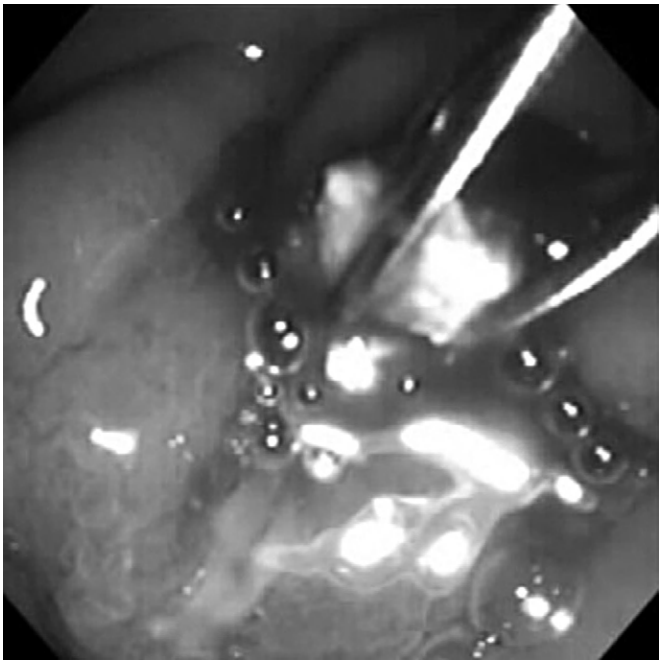

FIGURE 27.16. Extraction of pancreatic stone debris with a basket after extracorporeal shock-wave lithotripsy.

LITHOTRIPSY

Standard stone extraction techniques may fail when a stone is large, impacted, proximal to a stricture, or when stones are multiple. A variety of modalities are currently available to fragment these difficult stones before extraction, including mechanical lithotripsy, intraductal shock-wave lithotripsy, extracorporeal shock-wave lithotripsy, and dissolution therapy.

Mechanical Lithotripsy

Using mechanical lithotripsy, the stone is forcefully crushed in the arms of a Dormia basket after entrapment. This method is the simplest and most cost-effective of the lithotripsy techniques, with success rates of 80% to 90%. There are two variations to the technique of mechanical lithotripsy: a nonendoscopic method and a through-the-endoscope method. Using the nonendoscopic method, the stone is captured within a standard Dormia basket, the basket handle is cut off, and the endoscope is removed. A coiled metal sheath is inserted over the wire, until its tip is in contact with the stone, and mechanical lithotripsy is performed (Fig. 27.17). Using the through-the-endoscope method, a special lithotripsy basket contained within a metal sheath is inserted through the endoscope working channel (Fig. 27.18). The stone is captured in the basket, and lithotripsy is performed. Because the basket is part of a single-unit lithotriptor device, this method presumes that the endoscopist anticipates the need for mechanical lithotripsy before an attempt is made to extract the stone. If stone extraction is attempted with a standard Dormia basket, and the stone and basket become impacted in the bile duct, the endoscopist must use the nonendoscopic method to effect fragmentation.

Intraductal Shock-Wave Lithotripsy

Failure of mechanical lithotripsy is usually due to an inability to capture the stone in the basket, which may occur if the stone is firmly impacted or very large. An alternative modality to achieve stone fragmentation is to use shock waves, which can be delivered intraductally or extracorporeally. Intraductal lithotripsy is performed using flexible probes that can be introduced into the bile or pancreatic duct. The shock waves are generated using electrohydraulic or laser technology and are applied directly to the stone surface. Because shock waves can cause injury to the duct wall, intraductal lithotripsy generally is performed under endoscopic guidance using a "baby scope" inserted into the duct via the duodenoscope, or "mother scope" (Fig. 27.19; Swahn et al, 2009). The lithotripsy probe is inserted through the operating channel of the baby scope, and shock waves are fired under visual guidance, until adequate stone fragmentation is achieved (Fig. 27.20). In patients with an altered anatomy, a nonoperative approach can be taken, using a holmium laser delivered through a choledochotomy (Bark et al, 2009).

Extracorporeal Shock-Wave Lithotripsy

Extracorporeal shock-wave lithotripsy (ESWL) has been shown to be an effective and safe method to fragment bile and pancreatic duct stones that defy endoscopic extraction. The technique can be used for fragmentation of bile duct stones using fluoroscopic or ultrasound guidance (Amplatz et al, 2007). However, if the stone is not visible by fluoroscopy or ultrasound, ESWL is not possible (Merrett & Desmond, 1990). After fragmentation of any stones, the residual fragments must be removed, usually aided by endoscopic sphincterotomy (Tandan et al, 2009). The need for ESWL has decreased as the effectiveness of mechanical lithotripsy has improved. Pancreatic stone fragmentation

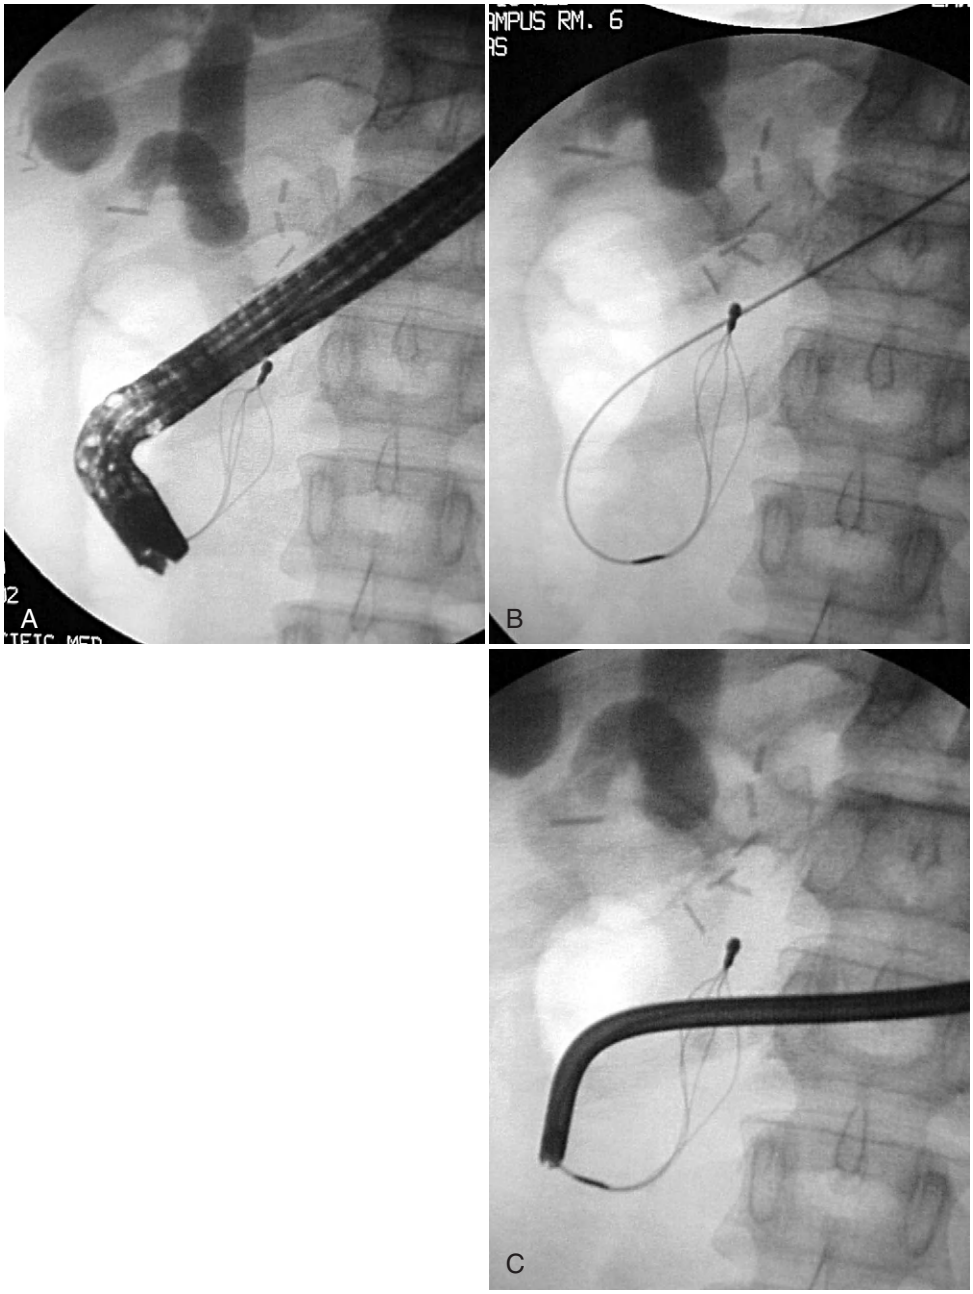

FIGURE 27.17. Radiographs showing intraductal mechanical lithotripsy of a large stone using the nonendoscopic approach. **A,** Impacted stone captured in standard Dormia basket. **B,** Endoscope removed. **C,** Lithotripsy cable sheath advanced to the stone for mechanical lithotripsy.

with ESWL requires multiple sessions and endoscopic management that includes pancreatic sphincterotomy and stent placement (Brand et al, 2000).

Chemical Dissolution

Monooctanoin and methyl tert-butyl ether (MTBE) have been used to dissolve common bile duct stones via nasobiliary drainage catheters and T-tubes (Tandon et al, 1990). Despite encouraging initial reports, this approach has been abandoned because of the cumbersome and time-consuming technique, poor overall results, and adverse effects related to leakage of the solvent into the duodenum. The administration of ursodeoxycholic acid in combination with endoscopic stent placement was shown in one study to soften and decrease the size of common bile stones, facilitating endoscopic extraction (Han et al, 2009). This approach is taken when initial stone extraction and fragmentation is unsuccessful.

STRICTURE DILATION

Stricture dilation can be performed using push-type dilation catheters (bougies) or high-pressure hydrostatic balloons (see Chapter 28). Hydrostatic balloons are commonly used to dilate

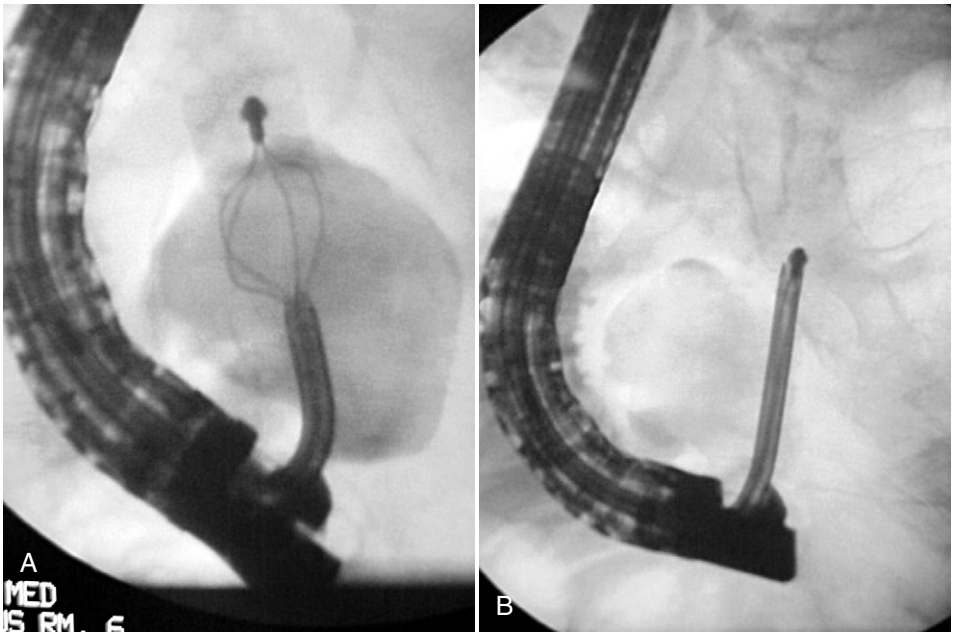

FIGURE 27.18. Radiographs showing through-the-endoscope lithotripsy. **A,** Impacted stone captured in the lithotriopsy basket. **B,** Lithotriopsy cable advanced through the endoscope to perform lithotriopsy.

benign strictures caused by chronic pancreatitis, sclerosing cholangitis, or operative injury (Freeman et al, 2001). When inflated, the balloon applies radial dilating force, and balloons are available in varying lengths (2, 3, and 4 cm) and diameters (4, 6, and 8 mm). The balloon is inflated with diluted contrast material to the maximum atmospheric pressure allowable, and it is kept inflated until the stricture "waist" disappears, generally after 30 to 60 seconds. Dilation is painful, and this may limit the duration of inflation; sequential brief dilations may be better tolerated. Balloon dilation is usually used in conjunction with stent placement except in liver transplantation patients, in whom chronic stenting may be associated with complications (Kulaksiz et al, 2008). The duration of stenting required to achieve a permanent dilation effect varies. Postoperative biliary strictures and pancreatic strictures secondary to chronic pancreatitis may require more than a year of stenting (Weber et al, 2009b), and bile duct strictures associated with chronic calcified pancreatitis are less likely to respond to plastic stenting (Kahl et al, 2003). The placement of multiple stents by adding a stent at 3-month intervals may optimize the dilation effect (Fig. 27.21; Sakai et al, 2009). Similar approaches have been successful for strictures in the ducts of Santorini and Wirsung (Costamagna et al, 2006).

Tight strictures that do not permit passage of a bougie or balloon catheter can be opened with the Soehendra Stent Retriever (Cook Medical, Winston-Salem, NC) (Brand et al, 2000). The device has a threaded tip at its end with a central lumen for coaxial guidewire insertion, and it is rotated to core a path through a high-grade stricture. After placement of a guidewire across the stricture, the Retriever is coaxially inserted until it engages the stricture. The rotational device is rotated clockwise at the handle by the assistant, while the endoscopist advances the device across the stricture (Fig. 27.22). Strictures should be sampled with brushings for cytology or forceps for histologic material (Higashizawa et al, 2002).

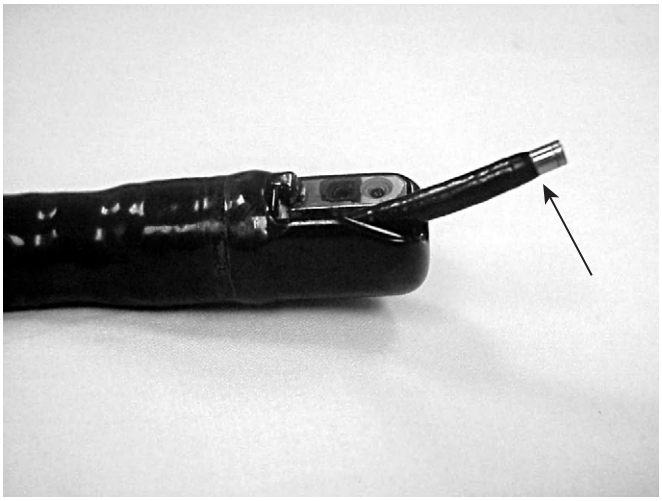

FIGURE 27.19. "Baby scope" (*arrow*) inserted through the working channel of the "mother scope" (duodenoscope).

STENTING

Endoscopic transpapillary stent placement is a well-standardized technique that can be carried out with an overall success rate of greater than 90%. Stenting has become the treatment of choice for the palliative decompression of malignant distal biliary obstruction (see Chapters 50B, 58, 59, and 63B), and it may be an alternative to surgery for the treatment of benign distal biliary and pancreatic strictures, although not all authors agree regarding the long-term efficacy (see Chapter 42). Stenting also has been found to be an effective treatment for bile duct leaks

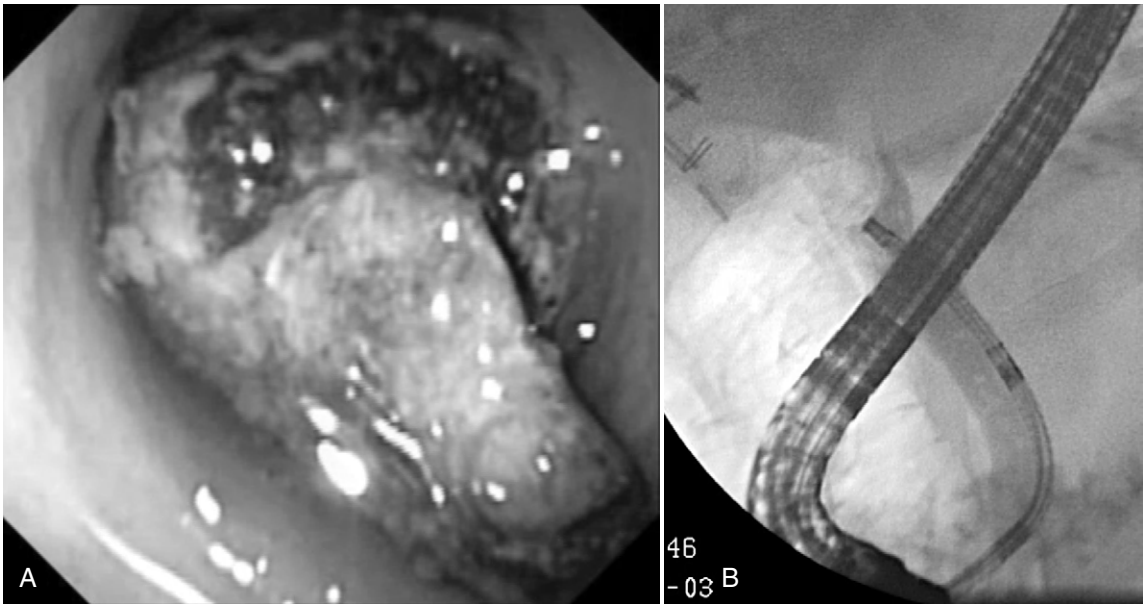

FIGURE 27.20. Intraductal shock-wave lithotripsy. **A,** The video cholangioscope has been inserted into the bile duct to visualize the stone. **B,** Radiographic view showing lithotripsy under direct cholangioscopic vision.

after surgery or trauma (Coelho-Prabhu & Baron, 2009); a biliary sphincterotomy should be performed at the time of the stent placement and may be used as the sole treatment (Aksoz et al, 2009). Pancreatic duct leaks are also effectively treated, particularly with stenting across the duct defect.

Types of Stents

Two types of stents are used, made of either plastic and expandable metal (Fig. 27.23). Plastic stents may be straight, with flaps for anchorage, or they may be a single or double pigtail (Jain et al, 2000). Expandable metal stents may be uncovered or covered. The covering of the expandable stent may block drainage of a neighboring duct, so covered stents should be restricted to distal bile duct strictures and must be used cautiously in patients with a gallbladder. Covered stents may extend patency rates by preventing tumor or hyperplastic tissue ingrowth, but this requires further study. Plastic stent migration out of the stricture is more commonly seen in benign strictures requiring the use of longer stents (Arhan et al, 2009), and the frequency

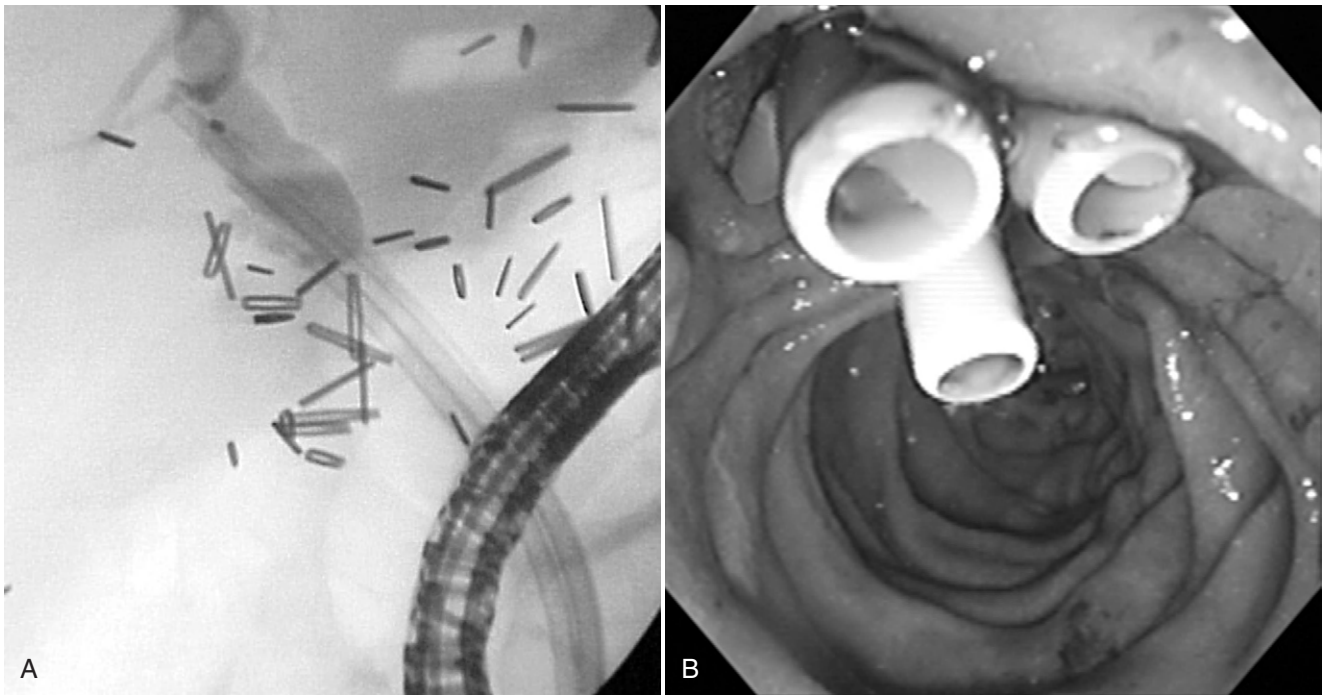

FIGURE 27.21. Radiographic (**A**) and endoscopic (**B**) images of multiple stents dilating a high-grade postoperative bile duct stricture.

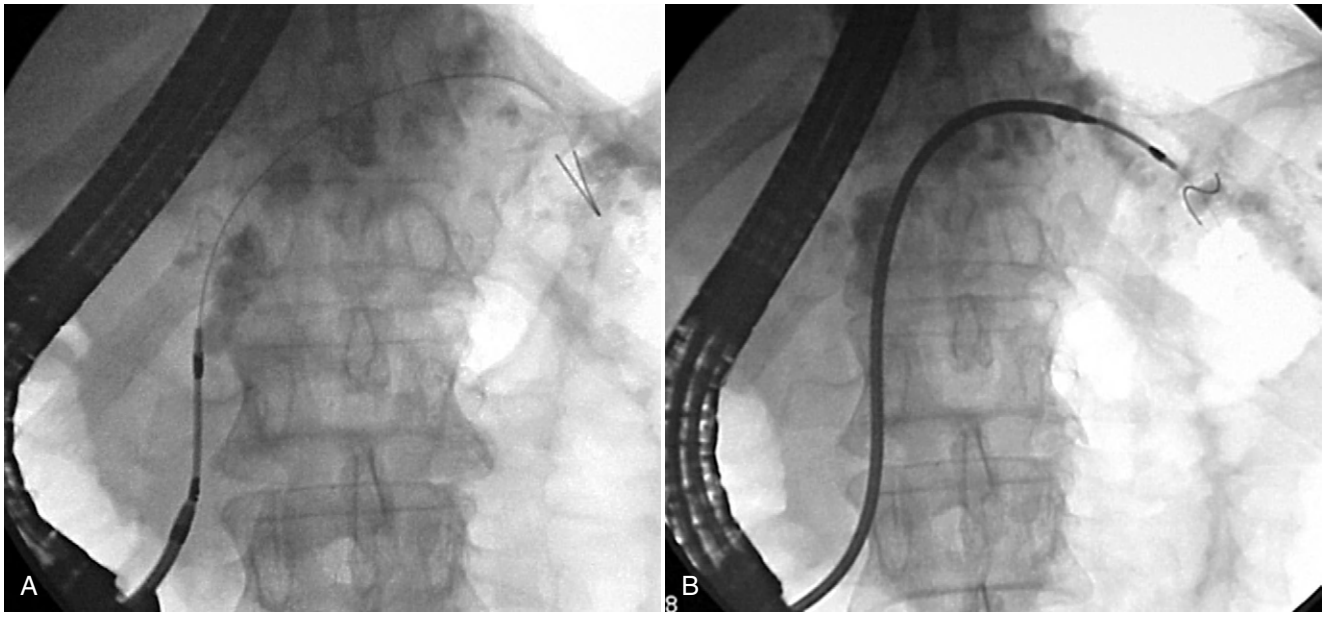

FIGURE 27.22. Radiographs before (**A**) and after (**B**) dilation of a tight stricture in the pancreatic head using the Soehendra Stent Retriever. *(Courtesy Cook Medical, Winston-Salem, NC.)*

of stent occlusion is related to the diameter of the metal stent (Loew et al, 2009). Recently, the use and removal of covered metal stents in benign disease has been demonstrated but is associated with a complication rate of 14%. Special "pancreatic" stents made of soft plastic with multiple side holes for drainage of side branches are used in the pancreatic duct. Pancreatic duct stents with large side holes remain patent for longer periods than stents with small side holes (Buscaglia et al, 2009); however, most pancreatic stents are placed for short-term prophylaxis to maintain sphincter patency (Chahal et al, 2009). Long-term use of fully covered metal stents in pancreatic duct strictures has been reported, but the migration rates are high (Park et al, 2008).

Technique of Stent Placement

After diagnosing the type and site of the obstruction with a diagnostic ERCP, a small sphincterotomy is often performed to facilitate insertion of instruments. The stricture is negotiated with a guidewire; use of short guidewires may decrease the duration of the procedure and time spent on wire exchanges (Reddy & Draganov, 2009). The technical success of stent placement has been enhanced by the use of hydrophilic wires, which allow easier and less traumatic passage through strictures. In addition, various maneuvers may facilitate the negotiation of a tight stricture: The angle of access to the stricture can be changed by adjusting the position of the guide catheter tip, and an angulated guidewire tip may be helpful for negotiating eccentric strictures. For concentric strictures, an inflated balloon catheter inserted over the guidewire centers the guidewire in the lumen. When the stricture is passed with a wire, a dilating catheter is coaxially inserted to dilate the stricture and obtain a complete cholangiogram. Cytology brushings can be obtained at this point to confirm malignant obstruction. A stent (plastic or expandable metal) is inserted using the Seldinger technique. Decompression of the obstructed biliary tree is typically indicated by a gush of dark stagnant bile into the duodenum.

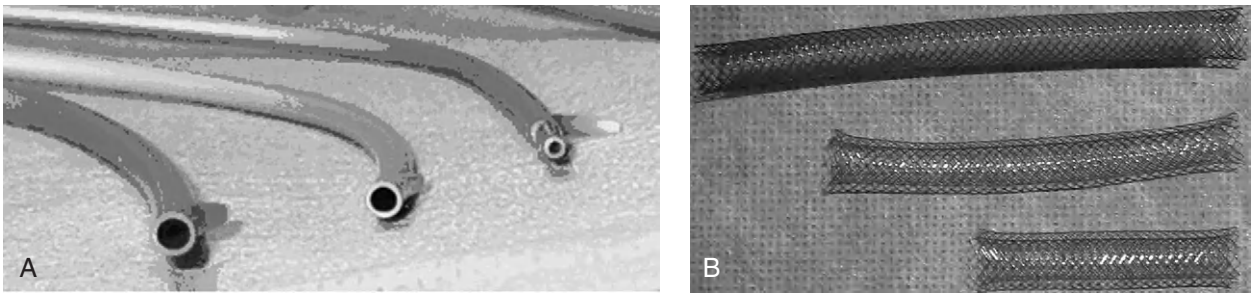

FIGURE 27.23. Straight plastic (**A**) and expandable metal (**B**) stents.

Hilar Strictures

Hilar strictures are often difficult to stent, because they are further away from the endoscope and tend to be tortuous and sclerotic (see Chapters 28 and 50D). For obstructing hilar cholangiocarcinoma (Klatskin tumors), the success rate of transpapillary stenting varies according to the level of obstruction. For type I strictures (involvement of the common hepatic duct), the success rate is around 86%, but it decreases to 45% for type II strictures (involvement of both main hepatic ducts) and 15% for type III strictures (involvement of secondary intrahepatic branches). Controversy exists as to whether both lobes of the liver need to be drained when a bifurcation lesion obstructs both lobes. Although some studies suggest that unilateral stenting is associated with a high frequency of jaundice resolution, two subsequent studies showed bilateral drainage to be associated with a significantly lower complication rate (Naitoh et al, 2009). Both lobes should be drained in type II and III obstruction if contrast medium fills both hepatic ductal systems and fails to drain. Endoscopic transpapillary stenting may need to be complemented by percutaneous transhepatic stenting when drainage is not complete and jaundice fails to resolve adequately (see Chapters 28 and 50D; Paik et al, 2009).

Dual-stent or multiple-stent insertion for hilar strictures requires a clear outline of the ductal anatomy on cholangiography. The anatomy is best appreciated with the patient in the supine position, because the right and left ductal branches are separated. A wire is advanced into each duct for which stent drainage is planned. A super-stiff 0.038-inch Amplatz guidewire (Boston Scientific, Natick, MA) assists stenting of a tight, angulated stricture. After wire placement, the strictures are dilated with a balloon to facilitate subsequent stent insertion; a 6 mm balloon is generally used. If a balloon catheter cannot be negotiated across a tight stricture, a 7-Fr Soehendra Stent Retriever can be used to core a path through the stricture (van Someren et al, 1996). The left hepatic duct should be stented first, because the left duct has a more acute angle of takeoff from the common hepatic duct (Fig. 27.24).

For malignant hilar strictures, self-expandable metal stents have numerous advantages over plastic stents. Drainage is superior because of the larger diameter and open mesh design that provides drainage of side branches. A sphincterotomy is not required when the distal (bottom) ends of metal stents are positioned within the duct, which may reduce the risk of post-stenting cholangitis. Many authors disagree with endoscopic approaches to hilar strictures and advocate intubation for obstruction at this level by percutaneous methods (see Chapter 52; Paik et al, 2009).

Chronic Pancreatitis (See Chapter 55)

Focal strictures of the main pancreatic duct may be stented to improve drainage and provide pain relief (Ponchon et al, 1995). As a rule, large diameter stents should be left in place, until the stricture either resolves or is significantly improved, but only in the face of well-established chronic pancreatitis. Persistent stenting has been used to achieve an adequate dilation effect with normalization of ductal caliber (Fig. 27.25). If the stricture is persistent or recurs, multiple stents can be placed to achieve greater dilation. Despite symptomatic improvement, the use of intraductal stents for prolonged periods is associated with a significant risk of duct damage (Somogyi & Forsmark, 1998). Migrated pancreatic duct stents can be managed with endoscopic balloon retrieval (Price et al, 2009).

Stent Clogging

Clogging of plastic stents is a common problem that necessitates a stent exchange. The mean duration of patency of plastic biliary stents is approximately 5 months. Exploring ways to prolong stent patency has been the subject of considerable research over the years and remains unresolved. Expandable metal stents can be inserted through the duodenoscope in a compressed state and can expand to a diameter threefold that of plastic stents and are less prone to clogging (Weber et al, 2009b). Small diameter metal stents occlude more rapidly than large diameter stents (Loew et al, 2009). Conformable stents do not offer any better patency rate than nonconformable metal stents (Yang et al, 2009); and despite a need for fewer procedures with the use of metal stents, cost savings may not be significant (Yoon et al, 2009). Uncovered metal stents are not removable, which may present a problem if they become occluded, or if surgery is considered at a later time, and expandable stents should be reserved for unresectable malignant strictures. Covered metal stents may be removed, although with a significant complication rate (Mahajan et al, 2009).

Pancreatic stents occlude over time, but only a few patients become symptomatic (Buscaglia et al, 2009). The low incidence of pain or pancreatitis despite stent occlusion suggests that the stent functions as a wick around which pancreatic fluid continues to drain. In contrast to the bile duct, infection of the pancreatic duct (ductitis) is rarely seen as a complication of stent clogging.

Replacement of a clogged plastic stent can be performed by either removing the clogged stent with a snare or forceps and inserting a new stent or by exchanging the stent over a guidewire using a stent retriever (Fig. 27.26; Chaurasia et al, 1999). Foreign body forceps are used for biliary stents impacted in the wall of the duodenum. The metal spiral stent retriever is used when guidewire access to the bile duct is necessary.

Endoprosthesis for Stone Impaction

Failure to clear the duct of stones after sphincterotomy and ductal instrumentation places the patient at substantial risk for ductal infection (cholangitis, pancreatitis) and sepsis. Stent placement provides persistent drainage despite the presence of bile duct stones (Sharma et al, 2009). The placement of a 7- or 10-Fr endoprosthesis may be used as a temporizing measure to maintain drainage and prevent stone impaction pending more definitive management (Sharma et al, 2009). Stent placement also may be preferable to attempting stone extraction in a septic patient; clearance of the duct can be performed when the sepsis has resolved, and the patient's condition has stabilized (Chopra et al, 1996). Stents should not be left in place as definitive treatment or over an extended time, because late complications, mainly cholangitis, have been reported. Surgical treatment of the problem must be considered when endoscopic techniques fail (see Chapters 29, 34, and 35).

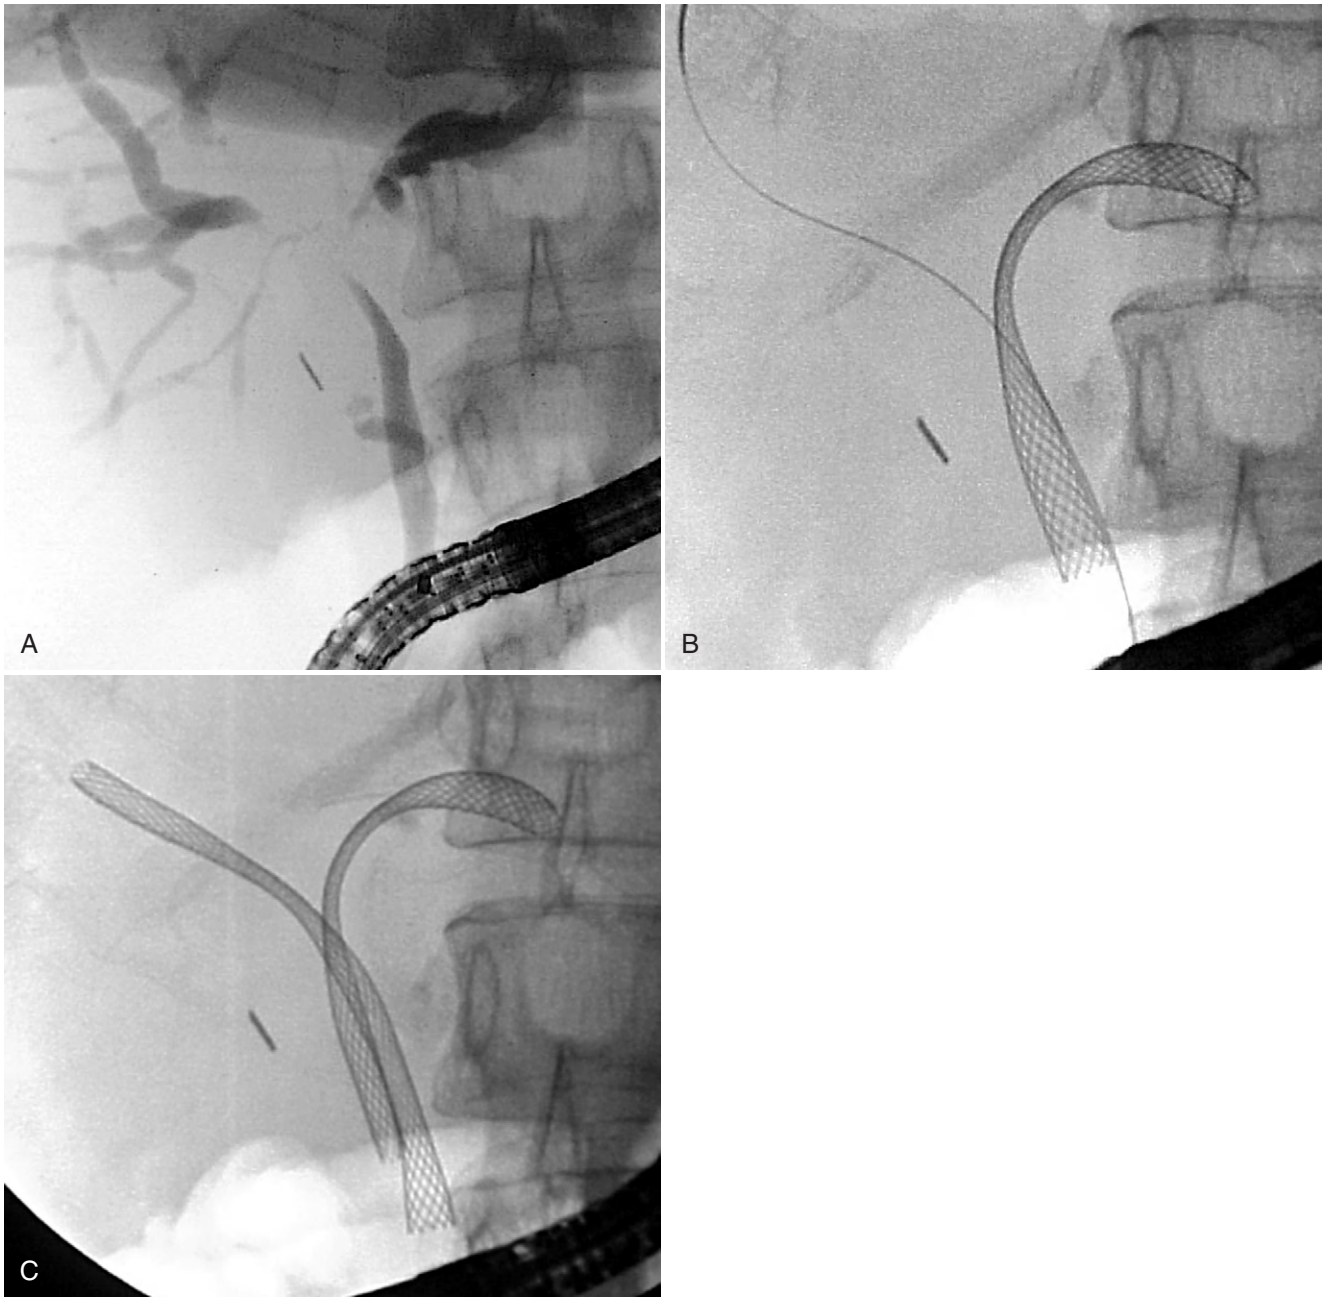

FIGURE 27.24. Radiographs showing type III malignant hilar obstruction with upstream dilation of the right and left hepatic ducts (**A**), placement of a left-sided biliary metal stent to drain the left hepatic lobe (**B**), and placement of a second right-sided biliary metal stent to drain the right hepatic lobe (**C**).

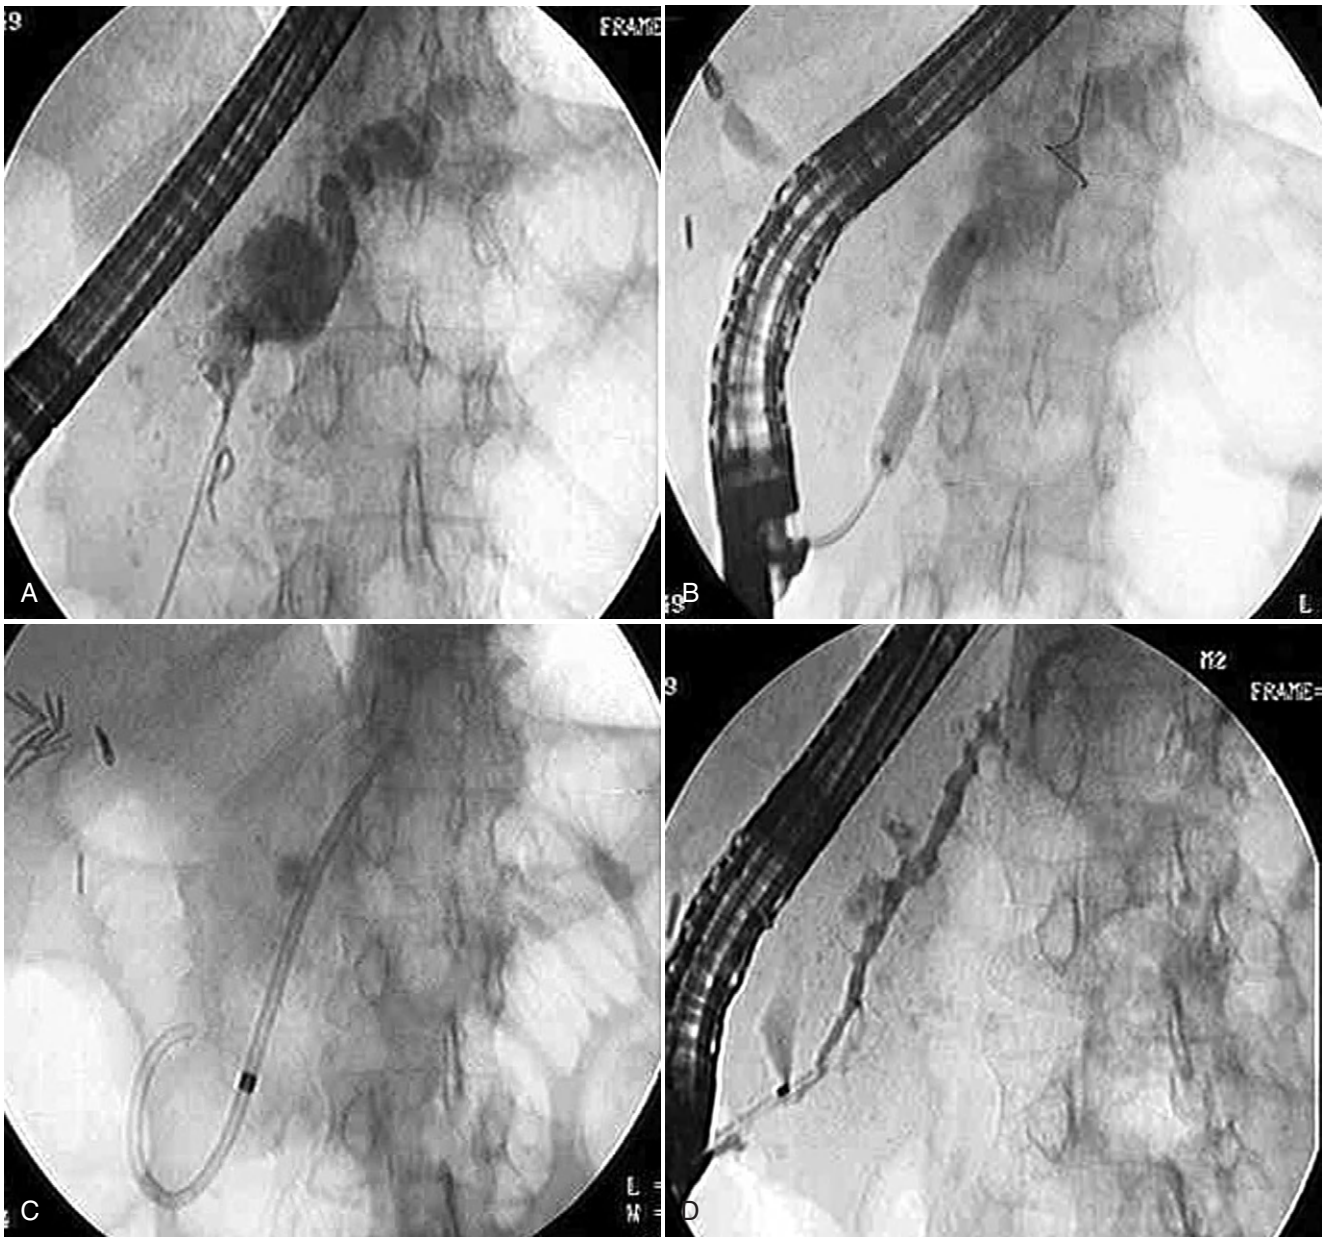

FIGURE 27.25. Radiographs showing a high-grade stricture in the pancreatic head with upstream dilation (**A**) followed by balloon dilation (**B**) and placement of a pancreatic pigtail stent (**C**). Resolution of the stricture and normalization of pancreatic duct caliber after stent removal (**D**).

PHOTODYNAMIC THERAPY

Photodynamic therapy has been used in conjunction with biliary stenting to improve biliary drainage in patients with non-resectable cholangiocarcinoma. A photosensitizing cytotoxic agent is administered intravenously that is selectively taken up by tumor cells. Subsequent exposure to laser light of the proper wavelength activates the photosensitizing agent and results in tumor destruction. Application of laser light is performed with thin laser fibers. A recent randomized trial found that stenting plus photodynamic therapy was superior to stenting alone in prolonging survival in patients with advanced cholangiocarcinoma (Kahaleh et al, 2008). Laser light therapy can be delivered through a metal stent (Wang et al, 2008).

SPHINCTER OF ODDI MANOMETRY (SEE CHAPTER 12)

Sphincter of Oddi manometry is used in some centers to diagnose sphincter of Oddi dysfunction (SOD), a poorly understood entity associated with recurrent abdominal pain and at times with abnormal liver function tests and serum amylase values. The technique of sphincter of Oddi manometry has become fairly standardized, using special endoscopic manometry catheters introduced into the bile or pancreatic duct (Fig. 27.27). Solid-state catheters provide results nearly identical to water-perfused catheters (Draganov et al, 2009); the bile and pancreatic sphincter pressures are measured separately. Sphincterotomy has been shown to result in symptomatic

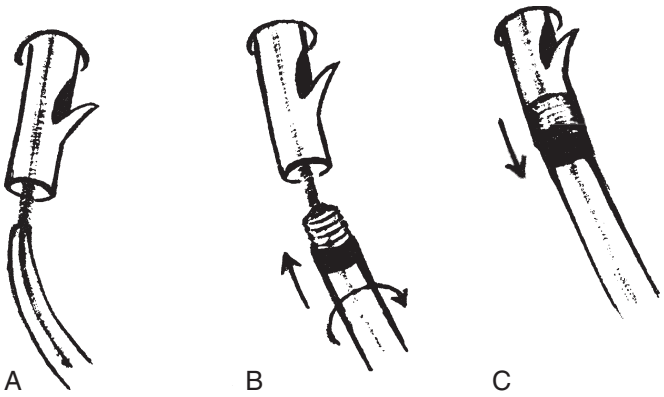

FIGURE 27.26. Stent replacement using the Soehendra Retriever. **A,** With the aid of an endoscopic retrograde cholangioplasty catheter, a conventional 0.035-inch Teflon-coated guidewire is inserted through the prosthesis. **B,** The catheter is removed, and the Retriever is inserted over the wire, until it abuts against the distal end of the prosthesis. The stent is rotated clockwise to screw the Retriever tip into the prosthesis. **C,** The stent is removed over the indwelling guidewire. *(Courtesy Cook Medical, Winston-Salem, NC.)*

improvement of biliary pain in patients documented to have SOD and abnormal liver function tests (Elmi & Silverman, 2009). High-risk patients should have a prophylactic pancreatic stent placement and needle-knife fistulotomy (Madacsy et al, 2009). Small diameter pancreatic duct stents, as small as 3 Fr, are safer and have a higher rate of spontaneous passage (Rashad et al, 2004). Unsuccessful pancreatic stent placements are associated with a high rate of pancreatitis (Freeman et al, 2004).

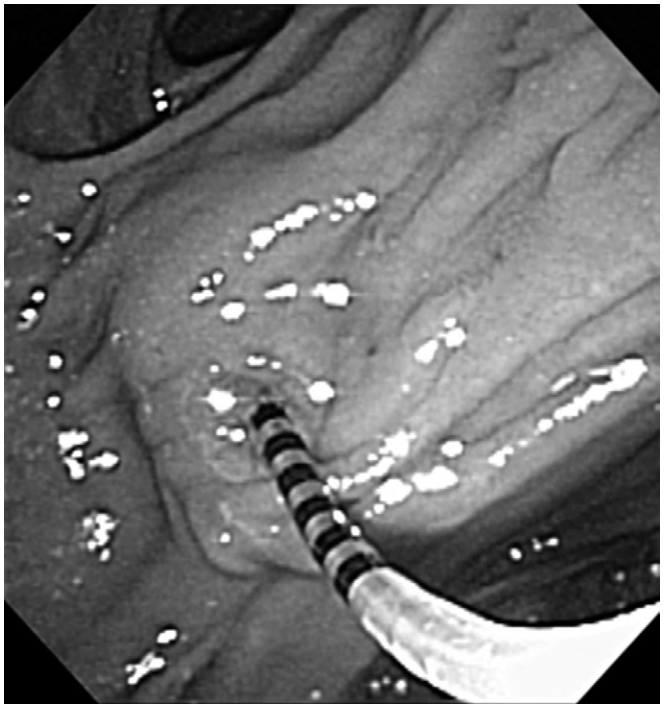

FIGURE 27.27. Endoscopic view of sphincter of Oddi manometry using a standard triple-lumen manometry catheter. *(Courtesy Cook Medical, Winston-Salem, NC.)*

Pancreatic sphincterotomy, often in conjunction with biliary sphincterotomy, is performed for patients with recurrent pancreatitis using a wire-guided papillotome (Joo et al, 2009).

AMPULLECTOMY

Benign adenomas of the papilla of Vater can be removed together with the papilla of Vater using a diathermic snare in an analogous manner to colon polypectomy (snare ampullectomy). Endoscopic ultrasonography may aid in assessing these tumors and for selecting patients suited to this approach (see Chapter 14) The technique entails snaring of the papilla flush with the duodenal wall (Fig. 27.28; Menees et al, 2009). Saline does not need to be injected prior to the ampullectomy. This is an alternative to local surgical resection, if complete excision of the adenoma and ampulla is achieved; however, it is crucial that

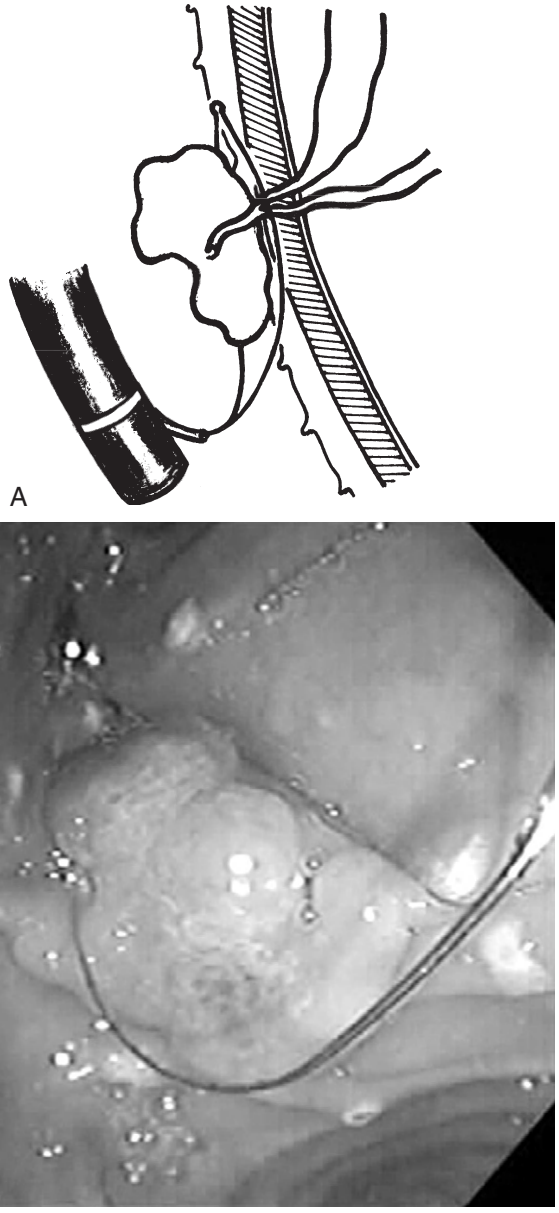

FIGURE 27.28. Schematic (**A**) and endoscopic (**B**) views showing the technique of snare ampullectomy of a benign ampullary adenoma.

FIGURE 27.29. Radiographic views of a pancreatic duct leak at the neck region. **A,** Before stenting. **B,** After stenting.

the excised tissue specimen be retrieved and submitted for complete histologic evaluation. Surgical resection is indicated if the specimen shows malignancy or complete excision cannot be achieved endoscopically (see Chapter 59). Prophylactic pancreatic stent placement is used to prevent pancreatitis (Yamao et al, 2009; Harewood et al, 2005). Periodic endoscopic surveillance is mandatory to evaluate for adenoma recurrence.

Pseudocysts and Leaks

To determine whether a cyst communicates with the pancreatic duct, ERCP may be indicated in patients with pseudocysts that fail to resolve or those that recur (Lakhtakia & Reddy, 2009). Outflow obstruction secondary to a stricture, stone, or ampullary stenosis should be treated with sphincterotomy and/or stenting (Habashi & Draganov, 2009). Stenting also has been found to be effective in the management of partial and complete ductal leaks, fistulas, and ascites (Fig. 27.29; Kozarek et al, 1997). Endoscopic approaches to internal drainage of nonneoplastic pancreatic cysts are described in Chapter 14.

CHAPTER 28

Radiologic hepatobiliary interventions

Mark D. Mamlouk, Eric vanSonnenberg, Nasir H. Siddiqi, Risteard O'laoide, and Maureen Martin

RADIOLOGIC INTERVENTION

Radiologic intervention is applicable for a wide range of hepatobiliary diseases (see also Chapters 12, 19, 25, and 32). The use of these techniques in pancreatic disease is referred to in Chapters 25, 32, 54, 55, and 63.

TREATMENT OF HEPATIC CYSTS

Simple, nonparasitic hepatic cysts (see Chapters 69A and 69B) are the second most common benign lesions that involve the liver, following hemangiomas. They are found in approximately 1% to 2.5% of adults and occur more commonly in women and in the right liver. These cysts are lined with bile duct epithelium, contain clear fluid, and almost never communicate with the biliary tree (Forbes & Murray-Lyon, 1991). Simple cysts can be acquired from processes such as trauma or inflammation, or they may be congenital, such as in polycystic disease (see Chapter 69), with cysts possibly present in the kidneys and pancreas as well.

Typically, simple hepatic cysts are asymptomatic and are discovered incidentally on liver imaging done for other indications. When present, symptoms include nonspecific abdominal discomfort and early satiety, with or without weight loss. Although usually chronic in nature, the symptoms may occur acutely with cyst rupture, intralesional hemorrhage, infection, or torsion of a pedunculated cyst. Infrequently, a patient may be seen initially with jaundice or leg swelling related to the mass effect of a cyst on the bile duct or the inferior vena cava, respectively.

On cross-sectional imaging, the requisite feature of a simple hepatic cyst is a circumscribed, thin-walled, nonseptated lesion with lack of enhancement after intravenous contrast medium administration. Imaging modality–specific features include posterior acoustic enhancement on ultrasound (US), low attenuation on computed tomography (CT), and signal intensity similar to that of free water on magnetic resonance imaging (MRI). Wall thickening, the presence of septations, or lack of enhanced through-transmission on US should raise the question of another pathology, such as cystic metastasis, cystadenoma (see Chapter 79B), or hydatid disease (see Chapter 68), which must be thoroughly investigated (Mortele & Ros, 2001; Nisenbaum & Rowling, 1995). This evaluation is especially important before beginning treatment, and periodic imaging follow-up early in the course of therapy is prudent.

In the absence of symptoms or signs, simple liver cysts require no treatment. Traditional therapy of symptomatic cysts has been surgical, with laparoscopic deroofing currently favored by many surgeons (Gall et al, 2009; Mazza et al, 2009; see Chapter 65). Interventional radiologic techniques such as fine needle aspiration (FNA) and catheter drainage without or with cyst sclerosis have been used to treat simple cysts. With these techniques, symptomatic relief usually is achieved, although recurrence is common with aspiration alone.

Percutaneous chemical sclerosis of cysts with a variety of agents—including alcohol, tetracycline antibiotics, and povidone-iodine—either at the time of initial aspiration or after a period of catheter drainage usually provides successful therapy (vanSonnenberg et al, 1994). In the case of alcohol, it fixes the cells lining the cyst cavity, thereby preventing secretion of cyst fluid and subsequent enlargement (Bean & Rodan, 1985). Tikkakoski and colleagues (1996) described single-session treatment with alcohol for 59 symptomatic hepatic cysts in 25 patients. The cysts were evacuated via a 5-Fr drainage catheter, and absolute alcohol was instilled and left in for 20 minutes with the patient turned in various positions to maximize cyst wall exposure to the agent. In some cases, the procedure was repeated once or twice during the same session, after which the entire volume of injected ethanol was aspirated, and the catheter was removed.

Yoshida and colleagues (2003) successfully treated symptomatic solitary hepatic cysts with multiple minocycline injections and noted complete cyst regression without recurrence. Lopes and colleagues (1998) successfully treated seven patients with hepatic cysts by aspiration followed by instillation of tetracycline with a resultant decrease in all lesions. Kimura and colleagues (2005) performed repeated percutaneous instillations of alcohol after cyst aspiration and achieved subtotal or total cyst regression. Another study compared single-session alcohol sclerotherapy versus prolonged catheter drainage with negative pressure; they reported no differences in average volume reduction, final volume, and cyst regression (Zerem et al, 2008).

Typically, aspiration and cyst sclerosis are done as an outpatient procedure, and the patient is discharged home after a short period of observation. The benefits of this approach are the minimally invasive nature, low risk of complications, short recovery period, avoidance of general anesthesia and a long hospital stay, and cost effectiveness.

Laparoscopic cyst fenestration and deroofing are safe and are currently the most effective surgical approaches for symptomatic simple hepatic cysts. Image-guided (US or CT) hepatic cyst aspiration with chemical sclerosis using tetracycline or alcohol should be the treatment of choice for patients who are poor operative risks (Mazza et al, 2009).

FIGURE 28.1. Pylephlebitis. **A,** Computed tomography (CT) scan showing complex mass in the caudate lobe and portal vein thrombosis. The unusual pattern of parenchymal liver enhancement with central low density is characteristic in patients with portal vein occlusion. **B,** CT scan 1 month after treatment with antibiotics shows that the abscess in the caudate lobe has largely resolved. **C,** Findings of cavernous transformation of the portal vein on ultrasound.

Pyogenic Hepatic Abscess Drainage

Pyogenic hepatic abscesses result in considerable morbidity, and mortality occurs if abscesses are left untreated. Advances in cross-sectional imaging and interventional radiology have revolutionized the diagnosis and therapy of liver abscesses with a dramatic improvement in prognosis (see Chapter 66). Mortality has decreased from 65% (1952–1972) to 31% (1973–1993). This decrease occurred in the face of no significant change in patient characteristics, such as age and sex distribution, or incidence of associated conditions, such as diabetes mellitus, steroid use, chronic liver disease, chronic pancreatitis, and pyelonephritis (Huang et al, 1996). Another study from Denmark found the incidence rate of pyogenic abscesses increased from 6 to 18 per 1 million men and from 8 to 12 per 1 million women, and the 30-day mortality rate decreased from 40% for men and 50% for women to around 10% for both genders (Jepsen, 2005).

The liver is the most common site of abdominal visceral abscesses. Liver abscess is a result of either direct spread of infection from a contiguous focus, such as the biliary tree, or hematogenous seeding of the liver via the portal vein or hepatic artery. Biliary tract pathology is the most common cause of liver abscess. Of the nonbiliary diseases that lead to hepatic abscess, appendicitis with rupture and suppurative pylephlebitis, usually from infection in the female genital tract, are frequent causes (Zaleznik & Kasper, 1998).

The constellation of a liver abscess and portal vein thrombosis with cavernous transformation of the portal vein may mimic the findings seen in hepatocellular carcinoma (HCC; Fig. 28.1). Clues to the correct diagnosis are the clinical and laboratory parameters that suggest infection and the absence of cirrhosis and portal hypertension, both of which are commonly seen with HCC. With successful treatment, complete resolution of both the abscess (see Fig. 28.1B) and the cavernous transformation of the portal vein (see Fig. 28.1C) is seen in many cases.

Hematogenous seeding of the liver via the hepatic arterial system is unusual and should be suspected if nongastrointestinal flora—particularly a single organism, such as *Staphylococcus aureus* or streptococcal species—is isolated from a liver abscess. Cryptogenic abscesses may be seen in diabetic patients; however, a diligent search should always be made for a primary cause, such as diverticulitis.

The microbial flora often reflect the source of the infectious process (see Chapter 11). In a study of 111 patients with pyogenic liver abscesses, *Klebsiella* species and *Escherichia coli* were the most common offenders (Lok et al, 2008). Anaerobes generally are encountered with a previous history of biliary intervention (e.g., surgery or stenting). With nonbiliary

gastrointestinal (GI) sources of infection, polymicrobial gram-negative aerobes and anaerobes predominate, whereas systemic bacteremia is more likely to give rise to a single isolate, often *S. aureus.* Other reported microbes reflect individual patient factors, such as *Entamoeba histolytica* with a history of residence in or travel to endemic areas, and *Candida* species in neutropenic patients.

Clinical symptoms and signs are nonspecific. Of 111 patients with pyogenic liver abscess (Lok et al, 2008), 91% were seen initially with fever, 79% with right upper quadrant pain, 18% with anorexia, and 18% with septic shock. Laboratory abnormalities also are nonspecific. In the same study, 93% had hypoalbuminemia, 75% leukocytosis, 72% elevated alkaline phosphatase, and 59% elevated alanine transaminase.

US and CT are the imaging modalities of choice (Zaleznik & Kasper, 1997). Radionuclide scans (gallium, indium, and technetium) and MRI can provide further diagnostic information, but rarely are necessary.

Decompression of the abscess cavity and systemic antibiotic therapy are the mainstays of treatment for liver abscess. Decompression evacuates the pus and endotoxins and relieves the intracavitary pressure; this ameliorates systemic toxic symptoms by decreasing hematogenous dissemination of toxins. It also allows better penetration of antibiotics into the wall of the abscess. In general, large abscess cavities should be drained, and aspiration alone should only be considered for smaller lesions.

Uncomplicated pyogenic liver abscesses may be single or multiple, often are unilocular, and may be septated (Fig. 28.2). It may be impossible to evacuate complex multiloculated abscesses completely at the time of initial catheter placement (see Fig. 28.2B). Typically, there is free communication between the loculi (see Fig. 28.2C); consequently, most resolve completely when treated with a single catheter (see Fig. 28.2D) and appropriate antibiotics. If in doubt about adequate drainage of multiple locules or multiple abscesses, more than one catheter is indicated. Communication with the biliary tree may be seen when the drainage catheters are injected with contrast material as a part of performing an abscessogram (see Fig. 28.2C). The catheter contrast injections should not be performed until the pus has been evacuated to ensure that septicemia is not provoked iatrogenically.

Regarding the choice of percutaneous needle aspiration versus catheter drainage, opinions vary. Giorgio and colleagues (2006) described their experience with 118 patients treated with US-guided percutaneous needle aspiration and systemic antibiotic therapy. Cure was achieved in all 118 patients, and in 36 instances with only a single puncture. No recurrences were seen at 7 to 42 months of follow-up. The use of percutaneous needle aspiration and antibiotics is simple, less expensive, and more comfortable for the patient than catheter drainage. In practice, however, more than one aspiration is usually necessary for complete treatment with this strategy. Yu et al (2004) performed percutaneous needle aspiration in 64 patients with pyogenic liver abscess and concluded it was probably as effective as continuous percutaneous catheter drainage; however, their data were not statistically significant. Rajak and colleagues (1998) also compared the two methods of percutaneous treatment in 50 patients; they concluded that percutaneous catheter drainage was more effective than percutaneous needle aspiration. A failure of treatment was defined as a lack of response to a second attempt of percutaneous needle aspiration.

A more recent study (Zerem, 2007) also compared the two treatment methods in 60 patients, with the lack of response to percutaneous needle aspiration defined at three attempts. These authors agreed with Rajak and colleagues (1998) and concluded that percutaneous catheter drainage was more effective than percutaneous needle aspiration in the management of liver abscess. They opined that percutaneous catheter drainage is more efficient for multiloculated liver abscesses, and that percutaneous needle aspiration is a valid alternative for abscesses 5 cm or less in greatest diameter. Currently, treatment of pyogenic liver abscess with drainage catheter placement is the most commonly accepted method among interventional radiologists. Percutaneous aspiration without catheter drainage is not recommended except for occasional patients with one or more small liver abscesses that are too small for a catheter.

Surgical intervention for liver abscesses should be reserved for cases with coexisting surgically correctable causes of liver abscess (e.g., biliary tree abnormalities) or for cases of failed percutaneous therapy (see Chapter 66). A recent study demonstrated that partial liver resection is a safe and successful treatment for large, multiloculated complex pyogenic liver abscesses (Hope et al, 2008). Some associated biliary tree abnormalities may be amenable to endoscopic correction. In this subset of patients, endoscopic retrograde cholangiopancreatography (ERCP) might be preferred over surgery (Lam et al, 1999). Another study reported that previous endoscopic sphincterotomy was a good prognostic factor for early resolution of liver abscesses within 6 weeks (Wong et al, 2002).

Empiric antibiotic therapy is initiated on the suspected source of infection, with later adjustment based on the results of culture and sensitivity of the aspirated specimen. Several weeks of therapy may be required. Sending aspirates to the laboratory for aerobic and anaerobic cultures at the time of initial access is crucial for prescribing an appropriate antibiotic regimen.

Amebic Abscess

In a patient with a hepatic abscess and a history of travel to or residence in endemic areas, the possibility of infection with *Entamoeba histolytica* should be considered (see Chapter 67). Hepatic amebic abscess is the most common extraintestinal manifestation of amebiasis. Conditions that affect cell-mediated immunity—such as extremes of age, pregnancy, corticosteroid therapy, malignancy, HIV infection, and malnutrition—also may increase the chance that enteric *E. histolytica* infection results in extraluminal disease with liver involvement. The clinical findings are similar to the findings for pyogenic abscess; in addition, amebic abscesses may have superimposed bacterial infection, and they usually are solitary and most commonly located in the right lobe, adjacent to the liver capsule (Brindicci et al, 2006).

Serologic testing is the most widely used method to diagnose hepatic amebic abscess. Aspiration may be used to establish the diagnosis and to exclude secondary bacterial infection. When aspiration is used for diagnosis, the cavity should be aspirated as completely as possible. Amebic abscesses contain acellular, proteinaceous debris and an "anchovy paste," a chocolate-colored fluid consisting predominantly of necrotic hepatocytes. Antigen tests and polymerase chain reaction on aspirated material may be helpful to confirm the diagnosis. Biopsy of the abscess wall may also establish the diagnosis if the other tests are inconclusive, which is the case in about 10% of patients (vanSonnenberg et al, 1985).

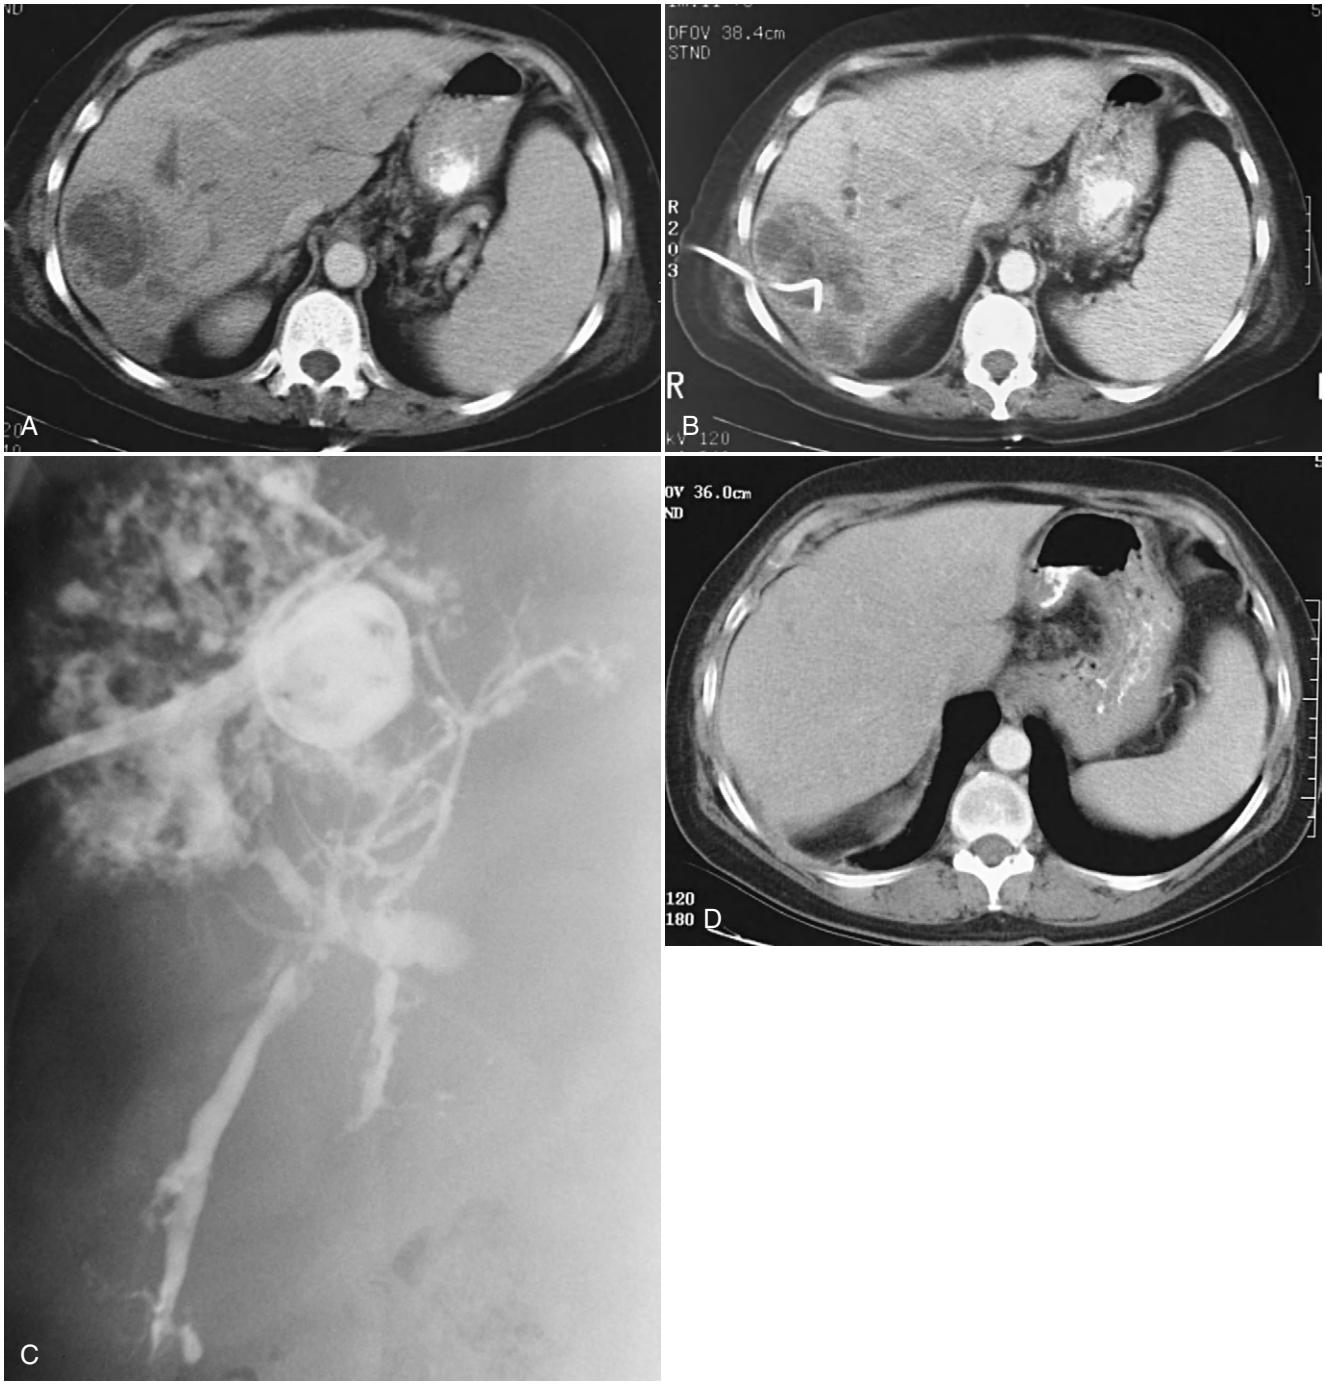

FIGURE 28.2. Liver abscess. **A,** Computed tomography (CT) scan showing multiloculated abscess in right lobe with dilated intrahepatic bile ducts. **B,** CT scan at the time of drainage catheter placement. **C,** Contrast study via the drainage catheter shows typical, irregular, loculated-type appearance and communication with biliary tree. **D,** Follow-up CT scan 3 months after treatment of hepatic abscess shows complete resolution.

Amebic liver abscesses can generally be treated successfully with antibiotics alone (Chavez-Tapia et al, 2009). With clinical suspicion of amebic liver abscess, empiric treatment with metronidazole and a luminal agent (paromomycin or iodoquinol) may be started while awaiting confirmatory tests. Indications for catheter drainage of amebic abscess include failed medical therapy, secondary pyogenic infection, pregnancy, perforated abscess, false-negative serology, and left lobe abscess because of the proclivity to rupture or spread into the pericardium (vanSonnenberg et al, 1985; Ken et al, 1989; Hanna et al, 2000).

Echinococcal Disease

Echinococcal disease is an endemic zoonosis acquired from ingestion of *Echinococcus granulosus* eggs from infected animals (see Chapter 68). The most common location of hydatid cysts is the liver. Echinococcal cysts in the liver have a characteristic

multiloculated or finely multiseptated appearance, and the right lobe is affected in 60% to 85% of cases.

Echinococcosis rarely manifests with an acute illness. Symptoms are unusual before the cyst has reached at least 10 cm in diameter. A large cyst can produce hepatomegaly with or without associated right upper quadrant pain, nausea, and vomiting. *Echinococcus granulosus* cysts can rupture into the biliary tree and produce biliary colic, obstructive jaundice, cholangitis, or pancreatitis. Pressure or mass effect on the bile ducts, portal and hepatic veins, or inferior vena cava can result in cholestasis, portal hypertension, venous obstruction, or Budd-Chiari syndrome. Liver cysts also can rupture into the peritoneum causing peritonitis, or they can rupture transdiaphragmatically into the bronchial tree, causing pulmonary hydatidosis or a bronchial fistula. Secondary bacterial infection of the cysts can result in liver abscesses. Serologic tests are often useful to establish the diagnosis, in conjunction with the typical clinical and radiologic presentation.

Traditionally, surgery has been the recommended treatment for hepatic cysts (World Health Organization, 1996), but the combination of percutaneous drainage with drug therapy is a more recent alternative. Although percutaneous aspiration previously was contraindicated because of the risk of anaphylaxis, this complication has been shown to be rare (Akhan et al, 1996). Bret and associates (1988) demonstrated the safety of aspiration or drainage of these cysts in 13 patients, and none of the patients who underwent drainage was premedicated. If a catheter was placed for drainage, a scolicidal agent was injected into the cyst cavity after cystography. No complications or recurrences were reported 6 months to 1 year after treatment. Khuroo and colleagues (1997) compared percutaneous drainage with surgery for hepatic hydatid cysts and reported that percutaneous drainage, combined with albendazole, is an effective alternative to cystectomy. They demonstrated similar efficacy in cyst regression and disappearance, with advantages of a shorter hospital stay and a lower complication rate. Zerem and Jusufovic (2006) treated 72 patients with univesicular and multivesicular hepatic hydatid cysts with US-guided percutaneous drainage combined with albendazole, and 81% of the cysts in the univesicular group and 63% in the multivesicular group disappeared.

Percutaneous evacuation of cyst content (PEVAC) has been reported as a safe and effective treatment of multivesicular echinococcal cysts with or without cystobiliary fistulas, which contain undrainable material (Schipper et al, 2002). Hydatid cysts commonly have a communication with the biliary tree, which is a contraindication to injection of sclerosing agents, because this may cause diffuse injury to the biliary epithelium (Belghiti et al, 1986).

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

The concept of transjugular hepatic intervention dates back to 1967, when Hanafee attempted diagnostic cholangiography via the transjugular intrahepatic route as a safer alternative to the percutaneous technique. At times, he inadvertently punctured portal vein radicles (Hanafee & Weiner, 1967). In 1969, Rosch and colleagues explored the transjugular route to visualize the portal venous system as an alternative to other available methods, such as splenoportography. The same year, Rösch and colleagues created the first transjugular intrahepatic portosystemic shunt (TIPS; see Chapter 76E) in dogs, using coaxial catheters to dilate the intrahepatic tract (Rösch et al, 1969, 1971). They discovered that without support, the tract would close; the plastic tubing used to "stent" the tract either thrombosed or migrated. Balloon dilation (Burgener & Gutierrez, 1979) and cryoprobes (Colapinto et al, 1983) were tried, but keeping the intrahepatic tract from shutting down remained a major problem. In the first human application of TIPS, Colapinto and associates (1982) used prolonged balloon inflation for 12 hours to keep the tract patent, but ultimately without success. The technique became a viable clinical option after refinement of metal stent technology in the late 1980s, when Richter and colleagues (1989) performed a landmark TIPS using a balloon-expandable Palmaz stent to maintain tract patency. The availability of Wallstents led to the rapid expansion and acceptance of the procedure.

Indications

The main indication for TIPS is the treatment of acute or recurrent variceal bleeding that has failed or is refractory to medical or endoscopic therapy, or both (see Chapters 75 and 76). This is especially true for patients who are bleeding from gastric or peristomal varices and those with severe portal hypertensive gastropathy. It is the preferred technique as a bridge to liver transplant, compared with surgical portosystemic shunts, because when performed correctly, TIPS does not alter extrahepatic vascular anatomy. It also is indicated for the control of refractory ascites and hepatic hydrothorax. TIPS may be used to treat Budd-Chiari syndrome in patients with moderate disease who fail to improve with anticoagulation (Boyer & Haskal, 2010).

Contraindications

There are several absolute and relative contraindications to TIPS placement. Absolute contraindications include congestive heart failure, sepsis, unrelieved biliary obstruction, severe pulmonary failure, and as the primary prevention of variceal bleeding (Boyer & Haskal, 2010). Relative contraindications to TIPS include the presence of HCC or hepatic metastases along the expected path of TIPS, hepatic vein obstruction, portal vein thrombosis, severe encephalopathy, polycystic disease of the liver, uncorrectable coagulopathy, and thrombocytopenia.

Technique (See Chapter 76E)

Various techniques and different systems are available for performing TIPS (Fig. 28.3). An imaging study using US, intravenous contrast-enhanced CT, or MRI to show a patent portal vein, hepatic veins, and hepatic venous anatomy is required. In an acutely bleeding patient, upper GI endoscopy confirms esophageal varices, excludes other sources of upper GI bleeding, and allows an attempt at endoscopic treatment. TIPS usually is performed under conscious sedation, but general anesthesia also may be used. Right internal jugular access is preferred, and a vascular sheath is placed. A selective catheter is advanced into one of the hepatic veins (see Fig. 28.3A).

The right hepatic vein is most commonly accessed for TIPS creation. Right atrial and free and wedged hepatic venous pressures are obtained, followed by hepatic and wedged hepatic venography. A specially designed needle is passed via the

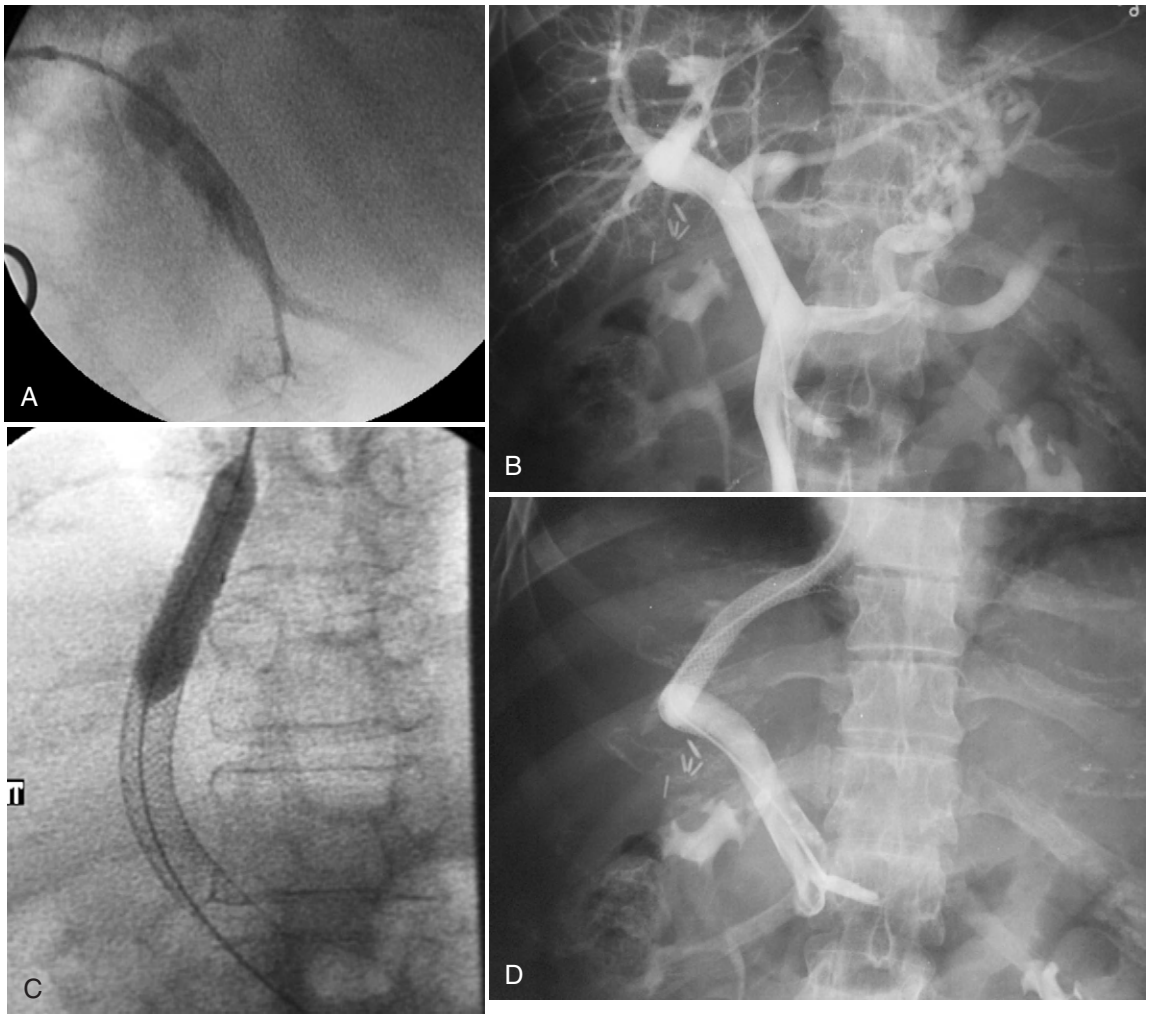

FIGURE 28.3. Transjugular intrahepatic portosystemic shunting. **A,** Right hepatic venogram performed via a transjugular catheter. **B,** Portogram shows enlarged coronary vein with opacification of gastroesophageal varices. **C,** Balloon dilation of the transhepatic tract between the right hepatic and right portal veins. **D,** After shunt placement. The dilated coronary vein and varices are no longer opacified.

transjugular route from the right hepatic vein across the liver parenchyma into the right portal vein 2 to 3 cm from the main portal vein confluence. A guidewire is advanced into the superior mesenteric vein or splenic vein and is used to place a catheter for pressure measurements and venography (see Fig. 28.3B). The tract is predilated with a balloon (see Fig. 28.3C); an appropriately sized (8 to 12 mm) self-expanding bare stent or a specially designed covered stent is deployed, and the balloon is dilated to an appropriate size. Pressures are obtained, with the goal being a portal–systemic gradient of less than or equal to 12 mm Hg. If the gradient is greater than 12 mm Hg, certain stents (Wallstents) may be dilated with a 12-mm balloon. If this dilation does not result in a satisfactory pressure gradient, and collaterals fill persistently, or when stents other than Wallstent have been used, parallel TIPS should be considered. If the result is satisfactory (see Fig. 28.3D), the procedure is concluded, and baseline US studies are performed within the following few days.

Results (See Chapter 76E)

In a review of 1750 patients at nine institutions in the United States and abroad (Barton et al, 1995), the technical success rate of TIPS was 97%. Failures were related to portal vein thrombosis, extremely hard livers, and massive ascites. The procedure controlled acute bleeding in 91% of patients. Rebleeding increased with time, with a 6% incidence at 3 months, 17% at 6 months, and 21% at 1 year. Higher Model for End-Stage Liver Disease (MELD), Acute Physiology and Chronic Health Evaluation (APACHE II), and Child-Pugh scores are associated with decreased survival. The Society of Interventional Radiology states technical success for TIPS should be achieved in 95% of patients, and clinical success should be achieved in more than 90% (Haskal et al, 2003).

Complications include TIPS thrombosis or occlusions, transcapsular puncture, stent migration, exacerbation of hepatic encephalopathy, right heart failure, procedure-related hemorrhage, hemobilia, contrast-induced acute tubular necrosis, hypersensitivity reactions to contrast material, fever, and pulmonary edema. Fatal outcomes were reported in 1.7% of patients, caused by intraperitoneal, retroperitoneal, and mediastinal hemorrhage; laceration of hepatic arteries, portal vein branches, and the liver capsule; and right heart failure (Barton et al, 1995). Mortality rates for TIPS are dependent on the indication and the patient's health status based on the

aforementioned scoring systems. The 1-year survival for TIPS performed for bleeding varices ranges from 48% to 90%, with lower survival rates when performed for refractory ascites (Boyer & Haskal, 2010).

Stenoses and occlusions occurred in 35% to 85% of bare stents (Barton et al, 1995). This wide range reflects differences in follow-up protocol, with some centers using US and some using venography. In addition, routine surveillance was done at some centers, whereas at others, patients were not studied unless they became symptomatic. With repeat intervention, assisted patency of TIPS can be maintained in 95% of patients. The use of specially designed covered stents has dramatically improved the primary patency rates of TIPS (Rossi et al, 2004; Saxon, 2004). Bureau and colleagues (2007) composed a randomized controlled study of 80 patients to compare covered stents with bare stents and showed a primary patency rate of 76% and 36% at 2 years, respectively. Rates of being free of encephalopathy were 67% in the covered-stent group compared with 51% in the bare-stent group; thus, performing TIPS with covered stents is the current recommendation (Boyer & Haskal, 2010).

PORTAL VENOUS EMBOLIZATION

Branches of the portal vein may be embolized to induce ipsilateral atrophy and contralateral liver hypertrophy in the preoperative management of select liver and biliary tumors. The resulting hypertrophy of the future liver remnant reduces the risk of postresection liver failure in selected patients. The role and technique of preoperative portal vein embolization are discussed in detail in Chapters 93A and 93B.

BILE DUCTS AND GALLBLADDER

Percutaneous Transhepatic Cholangiography

Percutaneous transhepatic cholangiography (PTC) is performed much less commonly for diagnostic purposes than in the past (see Chapter 18). Noninvasive imaging of the biliary tree such as with US (Chapter 13), CT (Chapter 16), and MR cholangiopancreatography (Barish & Soto, 1997; see Chapter 17) has greatly reduced the need for invasive PTC to diagnose biliary tract disorders. Indications for PTC have included defining the level of obstruction in patients with dilated bile ducts, to evaluate for suspected bile duct stones, to determine the etiology of cholangitis, to evaluate suspected bile duct inflammatory disorders, and to demonstrate the site of a bile duct leak (Burke et al, 2003). The complications of the procedure are uncommon and include sepsis, cholangitis, bile leak, hemorrhage, or pneumothorax (Burke et al, 2003).

Percutaneous Cholecystostomy

Percutaneous cholecystostomy is indicated for patients with acute calculous cholecystitis who are too ill to undergo cholecystectomy or for patients with acalculous cholecystitis (see Chapters 31 and 32; Welschbillig-Meunier et al, 2005; Akhan et al, 2002; vanSonnenberg et al, 1992). In the case of acute calculous cholecystitis, management depends on patient-related factors. In a patient with a long life expectancy, percutaneous cholecystostomy is a temporizing method to allow the patient to recover from the critical illness. When the patient's condition stabilizes, cholecystectomy can be performed on a nonemergent basis. Conversely, for a patient with limited life expectancy and/or multiple comorbidities, if cystic and common bile ducts are patent, stones may be removed from the gallbladder and/or the common bile duct percutaneously or endoscopically.

Before catheter removal, after the tract has matured, it must be understood that a diseased gallbladder will be left behind. The recurrence rate of acute calculous cholecystitis after percutaneous cholecystostomy is approximately 25% (Van Steenbergen et al, 1990). Some patients with extreme debility and obstructed cystic or bile ducts may require long-term percutaneous cholecystostomy. In such cases, the catheter should undergo periodic exchange to avoid clogging and fragmentation.

Acute acalculous cholecystitis usually is considered in elderly patients with an unexplained sepsis syndrome; such patients often are being managed in intensive care units when imaging, usually US, reveals a distended, tender gallbladder. The facility with which the procedure can be performed, even at the bedside, along with the low complication rate allows percutaneous cholecystostomy to serve a diagnostic and therapeutic function. Even patients with gas within the gallbladder wall can be treated with percutaneous cholecystostomy. A 56% to 80% clinical response to percutaneous cholecystostomy has been reported (Boland et al, 1994). A more recent study (Chuang et al, 2007) reported percutaneous cholecystostomy followed by cholecystectomy as a treatment for emphysematous cholecystitis in four patients, none of whom suffered a complication.

Initially, thick, viscous, dark bile is aspirated from the distended gallbladder in these patients. As inflammation subsides and cystic duct patency is restored, normal-appearing bile begins to drain from the catheter. At that point, a contrast study of the catheter can be performed to document patency of the cystic and the common bile ducts, and the percutaneous cholecystostomy catheter may be clamped. It is important not to remove the catheter until a mature tract to the skin has formed to avoid intraperitoneal leakage of bile. Depending on the nutritional status of the patient and whether a transhepatic or transperitoneal approach was used to enter the gallbladder, catheter removal typically occurs no sooner than week 2 or 3 after the procedure (Hatjidakis et al, 1988; vanSonnenberg et al, 1992).

Percutaneous cholecystostomy also may be performed as a means of relieving distal common bile duct obstruction in patients who are too ill to tolerate another, more definitive procedure; in patients who have minimal or no intrahepatic biliary ductal dilation; or in those who have failed or cannot undergo endoscopic retrograde biliary endoscopy, provided that the cystic duct is patent. Percutaneous cholecystostomy is quicker, easier, and safer than percutaneous transhepatic biliary drainage under these circumstances, and it can be performed at the bedside with US guidance. Patients without significant dilation of intrahepatic ducts can have a percutaneous cholecystostomy catheter placed that can be injected with contrast medium at a later time to opacify the intrahepatic ductal system, facilitating conventional transhepatic access to the biliary tree for a variety of interventions (vanSonnenberg et al, 1990a, 1992).

Interventional Radiologic Management of Bile Duct Stones

Retained common bile duct stones after surgery may be treated successfully via a T-tube tract in most patients or via a transhepatic approach (Fig. 28.4; see Chapters 35, 36, and 39). Stones can be extracted or crushed with baskets, or they can be swept

FIGURE 28.4. Common bile duct calculi. **A,** Note multiple angular filling defects in the common duct, representing stones. **B,** Balloon inflated during dilation of the sphincter at the ampulla of Vater. **C,** Final study obtained after clearance of stones from the common bile duct.

into the bowel with balloon catheters. Balloon dilation of the sphincter (see Fig. 28.4B) is performed to allow for passage of small fragments, typically with a 10-mm balloon. An older, classic study on stone extraction surveyed 39 institutions and reported 5% morbidity and no deaths in 612 extraction procedures (Burhenne, 1976). With the development of more sophisticated devices for minimally invasive procedures—including steerable catheters, cholangioscopes, and contact lithotripsy probes—the success rate for treatment of retained common bile duct stones is even greater. These techniques and devices also can be applied to the transhepatic removal of intrahepatic stones (see Chapter 39 and 44).

The principal drawback to T-tube stone extraction is that a 4- to 6-week period is required for tract maturation. In select cases, attempts can sometimes be made earlier with tract protection by sheaths. Endoscopic sphincterotomy and stone extraction (see Chapter 36) may be performed sooner, typically after 7 to 10 days, with 90% to 95% success rate (Becker et al, 1993; O'Doherty et al, 1986). Complication rates are 4% to 19% with a 0% to 2% mortality rate. Christoforidis and colleagues (2004) stated that the endoscopic technique is a safe and efficient treatment for residual stones after common bile duct exploration with a T-tube insertion, offering immediate cure compared with percutaneous techniques.

The location of bile duct stones and previous surgeries are important factors in deciding the method of treatment. Intrahepatic bile duct stones are more readily accessible by interventional radiologists than gastroenterologists. Furthermore, previous operations such as hepaticojejunostomy make an endoscopic approach impossible, thus percutaneous routes by interventional radiologists are indicated for these patients. A series of six patients with extensive and complicated recurrent pyogenic cholangitis (see Chapter 44) who all had previous biliary surgery underwent numerous percutaneous techniques—basketing, flushing, crushing, balloon occlusion, and chemical dissolution—to remove innumerable retained intrahepatic and extrahepatic stones (vanSonnenberg 1986).

Percutaneous Transhepatic Biliary Drainage

Percutaneous transhepatic biliary drainage (PTBD) is indicated for relief of biliary obstruction, especially of the proximal biliary tree, and is associated with pruritus and cholangitis (see Chapters 20, 26, 27, 42, and 50D). In general, distal biliary disease is addressed by biliary endoscopy. PTBD is indicated in some patients as the initial step in the planned treatment of benign and malignant bile duct strictures, biliary stones, or locoregional treatment of primary and metastatic liver neoplasms. PTBD is also indicated for severe cholestasis but should not be performed solely for the relief of jaundice or for the cosmetic treatment of dilated bile ducts; this is due to the invasiveness of the procedure and its associated potential complications, including bleeding, bile peritonitis, and sepsis. Preoperative biliary decompression in jaundiced but otherwise asymptomatic patients is controversial (see Chapters 50A, 50B, 50C, 50D, and 62A). PTBD also may be indicated for lowering serum bilirubin levels to permit the use of chemotherapeutic agents with biliary excretion routes. Lastly, in select complicated situations, the surgeon may request catheterization of the bile ducts to help identify the ducts to avoid injury at surgery.

In general, surgery, biliary endoscopy, and PTBD all should be weighed as options for each individual patient. A multidisciplinary consensus involving hepatobiliary surgeons, gastroenterologists, and diagnostic and interventional radiologists regarding the need for, and proper technique of, biliary drainage for an individual patient or clinical problem is the optimal approach.

Preprocedure Evaluation

Preprocedure evaluation should include a complete blood cell count (including platelets), prothrombin time, partial thromboplastin time, international normalized ratio, and liver function tests. Diagnostic imaging of the liver and biliary tree is a prerequisite. US is a safe, cost-effective technique to demonstrate biliary obstruction and the level of obstruction. CT and MR cholangiopancreatography (MRCP; see Chapters 16 and 17) are extremely useful to show hepatobiliary anatomy and pathology in great detail. CT is the procedure of choice for procedural planning. Findings such as liver atrophy are readily identified on any cross-sectional imaging modality, but other anatomic considerations—such as colonic interposition and identification of calcifications or surgical clips that may serve as useful fluoroscopic landmarks—are readily evident on CT. Translation of this information into three-dimensional images greatly facilitates the drainage procedure, and three-dimensional postprocessing CT can be performed if desired.

Patients undergoing biliary drainage have a high incidence of bacterobilia, particularly when there has been previous operation or biliary instrumentation (Brody et al, 1998). Prophylactic antibiotics are indicated in all cases of PTBD. Broad-spectrum agents that cover enterococci, streptococci, and aerobic and anaerobic gram-negative bacilli typically are administered before the interventional radiology procedure commences (Lipsett, 1996; see Chapter 11).

Technique

The choice of a right- or left-sided approach for PTBD is based on many factors. Drainage of an atrophic portion of the liver does nothing to conserve or improve hepatic function or to lower serum bilirubin (see Chapter 5). The only reason to drain an atrophic segment would be for unrelenting biliary sepsis after satisfactory drainage of the functional liver parenchyma. In general, high bile duct obstruction is more likely to result in isolation of the right anterior and right posterior sectoral ducts and to extend to involve second-order branches. Such isolation of segmental ducts occurs later on the left, because the left hepatic duct is typically longer compared with the main right duct, which is shorter and has a more palmate branching pattern. In addition, the right posterior sectoral duct joins the left hepatic duct, rather than its anterior right counterpart, in at least 20% of cases (see Chapter 1B).

In high obstruction, in the absence of left portal vein compromise, a left-sided approach may be preferred. Other advantages of left-sided access are a more favorable angle for biliary intervention; better use of US to guide safe puncture of the duct, which is easier to visualize on the left; avoidance of pleura; less discomfort associated with an intercostal route; and less chance of an ascites leak around the catheter with an anterior left subxiphoid approach rather than a right lateral intercostal approach. The advantages of a right-sided approach are decreased exposure of the operator to radiation and in general more operator familiarity with right-sided access. In certain cases, access from both sides may be needed (vanSonnenberg, 1986). In patients who are being considered for operation,

left-sided drainage catheters are often close to or in the line of the intended incision, although this should not be an overriding concern if left-sided drainage is required.

An attempt should be made to puncture a peripheral bile duct; this limits the risk of injuring a major vessel near the hilum and ensures an adequate number of sideholes in the catheter above the obstruction for effective drainage. It is important to avoid puncturing the left ductal system from the right side, and vice versa, because this makes further catheter manipulations difficult. It is usually possible to place an 8-Fr catheter across the obstructed area down into the duodenum at the time of initial drainage, allowing for drainage of bile into the bowel. If this cannot be accomplished initially or in the presence of cholangitis, when undue manipulation within the biliary tree is inadvisable, we leave an external drainage catheter and cross the obstruction a few days later, after the patient has become stable clinically. In most patients, when the inflammatory component of the obstruction has resolved, conversion to an internal/external catheter or placement of a biliary stent is possible.

Patients with high bile duct obstruction frequently exhibit complete or near-complete isolation of the right and left hepatic ducts. In some cases, isolation extends to the sectoral or segmental level, which is more frequent on the right side, as discussed earlier. A single drainage catheter is placed at the initial encounter with the patient. It is necessary to have approximately 30% of the hepatic parenchyma drained and functional to alleviate jaundice; this is frequently accomplished with drainage of either the right or the left ductal system. Pruritus is related to bile salt deposition within the skin and usually responds immediately and dramatically to drainage of any part of the liver. It may take 2 weeks for the bilirubin level to decrease and plateau, particularly in long-standing obstruction, and it is advisable to withhold further intervention until the serum bilirubin has stabilized. If the serum bilirubin does not decline to an acceptable level after this time, or if biliary sepsis is the predominant problem, it may be necessary to place more than one catheter or consider a coexistent medical cause for jaundice as well.

At the time of initial drainage of patients with malignant biliary obstruction and limited life expectancy, placement of an internal biliary endoprosthesis should be considered. Plastic and metal endoprotheses are available. Metal stents have a longer median patency (3.6 to 9.1 months) relative to plastic stents (1.8 to 5.5 months), but there is no difference in median survival (Levy et al, 2004). Tsuyuguchi and colleagues (2008) suggest that metal stents are recommended in patients who are expected to survive longer than 6 months, whereas plastic stents should be used in patients with a suspected survival of less than 6 months. The difference in cost also serves as a factor in this management recommendation, because metal stents are more expensive than plastic stents if reintervention is not required (Davids et al, 1992). Metal stents also may be covered with polyurethane, and these were found to prevent tumor ingrowth and had higher patency, but complications of acute cholecystitis (Isayama et al, 2004) and stent migration also occurred (Yoon et al, 2006). Thus further studies are needed to establish the indications for covered versus bare metal stents.

Metal stents most commonly used for malignant disease within the biliary tree are the Wallstent and Strecker stents. These are nonremovable, self-expanding, flexible, braided, or woven stents that are placed through 7- to 10-Fr sheaths, and they can expand to diameters of 6 to 10 mm. Because these metallic stents are permanent, they should be used only when the patient has no possibility of undergoing curative resection. Hepatobiliary surgical resections are much more difficult after a metal stent has been placed. In patients with mid to distal common bile duct obstruction without signs of infection, and when placement of additional drainage catheters is not a consideration, this approach allows for biliary stenting at the time of the initial biliary drainage procedure. When satisfactory lumen and flow have been restored, the percutaneous access can be removed immediately but preferably the following day.

Patients with high bile duct obstruction or isolated obstructed segments of the liver may require more than one drainage procedure. In such patients and in patients with signs of infection, it is best to wait to consider metal stent placement until the patient shows a clinical response, such as decrease in serum bilirubin and resolution of sepsis, and then devise a clear strategy for treatment. Although drainage catheters and endoprostheses can be placed through the interstices or alongside an existing stent, it is much easier for both operator and patient if the stents are deployed simultaneously in a carefully preplanned manner.

In the case of isolation of the right and left hepatic ducts, management can be accomplished in one of two ways. From one transhepatic approach (Fig. 28.5), a stent can be placed across the confluence of the bile ducts to the contralateral side, and the second stent can be deployed from the ipsilateral side into the common hepatic and/or common bile duct. Alternatively, especially when the patient has failed to respond to a single drainage, the contralateral side can be approached percutaneously (Fig. 28.6), allowing for simultaneous placement of side-by-side stents across the obstruction at the ductal confluence into the distal common bile duct. We agree with Morgan and Adam (1996) that the latter approach is preferable in the event that it is necessary to intervene again for subsequent stent occlusion. For hilar lesions, we are careful to "overstent" (Lammer et al, 1996) in an effort to avoid occlusion related to tumor overgrowth. One way is to predilate and/or postdilate when placing Wallstents. Some patients find balloon dilation to be quite painful, and although general anesthesia is not used routinely, it may be advantageous in select patients. Satisfactory stent expansion typically is achieved within 24 hours (see Figs. 28.5B and 28.6B) without the aid of balloons.

There is a role for balloon dilation if, after deployment, contrast material does not flow promptly across the stent. After stent deployment, the introducer system is removed, and a 4- to 5-Fr end-hole catheter, such as a Kumpe (Cook, Bloomington, IN), is left as a protective catheter. If dual access has been used, two protective catheters are left. These catheters are used for subsequent follow-up cholangiography (see Figs. 28.5C and 28.6C) and to ensure that there has not been asymmetric stent shortening or some other occurrence that would require placement of additional stents or other intervention. In 95% of cases, no other intervention is necessary.

Bile Duct Biopsy

Faced with inoperable, presumed malignant bile duct obstruction, a tissue diagnosis is necessary before initiating brachytherapy or sometimes simply in an effort to give meaningful prognostic information to the patient and family. A diagnosis can be arrived at in several ways. Bile cytology obtained at the time of initial drainage, although insensitive, has been found to

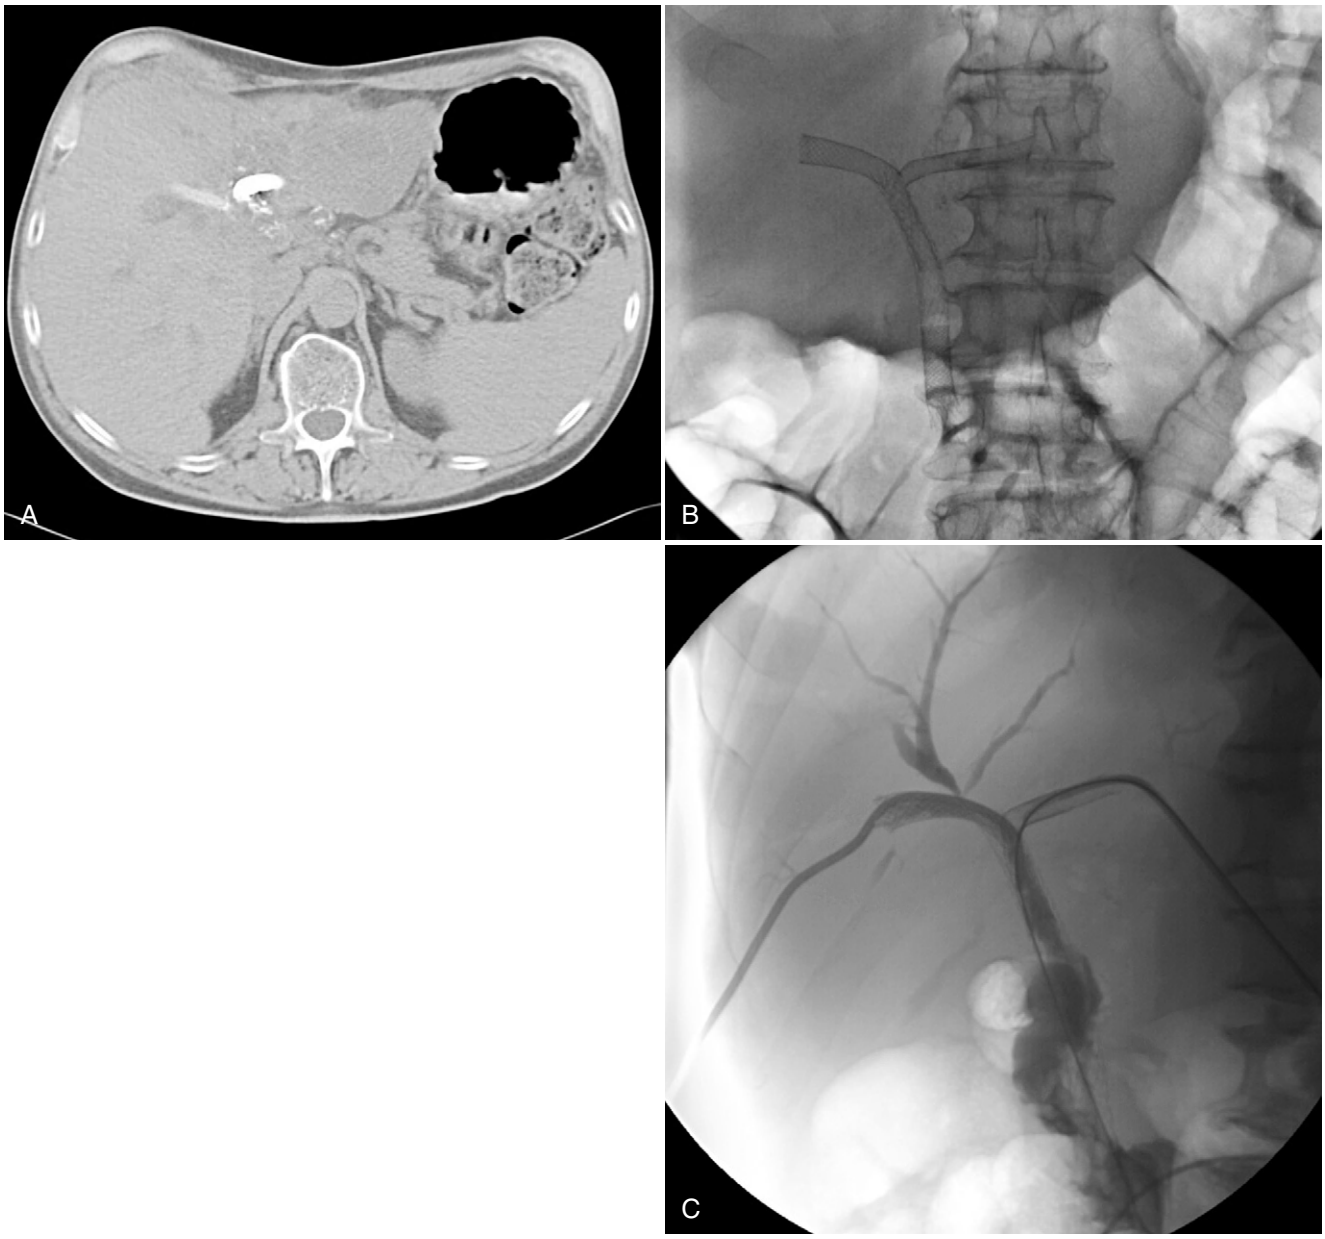

FIGURE 28.5. Wallstents. **A,** Patient with gallbladder cancer and hilar obstruction. Wallstents are deployed simultaneously from the left hepatic duct into the right hepatic duct and from the left hepatic duct into the common bile duct. Right-sided access was performed when cholangitis did not respond to drainage of the left side alone. **B,** Wallstents 24 hours after placement, expanded without balloon dilation. **C,** Right catheter cholangiogram shows the stents to be well positioned and widely patent.

be quite specific (Savader et al, 1988), and there is virtually no disadvantage to sending a specimen. Cytology can be obtained also with intraluminal brushes; the reported sensitivity ranges from 44% to 67% (Ryan, 1991; Cropper & Gold, 1983; Mendez et al, 1980). Percutaneous transluminal forceps biopsy has shown better diagnostic capabilities with a sensitivity of 78.4% and specificity of 100% in cases of malignant biliary obstruction (Jung et al, 2002; see Chapter 20). If these methods fail, a cholangiographically guided percutaneous needle biopsy can be performed, which frequently yields a diagnosis. If a mass is visualized on CT or US, these modalities can be used to guide the biopsy. These options will usually yield a biopsy diagnosis, and the choice is tailored to the patient's situation and the radiologist's preference.

Brachytherapy

Brachytherapy involves the local delivery of radiation to a tumor and can be used percutaneously to treat unresectable or recurrent cholangiocarcinoma (see Chapters 50A, 50B, 50C, and 50D). We also have used this method to treat intraductal metastatic colorectal carcinoma and bile duct carcinoma. Conventional biliary drainage is performed first, placing one or more internal/external catheters. After the

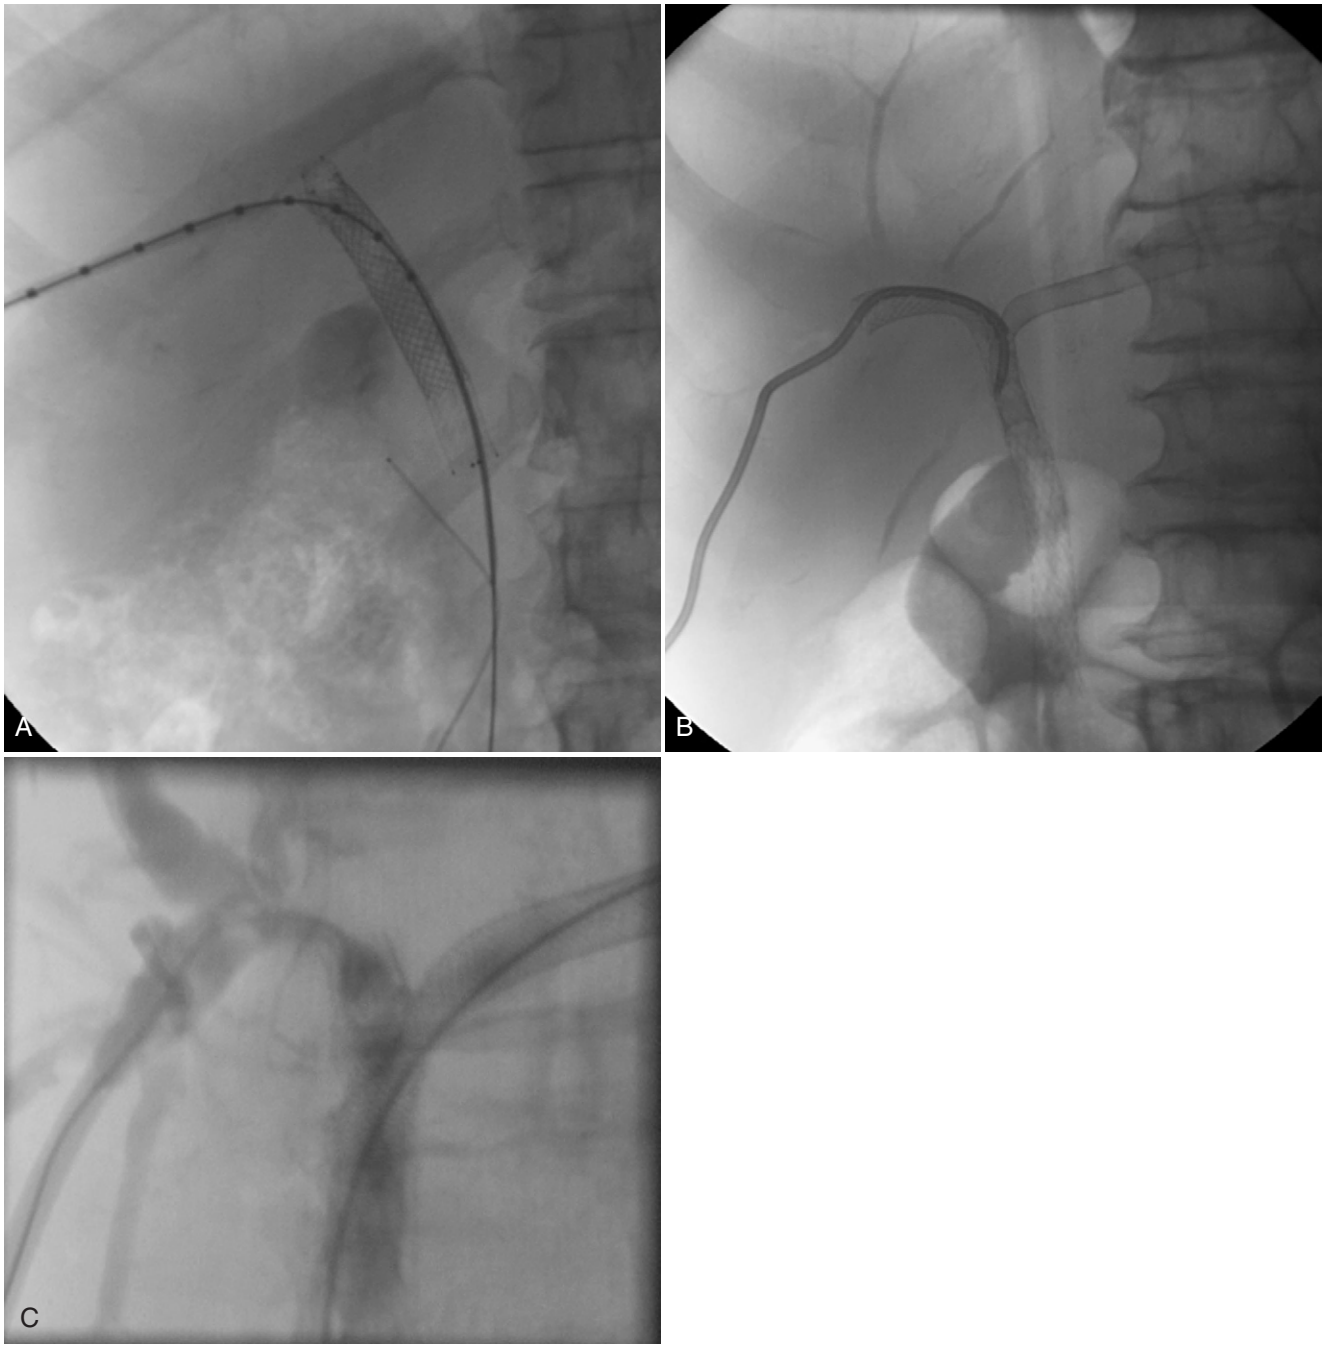

FIGURE 28.6. Wallstents. **A,** Patient with hilar obstruction secondary to cholangiocarcinoma. Bilirubin level was not low enough for chemotherapy after drainage of the right hepatic ducts; the patient subsequently underwent drainage of the left hepatic ducts and side-by-side Wallstent placement. **B,** After 24 hours, the Wallstents are well expanded without balloon dilation. **C,** Cholangiography shows the stents to be well positioned and widely patent.

bilirubin has normalized and any underlying infection has subsided, a Wallstent is introduced to bridge the area of obstruction, and a simulation catheter is positioned through the Wallstent. After dosimetry is performed, the radiation source is loaded within 24 hours and remains in place for a predetermined time, depending on dosimetry calculations. When therapy is complete, the catheter and radiation source are removed at the bedside. This method is not only a means for local tumor therapy but also seems to prolong Wallstent patency by decreasing the rate of tumor ingrowth (Eschelman et al, 1996), at least when combined with external-beam therapy.

Bile Duct Injury

Much of what we know about the role of interventional radiology in the management of traumatic injury to the bile ducts has been learned from complications of iatrogenic trauma, particularly after laparoscopic cholecystectomy (Boland et al, 1996; Lillemoe et al, 1997; Lund & Winick, 1996; vanSonnenberg et al, 1990c).

Similar principles would apply to the treatment of noniatrogenic injuries, although these are rarely seen. Patients with strictures who do not have a previous history of biliary surgery or significant right upper quadrant trauma should be investigated aggressively in an effort to establish that the stricture is not malignant prior to treatment (see Chapters 38, 42A, 42B, and 102).

In general, small postoperative bile leaks typically heal spontaneously, assuming there is no outflow obstruction, and usually all that is required is percutaneous drainage of any collection that may have formed (see Chapters 42A and 42B). Cystic duct leaks after cholecystectomy may respond best to endoscopic placement of a plastic biliary endoprosthesis. Major bile duct injuries consist of duct transection, laceration, and/or partial or complete ligation (vanSonnenberg et al, 1990c). These injuries are categorized according to the anatomic site of injury. Normal anatomic variants also pose challenges. Christensen et al (1992) discussed how aberrant right hepatic ducts are the most common biliary tract anomaly susceptible to injury at cholecystectomy. Complications include biliary leakage and fistulas, bilomas, pain, fever, and sepsis. An accidentally ligated aberrant right hepatic duct may not be appreciated at ERCP. Prudent evaluation with US, CT, MRCP, and PTC of sequestered posterior right hepatic duct dilation is essential for proper diagnosis. A preoperative biliary catheter may aid the surgeon in subsequent ductal reconstruction.

The length of duct available for surgical reconstruction and the integrity of the hepatic duct confluence greatly influence treatment options. Most surgeons and radiologists agree that the best chance for a trouble-free long-term outcome can be expected after primary surgical repair (Boland et al, 1996; Lillemoe et al, 1997). In the study by Lillemoe and colleagues (1997), patients treated surgically showed improved outcomes compared with patients treated with interventional techniques, including drainage and balloon dilation. All of the patients treated with interventional techniques had previous surgical attempts at reconstruction. In the interventional group, patients who presented late and with low (Bismuth type 1; see Chapters 42A and 42B) injuries fared significantly better. These patients require a team approach. Patients who are poor surgical candidates, those who have portal hypertension, and those who have had multiple previous attempts at surgical repair might be treated best with percutaneous drainage and balloon dilation (see Chapters 27, 42A, and 42B).

Mid to distal common bile duct strictures can be dilated with a balloon catheter. Balloons should be sized slightly larger than the duct being dilated, usually 8 to 12 mm, and inflated to eliminate any "waist." When dilating strictures at the hilum (Fig. 28.7), balloon dilation may require two or more catheters, which may be used sequentially to dilate from side to side and into the common hepatic duct, across a biliary-enteric anastomosis (see Fig. 28.7B), or simultaneously. When the simultaneous or "kissing balloon" technique is used, with one balloon placed from the right and one from the left, size should be adjusted appropriately. There is no evidence that prolonged inflation or multiple inflations enhance patency, and some authors believe this may promote ductal ischemia. Occasionally, bile duct rupture occurs (see Fig. 28.7C), and we have seen a related arterial vascular injury (see Fig. 28.7D) that required embolization; however, we have not found it necessary to treat bile duct rupture with anything other than continued drainage (see Fig. 28.7E).

How long a catheter should be left in place after balloon dilation is controversial (Boland et al, 1996). We leave a 10- or 12-Fr drainage catheter in place for 2 to 4-weeks, at which time we reevaluate the patient cholangiographically. If the stricture site is widely patent, we exchange for a drainage catheter above the treated area; if the patient tolerates a clamping trial, this catheter is removed in a few days. If the follow-up cholangiogram shows residual or recurrent narrowing, the site is dilated again with a slightly larger balloon, followed by another 4-week observation period and a cholangiogram. Again, a drainage catheter is left above the dilated site and clamped. If the patient tolerates this "capping trial," the catheter is removed.

Biliary pressure measurements and bile duct perfusion with manometry offer the only real objective information about bile duct dynamics and the status of balloon dilation (vanSonnenberg et al, 1983, 1990b). We utilize manometry and perfusion dynamics if evaluation of the dilatation, patency, and flow dynamics are not straightforward (relatively common). Patients who fail repeated dilations should undergo either continued catheter drainage or surgical treatment. We believe that self-expanding metallic stents should not be used to treat benign strictures, unless the patients are extremely poor surgical candidates or they have limited life expectancy because of comorbid conditions. Surgically treated patients have better outcomes, and when a metallic stent is placed, it makes subsequent surgical repair more difficult (vanSonnenberg et al, 1986). These decisions should always be made with the surgeon and interventional radiologist in concert.

Vascular Injury

Sclafani (1985) showed that angiographic methods could be used to control hemorrhage from injuries to the liver and spleen (see Chapters 19, 50D, 104, and 105). Hagiwara and colleagues (1997) concurred more recently that this method is an effective alternative to surgery. All but the most severe hepatic venous bleeding is self-limiting, and angiographic methods are suitable to treat hemorrhage secondary to blunt or penetrating trauma, including iatrogenic arterial injuries resulting from biliary interventions (Fig. 28.8). When the site of injury is established—by the presence of pseudoaneurysm formation (Fig. 28.8B), extravasation (Fig. 28.9A), abrupt vessel cutoff, or spasm—the injured vessel may be occluded with absorbable gelatin sponge (Gelfoam), metal coils, or both (Fig. 28.8C). If small coaxial catheters are necessary, microcoils or polyvinyl alcohol particles may be used. The dual blood supply to the liver makes it extremely tolerant of arterial occlusion for hemostasis; however, caution must be exercised in jaundiced patients, because significant compromise of arterial inflow can result in hepatic necrosis.

Percutaneous Tumor Ablation

Many percutaneous methods for tumor ablation are currently in use, including heating, freezing, alcohol injection, and combinations of these techniques. Although radiofrequency ablation (RFA) is the most common ablation method in the United States, treatment should be tailored to the individual patient's situation (vanSonnenberg et al, 2005). For example, in a patient with metastatic pheochromocytoma to the liver, a combination of alcohol and RFA was used to synergistically enhance tumor kill (Fig. 28.10; Mamlouk et al, 2009; Shankar et al, 2004). Nonresectional ablation of liver tumors is covered further in Chapters 83, 84A, 84B, 85A, 85B, 85C, and 85D).

CHAPTER 29

Bile duct exploration and biliary-enteric anastomosis

Clifford S. Cho and Michael I. D'Angelica

OVERVIEW

Rapid evolution in the management of biliary tract disorders over the past 3 decades has resulted in a number of alternatives to formal operative intervention. Nevertheless, the need for biliary exploration or restoration of biliary-enteric continuity because of obstruction by calculus or tumor remain important indications for surgical intervention. The operative conduct of biliary-enteric anastomosis demands a considerable appreciation for relevant anatomy and alternative technical strategies, which are discussed in this chapter.

ANATOMY

Safe operative planning and technique demand a comprehensive understanding of the extrahepatic biliary anatomy and a thorough appreciation for the common anatomic variants that may be encountered. Hepatobiliary anatomy is discussed at length in Chapter 1B; in this section, we will highlight specific aspects deserving of additional emphasis.

The typically short extrahepatic course of the right hepatic duct makes operative access to the segmental or sectional drainage of the right hemiliver rather difficult. However, the biliary anatomy of the right hemiliver is rather prone to variation, and aberrant drainage from the right anterior or posterior section may assume a long extrahepatic course before joining with the left hepatic ductal system. In comparison, the left biliary system is relatively consistent. Also in contrast to the right, the left hepatic duct invariably has a longer extrahepatic course as it runs along the undersurface of segment IVb (Fig. 29.1). In cases where the base of segment IVb is broad, the left hepatic duct assumes a longer and more transverse course; in cases where the base of segment IVb has a narrower and pyramidal configuration, the course of the left hepatic duct is shorter and more oblique. Drainage from most of segment I enters into the left hepatic duct just before its convergence with the right hepatic duct; drainage from the right portion of segment I typically enters into the right posterior sectoral duct. The left hepatic duct runs along the left portal vein within a peritoneal reflection of the gastrohepatic ligament, and it is best exposed by lowering the hilar plate along the base of segment IVb (Fig. 29.2). These structures are joined by the left hepatic artery as they enter the umbilical fissure, where arterial and venous branches to and biliary ducts from segments II, III, and IV are found. The ligamentum teres along the lower edge of the falciform ligament runs across the umbilical fissure, which is often covered by a bridge of hepatic tissue that crosses from the left lateral section to the base of segment IV. This bridge of tissue must often be divided to permit full exposure of and access to the biliary and vascular structures to and from segments II, III, and IV (Fig. 29.3).

BILE DUCT EXPLORATION

Overview

The most common indication for exploration of the biliary system is the presence of common bile duct stones. Contemporary percutaneous and endoscopic techniques have largely replaced operative interventions for this indication, and nonoperative, laparoscopic, and open operative strategies are addressed in greater detail in Chapters 34, 35, and 36, respectively. In this chapter, we highlight the various operative approaches for open exploration of the bile ducts.

Incision and Exposure

A right subcostal incision generally affords satisfactory exposure of the extrahepatic biliary system. The hepatic flexure of the right hemicolon is mobilized, and the proximal transverse colon is mobilized off the duodenum. Downward retraction of the proximal transverse colon facilitates exposure of the duodenum, whose retroperitoneal attachments are freed with a generous Kocher maneuver. A cholecystectomy is often performed in conjunction with bile duct exploration for patients with calculous disease, and removal of the gallbladder greatly enhances exposure of and access to the porta hepatis. Alternatively, retraction of the mobilized gallbladder can be useful for exposing the junction of the cystic duct and common bile duct. Cephalad retraction of the undersurface of the liver along the base of segment IVb also enhances optimal visualization of the extrahepatic biliary system (Fig. 29.4).

Supraduodenal Exploration (See Chapter 35)

Choledochotomy

Open exploration of the extrahepatic biliary system is best undertaken through a longitudinal distal choledochotomy. Opening the common bile duct distally toward the duodenum facilitates exploration of the distal biliary system and permits easy construction of a choledochoduodenostomy, if necessary. Care must be taken to verify the anatomic relationship between the cystic duct and common bile duct, as low or anterior

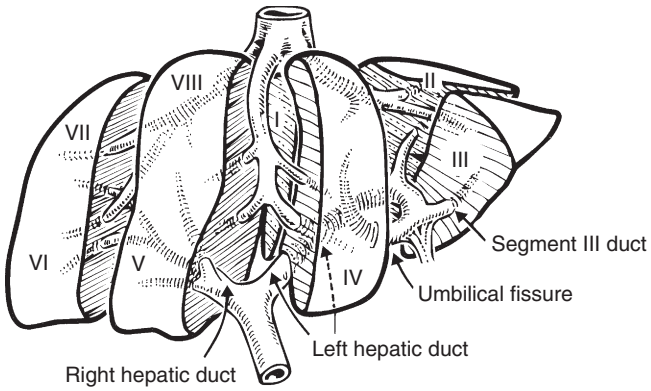

FIGURE 29.1. Diagrammatic expanded view of the liver showing its segmental structure. Elements of the portal triad are distributed to the right and left liver on a segmental basis. The left hepatic duct always pursues an extrahepatic course beneath the base of the quadrate lobe (segment IV) in the groove separating the quadrate from the caudate lobe (segment I; see Fig. 29.2). The ligamentum teres marks the umbilical fissure and runs to join the umbilical portion of the left branch of the portal vein. Each portal triad is composed of hepatic artery, portal vein, and biliary duct. Note the distribution of the left portal triad in the umbilical fissure; major branches recurve to the quadrate lobe medially, and two major branches pursue a lateral course to segments II and III of the left lobe.

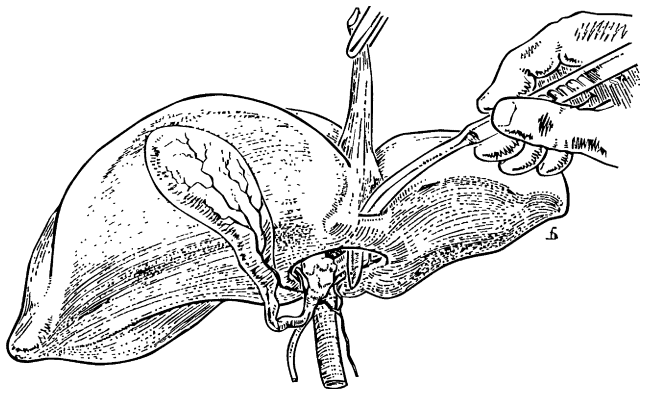

FIGURE 29.3. The bridge of liver tissue frequently present between the base of the quadrate lobe (segment IV) and the left lobe of the liver can be divided. This is conveniently done by passing a curved director beneath it and cutting it with diathermy. Such division can be useful in aiding an approach to the left hepatic duct, particularly if the course of the duct is vertical and the base of the quadrate lobe is short. If the bridge of tissue is present, the maneuver is always necessary to allow dissection of the segment III duct (see Fig. 29.8).

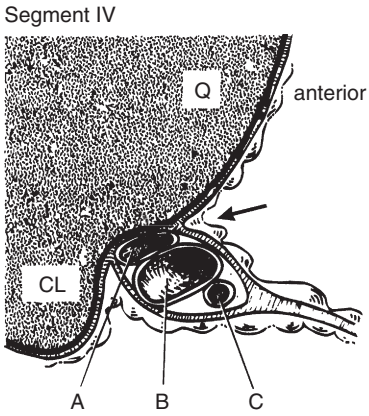

FIGURE 29.2. Sagittal section showing the relationship of the quadrate (*Q*) and caudate lobe (*CL*) to the left portal triad, which is encased within a reflection of the lesser omentum that fuses with the Glisson capsule at the base of the quadrate lobe. The *arrow* indicates the point of incision for the dissection to lower the hilar plate (see also Fig. 29.5). *A,* Left hepatic duct. *B,* Left branch, portal vein. Note the left hepatic artery (*C*) joins the left duct and left branch of the portal vein at the umbilical fissure.

insertion of the cystic duct can result in unintended injury to this structure (Fig. 29.5). Placement of the incision in an anterior location minimizes the risk of injury to the periductal vasculature, which typically runs along the medial and lateral aspects of the common hepatic and common bile ducts. The length of the choledochotomy is dictated by the diameter of the duct and the size of the stones present within its lumen, but length typically ranges between 1 to 2 cm.

A number of options exist for bile duct exploration, and these are discussed in further detail in Chapters 34 and 35;

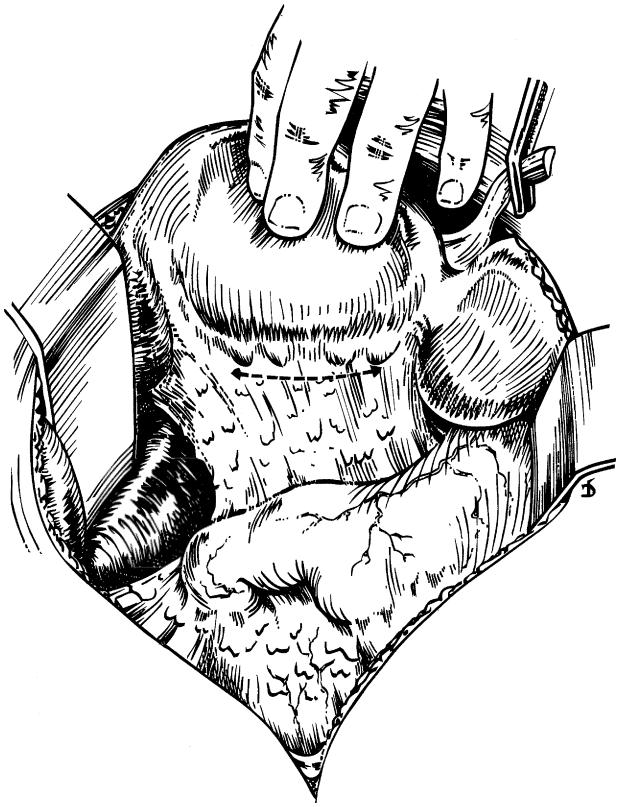

FIGURE 29.4. The initial line of incision for an approach to the left hepatic duct by lowering of the hilar plate. The liver is elevated, and the quadrate lobe is retracted upward. The incision is made at precisely the point at which the Glisson capsule reflects to the lesser omentum (see Fig. 29.2).

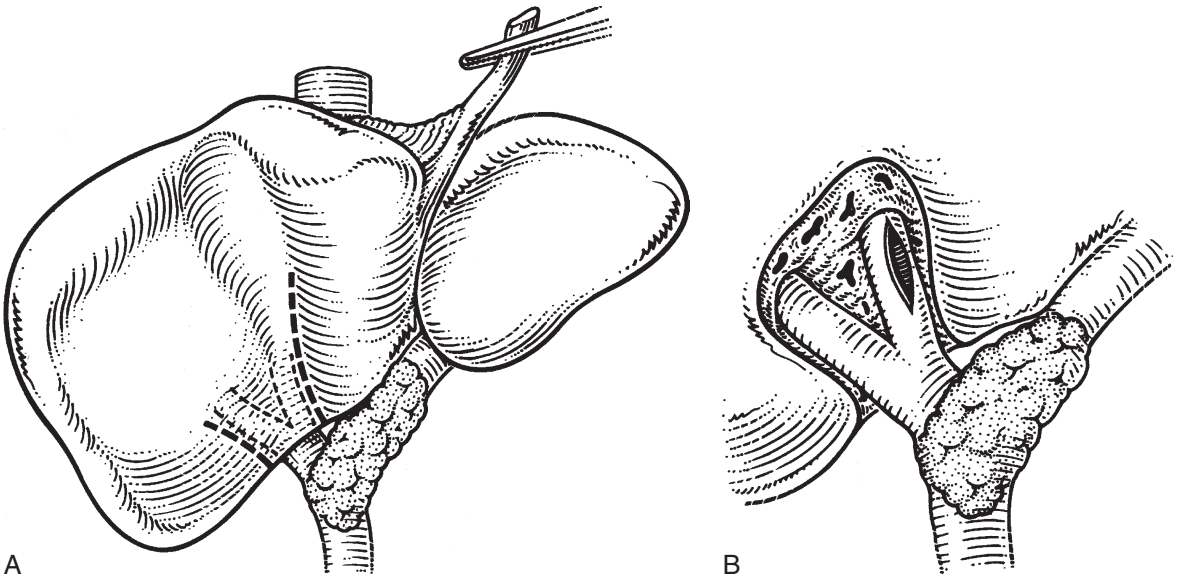

FIGURE 29.5. **A,** Exposure of the right hepatic pedicle. The liver is opened as indicated, and liver tissue is cleared over a small distance. **B,** The relevant duct, usually the anterior sectoral duct, is opened, and anastomosis is carried out.

regardless of the method used, care must be taken to be as atraumatic as possible (Orloff, 1978). Iatrogenic injury to the duct mucosa can result in delayed stricture formation, and inaccurate delivery of rigid instrumentation can create false passages into the duodenum or pancreas. Fiberoptic choledochoscopy permits excellent visualization when saline is infused at a low rate through the endoscope. This is particularly effective for exploring the smaller intrahepatic radicles of the proximal biliary system.

T-Tubes (See Chapter 35)

Following bile duct exploration, the choledochotomy is typically closed over a T-tube. One advantage of T-tube insertion is the ability to ensure adequate decompression of the biliary tree, particularly after manipulation of the papilla. Postprocedural edema or spasm resulting in biliary outflow obstruction can result in bile leakage from the choledochotomy closure site. Another advantage is the ability to directly access the biliary system postoperatively through the T-tube for detection and treatment of retained stones. A 14-Fr or larger T-tube should be used if the size of the common bile duct permits, as this will allow for subsequent cholangiography or choledochoscopy through the T-tube.

Postoperatively, the T-tube is placed to dependent drainage. The volume of drainage should decline as postoperative edema resolves and normal biliary drainage into the duodenum is restored. If high outputs persist through the T-tube, or if bile drainage around the T-tube into the closed suction drain is seen, T-tube cholangiography should be undertaken to evaluate for tube malfunction, dislodgment, or distal obstruction from a retained stone. If no problems are encountered, tube removal can be performed at the bedside as early as 1 week postoperatively, if T-tube cholangiography is normal. If retained gallstones are found, the T-tube can be clamped, with instructions to open the T-tube in the event of fevers, jaundice, or pain, and repeat cholangiography is obtained in 1 month; if choledocholithiasis persists, stone extraction may be undertaken either percutaneously through the T-tube or via endoscopic papillotomy.

Transduodenal Exploration

In unusual cases in which gallstones are impacted at or near the ampulla of Vater, or in patients whose surgically altered anatomy makes endoscopic techniques difficult (e.g., after Roux-en-Y gastrojejunostomy), transduodenal exploration may be warranted. Transduodenal access to the distal biliary system requires operative sphincterotomy, which in turn requires operative sphincteroplasty to avoid postoperative papillary stenosis. Chapter 62C discusses transduodenal resections for neoplastic disease, the details of which are not dissimilar to the approach used for calculous disease (see Chapter 35).

Outcomes After Bile Duct Exploration

Advances in endoscopic and percutaneous approaches have vastly limited the indications for operative bile duct exploration. Nevertheless, it is important to recognize that historical analyses have largely substantiated the safety and efficacy of operative bile duct exploration. In a representative single-center North American series of 100 consecutive, open, supraduodenal common bile duct explorations, no operative mortalities were encountered, and the overall morbidity rate was 15.7%, including a 5.3% rate of retained common duct stones (Pappas et al, 1990). Similar observations have been reported in retrospective analyses of transduodenal sphincteroplasties and common bile duct explorations (Kibria & Hall, 2002; Morgan et al, 2008; Sellner et al, 1988), highlighting low rates of morbidity and recurrent choledocholithiasis.

BILIARY-ENTERIC ANASTOMOSIS

Overview

The operative conduct of the biliary-enteric anastomosis centers around three technical steps: 1) identification of healthy bile duct mucosa proximal to the site of obstruction; 2) preparation of a segment of alimentary tract, most often a Roux-en-Y jejunal limb; and 3) construction of a direct mucosa-to-mucosa anastomosis between these two.

For this reason, preoperative planning must incorporate comprehensive radiographic evaluation of the relevant biliary anatomy; these strategies and techniques are addressed in Chapters 13, 16, 17, and 18. In some cases, preoperative insertion of percutaneous transhepatic biliary stents may facilitate intraoperative identification of the right or left hepatic ducts. However, it is important to recognize that stent insertion is associated with a risk of procedural complications and inevitably results in bacterial contamination of the biliary tree that can lead to cholangitis and periductal inflammatory changes that may delay or hinder operative intervention. Because of these risks, and because the hepatic ducts can be identified without stents at the time of operative exploration, we have not routinely used preoperative biliary stents. When undertaken, caution must be exercised to avoid attempted percutaneous drainage if it is unlikely that the stent can be placed across the obstructing lesion. Insertion of a percutaneous drain into an excluded biliary segment will result in bacterial colonization of static bile; if that hepatic segment cannot be decompressed by a subsequent operative intervention, it will not be possible to remove that external drain without risking refractory cholangitis.

Options for biliary-enteric anastomosis include hepaticojejunostomy, choledochojejunostomy, choledochoduodenostomy, cholecystojejunostomy, and cholecystoduodenostomy. Selection of the proper anastomosis is dictated by the indication for biliary decompression and the anatomic location of the biliary obstruction. The indications for and operative conduct of these surgical options are detailed below.

Incision and Exposure

A right subcostal incision with or without an upper midline extension or left subcostal extension provides adequate exposure for construction of the biliary-enteric anastomosis. Use of retractors capable of upward elevation and cephalad retraction of the costal edges are quite valuable for optimizing visual exposure of the relevant hilar anatomy. Division of the ligamentum teres and mobilization of the falciform ligament off the anterior surface of the liver also facilitate operative exposure; anterocephalad retraction of the ligamentum teres and division of the bridge of tissue overlying the umbilical fissure are critical for optimal visualization of the vascular inflow and biliary drainage of segments II, III, and IV (see Fig. 29.3).

If direct surgical decompression of the gallbladder is not to be undertaken, cholecystectomy will also facilitate access to the extrahepatic biliary system by exposing the cystic duct, which can be followed to its origin off the common hepatic duct or right hepatic duct. Cholecystectomy also exposes the cystic plate, which runs in continuity with the hilar plate. Lowering of the hilar plate permits exposure of the left hepatic duct as it courses along the base of segment IVb. In cases of unilateral hepatic atrophy as a result of long-standing biliary obstruction or preoperative portal vein embolization, it is critical to understand that the normal anatomic relationships of the portal structures are altered. In the more common circumstance of right-sided atrophy, the portal and hilar structures are rotated posteriorly and to the right; as a result, the portal vein, which is typically most posterior, is often encountered first; meticulous dissection is necessary to identify the common bile duct and hepatic duct deep within the porta hepatis (Pottakkat et al, 2009).

Hepaticojejunostomy

Approach to the Right Hepatic Duct

A plane of dissection between the Glisson capsule along the base of segment IVb and the peritoneal reflection enveloping the porta hepatis is developed, effectively lowering the hilar plate. In this way, the confluence of the right and left hepatic ducts may be exposed (see Fig. 29.4). If the extrahepatic course of the right hepatic duct is too short to be visualized in this way, as is often the case, the intrahepatic right portal pedicle may be exposed through hepatotomies created along the base of the gallbladder fossa and the caudate process (see Chapter 90A; Launois & Jamieson, 1992). The right portal pedicle may be encircled and delivered, and further mobilization can permit delivery of the right anterior and posterior sectional ducts (see Fig. 29.5).

Approach to the Left Hepatic Duct

The ligamentum teres is ligated with a firm tie and divided to permit anterocephalad retraction; this enhances exposure of the undersurface of the left hemiliver (see Fig. 29.3). The left hepatic duct runs with the left portal vein within a peritoneal reflection along the undersurface of the left hemiliver and is best approached by lowering the hilar plate (Fig. 29.6; Blumgart & Kelley, 1984). This dissection is greatly facilitated by placing a curved or malleable retractor to elevate and retract segment IVb in an anterocephalad direction.

Approach to the Segment III Hepatic Duct

On occasion, the presence of bulky, irresectable tumor along the hepatic hilus may make operative exposure in that region impermissible. In this circumstance, access to the left hepatic duct upstream of the point of obstruction may provide a means of adequately draining the obstructed liver. This can be achieved by exposing the left hepatic duct within the umbilical fissure (Bismuth & Corlette, 1975; Voyles et al, 1983). If the left hemiliver has not atrophied from long-standing biliary obstruction, unilateral left-sided biliary drainage will effectively relieve obstructive jaundice and restore adequate hepatic function, even when the biliary drainage of the excluded right hemiliver remains completely obstructed (Baer et al, 1994). As before, the ligated falciform ligament is elevated, and the bridge of hepatic tissue overlying the umbilical fissure (if present) is divided to optimize exposure of the segment III duct. This can be facilitated by dividing the liver tissue along the left of the ligamentum teres, through which the segment III duct may be exposed and opened without fear of injury to the vascular inflow to segment III (Fig. 29.7). On occasion, a wedge resection of a portion of segment III can also be performed to provide exposure of the segment III duct (Fig. 29.8).

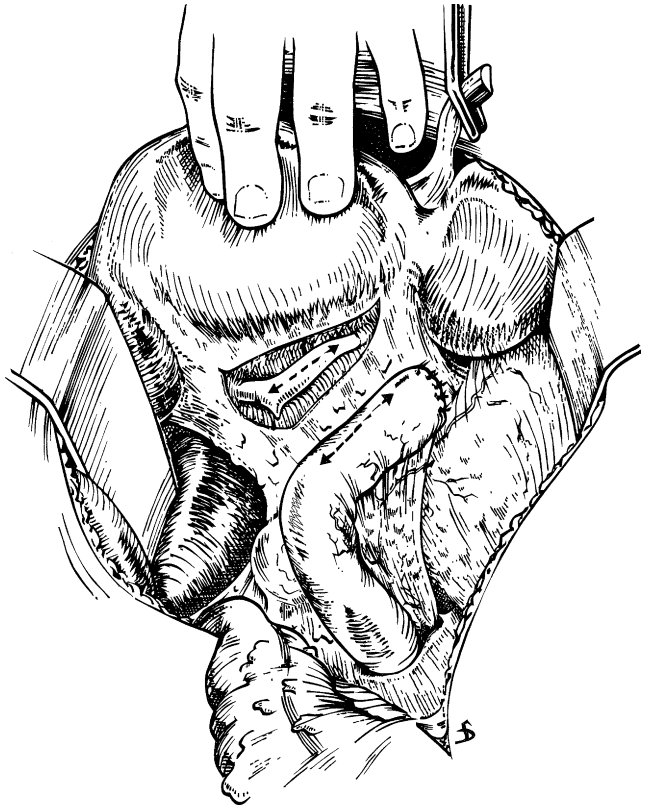

FIGURE 29.6. The hilar plate is lowered, and the left hepatic duct is exposed for dissection. The exposure is carried medially and to the right to expose the confluence and the right hepatic duct.

Anastomotic Technique

We have used a standardized technique for hepaticojejunostomy that can be applied for nearly all circumstances of proximal biliary drainage. This technique is of particular utility for difficult high anastomoses, where duct mobility and size are limited. A 70-cm Roux-en-Y limb of jejunum is prepared and delivered through a transverse mesocolonic defect fashioned to the right of the middle colic vessels. A small jejunotomy, whose diameter is slightly smaller than that of the duct, is cut at the site of planned anastomosis. We do not typically use transanastomotic stents, but if a stent is to be used, it is preferable to pass it through the cut hepatic duct prior to construction of the anastomosis. The stent is affixed against the duct wall with a single 4-0 or 5-0 absorbable catgut suture, which is tied on the outside of the duct wall (Fig. 29.9); this maneuver helps to avoid inadvertent dislodgment of the tube during placement of the anastomotic sutures.

When more than one biliary duct orifice is present, every effort should be made to approximate them with a row of 4-0 or 5-0 absorbable sutures so that they may be treated as a single duct for anastomotic purposes (Fig. 29.10). Anastomotic construction begins with an anterior row of 4-0 or 5-0 absorbable sutures placed along the hepatic duct only, working from left to right. In cases where the duct orifice is small, interrupted sutures should be used. The needles are left on the sutures, which are then retracted in a cephalad direction so as to enhance exposure of the posterior duct wall. A posterior row of full-thickness sutures securing the duct mucosa to the jejunal mucosa is then placed, again working from left to right. Once this row is completed, the sutures are pulled to bring the duct and jejunum into close apposition. The anterior sutures are again retracted to facilitate exposure of the posterior wall of the anastomosis, the posterior sutures are tied, and all but the right and left corner stay sutures are cut. The anterior row of the anastomosis is then completed by suturing the remaining needles to the jejunum, working from right to left. These sutures are left untied so as to maximize exposure of the duct lumen; once this row is completed, the sutures are tied to complete the anastomosis (Fig. 29.11).

In cases where the duct orifice is large, we use a simpler and faster alternative anastomotic technique commonly used for choledochojejunostomy; it is described in detail below.

Choledochojejunostomy

Approach to the Extrahepatic Biliary System

Drainage of the common hepatic duct or common bile duct is typically undertaken after exploration of the extrahepatic biliary system for calculous disease or for biliary decompression in cases of periampullary obstruction. These procedures are only rarely performed in isolation, as they have been largely replaced by endoscopic and percutaneous approaches. An important exception can be found in circumstances where effective biliary decompression must be durable, as might be seen in young patients with benign or indolent etiologies for jaundice. It is quite likely that operative bypass of the extrahepatic biliary system may provide favorable long-term outcomes without the need for repeat stent replacements or revisions that are often eventually required after nonoperative biliary decompressive maneuvers.

Anastomotic Technique

The hepaticojejunostomy or choledochojejunostomy can be performed in an end-to-side or a side-to-side manner. When undertaken in an end-to-side manner, a cholecystectomy is performed, and the common hepatic duct or common bile duct is encircled at the point of planned transection. The duct is sharply transected, the endobiliary stent (if present) is removed, and a specimen of bile may be aspirated for microbiologic analysis. The distal aspect of the duct is oversewn with 3-0 absorbable suture, and a 70-cm Roux-en-Y limb of jejunum is prepared for construction of the biliary-enteric anastomosis to the proximal aspect of the duct. The posterior wall of the duct is sutured against the jejunum with a running row of 3-0 or 4-0 absorbable sutures. A corresponding jejunotomy is fashioned just opposite the duct, and a series of interrupted 3-0 or 4-0 absorbable sutures are used to approximate the exposed mucosa along the posterior wall of the jejunotomy against the posterior wall of the duct. The anterior row of the anastomosis is then completed with the running sutures used to construct the posterior row (Fig. 29.12). We use a single row of sutures; placement of a second layer merely introduces the risk of excessively narrowing the lumen of the anastomosis. Of course, care must be taken to ensure that the sutures are secured tightly and placed at close intervals so as to avoid bile leakage. Placement of a sponge circumferentially around the completed anastomosis provides an intraoperative opportunity to ensure the absence of a significant leak.

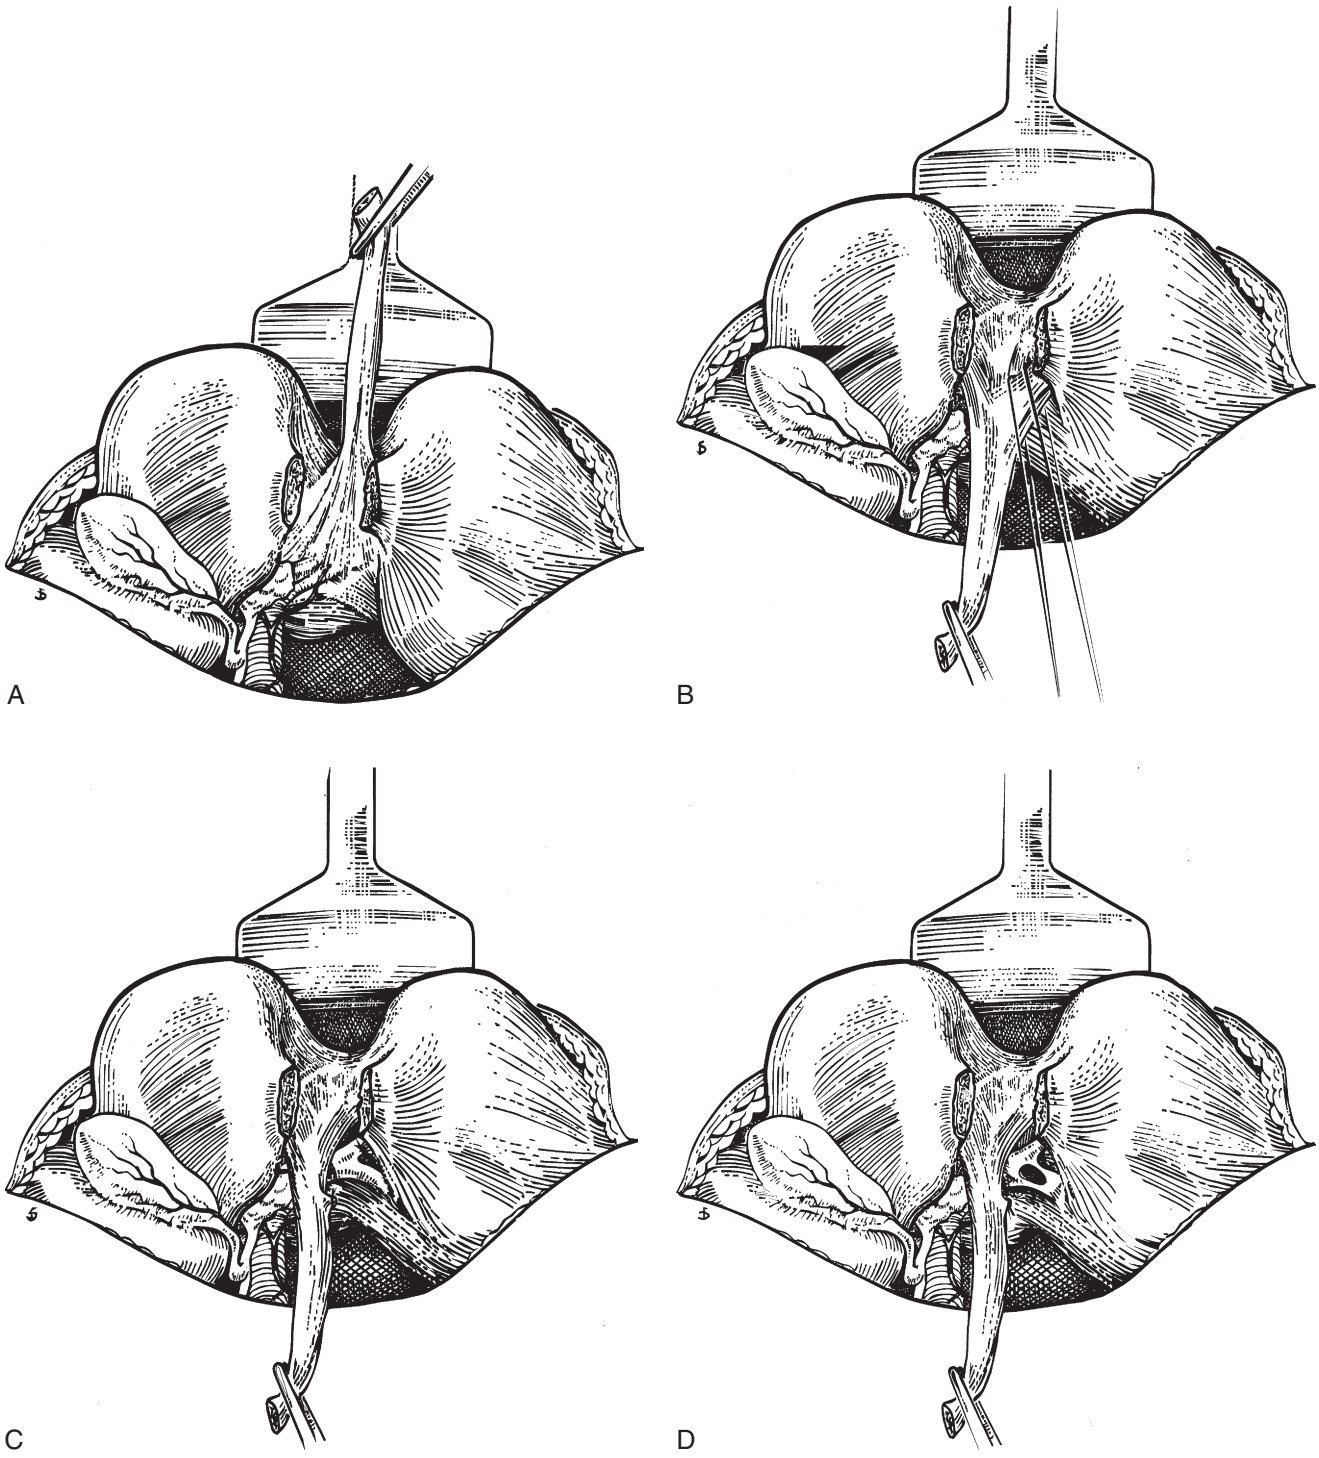

FIGURE 29.7. **A,** The liver is held up so that its inferior surface is seen. The bridge of liver between the quadrate lobe and the left lobe of the liver has been divided. The base of the ligamentum teres is seen. **B,** The ligamentum teres is then pulled downward. The peritoneum of its upper surface on the left side is incised, and the extensions passing into the liver are exposed. The left sides of these extensions are divided between ligatures, which must be passed carefully using aneurysm needles. This part of the dissection is tedious and should be carried out meticulously because hemorrhage within the recess adjacent to the segment III duct can be difficult to control. **C,** The segment III duct is exposed. **D,** The duct is opened longitudinally for anastomosis, which is carried out by the technique illustrated in Fig. 29.13.

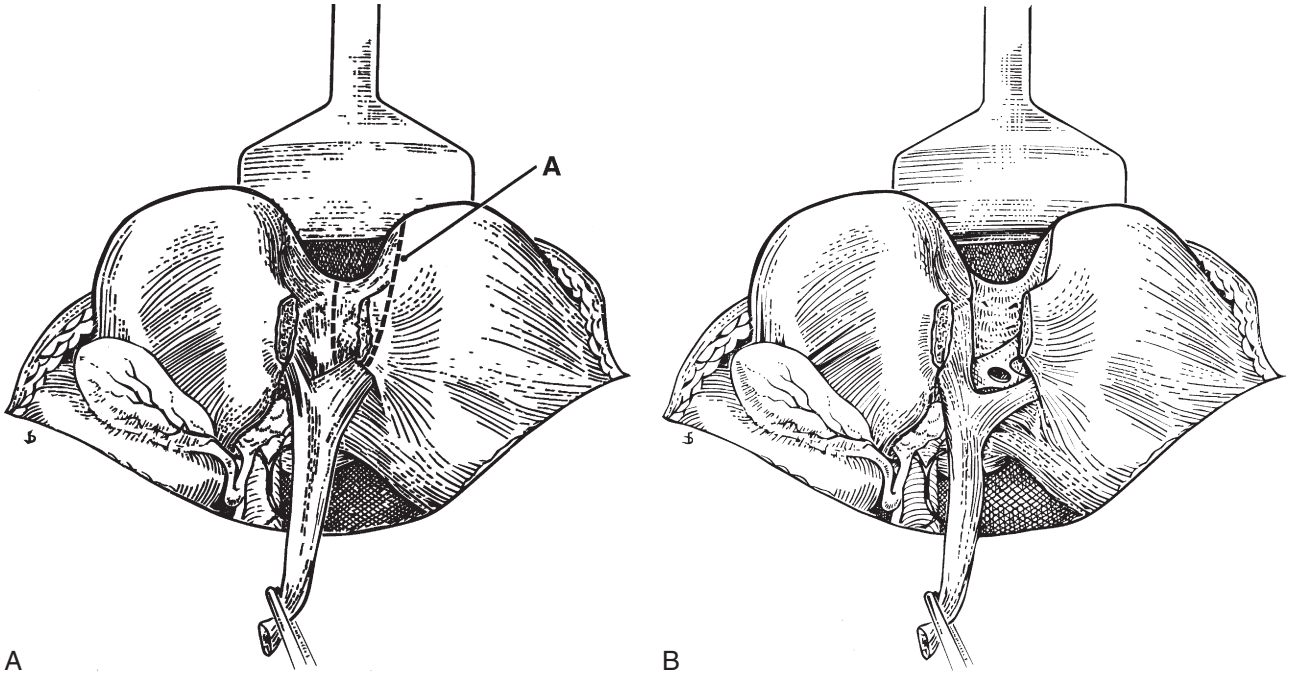

FIGURE 29.8. **A,** The liver is split to the left of the ligamentum teres in the umbilical fissure, and it may be necessary to remove a small wedge of liver tissue. **B,** The segment III duct is exposed at the base of the liver split above and behind its accompanying vein and is ready for anastomosis.

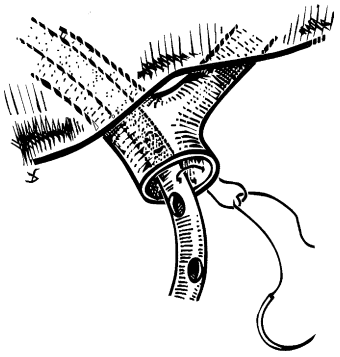

FIGURE 29.9. Manner of fixation of transanastomotic tubes. Note the introduction of the absorbable suture in a mattress fashion across the ductal wall proximal to the future site of anastomosis. This secures the tube conveniently during anastomosis.

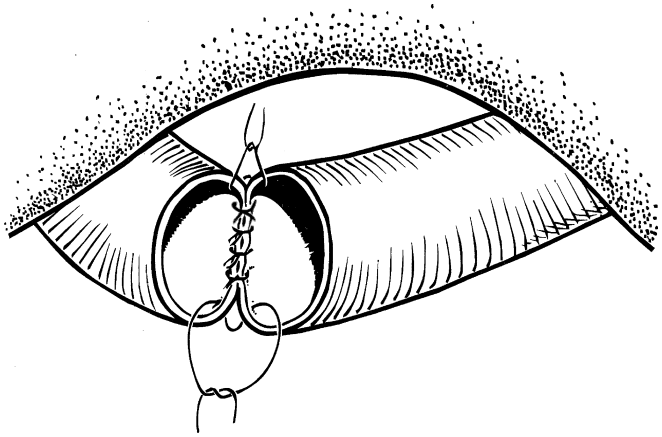

FIGURE 29.10. Adjacent ductal orifices may be approximated before anastomosis.

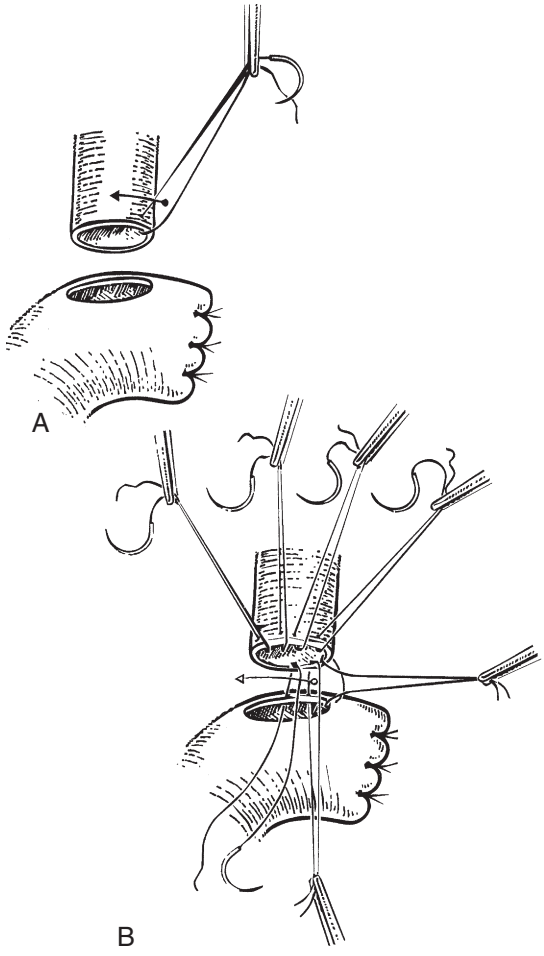

FIGURE 29.11. **A,** The initial step in the creation of hepaticojejunostomy Roux-en-Y. The anterior layer of suture (3-0 Vicryl) on the bile duct is inserted first, and the sutures are passed from the inside out, starting from the patient's left and working toward the right. The needles are retained, and the sutures are kept in order. **B,** The anterior layer of sutures is elevated. This displays the posterior ductal wall, and the posterior row of sutures is now placed, again from left to right.

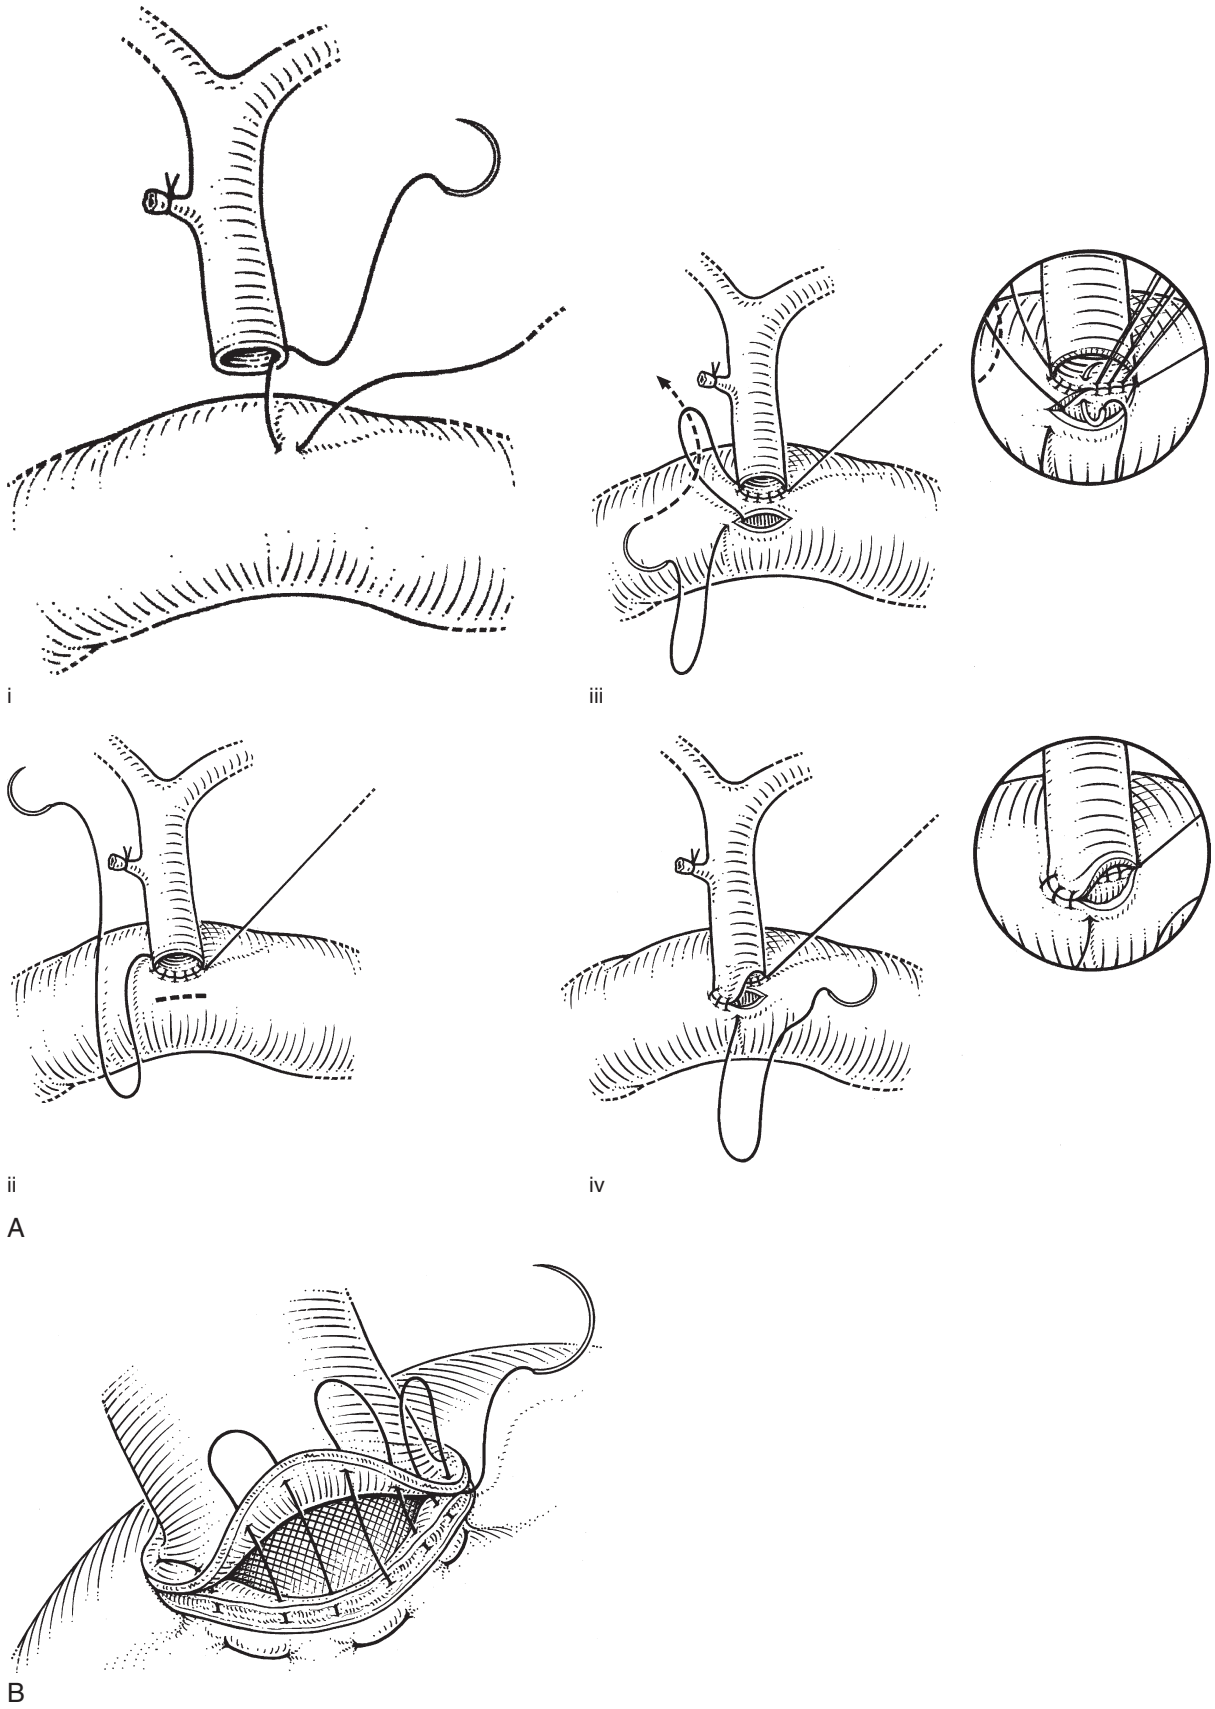

FIGURE 29.12. **A,** Technique for end-to-side anastomosis of the bile duct below the hilus to jejunum. *i,* A 3-0 Vicryl suture is used, and the serosa of the jejunum is sutured to the full thickness of the bile duct. *ii,* This suture is developed as the posterior wall of the bile duct is attached to the jejunal serosa. The *dotted line* marks the point of incision in the jejunum, which is made after the posterior layer is attached. *iii,* The suture is now developed either as a continuous or an interrupted suture on the anterior layer. The posterior layer of the jejunal mucosa is not sutured directly to the bile duct mucosa. Several interrupted sutures may be inserted before completing the anterior layer, however, to approximate the mucosa (*inset*). *iv,* The anastomosis is completed. The *inset* shows the posterior layer with mucosal apposition. **B,** Alternatively, the jejunum may be opened, and a mucosa-to-mucosa anastomosis may be performed with a continuous polydioxanone suture as illustrated.

Alternatively, the side-to-side anastomosis is initiated by placing stay sutures of 4-0 absorbable suture along either side of the planned longitudinal ductotomy, which is fashioned sharply. The biliary-enteric anastomosis is then constructed to a Roux-en-Y jejunal limb using a technique similar to that used for the choledochoduodenostomy (described below). Potential advantages of the side-to-side anastomosis include less devascularization of the untransected duct and the retention of biliary-duodenal continuity, in those circumstances in which future endoscopic retrograde cholangiographic procedures may be desirable (Winslow et al, 2009).

Choledochoduodenostomy

The choledochoduodenostomy can also be a useful operative maneuver when a distal periampullary stricture is present. It is most commonly performed after common bile duct exploration for calculous disease; in this way, a supraduodenal choledochotomy may be anastomosed to a duodenotomy instead of to an external T-tube. In this procedure, a longitudinal choledochotomy is made, through which the extrahepatic biliary system may be explored. For optimal anastomosis, the duct opening should measure at least 2.5 cm in length; this will typically require extension onto the common hepatic duct. A generous Kocher maneuver is performed to permit easy mobility of the duodenum, and a longitudinally oriented duodenotomy is made along the superior aspect of the postbulbar duodenum. Because of the flexibility of the duodenal wall, the duodenotomy may be considerably shorter in length than the ductotomy (Fig. 29.13). Three corner 4-0 or 5-0 absorbable sutures are placed between the ends of the duodenotomy and the midpoints of the ductotomy and between the distal end of the ductotomy and the midpoint of the posterior aspect of the duodenotomy. Retraction of these sutures reorients the distal portion of the ductotomy transversely, which facilitates placement of the posterior row of sutures. The fourth corner suture is then placed between the proximal end of the ductotomy and the midpoint of the anterior aspect of the duodenotomy. Retraction of this suture tents the remaining anterior wall of the anastomosis forward, which facilitates placement of the anterior row of sutures (Fig. 29.14). As with the hepaticojejunostomy and choledochojejunostomy, a single row of sutures is used.

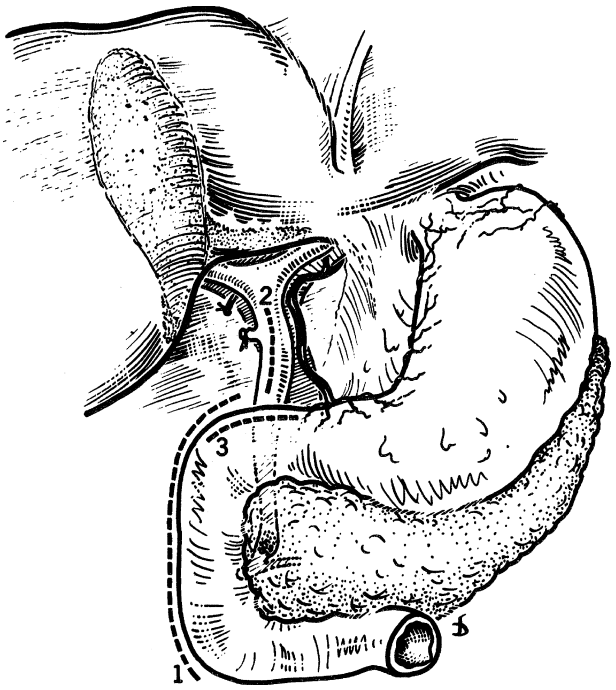

FIGURE 29.13. After the gallbladder is removed, the common bile duct is removed through a conventional longitudinal incision following a Kocher incision *(1)* freeing the lateral duodenum around the common duct. Routine common duct exploration is carried out. If indications for a choledochoduodenostomy exist, the anastomosis is performed. The incision in the common duct *(2)* is extended to 2.5 cm by direct measurement. In almost all instances, the incision in the duct carries into the common hepatic duct. The incision in the postbulbar duodenum *(3)* is slightly smaller because the stoma in the duodenum stretches to approximate the choledochal incision.

Cholecystoduodenostomy and Choledochojejunostomy

An alternative approach to cases of distal biliary obstruction is direct drainage of the gallbladder. High rates of patency failure have been documented, particularly with cholecystoduodenostomy; as a result, we typically do not use this procedure except when advanced malignancy mandates the use of a simple operative intervention (Dayton et al, 1980). Cholecystoenterostomy for palliative biliary decompression is particularly suitable where major tumoral obstruction obscures access to the porta hepatis. Prior to undertaking cholecystoenterostomy, it is imperative to confirm that the extrahepatic biliary obstruction does not extend to the level of the cystic duct insertion. In addition, the presence of significant stone burden within the gallbladder makes this operative strategy less attractive.

The gallbladder is almost invariably distended in patients who are appropriate candidates for cholecystoenterostomy. The gallbladder and cystic duct are carefully evaluated to confirm that the cystic duct does not insert distally into the common bile duct at the level of tumoral obstruction. If cholecystoduodenostomy is undertaken, a generous Kocher maneuver is performed to permit sufficient mobility of the duodenum. If cholecystojejunostomy is planned, a loop of jejunum is utilized; we do not routinely use construction of a Roux-en-Y jejunal limb for this purpose. The gallbladder fundus is secured to the small bowel with a row of 3-0 sutures, a longitudinal cholecystotomy is fashioned, and bile is aspirated. Any stones present in the lumen of the gallbladder are evacuated, and a bile specimen may be sent for microbiologic analysis. Decompression of the common hepatic duct is confirmed, and a corresponding longitudinal enterotomy is fashioned opposite the cholecystotomy. An anterior row of sutures is then placed to complete the anastomosis (Fig. 29.15).

Outcomes after Biliary-Enteric Anastomosis

Longitudinal analyses of outcomes after biliary-enteric anastomosis for benign and malignant diseases confirms the safety and efficacy of the operative approaches outlined in this section (Chapman et al, 1995; Jarnagin et al, 1998; Moraca et al, 2002; Tocchi et al, 1996). Comparative analyses of effectiveness of the various surgical options are limited, but short-term

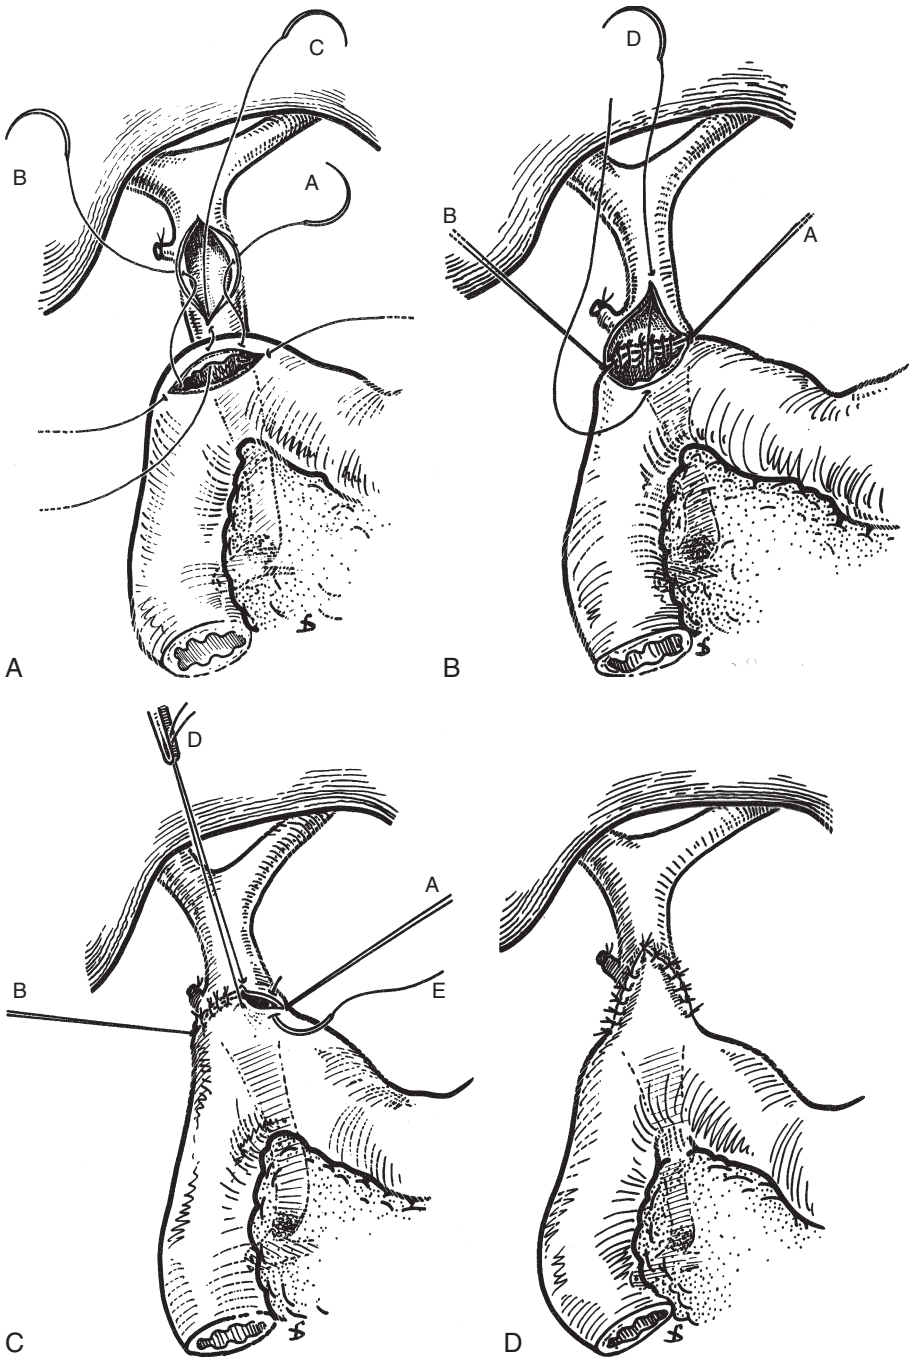

FIGURE 29.14. A, Each side of the choledochoduodenostomy is bisected by suture (*A* and *B*) of absorbable material (chromic catgut or polyglycolic acid) that passes from the end of the duodenal incision through the midpoint of the choledochal incision. Likewise, the duodenal incision is bisected by a suture through the posterior wall of the duodenal incision and the lower apex of the choledochal incision *(C)*. These stitches convert part of the longitudinal choledochotomy incision into a transverse ostium. The lax approximation of the duodenal and choledochal incisions occurs, with the duodenum mobilized, by placing tension on a lateral stay suture (*A* or *B*) and the middle stay suture *(C)*. **B,** Sutures may be placed to complete the posterior suture line approximating the common bile duct to the posterior duodenal incision. After placement of the sutures, they are tied so that the knots are within the lumen. The anterior wall is similarly approximated using a suture bisecting the anterior duodenal incision *(D)* and through the original apex of the bile duct incision. **C,** With this bisecting suture *(D)* tented forward, each of the segments between the tied lateral stay suture and this anterior suture is similarly approximated using interrupted sutures with the knots tied on the outside. The anastomosis is completed by completing the third segment of this triangle with sutures placed between the remaining lateral stay suture and the bisecting, anterior suture *(D)*. It is important in the placement of these last sutures that they do not catch the posterior suture line. The benefit of placing all the sutures in one line of the triangular closure and tying them all after placement is that it allows an internal inspection before the lumen of the choledochoduodenostomy is obscured. A single row of sutures is all that is used. A second row does nothing but decrease the choledochoduodenostomy orifice size and should be avoided. The sutures should be placed close enough for a bile-tight approximation. Digital pressure on the duodenum or the common duct should give no evidence of leakage. **D,** The completed anastomosis allows a thumb-sized defect to be palpated through the duodenal tongue that has been brought on to the common bile duct and common hepatic duct. The anastamosis may be drained or not, according to preference (the leak rate is 1%). The presence of a closed-suction drain (Jackson-Pratt type) obviates the need for a subsequent percutaneous drainage catheter if this uncommon complication occurs.

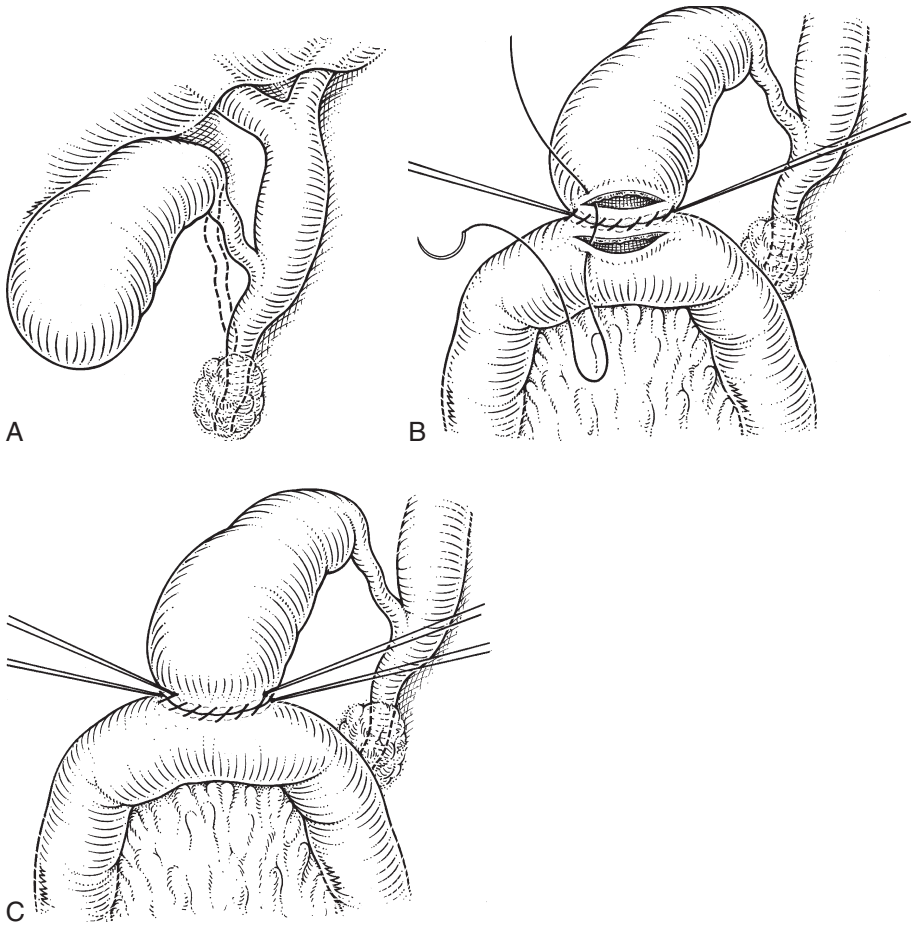

FIGURE 29.15. Technique of cholecystojejunostomy. **A,** The cystic duct should join the common bile duct above the tumor. If it enters at the level of the tumor (*dashed line*), the procedure is contraindicated. **B,** The posterior layer of the anastomosis is performed with a running suture between the openings at the fundus of the gallbladder and the jejunum. **C,** The anterior layer of the side-to-side anastomosis is completed. (We do not use an associated enteroenterostomy.)

perioperative morbidity and long-term patency appear favorable after segment III bypass when compared with bypasses to the right sectoral ducts. Of note is a measurable incidence of cholangiocarcinoma after biliary-enteric anastomosis; long-term follow-up of 1003 patients who underwent biliary bypass for benign disease identified 55 cases (5.5%) of primary bile duct cancer after intervals of 132 to 218 months (Tocchi et al, 2001).

PART 5: Biliary Tract Disease

SECTION I
Inflammatory, Infective, and Congenital

A. Gallstones and Gallbladder

CHAPTER 30

Natural history of gallstones and asymptomatic gallstones

Pierre F. Saldinger and Andrei Cocieru

HISTORY

Gallstones have been recognized since antiquity and have even been found during autopsies of Egyptian mummies. The Greek physician Trallianus described calculi within radicles of a human liver (Glenn & Grafe, 1966). Vesalius and Fallopius described gallstones in the gallbladders of dissected human bodies (Schwartz, 1981), and in 1882, Langenbuch performed the first successful cholecystectomy, setting the path for therapeutic intervention in cholelithiasis.

EPIDEMIOLOGY

Gallstones represent a sizeable problem for the contemporary health care system in both developed and developing countries alike. In the year 2000, there were 2,624,111 admissions and 778,632 outpatient visits for gallstones in the United States. With 6.3 million affected men and 14.2 million affected women between the ages of 20 and 74 years, and at an annual cost of $6.5 billion, cholelithiasis is the most expensive digestive tract disorder today in the United States (Shaffer, 2006). Incidence of gallstones and gallstone-related operations in developed countries appears to be increasing. With an overall prevalence of 10% to 15% in developed countries, geographic-specific prevalence is from 0% to 10% in Africa and up to 60% to 70% in certain populations, such as Pima Indians; this likely reflects combined differences in environmental, dietary, and genetic factors (Shaffer, 2006). The most common type of gallstones in developed countries are composed primarily of cholesterol, and the highest incidence is in the Native American population; moderate prevalence is seen in Hispanics, and the lowest prevalence is seen in black Americans, East Asians, and sub-Saharan Africans. Increased incidence of brown-pigmented stones are noted in East Asians, reflecting a higher rate of biliary tract infections (Shaffer, 2006; see Chapter 43). More detailed information about geographic disparities in the prevalence of gallstone disease can be found in Table 30.1.

Risk Factors for Gallstones Development

Gallstone disease clearly results from a complex interaction of genetic and environmental factors. This is confirmed by an altered incidence of gallstone detection when people from diverse geographical areas travel and settle in areas with a different dietary regimen, level of physical activity, and hygiene. The common mechanisms of gallstone formation include cholesterol hypersecretion, alteration in intestinal bile salt/cholesterol absorption, and gallbladder hypokinesia, which leads to bile cholesterol supersaturation and nucleation (see Chapter 7). Bacterial infection and an increase in bilirubin load play a role in the development of black and brown gallstones. The following is a quick overview of the most common risk factors for the development of gallstones.

Age

The incidence of gallstones increases with age across all ethnic groups, and it is very low among infants and children (Chen et al, 1998). Some specific populations such as Pima Indians,

Table 30.1

Geographic Prevalence of Gallstones as Assessed by Ultrasound

Study	Geographic Area	Male Population (%)	Female Population (%)
Everhart et al, 1999, 2002	North America	5.3-29.5	13.9-64.1
Miguel et al, 1998; Covarrubias et al, 1995; Moro et al, 2000	South America	8.3-14.5	10.0-49.4
Palasciano et al, 1989; Glambek et al, 1987; Misciagna et al, 1994; Mellström et al, 1988	Europe	0-37	4.8-50.5
Khuroo et al, 1989; Chen et al, 1998; Lu et al, 1990	Asia	0-10.7	4.6-29.1
Walker et al, 1989; Bagi Abdel, 1991	Africa	0-5.6	5.1-10

mentioned previously, have an increased incidence of gallstones (up to 70%) by 30 years of age, implicating hereditary metabolic factors (Sampliner et al, 1970). Pediatric populations with chronic hemolytic conditions, such as sickle cell anemia, also represent another distinct group in whom gallstones develop early.

Gender

Female gender is a risk factor for developing gallstones, surpassing males in the incidence of gallstones and the chance of having surgery by 2:1 or 3:1 in most studies (see Table 30.1). Pregnancy is associated with up to a 30% risk of developing biliary sludge, and low-dose estrogen therapy in postmenopausal women increases the risk of gallstone formation (Maringhini, et al, 1993; Hulley et al, 1998).

Obesity, Diet, Physical Activity, and Weight Loss

Obesity is a well-established major risk factor for the development of gallstones. The association with simple obesity is important in females; in males it is mostly associated with intraabdominal (central) obesity and metabolic syndrome (Maclure et al, 1989; Heaton et al, 1991; De Santis et al, 1997; Tsai et al, 2004).

The frequency of gallstones has almost doubled in the last 60 years, in parallel with the changed composition of stones from pigment to cholesterol. In humans, most cholesterol found in gallstones is from the diet, since de novo hepatic synthesis is only about 20% (Paigen & Carey, 2002). This emphasizes the importance of high caloric and carbohydrate intake as risk factors for the development of gallstones in modern society.

Bariatric patients are at a high risk for the development of cholelithiasis after weight-reduction surgery. Sludge and gallstones form in up to 35% of patients following bariatric procedures, with weight loss more than 1.5 kg/week being a risk factor (Shiffman, et al, 1991; Weinsier et al, 1995).

Patients receiving total parenteral nutrition (TPN) are another group with a high incidence of gallstone and sludge development. After 3 months of TPN therapy, approximately 45% of patients will develop gallstones; 100% of patients will develop sludge within 6 weeks (Shaffer, 2001; Murray et al, 1992). Low levels of physical activity are associated with development of gallstones in large observational and population studies also related to obesity and diet (Leitzmann et al, 1999). Finally, patients receiving long-term somatostatin analogue therapy for various disorders (acromegaly, functional neuroendocrine tumors) are at increased risk for gallstone formation as a result of reduced gallbladder motility and reduced bile flow (Bornschein et al, 2009).

Genetics

Population studies indicate a 30% genetic component in the development of gallstone disease. Hepatic cholesterol hypersecretion, resulting in bile supersaturation and cholesterol stone formation, may be caused by increased hepatic uptake and synthesis of cholesterol, decreased hepatic synthesis of bile salts, decreased hepatic synthesis of cholesterol esters for inclusion in very-low-density lipoprotein (VLDL), and derangements in the intestinal absorption of cholesterol and bile salts. Genes controlling hepatic cholesterol metabolism have been implicated in the pathogenesis of gallstone formation in transgenic/knockout mouse models and in humans (Table 30.2). Excess cholesterol load in smooth muscles of the gallbladder can affect signaling via the cholecystokinin A (CCK-A) receptor and contribute to the development of gallstones by inducing bile stasis. Intestinal cholesterol/bile salt absorption is tightly controlled and genes responsible for cholesterol absorption (*NPC1L1,* Niemann-Pick C1-like protein) or cholesterol efflux (*ABCG5*/*G8*) have been implicated in the development of gallstones in certain populations because of intestinal bile salt loss. Single-gene mutations result in hemolysis and increase the incidence of black stones because of an excess of unconjugated bile acids forming polymerized calcium bilirubinate stones. A summary of genes found to be involved in gallstone pathogenesis can be found in Table 30.2 (Grünhage & Lammert, 2006).

Other Risk Factors

Certain medical conditions and medications can cause gallstones by multiple mechanisms. Cirrhosis can induce decreased bile salt synthesis and bile salt malabsorption together with chronic hemolysis and a hyperestrogenic state. Inflammatory bowel disease (Crohn disease) or ileal resection can also interfere with bile salt absorption, estrogen can increase biliary cholesterol secretion, and progesterone can impair gallbladder motility. In addition to causing gallbladder hypomotility, octreotide increases the amount of reabsorbed deoxycholic acid and results in cholesterol supersaturation. Ceftriaxone is excreted in bile in significant amounts and can cause biliary pseudolithiasis and sludge, which usually disappears after antibiotic therapy is discontinued (Lambou-Gianoukos & Heller, 2008).

NATURAL HISTORY OF GALLSTONES

Gallstones do not cause any symptoms in up to 80% of carriers. Within 5 years, 10% to 20% became symptomatic. The risk of further symptoms is approximately 2% per year with an overall risk of biliary complications (acute pancreatitis and symptomatic choledocholithiasis) in asymptomatic patients of 0.3% per year; the risk of gallbladder cancer is 0.02% per year (Gibney, 1990; Thistle et al, 1984; Attili et al, 1995; Gracie & Ransohoff,

Table 30.2

Genes Involved in Gallstone Pathogenesis

Genes and Encoded Proteins	Mechanism	Significance in Humans
ABCB4, ATP binding cassette transporter B4	Decreased biliary phospholipid secretion	+
ABCB11, ATP binding cassette transporter B11	Decreased bile salts secretion	+
APOB, apolipoprotein B	Decreased hepatic VLDL secretion	+/?
APOE, apolipoprotein E	Increased intestinal cholesterol absorption, decreased bile acid secretion	+/?
CCKAR, cholecystokinin A receptor	Gallbladder hypomotility	?
CETP, cholesteryl ester transfer protein, plasma	Increased HDL metabolism	+
CFTR, cystic fibrosis transmembrane conductance regulator	Increased biliary bilirubin secretion and bile salt excretion in feces, decreased bile pH	+
ANK1, EPB42, SPTA1, SPTB, SLC4A1, associated with hereditary spherocytosis	Increased bilirubin load	+
HBB, hemoglobin-β, associated with sickle cell anemia and thalassemia	Increased bilirubin load	+
AK1, G6PD, GPI, GSR, PGK1, PKLR, associated with erythrocyte enzyme deficiencies	Increased bilirubin load	+
CYP39A1, oxysterol 7-alpha-hydroxylase	Induced hypercholesterolemia	+
UGT1A1, Gilbert syndrome–associated protein	Increased bilirubin load	+
NPC1L1, NPC1 (Niemann-Pick disease, type C1, gene)–like protein 1	Reduced cholesterol intestinal absorption	+
ABCG5/ABCG8, ATP binding cassette G5/G8, cholesterol transporter	Increased cholesterol intestinal efflux	?

ATP, adenosine triphosphate; HDL, high-density lipoprotein; VLDL, very-low-density lipoprotein; +, clear evidence; ?, potentially related but no definitive evidence

1982; Friedman, 1993; McSherry et al, 1985). Half of the patients with symptoms develop a second attack within a year, but in 30% of all cases, there is only one symptomatic attack. The analysis of the natural history of gallstones started with a landmark study by Gracie and Ransohoff (1982), which followed 123 Michigan University faculty members—110 men and 13 women—with asymptomatic gallstones at screening for 15 years. At 5, 10, and 15 years of follow-up, 10%, 15%, and 18% had become symptomatic, respectively. None of the subjects developed complications before the onset of typical symptoms. The approximate rate at which the subjects developed biliary pain was 2% per year for the first 5 years with a subsequent decrease over time. Three patients in this study developed biliary complications, all of which were preceded by biliary pain. The investigators concluded that, based on these results, prophylactic cholecystectomy for asymptomatic gallstones could not be recommended (Gracie & Ransohoff, 1982).

Attili and colleagues (1995) also followed 151 subjects with gallstones over 10 years. Of those subjects, 33 had symptoms, and 118 were asymptomatic at the beginning of the study. The cumulative probability of developing biliary colic was 12% at 2 years, 17% at 4 years, and 26% at 10 years. The cumulative probability of developing complications after 10 years was 3% in the initial asymptomatic group and 7% in the symptomatic group. The authors concluded that the natural history of gallstone disease might not be as benign as previously thought.

The results of several other natural history studies have been reported. In a Japanese study, Wada and Imamura (1993) found one third of 1850 patients with cholelithiasis to be symptomatic. Of the remaining 680 asymptomatic patients, 20% became symptomatic over a median follow-up of 13 years. Patients older than 70 years were more likely to become symptomatic than patients younger than 70 years. McSherry and colleagues (1985) followed 135 asymptomatic men and women with gallstones who were subscribers to the Health Insurance Plan of Greater New York. Of these subjects, 10% developed symptoms, and 7% required cholecystectomy over a median follow-up of 46 months. A placebo group of 193 asymptomatic patients who were part of a chemical dissolution trial were followed for 24 months (Thistle et al, 1984). In this study, 31% of patients eventually developed biliary pain, which is high but perhaps related to the intense surveillance or to the requirement that participants have no symptoms only for the 12 months preceding the trial. Cucchiaro and colleagues (1990) followed 125 asymptomatic patients for 5 years. Fifteen patients developed symptoms during that time, and 2 patients required emergent surgery for gallstone complications; 54 patients died during that period because of malignancies, cardiovascular disease, or renal insufficiency, but none died from gallstone disease. Friedman and coworkers (1989) followed 123 asymptomatic patients for 20 years and found that 6% of patients developed severe gallstone-related symptoms during the first 5 years after diagnosis. Halldestamm and colleagues (2004) followed 120 asymptomatic patients, 14 of whom required treatment for symptoms or gallstone-related complications over a median observation period of 87 months. The authors calculated that the cumulative risk of requiring treatment during the first 5 years after detection of gallstones was 7.6%. A summary of the natural history of gallstones as reported by various authors is shown in Table 30.3.

In a Marcov model, simulation investigators from the Netherlands attempted to predict the effect of cholecystectomy on adverse events during a 10-year period (Venneman et al, 2005). In this particular model, 3.2% of the small gallstone carriers developed acute cholecystitis, 1.8% developed symptomatic

Table 30.3

‡Symptoms or complications

choledocholithiasis, and up to 3.4% developed acute pancreatitis. There was no clear cost benefit and no life-years were gained from prophylactic cholecystectomy, indicating no clear-cut advantages of prophylactic cholecystectomy in asymptomatic cholelithiasis. As a result, in patients with asymptomatic gallstones, expectant management is recommended.

Patients with diabetes may have a higher incidence of gallstones from the indirect effects of the metabolic syndrome, obesity, and a family history of gallstones. No data show worse evolution of asymptomatic cholelithiasis in diabetics, and prophylactic cholecystectomy in asymptomatic gallstones carriers with diabetes is not recommended (Sleisenger & Fordtran, 1993).

The size of gallstones is thought to be linked to a higher risk for the development of gallbladder cancer, but this is controversial (see Chapter 49). Cholecystectomy is possibly indicated in some populations carrying a high risk of gallbladder cancer (Chilean Hispanics, Mapuche Indians, and Maoris from Easter Island), even when associated with asymptomatic cholelithiasis (Randi et al, 2006; Grimaldi et al, 1993). Prophylactic cholecystectomy also could be indicated in patients with active hemolytic anemias, before or during renal transplantation or during bariatric surgery (Bonatsos et al, 2001; Graham et al, 1995; Shiffman et al, 1993).

GALLSTONES, PORCELAIN GALLBLADDER, AND GALLBLADDER CARCINOMA (SEE CHAPTER 49)

Gallstones are closely associated with gallbladder cancer (level V evidence, descriptive studies only), and it is speculated that gallstones larger than 3 cm, family history of gallbladder cancer, and duration of cholelithiasis are all potential risk factors for the development of gallbladder cancer (Miyazaki et al, 2008). Gallstones are present in 60% to 90% of gallbladder cancer cases (Goldin & Roa, 2009), although no direct causal relationship between gallstones and gallbladder cancer has been proven. The presence of large gallstones could simply reflect the duration of cholelithiasis rather than causality, and a significant difference in prevalence of gallbladder cancer worldwide points to the influence of other factors. The risk of developing carcinoma is estimated to be 1% of calculous gallbladders 20 years after the initial diagnosis of gallstones, with the risk increased mainly in men (Maringhini et al, 1987); however, given the high incidence of gallstones and the rarity of gallbladder cancer, this estimate would seem to be high. In some series, no patients with gallstones developed gallbladder cancer over a 10-year period. As a result, cholecystectomy to prevent the development of gallbladder cancer in patients with gallstones is not recommended. Some populations such as Pima Indians, Chileans, and Pakistani women with gallstones have an unusually high incidence of gallbladder cancer (12 to 21 per 100,000; Goldin & Roa, 2009). In these unique populations, prophylactic cholecystectomy to prevent the development of gallbladder cancer is probably justified.

Calcification of the gallbladder is encountered in up to 0.8% of all gallbladder pathology specimens. Porcelain gallbladder or diffuse gallbladder calcification was long considered to be a significant risk factor for the presence of gallbladder cancer, ranging from 12% to 62% (Stephen & Berger, 2001; Towfigh et al, 2001; Cunningham & Alexander, 2007). Recently, two studies from the United States analyzed a large database of cholecystectomy specimens and reported much lower incidence rates of cancer in porcelain gallbladder than in previous studies (Stephen & Berger, 2001; Towfigh et al, 2001). Diffuse calcification appeared to confer little or no increased risk of cancer; by contrast, the incidence of cancer in gallbladders with selective, not diffuse, calcifications was much higher at 7% (Stephen & Berger, 2001). Based on this data, at least in Western populations, the incidence of cancer in porcelain gallbladder should be considered to be increased but not as high as reported previously. Taking into account that older studies from other populations (Japan and South America) are citing a much higher association of porcelain gallbladder with gallbladder cancer, and because gallbladder cancer is a highly lethal disease, careful decision making should be undertaken when assessing individual risk of cancer in patients with a calcified gallbladder.

CHAPTER 31

Cholecystitis

Kaitlyn Kelly and Sharon Weber

OVERVIEW

Cholecystitis, a common condition usually resulting from complications of cholelithiasis, occurs in two forms, acute and chronic. Acute cholecystitis requires urgent intervention, typically with antibiotics followed by cholecystectomy. In the setting of acute cholecystitis, cholecystectomy is optimally performed soon after the diagnosis is made. If urgent cholecystectomy is not feasible, operation can be delayed until after the acute episode has resolved, and then the operation may be performed electively, provided that the acute process can be controlled, and the symptoms resolve. Chronic cholecystitis is the manifestation of ongoing, intermittent inflammation or so-called biliary colic. Patients with this condition benefit symptomatically from elective cholecystectomy. A less common version of cholecystitis is acute acalculous cholecystitis, which occurs most often in critically ill patients. Although gallstones are, by definition, absent in this condition, cholecystectomy specimens in patients with acute acalculous cholecystitis often reveal biliary sludge.

ACUTE CHOLECYSTITIS

Pathogenesis

The cause of acute cholecystitis is an impacted gallstone in the outlet of the gallbladder, either in the infundibulum or in the cystic duct (Sjodahl et al, 1978). The impacted gallstone results in gallbladder distension and edema with acute inflammation, which eventually can result in venous stasis and obstruction, followed by thrombosis of the cystic artery. Ultimately, ischemia and necrosis of the gallbladder occur. Because the fundus of the gallbladder is the greatest distance from the cystic arterial blood supply, it is more sensitive to ischemia and is the most common location for necrosis of the gallbladder. The acute inflammation of cholecystitis may be complicated by secondary biliary infection. Positive biliary cultures are found in about 20% of patients with acute cholecystitis (den Hoed et al, 1998), the most common of which are gram-negative bacteria of gastrointestinal origin, such as *Klebsiella* spp. and *Escherichia coli.*

Clinical Manifestations

Most patients with acute cholecystitis present with severe, constant, right upper quadrant or epigastric pain, sometimes with radiation to the subscapular area. This pain may be preceded by intermittent, self-limited bouts of abdominal pain from episodes of biliary colic. Acute cholecystitis is frequently associated with fever and leukocytosis, findings that are not present in cases of uncomplicated biliary colic. Patients also may develop a Murphy sign, or inspiratory arrest on palpation of the right upper quadrant. Other presenting symptoms include nausea, vomiting, and anorexia.

Differential Diagnosis

Several disease processes can present similarly to cholecystitis and should be considered in the differential diagnosis. These include peptic ulcer disease, gastritis and gastroenteritis, irritable bowel syndrome, inflammatory bowel disease, right lower lobe pneumonia, and biliary dyskinesia. An initial chest radiograph is generally sufficient to assess for a right lower lobe infiltrate. The other diagnoses should be entertained and worked up appropriately in symptomatic patients without gallstones on ultrasound (US).

Diagnostic Evaluation and Imaging

Abdominal US (see Chapter 13) is useful for assessing patients suspected to have acute cholecystitis. Typical findings include gallstones, gallbladder wall thickening (>4 mm), and pericholecystic fluid (Fig. 31.1). In addition, the sonographer can assess for pain and inspiratory arrest when the gallbladder is directly compressed by the US probe (sonographic Murphy sign). Typically, conventional gray scale imaging is used, which is highly sensitive and specific for diagnosing acute cholecystitis, with an overall accuracy of greater than 90% (Soyer et al, 1998). Other techniques of imaging that assess blood flow, such as color velocity imaging, may improve accuracy in selected cases (Soyer et al, 1998; Uggowitzer et al, 1997).

Hepatobiliary scintigraphy (see Chapter 15) is a useful study in selected patients when the diagnosis is uncertain. This nuclear medicine study is performed with derivatives of aminodiacetic acid (hepatoiminodiacetic acid [HIDA], isopropylacetanilido imidodiacetic acid [PIPIDA], or di-isopropylacetanilido iminodiacetic acid [DISIDA]), which are taken up by hepatocytes and secreted in the bile. When the tracer is labeled with technetium, it is possible to visualize biliary function with scintigraphy. A normal scan delineates the biliary tree, including the gallbladder, and shows prompt emptying of the agent into the duodenum. Nonvisualization of the gallbladder on hepatobiliary scan is consistent with acute cholecystitis (Fig. 31.2).

An added utility of this test is that in addition to gallbadder filling or nonfilling, it also evaluates gallbladder emptying. Abnormal emptying is defined as an ejection fraction (EF) of 35% or less on scintigraphy, a finding suggestive of biliary pathology. Middleton and Williams (2001) reported on 141 patients with normal US and scintigraphy with normal gallbladder filling and an EF of 35% or less who underwent

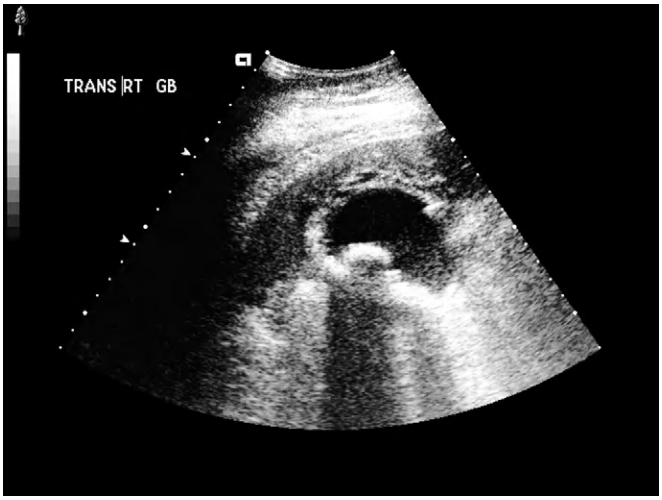

FIGURE 31.1. Transverse view of the gallbladder on ultrasound in a patient with calculous cholecystitis, revealing gallstones and gallbladder wall thickening.

cholecystectomy. Of these patients, 95% had significant improvement or complete resolution of symptoms after surgery, and 41% of these patients had cholecystitis on histologic evaluation of the gallbladder.

Hepatobiliary scintigraphy is not useful in patients with poor hepatic function because it requires hepatic excretion of bile, but it is accurate in about 90% of patients and may be more accurate than US alone. Hepatobiliary scintigraphy is more involved, more expensive, and requires a longer time than US; however, it should be reserved for selected cases (Chatziioannou et al, 2000; Kalimi et al, 2001). Mahid and colleagues (2009) have suggested a diagnostic approach that starts with US for patients with biliary symptoms. If no gallstones are definitively identified, this should be followed by esophagogastroduodenoscopy to exclude alternative causes of symptoms, such as peptic ulcer disease or gastritis. If this test result is negative, hepatobiliary scintigraphy should follow.

Computed tomography (CT; see Chapter 16) can also help diagnose acute cholecystitis and provides more detailed anatomic information than US. CT is particularly useful in patients whose symptoms suggest a complication such as pericholecystic abscess or an alternative diagnosis. The CT findings of acute cholecystitis are the same as those seen on US and include wall thickening, pericholecystic stranding, distension of the gallbladder, high-attenuation bile, pericholecystic fluid, and subserosal edema. CT generally is less sensitive than US for diagnosing acute cholecystitis, particularly early in the course, when the imaging findings may be subtle (Fidler et al, 1996; Harvey & Miller, 1999).

Treatment

Initial treatment with antibiotics active against enteric bacteria should begin as soon as the patient is diagnosed with acute cholecystitis. In addition, oral intake should be restricted, and intravenous resuscitation should be started in preparation for surgery with parenteral analgesics administered as needed.

The definitive treatment for acute cholecystitis is cholecystectomy. From the time this operation was first performed in 1882 by Langenbuch, open cholecystectomy has been the standard of care for patients with acute cholecystitis. With the advent of laparoscopic cholecystectomy in the 1980s, the standard approach has changed such that cholecystectomy is now routinely performed laparoscopically. The benefits of laparoscopic cholecystectomy are discussed in depth elsewhere (see Chapters 33 and 34), but they include a shorter postoperative stay and decreased analgesia requirements (Cox et al, 1993). Although the laparoscopic approach is now standard for most cases, it is interesting to note that two prospective, randomized studies suggested little or no difference in several outcome measures between laparoscopic versus small-incision open cholecystectomy (Majeed et al, 1996; Keus et al, 2008).

Early analysis of the results of laparoscopic cholecystectomy in patients with acute versus chronic cholecystitis showed increased morbidity and mortality rates for patients with simple or complicated acute cholecystitis. Because of the increased

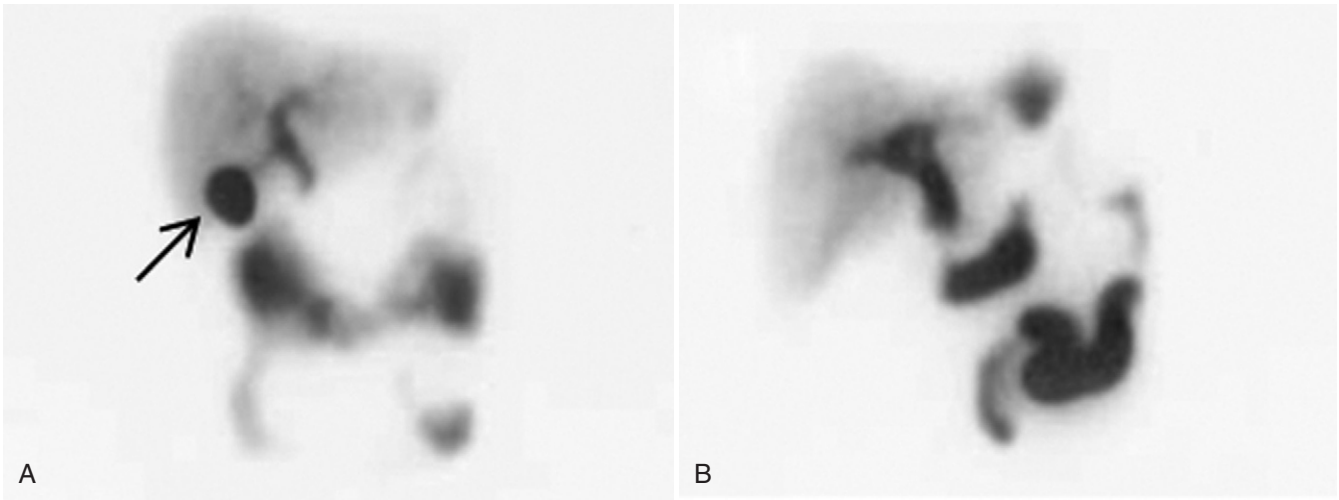

FIGURE 31.2. A, Normal hepatoiminodiacetic acid (HIDA) scan demonstrating contrast-filled gallbladder (*arrow*). **B,** Abnormal HIDA scan demonstrating nonfilling of the gallbladder consistent with cystic duct obstruction. *(Courtesy Dr. Scott Perlman, University of Wisconsin Hospital and Clinics.)*

morbidity and mortality, acute cholecystitis initially was considered a relative contraindication to laparoscopic cholecystectomy (Flowers et al, 1991). Subsequent reports have shown the improved safety of this technique in the acute setting (Chandler et al, 2000; Johansson et al, 2003; Lai et al, 1998; Lo et al, 1998). The conversion rate to an open procedure is higher for patients with acute cholecystitis compared with patients undergoing elective operations for simple biliary colic (Schirmer et al, 1991), but most patients with acute cholecystitis (>80%) can undergo laparoscopic cholecystectomy successfully (Papi et al, 2004). Retrospective series revealed that risk factors for conversion to open cholecystectomy include obesity (Rosen et al, 2002), elevated white blood cell count (Alponat et al, 1997; Kanaan et al, 2002), and male gender (Kanaan et al, 2002).

Other novel surgical techniques have been proposed to treat patients with acute cholecystitis, including so-called minilaparoscopic cholecystectomy (see Chapter 33), which uses 2- to 3-mm ports (Hsieh, 2003), and minicholecystectomy (Assalia et al, 1997), in which a small (mean, 5.5 cm) incision is used to remove the gallbladder. A prospective, randomized trial demonstrated that minilaparoscopic cholecystectomy resulted in decreased postoperative pain and superior cosmesis when compared with conventional laparoscopic cholecystectomy, with no significant difference in operative time, blood loss, or complications (Novitsky et al, 2005).

Laparoscopic subtotal cholecystectomy (LSC) has also been evaluated as a means of decreasing the conversion rate to open procedure in patients with acute cholecystitis (Horiuchi et al, 2008; Singhal et al, 2009). This procedure involves leaving the posterior wall of the gallbladder when it is significantly difficult to dissect from the liver bed, with cauterization of the remnant mucosa and suturing or stapling of the gallbladder neck in cases of severe inflammation of the triangle of Calot. Indeed, in the face of severe inflammatory change, such an approach is safter than risking injury to the common hepatic duct by pursuing dissection within the porta hepatis. Horiuchi and colleagues (2008) demonstrated a significant decrease in conversion rate to open procedure with the use of these techniques with no increase in postoperative complications. All patients undergoing LSC had temporary subhepatic drains placed in this study. This technique, although innovative, does not have wide clinical applicability because of limited availability of instruments, specialist surgeons trained in their use, or both. Laparoscopic cholecystectomy remains the standard therapy for definitive treatment of patients with acute cholecystitis, with conversion to an open procedure if necessary.

In patients with a high perioperative risk from sepsis or other underlying medical comorbidities, initial treatment of acute cholecystitis with percutaneous cholecystostomy tube placement is preferred (see Chapters 28 and 32). These tubes can be placed using either US or CT guidance (Hatzidakis et al, 2002). This procedure effectively decompresses the gallbladder, evacuating the infected bile and relieving the pain associated with gallbladder distension, and it is associated with a low complication rate (Akyürek et al, 2005; Byrne et al, 2003; Spira et al, 2002; Werbel et al, 1989). In addition, most patients (>80%) improve clinically within a short time (Byrne et al, 2003; Hatzidakis et al, 2002; Vauthey et al, 1993). After stabilization of the patient, and if the clinical situation otherwise warrants, delayed cholecystectomy should be performed, which often can be done laparoscopically (Spira et al, 2002). Akyürek and colleagues (2005) demonstrated decreased hospital stay and cost in high-risk patients undergoing percutaneous cholecystostomy followed by early laparoscopic cholecystectomy compared with those treated conservatively with intravenous (IV) antibiotics and bowel rest followed by delayed cholecystectomy. In high-risk patients in whom general anesthesia is contraindicated, percutaneous stone extraction has been used successfully (Gibney et al, 1987; Wong et al, 1999). More recently, single and repeated percutaneous transhepatic gallbladder aspiration has been shown to be successful in high-risk patients with acute cholecystitis who do not respond to conservative therapies (Tsutsui et al, 2007). This treatment modality is not widely practiced, however.

Timing of Surgery

The optimal interval of time between the diagnosis of acute cholecystitis and definitive treatment with cholecystectomy has been the subject of many prospective randomized trials, nine evaluating open cholecystectomy and five evaluating laparoscopic cholecystectomy (Papi et al, 2004; Siddiqui et al, 2008). The concern in operating on patients with early cholecystitis (typically defined as <3 days) is the potential for increased postoperative complications, including common bile duct injury. The risk of performing cholecystectomy late (weeks after the diagnosis of cholecystitis) is that a subset of patients have recurrent symptoms during the period between diagnosis and surgical treatment, which leads to recurrent hospital admissions and urgent surgery (Papi et al, 2004). In multiple randomized prospective trials evaluating the timing of open cholecystectomy, patients undergoing early operation experienced no increased perioperative morbidity or mortality and had a shorter length of hospital stay compared with patients undergoing delayed operation (Norrby et al, 1983; Van der Linden & Edlund, 1981). In addition, a meta-analysis of these trials demonstrated that more than 20% of patients failed medical management while awaiting definitive treatment, and approximately half of these patients required urgent surgical treatment as a result (Papi et al, 2004). In this same analysis, no increase in morbidity was seen in patients undergoing early definitive treatment with laparoscopic (P = .6) or open (P = .2) cholecystectomy compared with delayed treatment, but a clear difference was seen in length of hospital stay, with patients undergoing delayed treatment requiring a more prolonged hospitalization (Papi et al, 2004). Although it is safe to perform cholecystectomy either early or late after an episode of acute cholecystitis, patients benefit when surgery is performed early.

Performing laparoscopic cholecystectomy in patients with acute cholecystitis poses unique challenges to surgeons because of the potential for increased morbidity, including the most feared complication, common bile duct injury. The concern is that the acute inflammation may obscure the anatomy, leading to an increase in postoperative complications. Five prospective randomized trials have evaluated the outcome of patients with acute cholecystitis undergoing early versus late laparoscopic cholecystectomy (Table 31.1). Although a significant increase in operation time was experienced for those undergoing early compared with delayed cholecystecomy (P = .002), the results of these trials uniformly showed no significant difference in postoperative morbidity or mortality, including common bile duct injury, when surgery is performed early (Siddiqui et al, 2008). Additionally, no significant difference was found in the conversion rate to open cholecystectomy, although it was clearly

Table 31.1

Results of Five Prospective, Randomized Trials Comparing Early vs. Delayed Laparoscopic Cholecystectomy for Acute Cholecystitis

Reference	N	Definition	Morbidity Rate	Failure of Conservative Treatment in Delayed Group	Conversion to Open Cholecystectomy
Kolla et al, 2004	40	Early: <4 days	0%	25%	20%
		Late: 6-12 weeks		25%	15%
Johansson et al, 2003	145	Early: <7days	26%	31%	18%
		Late: 6-8 weeks		29%	10%
Chandler et al, 2000	43	Early: <3 days	32%	24%	10%
		Late: after symptom resolution		36%	9%
Lai et al, 1998	104	Early: <24 hours	16%	21%	9%
		Late: 6-8 weeks		24%	8%
Lo et al, 1998	99	Early: <3 days	20%	11%	13%
		Late: 6-8 weeks		23%	29%

higher (20% to 30%) in patients with cholecystitis compared with prior studies evaluating patients undergoing elective laparoscopic cholecystectomy in the nonacute setting. Perhaps the most important finding was that in all but one study, patients randomized to late cholecystectomy failed conservative management in 15% to 30% of cases. Although patients in the early group generally experienced a longer postoperative hospitalization ($P = .004$), most of these trials demonstrated a decrease in overall length of hospital stay in the early group versus the delayed group (cumulative $P < .001$) (Chandler et al, 2000; Johansson et al, 2003; Kolla et al, 2004; Lai et al, 1998; Lo et al, 1998). Early laparoscopic cholecystectomy is therefore the preferred surgical technique for patients with acute cholecystitis. Catena and colleagues (2009) have proposed the use of a harmonic scalpel for improved hemostasis and biliostasis in laparoscopic cholecystectomy, and preliminary data suggest it may decrease the conversion rate to open procedure in patients undergoing laparoscopic cholecystectomy for acute cholecystitis. A prospective, randomized controlled trial is underway to compare the use of harmonic versus monopolar diathermy for laparoscopic cholecystectomy (Catena et al, 2009).

The majority of trials of early versus delayed laparoscopic cholecystectomy define "early" as within 72 hours of symptom onset. A recent nonrandomized, prospective study by Tzovaras and colleagues (2006) assessed 129 patients undergoing laparoscopic cholecystectomy for acute cholecystitis during the index admission. The patients were divided into three groups regarding the timing of their surgery from symptom onset: within 3 days, between 4 and 7 days, and after 7 days. They found no significant difference in conversion rate, morbidity, or postoperative hospital stay among these groups and thus suggest that the benefits of early cholecystectomy are not limited to patients who present within 72 hours of symptom onset.

Another factor to consider is whether early or delayed laparoscopic cholecystectomy for acute cholecystitis is more cost effective. A meta-analysis of randomized and other studies performed by Lau and colleagues (2006) concluded that early surgery was more cost-effective because of reduced overall length of hospital stay and avoidance of readmissions for recurrent cholecystitis or biliary colic.

CHRONIC CHOLECYSTITIS

Pathogenesis and Clinical Manifestations

Chronic cholecystitis may result after one or more episodes of acute cholecystitis, or it may evolve, initially without symptoms, merely from the presence of gallstones. In most cases, patients describe one or more episodes of abdominal pain that is clinically consistent with biliary colic. The term *colic* is a misnomer, because the pain from chronic cholecystitis is usually constant in nature and is similar to that seen initially with acute cholecystitis, although it is self-limited and often less severe. The pain associated with chronic cholecystitis seems to be the result of intermittent obstruction of the gallbladder outflow.

There are numerous well-described risk factors for the development of gallstones and subsequent chronic cholecystitis. Patients at particularly high risk include obese women, in whom pathologic changes of chronic inflammation are found even in the absence of gallstones (Calhoun & Willbanks, 1987; Csendes et al, 2003); this may be due to an increase in the cholesterol saturation of bile in obese patients (St. George & Shaffer, 1993; see Chapter 7). These patients are often asymptomatic.

Diagnostic Imaging

US examination of the gallbladder most often reveals circumferential thickening of the gallbladder wall with cholelithiasis. In advanced cases, a small, shrunken gallbladder with a thickened wall and multiple gallstones are seen. Discomfort may be reproduced with direct pressure on the gallbladder with the US probe. Commonly, particularly in obese patients and in those with mild symptoms, the US examination shows no particular gallbladder wall abnormalities (Calhoun & Willbanks, 1987).

Treatment

Elective cholecystectomy is the treatment of choice for patients with symptoms of chronic cholecystitis. In most (≥90%) cases, cholecystectomy can be accomplished laparoscopically. Patients occasionally are seen with atypical pain (left hypochondrium) or with minimal or no pain but rather intermittent nausea or

bloating. In such cases, evaluation for other possible causes of symptoms should be undertaken, particularly if US shows gallstones, but no sequelae of chronic cholecystitis are seen.

ACUTE ACALCULOUS CHOLECYSTITIS

Pathogenesis

Acalculous cholecystitis usually occurs in patients with coexisting major illnesses, such as generalized sepsis, major trauma, or burns or in those undergoing a prolonged recovery from major operations who are unable to tolerate oral intake (Kalliafas et al, 1998). It has been speculated that in such situations, there is no stimulus of the gallbladder to contract, the bile becomes inspissated, and biliary sludge forms. The exact pathogenesis is unknown but likely involves some combination of ischemia, biliary stasis, and sepsis (Hakala et al, 1997; Warren, 1992), and inspissated bile and sludge seem to play some causative role. Although this condition traditionally has been described in the patient groups mentioned earlier, several reports suggest an increase in the de novo presentation of acalculous cholecystitis in the outpatient population, including patients with atherosclerotic vascular disease, such as seen in hypertension and diabetes (Parithivel et al, 1999; Ryu et al, 2003; Savoca et al, 1990). Overall, acalculous cholecystitis represents approximately 5% to 15% of all cases of acute cholecystitis. A male predominance is seen in cases of acalculous cholecystitis, in contrast to acute calculous cholecystitis, which occurs most often in women (Kalliafas et al, 1998; Ryu et al, 2003; Wang et al, 2003).

A prospective study evaluating trauma patients with serial US examinations found that the incidence of acalculous cholecystitis in severely injured patients (injury severity score ≥12, requiring intensive care for >4 days) was 11% (Pelinka et al, 2003), which is similar to other reports (Imhof et al, 1992). In addition, three factors were correlated with an increased risk of developing acalculous cholecystitis in this high-risk population: 1) high injury severity score, 2) increased heart rate, and 3) transfusion requirement at the time of admission. This study suggests that more acutely injured patients, who are expected to require prolonged ventilatory and nutritional support, are at higher risk for the development of acalculous cholecystitis (Pelinka et al, 2003).

Clinical Manifestations

Part of the difficulty in making the diagnosis of acalculous cholecystitis is that many patients presenting with this condition are critically ill and require ventilatory support and sedation. The symptoms and signs are often masked by the patient's underlying condition or the interventions used to treat it (Kalliafas et al, 1998). In the outpatient population seen with acalculous cholecystitis, the diagnosis is more straightforward, mimicking the signs and symptoms of acute calculous cholecystitis (Ryu et al, 2003).

The most frequent physical and laboratory findings are fever, right upper quadrant pain, leukocytosis, and hyperbilirubinemia. These findings are often nonspecific, however, in the setting of sepsis and critical illness (Kalliafas et al, 1998). Incidence of gangrene and perforation seems to be increased in patients with acalculous cholecystitis compared with acute calculous cholecystitis, likely because of the delay in diagnosis that is common with this disease. Severe gallbladder complications such as gangrene, perforation, and empyema occur more commonly in older patients with an elevated white blood cell count (Ryu et al, 2003; Wang et al, 2003). In many series, the risk of severe gallbladder complications was found to be 50% to 60% (Kalliafas et al, 1998; Swayne, 1986; Wang et al, 2003). This high risk may be the result of the disturbance in capillary microcirculation that has been shown in pathologic studies on gallbladder specimens after cholecystectomy for acalculous cholecystitis (Hakala et al, 1997; Warren, 1992). In addition, partly as a result of the severity of the patient's underlying condition, the mortality rates are high—15% in some series (Wang et al, 2003).

Diagnostic Evaluation and Imaging

Imaging algorithms for patients with suspected acalculous cholecystitis are similar to algorithms for patients with acute cholecystitis. The initial imaging test is usually US, which classically reveals gallbladder distension, a thickened gallbladder wall, and biliary sludge without stones (Fig. 31.3; Wang et al, 2003). The difficulty with interpreting these findings is that many critically ill, parenteral nutrition–dependent patients have these findings. Partly because of this difficulty, the accuracy of US to diagnose acalculous cholecystitis has been highly institution dependent, with some series showing it to be highly sensitive and specific (Pelinka et al, 2003) and others showing it to be less accurate (Kalliafas et al, 1998). US is widely available and easy to use, even in acutely ill patients, because it can be performed at the bedside, and it is inexpensive. US should be performed as the initial imaging modality for suspected acalculous cholecystitis.

Evaluating the natural history of abnormalities visualized on US in acutely injured patients is problematic; a prospective trial assessed 255 severely injured trauma patients with serial US examinations. In this trial, all patients with US findings consistent with acalculous cholecystitis and major clinical symptoms—abdominal pain or distension or both, hemodynamic instability, or organ failure—underwent cholecystectomy, and all had acalculous cholecystitis on final pathology. A few patients had positive US findings, but no major clinical symptoms were observed. In this group, all US findings returned to normal within 3 weeks. In addition, 15% of patients developed hydrops of the

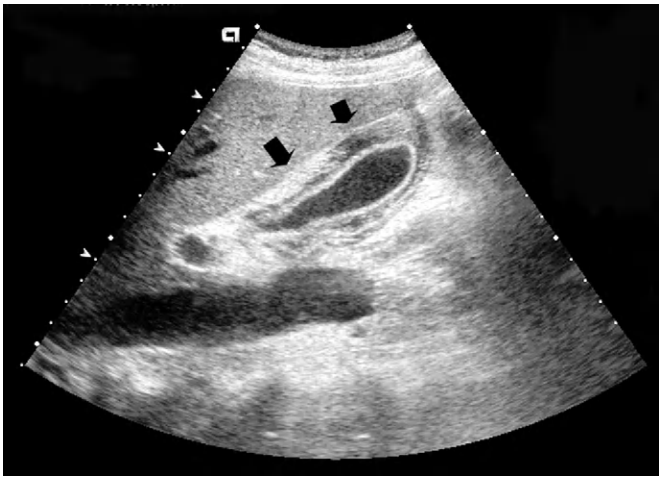

FIGURE 31.3. Ultrasound of a patient with acalculous cholecystitis reveals marked thickening of the gallbladder wall (*arrows*).

gallbladder without clinical symptoms, and subsequent normalization of the US was observed in all (Pelinka et al, 2003). These findings suggest that although many critically ill patients may develop US abnormalities consistent with acalculous cholecystitis, the combination of clinical symptoms and positive imaging findings will identify most patients who require intervention.

Because of the difficulty establishing a diagnosis in these critically ill patients, CT has been used as an additional imaging test. The advantage of CT is that imaging of the entire chest, abdomen, and pelvis can be obtained; this is particularly important in this patient cohort, in whom clinical signs and symptoms may be misleading or whose signs and symptoms may result from other causes. CT may be more sensitive and specific than US (Blankenberg et al, 1991; Mirvis et al, 1986), but it has the disadvantage of requiring transport of the patient outside of the intensive care unit.

When a patient's diagnosis is questionable based on physical findings or US evaluation or both, hepatobiliary scintigraphy may be used. In past reports, a high rate of false-positive results was seen in patients with acalculous cholecystitis (Mirvis et al, 1986), but more recent evaluation of this modality has shown improved accuracy in diagnosing acalculous cholecystitis (Kalliafas et al, 1998; Ryu et al, 2003). In some series, scintigraphy has been found to be more sensitive than CT or US in diagnosing acalculous cholecystitis (Kalliafas et al, 1998; Prevot et al, 1999; Puc et al, 2002; Ryu et al, 2003). The specificity of hepatobiliary scintigraphy can be improved by administering morphine to cause constriction of the sphincter of Oddi and improve gallbladder filling. This maneuver decreases the incidence of false-positive studies and improves specificity, but it does not result in improvements in sensitivity compared with conventional scintigraphy (Cabana et al, 1995; Flancbaum et al, 1989; Kalliafas et al, 1998).

Treatment

The definitive treatment for acalculous cholecystitis is cholecystectomy, which can be performed laparoscopically in most cases. In patients who are critically ill, placement of a percutaneous cholecystostomy tube allows for decompression of the gallbladder and drainage of contained, infected bile; this allows time for the patient to recover from the acute illness before considering proceeding with cholecystectomy (McClain et al, 1997; Akyürek et al, 2005). Percutaneous cholecystostomy may be the definitive treatment for acalculous cholecystitis, because there is no chronic obstruction of the gallbladder outlet as in acute cholecystitis (Davis et al, 1999; Vauthey et al, 1993; see Chapters 28 and 32).

COMPLICATIONS OF CHOLECYSTITIS

Gangrenous Cholecystitis

Gangrenous cholecystitis is a more common finding in diabetic patients with acute cholecystitis who present with a leukocytosis (Fagan et al, 2003). In addition, the risk of gangrenous cholecystitis is higher in patients with acalculous cholecystitis, likely owing to the delay in diagnosis that commonly occurs in this disease (Kalliafas et al, 1998; Swayne, 1986; Wang et al, 2003). As previously mentioned, the most common site for necrosis to occur is in the fundus. Full-thickness necrosis is by definition always present in patients with gangrenous cholecystitis, but this condition may or may not result in free perforation of the gallbladder. In patients with free perforation, bile-stained abdominal fluid is present.

Because these patients are generally ill, imaging with CT scan is often performed. Findings most specific for acute gangrenous cholecystitis on CT scan include air in the wall or lumen, intraluminal membranes, an irregular wall, or pericholecystic abscess. As expected, a contrast-enhanced CT scan may show a lack of mural enhancement in patients with gangrenous cholecystitis (Bennett et al, 2002).

Empyema

In cases of empyema, the gallbladder is filled with purulent bile. This condition usually is associated with acute cholecystitis and occurs in the setting of infected bile and an obstructed cystic duct. Most patients with empyema have calculous cholecystitis, but empyema also can occur in patients with acalculous disease (Tseng et al, 2000). The clinical course can mimic that of an intraabdominal abscess from other causes, and patients are often seen initially with clinical manifestations of sepsis. Patients with gallbladder empyema require urgent cholecystectomy or percutaneous cholecystostomy, depending on the severity of illness at the time of presentation (Tseng et al, 2000). Critically ill patients may be best served by a temporary cholecystostomy tube followed by elective cholecystectomy.

Emphysematous Cholecystitis

Emphysematous cholecystitis is a rare entity that results from the presence of gas-forming bacteria in the bile. Emphysematous cholecystitis may be seen in association with acute or gangrenous cholecystitis, and it is more common in men and diabetic patients (Tellez et al, 1999). The diagnosis occasionally can be made by simple abdominal radiographs, but more often it is diagnosed on US (Fig. 31.4) or CT scan (Fig. 31.5; Bennett & Balthazar, 2003; Gill et al, 1997; Konno et al, 2002). Patients should receive intravenous antibiotics to include coverage for *Clostridium* species, followed by emergent cholecystectomy.

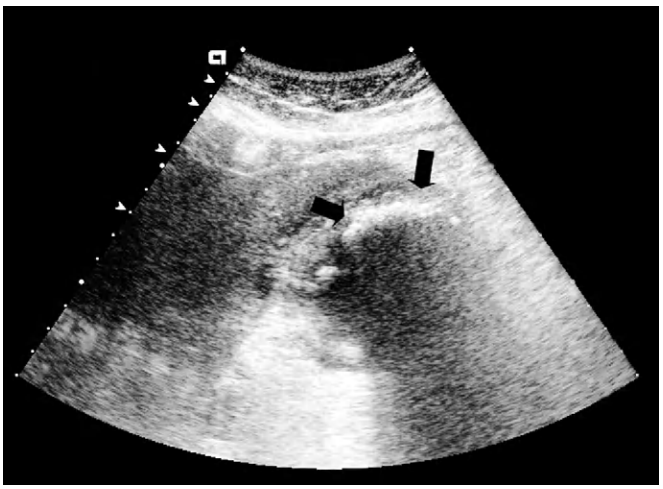

FIGURE 31.4. Ultrasound of the gallbladder revealing air within the gallbladder (*arrows*) consistent with emphysematous cholecystitis.

FIGURE 31.5. CT scan (noncontrast) in a patient with emphysematous cholecystitis showing gallbladder filled with air.

Mirizzi Syndrome

Mirizzi syndrome is defined as biliary obstruction secondary to cholecystitis. It occurs in 0.3% to 3% of patients undergoing cholecystectomy (Lai & Lau, 2006). An impacted stone in the gallbladder infundibulum or cystic duct can compress the bile duct, usually at the level of the common hepatic duct (type I), or a stone can erode from the gallbladder or cystic duct into the common hepatic duct, resulting in a cholecystocholedochal fistula (type II). Patients are seen with symptoms of acute cholecystitis but with the additional finding of hyperbilirubinemia and elevated alkaline phosphatase. A laparoscopic approach to this condition has been shown to result in high conversion and complication rates and is not recommended (Lai & Lau, 2006; Antoniou et al, 2009). Open cholecystectomy is the gold standard for treatment when this condition is identified preoperatively. If inflammation has obliterated the triangle of Calot, a partial cholecystectomy with removal of any stones may be all that is possible and usually resolves the condition. In the acute setting, the biliary obstruction often resolves after cholecystectomy and resolution of the inflammatory process. In some cases, however, the chronic inflammation leads to fistulation from the gallbladder to the bile duct, or a biliary stricture results, both of which will complicate the operative procedure and may require biliary reconstruction (see Chapters 42A and 42B).

Cholecystoenteric Fistula

Cholecystoenteric fistula, or perforation of the gallbladder into an adjacent hollow organ, is a rare complication of acute cholecystitis. The duodenum and the transverse colon are the most common sites of fistulation, which results in decompression of the gallbladder and may result in brief symptomatic improvement. This complication occurs most frequently in women in their sixth to seventh decades and has been shown to be associated with Mirizzi syndrome or an additional hepatobiliary abnormality such as gallbladder cancer (Beltran et al, 2008; Chowbey et al, 2006; Costi et al, 2009). Contamination of the biliary tree by enteric organisms may result, and patients may be seen with cholangitis and pneumobilia. Approximately 10% to 15% of patients with cholecystoenteric fistulae will pass gallstones into the small intestine and be seen with small bowel obstruction, termed *gallstone ileus.* In patients with cholecystocolonic fistula, chronic diarrhea is the most common presenting symptom in nonemergent cases (Costi et al, 2009).

Patients with cholecystoenteric fistula require cholecystectomy with takedown and closure of the fistula. When cholecystoenteric fistula is encountered at the time of surgery, concomitant Mirizzi syndrome should be considered. Patients with gallstone ileus require removal of the obstructing stone via enterotomy (Chowbey et al, 2006), and it is important to perform a thorough examination of the bowel for any other stones. Fistula takedown and cholecystectomy can be performed at the same procedure or at a second, delayed procedure if the patient is too unstable to tolerate a prolonged initial operation, or if the pericholecystic inflammation is so severe as to make initial cholecystectomy unsafe.

CHAPTER 32

Percutaneous approaches to the treatment of gallbladder disease

Christoph D. Becker and Sylvain Terraz

IMAGE-GUIDED INTERVENTION

Image-guided interventional techniques have been developed to provide minimally invasive treatment of gallbladder disease (see Chapters 28 and 31). Percutaneous, image-guided cholecystostomy is now an accepted method to decompress the acutely inflamed gallbladder if surgery is not indicated. Various methods aiming at elective, nonsurgical removal of gallbladder stones were introduced in the early 1990s, including extracorporeal shock-wave lithotripsy (ESWL), contact dissolution of gallstones with methyl tert-butyl ether (MTBE), and percutaneous mechanical cholecystolithotomy. As a result of the successful introduction of laparoscopic cholecystectomy (see Chapter 34), surgical treatment of cholecystolithiasis has become less invasive, and definitive treatment of cholecystolithiasis may be accomplished with much shorter hospitalization. Because none of the existing nonsurgical techniques of gallstone removal can prevent recurrent gallstone formation, the indication to perform percutaneous gallstone removal without surgery is now very limited. This chapter gives an overview of image-guided treatment methods for gallbladder disease.

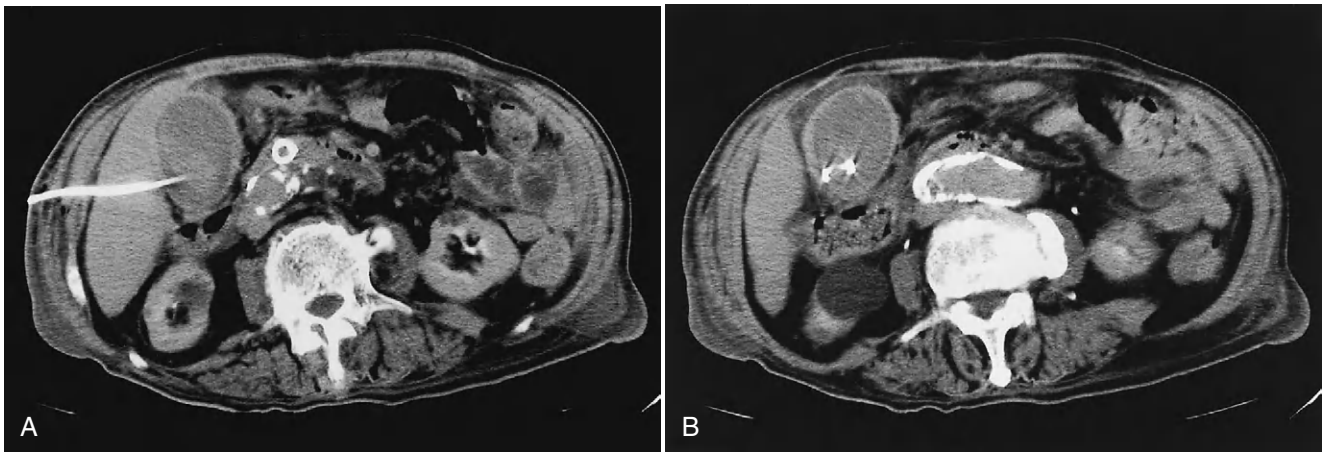
PERCUTANEOUS CHOLECYSTOSTOMY FOR ACUTE CHOLECYSTITIS

Surgical cholecystostomy (see Chapters 28 and 31) has long been used to provide external decompression of the acutely inflamed gallbladder in patients who are at high risk for operation or general anesthesia, such as those with sepsis, diabetes, or severe cardiac, pulmonary, hepatic, or renal failure. Percutaneous cholecystostomy was initially developed to provide a minimally invasive method of gallbladder decompression in elderly and very ill patients with acute acalculous or calculous cholecystitis or with gallbladder hydrops secondary to malignant disease (Elyaderani & Gabriele, 1979; Pearse et al, 1984). Percutaneous cholecystostomy also has been used to treat complications of cholecystitis (e.g., gallbladder perforation, empyema, or pericholecystic abscesses) or as an alternative to percutaneous transhepatic drainage of the bile ducts in obstructive jaundice. More recently, percutaneous cholecystostomy has been used to provide access to the gallbladder for elective gallstone treatment with stone dissolution techniques, percutaneous cholecystolithotomy, or other techniques.

The percutaneous access route to the gallbladder usually is determined with ultrasound (US) and is based on the individual anatomic situation. Computed tomography (CT) can be used if US does not provide sufficient information. Most authors favor the transhepatic approach to the gallbladder, because a puncture through the attached portion of the gallbladder should reduce the risk of bile leakage into the peritoneal cavity (Fig. 32.1). The area of attachment cannot be anticipated reliably with imaging techniques, and the direct, transperitoneal route also has been used successfully (Vogelzang & Nemcek, 1988). The acutely inflamed gallbladder is usually distended and immediately adjacent to the anterior abdominal wall, and the direct approach through the gallbladder fundus avoids the trauma to the liver that may be associated with percutaneous gallstone removal at a later date. The use of a removable percutaneous anchor was proposed to prevent the gallbladder wall from moving away from the trocar or from the catheter during exchange over a guidewire (Cope et al, 1990).

The initial gallbladder puncture is performed under local anesthesia, and prophylactic administration of atropine has been recommended to prevent vasovagal reactions (vanSonnenberg et al, 1984). With portable US equipment, the percutaneous cholecystostomy procedure can be performed at the patient's bedside (e.g., in the intensive care unit). If there is doubt regarding a safe access route, however, it may be preferable to combine US or CT with fluoroscopy (Fig. 32.2). Several suitable needle/catheter or needle/guidewire systems are available, and the optimal method of catheter introduction is a matter of personal preference. Repeat punctures with introducer needles should be avoided, because leakage of gallbladder content through the puncture channel may lead to internal decompression of the gallbladder into the peritoneal cavity and prevent further attempts to enter the gallbladder lumen. A catheter size of 6.5 to 7 Fr is usually sufficient to provide effective external gallbladder drainage, but 8 Fr or more may be necessary to drain gallbladder empyema or pericholecystic abscesses (Fig. 32.3; vanSonnenberg et al, 1991). If percutaneous cholecystostomy is done for acute cholecystitis, catheter manipulations should be kept to a minimum to avoid inadvertent perforation of the frail inflamed gallbladder wall or leakage of gallbladder contents alongside the catheter. To prevent inadvertent dislodgment of the catheter on the ward, it is preferable to use a self-retaining catheter. Diagnostic cholangiography through the cholecystostomy catheter may be obtained after a few days to assess the presence of gallstones and patency of the cystic duct. It is advisable to leave the cholecystostomy catheter in place for 7 to 10 days to let a tract develop and to avoid bile leakage into the peritoneal cavity.

Although transient right upper quadrant pain is a relatively common side effect of percutaneous cholecystostomy, serious procedure-related complications are uncommon. In a review of 252 percutaneous cholecystostomies reported in the English language literature, there were 4 cases of bile peritonitis and 1 death (0.3%); other procedure-related complications included vasovagal reaction or hypotension, self-limited hemobilia, and



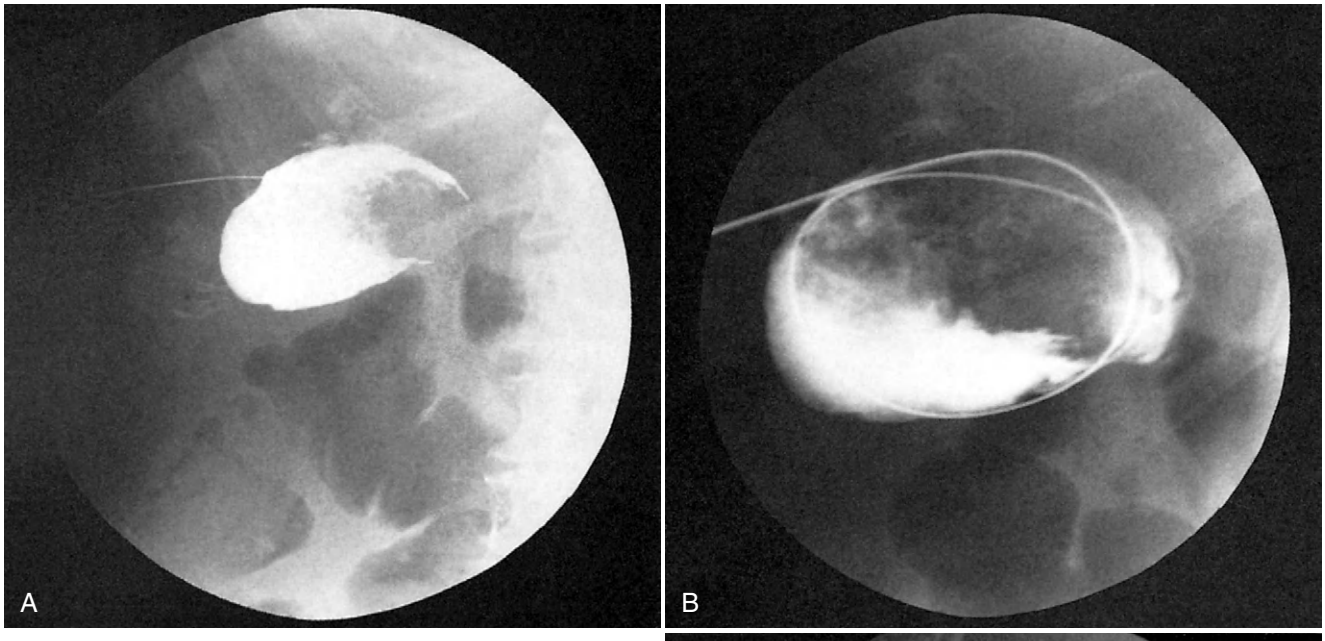


FIGURE 32.1. Percutaneous cholecystostomy for acute acalculous cholecystitis in a 74-year-old patient with recent myocardial infarction. **A,** Contrast-enhanced computed tomography (CT) for planning shows inflammation of the gallbladder wall and hyperdense content. **B,** The puncture of the gallbladder across liver parenchyma is performed with a 20-gauge needle under CT fluoroscopy. **C,** A 6-Fr pigtail drain is placed in the gallbladder using a Seldinger technique. **D,** Ten days later, the drain has been removed, and contrast-enhanced CT shows the gallbladder with decreased inflammation.

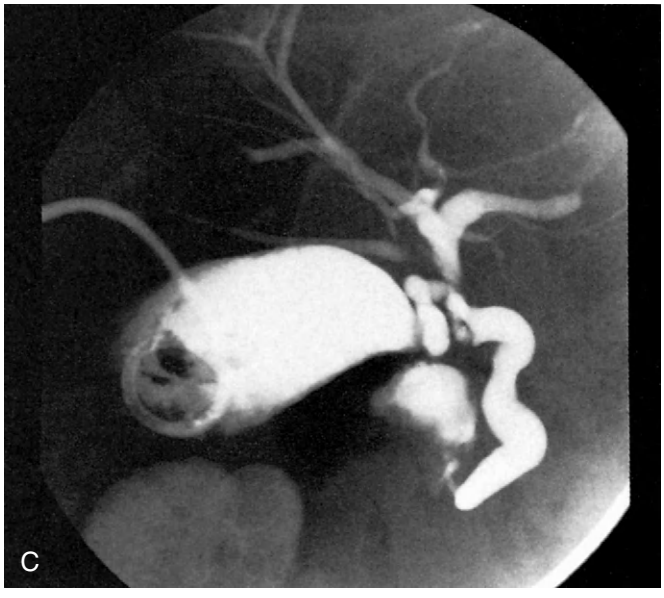

FIGURE 32.2. Percutaneous transhepatic cholecystostomy for acute acalculous hemorrhagic cholecystitis. After an initial gallbladder puncture under ultrasound guidance with a 22-gauge needle, the procedure was continued under fluoroscopic control. **A,** Direct cholecystography showed a large filling defect in the infundibulum of the gallbladder. **B,** The 22-gauge access was converted to a larger caliber, and a guidewire was introduced into the gallbladder. A 6.5-Fr self-retaining pigtail catheter was placed in the gallbladder lumen. There was no opacification of the cystic duct at the time of the initial procedure. **C,** Repeat cholangiography was done 1 week after emergency cholecystostomy. The cystic duct was patent, and there was unimpeded flow of contrast material into the duodenum. Most of the debris within the gallbladder had disappeared. The cholecystostomy catheter was removed 1 week after cholecystostomy; elective cholecystectomy was not required.

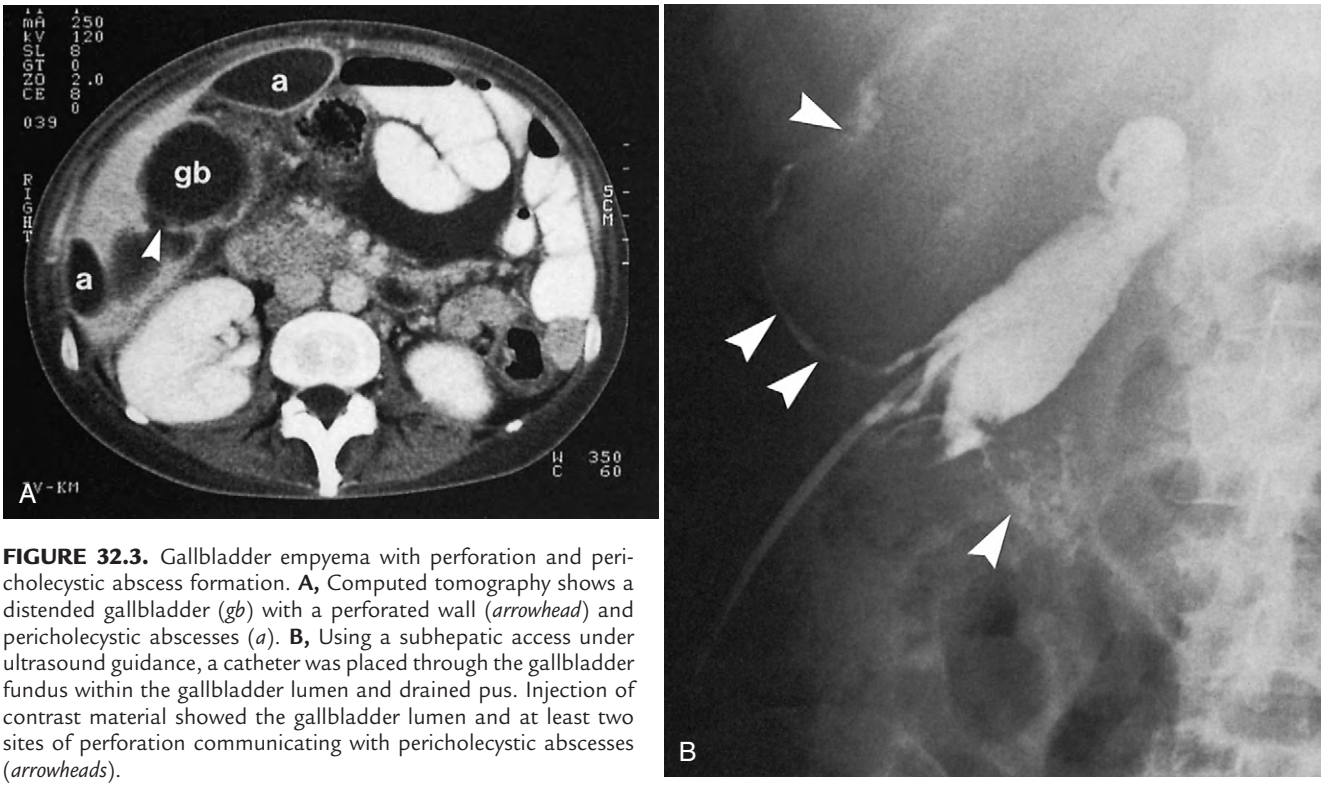

FIGURE 32.3. Gallbladder empyema with perforation and pericholecystic abscess formation. **A,** Computed tomography shows a distended gallbladder (*gb*) with a perforated wall (*arrowhead*) and pericholecystic abscesses (*a*). **B,** Using a subhepatic access under ultrasound guidance, a catheter was placed through the gallbladder fundus within the gallbladder lumen and drained pus. Injection of contrast material showed the gallbladder lumen and at least two sites of perforation communicating with pericholecystic abscesses (*arrowheads*).

acute cholecystitis secondary to an impacted stone in the cystic duct (Teplick, 1989). In a series of 127 patients undergoing gallbladder puncture and cholecystostomy, the reported rate of minor and major complications was 3.9% and 8.7%, respectively. The 30-day mortality rate of that series was 3.1%, but all deaths were due to underlying diseases (vanSonnenberg et al, 1992).

In view of the severely compromised health of most patients undergoing the procedure, percutaneous cholecystostomy is relatively safe. The efficacy of percutaneous cholecystostomy is difficult to determine, because the diagnosis of acute cholecystitis is often unreliable in patients with multiple concomitant medical and surgical problems (McGahan & Lindfors, 1988, 1989). If the indication for percutaneous cholecystostomy is restricted to patients with clinical or imaging findings of acute cholecystitis, a response rate of 90% can be expected (van Overhagen et al, 1996). If patients with unexplained abdominal sepsis are included, the response rate is lower (Boland et al, 1994; Lee et al, 1991; McGahan & Lindfors, 1989). In patients with acute acalculous cholecystitis, interval cholecystectomy may be unnecessary, and percutaneous cholecystostomy may be a definitive therapy (Vauthey et al, 1992). A randomized, controlled trial showed that percutaneous cholecystostomy and drainage is significantly more effective than simple gallbadder aspiration (Ito et al, 2004). Results of retrospective clinical studies on percutaneous cholecystostomy are summarized in Table 32.1. Current experience indicates that percutaneous cholecystostomy is an effective temporizing measure in elderly or critically ill patients with acute cholecystitis and a safe alternative to emergency surgery (Chok et al, 2010). Recently, this has been recognized by a surgical consensus conference (Miura et al, 2007). In clinical situations that warrant, interval cholecystectomy can be performed on an elective basis.

NONSURGICAL TECHNIQUES TO REMOVE GALLBLADDER STONES

Percutaneous Gallstone Removal via Cholecystostomy

Percutaneous Contact Dissolution of Gallbladder Stones with Methyl Tert-Butyl Ether

MTBE is the most potent cholesterol solvent available. Because of its boiling point of 55.2° C, it remains liquid at body temperature and is easier to handle than diethyl ether. Direct instillation of MTBE through a small percutaneous cholecystostomy catheter has been used successfully to dissolve cholesterol stones of the gallbladder within hours (Allen, 1985). Most treatments with MTBE have been done on an elective basis in patients who had an increased risk of surgery or anesthesia because of coexisting medical conditions or who refused to undergo surgery for other reasons (Hellstern et al, 1990; Thistle et al, 1989). The selection criteria for MTBE therapy includes symptomatic uncomplicated gallstone disease, uncalcified gallstones on CT, and normal hepatic laboratory test results.

The use of MTBE requires several precautions. Because of its unpleasant odor, inflammability, and anesthetic effect, MTBE must be used in a well-ventilated room. Catheters, syringes, and stopcocks must be made of special materials, such as Teflon, polyethylene, glass, and metal. After percutaneous cholecystostomy, a 5-Fr pigtail catheter is positioned within the gallbladder under fluoroscopic control so as to provide close contact with the gallstones to be dissolved. The gallbladder overflow volume is assessed by contrast injection into the gallbladder. A similar volume of MTBE is instilled and aspirated in continuous cycles (Fig. 32.4). Depending on the stone volume,

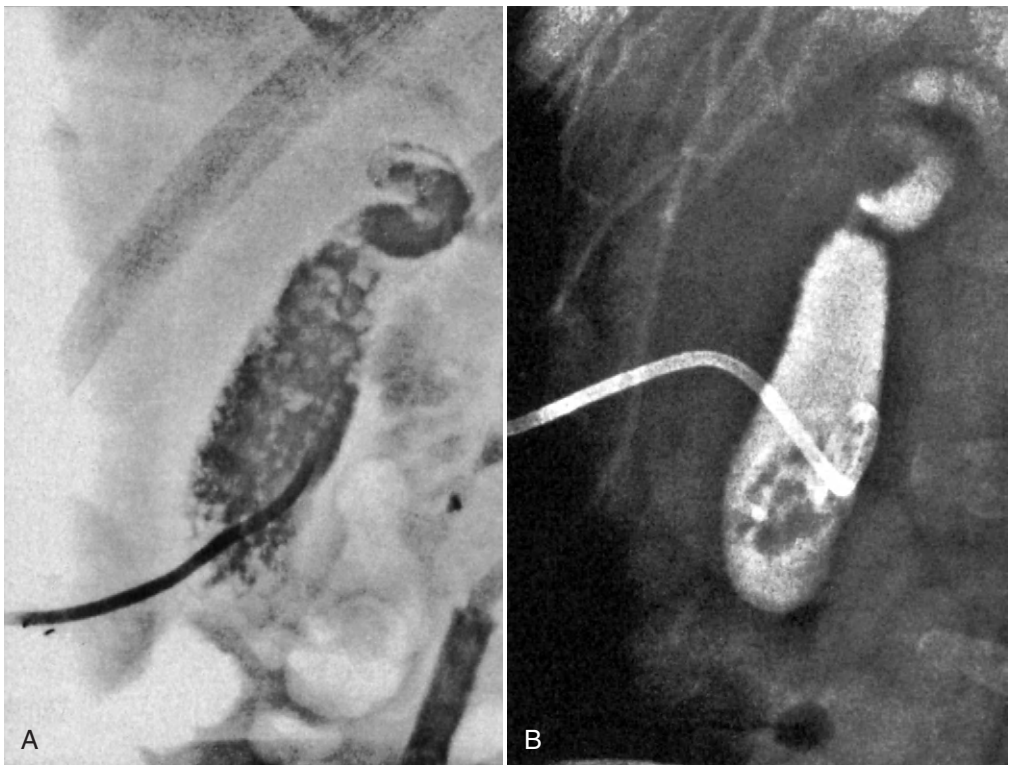

FIGURE 32.4. Percutaneous dissolution of cholesterol gallstones with methyl tert-butyl ether (MTBE). **A,** Direct cholangiography obtained through a cholecystostomy catheter showed multiple small calculi in the gallbladder lumen. **B,** After a few hours of MTBE dissolution treatment, the stone volume had diminished considerably.

complete dissolution is usually accomplished during a hospitalization of 2 to 3 days with several hours of treatment each day.

Minor side effects include nausea, vomiting, or a burning sensation in the right upper abdomen, which may be due to the drug itself, to minor leakage of bile alongside the catheter, or to catheter manipulations within the gallbladder. Serious complications, such as major bile leakage, hemobilia, or stone impaction in the cystic duct or common bile duct, are uncommon. The success rate of MTBE dissolution treatment has been reported to be 96%, although residual debris was still visible on US in many patients at the time of discharge (Hellstern et al, 1990; Thistle, 1991; Thistle et al, 1989). In the era of laparoscopic cholecystectomy, indications for MTBE dissolution treatment of gallbladder calculi are rare (see Chapter 34).

Percutaneous Cholecystolithotomy

The term *percutaneous cholecystolithotomy* is used to describe a variety of techniques to remove gallbladder stones percutaneously. In contrast to MTBE dissolution treatment, percutaneous cholecystolithotomy can be done regardless of the size, number, and composition of the calculi. A small, shrunken, thick-walled gallbladder generally is considered a contraindication to all forms of percutaneous cholecystolithotomy. The common steps of all techniques of percutaneous cholecystolithotomy are 1) percutaneous access to the gallbladder by means of percutaneous cholecystostomy; 2) immediate or sequential dilation of the cholecystostomy tract to a relatively large size, ranging from 10 to 30 Fr; 3) introduction of instruments for gallstone fragmentation and removal; and 4) external drainage of the gallbladder after the procedure (Akiyama et al, 1985; Kerlan et al, 1985).

Regardless of the technique used for tract dilation, the procedure is painful unless performed under intravenous sedation or general anesthesia. The most important risks are hemorrhage if a transhepatic access is used and bile leakage and loss of access if a subhepatic transperitoneal route is chosen. Smaller calculi can be removed with wire baskets (Cope et al, 1990). Fragmentation of larger calculi may be done with electrohydraulic, ultrasonic, or laser-mediated intracorporeal lithotripsy (Bogan et al, 1989; Burhenne, 1975; Gillams et al, 1992; Picus et al, 1989). These techniques require direct contact between the lithotripsy probes and the calculi under endoscopic vision. The *rotary gallstone lithotrite* was specially designed for percutaneous gallstone lithotripsy and enables pulverization of gallbladder calculi in a manner similar to a household blender: the device consists of a six-pronged basket surrounding a 3-mm impeller, which rotates in a 7-Fr catheter at 30,000 rpm, pulling the stones into the basket and crushing the stones into fragments smaller than 2 mm within minutes (Miller et al, 1991a, 1991b, 1991c). This technique can be performed under fluoroscopic vision and requires a percutaneous tract no larger than 10 Fr. Because the device must be able to open freely within the gallbladder, the stone volume should not exceed 75% of the volume of the gallbladder (Fig. 32.5).

The technical success rate of percutaneous cholecystolithotomy is 88% (Gillams et al, 1992). Procedure-related complications occur in 15% and include subhepatic bile collections, cholangitis, gallbladder perforation with pericholecystitis, and wound infections. Although in the early 1990s elective percutaneous cholecystolithotomy was proposed to avoid cholecystectomy in patients with symptomatic but uncomplicated cholecystolithiasis, this indication seems to be obsolete in the

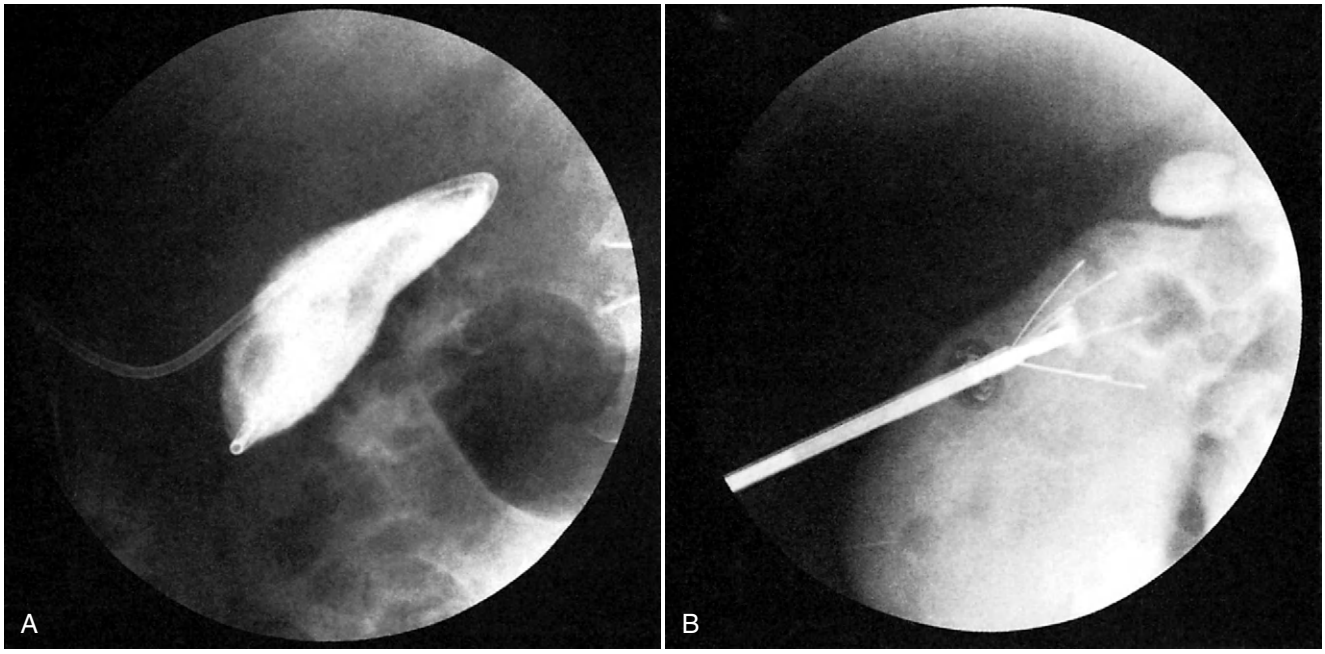

FIGURE 32.5. Percutaneous cholecystolithotomy with the rotational lithotrite. **A,** Access to the gallbladder was established by percutaneous transhepatic cholecystostomy using a right anterolateral entry into the gallbladder. The catheter entered the gallbladder wall in its distal half, and there were multiple filling defects as a result of calculi. **B,** After dilation of the percutaneous tract, the rotational lithotrite with its sheath has been introduced into the gallbladder lumen. The gallbladder was distended with dilute contrast material, and the calculi were well visualized. The struts around the propeller protected the gallbladder wall, whereas the calculi were attracted into the propeller by a vortex created within the gallbladder fluid.

era of laparoscopic cholecystectomy. Now most procedures are done on an elective basis.

Combined Surgical and Radiologic Intervention: Minicholecystostomy

The minicholecystostomy procedure was described by Burhenne and Stoller (1985) and included provision of emergency decompression of the gallbladder and the possibility of percutaneous stone removal 7 to 10 days later without the need for tract dilation. After localization of the gallbladder by US, a small abdominal incision is made over the gallbladder fundus under local anesthesia and intravenous analgesia. A 24-Fr Foley catheter is placed into the gallbladder, and the fundus of the gallbladder is sutured to the combined peritoneum and posterior layer of the rectus sheath, creating a short, wide tract. After 1 week of external gallbladder drainage, the gallstones can be removed under fluoroscopic control, usually without analgesia. Large stones can be fragmented with stone-crushing forceps and removed mechanically with a variety of instruments (Fig. 32.6).

The minicholecystostomy approach avoids the risks of hepatic hemorrhage, bile leakage, and vasovagal reactions associated with dilation of a percutaneous cholecystostomy tract, and it facilitates repeated subhepatic access to the gallbladder. The success rate of stone removal was 97% for gallbladder stones, 86% for cystic duct stones, and 63% for common bile duct stones; no serious complications and no deaths resulted (Burhenne & Stoller, 1985; Gibney et al, 1987). Given the safety and efficacy of laparoscopic cholecystectomy and percutaneous cholecystostomy, this technique is rarely indicated.

Extracorporeal Shock-Wave Lithotripsy

ESWL of gallstones was developed in the 1980s as a noninvasive form of treatment in selected patients with symptomatic, uncomplicated cholecystolithiasis (Burhenne et al, 1989; Sackmann et al, 1991; Sauerbruch et al, 1986). The original investigators and most subsequent investigators used relatively strict selection criteria, including a normal gallbladder on US, opacification of the gallbladder on oral cholecystography, and a limited number (one to three) and size (0.5 to 3 cm) of calculi. Cholestasis, pancreatitis, severe liver disease, hemorrhagic diathesis, abdominal aortic aneurysm, and pregnancy are considered contraindications, and most treatment protocols restrict ESWL treatment to calculi consisting of cholesterol, and they combine ESWL with adjuvant oral bile acid therapy. Usually two competing mechanisms lead to clearance of fragments from the gallbladder after ESWL: spontaneous passage of fragments through the cystic duct and fragment dissolution within the gallbladder by the adjuvant bile acids. ESWL alone also may lead to successful gallbladder clearance, regardless of the composition of the calculi, but a high number of shock waves and multiple treatment sessions are often needed (Fache et al, 1990; Rawat & Burhenne, 1990).

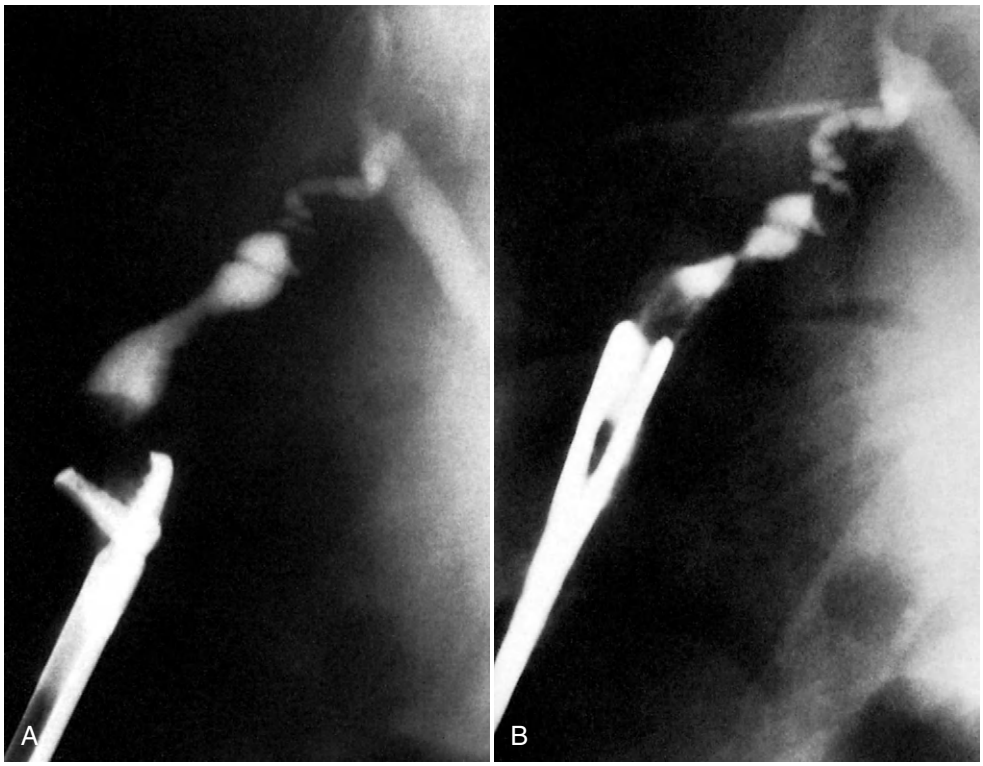

FIGURE 32.6. Mechanical cholecystolithotripsy through a subhepatic surgical minicholecystostomy. **A,** Because the gallbladder fundus had been sutured to the anterior abdominal wall at the time of emergency cholecystostomy, percutaneous tract formation was not necessary, and percutaneous gallstone removal was feasible 1 week later through a short, straight, 24-Fr percutaneous tract. The Storz stone-crushing forceps was introduced into the gallbladder, and a large calculus was fragmented. **B,** The fragments subsequently were extracted with the Mazzariello-Caprini forceps.

Three principal types of shock wave generators are available: 1) spark-gap, 2) piezoelectric, and 3) electromagnetic. The power settings and shock wave numbers may influence the result of ESWL considerably, but all three types of shock wave generators allow effective gallstone fragmentation. All devices of the current generation use water cushions with coupling membranes for transmission of the shock waves. ESWL requires no percutaneous cholecystostomy; targeting is accomplished with real-time US, and treatment can be done successfully in one or two sessions in an outpatient setting. Side effects of the treatment are minor and include cutaneous petechiae and occasional hematuria. Approximately one third of patients develop at least one attack of biliary pain attributable to fragment passage, and mild transient biliary pancreatitis is observed in approximately 2% of patients.

The rate of fragment clearance after ESWL depends on the total stone volume and on the size of the largest remaining fragment. On average, 70% of patients are stone free within 1 year, and 80% are stone free within 1.5 years after successful ESWL and adjuvant bile acid therapy (Becker et al, 1992; Ell et al, 1990; Sackmann et al, 1991). If only patients with solitary gallstones 2 cm in diameter are treated, the stone clearance rate is 80% to 90% within 6 to 18 months (Pauletzki et al, 1994; Sackmann et al, 1991). The problem of gallstone recurrence remains unresolved. Studies have shown that more than two thirds of patients develop recurrence within 6 years, and it is argued that laparoscopic cholecystectomy should be performed in the first place (Barkun et al, 1997; Borch et al, 1996; Cesmeli et al, 1999; Go et al, 1995).

Percutaneous Ablation of the Gallbladder

Despite successful gallstone removal, none of the percutaneous techniques can provide definitive cure of gallstone disease, because the abnormal, lithogenic gallbladder remains in place. It must also be considered that gallbladder-preserving treatment does not eliminate the risk of gallbladder carcinoma (So et al, 1990).

Nonsurgical ablation of the gallbladder may be defined as fibrotic obliteration of the gallbladder lumen. Ideally, the gallbladder mucosa would be eradicated completely, because this not only would eliminate the possibility of gallstone recurrence but also the long-term risk of gallbladder adenocarcinoma. Percutaneous gallbladder ablation was developed and tested experimentally and clinically to prevent gallstone recurrence by eliminating the functioning gallbladder through a cholecystostomy. A two-step approach was developed, including preliminary obliteration of the cystic duct by means of bipolar radiofrequency electrocautery and subsequent sclerotherapy of the gallbladder. Concentrated ethanol and sodium tetradecyl sulfate were used for gallbladder sclerotherapy without toxic side effects. Histologic studies in preliminary animal experiments revealed necrosis of the gallbladder wall within 2 weeks and fibrotic obliteration of the gallbladder within 8 weeks (Becker et al, 1988, 1989). The ablation procedure was tested in a group of 10 patients who, because of multiple medical risk factors, had undergone cholecystostomy instead of cholecystectomy for acute gallbladder disease (Becker et al, 1990). Although follow-up US studies gave no evidence of mucocele formation or stone recurrence, small gallbladder lumina remained visible in all patients, indicating that mucosal ablation was still incomplete. Although occasional attempts at gallbladder ablation have been reported by other investigators (van Overhagen et al, 1996), further technical improvements would be needed before wider clinical application.

SUMMARY

Percutaneous image-guided cholecystostomy offers a minimally invasive treatment of acute cholecystitis in high-risk patients. In acalculous disease, percutaneous cholecystostomy alone may be curative, unless the gallbladder wall already has become necrotic in the course of gangrenous cholecystitis. In calculous disease, interval cholecystectomy usually is required, although percutaneous gallstone removal through the cholecystostomy tract may be preferable in some cases. The indication for elective percutaneous gallstone removal by means of MTBE or percutaneous cholecystolithotomy has virtually disappeared, because the hospitalization required for these procedures is similar to that of laparoscopic cholecystectomy, and a definitive cure cannot be provided. ESWL is a noninvasive outpatient procedure and may be considered as a useful treatment option in the small group of patients who fulfill the selection criteria. Because of the relatively high recurrence rates observed in recent studies, however, laparoscopic cholecystectomy seems to be the more effective treatment.

CHAPTER 33

Technique of cholecystectomy

Shishir K. Maithel

OVERVIEW

The indications for performing open cholecystectomy have evolved since the advent and widespread use of laparoscopic cholecystectomy (see Chapter 34). Surgeons are now trained in laparoscopy at the initiation and for the duration of their training. In fact, as the pendulum has swung so far toward performing laparoscopic cholecystectomy, it may be argued that surgeons completing their training today are not appropriately versed in the techniques of the open operation, which ironically are most useful and best applied to the difficult gallbladder that is not amenable to laparoscopic excision. Along with discussing important anatomic and clinical considerations, this chapter focuses on three main techniques for performing open cholecystectomy: 1) *retrograde*, 2) *anterograde* (fundus-down), and 3) *partial* (subtotal) cholecystectomy for difficult situations.

LAPAROSCOPIC VERSUS MINILAPAROTOMY CHOLECYSTECTOMY

Any discussion of open cholecystectomy would be incomplete without briefly reviewing the major comparative studies that have addressed the different approaches mentioned above for removing the gallbladder. A small incision, or *minilaparotomy,* has been defined by most authors as an incision less than 8 cm in length. Many prospective randomized trials have compared the two techniques. Two such early studies were published in *The Lancet* in 1992 and 1994, and both reported advantages of the laparoscopic approach over a minilaparotomy, including shorter postoperative hospital stay and a decreased postoperative convalescence (Barkun et al, 1992; McMahon et al, 1994). However, a different conclusion was reported by Majeed and colleagues in 1996; they found no difference in hospital stay or time to return to work and full activity among patients who underwent cholecystectomy by the two techniques. Subsequent comparative analysis of the costs of laparoscopic versus small-incision cholecystectomy, based on the same population included in the Majeed study, suggested that small-incision cholecystectomy was less expensive than laparoscopic cholecystectomy (Calvert et al, 2000). This pattern of conflicting results has persisted in recent studies as well, as some trials report a benefit to the laparoscopic approach, but others report no difference, depending on the outcomes measured (Ros et al, 2001; Keus et al, 2008). Nevertheless, a market demand of sorts has popularized laparoscopic cholecystectomy as the technique of choice today.

INDICATIONS FOR OPEN CHOLECYSTECTOMY

The introduction of laparoscopic cholecystectomy has significantly influenced the treatment of patients with gallstones, as evidenced by an increase of 20% to 30% in the total number of cholecystectomies performed (Schwesinger & Diehl, 1996). This increase was predominantly in patients with uncomplicated cholelithiasis and in those undergoing elective surgery (Shea et al, 1998). Although it is likely that considerations such as reduced postoperative discomfort and smaller scars have made the procedure more acceptable to patients with minor symptoms, it is worth raising caution that the indications for cholecystectomy should not be extended simply because a minimally invasive approach is available.

Cholecystectomy usually is performed for symptomatic cholelithiasis and for its related complications, such as obstructive jaundice or biliary pancreatitis. Cholecystectomy for acalculous cholecystitis, gallbladder adenoma, or suspected gallbladder carcinoma is less frequent, with the open technique more appropriate for suspected carcinoma. Asymptomatic cholelithiasis has been suggested as an indication for cholecystectomy in diabetic or immunocompromised patients, but this indication remains controversial (Schwesinger & Diehl, 1996). Postcholecystectomy pain, which has been observed in as many as 30% of cases, may be the consequence of an operation performed for symptoms unrelated to the presence of gallstones (Bodvall & Overgaard, 1967).

In a multivariate comparison of complications after laparoscopic and open cholecystectomy, the overall complication rate was found to be distinctly lower after the laparoscopic approach (Jatzko et al, 1995). This finding was confirmed, and a lower mortality rate was observed, in a population-based cohort study comparing both surgical approaches (Zacks et al, 2002). However, in the laparoscopic era, it is exceedingly important to consider patient selection and preoperative factors when comparing the two techniques in a retrospective fashion. Wolf and colleagues (2009) recently reported on a single surgeon's experience with open cholecystectomy over a 9-year period from 1997 to 2006. In this study, more than half (56%) of patients who underwent an open cholecystectomy were American Society of Anesthesiologists class III or IV compared with only 10% of those who underwent a laparoscopic procedure. Furthermore, nearly 10% of patients in the open cholecystectomy group had prior upper abdominal surgery, compared with only 1% of those in the laparoscopic group. These factors clearly

predispose to the reported increase in morbidity and mortality rates associated with open cholecystectomy today.

Open cholecystectomy increasingly is performed only in cases in which laparoscopic techniques do not allow for a safe procedure or as part of a larger procedure, such as pancreaticoduodenectomy or partial hepatectomy. The presence of severe inflammation, such as in xanthogranulomatous cholecystitis (Guzman-Valdivia, 2005), or a concern for excessive bleeding in patients with cirrhotic portal hypertension are two examples of situations in which surgeons are much more likely to use the open technique. Although two prospective studies from centers where surgeons have considerable experience performing cholecystectomy in patients with cirrhotic portal hypertension have reported the feasibility and superiority of the laparoscopic approach in these patients (Ji et al, 2005; El-Awadi et al, 2009), it is the author's opinion that most surgeons still opt for an open procedure. These difficult cases may be recognized preoperatively or during laparoscopy. It has been suggested, however, that attempts at performing a laparoscopic operation prior to converting to an open technique might increase the incidence of major complications (Wolf et al, 2009). Finally, as mentioned above, a gallbladder mass that is concerning for malignancy is usually better suited to an open procedure. Concern over intraoperative gallbladder perforation (Z'Graggen et al, 1998; Weiland et al, 2002), inadequate staging, and an incomplete resection with a laparoscopic procedure are some of the reasons to choose an open technique when carcinoma is suspected.

PREOPERATIVE ASSESSMENT

Some clinical features should alert the surgeon to possible operative difficulties. A history of repeated and prolonged attacks of right upper quadrant pain might be associated with chronic inflammation and dense adhesions or fibrous obliteration of the triangle of Calot. Liver function tests should be performed routinely before cholecystectomy. Any abnormality (i.e., elevation) of the serum bilirubin or alkaline phosphatase requires serious attention, because it may not be caused by the presence of stones in the bile duct but may be a sign of other extrahepatic biliary tract disease. Possibilities of such alternate diagnoses include Mirizzi syndrome (Chapters 35 and 42A); tumors of the gallbladder (Chapter 49), bile duct (Chapter 50B), or pancreas (Chapter 58); a choledochal cyst (Chapter 46); and sclerosing cholangitis (Chapter 41). Although patients who are submitted to cholecystectomy usually will have undergone ultrasonography, more detailed investigations should be performed if any doubt exists as to the integrity of the bile duct. Computed tomography (CT; see Chapter 16) and magnetic resonance imaging cholangiography (see Chapter 17) are the initial studies of choice. Should further diagnostic evaluation be necessary, endoscopic retrograde cholangiography (see Chapter 18) usually helps identify stones or other ductal abnormalities. Attention should be directed to any anatomic variants in the biliary system or extrahepatic vasculature that may be visualized on the above imaging modalities. A mild elevation of the aspartate aminotransferase (AST) and alanine aminotransferase (ALT) may also signify considerable pericholecystic inflammation causing localized hepatocellular necrosis. This scenario is particularly relevant in the elderly population, in diabetic patients, and in patients who are relatively immunocompromised with a history and physical exam that is not indicative of the underlying severe inflammation.

Preoperative assessment may orient the operation toward either a laparoscopic or open technique. The results of these studies should not be used to condemn laparoscopic cholecystectomy for appropriate indications, but rather to argue for more critical preoperative evaluation of imaging studies that may alter the operative approach.

OPERATION

Two operative approaches are used to perform open cholecystectomy: 1) the *retrograde* technique, which entails initial dissection of the hilar structures of the gallbladder in the triangle of Calot, and 2) the *anterograde* or *fundus-down* technique, in which the gallbladder is first separated from the liver along the cystic plate, before the cystic duct and artery are ligated and divided. The retrograde approach was traditionally used in most cases, until the advent of laparoscopic cholecystectomy greatly altered the patient population undergoing open cholecystectomy. Now, given that open cholecystectomy is more frequently reserved for surgically difficult situations, the anterograde approach has gained popularity to avoid initial dissection in a hostile triangle of Calot. In addition, the anterograde technique has facilitated the use of small incisions.

Anatomy

A commanding knowledge of the anatomy of the bile ducts and of the possible variations is necessary to perform safe cholecystectomy, whether by a laparoscopic or open technique. Unidentified anatomic anomalies during operation may result in iatrogenic injuries to the biliary tree, so precise intraoperative identification of the anatomy is necessary before ligating or dividing any structure.

The triangle of Calot, first described in 1891, forms the basis of the anatomic dissection for performing safe cholecystectomy. As originally described, this triangle is formed by the cystic duct, common hepatic duct, and the cystic artery. A common misperception is that the superior border of this triangle is the inferior border of the liver. This, rather, is termed the *triangle of cholecystectomy,* and it has for its upper limit not the cystic artery but the inferior surface of the liver (Fig. 33.1; Rocko & Di Gioia, 1981). Routine meticulous dissection of this area will minimize iatrogenic injury and allow for safe cholecystectomy.

The normal location of the gallbladder neck and cystic duct junction is between the peritoneal surfaces within the right superior portion of the hepatoduodenal ligament. A variety of abnormalities can alter the standard anatomy or appearance of the gallbladder. A bilobar gallbladder or presence of septa usually is not relevant, as the gallbladder most often retains its normal location with respect to the liver and vital portal structures. Duplication of the gallbladder is rare and might be associated with one or two cystic ducts. Complete gallbladder agenesis is extremely rare, and the perceived absence of a gallbladder is most often associated with an intrahepatic location. In such cases, the gallbladder infundibulum is usually visualized extrahepatically. The gallbladder may be lying on the left side of a right-sided round ligament, still attached to the right side of the liver. In even rarer instances, the gallbladder has been observed attached to the left lobe of the liver, situated to the left of the round ligament (Fig. 33.2) (Fujita et al, 1998).

Variations in the junction between the cystic duct and common bile duct should be considered the rule rather than the

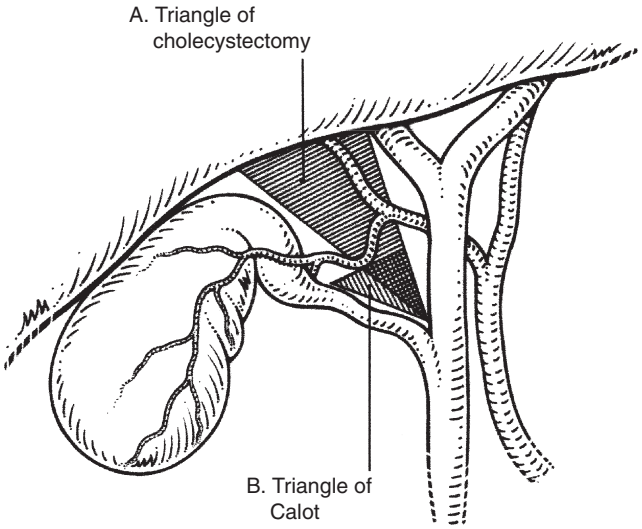

FIGURE 33.1. **A,** Triangle of cholecystectomy limited by the common hepatic duct, right hepatic duct, cystic duct, and inferior liver edge. **B,** The triangle of Calot limited by the common hepatic duct, cystic duct, and cystic artery.

exception in order to maintain a healthy respect for the anatomy and minimize iatrogenic injury during cholecystectomy (Figs. 33.3 and 33.4). The cystic duct may join the right side of the common bile duct after a long parallel course, or it may be very short and almost nonexistent. For the latter, it is imperative not to mistake the common bile duct for the cystic duct, which can lead to inadvertent ligation and division of the common bile duct. On the contrary, a perceived short cystic duct might actually be a long structure that is fused and running parallel to the common hepatic duct, or it may be draining directly into the right hepatic duct. The cystic duct also may empty into the left side of the hepatic duct, having crossed it anteriorly or posteriorly. The cystic duct occasionally may be contracted as a result of a chronic inflammatory process.

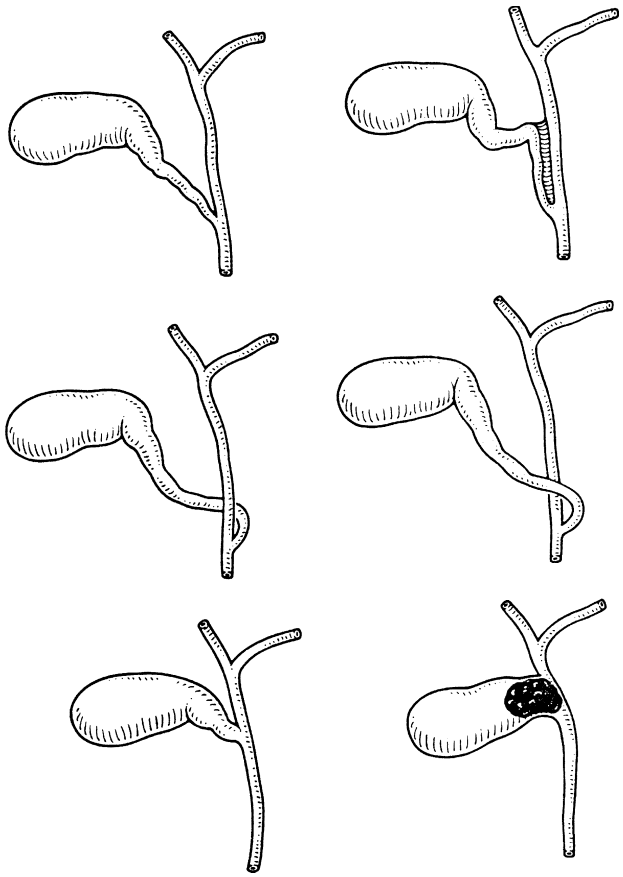

FIGURE 33.3. Variations in the confluence of the cystic duct and common hepatic duct.

FIGURE 33.2. Gallbladder located on the left side of the umbilical fissure and the ligamentum teres, attached to segment III of the liver.

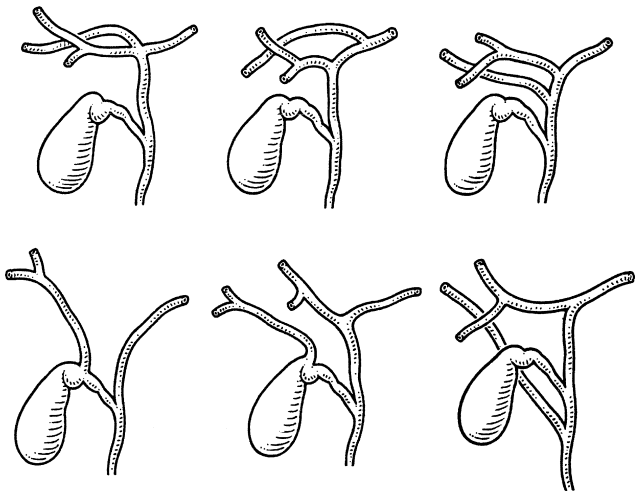

FIGURE 33.4. Variations in the confluence of the extrahepatic bile ducts and cystic duct.

An unrecognized abnormal confluence of the hepatic ducts probably represents the most important source of error leading to damage to the biliary tract during cholecystectomy (see Chapter 42A). A common anomaly that is worth noting is an early takeoff of the right posterior sectoral bile duct from the common duct either just above or below the cystic duct insertion. This sectoral duct may be confused for the cystic duct as it travels just inferior to or through the triangle of Calot. Alternatively, the cystic duct may actually arise from the right posterior sectoral duct. An abnormal confluence of the hepatic ducts has been reported in 43% of cases, and a low-lying right posterior sectoral duct has been reported in up to 20% of cases (Couinaud, 1957; Puente & Bannura, 1983; Champetier et al, 1989; see Fig. 33.4).

Although the necessity to systematically perform intraoperative cholangiography has been controversial for decades (Talamini, 2003), some surgeons have advocated the routine use of this procedure for many years. Besides showing unidentified stones or pathology in the intrahepatic or extrahepatic bile ducts, intraoperative cholangiography provides a precise view of the anatomy of the biliary ductal system. This view may help to avoid errors that result in severe biliary injury, or at least may facilitate early intraoperative detection of an injury (see Chapter 42A). In a review of 78 postcholecystectomy biliary strictures, intraoperative cholangiography was performed in only 29% (Kelley & Blumgart, 1985). Although some investigators advocate routinely performing intraoperative cholangiography in an effort to lower the incidence of iatrogenic bile duct injuries (Flum et al, 2003), its selective application still remains justified (Livingston et al, 2007).

Unrecognized abnormalities of the arterial anatomy may result in inadvertent ligation and division of the right branch of the hepatic artery. The cystic artery normally runs transversely toward the gallbladder as it branches off the right hepatic artery. The right hepatic artery travels posterior to the common hepatic duct in 80% of cases, thus an anterior location may be unexpected and predisposes it to injury, as it may be confused for the cystic artery. An accessory or replaced right hepatic artery that originates from the superior mesenteric artery is located posterolateral to the common bile duct and behind the cystic duct, where it also may be vulnerable to injury if unrecognized. Under normal circumstances, the cystic artery is a small vessel; if it appears to be unusually large, dissection must be continued to delineate the anatomy prior to dividing any structures to avoid injury to the right hepatic artery.

Technique

The retrograde technique, which involves initial dissection of the hilar structures of the gallbladder and of the cholecystectomy triangle, can be chosen when there is clear visualization of its anatomic limits. Whenever the features in this region are not clear because of acute or chronic inflammation, the anterograde or fundus-down technique is generally considered safer, because initial dissection of the gallbladder from the fundus allows progressive demonstration of the anatomy down to the infundibulocystic junction. The cystic duct may be safely ligated only when its relation with the gallbladder has been clearly delineated. Obtaining the "critical view" prior to cystic duct division as advocated by Strasberg (2002) for laparoscopic cholecystectomy is not only applicable but necessary for open cholecystectomy and to minimize iatrogenic biliary injury. The basic tenet of dissecting close to the gallbladder and clearly demonstrating every structure prior to ligation and transection should be adhered to for every procedure.

Incision

The operating surgeon usually stands to the right of the patient and has a choice of various types of incisions to gain access to the gallbladder. Three common incisions used include 1) an upper midline incision, 2) a right subcostal incision, and 3) an upper midline with right lateral extension. Depending on the clinical situation and the patient's body habitus, one incision may be preferred over the others; a right subcostal incision is most commonly performed, as it provides good, direct access to the gallbladder.

The increased emphasis on minimally invasive surgery across all surgical disciplines has resulted in a trend toward making shorter incisions. The safety of the procedure should not be compromised because of lack of exposure, especially because most open cholecystectomies are now performed for technically difficult situations. Ultrasound and axial images (computed tomography or magnetic resonance imaging) obtained preoperatively may help to localize the gallbladder and select the best incision. The minilaparotomy incisions have been described as the "minimum necessary" and "tailored to the individual patient," and their length may range from 2.5 to 10 cm (Majeed et al, 1996). When utilizing small incisions, it is important to maintain adequate exposure of the triangle of Calot in the right paramedian region, at the level of the twelfth thoracic vertebra. Exposure of the fundus of the gallbladder is less important, as it can be mobilized by traction into the operative field. To reduce abdominal wall trauma and minimize postoperative pain, small incisions should be optimized by using muscle-splitting techniques.

The *minimal-stress triangle* is located in the subxiphoid area and has for its base a horizontal line, joining the bilateral eighth costochondral cartilages, and for its vertex, the xiphoid process; the *triangle of Calot* lies within the boundaries of the minimal-stress triangle. Because the abdominal wall is less subject to tension and movement at this level during ventilatory and other movements, an incision in the minimal-stress triangle is reported to result in less operative pain (Tyagi et al, 1994).

The technique of microceliotomy described by Tyagi and colleagues (1994) uses a 3-cm transverse skin incision to the right of midline at the level of the base of the minimal stress triangle with a corresponding vertical incision of the anterior and posterior rectus sheath 1 cm lateral to the linea alba for approximately 5 cm in length extending inferiorly from the xiphoid process. This incision involves a muscle-splitting technique with lateral retraction of the rectus muscle and incision of the peritoneum through the falciform ligament. Clezy (1996) described a transverse incision situated 8 cm below the xiphoid process and to the right of midline followed by an incision of the anterior rectus sheath, medial retraction of the rectus muscle, and incision of the posterior sheath to allow access to the triangle of Calot.

The advantages of performing a cholecystectomy through a minimal incision versus a conventional one are controversial. Some prospective randomized studies have not demonstrated a clear advantage of small-incision cholecystectomy over conventional cholecystectomy after elective operations (Schmitz et al, 1997), but others have found the small incision to be associated with less postoperative pain, a shorter hospital stay, and an

earlier return to full activities after emergency cholecystectomy (Assalia et al, 1997).

Initial Assessment

Adhesions to the gallbladder may be present, especially in cases of severe cholecystitis. Such adhesions may be dense, vascular, and inflammatory, thus obscuring the anatomy. Dissection should be performed close to the gallbladder, keeping in mind that a cholecystocolic or cholecystoduodenal fistula might be present. In this case, the fistula must be divided in order to expose the gallbladder, with the opening in the colon or duodenum subsequently sutured closed or attended to in the most appropriate manner. If the gallbladder cannot be identified, one should suspect that it is scarred and contracted or that it is located within the liver parenchyma. In this instance, an intraoperative ultrasound examination may be useful. It may be feasible and safe to try to identify first the distal bile duct and trace it superiorly toward the infundibulum of the gallbladder and cystic duct junction, but this maneuver is not routinely recommended.

An abdominal exploration and manual palpation of other organs should be performed whenever possible, with special emphasis on the liver, hepatoduodenal ligament, and pancreas. The gallbladder must be palpated gently and not emptied by compression to prevent distal migration of small stones into the common bile duct.

Placement of Retractors and Optimizing Exposure

A self-retaining retractor that is fixed to the operating table is best used to provide adequate and constant body-wall retraction and spare the hand of the assistant. A fixed retractor should be placed in the right upper quadrant to provide upward and lateral retraction on the costal margin, regardless of which incision is used. For minilaparotomy incisions, however, retraction may need to be frequently altered and thus may be best suited for manual retraction. If feasible, upward retraction on segment VI and the left lateral segments of the liver facilitates exposure of the triangle of cholecystectomy (see Fig. 33.1). Care must always be taken not to compromise blood flow in the left portal pedicle with excessive or improperly placed retraction and not to tear the liver capsule. Moist laparotomy pads help to expose and isolate the operative field; pads placed behind and posterior to the right hepatic lobe serve to push the gallbladder into the wound. Perhaps the most crucial maneuver to optimize exposure is caudal retraction of the duodenum, gastric antrum, and colon. This is best accomplished with the assistant's hand or a hand-held, wide, malleable retractor or carefully applied fixed retraction to provide gentle traction on the hepatoduodenal ligament.

Emptying the Gallbladder

The dissection usually is facilitated by slight distension of the gallbladder, and thus routine aspiration of the gallbladder contents should not be performed; however, gross distension may obscure adequate exposure and inhibit the surgeon's ability to handle the gallbladder. In this circumstance, one may choose to puncture the fundus and aspirate bile, and bile culture is indicated for cholecystitis or cholangitis. Opening the gallbladder or spillage of bile should be avoided at all costs when there is a suspicion of gallbladder cancer. Spilled bile from a gallbladder containing malignant cells can result in peritoneal cavity seeding and tumor implantation, thus converting a potentially curable situation into an incurable disease.

Retrograde Cholecystectomy

A large Kelly clamp or similar instrument is placed to grasp the fundus of the gallbladder in the region of the Hartmann pouch (Fig. 33.5A), and dissection of the cholecystectomy triangle is started. The peritoneum covering the hepatoduodenal ligament is incised anteriorly across the region of the Hartmann pouch; this incision is continued posteriorly in the same way, giving complete access to the infundibulum of the gallbladder. It is important to keep the dissection close to the gallbladder and to delineate the junction between the gallbladder and the cystic duct. The lower limit of the triangle is the cystic duct, and a suture ligature is passed around it but is not tied; the slight tension produced by a clamp hanging on this ligature helps prevent migration of stones from the gallbladder into the cystic duct. The cystic artery is normally found just above the cystic duct, although a posterior location is also possible. It is important to dissect the artery toward the gallbladder to see its final distribution into the gallbladder wall (Fig. 33.5B) to prevent inadvertent ligature of an aberrant or anterior right hepatic artery. At this stage, the junction of the gallbladder infundibulum with the cystic duct and the distribution of the cystic artery into the gallbladder wall should be clearly visible. The cystic duct is palpated to detect stones, which if present should be "milked" back into the gallbladder (Fig. 33.6), and the cystic artery is ligated and transected (Fig. 33.7).

At this juncture, if a cholangiogram will be performed, a ligature or a clip is placed at the junction of the gallbladder and the cystic duct, and the cystic duct is partially opened through a small transverse incision approximately 2 to 3 mm distal. A 5-Fr catheter for cholangiography is inserted gently into the cystic duct, taking care not to tear the duct (Fig. 33.8). If easy passage is inhibited, and if the presence of a stone has been excluded by palpation, a valve or tortuous cystic duct may be the cause. It is helpful in this event to insert the end of a fine clamp into the cystic duct to dilate it gently; this often facilitates passage of the catheter. The tip of the catheter should remain in the cystic duct.

The catheter is fixed by tying the previously passed ligature around the cystic duct or by the loose application of a clip. Some catheters are equipped with an inflatable balloon that prevents the catheter from dislodging. Prior to performing cholangiography, the biliary system should be flushed with 10 to 20 mL of saline. This often allows for passage of small stones measuring less than 4 mm in diameter. All instruments and retractors are removed, and the patient is slightly rotated (20 degrees) to the right before contrast medium is injected. It is important to initially inject a small quantity (1 to 2 mL) of the contrast agent to be able to identify small stones in the bile duct. The ductal system of the biliary tract should be fully displayed, including intrahepatic ducts and free passage into the duodenum on the fluoroscopic images. Intravenous administration of 1 to 2 mg of glucagon may help to relax the sphincter of Oddi to faciliate passage of small stones. Once the biliary system is clear, the cholangiogram catheter is removed, and the cystic duct is ligated with a resorbable suture ligature; it is my preference to use a 3-0 vicryl suture (Fig. 33.9) and to place a clip to ensure biliary stasis from the cystic duct stump.

The gallbladder is dissected from its fossa with diathermy, gentle traction, or occasionally suction dissection. The dissection

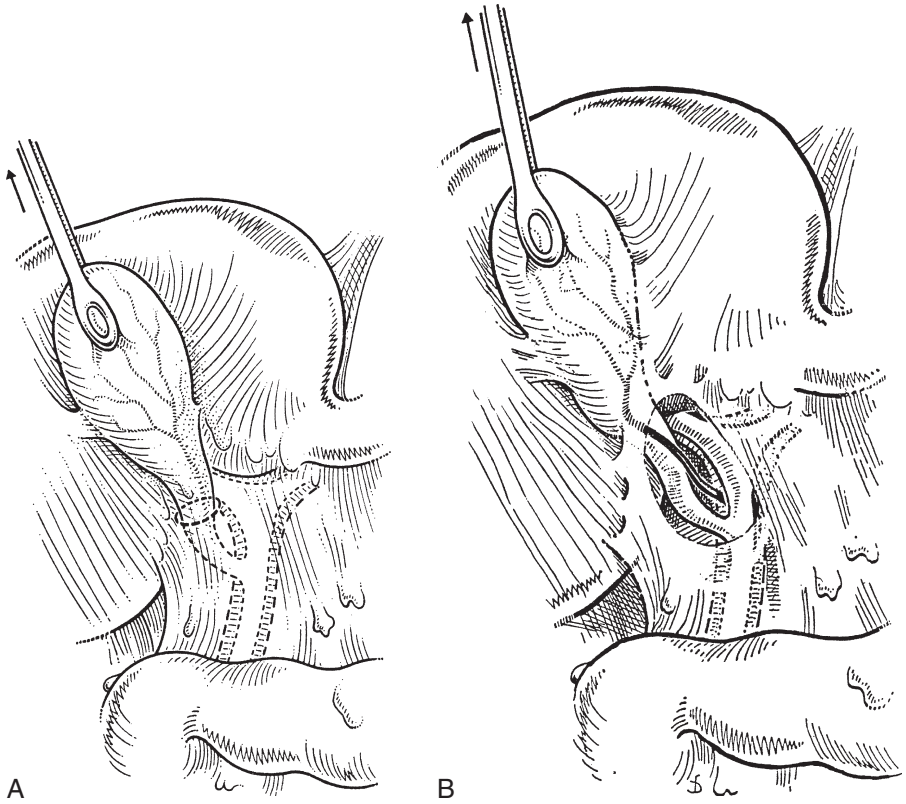

FIGURE 33.5. **A,** The gallbladder is grasped with a clamp, and dissection of the cholecystectomy triangle is started. **B,** The cystic artery is in its normal position, above the cystic duct.

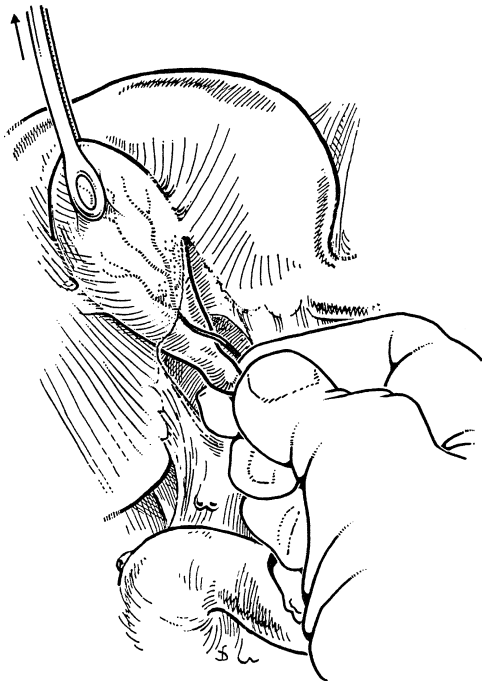

FIGURE 33.6. Palpation reveals a stone in the cystic duct, which may be "milked" back into the gallbladder.

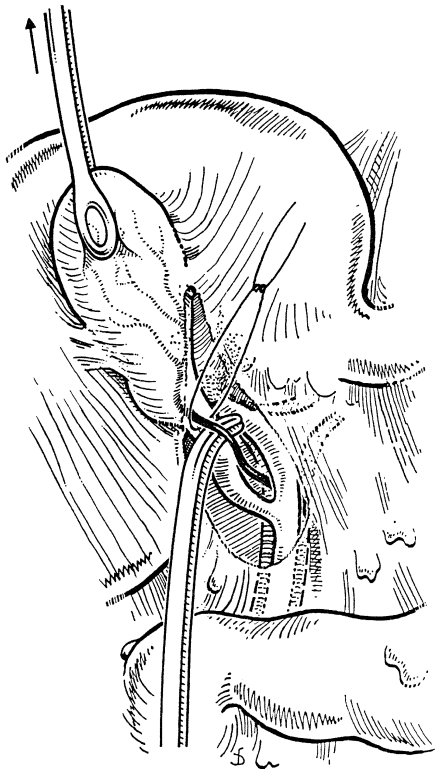

FIGURE 33.7. The cystic artery is ligated close to the gallbladder wall.

should be kept close to the gallbladder and within the cystic plate to avoid damage to the liver parenchyma, which nevertheless may occur in the presence of severe inflammation. In cases of acute cholecystitis with considerable edema, this plane may be best found by sharp dissection.

Occasionally, small bile ducts may connect the gallbladder to the intrahepatic bile ducts. Transection of these so-called *ducts of Luschka* is usually without consequence, when the biliary tree

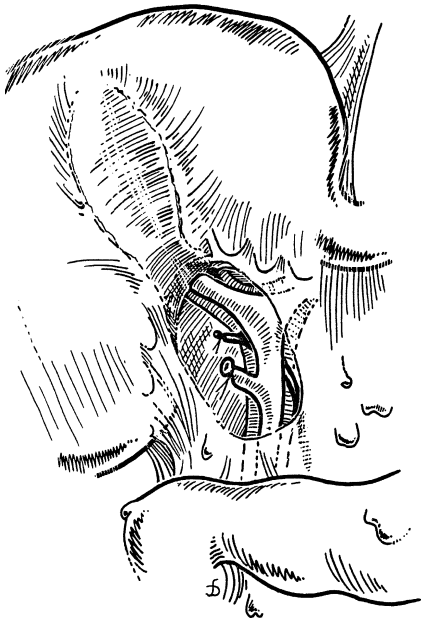

FIGURE 33.9. The catheter is removed, and the cystic duct is suture ligated.

is not obstructed distally. Hemostasis of the gallbladder fossa is obtained and, if available, the argon beam coagulator may be valuable here. If the liver parenchyma has been lacerated, however, a gauze pack should be placed in the gallbladder bed and held in place with constant pressure for at least 5 to 10 minutes. If the hemorrhage is not controlled with simple pressure, deep hemostatic sutures can be placed. Care should be taken to ensure that such sutures do not entrap major branches of the right portal pedicle, which can lie in close proximity. Formal closure of the gallbladder bed is not necessary and may even predispose to formation of a postoperative local fluid collection.

Once removed, the gallbladder should be routinely opened and assessed for the presence of tumors. The insertion of a drain before closing the abdominal wall is controversial and in most cases unnecessary. If a small bile leak is suspected or identified, insertion of a drain positioned close to the gallbladder bed usually prevents collection of bile. A small leak is without consequence and closes spontaneously within a few days if the distal bile duct is not obstructed. If only serosanguinous fluid drains during the first 48 hours, the drain can be safely removed; however, the drain should be retained if excessive oozing or leakage of bile occurs.

Anterograde, or Fundus-Down, Cholecystectomy

A large Kelly clamp or similar instrument is placed to grasp the fundus of the gallbladder, and an Adson (tonsil) clamp is used to grasp the peritoneum at the interface of the gallbladder and liver edge. An incision of the gallbladder serosa is performed 0.5 cm from the liver edge using diathermy, and a plane is developed between the serosa and the gallbladder wall to allow entry to the cystic plate. This plane is developed medially and laterally to dissect the gallbladder away from the liver. It is important to complete this dissection posterolaterally to facilitate lateral retraction of the gallbladder to best expose the cystic duct and artery. The gallbladder is still vascularized via the cystic artery (Fig. 33.10), and this structure is encountered as the medial dissection is continued toward the triangle of Calot. In the region of the infundibulum, the cystic artery is seen to enter the gallbladder wall (Fig. 33.11). After ligature and division of the cystic artery close to the gallbladder wall, thus protecting the right hepatic artery, the infundibulum is dissected free down toward its junction with the cystic duct. This technique may cause migration of stones from the gallbladder into the cystic duct, but careful palpation should identify these stones after the cystic duct has been isolated. If detected, the stones should be milked back into the gallbladder. Not more than 0.5 to 1 cm of cystic duct should be dissected to prevent injury to the common bile duct. Cholangiography and cystic duct ligature are performed in the same way as described for the retrograde technique.

Cholecystectomy Through Small Incisions

There is no fundamental difference between small-incision cholecystectomy and the techniques described above. Some authors prefer operating from the left side of the patient when a small incision is used; smaller retractors are adequate, and an additional light source (head lamp, light retractor, light suction) may be useful. The anterograde technique is the preferred approach through small incisions. The use of clips for controlling the

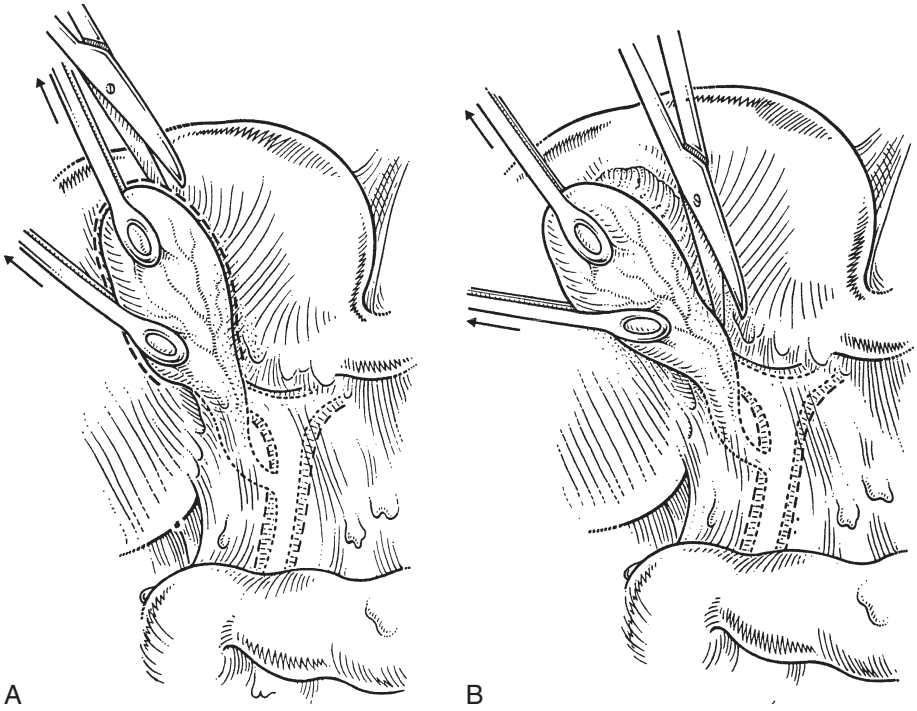

FIGURE 33.10. A, Anterograde, or fundus-down, cholecystectomy; the serosa of the gallbladder is incised 5 mm from the liver edge around the fundus. **B,** A plane is developed between the serosa of the gallbladder and the gallbladder wall, then between the liver and the gallbladder within the cystic plate.

cystic artery and the cystic duct may be safer than awkwardly tying through a small incision.

Partial Cholecystectomy

Cholecystectomy may be hazardous when only the fundus of the gallbladder can be recognized, and when the region of the infundibulum cannot be delineated because of fibrosis and inflammation obscuring the triangle of Calot (Fig. 33.12). In this case, it is often judicious to open the fundus and introduce a finger into the gallbladder to guide the dissection (Fig. 33.13A). Once the gallbladder is open, if no bile appears, the cystic duct is probably occluded by fibrosis and inflammation. If visualized, impacted stones should be removed, and care should be taken not to push any stones further into the cystic duct. If a gush of bile appears when a big impacted stone is

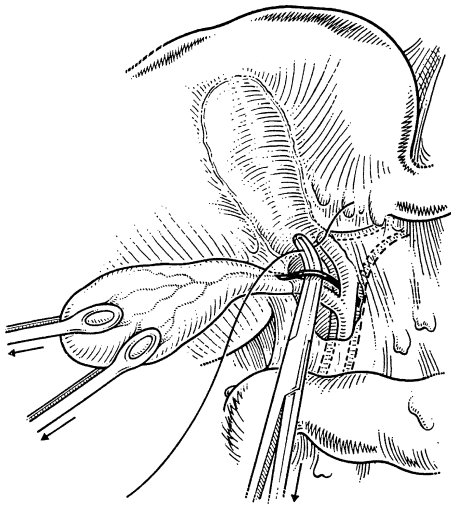

FIGURE 33.11. As the anterograde dissection progresses toward the gallbladder neck medially, the cystic artery is identified, ligated, and divided.

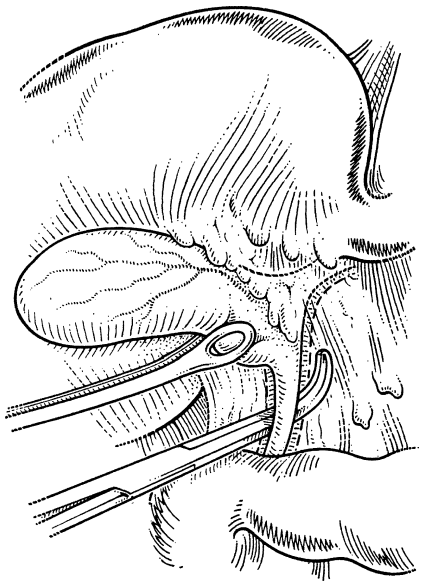

FIGURE 33.12. The common hepatic duct can be mistaken for the cystic duct when the region of the infundibulum cannot be delineated because of fibrosis and inflammation.

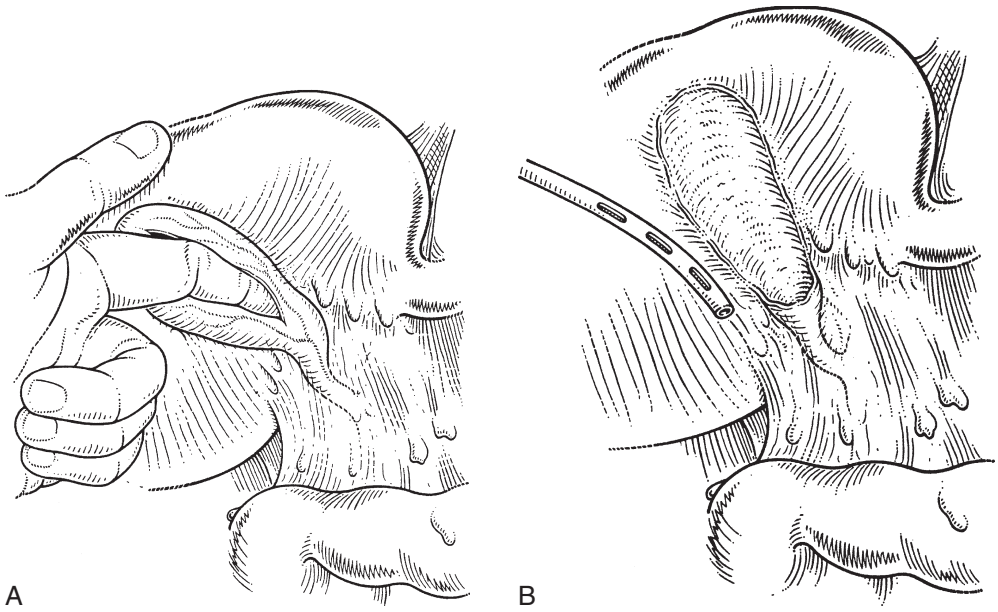

FIGURE 33.13. A, The fundus of the gallbladder has been opened, and a finger is introduced into the gallbladder for palpation. **B,** Partial cholecystectomy. The superficial part of the fundus and body of the gallbladder has been excised, leaving in place its attachment to the liver. The remaining mucosa is removed by curettage and/or fulgurated with electrocoagulation, and a closed-suction drain is placed near the infundibulum.

removed from the infundibulum, a cholecystocholedochal fistula may be present (Mirizzi syndrome type II; see Chapter 42A). In this circumstance, continued dissection to identify the cystic duct–bile duct junction risks significant biliary injury.

In cases of severe inflammation, a partial cholecystectomy may be the safest procedure (Di Carlo et al, 2009; Sharp et al, 2009). The anterior visible wall of the gallbladder is excised, but the posterior wall that contacts the liver is left in place down to the region of the infundibulum. The posterior wall mucosa may be removed by curettage, or it may be fulgurated with electrocoagulation or argon beam coagulation, although this last step is not mandatory. A closed-suction drain is placed in the region of the infundibulum (Fig. 33.13B). When the regional anatomy is severely altered by inflammation, any attempt at ligating the cystic duct may predispose to injury and can usually be safely avoided, particularly when no bile leakage is visualized. Should the anatomy favor an attempt at cystic duct closure, or when bile leakage is observed, the orifice of the cystic duct is best closed from within the gallbladder, using a purse-string or oversew technique. When a cholecystocholedochal fistula is suspected, it is advisable to keep a rim of gallbladder wall intact to allow for a subsequent cholecystoduodenostomy or a cholecystojejunostomy (see Chapters 29 and 42A). Adequate biliary drainage with closed-suction drains obviates the need for immediate definitive repair and/or reconstruction; it can be delayed, possibly even avoided, with postoperative endoscopic stenting procedures. Attempts at immediate, direct repair of the fistula are unnecessary, difficult, and potentially hazardous (Baer et al, 1990).

Partial cholecystectomy has also been advocated for patients with severe portal hypertension to prevent significant hemorrhage during dissection of the triangle of Calot (Bornman & Terblanche, 1985; Cottier et al, 1991). Bleeding from the transected wall of the remaining gallbladder is controlled with a running absorbable suture.

INTRAOPERATIVE PROBLEMS

Intraoperative problems have been related to three main causes: 1) dangerous surgical technique, 2) dangerous anatomy, and 3) dangerous pathology (Johnston, 1986; see Chapter 42A). Insufficient preoperative assessment of a complicated situation is another avoidable reason for intraoperative difficulties.

Dangerous technique arises from inadequate or imprecise application of the principles of cholecystectomy, insufficient experience, inadequate incision and exposure, or inadequate assistance (Andren-Sandberg et al, 1985). Some of the anatomic variations that have been mentioned previously are particularly dangerous, especially a narrow common bile duct, which can be mistaken for the cystic duct (see Chapter 42A).

Dangerous pathology includes chronic or acute inflammation that results in obscured anatomy and increased vascularity in the region of the cholecystectomy triangle (see Fig. 33.12). Portal hypertension is associated with increased venous collateralization, which makes the dissection hemorrhagic and dangerous. Partial cholecystectomy has been advocated in both situations (Bornman & Terblanche, 1985; Cottier et al, 1991).

Hemorrhage in the cholecystectomy triangle represents a potential danger, because attempts at hemostasis by placing clamps with obstructed and insufficient view may result in inadvertent clamping of the right or common hepatic artery or of the bile duct (Fig. 33.14). In this situation, the surgeon should first attempt to control the hemorrhage by digital compression or by clamping the hepatoduodenal ligament (Fig. 33.15) to localize its precise origin. Grasping the bleeding vessel should be done with precision so as to limit the risk of including another structure in the ligature. Cholangiography, even if already performed, may be repeated and analyzed carefully after hemostasis is achieved, because it may reveal an iatrogenic

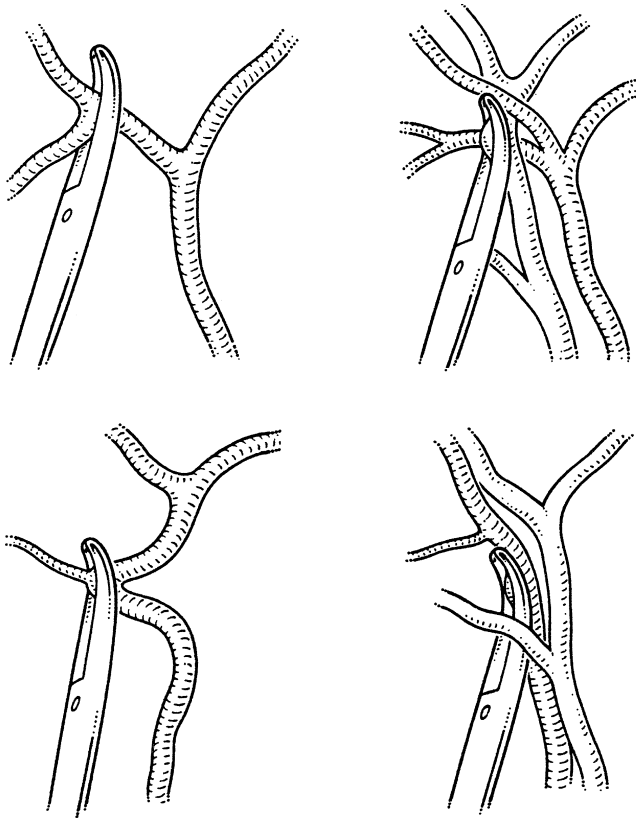

FIGURE 33.14. Blind placement of clamps for hemostasis can result in injury to the hepatic artery or bile duct.

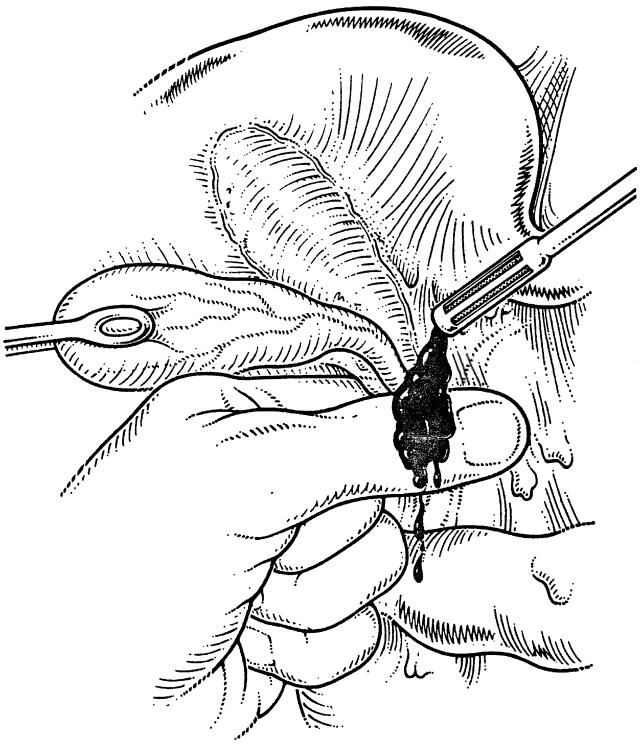

FIGURE 33.15. Hemorrhage should be controlled first by manual clamping of the hepatoduodenal ligament until exposure is optimized, thus facilitating precise hemostasis.

injury to the bile duct, such as a leak or an incomplete or complete occlusion. Methods to deal with intraoperative recognition of an iatrogenic injury of the bile duct are discussed in Chapter 42A.

CHAPTER 34

Laparoscopic cholecystectomy and choledocholithotomy

Alexander Nagle and Nathaniel J. Soper

OVERVIEW

Gallstones are an extremely common condition, occurring in approximately 10% to 20% of the adult population. It has long been recognized that the treatment for symptomatic gallstones is cholecystectomy, one of the most commonly performed abdominal surgical procedures. In developed countries, most cholecystectomies are performed laparoscopically. To give an example, 90% of cholecystectomies in the United States are performed laparoscopically (Csikesz et al, 2009). Laparoscopic cholecystectomy is considered the gold standard for the surgical treatment of gallstone disease, because it results in less postoperative pain, better cosmesis, shorter hospital stays, and less disability when compared with open cholecystectomy (Soper et al, 1992c). The early experience with laparoscopic cholecystectomy was associated with an increased risk for common bile duct (CBD) injuries. However, through advances in education and training, this risk has been decreased. In the hands of properly trained surgeons, laparoscopic cholecystectomy can be safely performed in the majority of patients.

Over the past several years, much investigation has been done on techniques to improve outcomes from laparoscopic cholecystectomy. One approach has been to use smaller diameter ports and instruments to perform the operation (Gurusamy et al, 2010); however, the limited variety of 2 mm diameter instruments and their lack of robustness have hindered this approach. More recently, there has been an upsurge in interest in the performance of laparoscopic cholecystectomy using a single incision at the umbilicus or via natural orifice translumenal endoscopic surgery (NOTES). Up to this time, no study has definitely proven the advantage of either smaller incisions or fewer incisions compared with standard multiport laparoscopic cholecystectomy, other than the potential for improved cosmesis. This chapter discusses the history and current status of laparoscopic cholecystectomy and the laparoscopic management of CBD stones.

HISTORY

Gallbladder disease has plagued humanity since antiquity, and gallstones have been found in Egyptian mummies dating from more than 2000 years ago (Beal, 1984). Some have even conjectured that the death of Alexander the Great was caused by acute cholecystitis. Although the presence of the gallbladder was acknowledged by anatomists beginning in the fifth century, the gallbladder's true function was not elucidated until relatively recently. The potential for elective surgical treatment of gallstones was limited by the crude diagnostic techniques available, but the first successful cholecystolithotomy likely occurred in 1676, when Joenisius apparently extracted gallstones from a biliary fistula of the abdominal wall (Beal, 1984). By the eighteenth century, physicians increasingly realized that cholelithiasis could cause abdominal pain and jaundice. As surgical treatment was not considered to be feasible, numerous treatments were described, including purgatives, therapeutic bleeding, and emetics. It was not until 1867 that John S. Bobbs of Indianapolis performed an elective cholecystotomy for hydrops of the gallbladder under chloroform anesthesia (Cutter, 1928). Various other surgeons then described techniques for performing cholecystolithotomy in this era, as Listerian principles were being adopted around the world.

Carl Langenbuch of Berlin performed the first elective cholecystectomy in 1882 on a patient who had been suffering from symptomatic cholelithiasis for more than 10 years. Although the patient was found "smoking a cigar" the following day, he was not discharged from the hospital for two months. Dr. Langenbuch stated, "My opinion is that a cholecystectomy is suitable for those cases in which both the patient and physician have reached the end of their patience" (Langenbuch, 1882). The first cholecystectomy was not performed in the United States until 1886, by Justus Ohage of Minnesota. For the next 30 years, considerable debate followed at surgical meetings as to whether a cholecystolithotomy or cholecystectomy would be preferable for gallstone disease. By the 1920s it was generally accepted that cholecystectomy was most suitable, except in the face of severe inflammation, rendering the dissection hazardous to the patient.

Over the ensuing 6 decades, open cholecystectomy was the procedure of choice for patients with symptomatic cholelithiasis. Great strides were made in developing diagnostic methods for demonstrating the presence of gallstones, using either cholecystography or ultrasound (US). Throughout much of this time, many of the operations were done by family physicians not well trained in surgical techniques, and thus bile duct injuries were seen relatively frequently. In Christopher's *Textbook of Surgery* from 1936 it states, "Frank hemorrhage from the cystic artery and injury to the CBD are the two great dangers in performing cholecystectomy. Cholecystectomy will not only be easier but safer if it is begun at the cystic duct, since the circulation will be controlled at the outset." Later, other surgeons suggested that a top-down or fundus-first technique for performing cholecystectomy would be less likely to result in CBD injury. Various surgical debates included whether to perform intraoperative cholangiography on a routine or selective basis and the appropriate timing for performing cholecystectomy in the face of acute cholecystitis. Some surgeons advocated performing cholecystectomy via a small incision (minicholecystectomy) to minimize the discomfort and disability brought

about by larger incisions during gallbladder removal (Basu et al, 2006).

By the 1980s, the rates of morbidity and mortality for open cholecystectomy were quite acceptable. In published reports of large series taken from population-based studies or from single institutions, mortality rates ranged from 0.1% to 0.6%, and overall morbidity was 10% to 15% with bile duct injuries occurring in 0.1% to 0.2% of patients. It was also shown clearly that complications occurring with open cholecystectomy were directly related to the condition of both the patient and the gallbladder at the time of operation. Postoperative hospital length of stay for open cholecystectomy varies widely, but most elective cases are discharged within 4 days of operation (Hall, 1987).

Medical Therapy for Gallstone Disease

The prevailing public perception of open cholecystectomy as a procedure that results in pain, disability, and a disfiguring scar engendered many attempts in the 1980s and 1990s at nonoperative treatment of gallstones (Schoenfield & Lachin, 1981; Schoenfield et al, 1990). In addition, an understanding of the chemistry of gallstones led to numerous attempts to develop agents that could dissolve cholesterol gallstones. By the mid-1980s, ursodeoxycholic acid was made commercially available for oral administration, and its use was described in several clinical studies. Unfortunately, the indications for this agent were limited, and the 40% rate of complete gallstone dissolution in this highly selected group was disappointing (Roda et al, 1982). In the late 1980s gastroenterologists and interventional radiologists tried to increase this dissolution rate by attempting direct contact dissolution of gallstones. The biliary tree was accessed percutaneously, and methyl tert-butyl ether (MTBE) was instilled in the gallbladder. This therapy was invasive and had significant side effects, thus it was rapidly abandoned (Thistle et al, 1989).

In the early 1980s, extracorporeal shock wave lithotripsy (ESWL) was shown to be efficacious therapy for kidney stones. Others extrapolated that shock wave therapy might also break gallstones into smaller fragments that could then be more effectively dissolved. A brief flurry of interest and activity in the use of ESWL for gallstones followed, but the selection criteria limited this to fewer than 20% of gallstone patients. Despite strict selection criteria, the efficacy of treatment at 6 months was only 22%, and the gallstone recurrence rate of 10% per year for the first 5 years left much to be desired (Sackmann et al, 1990).

These disappointing results with therapies that dissolve or fragment gallstones while leaving the gallbladder in situ reinforced the concept that cholecystectomy was the only therapy that cured symptomatic cholelithiasis immediately and permanently. At the same time that the poor results of ESWL were being disseminated, a revolutionary new means of gallbladder removal was being developed.

Laparoscopic Cholecystectomy

The technique of laparoscopy (*lapara,* the flank; *skopein,* to examine) was initially developed near the outset of the twentieth century. However, until the 1960s, its use was strictly limited to diagnostic procedures within the peritoneal cavity. Gynecologists first used laparoscopic techniques to perform tubal ligation. By that time, the laparoscopic optics, light sources, and carbon dioxide insufflators had been markedly improved, but the eyes of the surgeon were wedded to the eyepiece of the laparoscope during performance of the operation. Despite this limitation, Dr. Kurt Semm of Kiehl, Germany, the father of "pelviscopy," performed the first laparoscopic appendectomy in 1980 (Semm, 1982). By 1983, Semm stated that "laparoscopic cholecystectomy and the bowel anastomosis under laparoscopic vision had moved into the domain of the possible" (Manegold, 1985). Two years later, a German surgeon named Eric Muhe working in Böblingen, West Germany, performed the first laparoscopic cholecystectomy (Litynski, 1996). He used a modified operating laparoscope placed at the umbilicus after establishing pneumoperitoneum. Muhe later changed his technique to perform cholecystectomies through a small, open tube placed in the right upper quadrant without pneumoperitoneum. Despite presenting his initial work at the congress of the German Surgical Society in 1986, Muhe's approach was rejected by German surgeons and largely forgotten. In 1987 a French surgeon, Phillipe Mouret of Lyon, France, performed laparoscopy on a woman with both gallstones and a gynecologic disorder. He performed the first video laparoscopic cholecystectomy by using a camera attached to the laparoscope, thereby allowing the entire operating team to view the operative field. As he was in private practice, few other surgeons learned of his work initially, but word spread within France. The following year both François DuBois in Paris and Jacques Perissat in Bordeaux, working in academic centers, performed laparoscopic cholecystectomy. Relatively soon thereafter, two groups of general surgeons in the southern United States performed laparoscopic cholecystectomy. They used a laser to dissect the gallbladder away from the liver bed, as it was thought that monopolar electrocautery used within the closed abdomen was potentially a hazard for combustion. The first publication of the "laparoscopic laser cholecystectomy" was published in the industry publication "Laser Practice Report" by Reddick in December 1988, whereas DuBois and colleagues published their first 36 cases (in English) in 1990.

All of these early pioneers in laparoscopic cholecystectomy used a four-port technique with the laparoscope placed at the umbilicus, albeit the French surgeons stood between the patient's legs, and the Americans worked from the patient's left side. Word of this new laparoscopic operation spread relatively rapidly after its introduction at the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) meeting in Louisville in April 1989, and the subsequent American College of Surgeons meeting in Atlanta in October 1989. Given that cholecystectomy makes up nearly a third of the work in many general surgeons' practices, surgeons in the United States feverishly attempted to learn this technique for a competitive advantage. Numerous courses sprang up across the United States and Europe. Many of these courses were sponsored by industry and provided little hands-on experience for surgeons who generally were poorly trained in basic laparoscopic techniques. It must be remembered that laparoscopy differs significantly from traditional open surgery in several important ways: 1) a satisfactory pneumoperitoneum of carbon dioxide gas must be established in the abdominal cavity; 2) the laparoscopic image of the operative field is controlled by someone other than the surgeon, and this image is highly magnified and two-dimensional; 3) the surgeon views a video screen, rather than the operative field itself; and 4) the laparoscopic ports act as a fulcrum, so the tips of the instruments move in the direction opposite the surgeon's

hands. Given these and other differences, it is not surprising that a learning curve effect was quickly recognized, whereby the incidence of bile duct injuries was much higher in a surgeon's early cases compared with later in his or her experience (Meyers & Southern Surgeons Club, 1991).

Despite the increased incidence of bile duct injury, which was not initially acknowledged, the visible evidence of diminished incision length and anecdotal reports of less postoperative pain rapidly caught the eye of the lay public. Articles appeared in newspapers and news magazines touting the advantages of "minimally invasive surgery," "minimal access surgery," and other monikers such as "belly button surgery," "laser surgery," and so on, with the result that those who required cholecystectomy demanded that the operation be performed laparoscopically.

Going from an unheard of procedure in 1988 to one that had become the subject of numerous published case series by 1992, the adoption rate of this technology in the United States was unprecedented. In 1992, the National Institutes of Health (NIH) organized a consensus development conference titled "Gallstones and Laparoscopic Cholecystectomy," which was sponsored by the National Institute of Diabetes and Digestive and Kidney Diseases and the NIH office of Medical Applications of Research. At the conclusion of the conference, it was determined that laparoscopic cholecystectomy "provides a safe and effective treatment for patients with symptomatic cholelithiasis" and "provides distinct advantages over open cholecystectomy" but that "the outcome of laparoscopic cholecystectomy is influenced greatly by the training, experience, skill, and judgment of the surgeon performing the procedure" (Gollen et al, 1993).

It was also in 1992 that the first of several small prospective randomized trials comparing laparoscopic to open cholecystectomy was published. Each of these showed that the laparoscopic approach was associated with less pain, shorter hospitalization, and a more rapid return to full activity (Barkun et al, 1992). Coincidentally, 1992 was also the year in which a publication of a large series of laparoscopic cholecystectomies first suggested that this technique may become the new gold standard for performance of the operation (Soper et al, 1992b). By contrast, a relatively large randomized trial comparing laparoscopic with open cholecystectomy using a minilaparotomy showed no difference in many standard outcome measures (Majeed et al, 1996).

Over the ensuing years, a number of trials confirmed what had previously been shown in the open cholecystectomy literature. The aphorism "get it while it's hot" could be used to describe the preferred approach to laparoscopic cholecystectomy for acute cholecystitis: prospective randomized trials showed that early cholecystectomy resulted in fewer complications and shorter hospitalization than interval cholecystectomy (Lo et al, 1998). Intraoperative cholangiography was performed on a selective basis by the majority of practicing surgeons, despite several population-based studies showing decreased rates of bile duct injury when performed by surgeons using cholangiography routinely during laparoscopic cholecystectomy (Flumm & Massarweh, 2007). Numerous reports were published concerning the causes of bile duct injury during laparoscopic cholecystectomy and the means by which these injuries could be minimized, including dissecting "the critical view of safety" before clipping or dividing the cystic structures (Strasberg et al, 1995).

Table 34.1

Indications for Laparoscopic Cholecystectomy

Symptomatic cholelithiasis
Biliary colic
Acute cholecystitis
Asymptomatic cholelithiasis
Sickle cell disease
Total parenteral nutrition
Chronic immunosuppression
No immediate access to health care facilities (e.g., missionaries, military personnel, Peace Corps workers, relief workers)
Incidental cholecystectomy for patients undergoing laparoscopic procedure for other indications
Acalculous cholecystitis (biliary dyskinesia)
Gallstone pancreatitis
Gallbladder polyps greater than 1 cm in diameter
Porcelain gallbladder

INDICATIONS

An increase in the number of cholecystectomies performed has been documented since the introduction of laparoscopic cholecystectomy (Escarce et al, 1995; Legorreta et al, 1993; Nenner et al, 1994; Steiner et al, 1994). It is unclear whether patients are more willing to undergo a laparoscopic procedure, rather than to endure biliary colic, or whether the indications for cholecystectomy have become more liberal with the advent of laparoscopic cholecystectomy.

The indications for laparoscopic cholecystectomy are, and should be, the same as the indications for open cholecystectomy (Table 34.1). Patients generally have documented cholelithiasis and symptoms attributable to a diseased gallbladder (see Chapter 30). Biliary colic is typically a severe and episodic right upper abdominal or epigastric pain that often radiates to the back. Attacks frequently occur postprandially, or they awaken the patient from sleep. Patients with asymptomatic gallstones have less than a 20% chance of ever developing symptoms, and the risks associated with prophylactic operation outweigh the potential benefit of surgery in most patients (Fendrick et al, 1993; Ransohoff & Gracie, 1993; Ransohoff et al, 1983). Prophylactic laparoscopic cholecystectomy for asymptomatic cholelithiasis may be justified for certain patients, however, such as those with sickle cell disease, those who require long-term total parenteral nutrition, and those who are therapeutically immunosuppressed after solid organ transplantation. Patients with sickle cell disease often have hepatic or vasoocclusive crises, which can be difficult to differentiate from acute cholecystitis (Tagge et al, 1994). In transplant patients, there is concern that immunosuppression would mask the signs and symptoms of inflammation until overwhelming infection had occurred (Hull et al, 1994). Recommendations in the literature range from mandatory screening and treatment of biliary disease before transplantation (Girardet et al, 1989) to prophylactic cholecystectomy 6 months after transplantation (Boline et al, 1991) to expectant management of all asymptomatic patients (Fendrick et al, 1993; Steck et al, 1991). Other possible indications for prophylactic laparoscopic cholecystectomy include known gallstones in patients who may not have access to modern health care facilities for an extended period, such as missionaries and military personnel, and patients who already are undergoing laparoscopic abdominal surgery for other indications (incidental laparoscopic

Table 34.2

Contraindications to Laparoscopic Cholecystectomy

Absolute

Unable to tolerate general anesthesia
Refractory coagulopathy
Suspicion of carcinoma

Relative

Previous upper abdominal surgery
Cholangitis
Diffuse peritonitis
Cirrhosis or portal hypertension
Chronic obstructive pulmonary disease
Cholecystenteric fistula
Morbid obesity
Pregnancy

cholecystectomy). Less commonly, individuals without gallstones but with typical biliary symptoms (i.e., acalculous cholecystitis or biliary dyskinesia) may be considered for the procedure (Soper, 1991). Other indications for laparoscopic cholecystectomy include gallstone pancreatitis and gallbladder polyps greater than 1 cm in size (see Chapter 49).

CONTRAINDICATIONS

Absolute and relative contraindications to performing laparoscopic cholecystectomy (Table 34.2) have decreased since the 1990s, as minimally invasive surgical equipment and skills have improved. Absolute contraindications include the inability to tolerate general anesthesia or laparotomy, refractory coagulopathy, diffuse peritonitis with hemodynamic compromise, cholangitis, and potentially curable gallbladder cancer. Diffuse peritonitis with hemodyInamic compromise represents a surgical emergency in which attempted laparoscopic cholecystectomy is not prudent, because the cause of the peritonitis is unclear or uncertain. Standard open laparotomy allows rapid determination of the cause and more expeditious management of the disorder, and pneumoperitoneum may exacerbate hypotension by diminishing venous return. Suspicion of gallbladder malignancy generally mandates that standard open resection be undertaken; this is because of persistent concerns with adequacy of resection and reports of port-site metastases associated with the use of minimally invasive surgical techniques for the treatment of intraabdominal malignancies (see Chapter 49). Relative contraindications are dictated primarily by the surgeon's philosophy and experience. These include previous upper abdominal surgery with extensive adhesions, cirrhosis, portal hypertension, severe cardiopulmonary disease, morbid obesity, and pregnancy.

Previous Abdominal Surgery

Intraabdominal adhesions secondary to previous abdominal surgery can tether underlying viscera and consequently increase the risk of hollow organ injury during placement of laparoscopic trocars (Wolfe et al, 1991). Previous lower abdominal operations typically add little difficulty in performing cholecystectomy, but patients with previous *upper* abdominal operations, especially in the right upper quadrant, present much more difficulty in gaining access to the area around the gallbladder. To diminish the risk of intraperitoneal injury, we routinely use the open Hasson technique for placement of the initial trocar. Other surgeons advocate the use of the Veress needle and percutaneous insertion of the initial trocar at a site remote from the abdominal wall scars. Once the initial trocar is placed, additional trocars are placed under direct laparoscopic visualization in an area free of adhesions. Some degree of laparoscopic adhesiolysis may be necessary to allow optimal port placement. Although early series demonstrated that previous abdominal surgery with the accompanying risk of adhesions was a predictor of conversion, it is clear that laparoscopic cholecystectomy may be performed safely on most of these patients.

Cirrhosis

Cirrhosis (see Chapter 70B) results in a brittle, friable, heavy liver that may be difficult to retract in the cephalad direction, limiting exposure of the porta hepatis and gallbladder. Cirrhosis also may be accompanied by decreased synthetic function of the liver, resulting in coagulopathy and portal hypertension. Coagulopathies should be reversed before performance of laparoscopic cholecystectomy.

The ability to achieve effective hemostasis laparoscopically is significantly compromised compared with that of open exposure. Portal hypertension and aberrant portosystemic venous collateralization may lead to exsanguinating hemorrhage from small veins in the liver bed and porta hepatis or from large veins in the abdominal wall (e.g., a recanalized umbilical vein) at risk for laceration during trocar puncture. Laparoscopic cholecystectomy may be attempted with care in these patients by experienced surgeons. Various hemostatic agents and energy sources need to be available in case bleeding develops; the argon cautery device can be quite useful. Prompt conversion to an open procedure is recommended in the face of unusual bleeding, regardless of the stage of the operation (Soper, 1993). Additionally, particular care should be taken in making watertight closures for all incisions to minimize postoperative ascitic leak (Poggio et al, 2000).

Cardiopulmonary Disease

Preexisting cardiac conditions mandate vigilant intraoperative observation for significant arrhythmias known to be associated with establishment of a carbon dioxide pneumoperitoneum, including bradycardia and ventricular ectopy. In patients with cardiac pacemakers, alternative energy sources, such as bipolar electrosurgery or ultrasonic coagulation, should be used because of known interference problems caused by monopolar electrosurgical devices.

Most patients undergoing laparoscopic cholecystectomy exhibit mildly elevated P_{CO_2} (Liu et al, 1991). Chronic obstructive pulmonary disease may predispose patients to carbon dioxide retention disproportionate to the measured end-tidal value during laparoscopic cholecystectomy (Wittgen et al, 1991). Prudent measures in these patients include obtaining preoperative pulmonary function tests, making arterial blood gas determinations, and maximizing pulmonary function by smoking cessation and bronchodilator therapy. An intraoperative arterial catheter also should be placed to allow frequent measurement of P_{CO_2} and pH. Hypercarbia may manifest as hypertension, tachycardia, or ventricular arrhythmias; these should be addressed by immediate evacuation of the

pneumoperitoneum and stabilization. Gradual reestablishment of the pneumoperitoneum with a low pressure limit may be attempted, but the procedure should be terminated or converted to open if the hypercarbia recurs and is refractory to continued pneumoperitoneum.

Morbid Obesity

Morbid obesity was initially a relative contraindication to laparoscopic cholecystectomy primarily because of thickness of the abdominal panniculus relative to the length of early trocar and sheath designs, making institution and maintenance of a pneumoperitoneum problematic if not impossible. Various instrument manufacturers have since developed longer trocars to obviate this problem. The extra thickness of the wall inhibits the mobility of the trocars; therefore the trocars should be placed at the angle most likely to be used during the cholecystectomy. Longer trocars are also needed to traverse the abdominal wall to avoid trocar displacement and subsequent insufflation within the abdominal wall and subcutaneous emphysema. Longer instruments may be required to reach the gallbladder, and the initial umbilical trocar may need to be placed at a supraumbilical position.

Other challenging factors associated with morbid obesity include the presence of an enlarged, friable, fatty liver and an increased amount of adipose tissue around the gallbladder and in the area of the triangle of Calot. The surgeon should not hesitate to place additional trocars if needed (Schirmer et al, 1992). Retrospective and prospective studies have shown modestly increased operative times with performance of minimally invasive procedures in obese patient groups (Schirmer et al, 1992; Underwood et al, 1998). Today, laparoscopic cholecystectomy is commonly performed in morbidly obese patients and seems to offer the same advantages as in nonobese patients; it may also offer advantages more specific to obese patients, such as a decrease in wound infections, incisional hernias, and thrombotic complications (Miles et al, 1992; Talamini & Gadacz, 1992). Rather than being contraindicated in morbidly obese patients, laparoscopic cholecystectomy may become the preferred mode of therapy for these patients.

Pregnancy

Pregnancy is a controversial relative contraindication to laparoscopic cholecystectomy because of the unknown effects of prolonged carbon dioxide pneumoperitoneum on the fetus. It is generally accepted that elective laparoscopic cholecystectomy for biliary colic should be deferred until after pregnancy if possible. If necessary, laparoscopic cholecystectomy should be restricted to the second trimester, after organogenesis is complete and before the size and height of the uterine fundus cause it to encroach on the operative field. In the right upper quadrant, an open insertion of the initial port or alternative location of the initial port should be used to avoid injury to the gravid uterus, and the insufflation pressure should be limited to less than 12 mm Hg to avoid respiratory embarrassment and decreased vena caval return. The patient should be positioned in the left lateral decumbent position to minimize compression of the vena cava, and maternal hyperventilation with close monitoring of end-tidal carbon dioxide should be undertaken to prevent fetal acidosis. When visualization of the biliary tree is required, laparoscopic ultrasound (LUS) is used in place of cholangiography to avoid fetal radiation exposure. Finally, perioperative consultation with an experienced obstetrician is advisable, as is perioperative monitoring of the fetal heart.

Studies have shown that laparoscopic cholecystectomy can be performed safely during pregnancy, but only with great care (Soper et al, 1992a); A retrospective cross-sectional analysis of hospital discharge data from the Healthcare Cost and Utilization Project Nationwide Inpatient Sample database was conducted to study outcomes after cholecystectomy during pregnancy (Kuy et al, 2009). In this study, 9714 pregnant women who underwent cholecystectomy experienced significantly higher surgical, maternal, and fetal complication rates, lengths of stay, and costs with open cholecystectomy compared with laparoscopic surgery (Kuy et al, 2009). This may reflect the reasons for choosing an open cholecystectomy—such as prior surgery, gangrenous gallbladder, or trimester of pregnancy—rather than a true difference in complication rates between the procedures. High-volume surgeons, defined as those providers above the 75th percentile based on the annual number of cholecystectomies performed, had significantly lower rates of surgical complications.

PREOPERATIVE EVALUATION AND PREPARATION

Laboratory Test and Imaging Studies

Patients undergoing elective laparoscopic cholecystectomy for biliary colic should have preoperative liver function tests (LFTs). Elevations in these tests suggest the presence or recent passage of CBD stones. In patients with cholecystitis, LFTs are not typically elevated, because the obstruction is limited to the gallbladder; if present, elevated LFTs should raise concerns about complicating conditions such as cholangitis, choledocholithiasis, or Mirizzi syndrome (a gallstone impacted in the distal cystic duct causing extrinsic compression of the CBD; see Chapter 35).

In a patient with typical biliary colic, the only diagnostic study necessary before laparoscopic cholecystectomy is an abdominal US revealing gallstones. US shows the size and number of stones, the thickness of the gallbladder wall, the presence or absence of pericholecystic fluid, and the diameter of the CBD and other components of the biliary ductal system (see Chapter 13). Other nonbiliary disorders, such as hepatic lesions or steatosis, masses in the pancreas, or renal tumors, also may be diagnosed. When US results are negative despite typical biliary symptoms, cholecystokinin-stimulated biliary scintigraphy showing a low gallbladder ejection fraction with or without pain reproduction suggests acalculous cholecystitis or gallbladder dyskinesia (Soper, 1993).

If a patient with gallstones has atypical symptoms, however, a more extensive workup that includes upper gastrointestinal contrast radiography or endoscopy, computed tomography (CT), or cardiac and pulmonary evaluation may be appropriate to rule out significant nonbiliary disease processes. Magnetic resonance cholangiopancreatography (MRCP) may be useful to evaluate the common duct in patients with mild elevations of their transaminases or mild CBD dilatation on US (see Chapter 17). Additionally, if a patient has a dilated CBD, CBD stones, or jaundice, consideration should be given to a preoperative endoscopic retrograde cholangiopancreatography (ERCP) with

clearing of the stones followed by laparoscopic cholecystectomy (see Chapter 18).

Antibiotics

Routine preoperative antibiotic administration for elective laparoscopic cholecystectomy is controversial, with strong opinions on both sides. A recent meta-analysis of randomized controlled trials concluded that prophylactic antibiotics do not prevent infections in low-risk patients undergoing laparoscopic cholecystectomy; the usefulness of prophylaxis in high-risk patients—those older than 60 years and those with diabetes, acute colic within 30 days of operation, jaundice, acute cholecystitis, or cholangitis—remains uncertain (Choudhary et al, 2008). The most recent randomized, prospective study included in the above-mentioned meta-analysis showed no difference in the postoperative wound infection rate, although the control group had a 1.5% infection rate, and the antibiotic group had a 0.7% infection rate; however, because there was a total of 277 patients in the study, a type II error might have been made (Chang et al, 2006). Among papers that suggest a benefit of antibiotic prophylaxis is a recent randomized study that found fewer wound infections with ampicillin-sulbactam versus cefuroxime, particularly for infection caused by *Enterococcus* in the setting of high-risk patients undergoing elective cholecystectomy (Dervisoglou et al, 2006).

Accordingly, the routine use of antibiotic prophylaxis remains controversial. However, patients at high risk for having bacterial contamination of the bile should be given prophylactic antibiotics. These patients include those with acute cholecystitis, prior biliary tree instrumentation, choledocholithiasis, or those who are older than 70 years. Patients who are immunosuppressed and those with prosthetic devices also should receive preoperative antibiotics. Prophylactic antibiotics should be given within 1 hour of the skin incision, and the patient should be redosed if the procedure lasts more than 4 hours. The recommended antibiotics are cefazolin (1 to 2 g intravenously) or, in patients allergic to penicillins and cephalosporins, clindamycin plus one of either ciprofloxacin, levofloxacin, gentamicin, or aztreonam.

Deep Venous Thromboembolism Prophylaxis

The increased intraabdominal pressure as a result of pneumoperitoneum, reverse Trendelenburg position, and systemic vasodilation associated with general anesthesia in laparoscopic cholecystectomy may confer theoretical increased risk of deep venous thromboembolism (DVT). Despite scientific studies that demonstrate diminished venous outflow in femoral veins of patients undergoing laparoscopic procedures, implying venous stasis, no study to date has demonstrated a decrease in DVT with pharmacologic prophylaxis (unfractionated or low-molecular-weight heparin). Given the low rate of DVT in this patient population, an appropriately powered study designed to show a benefit of prophylaxis would require a vast number of patients. In the absence of convincing evidence in the literature, we recommend DVT prophylaxis with calf-length pneumatic compression devices in all patients undergoing laparoscopic cholecystectomy. In patients with additional risk factors—previous DVT, cancer, obesity, exogenous estrogens, projected operating time longer than 2 hours, age over 40 years—we recommend the addition of pharmacologic prophylaxis.

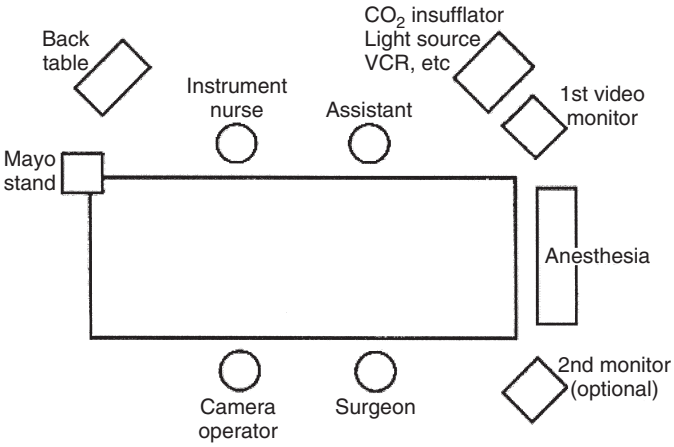

FIGURE 34.1. Room setup for laparoscopic cholecystectomy.

OPERATIVE TECHNIQUE

Operating Room Setup

Using the "American" technique, the surgeon stands to the left of the patient, the first assistant stands to the patient's right, and the laparoscopic video camera operator stands to the left of the surgeon (Fig. 34.1). In the "French" technique, the patient's legs are abducted, and the surgeon stands between them. The camera operator always must maintain the proper orientation of the camera and keep the operating instruments in the center of the video image. Following all instruments as they enter or exit the operative field is a matter of surgeon preference. Sharp instruments should never be moved intracorporeally unless they are under direct videoscopic vision.

Pneumoperitoneum

A working space, generally provided by a pneumoperitoneum, is essential for the surgeon to both view and operate within the abdominal cavity. Carbon dioxide has the advantage of being noncombustible and rapidly absorbed from the peritoneal cavity; however, it may lead to hypercarbia in patients with significant cardiopulmonary disease (Fitzgerald et al, 1992). Pneumoperitoneum can be established by either a closed or an open technique. In the closed technique, carbon dioxide is insufflated into the peritoneal cavity through a Veress needle placed blindly into the abdominal cavity; the needle is subsequently replaced with a laparoscopic port. In the open technique, a laparoscopic port is inserted under direct vision into the peritoneal cavity via a small incision; pneumoperitoneum is established only after ensuring definitive and safe peritoneal entry. Both techniques have advantages and disadvantages, and surgeons performing laparoscopic cholecystectomy should learn both techniques and use them selectively.

For the closed technique, the surgeon should perform various tests to ensure the safety of the needle insertion before insufflation. A syringe containing 5 mL of normal saline solution is attached to the end of the needle to aspirate and show the absence of blood, urine, or enteric contents. If any one of the aforementioned fluids is recovered, the needle should be removed and its position changed. If no fluid is aspirated, an assessment is made of the ease with which saline solution flows by gravity into the zero-pressure abdominal cavity, or the "drop

test." This test is done either by instilling a few drops of saline solution into the hub of the needle or by removing the barrel of the syringe. Manually elevating the abdominal wall near the needle site decreases intraabdominal pressure and enhances free flow; the fluid flows much more slowly, or not at all, if the needle is in an extraperitoneal position.

Insufflator tubing is connected to the Veress needle, and carbon dioxide is insufflated at a low flow rate of approximately 1 L/min. The initial pressure of the abdomen is usually 2 to 6 mm Hg and should not increase appreciably during the early phase of insufflation. Asymmetric distension, a rapid increase in pressure with low insufflated volume, or an initial pressure greater than 10 mm Hg suggests that the needle is not in the proper position. The abdomen should be serially percussed to confirm symmetric tympany associated with insufflation. The abdomen is fully insufflated with the upper pressure limit set at 12 to 15 mm Hg; this usually requires 3 to 6 L of carbon dioxide, depending on the size of the abdominal cavity and degree of muscle relaxation. If intraabdominal pressures exceed 20 mm Hg, central venous pressures and blood pressures decrease because of decreased venous return and diminished cardiac output (Chui et al, 1993; Sharma et al, 1997). Studies also have shown direct negative effects on urine output relative to increased intraabdominal pressures (McDougall et al, 1996, 1997).

During the initial period of insufflation, the patient must be monitored closely for signs of gas embolism (hypotension, decreased oxygen saturation, decreased end-tidal carbon dioxide, "mill-wheel" heart murmur), vagal reaction (hypotension, bradycardia), ventricular arrhythmias, and hypercarbia with acidosis. Most of these complications require immediate treatment by desufflation followed by gradual reestablishment of the pneumoperitoneum after the patient's condition has stabilized. Gas embolism results in an "air lock" right ventricular outflow obstruction with a dramatic decrease in end-tidal carbon dioxide concentration. When suspected, this problem should be treated by placing the patient in a steep Trendelenburg and left lateral decubitus position followed by insertion of a central venous catheter to aspirate the carbon dioxide from the apex of the right ventricle (Chui et al, 1993; Hanney et al, 1995; Lantz & Smith, 1994; Sharma et al, 1997).

After the pneumoperitoneum is established, the Veress needle is replaced with a trocar/port through a periumbilical incision into which the laparoscope may be inserted. This port is inserted carefully while manually elevating the abdominal wall to avoid iatrogenic injury to intraabdominal viscera or retroperitoneal structures.

Using the open technique, the pneumoperitoneum is established similarly to an open diagnostic peritoneal lavage. A 1.5-cm skin incision is made in the infraumbilical or supraumbilical skin fold. Dissection of the subcutaneous tissue is performed at the base of the umbilical raphe to reach the fascia rapidly, even in obese patients, because this is the thinnest part of the abdominal wall. Kocher clamps are applied to both sides of the linea alba, and a small vertical incision is made to gain access to the peritoneal cavity. A finger is placed into the wound to ensure that the free peritoneal cavity has been entered and to sweep away any adhesions that may be present. If a Hasson trocar (Weck & Co, Research Triangle Park, NC) is available, two sutures are placed on both sides of the fascial incision and are tied to the wings of the wedge-tipped sheath after it is inserted into the peritoneal cavity under direct vision

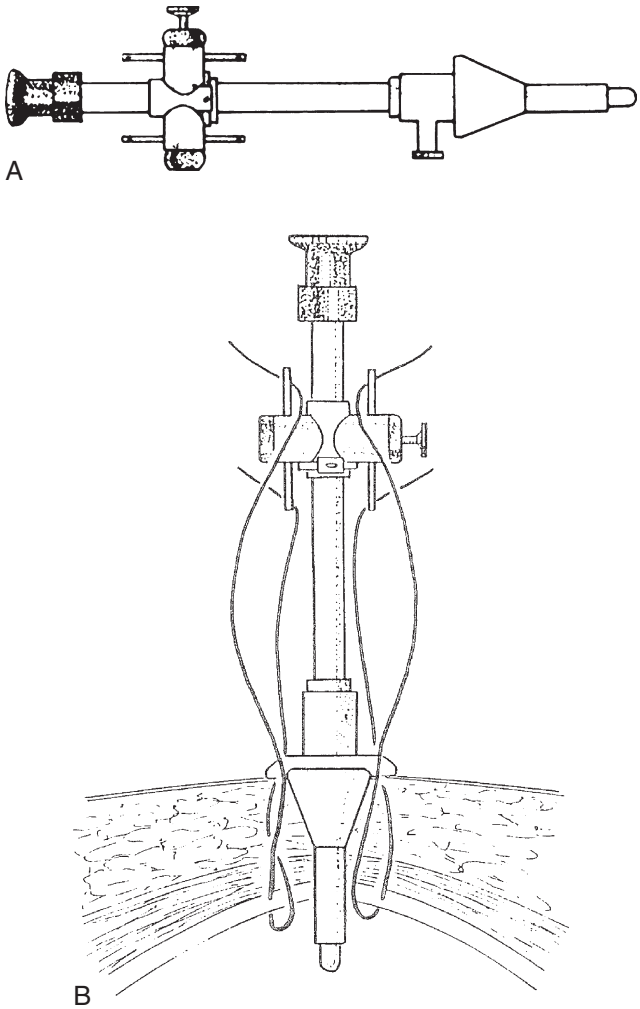

FIGURE 34.2. A, Reusable Hasson trocar/cannula. **B,** Securing the Hasson cannula to the abdominal fascia. The fascial stay sutures are wound around the wings of the cannula to secure it in place and seal the fasciotomy and peritoneotomy. *(Courtesy Quality Medical Publishing, St Louis, MO.)*

(Fig. 34.2). Alternatively, standard laparoscopic sheaths can be used after placing two concentric polypropylene purse-string stitches around the fascial incision. After removing the sheath at the conclusion of the procedure, the outer purse-string suture is removed, and the inner one is tied. Open insertion of the initial port takes a few minutes longer than its closed counterpart. Extraction of the gallbladder at the conclusion of the operation is easier, however, which equalizes the time differential of the two access techniques.

Port Placement and Exposure

Depending on the surgeon's preference, a 5- or 10-mm laparoscope is inserted into the abdomen through the umbilical port. The area immediately posterior to the umbilicus is viewed initially to ensure that there is no injury as a result of trocar insertion. Thorough intraabdominal visual exploration is performed; the pelvic viscera are examined for pathologic abnormalities before evaluating the upper abdomen, and the anterior surface of the intestines, the omentum, and the stomach also

are examined for disease. The patient is placed in a reverse Trendelenburg position of 30 degrees while rotating the table to the left by 15 degrees. This maneuver allows the colon and duodenum to fall away from the liver edge. The falciform ligament and both lobes of the liver are examined carefully for abnormalities. The gallbladder usually can be seen protruding beyond the edge of the liver.

Two small accessory subcostal ports are placed under direct vision. The first 5-mm trocar is placed along the right anterior axillary line between the twelfth rib and the iliac crest. A second 5-mm port is inserted in the right subcostal area in the midclavicular line. Grasping forceps are placed through these two ports to secure the gallbladder. The assistant manipulates the lateral grasping forceps, which are used to elevate the liver and expose the fundus of the gallbladder. The surgeon uses dissecting forceps to raise a serosal fold in the most dependent portion of the fundus. The assistant's heavy grasping forceps are locked onto this fold using either a spring or a ratchet device. With these axillary grasping forceps, the fundus of the gallbladder is pushed in a lateral and cephalad direction, rolling the entire right lobe of the liver cranially; this maneuver is complicated in patients with a fixed, cirrhotic liver or a heavy, friable liver resulting from fatty infiltration.

In patients with few adhesions to the gallbladder, pushing the fundus cephalad exposes the entire gallbladder, cystic duct, and porta hepatis. Most patients have adhesions between the gallbladder and the omentum, hepatic flexure, or duodenum; these are generally avascular and may be lysed bluntly by grasping them with dissecting forceps at their site of attachment to the gallbladder wall and gently stripping them down toward the infundibulum. After exposing the infundibulum, blunt grasping forceps placed through the midclavicular trocar are used to grasp and place traction on the neck of the gallbladder. The operative field is established, and the final working port is inserted.

A final operating trocar/port is placed through an incision in the midline of the epigastrium. This trocar usually is inserted approximately 5 cm below the xiphoid process, but the precise position and angle depend on the location of the gallbladder and the size of the medial segment of the left lobe of the liver. When the appropriate position for this trocar is hard to determine, a Veress needle may be placed first at the proposed site to ascertain whether its location and angle of insertion seen through the laparoscope are optimal. The trocar is inserted in a controlled fashion, angling its tip just to the right of the falciform ligament, aiming toward the gallbladder. Dissecting forceps are inserted and directed toward the gallbladder neck. The orientation of the laparoscope is generally parallel to that of the cystic duct when the fundus is elevated, whereas the instruments placed through the other three ports enter the abdomen at right angles to this plane (Figs. 34.3 and 34.4).

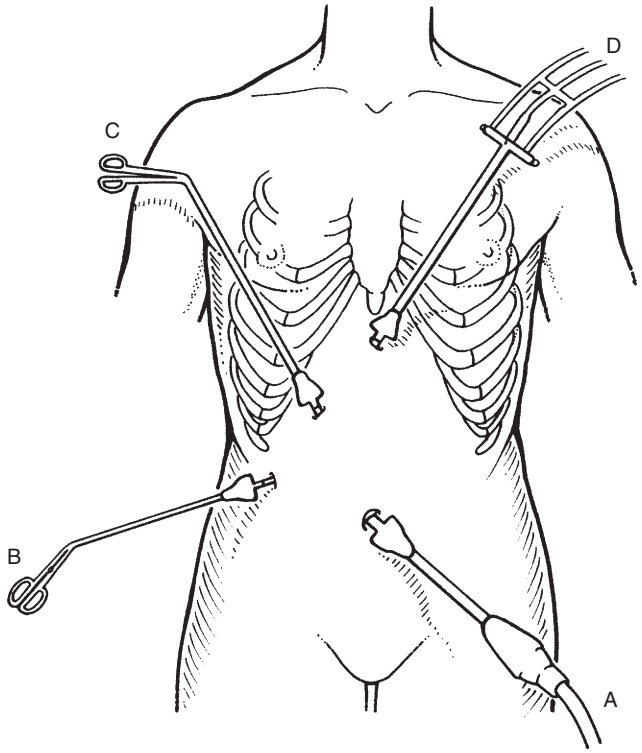

FIGURE 34.3. Positions for insertion of the initial (*A*) and accessory sheaths (*B* through *D*).

Dissection

A grasping instrument on the infundibulum exerts traction on the gallbladder away from the CBD in a superior and lateral direction. Fine-tipped dissecting forceps are used to dissect away the overlying fibroareolar structures from the infundibulum of the gallbladder. This is done with a blunt stripping action, always starting on the gallbladder and stripping the tissue toward the porta hepatis (Fig. 34.5). The dissection should begin on a known structure (e.g., the gallbladder), rather than in an unknown area, to avoid damage to the underlying structures, such as the bile duct or the hepatic artery.

It is important to identify clearly the structures forming the sides of the triangle of Calot (i.e., cystic duct, cystic artery, and common hepatic duct), the standard ventral aspect, and its reverse (dorsal) aspect (Fig. 34.6). Distinction is made here with the hepatocystic triangle proper, which is the ventral aspect of the area bounded by the gallbladder wall and cystic duct, the liver edge, and the common hepatic duct; the cystic artery and the triangle of Calot lie within this space. The hepatocystic triangle is maximally opened and converted into a trapezoid shape

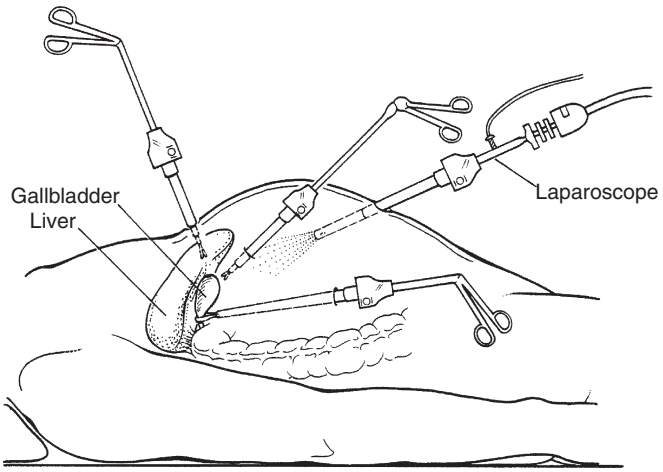

FIGURE 34.4. Diagram of the abdomen after the creation of a pneumoperitoneum and the insertion of laparoscopic instruments.

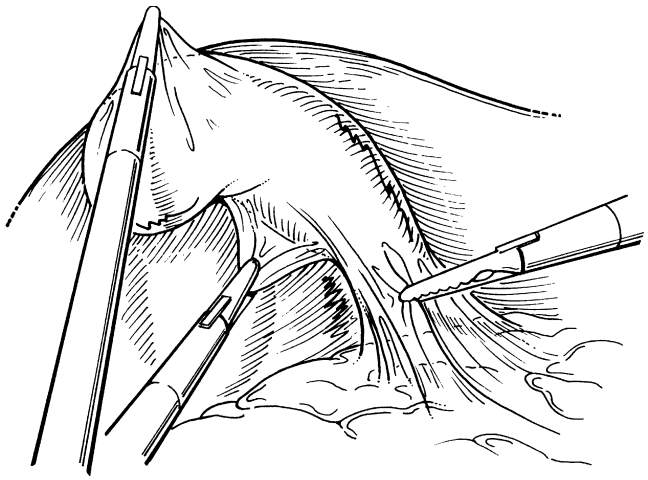

FIGURE 34.5. The omentum and adhesions are bluntly divided by carefully pulling them away with atraumatic grasping forceps.

by retracting the infundibulum of the gallbladder inferiorly and laterally, while maintaining the fundus under traction in a superior and medial direction. A lymph node usually lies adjacent to the cystic artery, and occasionally it is necessary to use a brief application of electrosurgical coagulation to obtain hemostasis as the lymph node is bluntly swept away. To expose the reverse of Calot's triangle, the infundibulum of the gallbladder is pulled in a superior and medial direction (see Fig. 34.6).

After clearing the structures from the apex of the triangle, the junction between the infundibulum and the origin of the proximal cystic duct can be identified clearly. The strands of peritoneal, lymphatic, and neurovascular tissue are stripped away from the cystic duct to clear a segment from the surrounding tissue. Curved dissecting forceps are helpful in creating a window around the posterior aspect of the cystic duct to skeletonize the duct itself. Alternatively, the tip of the hook cautery can be used to encircle and expose the duct. It is generally unnecessary and potentially harmful to dissect the cystic duct down to its junction with the CBD.

Next, the cystic artery is separated from the surrounding tissue by similar blunt dissection. If the cystic artery crosses anterior to the duct, the artery may require dissection and division before approaching the cystic duct. The neck of the gallbladder is dissected away from its liver bed, leaving only two structures entering the gallbladder: the cystic duct and artery. No structure should be divided until the cystic duct and cystic artery are unequivocally identified. This is the "critical view" of safety (Fig. 34.7) essential to prevent bile duct injury during laparoscopic cholecystectomy (Strasberg et al, 1995).

Intraoperative Evaluation for Choledocholithiasis

After initially dissecting the proximal cystic duct, the CBD should be imaged if there is any concern for choledocholithiasis or any question regarding the biliary anatomy. This can be achieved by radiographic intraoperative cholangiography (IOC) or intracorporeal LUS (see Chapter 21). Before either procedure, a clip is applied high on the cystic duct at its junction with the gallbladder to prevent stones from migrating down the duct. To perform IOC, the anterolateral wall of the cystic duct is

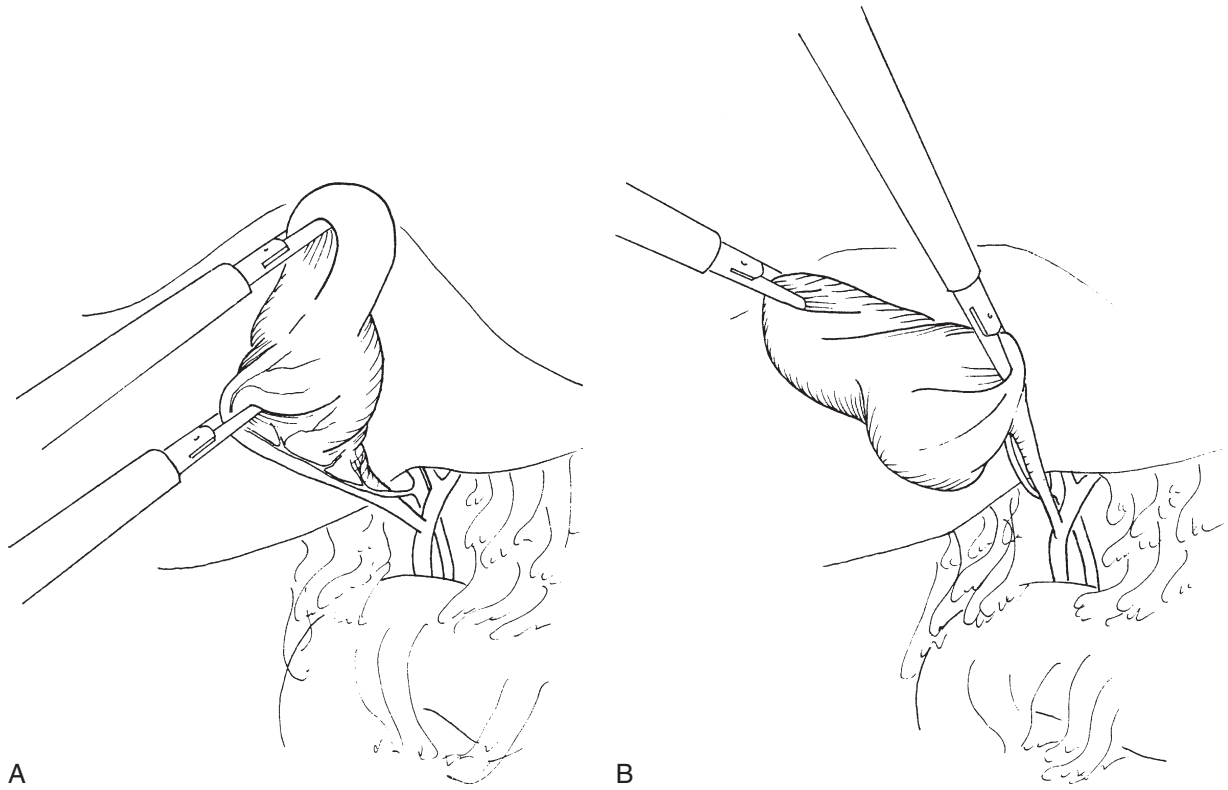

FIGURE 34.6. Proper gallbladder retraction for exposure of Calot's triangle (**A**) and reverse Calot's triangle (**B**). *(Courtesy Quality Medical Publishing, St Louis, MO.)*

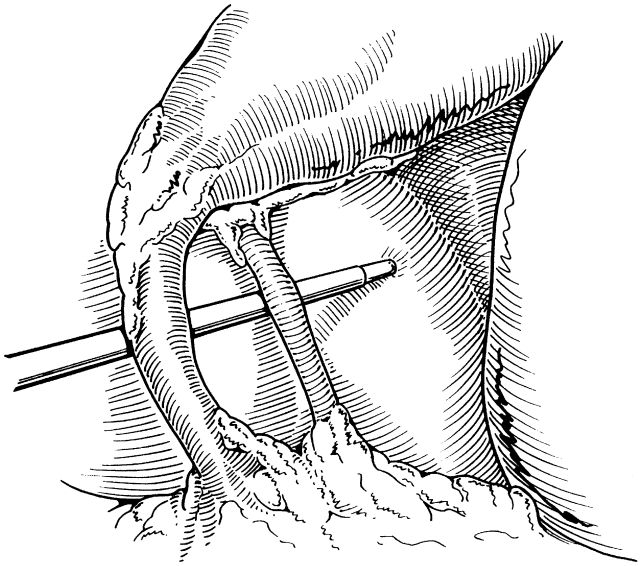

FIGURE 34.7. Critical view. Hepatocystic triangle is dissected free of all tissue except for the cystic duct and artery, and the base of the liver bed is exposed. When this view is achieved, the two structures entering the gallbladder can only be the cystic duct and artery.

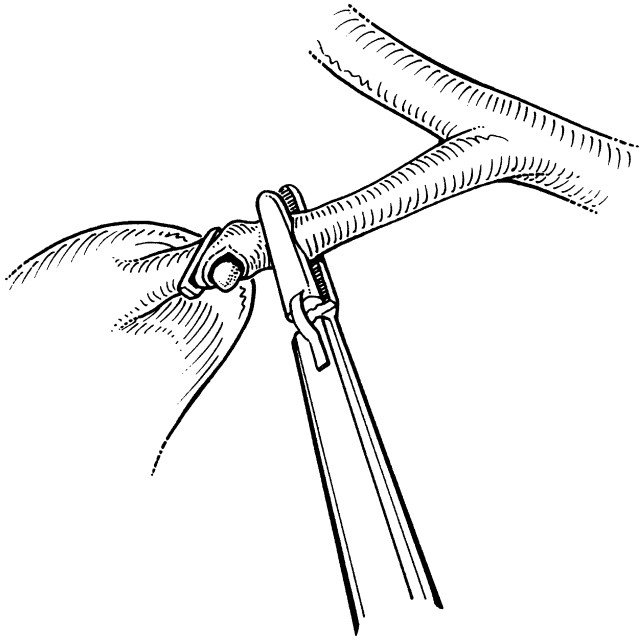

FIGURE 34.9. A cystic duct stone is "milked" out of the ductotomy.

incised, and dissecting forceps are used to compress the cystic duct gently and systematically back toward the gallbladder, "milking" stones away from the CBD and out the ductotomy (Figs. 34.8 and 34.9). A 4- to 5-Fr catheter is inserted into the duct through a hollow, 5-mm metal tube that has an appropriate gasket to prevent carbon dioxide leakage around the catheter itself. The cholangiography catheter is inserted into the cystic duct, and a clip is applied loosely to secure the catheter in place (Fig. 34.10). If the introducer has grasping jaws, it can be used to secure the catheter into the duct (Fig. 34.11). Alternatively, catheters equipped with balloons proximal to the tip may be used for fixation.

Cholangiography can be performed by either real-time fluoroscopy (dynamic IOC) or by obtaining two standard radiographs (static IOC) after injecting 5 mL and 10 mL of water-soluble contrast medium (Figs. 34.12 and 34.13). The films should be inspected for the following: 1) the length of cystic duct and location of its junction with the CBD, 2) the size of the CBD, 3) the presence of intraluminal filling defects, 4) free flow of contrast material into the duodenum, and 5) anatomy of the extrahepatic and intrahepatic biliary tree. After the cholangiocatheter is removed, the cystic duct is doubly

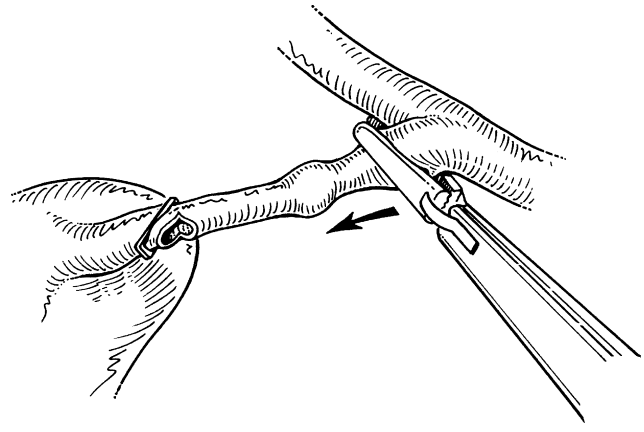

FIGURE 34.8. After a clip is placed across the junction of the gallbladder with the cystic duct, and a cystic ductotomy is made on the anterior side, the cystic duct is gently "milked" back toward the ductotomy.

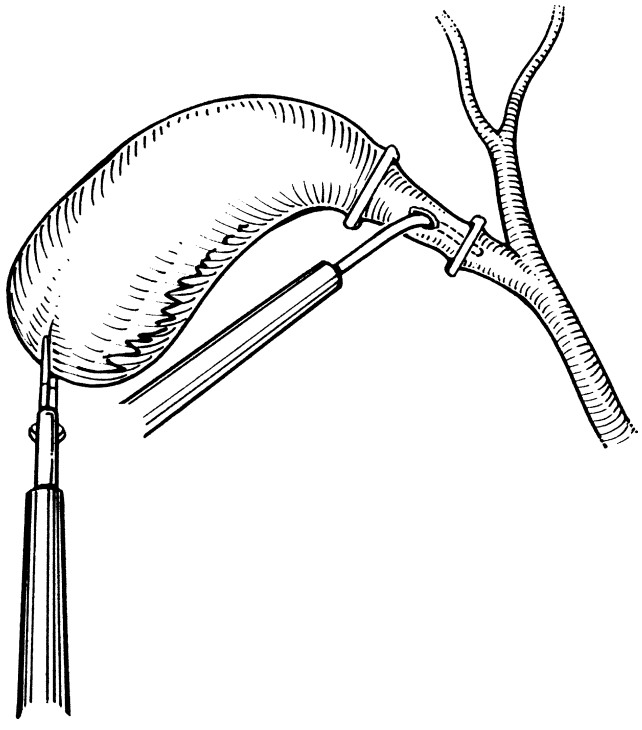

FIGURE 34.10. Cystic duct cholangiography can be performed with a catheter clipped into place.

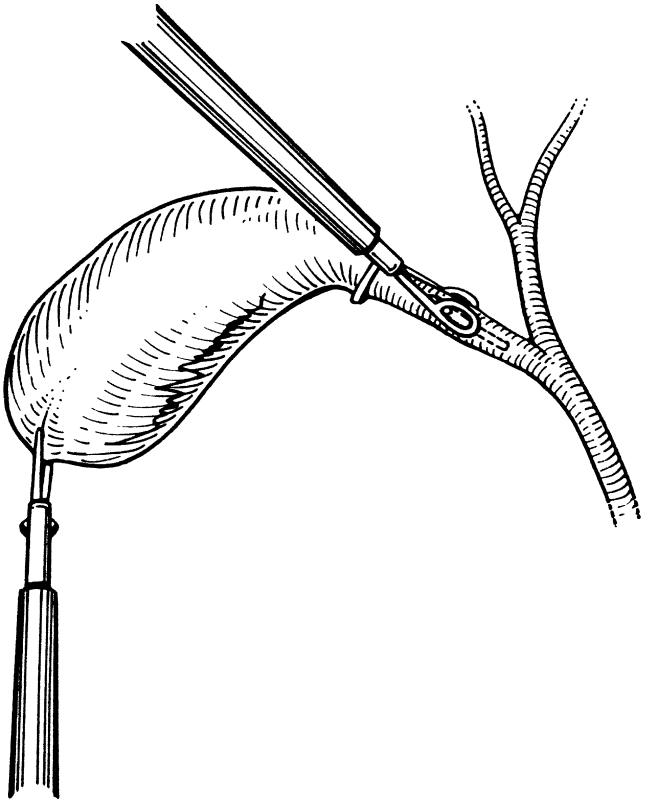

FIGURE 34.11. Alternatively, a cholangiogram catheter can be held in place with a clamp.

FIGURE 34.12. Intraoperative cholangiogram showing absence of a bile duct calculus with free flow of contrast medium into the duodenum. *(From Blumgart LH, Fong Y [eds], 1997: Surgery of the Liver and Biliary Tract CD-ROM. Philadelphia, Churchill Livingstone.)*

FIGURE 34.13. Intraoperative cholangiogram showing a filling defect of the distal common bile duct. Philadelphia, Churchill Livingstone.)*

clipped below the ductotomy, with care taken to avoid the wall of the CBD, and divided. The posterior jaw of the clip applier must be visualized before applying each clip to avoid injury to the surrounding structures. Great care should be taken so that the CBD is not "tented up" into the clip. If the cystic duct is particularly large or friable, it may be preferable to replace one of the clips with a hand-tied or preformed suture.

Evaluation of the CBD by LUS is an alternative to cholangiography. Several studies performed at open cholecystectomy reported LUS to be more accurate than IOC in assessing the CBD for stones (97% to 99% vs. 89% to 94%; Machi et al 1993a, 1993b; Orda et al, 1994a, 1994b). Although few surgeons have adopted US for this purpose, LUS has been used in several centers during laparoscopic cholecystectomy and is gaining popularity (Jakimowicz, 1993; John et al, 1994; McIntyre et al, 1994; Orda et al, 1994a, 1994b; Steigmann et al, 1994). With LUS, the transducer has a higher frequency with improved resolution compared with that used with transabdominal US. In experienced hands, LUS seems to be as accurate as cholangiography for showing choledocholithiasis, but it can be performed more rapidly (Steigmann et al, 1995). In a prospective multicenter trial with 209 laparoscopic cholecystectomy patients, the time to perform LUS (7 ± 3 min) was significantly less than that of IOC (13 ± 6 min; Steigmann et al, 1995). The study showed that LUS was more sensitive for detecting stones but that IOC was better in delineating intrahepatic anatomy and defining anatomic anomalies of the ductal system. The authors concluded that the two methods of ductal imaging were complementary. Despite these promising data,

more clinical experience is needed to establish the appropriate role of LUS for the detection of choledocholithiasis during laparoscopic cholecystectomy (Soper, 1997; Wu et al, 1998a).

Completion of Cholecystectomy

After clip ligation and division of the cystic duct, the cystic artery is dissected from the surrounding tissue for an adequate distance to permit placement of three clips. The surgeon must ascertain that the structure is the cystic artery and not the right hepatic artery, looping up onto the neck of the gallbladder, or an accessory or replaced right hepatic artery (see Chapter 1B). After an appropriate length of cystic artery has been dissected free, it is clipped proximally and distally before its transection. Electrocautery should not be used for this division, because the current may be transmitted to the proximal clips and lead to subsequent necrosis and hemorrhage. A common error is to dissect and divide the anterior branch of the cystic artery, mistaking it for the main cystic artery; this may result in hemorrhage from the posterior branch during dissection of the gallbladder fossa.

The ligated stumps of the cystic duct and the artery are examined to ensure that there is no leakage of either bile or blood and that the clips are placed securely; they should compress the entire lumen without impinging on adjacent tissues. A suction-irrigation catheter is used to remove any debris or blood that has accumulated during the dissection. Separation of the gallbladder from its hepatic bed is initiated using an electrosurgical probe to coagulate small vessels and lymphatics. While maintaining cephalad traction on the fundus of the gallbladder with the axillary forceps, the midclavicular forceps pulls the neck of the gallbladder anterosuperiorly and then alternatively medially and laterally to expose and place the tissue connecting the gallbladder to the fossa under tension (Fig. 34.14). An electrocautery spatula or hook is used in a gentle sweeping motion with low power (25 to 30 W) to coagulate and divide the tissue. Intermittent blunt dissection facilitates exposure of the proper plane.

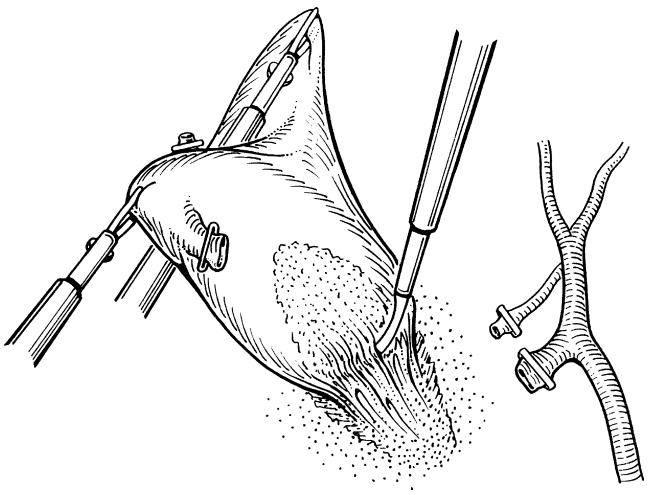

FIGURE 34.14. Separation of the gallbladder from its bed by dissection with a blunt-tipped thermal energy probe. The neck of the gallbladder is placed on traction in a superior direction, then twisted to the left and right to place tension on the junction between the gallbladder and the hepatic fossa.

Dissection of the gallbladder fossa continues from the infundibulum to the fundus, progressively moving the midclavicular grasping forceps cephalad to allow maximal countertraction. The dissection proceeds until the gallbladder is attached by only a thin bridge of tissue. At this point, before completely detaching the gallbladder, the hepatic fossa and porta hepatis are inspected again for hemostasis and bile leakage. Small bleeding points are coagulated, and the right upper quadrant is liberally irrigated and aspirated dry while checking for any residual bleeding or bile leakage. The final attachments of the gallbladder are divided, and the liver edge is examined again for hemostasis.

After the cholecystectomy has been performed, the gallbladder must be removed from the abdominal cavity. If the stone burden is small, the gallbladder can be extracted at the subxiphoid port site. Usually, the gallbladder is most easily removed at the umbilical port site, where there are no muscle layers anterior to the fascial plane. Also, if the fascial opening needs to be enlarged because of large or numerous stones, extension of the umbilical incision causes less postoperative pain and has better cosmesis than does enlarging the subxiphoid incision. The laparoscope is removed from the umbilical port and placed through the epigastric port. Large, claw-like grasping forceps are introduced through the umbilical port to grasp the infundibulum of the gallbladder. The forceps, trocar, and gallbladder neck are retracted as a unit through the umbilical incision, and the neck of the gallbladder is exteriorized through the anterior abdominal wall with the fundus remaining within the abdominal cavity.

If the gallbladder is not distended with bile or stones, it can be withdrawn with gentle traction. In most cases, a suction catheter introduced through an incision in the gallbladder neck is used to aspirate bile and small stones. Stone forceps also can be placed into the gallbladder to extract or crush calculi if necessary (Fig. 34.15). Occasionally, the fascial incision must be extended to extract larger stones or thick-walled gallbladders. After the gallbladder is extracted, the operator's finger is used to occlude the port entry site. If any question concerning hemostasis or contamination of the right upper quadrant remains, the umbilical port can be replaced under direct vision, and the upper part of the abdomen can be copiously irrigated and aspirated again. If not, all laparoscopic ports are removed after allowing escape of the carbon dioxide.

Each incision is infiltrated with bupivacaine for postoperative analgesia, and the fascia of the umbilical incision is closed with one or two large, absorbable sutures. Closure of the subxiphoid fascia is optional, because visceral herniation is unlikely to occur owing to the oblique entry angle of the trocar into the abdominal cavity and its location anterior to the falciform ligament. The skin of the subxiphoid and umbilical incisions is closed with subcuticular absorbable sutures. The skin incisions at both 5-mm port sites can be closed with adhesive strips or skin closure adhesives. The orogastric tube is removed in the operating room, and the patient is transferred to the postanesthesia care unit.

Intraoperative Treatment of Common Bile Duct Stones

The reported incidence of CBD stones found during laparoscopic cholecystectomy ranges from 3% to 10% (see Chapters 30 and 34 through 37) (Barkun et al, 1993; Frazee et al, 1993). It is unclear whether uncomplicated and asymptomatic

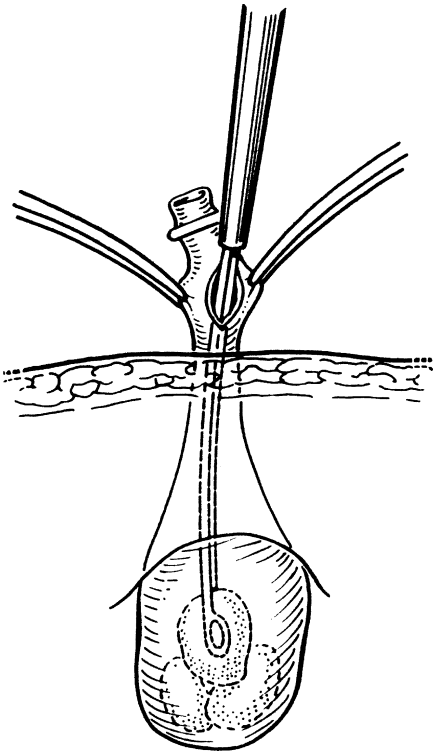

FIGURE 34.15. Gallstones contained within the fundus may be crushed or removed after delivering the neck of the gallbladder through the umbilical incision.

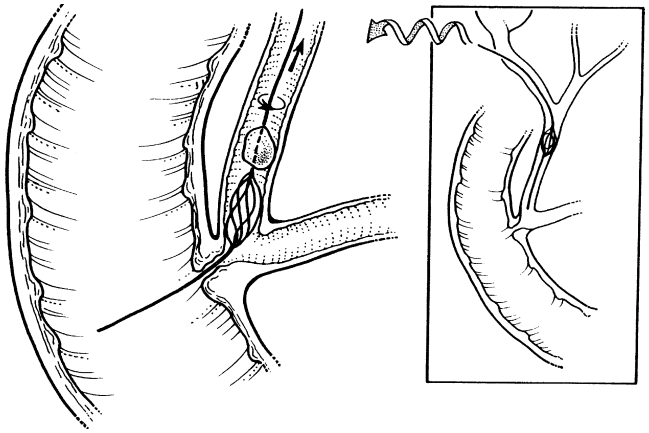

FIGURE 34.16. Transcystic retrieval of common bile duct stones using a helical basket under fluoroscopy.

choledocholithiasis requires treatment. Autopsy series have shown that many patients with silent gallbladder stones also harbor silent CBD stones (Crump, 1931). Smaller stones are known to pass through the ampulla of Vater, as shown by stool analysis in patients with acute pancreatitis (see Chapter 53) or acute biliary colic (Acosta & Ledesma, 1974; Kelly, 1980). In one study, the rate of symptoms or complications in patients with retained CBD stones after cholecystectomy was 94%, with a mortality rate of 3% over 5 years (Hicken & McAllister, 1964). It is unclear what stone size precludes passage or which indicators predict complications of cholangitis (see Chapter 43) or pancreatitis if the stones are left in situ.

It is generally recommended to treat choledocholithiasis when it is discovered intraoperatively; options include laparoscopic CBD management, open CBD exploration, and postoperative endoscopic or percutaneous transhepatic stone extraction. In the current state of evolving techniques, and in the absence of definitive prospective randomized trials guiding the management of patients with choledocholithiasis, the technical expertise of the local physicians is a major determining factor in CBD stone management.

Laparoscopic CBD exploration can take the form of accessing the CBD through the cystic duct (transcystic technique) or directly incising and opening the CBD with stone retrieval (laparoscopic choledochotomy). In the transcystic duct approach, stones smaller than 4 mm often can be flushed through the ampulla into the duodenum, a technique that is facilitated by pharmacologic relaxation of the sphincter of Oddi using sublingual nitroglycerin or intravenous glucagon. When these simple methods fail, a helical stone basket can be passed over a guidewire through the cystic duct and into the CBD to extract stones under fluoroscopic guidance (Fig. 34.16) (Hunter, 1992).

If attempts at transcystic basket extraction fail, the next step is to insert a 7- to 8-Fr choledochoscope to remove the stones under direct vision. If the CBD stone is larger than the lumen of the cystic duct, the duct should be balloon dilated first to a maximum of 8 mm in diameter, but never larger than the internal diameter of the CBD (Hunter & Soper, 1992). The choledochoscope is passed into the peritoneal cavity through the midaxillary port, using a sheath to prevent damage to the scope by the port's valve. The choledochoscope is inserted through the cystic duct into the CBD under direct vision. The lumen of the duct is optimally visualized by continuously infusing saline through the biopsy channel. Under visual guidance, the tip of a Segura-type stone basket is advanced beyond the stone and opened. As the basket is pulled backward and rotated, the stone is ensnared (Fig. 34.17; Jones & Soper, 1996).

A completion cholangiogram should always be performed to ascertain clearance of the duct. Because of tissue edema secondary to ductal dilation and manipulation, the cystic duct stump is ligated, rather than clipped, for added security. Successful extraction has been reported in 67% to 96% of patients treated in most series (Table 34.3; Bagnato, 1993; DePaula et al, 1994; Dion et al, 1994; Ferzli et al, 1994; Franklin et al, 1994; Hunter, 1992; Petelin, 1993; Phillips et al, 1994). Complications such as infection and pancreatitis have been reported in 5% to 10% of patients, with a mortality rate of 1% to 2%. The duration of hospitalization after an uncomplicated transcystic duct stone extraction is the same as that for laparoscopic cholecystectomy alone, averaging 1 to 2 days. The main advantage of the transcystic approach is that it avoids the need to incise the CBD, with subsequent suture closure and placement of a T-tube. Poor candidates for transcystic extraction techniques are patients with large or multiple CBD stones, patients with stones in the proximal ductal system, and patients with small or tortuous cystic ducts.

If the transcystic approach fails, we recommend direct incision of the CBD laparoscopically. Indications for laparoscopic choledochotomy are stones that are multiple, large, or positioned within the proximal bile ducts in patients with a CBD diameter larger than 8 to 10 mm (Dion et al, 1994; Phillips

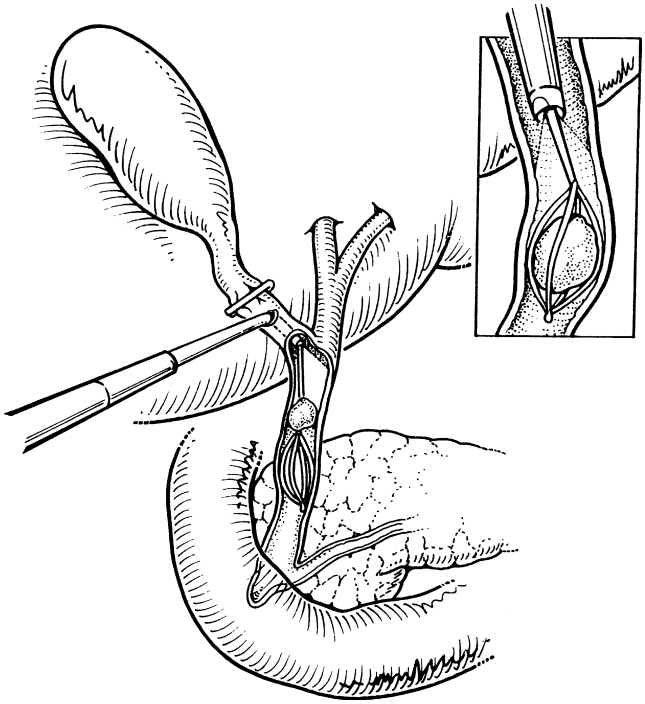

FIGURE 34.17. Transcystic choledochoscopy. The flexible choledochoscope is passed into the common bile duct through the cystic duct. Under direct vision, the basket is advanced distal to the stone and opened. *Inset,* As the basket is withdrawn through the working channel of the choledochoscope, the stone is ensnared. The basket, stone, and choledochoscope are removed as a unit.

et al, 1994). Stay sutures usually are placed on either side of the midline of the CBD wall to allow anterior traction on the duct. A longitudinal choledochotomy is made on the distal CBD, with adequate length to allow easy placement of a choledochoscope and removal of the largest stone. Stones are removed under endoscopic visualization, and an appropriate-size T-tube is placed in the duct. The ductotomy is closed with fine absorbable sutures using intracorporeal suturing techniques, and the T-tube is exteriorized through the lateral port site. The patient generally is discharged 2 to 4 days postoperatively and returns for a final T-tube cholangiogram and removal of the T-tube at 14 to 21 days postoperatively. Retained stones shown by T-tube cholangiography may be effectively removed percutaneously after allowing maturation of the T-tube tract. Percutaneous extraction is successful in more than 95% of patients with retained stones (Burhenne, 1980).

Overall, laparoscopic choledochotomy is successful in more than 90% of patients, with a minor morbidity rate of 5% to 10% and a mortality rate of 1% to 2% (see Table 34.3). Complications of this technique include laceration of the CBD, bile leakage, sewn-in T-tubes, and postoperative CBD strictures (Dion et al, 1994). Many surgeons have not mastered laparoscopic suturing to the point that they feel comfortable closing the choledochotomy, for fear of a resultant stricture. Nevertheless, advantages of the direct laparoscopic approach are that every portion of the ductal system can be accessed, and stone size is unimportant. The alternative approach of open operation with exploration of the CBD with or without choledochoduodenostomy should always be considered in difficult cases (see Chapters 29 and 35).

The possibility of finding CBD stones and the means by which they can be treated must be discussed with the patient before operation to formulate a plan of therapy. Many surgeons routinely leave CBD stones in place during laparoscopic cholecystectomy for planned postoperative endoscopic removal (see Chapter 27). Factors favoring postoperative endoscopic therapy include the presence of small, nonobstructing duct stones; a patient with significant comorbidities, making a prolonged operation risky; and a small CBD prone to postoperative stricture. In resorting to postoperative endoscopic retrograde cholangiography and sphincterotomy, the goals of minimally invasive surgery are maintained with a rapid return to full activity. Relying on postoperative endoscopic sphincterotomy (ES) subjects the patient to an additional procedure, with its associated morbidity and possibly a second operation if endoscopic stone extraction fails. In experienced hands, ES has an overall failure rate for stone clearance of 5% to 10% (Cotton, 1993).

Leaving a transcystic catheter in the CBD at the time of laparoscopic cholecystectomy may decrease the likelihood of failure by allowing a guidewire to be passed into the duodenum to facilitate cannulation of the CBD (Deslandres et al, 1993). It is reasonable to submit a patient to postoperative endoscopic stone extraction when the endoscopic expertise is high, whereas an open CBD exploration should be strongly considered when only an inexperienced endoscopist is available in the local setting. The expertise of the laparoscopist and the endoscopist are critical determinants of the means by which CBD stones are managed (Cotton, 1993).

Table 34.3

Techniques for Treatment of Choledocholithiasis

Method	Success Rate (%)	Length of Stay (Days)	Return to Work (Days)
Transcystic duct extraction	67-96	1-2	7-10
Laparoscopic CBDE	85-100	4-7	14-30
Open CBDE	90-100	5-10	20-42
ERC/ES	85-95	2-3	7-14

CBDE, common bile duct exploration; ERC, endoscopic retrograde cholangiography; ES, endoscopic sphincterotomy

POSTOPERATIVE MANAGEMENT

Patients may be observed in the hospital overnight or discharged later the same day. The patient is allowed clear liquids in the immediate postoperative period and is advanced to a regular diet as tolerated. Postoperative referred shoulder and neck pain may occur transiently as a result of diaphragmatic irritation. No activity restrictions are placed on the patient; functional status depends entirely on the degree of abdominal tenderness, which usually subsides by postoperative day 2 or 3. The patient may return to work as soon as the abdominal discomfort is tolerable, often within the first week.

Although laparoscopic cholecystectomy was initially thought of as a procedure that could reduce a typical 5-day hospital stay for an open cholecystectomy to 1 to 2 days, third-party payers in the United States have begun to push for discharge of the

patient on the same day of surgery; the principal advantage is reduction of hospital costs. Nevertheless, not all patients are candidates for outpatient laparoscopic cholecystectomy. In a prospective analysis of 506 consecutive laparoscopic cholecystectomy cases, Saunders and colleagues (1995) argued that most complications, including life-threatening complications, were not apparent by 8 hours postoperatively and were clinically detected only 39% of the time at 24 hours after the procedure. These investigators recommended great caution in selecting patients for outpatient laparoscopic cholecystectomy. Patients who may benefit from an overnight stay include elderly patients, those with significant comorbid illnesses, those requiring substantial analgesia postoperatively, and patients with complications. For same-day discharge, patients should be healthy, reliable, and sensible; have undergone an uncomplicated operation; and have good home support. Written instructions are given to the patient and the family, with detailed advice concerning signs of potential problems. Routine postoperative follow-up at 2 to 4 weeks is advised for all patients.

SPECIAL CONSIDERATIONS

Acute Cholecystitis

Numerous reports indicate that laparoscopic cholecystectomy can be done safely for patients with acute cholecystitis (Prakash et al, 2002; Suter & Meyer, 2001). There is a higher rate of conversion in the setting of acute cholecystitis; in particular, after 72 hours, the rate of conversion increases significantly (Madan et al, 2002).

The timing of laparoscopic cholecystectomy for acute cholecystitis has been a long-standing matter of debate. Based on several prospective studies, early surgical intervention has economic, social, and medical benefits and is the preferred approach for experienced laparoscopic surgeons in the management of acute cholecystitis (Feldman et al, 2002). Our practice is to proceed with laparoscopic cholecystectomy immediately after the diagnosis of acute cholecystitis has been made. In a patient who is seen after 72 hours of symptoms, a laparoscopic cholecystectomy is attempted only if the patient has no preexisting medical conditions that preclude an open cholecystectomy. If the patient does have significant comorbid illnesses, we continue with antibiotic therapy and possibly a percutaneous cholecystostomy tube (see Chapter 32) and subsequent elective laparoscopic cholecystectomy 6 to 8 weeks later.

Intervention during the early phase reveals an inflamed, thick-walled, tensely distended organ. To gain adequate traction on the gallbladder with the grasping forceps, it may be necessary to decompress the gallbladder by aspirating its contents with a large-gauge needle. As long as the inflammation is limited to the gallbladder, laparoscopic cholecystectomy is usually technically feasible. If inflammation extends to the porta hepatis, however, great care must be taken in proceeding with the operation. The normally thin, minimally adherent tissue that invests the cystic duct and artery is markedly thickened and edematous and may not separate readily from these structures with the usual blunt dissection techniques. The duct wall also may be edematous, making its external diameter similar to the gallbladder neck and CBD. If the anatomy is unclear, cholangiography must be performed before clipping or dividing tissue.

When acute inflammation has been present for several days or weeks before operation, the pericholecystic tissue planes may be obliterated by thick, "woody" tissue that is difficult to dissect bluntly. In these cases, some authors recommend attempting a fundus-first technique and possibly even a subtotal cholecystectomy (Beldi & Glattli, 2003; Mahmud et al, 2002). Subtotal cholecystectomy involves transecting the infundibulum as close to the cystic duct as possible and extracting all stones. The gallbladder neck is then sutured closed if possible, and a drain is placed in the gallbladder bed. This transection of an edematous, friable wall may be facilitated by using the ultrasonic shears. The surgeon must be comfortable in his or her ability to safely perform the procedure laparoscopically; however, the decision to convert to an open procedure should not be considered a complication but rather good surgical judgment based on the existing anatomy, local conditions, and the surgeon's experience and confidence in his or her ability to complete the procedure using minimal-access techniques.

In a gallbladder densely adherent to the liver, where the plane between the two is obliterated, or in the presence of portal hypertension, it may be preferable to leave the back wall of the gallbladder intact and fully cauterize its mucosa (Beldi & Glattli, 2003). An active suction drain should be left beneath the liver if the integrity of the cystic duct closure is in question or with any suspicion of bile leakage from the gallbladder bed. We do not place a drain to monitor for bleeding.

Several authors have reported performing laparoscopic cholecystectomy in the face of acute inflammation with success, but with a higher conversion rate than for elective laparoscopic cholecystectomy (Cooperman, 1990; Hermann, 1990; Rattner et al, 1993; Reddick et al, 1991; Unger et al, 1991). Lo and colleagues (1996) reported in their prospective study that despite longer operative times and postoperative stays for early laparoscopic cholecystectomy in patients with acute cholecystitis (treatment within 5 days) versus delayed laparoscopic cholecystectomy (initial conservative treatment followed by laparoscopic cholecystectomy 3 to 4 months later), the advantage of early laparoscopic cholecystectomy was the reduction in the total hospital stay, from 15 to 7 days.

Rattner and associates (1993) retrospectively reviewed 20 patients who underwent attempted laparoscopic cholecystectomy for acute cholecystitis and examined factors that were predictive of a successful procedure. Seven of the 20 patients (35%) required conversion to open cholecystectomy. The interval from admission to cholecystectomy in the successful cases was 0.6 days versus 5 days in the cases requiring conversion to open cholecystectomy. Converted cases also had a significantly higher white blood cell count, alkaline phosphatase levels, and Acute Physiology and Chronic Health Evaluation (APACHE II) scores compared with cases involving successful laparoscopic cholecystectomy. US findings, such as gallbladder distension, wall thickness, and pericholecystic fluid, did not correlate with the success of laparoscopic cholecystectomy.

In a prospective study of 105 patients randomized to early laparoscopic cholecystectomy (within 24 hours of diagnosis of acute cholecystitis) versus delayed laparoscopic cholecystectomy (6 to 8 weeks later), no significant difference was found in conversion rate (early 21% vs. delayed 24%), postoperative analgesic requirement, or number of postoperative complications. The early group did have a longer operative time (123 minutes vs. 107 minutes, $P = .04$), but total hospitalization was shorter (8 days vs. 12 days, $P = .001$) (Lai et al, 1998). Laparoscopic cholecystectomy should be performed immediately after the diagnosis of acute cholecystitis. Delaying surgery

Table 34.5

When to Convert from Laparoscopic to Open Cholecystectomy

Injury to major blood vessels, viscus, or bile duct
Anatomy unclear
Failure to progress in a timely fashion
Pathology not amenable to minimal access surgical techniques
Choledocholithiasis untreatable by minimal-access surgical techniques or postoperative endoscopic techniques

allows inflammation to become more intense and neovascularized, increasing the technical difficulty of laparoscopic cholecystectomy.

COMPLICATIONS

Many complications related to laparoscopic removal of the gallbladder are similar to the complications that occur during traditional open cholecystectomy (Table 34.4) and include hemorrhage, bile duct injuries, bile leaks, retained stones, pancreatitis, wound infections, and incisional hernias (see Chapter 33). Other potential complications are pneumoperitoneum related (gas embolism, vagal reaction, ventricular arrhythmias, or hypercarbia with acidosis) and trocar related (injuries to the abdominal wall, intraabdominal organs, or major blood vessels). Most complications occur early in the surgeon's experience. In a multivariate regression analysis of 8839 laparoscopic cholecystectomies, in which 15 bile duct injuries occurred, the only significant factor associated with an adverse outcome was the surgeon's experience with the procedure (Moore & Bennett, 1995). The regression model predicted that a surgeon had a 1.7% chance of a bile duct injury occurring in the first case and 0.17% chance of a bile duct injury in the fiftieth case.

Conversion to Open Operation

Surgeons performing laparoscopic cholecystectomy should not think of conversion to open operation as a failure but rather as mature judgment. A surgeon should not hesitate to convert to a traditional open cholecystectomy if the anatomy is unclear, complications arise, or reasonable progress cannot be made in a timely manner (Table 34.5). It is better to open one too many than to open one too few, even if it means a longer hospital stay for the patient. Some complications requiring laparotomy are obvious, such as massive hemorrhage, bowel perforation, or major injury to the bile duct. Open laparotomy allows the additional tool of manual palpation and tactile sensation and should be performed when the anatomy cannot be delineated because of inflammation, adhesions, or anomalies. Fistulae between the biliary system and bowel are rare but may require laparotomy for optimal management. The demonstration of potentially resectable gallbladder carcinoma (see Chapter 49) also dictates an open exploration. Finally, when CBD stones cannot be removed laparoscopically and are unlikely to be extracted endoscopically owing to Billroth II anastomosis, previously failed ERCP, or an inexperienced endoscopist, the procedure should be converted to open operation without hesitation.

Anatomic Variations

One of the most frequent anomalies is a right hepatic artery that loops up onto the infundibulum of the gallbladder (see Chapter 1B). This anomaly may be misidentified as the cystic artery, leading to injury to the hepatic artery (Berci & Sackier, 1994). The surgeon also occasionally notices only a small cystic artery on the medial aspect of the gallbladder; when this occurs, the surgeon should be alert for a posterior branch leading onto the dorsal aspect of the gallbladder. If great care is not taken, brisk hemorrhage may occur.

A short cystic duct is seen frequently and may be draining into the right hepatic duct or a low-entry right sectoral hepatic duct (2%) or common hepatic duct (1%), or it may connect the infundibulum with the CBD by a duct of only a few millimeters in length in 5% to 6% of cases (Berci, 1992; Reid et al, 1986). During open cholecystectomy, this is relatively easy to recognize, especially if the cholecystectomy is performed in a fundus-first fashion. During laparoscopic cholecystectomy, these ducts are in danger of being mistaken for a normal cystic duct and divided (Fig. 34.18; Meyers et al, 1996). The most dangerous variant is when the cystic duct joins a low-lying aberrant right sectoral duct. These injuries are underreported, because occlusion of an aberrant duct may be asymptomatic and even unrecognized. In addition to anomalous biliary ducts, accessory ducts may drain into the cystic duct or from the liver directly into the gallbladder (ducts of Luschka). Since the widespread use of laparoscopic cholecystectomy, there has been an increased occurrence of bile leaks from the so-called ducts of Luschka. It is likely that many of these bile leaks are due to dissection into the liver substance with injury to a normal, albeit superficial, intrahepatic biliary radicle.

Intraoperative Gallbladder Perforation

Perforation of the gallbladder with bile or stone leakage can be a nuisance, but it should not ordinarily require conversion to open cholecystectomy. Perforation may occur secondary to traction applied by the grasping forceps or electrosurgical thermal injury during removal of the gallbladder from its bed. In our experience, almost one third of the patients have had

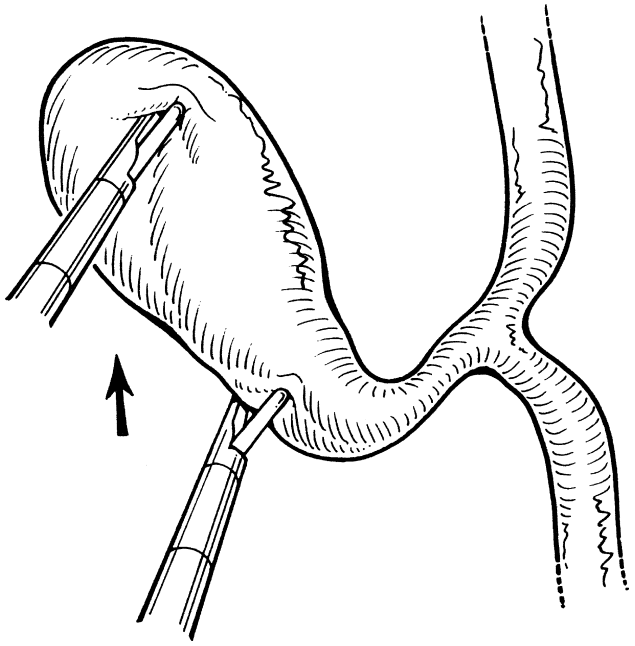

FIGURE 34.18. With a short cystic duct at the junction of the common hepatic duct and the common bile duct, pulling the infundibulum can result in tenting of the common bile duct. This can mimic the appearance of the cystic duct.

intraoperative spillage of bile or stones (Jones et al, 1995). Patients with a bile leak have not experienced an increased incidence of infection, prolongation of hospitalization or postoperative disability, or adverse long-term complications (mean follow-up of 41 months in 250 consecutive laparoscopic cholecystectomy patients). The only difference between patients with and without bile leakage was that the operating time for patients with a gallbladder perforation was approximately 10 minutes longer, presumably owing to the time spent cleaning up the operative field. When perforation does occur, the bile should be aspirated completely, and irrigation should be used liberally. The hole in the gallbladder is best secured with a grasping instrument and sutured or tied with an endoloop, and the stones should be retrieved and removed. Gallbladder spillage, when treated in this manner, results in no adverse short-term or long-term complications.

Escaped stones composed primarily of cholesterol pose little threat of infection. Pigment stones frequently harbor viable bacteria, however, and may lead to subsequent infectious complications if allowed to remain in the peritoneal cavity (Deziel et al, 1993). The long-term complications of retained stones, either intraabdominally with resultant abscess formation or intramurally with resultant port-site abscess, have not been prospectively studied, but case reports and case series in the surgical literature document a clear potential for long-term infectious complications (Carlin et al, 1995; Horton & Florence, 1998; Parra-Davila et al, 1998; Shocket, 1995; Zamir et al, 1999). The relative infrequency of these complications probably does not justify conversion to open operation in the face of spilled stones, but vigilance in avoidance of perforation, a careful search for escaped stones, and liberal use of a plastic retrieval bag for large and friable gallbladders are recommended (Zamir et al, 1999).

Biliary Injury

Of all the potential complications, biliary injuries have received the most attention; these are discussed at length elsewhere in this text (see Chapter 42A). Most series quote major bile duct injury rates of 0.30% or less during open cholecystectomy, whereas the incidence of bile duct injuries during laparoscopic cholecystectomy is 0.40% or higher (Strasberg et al, 1995). These injuries can cause major morbidity, prolonged hospitalization (Cates et al, 1993), high costs, and litigation (Asbun et al, 1993). In addition to aberrant anatomy and the surgeon's inexperience, many reports mention acute or chronic inflammation with dense scarring, operative bleeding obscuring the field, or fat in the portal area contributing to biliary injuries (Adams et al, 1993; Davidoff et al, 1992; Moosa et al, 1992; Soper et al, 1993). The classic biliary injury occurs, however, when the CBD or a right hepatic duct is mistaken for the cystic duct and is divided between clips. Many surgeons attribute this misidentification to the direction of traction of the gallbladder (i.e., pulling the CBD and the cystic duct into alignment, making them appear to be one). Other contributing factors to misidentification are a short cystic duct; a large stone in the Hartmann pouch, making retraction and display of the cystic duct difficult; or tethering of the infundibulum to the CBD by acute or chronic inflammation (Figs. 34.19 and 34.20). Constant awareness of these potential misidentifications and technical causes of biliary injuries is the best method of prevention. If a bile duct injury occurs, an immediate repair should be

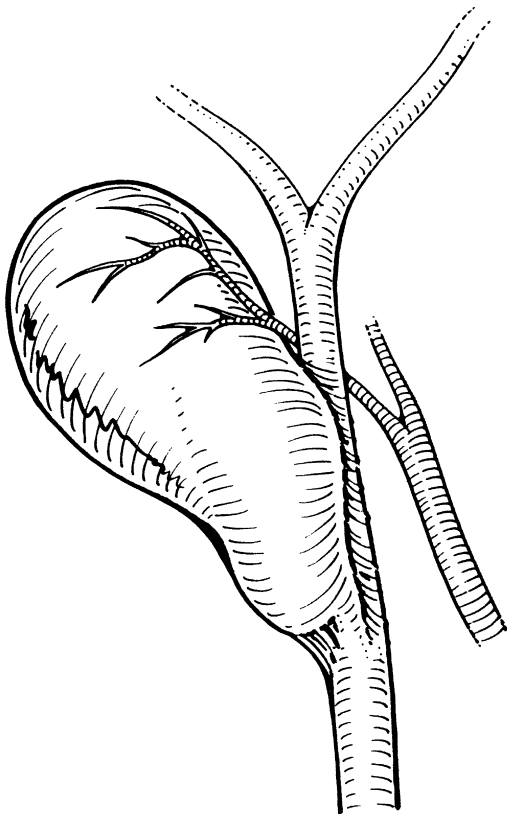

FIGURE 34.19. Severe acute cholecystitis or long-standing chronic cholecystitis may result in the cystic duct and infundibulum of the gallbladder becoming partially adherent or difficult to separate from the common bile duct itself.

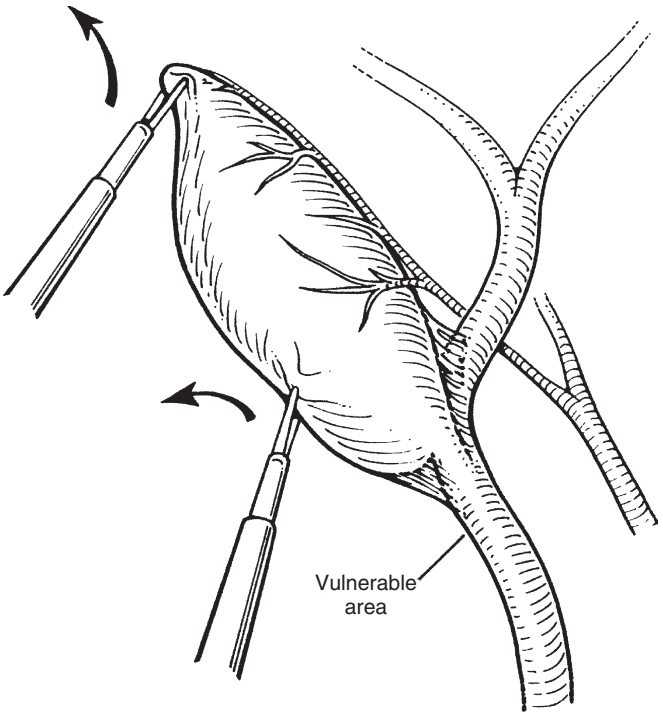

FIGURE 34.20. With excessive traction on the neck of the gallbladder, the common bile duct (CBD) becomes tented and appears to be entering the gallbladder directly. The marked portion of the CBD is most vulnerable to injury during laparoscopic cholecystectomy.

performed with no hesitation in asking for the help of a surgeon experienced in biliary repair.

A bile injury may also be unrecognized at the time of surgery but evident in the postoperative period. A postoperative bile leak occurs in less than 1% of cholecystectomies. Symptoms usually occur 4 to 10 days after surgery and consist of abdominal pain, fever, and abdominal distension. In this setting, it is mandatory to evaluate for biliary injury. Many postoperative bile leaks are considered minor biliary injuries, such as a cystic duct stump leak or an unclipped duct of Luschka. When a bile duct injury is discovered in the postoperative period, a coordinated effort by radiologists, endoscopists, and surgeons is necessary to optimize management (Strasberg et al, 1995). The initial diagnostic study should be US or CT of the abdomen. Fluid will typically be seen in the gallbladder fossa, hepatorenal recess, right gutter, and right subdiaphragmatic spaces. The biloma can be drained percutaneously, and the biliary anatomy should be evaluated with ERCP, which is preferred because it is both diagnostic and potentially theurapeutic. For example, a cystic duct stump leak can be treated successfully in the majority of cases with a temporary transsphincteric biliary stent.

Bleeding

The incidence of uncontrollable bleeding from laparoscopic cholecystectomy is 0.1% to 1.9% and can occur from three distinct sites: 1) the liver, 2) arterial sources, and 3) port insertion sites. Significant bleeding from the liver bed is fairly common and is now appreciated to be from the often close proximity of the middle hepatic vein and its radicals to the gallbladder fossa in up to 10% to 15% of patients. Bleeding usually occurs during the final aspects of the removal of the gallbladder from the hepatic fossa and generally requires immediate conversion to open surgery to control profuse hemorrhage through stitch ligation, if initial attempts at laparoscopic hemostatic control fail. Arterial control issues involving the cystic artery can be identified immediately and controlled with clips, but only if anatomical landmarks can be safely ensured because of a high association with right hepatic arterial injury; such issues may also first be evident postoperatively as an acute hemodynamic decline requiring resuscitation, transfusions, and often reoperation—the culprit is usually a dislodged clip in this scenario. Finally, incision or trocar sites can bleed.

When a trocar injury to a major blood vessel is suspected, the patient must be opened immediately without removing the trocar, and the involved blood vessel must be isolated. In contrast, if the small-bore Veress needle enters a viscus or blood vessel, the operation generally can be completed, and the patient is monitored closely for signs of complications in the postoperative period. Additionally, bleeding may occur if a trocar lacerates a blood vessel within the abdominal wall, such as the epigastric artery or one of its branches. Before removal, each trocar should be visualized from the peritoneal aspect using the laparoscope. If significant hemorrhage is seen, it generally can be controlled with cautery or a through-and-through suture on each side of the trocar insertion site.

Bowel Injury

Inadvertent bowel injury has been described in approximately one to four patients in 1000 laparoscopic procedures. The injury typically occurs during insertion of the initial trocar, and it may occur with either the Veress or open technique. After the initial trocar is inserted, a brief inspection should be performed to evaluate for bowel injury. All other additional trocars should be placed under direct laparoscopic visualization and only in an area free of adhesions. The "protective" shield on disposable trocars is not a guarantee against perforation of intestine or major vessels, especially after previous abdominal operations. Trocar insertion should never be aimed toward the spine or the great vessels, and a hand should be used as a "brake" to prevent inadvertently introducing the trocar too far. Management of this complication is dictated by the clinical scenario. If the injury is identified at the time of surgery, conversion to an open procedure for repair is indicated, if it cannot be repaired through the laparoscope.

One of the most dreaded complications after any laparoscopic surgery is a missed enterotomy. Patients may present with trocar site pain, abdominal distension, diarrhea, leukopenia, and cardiovascular collapse from sepsis, typically within 96 hours of the procedure. If the patient is septic or has free air, an emergent laparotomy is indicated. When the presentation is more indolent and controlled, standard enterocutaneous fistula management with nutritional support and adequate drainage and wound care may be appropriate.

Postcholecystectomy Syndrome

The term *postcholecystectomy syndrome* (PCS; see Chapter 38) describes the presence of symptoms after cholecystectomy. These symptoms can represent either the continuation of symptoms thought to be caused by the gallbladder or the development of new symptoms normally attributed to the gallbladder. PCS also includes the development of symptoms

caused by removal of the gallbladder and is caused by alterations in bile flow resulting from loss of the reservoir function of the gallbladder. Two types of problems may arise: The first is continuously increased bile flow into the upper gastrointestinal (GI) tract, which may contribute to esophagitis and gastritis. The second is related to the lower GI tract, where diarrhea and colicky lower abdominal pain may result. PCS affects about 10% to 15% of patients; however, it is usually a temporary diagnosis, and an organic or functional diagnosis is established in most patients after a complete workup (Jaunoo et al, 2010). Postoperative symptoms may occasionally be caused by retained CBD stones or stones in the cystic duct remnant. Initial workup includes LFTs and US. MRCP or ERCP may be indicated if a retained CBD stone is suspected. A thorough preoperative evaluation is essential to minimize PCS, and patients should be warned of the possibility of postoperative symptoms. Although attempts to preoperatively identify patients at increased risk for PCS have largely been unsuccessful, the consensus opinion holds that the more secure the preoperative diagnosis, the lower the risk of PCS.

RESULTS OF LAPAROSCOPIC CHOLECYSTECTOMY SERIES

Several prospective, randomized trials have compared open cholecystectomy with laparoscopic cholecystectomy, and results have been mixed in showing advantages of laparoscopic cholecystectomy over an open approach in treating elective symptomatic cholelithiasis (Table 34.6). The largest study prospectively randomized 310 patients to laparoscopic cholecystectomy versus minilaparotomy open cholecystectomy with 155 patients in each group. Conversion to large-incision cholecystectomy was significantly more common with laparoscopic cholecystectomy (13% vs. 4%), and complications were significantly more frequent with laparoscopic cholecystectomy (9% vs. 3%). When laparoscopic cholecystectomy was successful, hospital stay was significantly shorter than for open cholecystectomy (2 days vs. 3 days), but overall the hospital stay was not significantly different. Postoperative analgesia requirements were reduced, and return to normal activities and to work was faster after laparoscopic cholecystectomy, but no significant cost difference was reported between the two procedures (McGinn et al, 1995).

Similarly, another study prospectively randomized 200 patients in a single-blinded fashion (identical wound dressings were applied in both groups so that caregivers would be blinded to the type of operation) to laparoscopic cholecystectomy versus minilaparotomy open cholecystectomy. Laparoscopic cholecystectomy took significantly longer than small-incision cholecystectomy (median, 65 min vs. 40 min; $P < .001$). No significant difference was reported in length of stay (median, 3 days for laparoscopic cholecystectomy vs. 3 days for small-incision open cholecystectomy; $P = .74$), return to work (median, 5 weeks vs. 4 weeks; $P = .39$), and time to full activity (median, 3 weeks vs. 3 weeks; $P = .15$) (Majeed et al, 1996).

A follow-up to this study prospectively randomized 200 additional patients to laparoscopic cholecystectomy or minilaparotomy open cholecystectomy. Postoperative pain, analgesic and antiemetic consumption, perceived health, and metabolic and respiratory responses were compared. Pain scores in both groups were low, but laparoscopic cholecystectomy was associated with lower postoperative pain scores and analgesic requirements compared with small-incision open cholecystectomy, however, the antiemetic requirements were greater after laparoscopic cholecystectomy. The duration of hospital stay and the perceived

*Includes intraoperative and postoperative complications

health after operation were the same, and both procedures were associated with a similar reduction of respiratory function. Twenty-four hours after operation, the inflammatory (C-reactive protein) response to laparoscopic cholecystectomy (22 ± 20 mg/L) was significantly lower than after small-incision open cholecystectomy (68 ± 30 mg/L), but the neuroendocrine (cortisol) response was similar (laparoscopic cholecystectomy, 475 ± 335 nmol/L compared with small-incision open cholecystectomy, 710 ± 410 nmol/L; Squirrell et al, 1998).

Numerous clinical series of laparoscopic cholecystectomy, accrued prospectively or retrospectively, also have been reported (Table 34.7). Among our personal series of more than 1,500 laparoscopic cholecystectomies performed in a teaching institution, the conversion rate was 2.1% with one perioperative death (<0.1%) owing to myocardial infarction at 1 week postoperatively. Significant postoperative complications occurred in 2.7%, including three minor duct injuries (0.2%). The mean operative time decreased from more than 100 minutes in the first 100 patients to 85 minutes in the most recent 100 patients. The postoperative course in most patients was uneventful, with more than 90% of patients discharged from the hospital within 24 hours of surgery; only 10% required parenteral narcotics after leaving the recovery room. Similarly, the duration of disability was minimal, with the average postoperative interval to return to full activity being 10 days. These results compared favorably with the results of traditional open cholecystectomy, in which the morbidity and mortality rates were similar, but hospitalization for 3 to 5 days and return to work at 1 month after surgery were standard (Wu et al, 1998b).

Our data mirror those from most series of laparoscopic cholecystectomy reported to date. Morbidity rates range from 1.5% to 8.6%, and bile duct injuries range from 0.2% to 0.7%. Death is rare after this procedure and usually is attributed to unrelated events. The conversion rates from laparoscopic to open operation in most series range from 1.8% to 7.8% and generally are greater early in the surgeon's experience with the procedure. A nationwide study reported a conversion rate to open procedure of 5% to 10% (Livingston & Rege, 2004). In addition, studies have shown that advanced age, longer duration of procedure, and acute cholecystitis significantly increase postoperative morbidity and the length of stay (Lyass et al, 2000; Perraux et al, 2000).

As would be predicted for this excisional procedure, laparoscopic cholecystectomy effectively treats gallstone disease. Postcholecystectomy problems (see Chapter 38) occur in some patients, however. Kane and colleagues (1995) noted 89% of patients undergoing laparoscopic cholecystectomy had preoperative biliary-type pain, and only 10.6% of the patients had similar pain postoperatively. Similarly, Ure and colleagues (1995) found that the percentage of patients with biliary colic was reduced from 83% before laparoscopic cholecystectomy to 6.4% after laparoscopic cholecystectomy. Fenster and associates (1995) examined symptom relief in 225 patients who underwent laparoscopic cholecystectomy, followed postoperatively for 3 weeks to 3 months. They differentiated symptomatic gallstones from acalculous cholecystitis and discovered that 82% of patients with biliary colic and gallstones had complete relief of upper abdominal pain after the operation compared with only 52% of patients with acalculous cholecystitis (Fenster et al, 1995). These data are comparable to the data for open cholecystectomy, which showed that biliary-type pain persisted at follow-up (<1 year) in 9% to 34% of patients with

symptomatic gallstones (Bates et al, 1991; Gilliland & Traverso, 1990; Scriven et al, 1993). In terms of cost-effectiveness, several studies have shown that laparoscopic cholecystectomy is less expensive than an open procedure (Bass et al, 1993; Fullarton & Bell, 1994), whereas others have shown the opposite (McMahon et al, 1994).

EMERGING TECHNIQUES

Natural Orifice Translumenal Endoscopic Surgery Cholecystectomy

Over the past few years, many technical innovations have attempted to further minimize the field of laparoscopy. In 2004, peritoneoscopy was performed in an animal model by passing a flexible endoscope through the wall of the stomach and into the peritoneal cavity (Kalloo et al, 2004). This resulted in the concept of natural orifice translumenal endoscopic surgery (NOTES), with its general goal of minimizing trauma by eliminating incisions through the abdominal wall and utilizing natural orifices. Although a number of potential natural orifices can theoretically be used to access the abdominal cavity, clinical cases have thus far only used transgastric (TG) and transvaginal (TV) approaches. Human applications currently have been limited and have relied on laparoscopic-assisted or so-called hybrid techniques.

TG and TV cholecystectomy were both first described in humans in the United States in 2007. Compared with TG cholecystectomy, TV cholecystectomy is technically easier to perform because of the direct vision-guided access and a straight route to the upper abdomen. In addition, the TV route obviates the risk of gastric content leakage via an imperfectly closed gastrotomy access site. As a consequence, many more NOTES cholecystectomies have been performed in humans via a TV approach as opposed to a TG approach. All reports of NOTES cholecystectomy have highlighted the limits imposed by the inadequacy of current instrumentation, resulting in lack of exposure, fine dissection, and safe cystic duct ligation, therefore requiring a hybrid technique to perform the operation safely. In general, TV procedures take up to twice as long as standard laparoscopic operations, whereas TG operations triple the operating time. Few complications have been reported to date. Currently, NOTES remains investigational and is only performed at a few centers worldwide. Many of the limitations remain centered on instrument development, very few data exist to quantify postoperative pain and disability, and no prospective randomized trials comparing NOTES cholecystectomy to laparoscopic cholecystectomy have been done. Again, given the high bar that has been set for the results of laparoscopic cholecystectomy, it may be difficult to show a meaningful clinical advantage of NOTES cholecystectomy. However, the concept of NOTES has challenged surgeons to further advance surgery, and it continues to drive the development of new technology and techniques.

Single-Incision Laparoscopic Surgery Cholecystectomy

Single-incision laparoscopic surgery (SILS) cholecystectomy was first described in the Italian literature in the mid-1990s. Navarra and colleagues (1997) published the first case series of 30 patients who underwent what they described as "one-wound laparoscopic surgery." Their method used three extracorporeal stay sutures and two 11-mm working ports in the umbilicus, and the incisions were connected at the end of the case to facilitate the removal of the gallbladder. The mean operative time was 123 minutes, and the mean postoperative stay was 1.8 days. These initial reports did not receive much attention, but recently a resurgence of interest in SILS has been seen with a concurrent rapid development of instrumentation.

SILS emphasizes the concept of surgery through one small transabdominal incision, rather than the standard multiple trocar sites, with theoretic benefits of less pain and better cosmesis. The allure of SILS is that the surgeon can use relatively standard laparoscopic instruments and skills without the technical difficulties associated with NOTES. As a result, SILS can be more readily implemented and is likely to have a higher degree of acceptance. Several small series have demonstrated the feasibility and safety of SILS cholecystectomy. However, because it is relatively new and in evolution, many techniques have been described, and no widely accepted standard exists.

Although SILS cholecystectomy provides an apparent cosmetic advantage by hiding the surgical scar in the umbilicus, other proposed benefits are yet to be determined. Concerns revolve around the surgeon's limited ability to triangulate and to exercise traction and countertraction on tissue dissecting planes. In addition, the view is often in line with the camera, which may compromise depth perception and visualization. It is of paramount importance to maintain the same surgical principles and not to compromise visualization of the anatomic landmarks to avoid unnecessary complications, such as bile duct injuries. Supplemental stab incisions or extracorporeal stay sutures in the right upper quadrant are often needed to provide adequate retraction of the gallbladder and proper visualization of the triangle of Calot. Specialized instrumentation, such as reticulating instruments and multichannel ports, have been also developed to help overcome some of these limitations. Standard four-port laparoscopic cholecystectomy remains the gold standard treatment for benign gallbladder disease, but SILS cholecystectomy will continue to develop and may have a role in select groups of patients. Well-designed clinical trials powered adequately are needed to better understand the risk-benefit profile of SILS cholecystectomy.

CONCLUSION

The vast majority of cholecystectomies in the developed world are performed laparoscopically with excellent results. Many patients now can undergo this operation in an ambulatory setting. Most CBD stones can be removed at the time of laparoscopic cholecystectomy, extracted through the cystic duct or by direct choledochotomy. Attempts at improving outcomes from laparoscopic cholecystectomy are valuable and will drive the development of novel surgical instrumentation. The newer approaches to cholecystectomy, including single-incision laparoscopy and NOTES procedures, should be pursued but must also be compared honestly and openly to the current gold standard of laparoscopic cholecystectomy.

CHAPTER 35

Stones in the bile duct: clinical features and open surgical approaches and techniques

Katia Papalezova and Bryan Clary

OVERVIEW

Although the era of intervention for choledocholithiasis can be traced to over a century ago, with the first successful common bile duct (CBD) exploration by Thornton in 1889 and with the introduction of catheter-based biliary decompression by Courvoisier and Kehr, significant advances and refinements did not occur until recent decades. For many years, open cholecystectomy and exploration of the CBD remained the standard treatment for patients with choledocholithiasis, and it was a procedure carried out on a regular basis by most general surgeons. During that era, the morbidity and mortality rates of CBD exploration were very low, the percentage of retained stones was only 1% to 3%, and in long-term follow-up, revisional surgery was necessary in only about 10% of the patients (Gonzalez et al, 1997; Hammarström et al, 1995; Neoptolemos et al, 1987; Targarona et al, 1996).

The past 3 decades, however, have seen major changes in the management of choledocholithiasis, prompted by the introduction of high-quality noninvasive imaging, the more widespread availability of percutaneous and endoscopic approaches to duct clearance (see Chapters 27 and 28), and the introduction of minimally invasive surgical approaches in the performance of choleycstectomy and CBD exploration (see Chapter 34). Although the overwhelming majority of cholecystectomies are now performed laparoscopically, laparoscopic exploration of the common bile duct (LCBDE) is infrequently performed, given the advanced skills typically required and the availability of endoscopic retrograde cholangiopancreatography (ERCP; see Chapter 18). In a recent survey of general surgeons practicing in a rural area of the United States, the preferred approach to choledocholithiasis was ERCP (75%), followed by laparoscopic (21%) and open (4%) exploration. Time constraints and lack of equipment were the main factors preventing the application of the laparoscopic technique for treating choledocholithiasis (Bingener & Schwesinger, 2006).

Despite these considerations, there remain indications for operative choledochotomy and, more specifically, for open exploration. This chapter presents a review of the clinical features of choledocholithiasis with an emphasis on the technical aspects of open CBD exploration.

ORIGIN OF CHOLEDOCHOLITHIASIS

Most CBD stones are secondary in nature, having migrated from the gallbladder. This is in contrast to primary CBD stones that originate within the CBD. The existence of such primary stones is suggested by their occurrence in patients with congenital absence of the gallbladder and in those whose CBD had been previously cleared at the time of prior cholecystectomy. The practice of routine cholangiography during the era of open cholecystectomy was common and demonstrated an incidence of choledocholithiasis approaching 10% in patients without clinically evident common duct involvement (McSherry & Glenn, 1980; Hampson et al, 1981; Doyle et al, 1982; Lygidakis, 1983; Coelho et al, 1984; Ganey et al, 1986; DenBesten & Berci, 1986; Girard, 2000). Some 10% to 15% of gallstone patients concomitantly suffer from bile duct stones. In the United States and other Western countries, CBD stones are predominantly secondary, although primary stones are more common in Asia. This is associated with the high incidence of intrahepatic bile duct stones seen primarily in Southeast Asian countries, Taiwan, Hong Kong, and Singapore (Kim et al, 1995; see Chapter 39). The relative prevalence of intrahepatic bile duct stones in all gallstone cases in Taiwan is extremely high (>50%), and coexisting intrahepatic and extrahepatic bile duct stones are found in approximately 70% of these. Furthermore, the gallbladder stones are primarily cholesterol or black-pigment stones, whereas most bile duct stones are brown-pigment (calcium bilirubin stones).

CLINICAL FEATURES

The natural history of CBD stones is unpredictable, with many small stones passing spontaneously. In the era of open cholecystectomy, a healthy debate surrounded the need for routine intraoperative cholangiography in patients without clinical signs of choledocholithiasis. Detractors noted that although 10% to 15% of patients had cholangiographic findings of CBD stones when routine cholangiography was used, a much lower percentage of patients developed clinical sequelae of CBD stones in series that utilized a more selective approach to cholangiography.

More recent series of laparoscopic cholecystectomy with a selective approach toward cholangiography appear to confirm this same experience (Fogli et al, 2009). In one of the more notable recent experiences, Collins and colleagues (2004) identified filling defects consistent with stones in 4.6% of patients. In these patients, access was maintained for the performance of postoperative cholangiograms. At 48 hours, 26% of patients had a normal cholangiogram, and an additional 26% had evidence for passage of the stones by 6 weeks. Twenty-two patients (2.2% of total population) had persistent CBD stones at 6 weeks after laparoscopic cholecystectomy and underwent ERCP for retrieval (Collins et al, 2004).

Symptomatic presentations include biliary colic, jaundice, cholangitis, pancreatitis, or combinations of these. Infection in

the setting of CBD obstruction gives rise to the classic triad of fever with chills, jaundice, and pain; in some patients this can be associated with clinical signs of sepsis (see Chapter 43). In the absence of infection, jaundice may occur in an often fluctuating manner, as the stone intermittingly obstructs passage of bile. Over long periods, this process can lead to secondary biliary cirrhosis. After biliary colic, pancreatitis is the second most frequent symptomatic presentation of CBD stones (see Chapter 53). Depending on the timing of cholangiography, CBD stones can be identified in up to 50% of patients. Patients who have symptomatic bile duct stones are at risk of experiencing further symptoms or complications if left untreated. More than one half of patients who had retained bile duct stones experienced recurrent symptoms during a follow-up period of 6 months to 13 years (Johnson & Hosking, 1987), and 25% developed serious complications (Caddy & Tham, 2006). Given the potentially serious nature of CBD stones, it is critical that an approach be adopted to identify patients with CBD stones and ensure their clearance.

PREOPERATIVE DIAGNOSIS

The identification of patients with choledocholithiais in the absence of clinical signs requires a careful history and physical examination in conjunction with attention to routine blood work and abdominal ultrasound. Clinical, ultrasonographic, and serum chemistry data are sensitive in 96% to 98% and specific in 40% to 75% for identification of patients with choledocholithiasis (Alponat et al, 1997; Koo & Traverso, 1996; Trondsen et al, 1998). Liu and colleagues (2001) triaged patients before laparoscopic cholecystectomy using guidelines incorporating patient information obtained from clinical evaluation, serum chemistry analysis, and abdominal US and assigned them into four groups based on the level of suspicion for choledocholithiasis (group 1, extremely high; group 2, high; group 3, moderate; group 4, low). The occurrence of choledocholithiasis was 92.6%, 32.4%, 3.8%, and 0.9% for groups 1, 2, 3, and 4, respectively. Patient triage resulted in the identification of CBD stones during preoperative ERCP in 92.3% of the patients who were subsequently referred for endoscopic clearance. Many other groups have also demonstrated the value of liver function tests (LFTs) in predicting the presence of CBD stones (Peng et al, 2005; Sgourakis et al, 2005). Although the trends of bilirubin and alkaline phosphatase are more typically used, a raised gamma-glutamyltransferase level has been suggested to be the most sensitive and specific indicator of CBD stones. A value greater than 90 U/L has been proposed to indicate a high risk of choledocholithiasis, with sensitivity and specificity of 86% and 74.5%, respectively (Peng et al, 2005).

In patients identified to be at risk by clinical history and/or abnormalities in serum chemistries, if imaging and therapy are necessary, an efficient and thoughtful approach is required. Transabdominal ultrasound (TUS) is the most commonly used initial diagnostic tool for suspected biliary stones (see Chapter 13). It has the advantage of being noninvasive, widely available, and inexpensive; however, US is highly operator dependent. TUS has low sensitivity, 25% to 60%, for detection of bile duct stones, but it has a very high specificity, 95% to 100% (Sugiyama & Atomi, 1997; Amouyal et al, 1994). Indirect evidence, such as the presence of gallstones or biliary ductal dilation with a CBD diameter greater than 6 mm in the appropriate clinical setting, is predictive of bile duct stones.

Computed tomography (CT) scanning has a similarly low sensitivity in the detection of bile duct stones and is used primarily to document biliary dilation or to exclude other causes of biliary obstruction (e.g., a mass lesion; see Chapter 16). The role of helical CT cholangiography is still in evolution, particularly in the United States. Intravenously administered contrast agents combined with high-resolution helical scans and three-dimensional reconstructions can be very useful in diagnosing choledocholithiasis (Cabada Giadàs et al, 2002; Maniatis et al, 2003). The sensitivity of this technique can be as high as 97%, and the specificity is 85% to 96% (Polkowski et al, 1999; Cabada Giadas et al, 2002; Maniatis et al, 2003; Gibson et al, 2005; Kim et al, 2007). Although this accuracy is comparable to magnetic resonance cholangiopancreatography (MRCP), helical CT cholangiography is limited by 1) possible allergic reactions to the contrast agents, as high as 15% in one series using intravenous iotroxate (Gibson et al, 2005); 2) suboptimal ductal contrast opacification in the presence of significant jaundice, evidenced by bilirubin more than two or three times the upper limits of normal (Polkowski et al, 1999; Soto et al, 1999); and 3) limited visualization of intrahepatic duct branches, particularly when using oral contrast agents (Gibson et al, 2005; Chopra et al, 2000).

Since its introduction in 1991 (Wallner et al, 1991), MRCP has emerged as an accurate, noninvasive diagnostic modality for investigating the biliary and pancreatic ducts (Hallal et al, 2005) and has been recommended in some circles as the preoperative procedure of choice for the detection of CBD stones (Hallal et al, 2005; Taylor et al, 2002; Topal et al, 2003; see Chapter 17). MRCP provides excellent anatomic detail of the biliary tract and has a sensitivity of 81% to 100% and a specificity of 92% to 100% in detecting choledocholithiasis (Hallal et al, 2005). The accuracy of MRCP in diagnosing CBD stones is comparable with that of ERCP (see Chapter 18) and intraoperative cholangiogram (Hallal et al, 2005; Vargghese et al, 2000; see Chapter 21). It thus avoids the need for an invasive procedure in about 50% of patients (Demartines et al, 2000), allowing selective use of ERCP or surgical CBD exploration in those patients who require a therapeutic intervention. These results have led some practitioners to consider MRCP the new gold standard for biliary imaging (Hallal et al, 2005; Shanmugam et al, 2005), although MRCP may miss stones smaller than 5 mm in diameter. It can also underestimate the number of stones detected (Vargghese et al, 2000). MRCP is an expensive option that requires significant expertise for interpretation, and it may not always be readily available.

For years, the gold standard for preoperative visualization of the bile duct has been ERCP (see Chapter 18); however, the nonselective use of ERCP in all patients with suspected choledocholithiasis detects CBD stones in less than 50% (Behrns et al, 2008; Petrov et al, 2008) and results in over half of patients undergoing an unnecessary procedure, exposed to its associated morbidity and mortality. The first publications on the usefulness of the alternative, noninvasive modality, endoscopic ultrasonography (EUS), in diagnosing CBD stones appeared around 1990 (Amouyal et al, 1989; Edmundowicz et al, 1992; see Chapter 14). Since then, more than 25 prospective studies, incorporating more than 2500 patients with suspected choledocholithiasis, have shown excellent accuracy with EUS, as well as safety.

The overall diagnostic performance of EUS has been evaluated in two recent metanalyses (Garrow et al, 2007; Tse et al, 2008); the pooled sensitivity and specificity of EUS were 89% to 94% and 94% to 95%, respectively. A review of all randomized controlled trials of EUS-guided ERCP versus ERCP alone in patients with suspected choledocholithiasis demonstrated that by performing EUS first, ERCP may be safely avoided in two thirds of patients, and the use of EUS significantly reduced the risk of overall complications and post-ERCP acute pancreatitis (Petrov & Savides, 2009). The data suggest that the ERCP should be reserved solely for patients with a high probability of CBD stones.

Before the advent of laparoscopy, preoperative clearance of CBD stones with ERCP before open exploration was uncommon. Several well-performed studies did not demonstrate any improvement in morbidity or mortality with preoperative endoscopic sphincterotomy (Heinerman et al, 1989; Neoptolemos et al, 1988; Stain et al, 1991). One study showed an increase in morbidity when preoperative ERCP with sphincterotomy was added to open cholecystectomy compared with cholecystectomy and open CBD exploration (Stain et al, 1991). A Cochrane systematic review by Martin and colleagues (2006) showed that open surgery results in a lower primary treatment failure, fewer additional procedures, fewer average number of procedures required per patient, and less mortality. Largely based on these studies, preoperative ERCP with sphincterotomy was uncommon in the era of open cholecystectomy, and it did not become more widespread until laparoscopic approaches to cholecystectomy appeared.

When laparoscopic cholecystectomy was introduced, preoperative ERCP was frequently used for patients suspected of having choledocholithiasis, as evidenced by jaundice, elevated liver function tests, a history of pancreatitis, and a dilated biliary system. Even with these criteria, however, it is difficult to predict which patients will have choledocholithiasis, and a negative ERCP was performed in 40% to 70% of patients, because most of these abnormalities were caused by transient biliary obstruction secondary to stones that subsequently passed into the duodenum (Stain et al, 1991; Ponsky, 1992; Delorio et al, 1995; Cotton, 1993; Cuschieri et al, 1996).

Two prospective randomized controlled trials have compared preoperative ERCP with sphincterotomy followed by laparoscopic cholecystectomy during the same hospital admission with single-stage laparoscopic management (Cuschieri et al, 1999; Sgourakis et al, 2005). The results demonstrate equivalent success rates of duct clearance and patient morbidity for the two management options, but a significantly shorter hospital stay was reported with the single-stage laparoscopic treatment. Cuschieri and colleagues (1999) concluded that in fit patients (ASA I and II), single-stage laparoscopic treatment is the better option, and preoperative endoscopic sphincterotomy (ES) should be confined to poor-risk patients, such as those with cholangitis or severe pancreatitis.

Performing ERCP has clinical and financial costs that must be weighed against the likelihood of successful extraction of stones that otherwise would result in significant disease manifestation. Complications that include postprocedural pancreatitis, bleeding, infections, and perforations are not uncommon. ERCP has an overall complication rate of 10% and a mortality rate less than 0.5% (Ponsky, 1992; Delorio et al, 1995; Cotton, 1993; Davis et al, 1997). A recent systematic analysis of prospective studies has shown that complications continue to occur at a relatively consistent rate and that the majority of events are of mild to moderate severity (Andriulli et al, 2007).

Certain clinical situations mandate preoperative ERCP. Preoperative endoscopic drainage should be used in acute cholangitis for decompression and amelioration of sepsis (Cuschieri et al, 1999; Leung, 2003) and in patients with severe gallstone pancreatitis and evidence of persistent choledocholithiasis. Patients with other major comorbidities or limited life expectancy represent another indication for ERCP with endoscopic sphincterotomy (ES) and decompression (Cuschieri et al, 1999), often as the definitive management without cholecystectomy.

COMMON BILE DUCT EXPLORATION AT CHOLECYSTECTOMY

In the early 1970s, ES was introduced as a treatment modality for CBD stones. During the following decades, it gained wide acceptance as a less invasive, highly effective alternative for the treatment of biliary obstruction as a result of gallstones (see Chapters 18 and 27). However, in patients with residual stones in the gallbladder, subsequent cholecystectomy was considered necessary. In a prospective randomized trial, it was demonstrated that ES before open cholecystectomy did not lead to earlier recovery or less postoperative morbidity compared with primary open cholecystectomy combined with CBD exploration. In a prospective randomized trial published in 1995 by Hammarström and colleagues, an expectant policy after ES was compared with open cholecystectomy combined with CBD exploration. It appeared that 20% of the patients after ES alone needed cholecystectomy during follow-up.

Similar results were reported in 1996 by Targarona and colleagues. In this prospective randomized trial of high-risk patients, the policy of ES and subsequent open cholecystectomy was compared to ES alone. In their experience, patients who underwent elective open cholecystectomy had significantly fewer recurrent biliary symptoms (6% vs. 21%) and needed fewer readmissions (4% vs. 23%) than patients who did not undergo surgery after ES. (Targarona et al, 1996). Given the recognition that cholecystectomy is necessary in most patients with CBD stones, even in the presence of a papillotomy, the appropriate timing and method of CBD clearance must be considered.

In less developed health care environments, where endoscopic or percutaneous approaches to biliary decompression and stone clearance are limited, open cholecystectomy with bile duct exploration is indicated in patients with a strong clinical suspicion for common duct stones, such as those with abnormal LFTs or cholangitis, as well as when palpable stones are present in the CBD, or when stones are visualized on an intraoperative cholangiogram.

In more developed health care settings with access to endoscopic, radiologic, or laparoscopic expertise, there will still be some patients in whom an open approach to CBD exploration is required. These include 1) patients with large or impacted CBD stones, in whom biliary enteric drainage is indicated; 2) those with anatomic considerations that preclude endoscopic treatment, such as prior gastric resection, duodenal diverticulae, and so on; and 3) patients who require an open approach for cholecystectomy, including those with Mirizzi syndrome, biliary-enteric fistula, a high index of suspicion for cancer, and those with CBD stones demonstrated by palpation or cholangiogram.

Postcholecystectomy Choledocholithiasis

Incidence

Although most initial operations for gallstone disease with or without demonstrated choledocholithiasis are curative, a few patients are found later to have additional stones in the CBD. Approximately 1% to 2% of all patients who undergo cholecystectomy have stones left in the CBD that require further intervention (Roslyn, 1993). Although retained or overlooked calculi after open cholecystectomy without CBD exploration are rare (Bergdahl & Holmlund, 1976), their incidence after open cholecystectomy with concomitant CBD exploration has been reported to be less than 5% (Dayton et al, 1984; Kappes et al, 1982; Roslyn, 1993), with a higher frequency after positive than after negative CBD exploration. After a second operation on the biliary tract, a recurrence rate of approximately 20% has been reported (Saharia et al, 1977; Way, 1973), with even higher rates after subsequent reoperation (Allen et al, 1981).

Treatment

The choice of management is determined by the clinical presentation, condition of the patient, availability of equipment, availability of clinical expertise, and presence or absence of a T-tube. Currently, operative management of retained and recurrent CBD stones is resorted to only if nonoperative procedures have failed.

RETAINED STONES IN THE PRESENCE OF A T-TUBE

With the advent of laparoscopic biliary surgery, the use of the T-tube has become less common, eliminating methods for accessing the biliary tree postoperatively without an invasive procedure. If a patient with a retained CBD stone is in the immediate postoperative period and still has a T-tube in place, the management options are observation, mechanical extraction, or ES.

In the absence of biliary obstruction or infection, no treatment is necessary for 4 to 6 weeks. During this time, 10% to 25% of retained stones found on postoperative cholangiography can be expected to pass spontaneously into the duodenum, and no further treatment is required. If after 4 to 6 weeks the stone persists, the choice of treatment is between a radiologic approach through the T-tube tract (see Chapter 28) or endoscopic retrograde sphincterotomy (see Chapter 27). Because of its high success rate and low morbidity and mortality, nonoperative mechanical extraction through the T-tube tract is an attractive treatment choice. A success rate of 95% has been reported with a morbidity rate of only 4% (Mazzariello, 1978). Burhenne (1980) reported no deaths in 661 patients. When complications do occur, they can be treated medically in most instances, and only 0.2% of cases have required surgery (Mazzariello, 1978).

ES also has been shown to be effective in the management of retained stones in the early postoperative period after exploration of the CBD with a T-tube still in place (Hammarström et al, 1996; O'Doherty et al, 1986). Although ES has the considerable advantage that it can be carried out as soon as retained stones are discovered, treatment may be unnecessary in some patients, because stones may pass spontaneously. The results of mechanical stone extraction through the T-tube tract are better than any reported for ES (Lambert et al, 1988), which may be best used when the patient is clinically unstable, the T-tube is inappropriate in size and position, or mechanical extraction through the T-tube has failed. If these techniques fail, operative management can be resorted to with the expectation of a high success rate and rates for morbidity and mortality comparable to those for endoscopic retrograde sphincterotomy (Cameron, 1989; Girard & Legros, 1981).

RETAINED OR RECURRENT STONES IN THE ABSENCE OF A T-TUBE

For a patient without a T-tube in place, ES is the procedure of choice and should be attempted first (Cameron, 1989; Sivak, 1989). Most reports of ES indicate a success rate in achieving overall clearance of stones from the CBD of more than 85% (Cotton, 1984; Lambert et al, 1991). Although early complication rates for ES are 5% to 10%, with emergency surgery being required in 1% to 2% of cases, most complications can be managed conservatively (Cotton, 1984; Escourrou et al, 1984). Hemorrhage, pancreatitis, cholangitis, and perforation are the most frequent complications, and mortality usually is reported at 0.5% to 2% (Lambert et al, 1991; Sivak, 1989). Long-term complication rates, mainly from stenosis or new stones or both, are low (<10%), and most complications can be managed endoscopically (Cotton, 1984; Escourrou et al, 1984; Hammarström et al, 1996; Sivak, 1989).

If for any reason ES is contraindicated, or if it fails, operative management is a reasonable alternative (Cameron, 1989). Reoperation for retained or recurrent stones can be performed with negligible operative mortality and morbidity (Girard & Legros, 1981). This report, which included many series, showed that reoperation on the CBD for retained or recurrent stones is possible, with a mortality rate of less than 2%. Miller and colleagues (1988) reported 237 patients with CBD stones treated by CBD exploration or ES. Success was higher and mortality was lower for the operatively managed group. The complication rate was similar, but the complications tended to be more serious and more apt to require surgery in the ES group. These studies show that the success, morbidity, and mortality rates of surgery are comparable to those of endoscopic approaches and suggest that operation should not be forgotten in the treatment of retained or recurrent bile duct stones.

When performing reoperation for retained CBD stones, if the stones can be adequately and completely removed, the most appropriate surgical procedure is choledocholithotomy, choledochoscopy, placement of a T-tube, and completion cholangiography. This procedure is adequate for most patients, and the overall failure rate is only 3% (Girard & Legros, 1981). Others have reported failure rates of 18% and 30% (Allen et al, 1981; Saharia et al, 1977). Allen and colleagues (1981) and Lygidakis (1982) recommended a biliary-enteric drainage procedure in all patients with previous choledocholithotomy (see Chapter 29). Tompkins and Pitt (1982) and Cameron (1989) emphasized, however, that concomitant biliary drainage should not be done as a mandatory procedure in all patients with retained or recurrent stones. In general, biliary-enteric drainage at reoperation should be carried out if any of the following occur: 1) stricture or stenosis of the distal bile duct or sphincter of Oddi, 2) marked dilation of the duct of 2 cm or more, 3) multiple or primary bile duct stones, 4) inability to remove all stones from the duct, 5) a third operation.

Transduodenal sphincteroplasty (see further on), choledochoduodenostomy, or choledochojejunostomy is effective (Braasch et al, 1980; Johnson & Harding Rains, 1978; Jones, 1978). Sphincteroplasty is rarely necessary, because ES suffices in many cases. ES is of no value, however, in the presence of a

long stricture of the distal duct. Sphincteroplasty is the preferred operative approach in patients with a duct smaller than 1.5 cm in diameter to avoid possible stricture formation at the anastomosis, but it carries a greater risk of postoperative pancreatitis. Side-to-side or end-to-end choledochoduodenostomy and end-to-side Roux-en-Y choledochojejunostomy are suitable for CBDs larger than 1.5 cm and offer better decompression of an extremely large duct. The mortality rate of choledochoduodenostomy is lower than that attending transduodenal sphincteroplasty, and it has been shown to be a safe and simple operation with low morbidity and mortality, especially in elderly patients (Lygidakis, 1982; Schein & Gliedman, 1981). Occasionally, recurrent or primary stones are seen in patients with dilated ducts and a widely patent sphincter. In such cases, which also have been reported after endoscopic papillotomy, side-to-side choledochoduodenostomy or end-to-side Roux-en-Y choledochojejunostomy is necessary.

Table 35.1

Mortality Rates of Biliary Reoperation for Retained or Recurrent Bile Duct Stones

Reference	No. Operations	No. Deaths (%)
Saharia et al, 1977	30	0
Jones, 1978	22	0
McSherry & Glenn, 1980	341	7 (2%)
Allen et al, 1981	47	1 (2%)
De Almeida et al, 1984	24	1 (4%)
DenBesten & Berci, 1986	86	2 (2.3%)
Girard, 2000	88	0
TOTAL	920	15 (1.6%)

Results of Clinical Experience with Reoperation

The courses of all patients who had a reoperation for retained or recurrent choledocholithiasis at the Maisonneuve-Rosemont Hospital between 1969 and 1990 were reviewed (Girard, 2000). Eighty-five patients underwent a total of 88 operations, 43 of which were performed in patients older than age 60. Of the 88 operations, 85 were second operations, and 3 patients needed a third operation; CBD stones were confirmed in all patients before reoperation.

Three three types of bile duct reoperation were performed: choledocholithotomy with T-tube drainage (64 patients), choledocholithotomy with side-to-side choledochoduodenostomy (15 patients), and choledocholithotomy with transduodenal sphincteroplasty (6 patients). Choledocholithotomy with T-tube drainage in 1 patient and choledocholithotomy with side-to-side choledochoduodenostomy in 2 patients were performed at a third operation.

The average hospital stay was 9.3 days. No patient died despite the presence of associated risk factors in 44 patients. There were only six minor complications, and none of them necessitated urgent surgery. Two patients (3%) of the 64 who had choledocholithotomy with T-tube drainage developed recurrent bile duct stones 4 and 5 years after a second operation, and side-to-side choledochoduodenostomy was performed.

Taking Girard's (2000) experience with that of other reported series, there have been 15 deaths among 920 patients submitted for reoperation for recurrent bile duct stones (Table 35.1). In one of these series (McSherry & Glenn, 1980), choledocholithotomy was done for retained or recurrent stones in 341 patients; seven patients died after the procedure, resulting in a mortality of 2%. If three patients who underwent operation for cholangitis or pancreatitis were excluded, however, and only the elective procedures were considered, only four patients died (1%) after repeat choledocholithotomy. These results show that the overall mortality rate for retained or recurrent stones is less than 2%, with most deaths occurring in elderly patients. This mortality rate is comparable to that of ES.

Comments

Retained or recurrent bile duct stones can be managed safely with reoperation, which is associated with little or no mortality, low morbidity, and a high success rate. Reoperation is effective and safe and should not be forgotten. In a patient with a retained stone with a T-tube in place, extraction through the T-tube tract or ES should be attempted first; if a T-tube is not in place, ES should be attempted first. If ES is contraindicated, or if it fails, operative management is a reasonable alternative, with the expectation of a high success rate and comparable mortality and morbidity rates to sphincterotomy. Most patients do not require a biliary-enteric drainage procedure; however, a drainage procedure is required to prevent further problems in selected patients.

Many options are now available for the management of CBD stones. Gastroenterologists, radiologists, and surgeons working in close cooperation should assess patients. The traditional surgical management of patients with CBD stones has reached a high level of efficacy and safety, even in elderly patients. The choice between open surgery, laparoscopic surgery, and ES should take into account not only reported information and expertise but also the local availability and efficacy of the different methods. The goal of open CBD exploration for calculous disease is to explore patients with choledocholithiasis, detect and remove all stones within the bile ducts safely, and prevent retained and recurrent stones.

Before operation, the surgeon must make an accurate diagnosis, which should be confirmed by intraoperative cholangiography. The only reliable methods to confirm complete clearance of stones from the biliary tree at operation are postexploratory choledochoscopy and cholangiography (see Chapter 21). Biliary enteric drainage procedures should be used selectively when indicated. Patients with residual or recurrent CBD stones generally should be managed by ES, but other approaches may be used, depending on the general condition of the patient, the available expertise, and the presence or absence of a T-tube.

SURGICAL TECHNIQUES FOR EXPLORATION OF THE COMMON BILE DUCT

Routine exploration of the CBD (see Chapter 29) should be through a supraduodenal choledochotomy, and the transduodenal route should be reserved for patients in whom stones cannot be removed readily from above. Although impacted stones at the ampulla may be broken down and removed by a

supraduodenal approach, they probably should be removed by means of a transduodenal sphincteroplasty, because it is less traumatic in such circumstances (see Chapter 29).

The only reliable methods to confirm complete clearance of stones from the biliary tree are postexploratory choledochoscopy and cholangiography (see Chapters 21 and 28). The value of choledochoscopy has been confirmed by many authors (Dayton et al, 1984; Kappes et al, 1982; Nora et al, 1977). Postexploratory cholangiography also must be used and should be obtained before closure of the abdomen, not only because it can locate occasional missed stones, but also because it may reveal unsuspected disruption of the biliary ductal system. Although often regarded as unreliable because of the failure of contrast material to enter the duodenum and the difficulty of eliminating air bubbles, postexploratory cholangiography can be done reliably with attention to detail. Myatt and colleagues (1973) described a reliable technique that does not involve suture of the choledochotomy before postexploratory films are obtained. After exploration, a T-tube (at least 14 Fr) is left within the CBD to permit postoperative cholangiography and percutaneous extraction of retained stones if necessary. The techniques for exploration of the CBD are detailed in this section (see also Chapter 29).

The selective use of biliary-enteric drainage procedures is another method to decrease the incidence of subsequently symptomatic retained stones. Although we do not recommend routine biliary-enteric decompression at initial operation, it should be considered carefully in patients with multiple duct stones, particularly in dilated ducts in elderly patients and in those with a large stone, or stones, within a dilated duct. If these conditions pertain in an elderly or poor-risk patient, choledochoduodenostomy may obviate reexploration. Other indications include 1) the presence of irretrievable intrahepatic stones, 2) proven ampullary stenosis, or 3) an impacted ampullary stone.

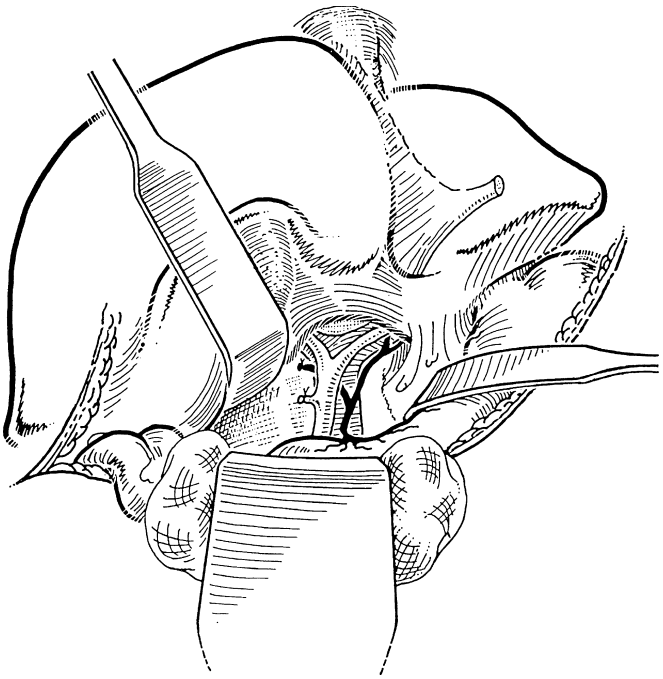
Supraduodenal Choledochotomy and Exploration of the Common Bile Duct

Exposure

The liver is retracted superiorly with a broad-bladed, slightly curved retractor. This retractor should be deep enough to displace the liver but not so curved as to traumatize it. The curved, broad-based Hartmann ("sweetheart") retractor often serves this purpose well. A pack should be put over the hepatic flexure of the colon down to the hepatorenal pouch and the medial part of the duodenum. This pack is retracted by a similar, broad-bladed retractor to prevent the colon or duodenum from obscuring vision (Fig. 35.1). The lesser omentum and stomach are retracted to the left after placement of another pack. The gallbladder usually is removed before exploration of the CBD, because it may obstruct vision, although in some cases it can be a useful aid to retraction. Palpation of the CBD and handling of its lower part during exploration and subsequent choledochoscopy cannot be done properly without having performed a classic Kocher maneuver (Fig. 35.2).

Choledochotomy

The site of the choledochotomy depends on several factors. Choledochoduodenostomy may become necessary (see Chapter 29), so the opening must be in the lowest part of the supraduodenal CBD that is consistent with an easy subsequent anastomosis (Figs. 35.3 and 35.4). A distal choledochotomy is recommended so that as much as possible of the CBD is left proximally, in case the duct is needed for some further procedure (e.g., repair of a stricture) in this part of the duct. Another reason why the choledochotomy should be placed distal and close to the duodenum is that the usual distance from this point to the papilla measures 7 cm or more. This is the exact length of the rigid choledochoscope used to do CBD exploration, and a clear view of the papilla of Vater is obtained. The anatomy of the cystic duct is so variable that care must be exercised to open the correct duct (see Chapter 1B). A cystic duct lying anterior or closely applied to the CBD can be easily opened in error (Fig. 35.5). Bile is aspirated by gentle suction, and a specimen should be sent for culture.



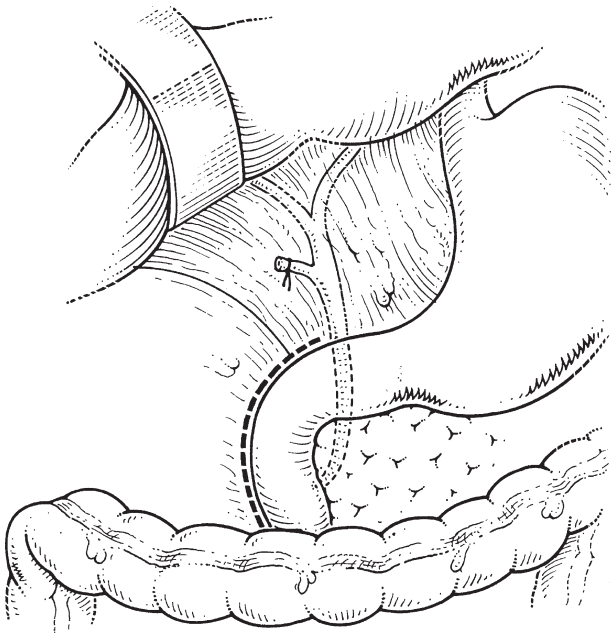


FIGURE 35.1. Exposure of the common bile duct by packs and retractors.

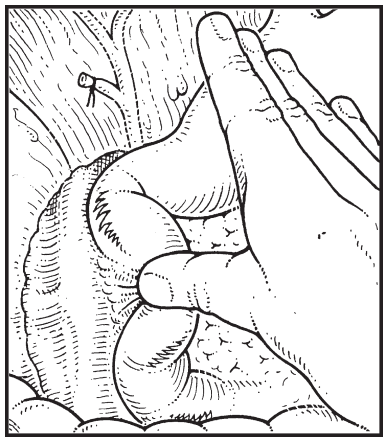

Exploration of the Duct (See Chapter 29)

Exploration should be as atraumatic as possible, and the use of rigid instruments should be avoided (Gunn, 1983; Orloff, 1978). Grasping forceps of any type may catch the wall of the duct and cause damage and possible late stricture formation. Bougies traditionally have been used, but metal instruments can create a false passage into the duodenum or the pancreas. The Fogarty balloon catheter has been found to be suitable for CBD exploration (Fogarty et al, 1968; Fox & Gunn, 1984).

The Fogarty probe is held in long forceps and introduced into the CBD. The forceps is held in the surgeon's dominant hand (Fig. 35.6), and the catheter is passed into the duodenum. The balloon is inflated, and the catheter is withdrawn until it impinges against the papilla (Fig. 35.7). As already mentioned, the duct is normally about 7 cm from the point of choledochotomy to the duodenum. The second part of the duodenum is palpated, and the balloon is identified to determine the site of the papilla in case duodenotomy is necessary. Any stone usually can be felt against the shaft of the catheter. The balloon is

A

B

FIGURE 35.2. A, The gallbladder has been removed. The *dotted line* indicates the incision in the retroperitoneum to allow mobilization of the duodenum by the Kocher maneuver (**B**).

deflated and gently withdrawn through the papilla, and this can be detected by a sudden easing of the pull on the catheter; the balloon is reinflated immediately. The catheter is held by the syringe in the surgeon's nondominant hand, and the degree of inflation is controlled by the thumb and the plunger. With gentle traction superiorly from long forceps held in the surgeon's dominant hand, the catheter is gradually pulled up to the choledochotomy site (Fig. 35.8), with care being taken to prevent any stone slipping into the proximal biliary tree. If the traction is anterior rather than superior, there is the risk of lacerating the opening into the duct (Fig. 35.9), and the risk is increased when the opening in the duct is longitudinal. The procedure is repeated until the distal duct is considered to be clear.

The catheter is withdrawn and reinserted upward into each of the main hepatic ducts, and the procedure is repeated again.

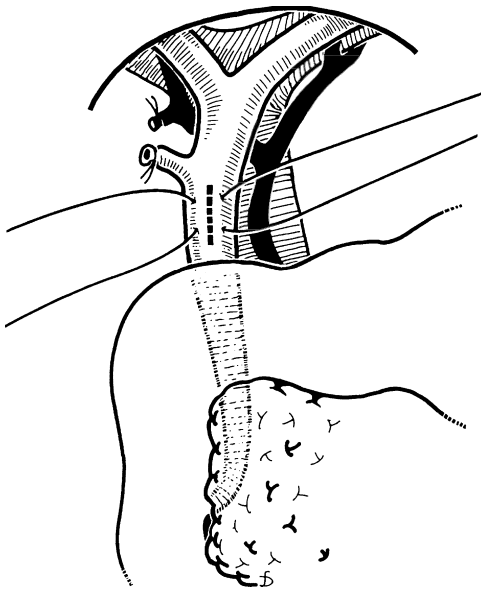

FIGURE 35.3. The common bile duct is opened just above the duodenum to leave room for a choledochoduodenostomy if necessary.

The balloon inflation needs to be correct: overinflation could damage the ducts, and underinflation could result in missing any stone that is present. Correct inflation can be achieved by inflating the balloon until the tension of the syringe plunger can be felt in the fingers. This tension is maintained as the catheter is withdrawn into the gradually widening duct.

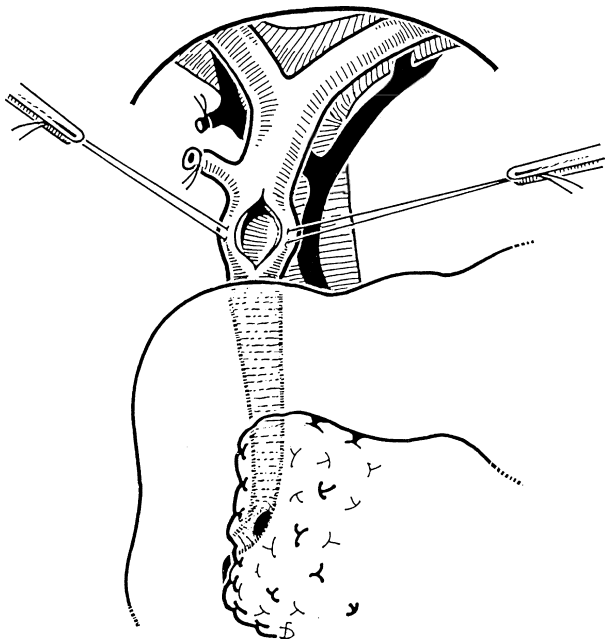

FIGURE 35.4. Two fine stay sutures of 3-0 polydioxanone suture or 3-0 polyglactin 910 (Vicryl) are used to lift and render the common bile duct (CBD) tense for an incision about 1 to 2 cm long, depending on the size of the duct and the size of the stones. If the CBD is not made tense, damage can be done to the posterior wall, or an irregular incision can be made.

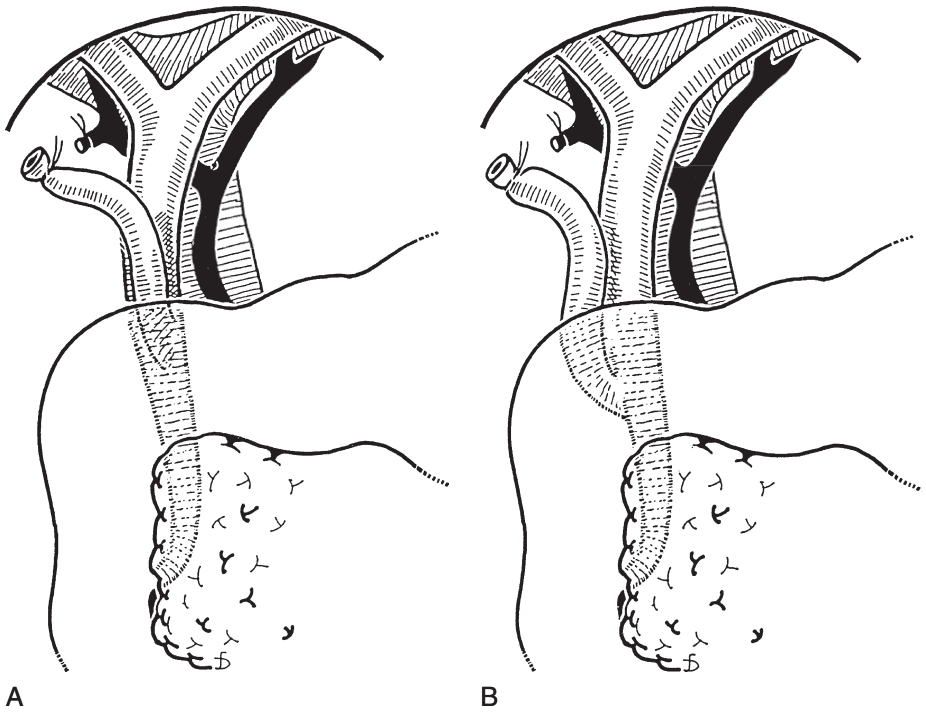

FIGURE 35.5. **A,** The cystic duct may lie anterior to the common bile duct (CBD) and may be opened in error. **B,** The cystic duct may run parallel to the CBD with a low entrance, mimicking a dilated duct.

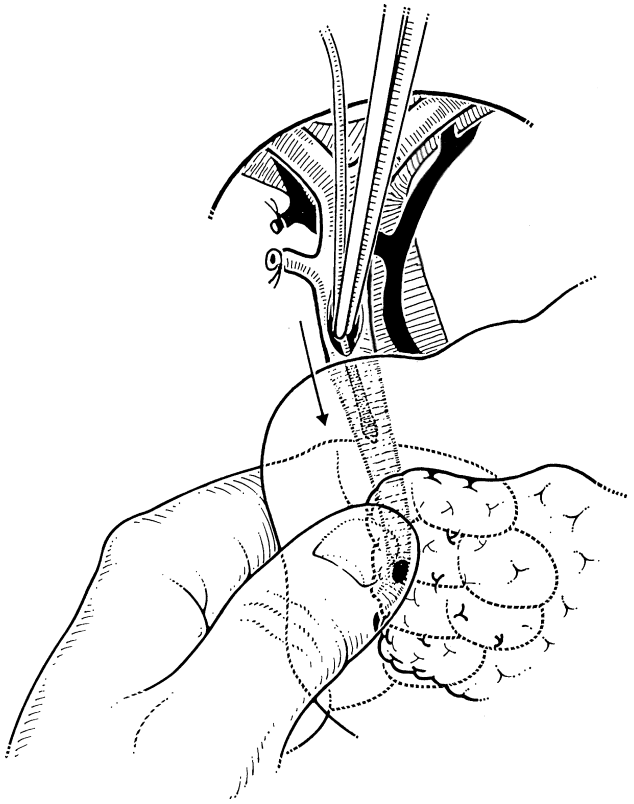

FIGURE 35.6. A Fogarty catheter is fed into the duct with forceps using the dominant hand. The operator's nondominant hand is used to grasp the mobilized duodenum, which allows palpation of the passage of the catheter and of any stones within the intrapancreatic portion of the common bile duct.

It is important to remove the stone when it appears at the choledochotomy opening and to avoid letting it fall into another part of the duct. The second step in CBD exploration is to irrigate the duct with saline. Small stones, sludge, and debris can be flushed into the duodenum or back into the choledochotomy opening by irrigating the ductal system. The last step in this technique is to pass the Fogarty catheter again into the duodenum, inflate the balloon, and retract it against the papilla. While the catheter is held in the surgeon's dominant hand, the index and middle fingers of the other hand are placed posterior to the duodenum with the thumb anterior; this allows palpation of the duct against the wall of the catheter for any residual stones.

Postexploratory Investigations

Following exploration, the surgeon must make every effort to ensure that the duct system is normal.

Choledochoscopy (See Chapter 21)

Choledochoscopy is the established method to ensure that the duct system is normal. Modern instruments are small enough to allow visualization of the major right and left hepatic ducts and intermediate hepatic ducts and to allow visualization of the orifices of the smaller biliary radicles. Some surgeons experienced in choledochoscopy recommend exploration of the CBD and removal of stones under direct vision using the choledochoscope (Berci, 2000).

T-Tube Cholangiography

After insertion of a T-tube and closure of the choledochotomy, T-tube cholangiography is another option for postexploratory investigation. With proper technique and use of fluoroscopy,

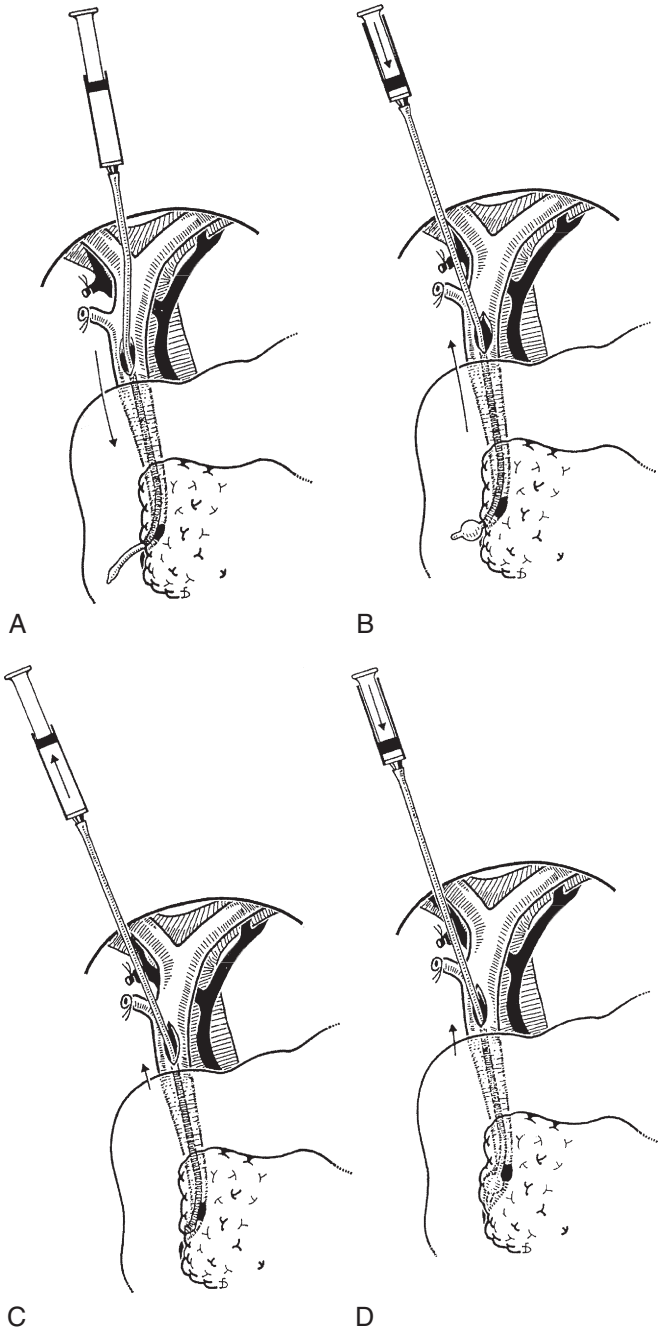

FIGURE 35.7. A, The Fogarty catheter is attached to a syringe, and the balloon is inflated in the duodenum. **B,** The Fogarty catheter is retracted with the balloon against the papilla. **C** and **D,** The balloon is deflated and gently withdrawn until it slips through the papilla; the balloon is then reinflated.

T-tube cholangiography is an excellent tool for detecting residual stones after CBD exploration (Fig. 35.10). The cystic duct stump, a possible location of residual stones, can be delineated, and incorrect placement of the T-tube can be detected to prevent complications after the operation. In case of residual stones, the T-tube has to be removed, and the duct needs to be explored again; this necessitates a second suture of the CBD, which is a major disadvantage of T-tube cholangiography. The technique described by Myatt and colleagues (1973), whereby the cholangiogram is done before closure of the duct, can be valuable in this regard.

T-TUBE DRAINAGE. The standard practice is to use a T-tube to allow spasm or edema of the sphincter to settle after the trauma of the exploration. Failure to drain the duct might result in a buildup of pressure in the extrahepatic ductal system and cause leakage at the disruption of the closure of the duct, along with biliary peritonitis. Another important reason for the use of a T-tube is for the detection and subsequent treatment of retained stones. In the event of a retained stone, the T-tube can be useful later for interventional radiologic techniques through the tract created by the tube (Fig. 35.11).

The use of a T-tube creates a fistula between the skin and the lumen of the duct, and both are potentially contaminated surfaces; the tract of the fistula crosses the peritoneal surface. The size of the T-tube should be adapted to the diameter of the CBD; 14 Fr is the smallest size that should be used, if a satisfactory tract is to be left for subsequent interventional radiology. A significant proportion of patients who have choledochoscopy and cholangiography have a greatly reduced number of residual stones, but a wise surgeon should accept that stones occasionally are left.

T-TUBE PLACEMENT. First, the limbs of the T-tube must be shortened (Fig. 35.12A). T-tubes can become obstructed, particularly if they are tight fitting, and they can be difficult to extract. This situation can be avoided by cutting off a strip of the wall (Fig. 35.12B). The practice of dividing the back wall of the T-tube makes subsequent interventional radiology more difficult, because the guidewire lodges in the posterior defect. In the main, this problem can be avoided by making the length of the T-tube appropriate or by limiting the division of the T-tube. The modified T-tube is held in Desjardin forceps, which conveniently grasps the T-junction of the tube, allowing it to be slipped into the choledochotomy (Fig. 35.13). The long limb of the tube is placed at the lower end of the opening, and repair is begun just above the upper apex of the incision using continuous or interrupted resorbable material. The final stitch should close the opening against the T-tube (Fig. 35.14).

AVOIDING PROBLEMS IN THE CLOSURE OF THE CHOLEDOCHOTOMY. Care must be taken that the wall of the T-tube is not caught in one of the sutures, and the end of the suture should not be tied around the tube. Either of these faults may result in the tearing of the duct when the tube is withdrawn. The proximal limb of the T-tube should not enter one of the hepatic ducts because this can produce obstruction (Fig. 35.15), and the distal end must not enter the duodenum, because this can act as a siphon. In addition, a tube through the papillary orifice may incite pancreatitis. The correct position of the T-tube is with the long limb emerging under the costal margin laterally (Fig. 35.16). This position facilitates radiologic techniques for later postoperative removal of stones should this be necessary. A suction drain is placed on the right, within the abdomen as high as possible in the hepatorenal pouch.

POSTOPERATIVE MANAGEMENT. Initially, bile is allowed to drain freely into a bile bag to allow any spasm or edema of the sphincter to settle before testing the suture line of the

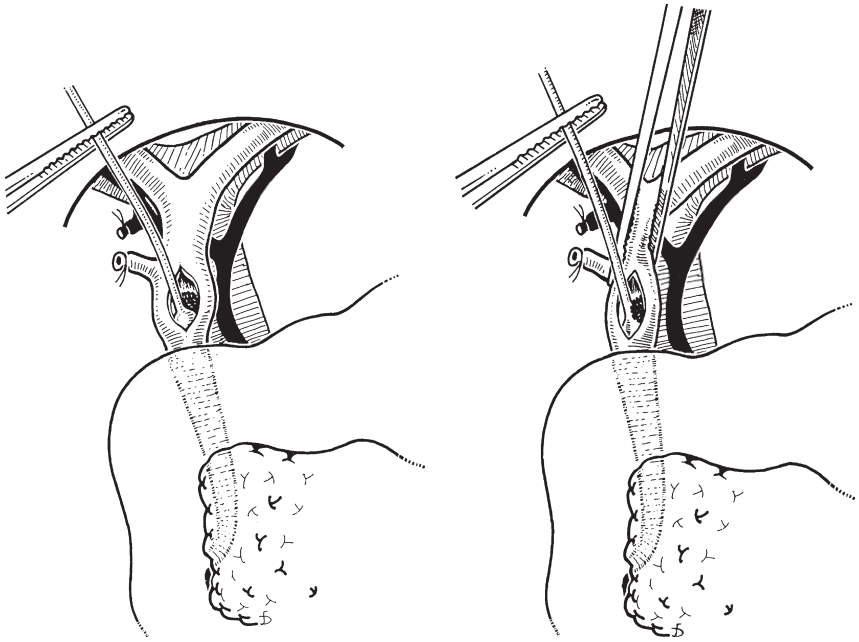

FIGURE 35.8. **A,** The balloon is withdrawn gently, revealing the stone. **B,** Long forceps can be used to obstruct the common hepatic duct to prevent the stone from slipping upward.

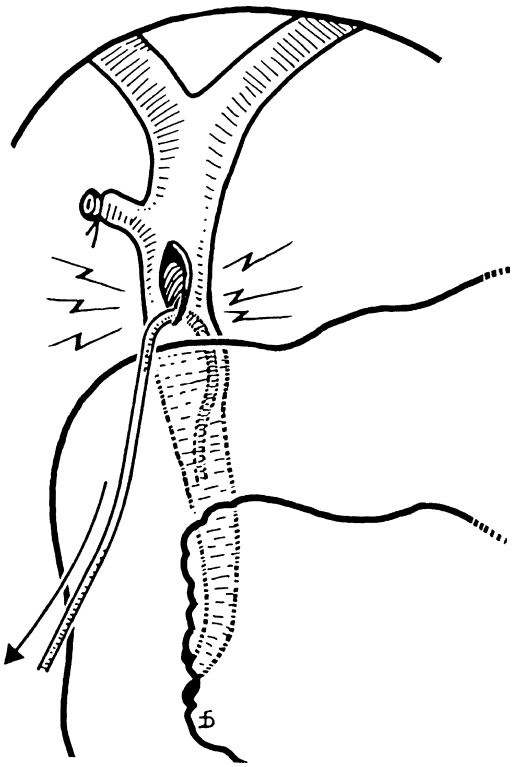

FIGURE 35.9. Angled traction on the Fogarty catheter results in tearing of the lower end of the choledochotomy.

FIGURE 35.10. A postexploration T-tube cholangiogram identifies a residual stone in the intrahepatic bile ducts that was missed during operative exploration of the bile duct.

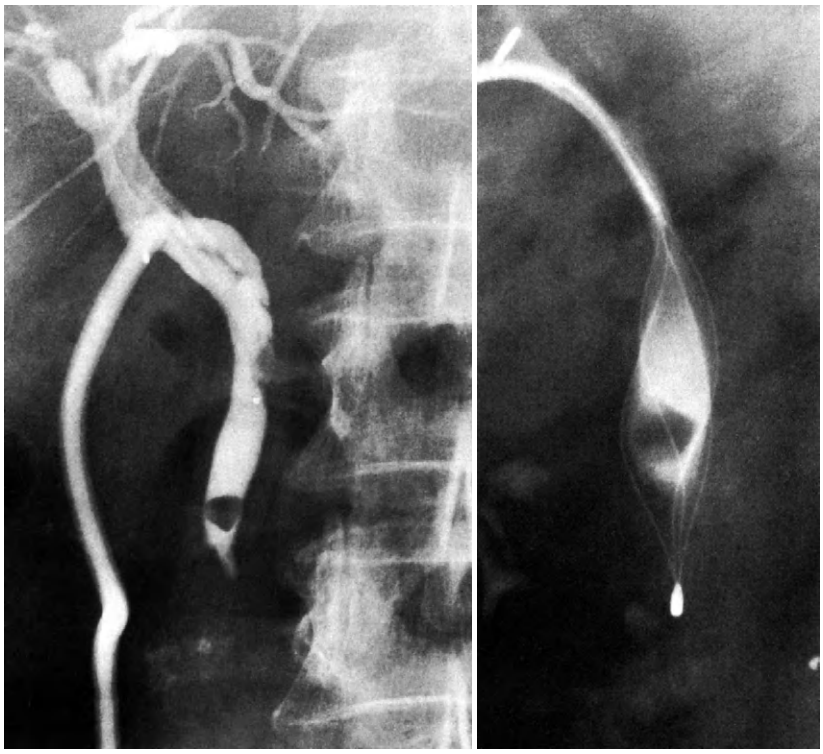

FIGURE 35.11. A, Faceted retained distal common bile duct (CBD) stone on T-tube cholangiography 1 week after operation. The T-tube is inserted in the common hepatic duct above the confluence of the cystic duct. **B,** The retained CBD stone is ensnared in the wire basket before extraction. This stone measured 5 mm in diameter and was extracted intact through the sinus tract of a 14-Fr T-tube.

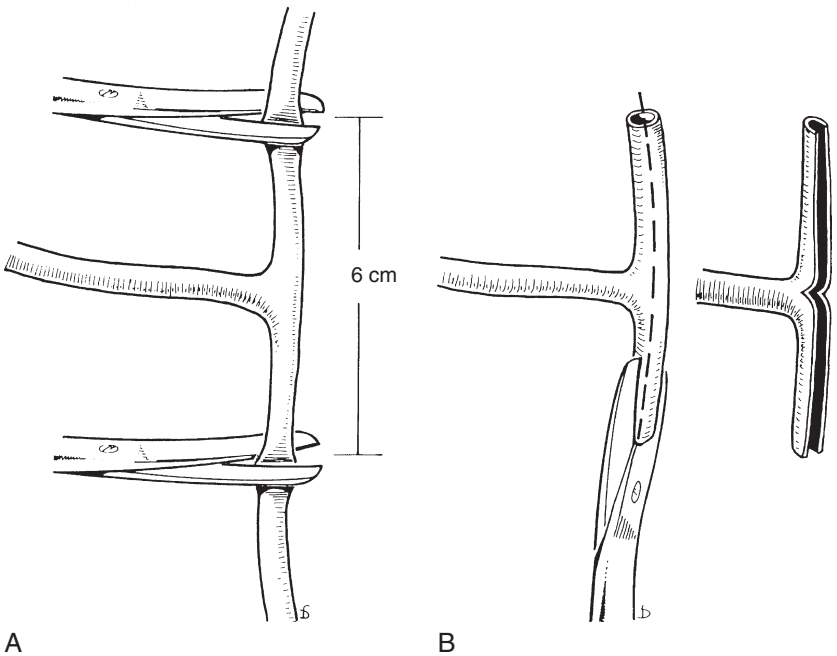

FIGURE 35.12. A, The T-tube is modified by shortening the limbs to prevent proximal obstruction and distal entry into the duodenum. **B,** A T-tube is modified by removing half the diameter to prevent obstruction and enable easy removal.

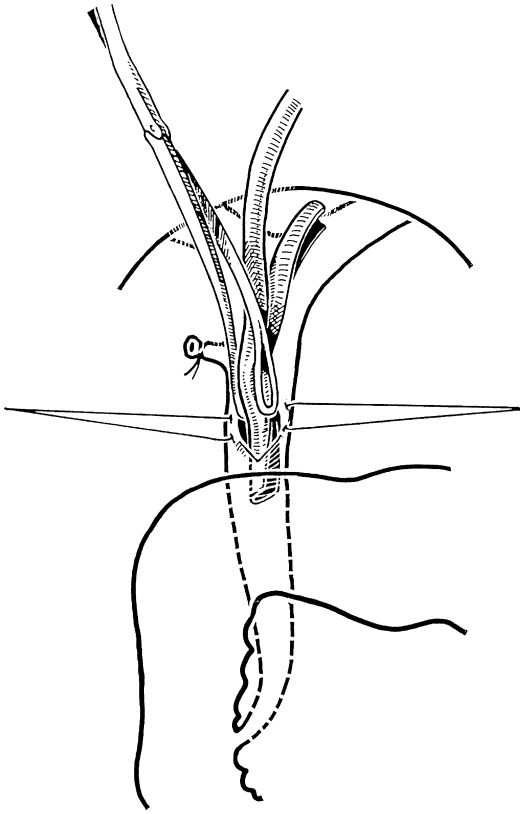

FIGURE 35.13. The T-tube is introduced by Desjardin forceps.

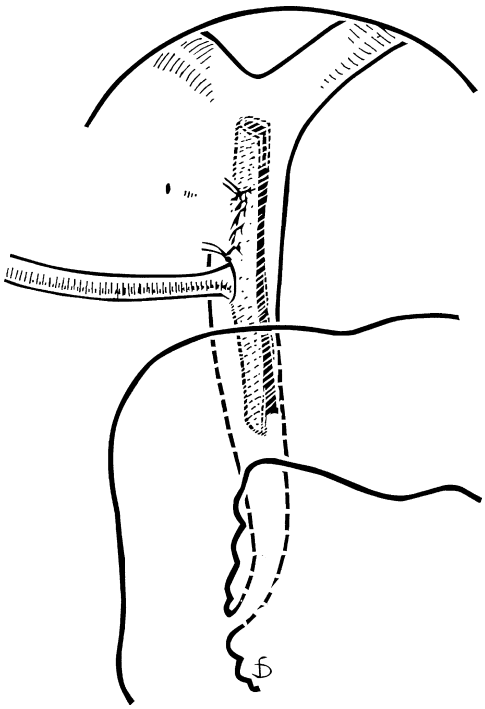

FIGURE 35.14. The choledochotomy closure is begun above with the T-tube emerging at the lower end of the repair.

choledochotomy. The volume drained varies, with the amount decreasing as flow increases through the sphincter. If the volume drained remains high or increases, the reason should be established. This increased volume may be due to continuing distal obstruction or to the distal limb lying within the duodenum. Similarly, there is a problem if there is no drainage of the bile, or if bile drains around the T-tube; the tube may have become blocked or dislodged from the duct.

The answer to all these problems is revealed by T-tube cholangiography. Provided that there have been no problems, subsequent management is aimed at waiting for the bile to flow easily through the papilla into the duodenum, and the bile bag should not be lifted or clamped. A T-tube cholangiogram is taken about 5 to 7 days after the operation. If it appears normal, the tube is removed on day 7 or 8 by gentle traction.

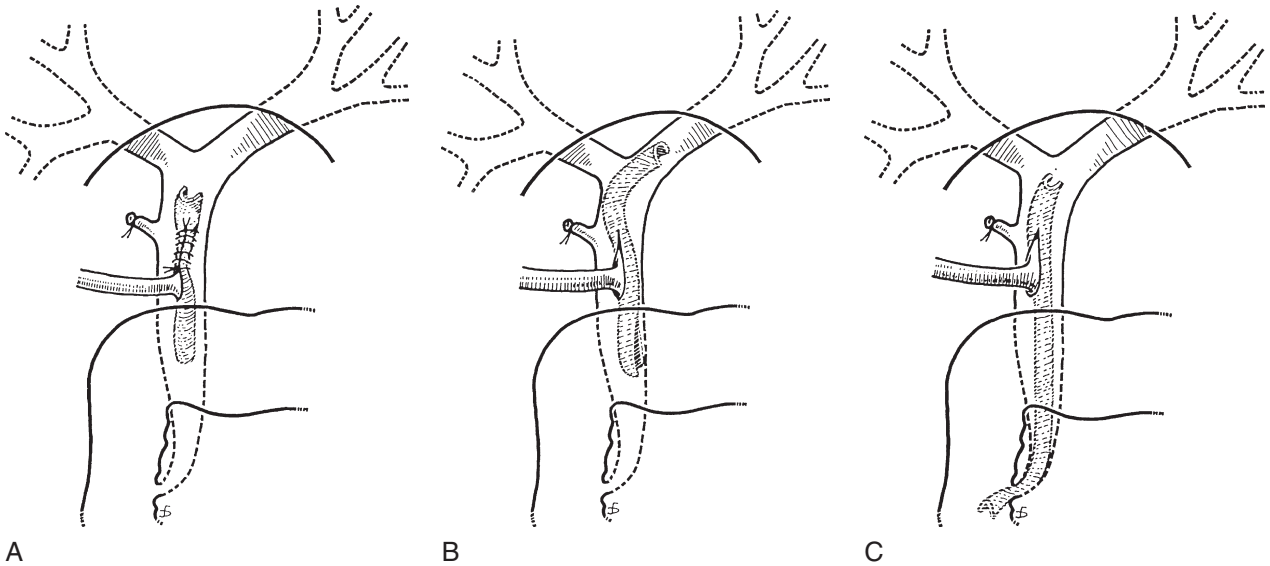

FIGURE 35.15. A, The suture must not catch the tube as shown here. **B,** The T-tube limb should not enter the hepatic duct, as shown here. **C,** The distal end of the T-tube should not enter the duodenum, as shown here.

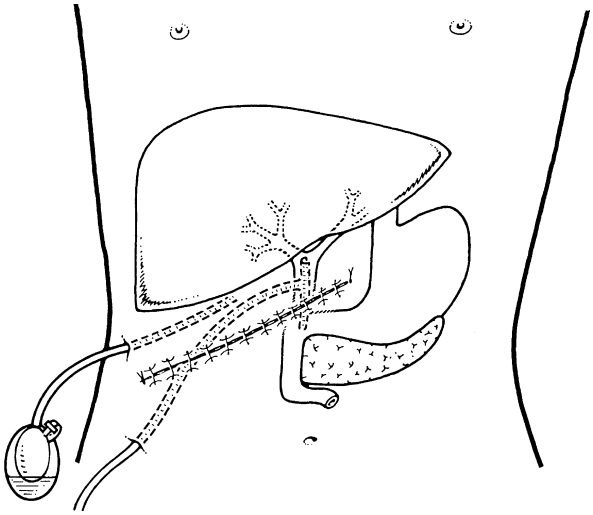

FIGURE 35.16. The T-tube should be brought out lateral to the wound, and a closed-suction drain should be placed in the hepatorenal space beneath the liver.

If there are residual stones or unclear findings on T-tube cholangiography, it is a good practice to repeat the procedure several days later. If a stone is still seen, it is managed initially by sending the patient home with a sealed drainage system and instructions to open the drain and connect it to a bag in the event of any problems. After about 5 weeks, further cholangiography is carried out. If the stone is still present, it is extracted via interventional radiology or endoscopic papillotomy (Fig. 35.17).

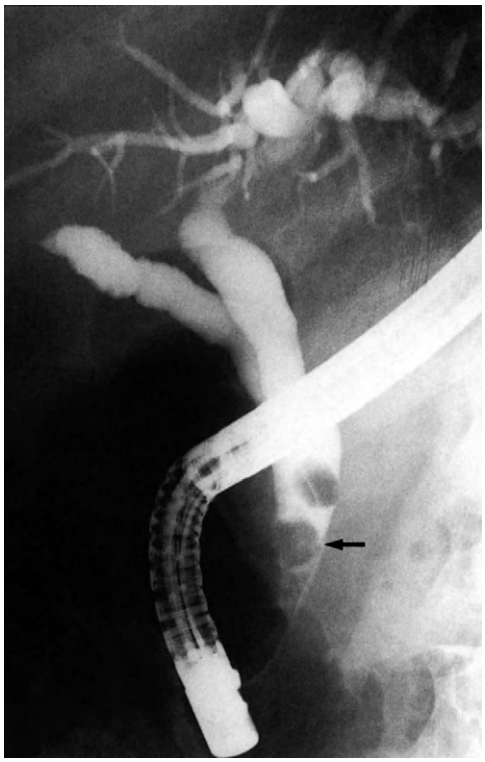

FIGURE 35.17. Balloon extraction of a single stone (*arrow*).

Transduodenal Sphincteroplasty

Transduodenal sphincteroplasty (see Chapter 29) has a place in the management of CBD stones, particularly if a stone is impacted at the ampulla or with failure of ES, in patients with Billroth II gastrectomy, and in patients with pancreatitis when a drainage procedure of the duct of Wirsung is indicated (Lehman & Sherman, 1998). Similarly, hydatid cyst remnants and membranes can be readily extracted from the CBD. Exploration may extend to the left and right hepatic ducts, and angled Randall forceps are useful for this purpose.

Sphincteroplasty consists of suturing the outer edge or both edges of a surgical sphincterotomy to avoid possible future stenosis of the incision. The stitches achieve hemostasis of the incision margins and help to avoid possible leakage of the duodenal contents should the excision extend beyond the common portion of the sphincter, incurring the risk of retroduodenal perforation. Transduodenal sphincteroplasty is contraindicated in the presence of a large CBD (>2 cm) or where there is a long suprasphincteric stricture. It also should not be attempted in the presence of a duodenal diverticulum or where there is severe periampullary inflammation.

Indications

The most common indications for transduodenal sphincteroplasty relate to bile duct stones and cholangitis.

STONES IMPACTED IN THE DISTAL AMPULLARY REGION. An impacted stone is often readily palpable, and the incision may be made safely using the stone as a guide. In such cases, extraction through a supraduodenal choledochotomy is often impossible without undue risk of creating a false passage and without significant risk of postoperative pancreatitis.

MULTIPLE AND RECURRENT COMMON BILE DUCT STONES. In cases of multiple and recurrent CBD stones, sphincteroplasty should provide long-term biliary drainage. When 20 or more stones are removed from the CBD, it is probable that one or more stones are still present (Stain et al, 1991). In this situation, choledochoduodenostomy or sphincteroplasty yields excellent results.

PAPILLARY STENOSIS. Papillary stenosis is encountered less frequently than in the past. When it is found at operation, transduodenal sphincteroplasty ensures good biliary drainage and prevents restenosis (Ramirez et al, 1994). ES is technically successful in only 60% to 80% of cases, and mortality rate exceeds 1% (Seifert et al, 1982). In addition, sphincterotomy for papillary stenosis is five times more likely to lead to restenosis than if the same procedure is performed for calculi (Tzovaras & Rowlands, 1998).

PYOGENIC CHOLANGITIS (SEE CHAPTER 43). If papillary stenosis or CBD stones or both exist together with cholangitis, transduodenal sphincteroplasty can be an excellent procedure for definitive biliary drainage.

CHRONIC PANCREATITIS AND ACUTE GALLSTONE PANCREATITIS (SEE CHAPTERS 53, 54, AND 55). In chronic pancreatitis, some authors report good long-term results with transduodenal sphincteroplasty alone (Hacaim et al, 1994) or in addition to transpapillary septectomy (Moody et al, 1983) or

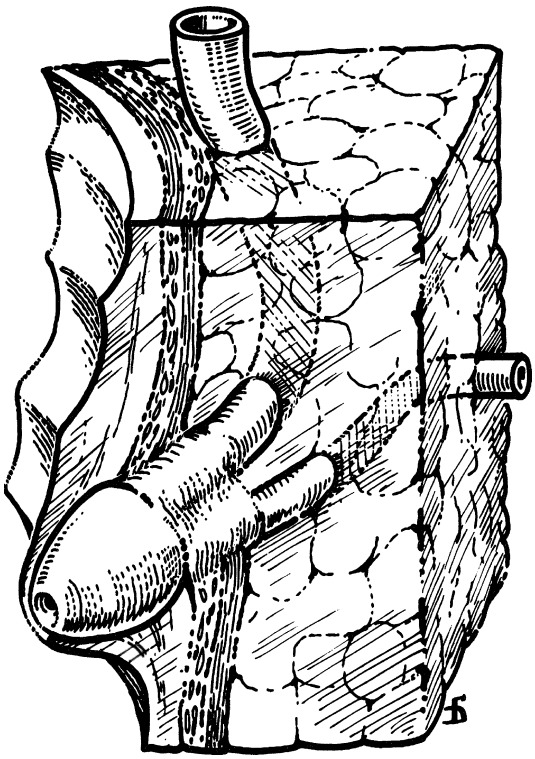

FIGURE 35.18. A section of the sphincter of Oddi. Note the distinction between the papilla, the common portion of the sphincter, and the sphincters of the common bile duct and duct of Wirsung.

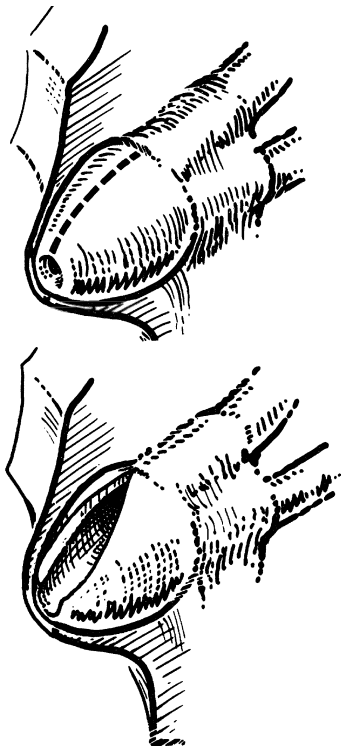

FIGURE 35.19. Subtotal lower sphincteroplasty involves only the papilla, whereas the common bile duct and the duct of Wirsung are preserved.

with other drainage procedures of the duct of Wirsung (Kestens et al, 1996). The presence of a stone at the lower end of the CBD or pancreatic duct may cause biliary pancreatitis, and transduodenal sphincteroplasty with clearance of the CBD is a treatment option.

Technique

Sphincteroplasty consists of the incision of the common portion of the sphincter of Oddi (Fig. 35.18) with partial suture of the incision margin. By this procedure, the sphincters of the CBD and the duct of Wirsung are not involved, and their functions are not impaired. The procedure also can be called a *subtotal lower sphincteroplasty* (Fig. 35.19; Stefanini et al, 1977). The approach to the sphincter of Oddi is through a minimal duodenotomy in the second part of the duodenum.

Preparation, Position of the Patient, and Incision

Preoperative preparation is routine. A nasogastric tube is introduced before operation and is maintained until postoperative day 3 or 4. The patient is placed in a supine position on a radiotransparent operating table. A transverse incision below the right costal margin is preferred (Vogt & Hermann, 1981). This incision allows optimal light and excellent access, it is particularly suitable in obese patients, and the incidence of postoperative incisional hernia is probably lower than with vertical and oblique incisions. The incision of the abdominal wall follows a transverse line, from the midaxillary to the median line at the level of the eleventh and twelfth ribs (Fig. 35.20).

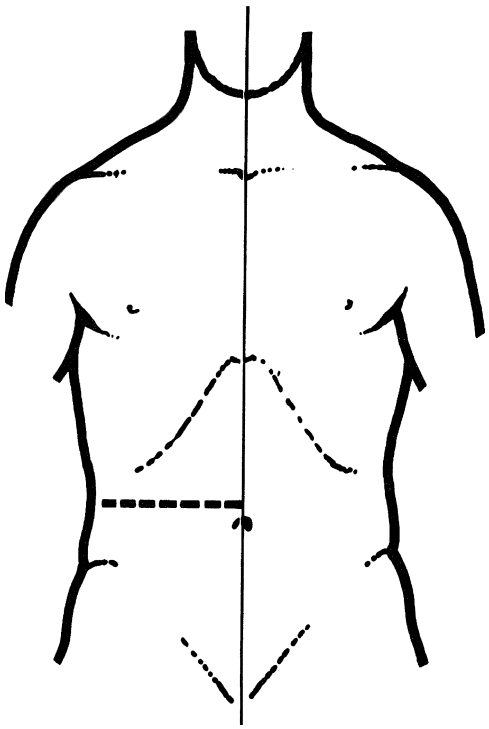

FIGURE 35.20. Transverse subcostal incision offers excellent exposure with a low incidence of postoperative incisional hernia.

FIGURE 35.21. It is important to expose and mobilize the third portion of the duodenum to easily identify and operate on the papilla and allow facile closure of the duodenotomy.

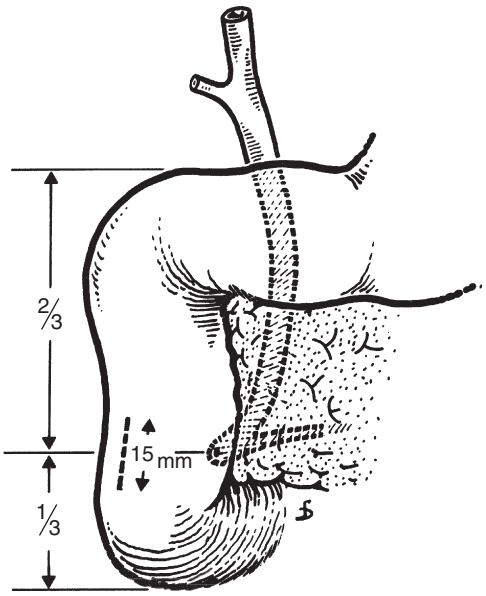

FIGURE 35.22. The duodenotomy is performed above the junction of the second and third portions of the duodenum; the surgeon takes into account that the papilla usually is located at the junction of the upper two thirds and lower third of the second part of the duodenum.

Preparation of the Operative Field and Exposure

The abdomen is opened, and a large retractor is positioned at the upper margin of the wound. The right flexure of the colon is displaced inferiorly, and the stomach is displaced to the left by means of two surgical pads. Viscera are maintained in this position with two large, curved Deaver retractors. For the performance of the sphincteroplasty, extended mobilization of the duodenum and pancreas (Kocher maneuver) is mandatory (Moody et al, 1983). The assistant surgeon displaces the second portion medially and forward, and the peritoneum is incised posteriorly along the curved lateral margin of the duodenum. The mesocolon of the right colic flexure is cleared inferiorly. At this point, the assistant surgeon also should displace the duodenum superiorly (see Fig. 35.2). Access is provided to the avascular space between the posterior aspect of the head of the pancreas anteriorly and the perinephric fat and inferior vena cava posteriorly; elevation of the structures should reach the left margin of the inferior vena cava. It is important to expose and mobilize the third portion of the duodenum to allow easy access to the papilla and for closure of the duodenotomy without tension (Fig. 35.21).

Duodenotomy

Duodenotomy is performed in the lateral duodenal wall by surgical diathermy. The cut is 10 to 15 mm long immediately above the inferior knee of the duodenum, with the surgeon taking account of the fact that the papilla usually is located at the junction of the lower third with the upper two thirds of the second portion of the duodenum (Fig. 35.22). The duodenal incision may be longitudinal or transverse; both types are suitable, provided that the suture of such incisions is always transverse. We prefer a longitudinal incision, because if the retractor on the duodenum widens the duodenotomy, this occurs longitudinally. In the case of a transverse duodenotomy, any inadvertent extension would cause a transverse enlargement of the wound.

Identification of the Papilla

After the duodenal incision, the papilla is readily shown on the medial duodenal wall in 15% to 20% of patients. It appears as a roundish elevation with a central orifice. When the papilla is not readily visible, it should be detected by displacement and flattening of the mucosal folds. This should be done with great care to avoid tearing of the mucosa, which would hinder good exposure. Identification of the papilla under direct vision is possible in 80% of patients. If this is not the case, digital palpation can be used running the forefinger, introduced through the duodenotomy, across the medial duodenal wall. The papilla is identified as a small elevation (Fig. 35.23). If digital palpation fails, a small (5 to 6 Fr) Nélaton catheter can be introduced via the cystic duct stump and advanced downward to emerge at the papilla. This maneuver should never be performed with rigid catheters, because this may result in the formation of false passages.

Sometimes a very small papilla is detected, and its catheterization is difficult or impossible. In such cases, the orifice is probably that of the duct of Santorini. The major papilla should be searched for in a lower position.

Sphincteroplasty

After the papilla has been identified, it is exposed by gentle extraction with an Allis or similar clamp. This clamp is applied laterally, never medially, to avoid trauma to the duct of Wirsung

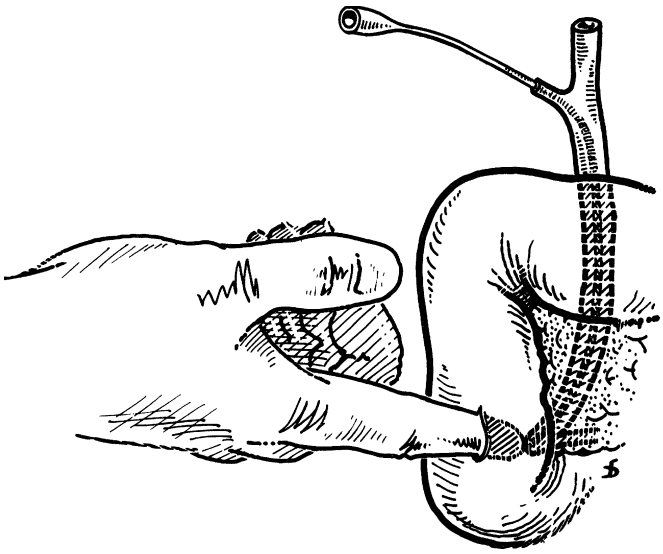

FIGURE 35.23. If the papilla is not easily seen, a small Nélaton catheter is introduced through the cystic duct stump until it is seen to protrude from the papillary orifice. The forefinger, introduced through the duodenotomy, detects the papilla as a small, thick elevation.

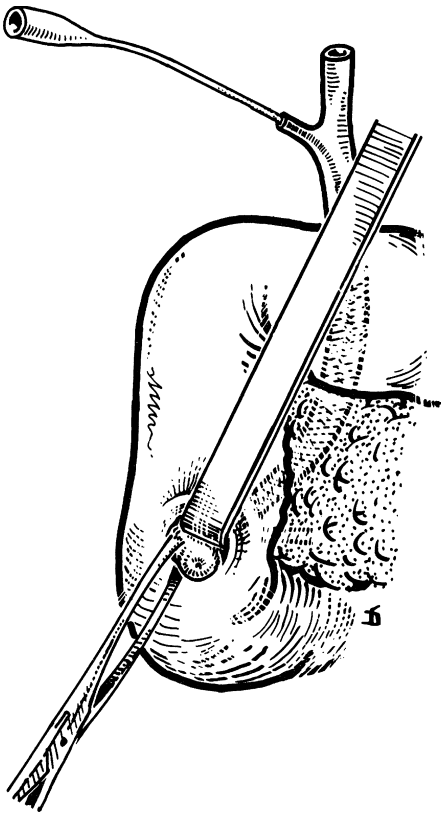

FIGURE 35.24. The duodenotomy is kept open by a suitable retractor placed in the upper margin of the duodenal incision. The papilla is exposed by gentle traction with an Allis clamp placed laterally, never medially, to avoid trauma to the duct of Wirsung.

(Fig. 35.24; Partington, 1977). A Nélaton catheter (4 to 5 Fr) is introduced from the outside or via the cystic duct. Following the line of the catheter—and avoiding plastic catheters, which melt when surgical diathermy is applied—the surgeon makes a cut using surgical diathermy. This cut is made superiorly (at the 11 o'clock position) for 4 to 5 mm (Fig. 35.25). We prefer surgical diathermy, because the instrument ensures good hemostasis. When a sample for biopsy is required, it should be obtained with a scalpel and be taken only from the outer margin of the incision. Possible bleeding from the cut, usually modest, can be arrested with a stitch. After sphincterotomy, two or three stitches are placed between the duodenal mucosa and the wall of the CBD on the outer margin using an atraumatic needle and 3-0 silk. Traction is applied to these sutures, and incision of the sphincter is extended for another 6 to 7 mm with sutures placed every 2 to 3 mm, all laterally, until the entire common tract of the sphincter of Oddi has been incised (Fig. 35.26). The incision is complete when it is 10 to 12 mm long and an appropriate forceps can be easily introduced (Fig. 35.27). Its entry into the CBD allows an abundant flow of bile owing to distension of its sphincter. Sutures should be placed only on the outer margin of the sphincterotomy to prevent the risk of damage to the duct of Wirsung. The opening of the duct of Wirsung usually is identified as a small orifice from which clear, colorless pancreatic juice flows.

Instrumental Exploration of the Common Bile Duct

After sphincteroplasty, instrumental exploration of the CBD and extraction of stones is performed (Speranza et al, 1982). An angled Randall forceps is introduced into the CBD, and the left and right hepatic ducts are carefully explored. The maneuver should be repeated several times to extract all stones. The next step is to rinse with saline solution, introduced under slight pressure with a Nélaton catheter (8 to 9 Fr) and abruptly withdrawn so that small fragments flow downstream with the siphoning (Fig. 35.28). Other means to extract stones from the CBD are with a Fogarty catheter and Dormia basket. The problem of residual stones is best prevented with choledochoscopy; the endoscope is introduced via the sphincteroplasty.

Duodenal Closure

As already emphasized, initial longitudinal duodenotomy always should be closed transversely to avoid stenosis of the duodenum. First, the superior and inferior margins of the incisions are approximated, and the resulting gaps are sutured with two extramucosal, nonabsorbable purse-string sutures. Three or four nonabsorbable seromuscular sutures are added (Fig. 35.29). The suture should not be under tension, and for this reason preliminary extended mobilization of the duodenum and pancreas is mandatory. The operation is now complete, and the wound is closed without abdominal drains.

Comment

It is not necessary to perform transduodenal sphincteroplasty combined with supraduodenal choledochotomy, which has a higher associated mortality rate (Scheridan et al, 1987). The cystic duct remnant may be used to introduce a Nélaton catheter to assist recognition of the papilla. There is no need to insert a T-tube, which lengthens the hospital stay and may predispose the patient to stenosis and infection of the CBD (Ratych et al, 1991; Scheridan et al, 1987). Patients with no drainage tubes or complications may be discharged on postoperative day 5 or 6.

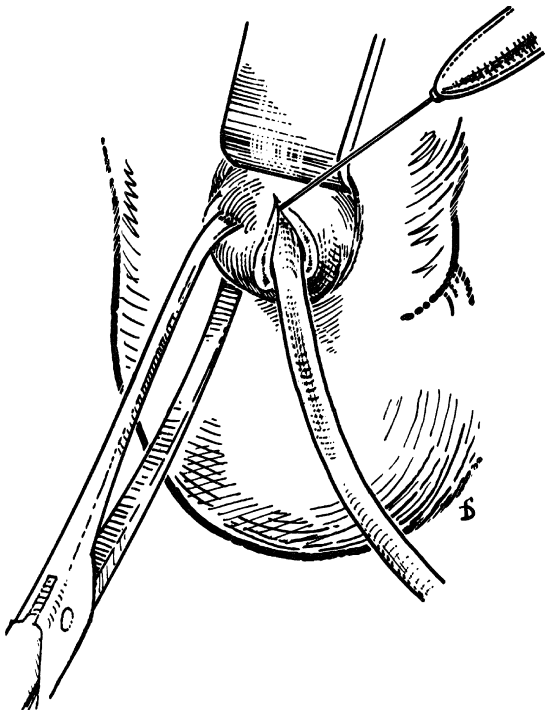

FIGURE 35.25. With a Nélaton catheter as a guide, a cut is made using surgical diathermy on the medial wall of the duodenum extending superiorly and slightly externally (11 o'clock position). With diathermy, good hemostasis is achieved.

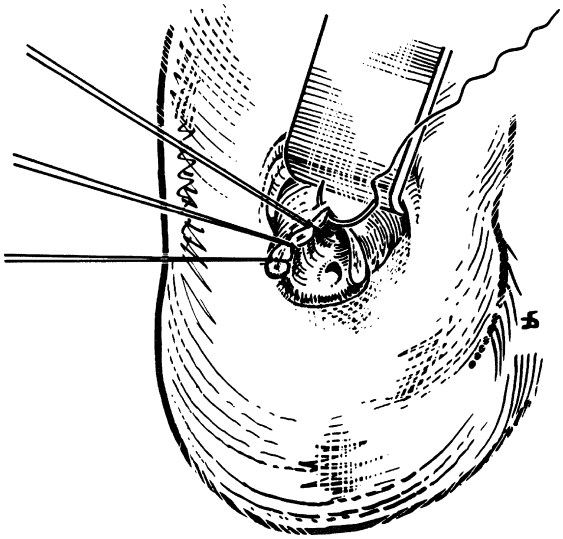

FIGURE 35.26. After sphincterectomy is performed, several stitches are placed between the duodenal mucosa and the wall of the common bile duct (CBD) using an atraumatic needle and 3-0 suture. Sutures should be placed only on the outer margin of the sphincterotomy to avoid the risk of damaging the duct of Wirsung, which in its distal portion runs inferiorly and medially along the length of the CBD.

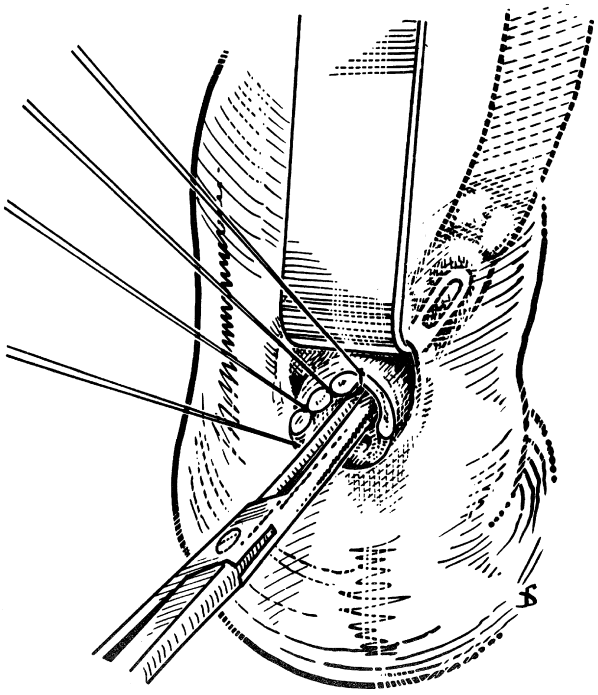

FIGURE 35.27. Sphincteroplasty is completed when the incision is 10 to 21 mm long, and a Randall forceps can be introduced easily into the common bile duct to extract stones or other foreign bodies.

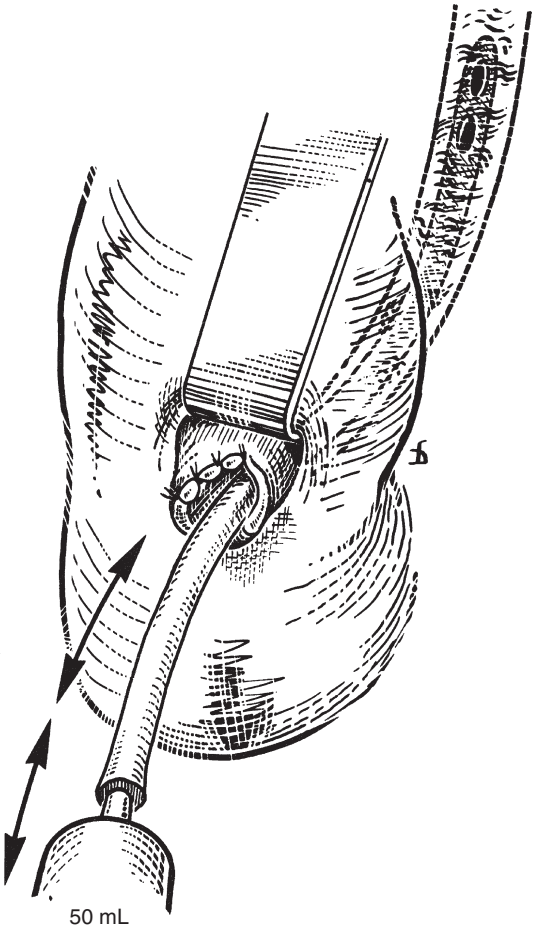

FIGURE 35.28. After the extraction of stones, the common bile duct is rinsed with saline solution introduced under slight pressure with a Nélaton catheter and with subsequent siphoning so that small fragments can run downstream.

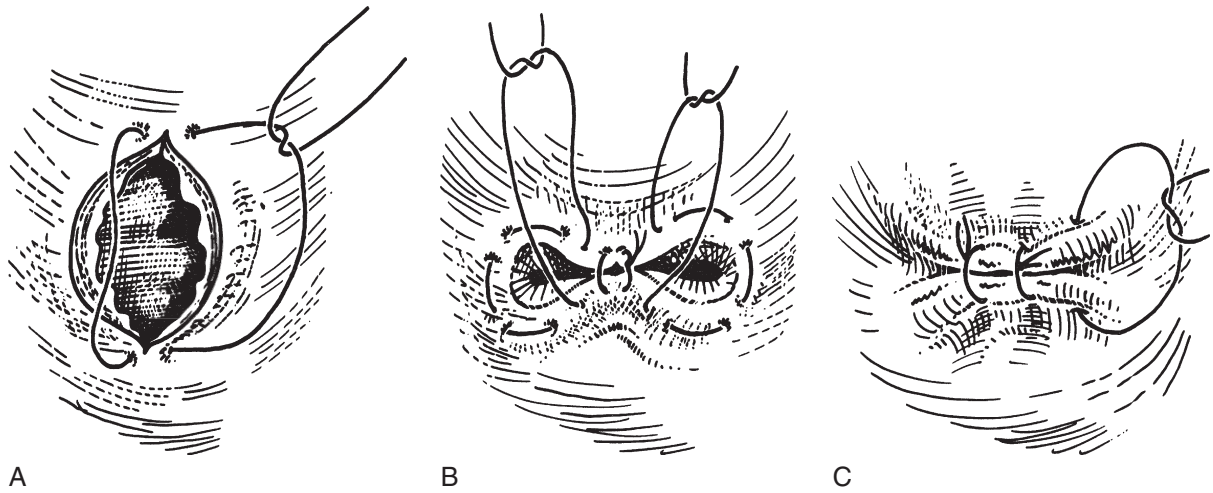

FIGURE 35.29. The duodenotomy always should be closed transversely to avoid stenosis of the duodenum. **A,** The superior and inferior angles are approximated. **B,** The resulting lateral gaps are sutured with two extramucosal nonabsorbable purse-string sutures. **C,** Three to four nonabsorbable seromuscular stitches are added as a second layer. The sutures should not be under tension.

Review of Reported Results

In a retrospective analysis of 25,541 transduodenal sphincteroplasties done by 130 surgeons in different countries, early transduodenal sphincteroplasty–related complications were bleeding (0.65%), acute pancreatitis (0.60%), dehiscence of the duodenal closure (0.55%), and cholangitis (0.50%), for an overall morbidity rate of 2.3% and a mortality rate of 0.8% (Negro et al, 1984). A retrospective study (Sellner et al, 1988) found that the factors affecting mortality in 2.1% of 333 patients (but only in 0.9% for sphincterectomy-related complications) were age older than 70 years and a bilirubin level greater than 85 mmol/L, diabetes, renal failure, and coagulopathy. The mortality rate increased when supraduodenal choledochotomy was combined with transduodenal sphincteroplasty and when a T-tube was used (Sellner et al, 1988). Transduodenal sphincteroplasty alone (Hacaim et al, 1994) or associated with transampullary septectomy (Kelly & Rowlands, 1996) has led to good long-term results in patients with chronic and acute recurrent pancreatitis, even in cases with pancreas divisum and in selected patients with abdominal pain of hepatobiliary origin.

CHAPTER 36

Stones in the bile duct: endoscopic and percutaneous approaches

Srinivas R. Puli and David L. Carr-Locke

HISTORICAL OVERVIEW

In the 1970s and 1980s, endoscopic retrograde cholangiopancreatography (ERCP) transformed the diagnostic approach to suspected biliary disease and jaundice (see Chapters 18 and 27). Similarly, in the years since it was first performed in humans (Classen & Demling, 1974; Kawai et al, 1974), endoscopic sphincterotomy (ES) has had a dramatic impact on the management of biliary disease, specifically in the treatment of common bile duct (CBD) stones. Approximately 150,000 endoscopic biliary sphincterotomies are performed annually in the United States, and the availability of this procedure undoubtedly influences surgical decision making, when CBD stones are diagnosed on imaging or suspected, and when ERCP and ES are readily available. The surgical community initially resisted the introduction of ERCP and ES into CBD stone management, until their roles became established when they were shown to reduce the mortality rate significantly in a range of situations (Carr-Locke & Cotton, 1985; Cotton, 1984). Interest in ERCP and endoscopic sphincterotomy as definitive therapy for CBD stones grew in the 1990s after the introduction of laparoscopic cholecystectomy. Patient-related factors, clinical judgment, availability of expertise, and current evidence from clinical trials must be combined to decide on an endoscopic, percutaneous, or surgical approach. Although ERCP as a diagnostic modality has been replaced by noninvasive imaging modalities such as magnetic resonance cholangiopancreatography (MRCP; see Chapter 17), it remains the major nonoperative tool to manage biliary diseases such as CBD stones and obstructive jaundice.

INDICATIONS FOR ENDOSCOPIC THERAPY

Patients with CBD stones may be seen initially with asymptomatic stones on noninvasive imaging or direct cholangiography or with a variety of clinical problems alone or in combination, such as cholestasis, pain, cholangitis, and pancreatitis (see Chapter 30). In the early days of ES—at a time when few endoscopy centers could offer the technique, and criticisms by surgical experts were common—it was considered justifiable only in elderly postcholecystectomy patients with recurrent or retained bile duct stones who were at high risk of serious complications from open surgical CBD exploration or reexploration (Blumgart & Wood, 1978). The impressive successes of ES in this group combined with expanded availability, a low rate of complications, and strong patient preference led many centers to widen their indications for the procedure to include younger and fitter postcholecystectomy patients and those with a gallbladder in situ. This change initially occurred in the absence of comparative trial data, and there was such enthusiasm for ES that the establishment of randomized trials was difficult, although nevertheless essential to clarify relative morbidity and mortality risks, as different groups of patients were likely to be treated empirically by endoscopic or surgical means and were not comparable (Cotton, 1984).

The endoscopist now must consider several clearly defined conditions for which endoscopic management may be indicated in patients with confirmed or suspected bile duct stones:

1. Acute cholangitis regardless of gallbladder status
2. Acute gallstone pancreatitis regardless of gallbladder status
3. Obstructive jaundice
4. Postcholecystectomy, stone shown on intraoperative cholangiogram
5. Postcholecystectomy, retained stone, early presentation
6. Postcholecystectomy, late presentation
7. Gallbladder in situ, variable risk factors for surgery, possible need for subsequent cholecystectomy

Many studies now show endoscopic therapy to be optimal in many of these settings, or they suggest it has a defined role in the treatment algorithm.

ENDOSCOPIC TECHNIQUES (SEE CHAPTER 27)

An endoscopy service to treat CBD stones must have access to an appropriate endoscopy facility, high-quality fluoroscopy, and either rapid film processing of permanent radiographs or digital storage that allows immediate review of stored images. The endoscopy team must be fully cognizant of all the basic procedures, less frequently used techniques, and potential complications and their management. It is essential to explain the nature of the procedure to the patient and to outline the purpose, benefits, advantages, alternatives, and potential hazards.

ES is usually the first therapeutic step and immediately follows diagnostic ERCP, which delineates the problem to be treated and allows accurate placement of instruments within the CBD. Standard pull-type sphincterotomes allow a vertical incision to be made from the papillary orifice in a cephalad direction along the intramural course of the CBD for a variable length (average, 10 to 15 mm) depending on local anatomy, the degree of CBD dilation, and the size of stone to be removed (Fig. 36.1). The incision is produced by the controlled application of monopolar electrocautery delivered by a generator specifically designed for endoscopic use, which does not exceed 150 W output. It is fundamental to good ES technique that complete control of wire tension and electrocautery be

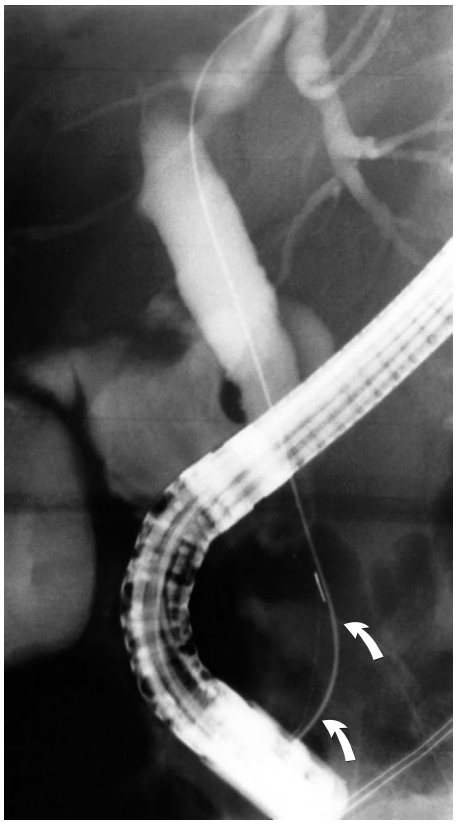

FIGURE 36.1. Endoscopic retrograde cholangiopancreatography showing cholangiography with dilated bile duct, a single duct stone just below the endoscope, a guidewire, and a sphincterotome in position during sphincterotomy (*arrows*).

maintained at all times, whether the ES incision is made as a single continuous movement or in incremental steps. "Smart" generators incorporate a pulsed generator (Erbe, Tubingen, Germany; ConMed Endoscopic Technologies, Billerica, MA) with feedback-controlled power output, and there is potential for increased safety in avoiding a "zipper effect" and reducing pancreatitis and bleeding.

Radiographic confirmation of correct sphincterotome placement within the CBD is mandatory to avoid pancreatic trauma. Occasionally, a *precut papillotomy,* more appropriately called an *access papillotomy,* is needed to initiate ES when the standard instrument cannot be inserted deeply. This incision is often needed when cannulation has been prevented by an impacted stone. The needle-knife is more useful in this situation, because the intramural CBD is usually grossly distended and easily incised, starting from the papilla and extending cephalad. Needle-knife fistulotomy is a variant of this technique; the incision is begun above the papilla to form a choledochoduodenal fistulotomy. This technique is similar in efficacy to needle-knife papillotomy, but more often it requires mechanical lithotripsy, although it may have a lower rate of pancreatitis (Mavrogiannis et al, 1999). Patients with Billroth II partial gastrectomy (Fig. 36.2) and Roux-en-Y bypass operations present special problems to the endoscopist, and numerous methods have been described to obtain successful cannulation (Lin et al, 1999; Wright et al, 2002) and removal of CBD stones (Bergman et al, 2001).

It is standard practice to attempt stone extraction from the CBD immediately after ES. The two accessory instruments

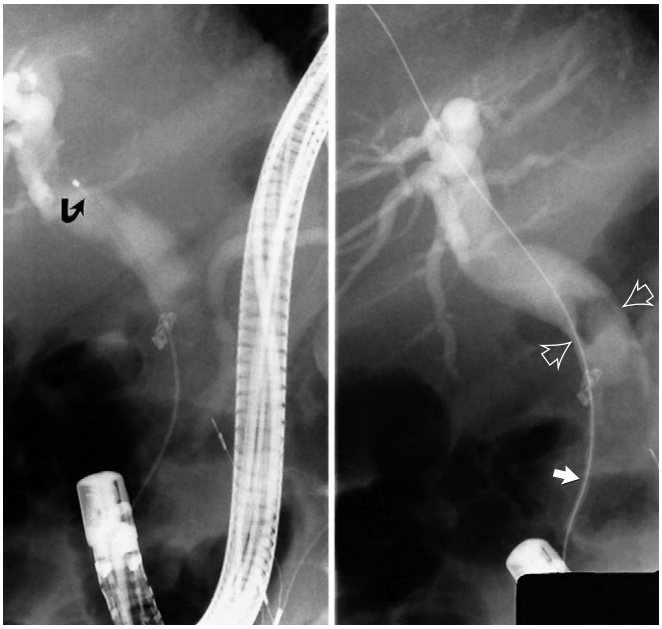

FIGURE 36.2. Endoscopic retrograde cholangiopancreatography in a patient with Billroth II partial gastrectomy showing insertion of a catheter (*curved arrow*) and placement of a guidewire and short biliary endoprosthesis (*solid arrow*) immediately before needle-knife sphincterotomy and demonstration of common bile duct stones (*open arrows*).

used most commonly for this are the Dormia basket (Fig. 36.3) and the Fogarty balloon (Fig. 36.4), which are greater than 90% successful in clearing the CBD. It also is possible to extract stones without a preliminary ES using a balloon dilator (Fig. 36.5) (Bergman et al, 1997). Randomized trials of balloon dilation of the papilla compared with ES have shown similar outcomes for successful stone removal but an increased need for lithotripsy, and although the overall complication rates were similar, there was a higher rate of post-ERCP pancreatitis after balloon dilation if sphincterotomy was not performed beforehand (Baron & Harewood, 2004; Bergman et al, 1997; Disario et al, 2004). Large-diameter balloon dilation after sphincterectomy has become a popular and safe technique (Attasaranya et al, 2008).

Difficult Stones

The most difficult circumstances encountered during endoscopic stone removal result from technical difficulties with achieving deep biliary cannulation or in performing ES. These difficulties are sometimes because of an inaccessible papilla related to aberrant anatomy or unfavorable duodenal or papillary structures, such as a periampullary diverticulum, or prior surgery, such as Billroth II or Roux-en-Y reconstruction. Techniques have been described for the unique challenge of selective bile duct cannulation in a patient with a Billroth II partial gastrectomy (Lin et al, 1999). The performance of ES is also a challenge, because the visualized anatomy is inverted. In especially difficult cases, needle-knife sphincterotomy with a stent, nasobiliary drain, or guidewire used as a guide for cutting may be an option, or specially designed reverse-direction accessories. The literature on techniques of cannulation and sphincterotomy in Roux-en-Y reconstructions is limited (Wright et al, 2002), but some success has been reported with balloon enterosocopy or

FIGURE 36.3. Endoscopic retrograde cholangiopancreatography showing large stone in the proximal bile duct (*arrows*) and basket extraction of a distal bile duct stone (*chevrons*) after endoscopic sphincterotomy.

overtube-assisted ERCP (Koornstra et al, 2008, Kikuyama et al, 2009).

When ES has been successfully performed, extraction may be hindered by a variety of stone factors—including size, number, consistency, shape, and location of stones—ductal factors such as contour and diameter at the level of and distal to the stones, and the presence of coexisting pathology (e.g., stricture or tumor). Stones that are likely to be more difficult to extract and may require adjuvant techniques to remove them

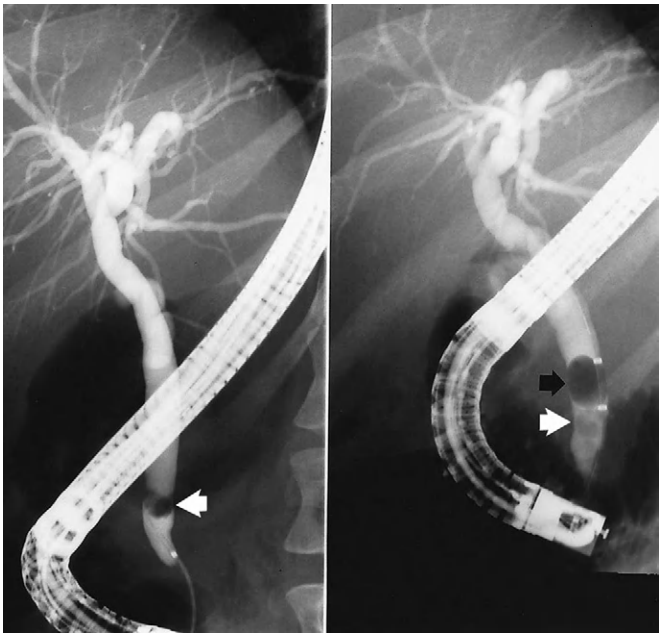

FIGURE 36.4. Endoscopic retrograde cholangiopancreatography showing a nondilated bile duct containing a single distal stone (*white arrow*) and extraction balloon (*black arrow, right*) placed above the stone immediately before its removal after endoscopic sphincterotomy.

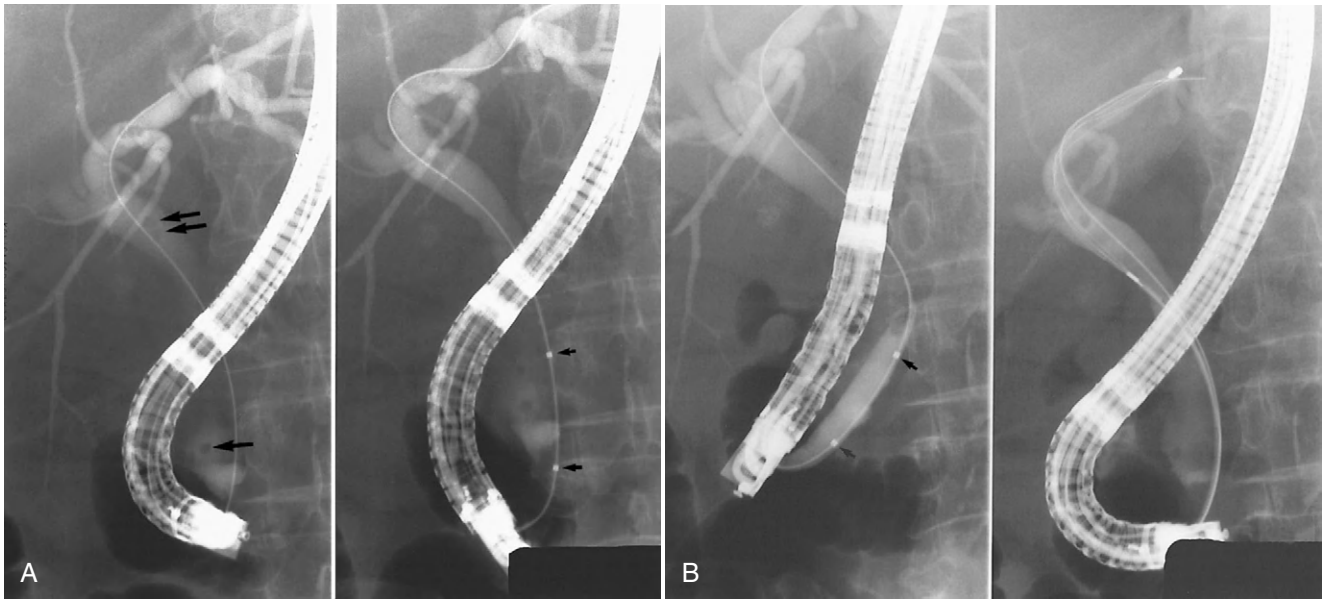

FIGURE 36.5. Endoscopic retrograde cholangiopancreatography series showing technique of balloon dilation of the papilla for extraction of small stones. **A,** Initial cholangiography with demonstration of three small stones (*long arrows, left*) and placement of a guidewire and insertion of an 8-mm dilating balloon located between two radiopaque markers (*small arrows, right*). **B,** Inflation of the dilating balloon (*left*) followed by insertion of an extraction basket for stone removal (*right*).

are those that appear larger than the endoscope on radiographic imaging (usually >15 mm); stones that are numerous or hard in consistency; stones that are square, piston shaped, or faceted that tightly fit the bile duct or that are packed against each other; intrahepatic stones; or stones located proximal to a stricture or narrowed distal bile duct or in a sigmoid-shaped duct. Techniques that have been developed to reduce stone size and facilitate endoscopic removal include mechanical lithotripsy, extracorporeal shock-wave lithotripsy (ESWL), intracorporeal lithotripsy with laser or electrohydraulic probes, and chemical contact dissolution therapy. Treatment options must be discussed jointly by the endoscopist, surgeon, and interventional radiologist when difficulties are encountered (Fig. 36.6; see Chapter 27).

Mechanical Lithotripsy

Removal of large CBD stones is a challenge for the most skilled endoscopist. Mechanical lithotripsy (see Chapter 27; Leung & Tu, 2004; Leung et al, 2001) remains the best initial option for stones that cannot be removed by conventional techniques, because it can be applied safely and effectively during the initial endoscopic procedure. Standard retrieval baskets contained within a polytef (Teflon) sheath may fail to crush large stones, because most exceed the breaking strength of the catheter. Standard-type, lithotripsy-compatible, and lithotripsy-convertible baskets are commercially available. Mechanical lithotripters are modifications of standard Dormia baskets and possess great tensile strength (Fig. 36.7). The reinforced basket is opened in the CBD, and the stone is entrapped within the braided wires. This procedure can be performed through the endoscope instrumentation channel, or it can be done after the endoscope has been removed from the patient and a metal sheath has been extended over the inner Teflon catheter. The end of the metal sheath is attached to a winding mechanism, which retracts the basket when cranked and impales the stone against the rigid distal end of the metal sheath leading to stone fracturing. The stone fragments can be removed with the same basket or a standard retrieval basket or balloon. In experienced centers, this technique allows removal of more than 90% of difficult bile stones that are refractory to standard extraction techniques (Chang et al, 2005; Shaw et al, 1993; Van Dam & Sivak, 1993).

Other Lithotripsy Modalities

For the 5% of patients with biliary stones resistant to ES and mechanical lithotripsy, other methods are available, including intracorporeal techniques (laser or electrohydraulic probes) and ESWL (Adamek et al, 1996). The choice between these methods or surgery depends largely on availability and local expertise.

Laser Lithotripsy

The first-generation laser systems using continuous wave energy neodymium:yttrium-aluminum-garnet (Nd:YAG) devices were ineffective at stone fragmentation and carried a high risk of thermal bile duct injury (Ell et al, 1988). Second-generation devices that have gained acceptance are based on high-energy, flashlamp, pulsed-dye laser technology. The application of the laser pulse leads to rapid expansion and collapse of a plasma on the stone surface, resulting in a mechanical shock wave. Initially, the only means to ensure laser-stone apposition was through the use of "mother and baby" dual endoscope systems (Cotton et al, 1990; Neuhaus et al, 1992a; Ponchon et al, 1991), but more recently, laser lithotripsy has been possible under fluoroscopic guidance with the use of devices that recognize the difference between stone and tissue. Two randomized trials comparing the xenon flashlamp pulsed rhodamine 6G laser with an integrated stone-tissue detection system with ESWL showed similar or improved efficacy in stone clearance, requiring fewer fragmentation and endoscopic sessions with use of the laser (Jakobs et al, 1997; Neuhaus et al, 1998).

Electrohydraulic Lithotripsy

Since its development during the 1950s in the former Soviet Union as a method to fragment rocks during mining, electrohydraulic lithotripsy has been adapted for medical use in the treatment of nephrolithiasis and, more recently, biliary tract calculi. The electrohydraulic probe consists of two coaxially isolated electrodes at the tip of a flexible catheter, which is capable of delivering electric sparks in short, rapid pulses leading to sudden expansion of the surrounding liquid environment and generating pressure waves that result in stone fragmentation (Picus, 1990). Stone contact with the electrode is achieved through the use of basket or balloon catheter systems (Siegel et al, 1990; Arya et al, 2004) or under direct visual targeting (Fig. 36.8) through the working channel of a daughter endoscope (Hixson et al, 1992), minimizing the risk of CBD injury and perforation. Reports document complete stone clearance after multiple sessions in 86% of patients (Adamek et al, 1996; Hixson et al, 1992; Siegel et al, 1990; Arya et al, 2004), and in a prospective nonrandomized trial, electrohydraulic lithotripsy was comparable to ESWL in stone clearance (Adamek et al, 1996). Its main advantages over laser lithotripsy are its lower cost and increased portability.

Extracorporeal Shock-Wave Lithotripsy

ESWL with a variety of lithotripsy machines is now an accepted alternative to endoscopic fragmentation of difficult bile duct stones. In contrast to intracorporeal techniques, direct contact with the stone is unnecessary. Most centers localize stones with fluoroscopic focusing during contrast perfusion of the bile duct through an endoscopically placed nasobiliary catheter or percutaneous drain (Gordon et al, 1991; White et al, 1998). Ponchon and colleagues (1990) reported ESWL success with an ultrasound localization system, although it was less effective when multiple stones were present. Several large series (Bland et al, 1989; Gilchrist et al, 1997; Sackman et al, 2001; Sauerbruch & Stern, 1989) indicated success rates for ESWL stone fragmentation of 53% to 91% and duct clearance in 58% to 90%. Minor complications are common and include hematuria, biliary pain, hemobilia, transient liver function test elevations, and cutaneous petechiae. Overall, with the use of endoscopic techniques such as mechanical lithotripsy, electrohydraulic lithotripsy, laser lithotripsy, and ESWL, one report showed successful stone removal in 98% of 217 patients, with only five patients requiring surgery (Schumacher et al, 1998).

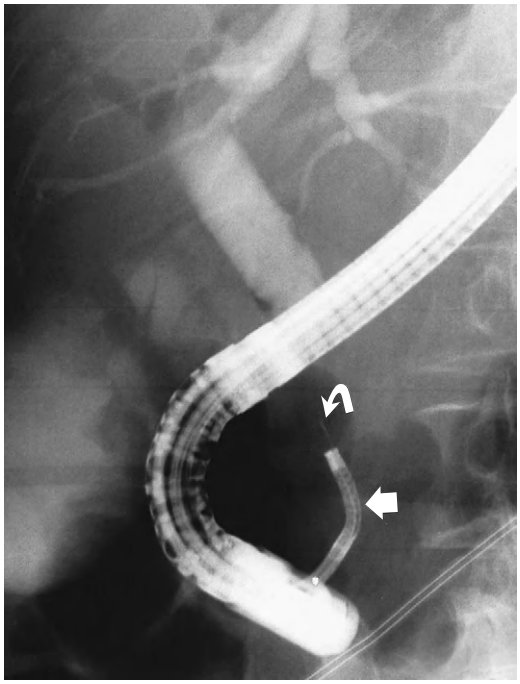

FIGURE 36.8. Use of carrier duodenoscope and direct cholangioscope (*arrow*) inserted within the bile duct with protruding electrohydraulic lithotripsy probe (*curved arrow*) in close proximity to the stone to be fragmented (not visible).

Dissolution Therapy

Contact chemical dissolution of stones (see Chapter 28) has been attempted by perfusing the CBD with solvents administered via an indwelling nasobiliary tube, percutaneous transhepatic catheter, cholecystostomy tube, or an existing T-tube. The initial results with these agents were disappointing because of incomplete stone dissolution and complications. A semisynthetic vegetable oil, monooctanoin, composed of 70% glycerol-1-monooctanoate and 30% glycerol-1,2-dioctanoate, was used experimentally for the dissolution of CBD stones beginning in 1977. Results collected from 222 clinicians treating 343 patients with CBD stones between 1977 and 1983 reported a success rate for complete stone dissolution of only 25.6% and an additional partial success rate of 28% (Palmer & Hoffmann, 1986). Serious adverse effects leading to discontinuation of treatment occurred in 5% of patients, including hemorrhage from duodenal ulceration, acute pancreatitis, jaundice, pulmonary edema, acidosis, anaphylaxis, septicemia, and leukopenia, but no deaths were reported. The use of organic solvents, such as the aliphatic

ether methyl tert-butyl ether (MTBE) (Allen et al, 1985), also has been disappointing, with complete stone dissolution achieved in only 30% to 45% and an unacceptable complication rate related to systemic absorption from spillover of solvent into the duodenum and intrahepatic bile ducts (Brandon et al, 1988; Diaz et al, 1992; Kaye et al, 1990; Murray et al, 1988; Neoptolemos et al, 1990). Sophisticated computer-controlled two-way pump systems may reduce complications and improve efficacy, but total success for large CBD stones using cholesterol solvents is unlikely, because these stones are composed primarily of bile pigments with small concentrations of cholesterol. Expectations of developing a solvent-chelating agent (ethylenediaminetetraacetic acid) for pigment stones have not been realized. As a result of its low efficacy and morbidity, contact dissolution therapy has not assumed an important role in patients with refractory CBD stones, and newer agents with better methods for instillation are awaited.

Endoprosthesis Placement

In the few situations in which stone extraction is incomplete or impossible because of stone size, local anatomy, bleeding, or technical difficulty leading to incomplete ES, a nasobiliary tube (Fig. 36.9) or endoprosthesis (Fig. 36.10) must be inserted to provide biliary decompression and prevent stone impaction in the distal CBD. This is a temporizing therapy to allow the patient's clinical condition to improve, until complete stone clearance is achieved via additional endoscopic maneuvers or surgery. In patients with uncertain duct clearance, a follow-up cholangiogram can be obtained via a nasobiliary tube without the need for repeat ERCP.

Nasobiliary tubes are rarely tolerated beyond a few days. The primary problem with tube placement has been accidental dislodgment, and this has led to the alternative therapy of temporary biliary endoprosthesis placement (Kiil et al, 1989; Rustgi & Schapiro, 1991). In a poor-risk surgical patient, ES and long-term placement of a biliary endoprosthesis has been proposed as a nonsurgical alternative (Cotton et al, 1987; Foutch et al, 1989; Nordback, 1989; Soomers et al, 1990). Stent patency is not of major clinical importance in this situation, because the sphincterotomy typically provides an adequate conduit for bile flow around the prosthesis, which then serves principally to prevent stone impaction. The use of oral ursodeoxycholic acid in these patients has resulted in CBD stone disappearance, but additional studies are necessary to determine the true efficacy in this setting (Johnson et al, 1991). Of 84 patients intentionally treated with permanent stents for endoscopically irretrievable stones and followed for a mean of 3 years, 49 (58%) developed biliary complications, and nine died as a result of complications. Most of the patients had a long, symptom-free interval, however, before complications developed, supporting stenting as effective short-term treatment (Bergman et al, 1995; Maxton et al, 1995). In a randomized study with a shorter mean follow-up (1.5 years) that compared placement of a plastic biliary stent with ES as definitive therapy with stone clearance by means of the basket, balloon, or mechanical lithotripter, the patients with stents had a significantly greater rate of cholangitis (36%) than the patients managed by a conventional endoscopic duct clearance approach (14%). The high risk of long-term complications does not support the concept of permanent stent therapy except for patients with severe comorbidity and a short life expectancy.

RESULTS OF ENDOSCOPIC THERAPY

Successful endoscopic treatment of CBD stones requires an adequate ES, which is now achieved in greater than 90% of attempts in most reported series, with noticeable improvement

as experience increases (Blumgart & Wood, 1978; Cotton, 1984; Cotton & Vallon, 1981; Geenen et al, 1981; Leese et al, 1985a; Schumacher et al, 1998; Seifert et al, 1982; Siegel, 1981). Although success rates for achieving ES are fairly uniform, rates for complete clearance of the CBD vary because not all endoscopists use extraction methods routinely, and follow-up ERCP may be incomplete. Most experts now would expect to extract stones in at least 90% of successful sphincterotomies. Failure to extract or pass stones may be due to the size or number of stones within the duct or unfavorable duct diameter, usually in its retropancreatic segment. Stones 10 mm in diameter do not give rise to many problems, but in general, with size greater than 15 to 20 mm, the chance of retention increases. Interpretation of success rates necessitates care, because centers with greater expertise are more likely to be referred difficult cases that may be failures from attempts elsewhere, and this would bias some results. Patient groups also vary considerably from unit to unit and country to country, reflecting different referral patterns, selection of patients, and attitudes toward endoscopic therapy. Results from centers around the world (Cotton, 1984; Cotton & Vallon, 1981; Freeman et al, 1996; Geenen et al, 1981; Leese et al, 1985a; Nakajima et al, 1979; Reiter et al, 1978; Safrany, 1978; Schumacher et al, 1998; Seifert et al, 1982; Sherman et al, 1991; Siegel, 1981; Vaira et al, 1989) with individual and collected series of 430 to 9041 patients range from 75% to 96% for duct clearance with a median value of 91%.

Complications of Endoscopic Therapy

Early complications of ES have been well documented, and despite the disparate indications and selection of patients among centers, the incidence seems to be remarkably consistent at 5% to 10% (Cotton, 1984; Cotton & Vallon, 1981; Freeman et al, 1996; Geenen et al, 1981; Leese et al, 1985a; Masci et al, 2001; Seifert et al, 1982; Siegel, 1981; Vandervoort et al, 1996). The expected higher complication rate during early experience with ES is reflected in a single-center series comparing the results of the first 394 procedures (Leese et al, 1985a), which carried an overall morbidity rate of 10.4%, with a subsequent consecutive group of 300 sphincterotomies, in which this rate decreased to less than 6%. However, the respective proportions of individual complications remain similar in most reports: acute hemorrhage from the sphincterotomy site, 2% to 2.9%; acute pancreatitis, 1.5% to 5.4%; cholangitis, 1% to 2.7%; and retroperitoneal perforation, 0.3% to 1%, with small numbers of other problems, such as impacted basket, gallstone ileus, and acute cholecystitis overall accounting for 1.1%. Emergency surgery was required in 1% to 2.5% of cases for bleeding, cholangitis, perforation, and pancreatitis in descending order of frequency. Complication rates must be interpreted with caution, because definitions of hemorrhage, acute pancreatitis, cholangitis, and perforation often differ and are not always given.

A consensus conference provided a set of standards for defining complications and their severity (Cotton et al, 1991a). We have always included any episode of overt bleeding (hematemesis or melena) and a decrease in hemoglobin of 2 g/dL or more after ES as significant hemorrhage, although some authors have included only episodes requiring transfusion. Use of aspirin or related drugs in the usual doses does not seem to increase the incidence of hemorrhage (Freeman et al, 1996). The diagnosis of pancreatitis and cholangitis must depend on the presence of clinically recognizable syndromes rather than asymptomatic hyperamylasemia or transient elevation of temperature alone. There does not seem to be a significant influence on the rate or type of complication based on the initial presentation of the CBD stone (pain alone, jaundice alone, pancreatitis, a combination of these), except that cholangitis and cholecystitis are more likely after ES if cholangitis is preexisting. Present evidence does not suggest that complications are more likely in older patients or after previous biliary surgery (Clarke et al, 2001).

Statistically significant risk factors for complications include difficulty in cannulation, access (precut) papillotomy, suspected sphincter of Oddi dysfunction, more than two pancreatic cannulations, acinarization of the pancreas, failed biliary access or drainage, and technical skill of the endoscopist; the age and general medical condition of the patient were not statistically significant (Freeman et al, 1996; Neoptolemos et al, 1989; Vandervoort et al, 2002). Duodenal diverticula, although sometimes rendering ERCP and ES technically more difficult, do not seem to add any further risk. Many series do not include nonendoscopic complications occurring after ES, such as cardiovascular, cerebrovascular, or respiratory events. In addition, although surgery for the treatment of complications is usually documented, surgery for failed endoscopic therapy is often not documented. These factors are important if comparative data from the surgical literature are to be interpreted correctly.

Management of Complications

The management of complications by centers performing ES is well standardized, but many patients are referred from other hospitals to which they are returned after the procedure, where experience in managing complications may be limited. Of all complications, hemorrhage usually requires surgical intervention, but this occurs only in a few cases. In the rare major arterial hemorrhage, endoscopic view of the papillary area is often obscured completely by blood, and further endoscopic therapy may be impossible. The sphincterotomy usually is converted to a formal surgical sphincteroplasty, which includes the likely bleeding artery. Immediate methods for hemostasis include balloon tamponade, direct bipolar electrocautery, injecting or washing the area with 1:10,000 epinephrine solution, application of hemostatic clips, laser coagulation, superselective arterial catheterization and embolization, and infiltration with sclerosant (Grimm & Soehendra, 1983; Leung et al, 1995; Wilcox et al, 2004).

Acute pancreatitis is managed in the standard fashion (see Chapters 53 and 54), and although many attacks are mild and self-limited, clinicians should not be complacent, because some attacks are more severe and should be graded and treated appropriately. Wire-guided cannulation decreases the risk of post-ERCP pancreatitis when compared to the contrast-injection method (Cennamo et al, 2009). There is no evidence that pre-ES or post-ES administration of aprotinin (Trasylol) or glucagon influences the incidence or severity of pancreatitis. In contrast to hemorrhage, the onset of pancreatitis may be delayed for several hours or, rarely, for 1 or 2 days. Gabexate, a synthetic protease inhibitor, and somatostatin have been shown in randomized, double-blind controlled trials to reduce the extent of enzyme elevations and the incidence of pancreatitis after ERCP (Cavallini et al, 1996; Masci et al, 2001; Poon et al, 2003). Gabexate was infused for 30 to 90 minutes before and for 6.5 to 12 hours after ERCP, whereas somatostatin was administered

FIGURE 36.11. Computed tomographic scan of the stomach with oral contrast administration showing extensive retroperitoneal, intraperitoneal, and subcutaneous air caused by a perforation from endoscopic sphincterotomy. The patient made an uneventful recovery on conservative treatment.

either as a bolus infusion or in a manner similar to gabexate (Bordas et al, 1998; Poon et al, 1999, 2003). A trial suggested diclofenac administered as a rectal suppository after ERCP reduced the incidence of post-ERCP pancreatitis (Murray et al, 2003). Trials using secretin are in progress.

Cholangitis is confined almost completely to patients in whom CBD clearance has not been achieved, and measures should be directed at providing adequate bile drainage (e.g., by nasobiliary catheter or endoprosthesis) and administering parenteral antibiotics (see Chapter 43). Emergency surgery for cholangitis carries high risk but is indicated in patients who do not improve within 24 hours.

Perforation may be asymptomatic and noticed only as retroperitoneal gas (Fig. 36.11) or extravasation of radiographic contrast material, but even in a symptomatic patient, conservative treatment is often effective, with spontaneous resolution and avoidance of potentially difficult surgery. Occasionally, this complication presents late after ES with a retroperitoneal collection of bile or pus in the flank or inguinal region (Neoptolemos et al, 1984a; Leese et al, 1985a) and requires percutaneous or surgical drainage.

Gallstone ileus is a rare complication, but its recognition needs to be emphasized, because symptoms may be obscure in elderly patients, and they occur many days after ES and stone release; treatment is along standard surgical lines.

The impaction of an extraction basket occurs rarely in experienced hands, because many endoscopic maneuvers have been learned to prevent or salvage this situation. These maneuvers include 1) avoiding basket closure during initial attempts to extract a large stone to prevent impaling the basket wires in the stone surface; 2) converting the standard basket into a crushing type by replacing the handle with a mechanical lithotripter; and 3) extending the ES incision by removing the duodenoscope over the impacted basket catheter and reintroducing it alongside the catheter, introducing a second duodenoscope, or passing a sphincterotome along the same instrument channel as the impacted basket catheter when using large channel (3.7 mm or 4.2 mm) endoscopes.

Mortality

Death after ES has not been reported in a standardized way. Deaths directly attributable to the procedure are fairly constant at 0.8% to 1.5% (Cotton, 1984; Cotton & Vallon, 1981; Geenen et al, 1981; Leese et al, 1985a; Nakajima et al, 1979; Reiter et al, 1978; Safrany, 1978; Seifert et al, 1982; Siegel, 1981; Sivak, 1989), with almost equal distribution of causes between hemorrhage, pancreatitis, cholangitis, and perforation. Most of the deaths are postprocedural. Mortality rate as a proportion of complications ranges from 7% to 17%, which presumably reflects the comprehensive reporting of all complications by some authors, but reporting of only more severe complications by others. Using the accepted method of reporting 30-day surgical mortality, mortality within 1 month of ES was 3.3% compared with 0.8% immediate postprocedural mortality (Leese et al, 1985a). The additional deaths were due to a variety of vascular, respiratory, renal, infectious, and malignant conditions in a group whose mean age was 79 years. Another group of 59 elderly patients considered unfit for surgery by surgeons underwent ES (Neoptolemos et al, 1984b) with only one death (1.7%).

Long-Term Morbidity

Long-term follow-up of 1 to 15 years after ES in postcholecystectomy patients (Cotton, 1984; Escourrou et al, 1984; Hawes et al, 1990; Ikeda et al, 1988; Rosch et al, 1981; Seifert et al, 1982; Sivak, 1989) shows more than 90% of patients to be well on symptomatic review and 7% to 11% have significant symptoms secondary to recurrent stones (5%), with or without stenosis of the ES site (1.5% to 3%) and cholangitis (2%). One study with long-term follow-up of 15 years after ES found an early complication rate of 15% with a high incidence of late complications, including recurrent stones and pancreatitis in 24% (Bergman et al, 1996); however, this study included only procedures performed between 1976 and 1980. A higher rate of asymptomatic stones and stenosis might result from the use of plain abdominal radiography for detecting pneumobilia, barium studies for detecting duodenobiliary reflux, radionuclide scanning, and repeat ERCP, which do not seem justified outside clinical trials. Most of these long-term complications are amenable to further endoscopic treatment.

Percutaneous Approach

In the 5% to 10% of patients for whom the endoscopic approach is unsuccessful at clearing the CBD of stones, two nonsurgical approaches are available: a *rendezvous procedure* and a *complete percutaneous procedure* (see Chapters 27 and 28). If the papillary region can be reached endoscopically, the rendezvous procedure may be used. This involves a two-stage procedure with the introduction of a percutaneous guidewire through the bile ducts and papilla into the duodenum in the first stage followed by an ERCP (Dowsett et al, 1989; Martin, 1994; Verstandig et al, 1993). In one report of rendezvous procedures for choledocholithiasis, 0.9% (15 of 1753) of ERCPs were unsuccessful at biliary cannulation, usually owing to duodenal diverticula or Billroth II anatomy (Calvo et al, 2001). Three patients

underwent surgery, and 93% of the remaining patients underwent a successful rendezvous procedure. There was one complication with a retroperitoneal perforation that required surgical management, and during follow-up, only one patient developed recurrent choledocholithiasis requiring a repeat rendezvous procedure. In the multicenter prospective trial of endoscopic biliary sphincterotomy complications (Freeman et al, 1996), the combined endoscopic-percutaneous approach was a risk factor for the development of complications, with a high rate of complications at 22.6% with 6.5% classified as severe.

The complete percutaneous approach is labor intensive and typically requires multiple sessions. It has been established as treatment for hepatolithiasis (Yeh et al, 1995; see Chapters 39 and 44), but it may be used for choledocholithiasis. The procedure involves initial establishment of a transhepatic fistula, followed by stone extraction under fluoroscopy or cholangioscopy 7 to 8 days after the fistula forms. In a series of 31 patients with failed endoscopic procedures, percutaneous biliary access was achieved in all patients, and stone clearance was complete in 87% after a mean of 5.6 sessions (Van der Velden et al, 2000). All patients underwent balloon dilation of the papilla, and most patients required additional means of stone fragmentation, including mechanical lithotripsy, electrohydraulic lithotripsy, and ESWL. Complications including pancreatitis and bacteremia occurred in 9.7% and did not require surgical intervention. The four patients who did not respond to percutaneous management underwent surgery. Bile duct access by endoscopic ultrasonography has largely removed the need for percutaneous approaches (see Chapter 14).

COMPLICATIONS, MORTALITY RATES, AND LONG-TERM RESULTS OF BILE DUCT SURGERY

Open Bile Duct Exploration (See Chapters 29 and 35)

Morbidity and mortality after open bile duct exploration have been well documented (Allen et al, 1981; Blamey et al, 1983; Dixon et al, 1983; Doyle et al, 1982; Girard & Legros, 1981; Glenn, 1974, 1975; Kune, 1972; McSherry & Glenn, 1980; Pitt et al, 1981; Vellacott & Powell, 1979; Way et al, 1972), with examination of specific risk factors (Blamey et al, 1983; Dixon et al, 1983; Pitt et al, 1981) that allow some prediction of the likelihood of complications and perhaps predict the need for preoperative biliary drainage. Direct comparison with the endoscopic data is not valid, because extremely diverse groups of patients are being treated by these modalities. This situation highlights the concept of "apples and oranges" succinctly stated by Cotton (1984), but mention must be made of published surgical figures to enable some clinical judgments to be made in the absence of randomized trials. It is immediately apparent that, in contrast to endoscopic therapy, surgical morbidity and mortality are determined by patient age, comorbidities (Glenn, 1975; McSherry & Glenn, 1980; Vellacott & Powell, 1979), hemotologic and biochemical factors (Blamey et al, 1983; Dixon et al, 1983; Pitt et al, 1981), and whether the operation is elective (Houghton & Donaldson, 1983; Sullivan et al, 1982) or emergent (Boey & Way, 1980; Thompson et al, 1982). Mortality rates range from 1% in relatively fit younger patients to 28% in unfit and elderly patients and 12% to 14% in younger patients undergoing emergency surgery for cholangitis. These figures nearly all refer to primary bile duct operations and should be compared only with results of ES when the gallbladder is in situ. Equivalent results for secondary bile duct explorations are less well recorded, but mortality rates of 2% are possible for elective surgery (Girard & Legros, 1981; McSherry & Glenn, 1980). Consideration also must be given to biliary drainage operations, which avoid problems of stone retention, although this may be at the expense of an increased postoperative morbidity and mortality. Average mortality rates are 1% to 5% for choledochoduodenostomy and transduodenal sphincteroplasty (Capper, 1961; Jones, 1978; Lygidakis, 1981; Madden et al, 1970; Speranza et al, 1982; Stuart & Hoerr, 1972). A review of 246 such operations (Baker et al, 1985) in which one of these drainage procedures was used revealed a mortality rate of 5.4% for each of the two types of operations and major morbidity rates of 12% for choledochoduodenostomy and 21% for transduodenal sphincteroplasty. The results stated here should be read in conjunction with those reported in Chapters 29 and 35.

Long-Term Follow-up of Surgically Explored and Reexplored Bile Ducts

Long-term follow-up data after open bile duct exploration are lacking. The wide variation in reported recurrent stone rates has been mentioned, but morbidity and the need for further surgery have been found in 5% after 5 years (Larson et al, 1966), 10% after 12 years (Peel et al, 1975), and 21% after 6 to 11 years (Lygidakis, 1983) when exploration without biliary drainage has been performed. After choledochoduodenostomy (see Chapter 29), there was no morbidity in a 6- to 11-year follow-up (Lygidakis, 1983) with similar results for transduodenal sphincteroplasty (Degenshein, 1964; Stuart & Hoerr, 1972). Follow-up of 90% of the survivors of one series of 246 patients 1 to 12 years postoperatively (mean, 4.4 years) revealed that complications had been treated in 3% of the choledochoduodenostomy group (mainly sump syndrome) and 6% of the transduodenal sphincteroplasty group (mainly cholangitis), with additional symptoms discovered on interview in 8% of the choledochoduodenostomy and 5% of the transduodenal sphincteroplasty groups.

Laparoscopic Common Bile Duct Exploration

Laparoscopic CBD exploration (see Chapter 34) was first performed in the early 1990s and is now used increasingly in experienced tertiary referral centers (Khoo et al, 1996; Martin et al, 1998; Rhodes et al, 1995). Ductal exploration may be accomplished through the cystic duct or directly through a choledochotomy. The transcystic route is the least invasive and generally does not require any ductal manipulation or drainage procedure, whereas choledochotomy requires either closure of the duct over a T-tube or primary closure of the choledochotomy with or without a biliary stent placed in an antegrade fashion without need for a T-tube (Huang et al, 1996; Rhodes et al, 1995). Bile duct clearance rates average 90%, with a median rate of conversion to open operation of 4% (Tranter & Thompson, 2002). Complication rate is 2.5%, with a median mortality rate of 1% (Strasberg et al, 1995).

In a randomized trial of laparoscopic CBD exploration versus postoperative ERCP for CBD stones (Rhodes et al, 1998), the clearance rates at the first intervention were the same

(75%). With subsequent treatment, predominantly in the form of repeated ERCP, duct clearance rates approached 100% in both groups. In a similar study sponsored by the European Association of Endoscopic Surgeons (Cuschieri et al, 1996), patients were randomized to preoperative ERCP followed by laparoscopic cholecystectomy or laparoscopic cholecystectomy with laparoscopic CBD exploration. Duct clearance was similar in the two groups, but there was a higher rate of conversion to open surgery and decreased length of stay with single-stage surgical treatment. Our group has shown that therapeutic ERCP can be performed safely as an outpatient procedure without need for hospitalization (Tham et al, 1997). To minimize hospital stay, the outpatient ERCP would need to be coupled with laparoscopic cholecystectomy, which requires good coordination between the surgeon and the endoscopist.

SPECIFIC CLINICAL PROBLEMS

Postcholecystectomy with T-Tube In Situ (See Chapter 29)

CBD stones of less than 10 mm in diameter detected in the early postoperative period on T-tube cholangiography may pass spontaneously or with hydrostatic pressure from flushing or perfusing the T-tube. Most of these stones require additional mechanical manipulation, however. Increased morbidity, mortality, and retained stone rate after secondary bile duct explorations stimulated the development of alternative techniques, including hydraulic T-tube irrigation with or without pharmacologic relaxation of the sphincter of Oddi with glucagon or nitrates (Tritapepe et al, 1988), T-tube infusion of cholesterol solvents (Tritapepe et al, 1988), T-tube tract choledochoscopy and lithotripsy (Josephs & Birkett, 1992), and percutaneous extraction of stones through a mature T-tube tract. Success rates with the last technique have ranged from 77% to 96%, but multiple sessions are often required and the technique may be complicated by sepsis, biliary trauma, and biliary leakage in 4% to 8% of patients (Burhenne, 1980; Caprini, 1988; Cotton, 1990; Mason, 1980; Nussinson et al, 1991; Tritapepe et al, 1988). Delays of 4 to 6 weeks are required before manipulation to allow maturation of the T-tube tract.

Alternatively, early ES can be applied safely and effectively after stone detection without the need for T-tube maturation, allowing timely discharge from hospital. The results from eight endoscopic series totaling 337 patients indicate an overall endoscopic success rate of 90% with a morbidity rate of 7% and mortality rate of 0.6% (Bickerstaff et al, 1988; Danilewitz, 1989; Lambert et al, 1988; Nussinson et al, 1991; O'Doherty et al, 1986; Simpson et al, 1985; Soehendra et al, 1981; Tandon et al, 1990). The choice between these two techniques depends on local expertise, because direct comparisons have not been made in controlled trials.

Postcholecystectomy Without T-Tube

The incidence of retained CBD stones is approximately 2% to 5% after conventional and laparoscopic cholecystectomy and 5% to 15% after CBD exploration. ES remains the treatment of choice for elderly patients seen days to years after cholecystectomy (Danilewitz, 1989), because these patients are at higher risk from further abdominal surgery (Cranley & Logan, 1980; Sheridan et al, 1987). ES also is recommended for choledocholithiasis in young, fit postcholecystectomy patients, even those with normal diameter ducts (Cotton et al, 1998).

Pregnancy

Symptomatic choledocholithiasis during pregnancy poses a diagnostic and therapeutic challenge. The frequency of choledocholithiasis in pregnancy requiring intervention may be 1 in 1200. Traditionally, intervention in these patients has been surgical. Although surgery has an overall low morbidity and mortality for the expectant mother, it carries a 4- to 6-week recovery period with a possible increased risk of fetal loss.

Endoscopic treatment can be performed safely with a complication rate comparable to that in nonpregnant patients (Jamidar et al, 1995; Kahaleh et al, 2004; Tham et al, 2003, Simmons et al, 2004). We reviewed our experience with 15 pregnant patients who underwent ERCP (Tham et al, 2003). Precautions were taken to minimize fetal exposure to radiation, which included covering the pelvis of all patients with an abdominal lead apron and minimizing fluoroscopy. No adverse outcomes occurred to the mother or the fetus, and the average fetal radiation dose was 310 mrad, which is below the 5- to 10-rad level considered teratogenic. These patients should undergo cholecystectomy on completion of pregnancy to prevent recurrence.

Patients with Gallbladder In Situ

In elderly patients or in patients with significant comorbidity, a deliberate decision often is made to leave the gallbladder in situ after ES and CBD stone removal. The short-term and long-term results and complications of ES in patients with gallbladders do not differ from those in postcholecystectomy patients (Kaw et al, 2002). One randomized study of high-risk surgical patients reported a higher rate of recurrent biliary symptoms in the ES group compared with patients who underwent open cholecystectomy with operative cholangiography (Targarona et al, 1996); however, details of the endoscopic procedure were not reported in the article, and the failure rate for ES was high at 20%. In view of their shorter life expectancy, high-risk patients can be managed expectantly, unless symptoms dictate otherwise. Careful follow-up for 5 to 10 years in patients with intact gallbladders indicates that approximately 10% develop gallbladder symptoms or complications sufficient to warrant cholecystectomy, and most occur in the first year (Davidson et al, 1988; Escourrou et al, 1984; Hill et al, 1991; Rosseland & Solhaug, 1984; Siegel et al, 1988; Tanaka et al, 1987). The risk for developing gallbladder symptoms is similar to that of patients with asymptomatic cholelithiasis (Gracie & Ransohoff, 1982). Most patients requiring cholecystectomy can be treated electively.

The risk of developing biliary symptoms seems to depend on the continuing presence of stones in the gallbladder. In two reports (Siegel et al, 1988; Tanaka et al, 1987), none of the patients with acalculous gallbladders at initial ES developed symptoms or complications that subsequently required cholecystectomy. In patients with gallstones, there were no reliable predictors to identify patients with cholelithiasis who were likely to develop gallbladder complications after ES. Nonfilling of the gallbladder with radiographic contrast material at ERCP (Worthley & Toouli, 1988) or with radiotracer by nuclear

scintigraphy (Holbrook et al, 1991) may confer a higher likelihood of developing symptoms, although results from other series do not concur (Davidson et al, 1988; Hill et al, 1991). These results suggest that the low risk of subsequent gallbladder complications after ES and bile duct clearance, when patients are kept under supervision, outweighs the known higher mortality rate of cholecystectomy in high-risk patients and mitigates against routine cholecystectomy in this group. Few physicians would recommend this approach in a fit patient, in whom the expectation for long-term survival and development of symptoms necessitating cholecystectomy are greater. The risk of elective cholecystectomy is probably smaller than the risk of subsequently developing gallbladder symptoms in this group, so elective cholecystectomy would seem most appropriate. This idea was confirmed by a study of 120 patients with known gallstones who underwent successful ES with bile duct clearance; the study excluded patients who were not surgical candidates, and patients were randomized to laparoscopic cholecystectomy within 6 weeks after ES or a wait-and-see policy with median 2.5-year follow-up. Nearly half the patients in the wait-and-see group developed biliary-related problems, including biliary pain and cholecystitis, which led to cholecystectomy or repeat ERCP or both, whereas none of the patients in the cholecystectomy group experienced biliary-related problems. The wait-and-see group also had a higher rate of conversion to an open procedure at the time of surgery (Boerma et al, 2002).

The place of preoperative ES in young, low-risk surgical patients with suspected choledocholithiasis has been examined to determine whether preoperative ES confers an advantage in terms of morbidity, mortality, and length of hospital stay compared with a conventional approach of open cholecystectomy, operative cholangiography, and CBD exploration. Two prospective, randomized controlled trials (Neoptolemos et al, 1987; Stiegmann et al, 1992) have addressed this question with the conclusion that no advantage is conferred by initial endoscopic bile duct clearance before cholecystectomy. High-risk surgical patients were excluded from these studies, and both studies were conducted in the era of open cholecystectomy, before the use of high-quality MRCP.

Laparoscopic Cholecystectomy and Endoscopic Retrograde Cholangiopancreatography

Laparoscopic cholecystectomy (see Chapter 34) has replaced open cholecystectomy as the procedure of choice for gallbladder removal in most patients with symptomatic cholelithiasis. Optimal management of patients with suspected or documented CBD stones varies according to the expertise available in a particular institution. Laparoscopic transcystic CBD exploration (Hunter, 1992) or direct choledochotomy (Jacobs et al, 1991) can be performed at the time of laparoscopic cholecystectomy, but these procedures require special expertise and equipment. Laparoscopic transcystic choledochoscopy is hindered by the small size and tortuosity of the cystic duct, making instrument passage and stone lithotripsy and removal potentially difficult.

In patients with suspected CBD stones, MRCP has replaced ERCP as the diagnostic modality of choice to identify the presence or absence of CBD stones (see Chapter 17). A need for endoscopic management has evolved, with ERCP playing a central role in preoperative and postoperative CBD stone removal. Initially, we and others (Cotton et al, 1991b) found it useful to stratify patients preoperatively into low, intermediate, and high likelihood for CBD stones (Table 36.1) based on established clinical and biochemical indicators, including elevated liver function tests, a dilated CBD (>8 mm on ultrasound), and a history of jaundice or pancreatitis (Del Santo et al, 1985; Hauer-Jensen et al, 1985; Lacaine et al, 1980). In the absence of clinical or biochemical indicators, CBD stones are present in only 2% to 3% of individuals (Neuhaus et al, 1992b). Small asymptomatic stones may be of minor clinical relevance, because their natural history is unknown, and conceivably many if not most of these calculi would pass spontaneously without ever coming to clinical attention. We have favored selective evaluation of the CBD only for patients with risk factors for choledocholithiasis.

Table 36.1

Cholangiography Stratification for Risk of Choledocholithiasis

High Likelihood (Preoperative ERCP)
Bilirubin >2 mg/dL
Alkaline phosphatase >150 U/L
Present/recent history of jaundice/pancreatitis
Dilated CBD/stone on sonography
Intermediate Likelihood (IOC)
Bilirubin 1.5-2 mg/dL
Alkaline phosphatase 110-150 U/L
Transaminases >2× normal
Remote jaundice/pancreatitis
Low Likelihood (No ERCP/IOC)
Normal liver function tests
No ductal dilation
No jaundice/pancreatitis

ERCP, endoscopic retrograde cholangiopancreatography; CBD, common bile duct; IOC, intraoperative cholangiography

We have proposed three general strategies to manage patients with suspected or documented CBD stones (Tham et al, 1998). Algorithm 1 offers the advantage of complete surgical management at a single procedure without the need for additional postoperative stone extraction. The major disadvantage is the high rate of conversion to an open procedure, which is not in keeping with the desire to maintain a minimally invasive approach to therapy, but it is required in some patients (Cuschieri et al, 1999; Huang et al, 1996). This strategy has not gained widespread acceptance, but it would be a reasonable approach in centers incapable of providing adequate endoscopic therapy, or when techniques are achieved for performing laparoscopic CBD exploration. Algorithm 2 focuses on endoscopic cholangiography and stone clearance before performance of laparoscopic cholecystectomy. This approach seems justified in a patient with a high likelihood of a CBD stone; it would avoid prolonging the operative procedure with intraoperative cholangiography while maintaining the minimally invasive approach and reducing the need for conversion to an open CBD exploration for laparoscopic failures (Tham et al, 1998; Wright et al, 2002). It is often possible to remove small stones (3 mm in diameter) during ERCP through the intact papilla, sparing the patient the potential short-term and long-term risks of ES (Cotton, 1993; Ibuki et al, 1992; Staritz et al, 1985). Algorithm

Table 36.2

Endoscopic Retrograde Cholangiopancreatography in 1847 Laparoscopic Cholecystectomies at Brigham & Women's Hospital (1990–1992)

Preoperative ERCP	135 (7.3%)
Normal	83 (62%)
Stones	43 (32%)
Mirizzi syndrome	1 (0.7%)
Aberrant anatomy	2 (1.5%)
Failed ERCP	2 (1.5%)
Intraoperative cholangiography	87 (5%)
Successful	39 (45%)
Stones	2 (2%)
Not attempted	1625/1847 (88%)

ERCP, endscopic retrograde cholangiopancreatography

3 uses laparoscopic transcystic cholangiography to detect CBD stones and postoperative ERCP to remove stones in patients with positive cholangiograms. This strategy relies heavily on ERCP expertise, because failed stone removal necessitates referral to a more experienced endoscopist or a second open operative procedure. The choice between these strategies should be strongly influenced by the surgical and endoscopic expertise available. It should be stressed that noninvasive imaging of the CBD with MRCP has replaced ERCP as the diagnostic modality of choice for patients with suspected CBD stones.

At our institution, in a prospective series of 1847 consecutive laparoscopic cholecystectomies (Table 36.2), preoperative ERCP (algorithm 2) was performed in 135 (7.3%) patients considered highly likely to have CBD stones based on a total bilirubin greater than 2 mg/dL, alkaline phosphatase greater than 150 U/L, a dilated CBD on ultrasound, or a recent history of jaundice or pancreatitis. ERCP was successful in 133 (98.5%) patients, and 43 (32%) were found to have CBD stones. All stones were removed after sphincterotomy, with nine complications: six cases of pancreatitis (three mild, three moderate), two of hemorrhage (one mild, one moderate), and one fever with negative blood cultures. Aberrant ductal anatomy was present in two ERCPs, Mirizzi syndrome (see Chapter 42) was present in one, and 83 were normal. Using stricter criteria for preoperative ERCP selection, we increased the preoperative detection rate of CBD stones from 32% to 56% predicted.

We suggest performance of precholecystectomy ERCP 24 to 48 hours before the planned surgery whenever logistically feasible to avoid the infrequent occurrence of stone migration from the gallbladder into the CBD during the ERCP-laparoscopy interval, resulting in the possibility of a retained CBD stone. This sequence of events occurred early in our series in one patient who passed a stone from the gallbladder into the CBD during a 3-week interval between the preoperative ERCP and laparoscopy, but it has not recurred with subsequent performance of preoperative ERCP at the recommended 24- to 48-hour interval. Selective intraoperative cholangiography (algorithm 3) was performed in 87 patients (5%) believed to be at intermediate risk for CBD stones based on preoperative indicators that included a total bilirubin elevation of 1.5 to 2 mg/dL, alkaline phosphatase of 110 to 150 U/L, transaminases greater than twice normal, or a remote history of jaundice or pancreatitis. Only two (2%) of these studies were positive. Patients without preoperative indicators (1625 patients) and considered low risk did not undergo cholangiography, and 21 (1.3%) were subsequently found to have retained stones, all managed successfully by ERCP and ES.

Acute Cholangitis

Acute cholangitis (see Chapter 43) resulting from CBD stones traditionally was managed by supportive measures and parenteral antibiotics, followed by early surgery if improvement was slow or absent. The mortality from emergency surgery ranges from 12% to 16% with higher rates for elderly patients (Boey & Way, 1980; Cotton, 1984; Thompson et al, 1982). In the 1980s, we analyzed the treatment outcomes of 82 patients with severe acute cholangitis and CBD stones admitted over a 7-year period during which ES was available (Leese et al, 1985b). Mean age was 71 years (range, 19 to 88 years), with 87% older than 60 years and 23% older than 80 years. Overall 30-day mortality rate was 14.6% but varied considerably with different modes of therapy. Eleven patients received conservative treatment only; of these, seven responded to antibiotics alone, but four (36.4%) were moribund and died before any treatment could be instituted. Seventy-one patients underwent early biliary decompression either surgically (n = 28) or endoscopically (n = 43). Of the 11 postcholecystectomy patients, four had early surgery with biliary-digestive bypass, with two deaths within 30 days (50%), and seven had early ES with no deaths. Of the 60 patients with gallbladders, 24 were treated surgically (mean age, 62 years) with a mortality rate of 16.7%; 13 had an ES followed by elective cholecystectomy (mean age, 64 years) with no deaths; and 23 had an ES with gallbladders in situ. Of these, six died from unrelated causes, and two required surgery for empyema of the gallbladder—at 19 days after ES in one and after recurrence of cholangitis at 5 months in the other. Complications after ES occurred in 10 patients: five hemorrhages, three exacerbations of cholangitis, one mild acute pancreatitis, and one gallstone ileus requiring surgical intervention. Bile duct clearance was achieved in 40 (93%) of 43 patients. Of the three failures, one patient died without further therapy, one underwent surgery 4 weeks later, and one remained asymptomatic, having declined further treatment. The 30-day mortality rate for patients treated by early surgery was 21.4% (six of 28), and 30-day mortality rate for patients treated by early ES, regardless of subsequent treatment, was 4.7% (two of 43). We concluded that patients not responding to standard initial therapy within 24 hours should be offered endoscopic biliary decompression and bile duct clearance if this is locally available. The only randomized trial of emergency endoscopic versus surgical management of severe calculous cholangitis (Lai et al, 1992) showed a threefold difference in mortality rate (10% vs. 32%; $P < .03$) in favor of ERCP.

Gallstone Pancreatitis

Acute pancreatitis (see Chapters 53 and 54) resulting from impaction of gallstones in the ampulla of Vater was first reported by Opie in 1901. From his observations in this study, an "obstructive theory" was derived to explain the mechanism responsible for gallstone pancreatitis. Stone impaction in the common channel of the pancreatic duct and CBD is postulated to result in obstruction of the two systems with resultant reflux of bile into the pancreatic duct (Moody et al, 1993). In support of the obstructive theory, gallstones can be recovered from the

feces of 85% to 95% of patients (Acosta & Ledesma, 1974; Kelly, 1980a, 1980b), and the incidence of CBD stones is 80% in patients undergoing urgent operative or endoscopic intervention compared with a 5% to 30% incidence when the procedure is delayed (Acosta et al, 1978; Kelly, 1980a, 1980b; Ranson, 1979; Stone et al, 1981).

The Ranson, Imrie, Glasgow, and Acute Physiology, Age, and Chronic Health Evaluation (APACHE II) assessments provide well-established criteria for assessing the severity of pancreatitis and predicting local adverse events—such as necrosis, hemorrhage, infection, and pseudocyst formation—and systemic complications of acute respiratory distress syndrome, disseminated intravascular coagulation, distant fat necrosis, and renal failure (see Chapters 52 to 54; Banks, 1991). Stratifying patients by severity based on these criteria has been helpful in directing appropriate management. Most patients experience mild pancreatitis resulting from transient impaction of a stone in the ampulla followed by spontaneous migration into the duodenum. These patients do well with conservative therapy alone and are unlikely to benefit from urgent intervention. In contrast, it has been proposed that more severe cases of pancreatitis result from persistent stone impaction or choledocholithiasis with infected bile, suggesting the possibility that early stone extraction by surgical or endoscopic techniques would halt progression of the acute event and prevent the development of future attacks in the short term.

Early surgical therapy in cases of acute gallstone pancreatitis has been challenged owing to the high operative morbidity and mortality. Results and conclusions from numerous series comparing early and late surgical therapy in gallstone pancreatitis are difficult to interpret. The mortality rates range from 2% to 67%, studies are retrospective with frequent comparisons to historical controls, and stratification for severity of illness has not been used (Acosta et al, 1978; Kim & Bosner, 1988; Osborne et al, 1981; Ranson, 1979). In one series, Kelly and Wagner (1988) prospectively randomized 165 patients with gallstone pancreatitis to early or delayed surgery. In the group with severe pancreatitis, mortality was 48% after urgent operative intervention compared with 11% mortality rate in patients in whom surgery for gallstones was delayed for more than 48 hours. In contrast, patients with mild pancreatitis had mortality rates of 3.3% and 0%, respectively. Another study of moderate to severe gallstone pancreatitis with peripancreatic fluid collections confirmed these results, with complications in 44% of patients in the early surgery group compared with 6% in the delayed surgery group (Nealon et al, 2004). These results would favor avoidance of early operative intervention in the acute phase of biliary pancreatitis, unless local complications from necrotizing disease dictate otherwise.

An endoscopic approach to gallstone pancreatitis offers the theoretical advantage of immediate relief of ampullary obstruction and ductal clearance without the risks of general anesthesia or surgery. There was initial reluctance to perform ERCP in patients with acute pancreatitis because of concerns that the procedure would exacerbate the illness and lead to death. The Leicester investigators (Neoptolemos et al, 1986) were the first to perform a controlled study to evaluate the efficacy of ERCP in biliary pancreatitis. A group of 121 patients with suspected gallstone pancreatitis was randomized to urgent (within 72 hours of hospitalization) ERCP or conventional nonendoscopic management. ES was performed if bile duct stones were present on ERCP. CBD stones were found in 63% of the patients in the predicted severe group and in only 26% of patients with predicted mild attacks. Patients with mild pancreatitis had favorable outcomes regardless of treatment strategy, with a similar incidence of complications and no deaths. In the group of patients with severe pancreatitis defined by modified Glasgow criteria, urgent ES significantly reduced the morbidity (local and systemic complications) from 61% to 24% and reduced the length of hospitalization from 17 days to 9.5 days compared with conservatively managed patients. Mortality was lower in the ERCP group (4% vs. 18%), but the difference did not reach statistical significance.

A second study published by the Hong Kong group (Fan et al, 1993) prospectively randomized 195 consecutive patients with pancreatitis of any cause to urgent (within 24 hours of hospital admission) ERCP with papillotomy or initial conservative treatment with selective ERCP only if the clinical condition deteriorated. In this region of the world, where biliary lithiasis is frequently responsible for acute pancreatitis, emergency ERCP resulted in a reduction of biliary sepsis from 12% in the conservatively treated patients to 0% in patients undergoing endoscopic papillotomy and stone extraction. Overall, no significant differences were found in the incidences of either local (10.3% vs. 12.2%) or systemic (10.3% vs. 14.3%) complications. In the subset of patients with severe pancreatitis and CBD stones, urgent ES resulted in a decrease in the combined incidence of local and systemic complications to 21% and mortality rate to 5.3% compared with the conservatively managed group, in which the rates were 68.8% and 25%, respectively.

A third randomized trial (Nowak et al, 1998) had a different design from the two preceding studies. All 280 patients with acute gallstone pancreatitis in the study underwent urgent duodenoscopy within 24 hours of onset of their disease; nearly 25% were found to have impacted stones at the papilla, which were treated by immediate sphincterotomy. The remaining 205 patients were randomized to conventional treatment or sphincterotomy regardless of the cholangiographic findings. Compared with conventional treatment, the authors showed a significant advantage for patients treated endoscopically with respect to morbidity (17% vs. 36%; $P < .001$) and mortality (2% vs. 13%; $P < .001$). Both rates also were more strikingly reduced the earlier the endoscopic intervention was undertaken. Because all patients seem to benefit regardless of severity, the conclusion was that emergency ERCP and sphincterotomy were indicated in all patients with acute gallstone pancreatitis, but further analysis of the data is required when the full report is available.

A much criticized fourth randomized multicenter study in Germany (Folsch et al, 1997) showed that endoscopic intervention in gallstone pancreatitis in the absence or low likelihood of bile duct obstruction or cholangitis did not show benefit, but increased morbidity and mortality rates were reported in the ERCP group that were not previously found in other trials. The study has been criticized because it randomized significantly fewer patients with severe pancreatitis, and 19 of 22 centers contributed fewer than two patients per year to the study.

These studies show that ERCP and endoscopic stone extraction can be performed safely in the setting of acute biliary pancreatitis. Urgent ERCP and ES can be performed with good rationale in patients with severe or progressive pancreatitis, owing to the resultant reduction in major local peripancreatic complications and the increasingly recognized coexistence of acute cholangitis, potentially translating to reduced mortality. Subsequent elective cholecystectomy should be considered,

although in a high-risk patient the gallbladder may be left in situ. In a patient with mild pancreatitis, no immediate intervention is advised. If a patient later is proved to have gallstones or microlithiasis (Lee et al, 1992; Targarona et al, 1995), elective laparoscopic cholecystectomy with preoperative ERCP or intraoperative cholangiography should be performed. In a postcholecystectomy patient, endoscopic therapy is definitive. The role of ES in lieu of cholecystectomy for a high-risk patient with an intact gallbladder and gallstone pancreatitis in the absence of choledocholithiasis requires further evaluation (May & Shaffer, 1991).

CONCLUSIONS

Endoscopic management of choledocholithiasis is widely accepted as a highly effective therapy for choledocholithiasis. Endoscopic techniques are well established, and accessories have been developed to enhance success and safety. ES is the standard of care in the management of elderly high-risk and fit patients with CBD stones in most clinical situations, regardless of the presence or absence of the gallbladder and in all patients presenting with CBD stones late after previous biliary surgery, when the only alternative is further surgical intervention. The endoscopic removal of retained stones in the early postoperative period has been shown to be effective, it carries a small risk of complications, and it allows early discharge from the hospital. In addition, patients of all ages with acute cholangitis not responding to conventional therapy should be considered for endoscopic management before emergency surgery if this is logistically feasible. The case for ERCP and ES in the treatment of patients with severe gallstone-associated pancreatitis has been made in controlled trials. Integrated endoscopic therapy for biliary disease is well established in centers where surgical and endoscopic clinicians work closely together and provide each other with a suitable forum for critical evaluation of alternative therapeutic techniques. This has become increasingly manifest with the establishment of laparoscopic cholecystectomy with more complex laparoscopic manipulations of the bile ducts. As arguments and clinical practice come full circle, it is tempting to suggest that the enthusiastic speculations of the early 1970s—that in stone disease, the surgeon should treat the gallbladder, and the endoscopist should treat the bile duct—has come to pass 3 decades later.

CHAPTER 37

Cholecystolithiasis and stones in the common bile duct: which approach and when?

Mark P. Callery, Norberto J. Sanchez, and Lygia Stewart

CHOLECYSTOLITHIASIS

Indications for Cholecystectomy

Asymptomatic Gallstones

Surprisingly, most patients with gallstones, about 65% to 80%, are asymptomatic (see Chapter 30). Studies of the natural history of *silent gallstones* have shown that symptoms develop in 1% to 2% of patients per year. Among patients with asymptomatic gallstones, about 10% develop symptoms in 5 years, and about 20% develop symptoms by 20 years. Additionally, most patients experience symptoms for some time before they develop a complication (National Institutes of Health [NIH] Consensus Statement Online, 1992; Stewart et al, 1989; Festi et al, 2010; McSherry et al, 1985). So, the majority of patients with asymptomatic gallstones can be observed, and surgical intervention (laparoscopic cholecystectomy) can be offered if symptoms develop.

Surgical treatment of asymptomatic gallstones is indicated in a number of patient populations for whom prophylactic cholecystectomy was once recommended. These populations comprise transplant patients and those with diabetes mellitus, chronic liver disease, sickle cell anemia or other chronic hemolytic anemia, patients undergoing bariatric or other gastrointestinal operations, and those with a potentially increased risk of gallbladder carcinoma (Table 37.1).

Prophylactic cholecystectomy for asymptomatic cholelithiasis was previously recommended for patients with diabetes mellitus. Studies in the late 1960s reported a higher mortality following emergency cholecystectomy in diabetic patients. Subsequent meta-analysis revealed that diabetes was not an independent variable; instead, cardiovascular, peripheral vascular, cerebrovascular, or prerenal azotemia were associated with more severe acute cholecystitis (Stewart et al, 1989; Hickman et al, 1988). More recent series have shown similar complication rates for acute cholecystectomy among diabetic and nondiabetic patients. Diabetic patients with asymptomatic gallstones today are managed expectantly.

The incidence of gallstones is twice as high in patients with chronic liver disease. Most of these patients remain asymptomatic. Operative morbidity and mortality rates for patients with chronic liver disease are also significantly higher. Meta-analyses report no increase in mortality in asymptomatic patients with an expectant management approach (Stewart et al, 1989; NIH Consensus Statement Online, 1992).

Patients undergoing bariatric surgery have a higher incidence of cholelithiasis, because obesity is associated with cholelithiasis, and gallstones may form during rapid weight loss. Studies report a cholelithiasis incidence of 27% to 35% before bariatric operations and a 28% to 71% increase in gallstone formation following bariatric surgery (Wudel et al, 2002). Many surgeons utilize bile salt medications during periods of rapid weight to help prevent cholesterol gallstones. But even if gallstones form, most are asymptomatic, and elective cholecystectomy is safe for symptomatic disease (NIH Consensus Statement Online, 1992).

Several factors must be considered for potential transplant patients with asymptomatic cholelithiasis: cholelithiasis is common, immunosuppression may increase infectious morbidity, and morbidity and mortality may be increased with emergency surgery. This problem was examined with a recent decision analysis, using probabilities and outcomes derived from a pooled analysis of published studies (Kao et al, 2005). The authors recommended prophylactic posttransplantation cholecystectomy for cardiac transplant recipients with asymptomatic cholelithiasis. For pancreas and kidney transplant patients with asymptomatic cholelithiasis, however, expectant management was recommended.

Asymptomatic gallstones found at another gastrointestinal operation should generally be removed if exposure is adequate, if the cholecystectomy can be done safely. Studies of expectant management for patients with asymptomatic gallstones undergoing laparotomy for other conditions have shown a high (up to 70%) incidence of symptoms and/or complications from the biliary system, and a significant percentage (up to 40%) of patients require a cholecystectomy within 1 year of the initial operation. Further, no increase in morbidity is associated with concomitant cholecystectomy (Stewart et al, 1989; Klaus et al, 2002).

The management of patients with asymptomatic gallstones undergoing abdominal aortic aneurysm (AAA) repair has recently evolved, especially with the advent of endovascular aortic procedures. In the past, when AAA repair and cholecystectomy were open operations, concomitant cholecystectomy was recommended to prevent the higher morbidity associated with the development of acute cholecystitis in the postoperative period. Studies reported no increase in graft infection or morbidity when cholecystectomy was done following closure of the retroperitoneum; however, more recent data show similar mortality rates with or without concomitant cholecystectomy. Today, laparoscopic cholecystectomy is typically performed after endovascular AAA repair, without increased morbidity (Cadot et al, 2002).

Children with asymptomatic gallstones comprise two main etiologic groups: those with hemolytic anemia (sickle cell

Table 37.1

Management of Asymptomatic Gallstones

Patient Population	Management
Healthy adults	Expectant
Children (without hemoglobinopathy or hemolytic anemia)	
Diabetes mellitus	
Chronic liver disease	
Previous bariatric procedure	
Abdominal aortic aneurysm repair	
Transplant	
Kidney or pancreas	Expectant
Cardiac	Cholecystectomy posttransplant
Undergoing gastrointestinal operation	Incidental cholecystectomy
Hemoglobinopathy/chronic hemolytic anemia (sickle cell disease, spherocytosis, elliptocytosis, β-thalassemia)	Elective cholecystectomy
High-risk group for gallbladder carcinoma (>3 cm gallstones, calcified gallbladder, Native American race)	

disease, β-thalassemia, hemoglobinopathies) and those whose cholelithiasis stems from some other cause (total parenteral nutrition, short bowel syndrome, cardiac surgery, leukemia, lymphoma). Expectant management for children with hemolytic anemia is associated with a significant increase in morbidity and postoperative hospital stay, so elective cholecystectomy is recommended (Curro et al, 2007). For patients with sickle cell disease and asymptomatic gallstones, elective cholecystectomy is advised, because expectant management yields more than a twofold increase in morbidity. Further, the diagnosis of acute cholecystitis can be difficult to differentiate from acute vasoocclusive sickle cell crisis (Curro et al, 2007). In contrast, children with asymptomatic gallstones caused by other etiologies can be safely managed expectantly. These gallstones even regress in 17% to 34% of cases.

Finally, gallstones have a proven association with gallbladder carcinoma (Tewari, 2006; see Chapter 49). In a review of 200 consecutive calculous cholecystitis specimens, Albores-Saavedra and colleagues (1980) reported that 83% exhibited epithelial hyperplasia, 13.5% atypical hyperplasia, and 3.5% carcinoma in situ. The risk of gallbladder carcinoma increases with larger gallstones: the relative risk rises from 2.4 for stones 2 to 2.9 cm in diameter to 10 for gallstones larger than 3 cm. Native Americans and patients with gallbladder calcification also have a higher incidence of gallbladder cancer. Elective cholecystectomy has been recommended in patients with gallstones greater than 3 cm in diameter, but no proof is available to support that such an approach is warranted from an oncologic standpoint.

Symptomatic Gallstones

Approximately 30% of patients with gallstones develop symptoms. Cholecystectomy is indicated to relieve suffering and to prevent complications of gallstones. The spectrum of severity characterizing symptomatic gallstones ranges from episodic pain to life-threatening infection and shock.

BILIARY COLIC. Biliary colic is the most typical clinical presentation of symptomatic gallstones. It usually occurs a few hours after a meal, especially one of high fat or spice content, as a slowly progressive and constant pain that occurs in the epigastrium and right upper quadrant (RUQ) of the abdomen and often radiates posteriorly to the scapula and right shoulder. This visceral pain likely reflects the gallbladder contracting against a cystic duct blocked by an impacted gallstone. If it persists and escalates, it heralds a worse complication of gallstones, such as cholecystitis, cholangitis, or pancreatitis. Typically, it remits after several hours, rendering a false sense of security in some patients that it can be overlooked. More than 60% of patients will suffer recurrent pain within 2 years after their initial attack. Several studies have indicated that gallstone-associated complications occur more frequently in patients suffering biliary colic. For these reasons, biliary colic is the most common indication for cholecystectomy.

CHOLECYSTITIS. Acute cholecystitis occurs in about 20% of patients with symptomatic gallstones (see Chapter 31). The pathogenesis is prolonged calculous obstruction of the cystic duct with resulting inflammation. The inflamed gallbladder becomes dilated and edematous, manifested by wall thickening, and an exudate of pericholecystic fluid can develop. If the gallstones are sterile, the inflammation is initially sterile, which can occur in patients with cholesterol gallstones. In other cases, however, gallstone formation occurs as a result of bacterial colonization of the biliary tree, rendering pigmented gallstones containing bacterial microcolonies (Stewart et al, 2002). In these cases, obstruction of the cystic duct results in a contained infection of the gallbladder. Research on the pathogenesis of gallstone-associated infections has shown that patients with bacteria-laden gallstones have more severe biliary infections. In addition, acute cholecystitis can coexist with choledocholithiasis, cholangitis, or gallstone pancreatitis. In the general population, 5% of patients presenting with cholecystitis have coexisting common bile duct stones. In the elderly, however, this figure rises to 10% to 20% (Siegel & Kasmin, 1997).

The initial treatment for patients with acute cholecystitis is intravenous hydration, antibiotics, and bowel rest. Many patients should be offered early cholecystectomy, but others will benefit from delayed intervention, either following conservative therapy or percutaneous gallbladder drainage. Several factors govern the approach to patients with acute cholecystitis. One consideration is patient comorbidity; emergency cholecystectomy in patients with significant comorbidities can be associated with high morbidity (20% to 30%) and mortality (6% to 30%) rates. Guidelines for the management of acute cholecystitis and acute cholangitis were described at an international consensus meeting held in Tokyo in 2006 (Takada et al, 2007). The Tokyo Guidelines define three levels of severity for acute cholecystitis and serve as a useful tool in the management of acute cholecystitis (Table 37.2).

Grade I Acute Cholecystitis. Patients presenting with mild grade I acute cholecystitis should be offered early cholecystectomy, performed laparoscopically if possible; numerous studies document a high success rate for laparoscopic cholecystectomy when the procedure is performed within 48 to 96 hours of onset

Table 37.2

Tokyo Guidelines for Acute Cholecystitis

Grade	Criteria
I Mild	Acute cholecystitis that does not meet the criteria for a more severe grade Mild gallbladder inflammation, no organ dysfunction
II Moderate	The presence of one or more of the following: 1. Elevated while blood cell count (>18,000/mm^3) 2. Palpable tender mass in the right upper abdominal quadrant 3. Duration of complaints >72 h 4. Marked local inflammation (biliary peritonitis, pericholecystic abscess, hepatic abscess, gangrenous cholecystitis, emphysematous cholecystitis)
III Severe	The presence of one or more of the following: 1. Cardiovascular system: hypotension requiring dopamine >5 μg/kg/min or any dose of dobutamine 2. Nervous system: decreased level of consciousness 3. Respiratory system: Pao_2/Fio_2 ratio <300 4. Renal system: serum creatinine >2.0 mg/dL 5. Liver: PT-INR >1.5 6. Hematologic system: platelet count <100,000/mm^3

PT-INR, prothrombin time/international normalized ratio

of acute cholecystitis (Hadad et al, 2007). Further, a Cochrane review of five randomized trials showed a shorter hospital stay for early cholecystectomy patients and no significant difference in complication rates or conversion rates between early laparoscopic cholecystectomy (within 7 days) versus delayed laparoscopic cholecystectomy (6 to 12 weeks; Gurusamy & Samraj, 2006). Conversion rates, however, were 45% among patients randomized to the delayed group, those who required a cholecystectomy between 1 and 6 weeks. For patients with significant medical problems, cholecystectomy may need to be delayed to maximize medical therapy. Most patients with acute cholecystitis can be safely managed with antibiotics and bowel rest with resolution of their acute illness; they can then undergo an elective cholecystectomy once their medical problems have been addressed.

Grade II Acute Cholecystitis. Patients presenting with grade II acute cholecystitis are a more diverse group. Many will be well managed with early cholecystectomy; this is particularly true for cases with delayed presentation as their only grade II finding. In these cases, laparoscopic cholecystectomy should be performed if possible within 7 days of the acute illness. In cases with severe local inflammation, early gallbladder drainage (percutaneous or surgical) is recommended as the initial treatment of choice, followed by elective cholecystectomy once the acute inflammation resolves. The key is to identify which patients have such an inflammatory process. Several studies have correlated such findings as age older than 50 years, male sex, presence of diabetes, elevated bilirubin level (>1.5 mg/dL), and leukocytosis (while blood cell count >15,000 mm^3) in the setting of gangrenous cholecystitis (Nguyen et al, 2004). These findings are also frequently associated with a severe inflammatory process. Other factors suggestive of an inflammatory process include symptoms of gastric outlet obstruction. Patients with such symptoms should have cross-sectional imaging, with either computed tomography (CT) or magnetic resonance imaging (MRI), to determine whether a severe inflammatory process is present (Fig. 37.1), followed by percutaneous cholecystostomy if such is found (Takada et al, 2007).

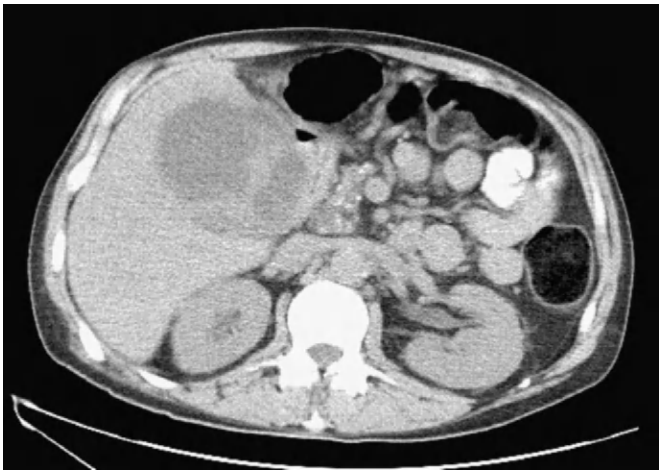

FIGURE 37.1. Computed tomographic scan demonstrating a severe inflammatory process in the setting of acute cholecystitis. This patient was treated with percutaneous cholecystostomy followed by elective laparoscopic cholecystectomy once the inflammatory process had resolved.

Grade III Acute Cholecystitis. Patients presenting with grade III acute cholecystitis have associated organ dysfunction, and they require intensive organ support and medical treatment. Because the source of their inflammatory (septic) response and organ dysfunction is the severe cholecystitis, percutaneous cholecystostomy is necessary to treat the severe infection as well as the associated organ dysfunction. Numerous studies have documented the success of percutaneous cholecystostomy in achieving control of the underlying infection within 24 to 48 hours (Howard et al, 2009). In rare cases, urgent cholecystectomy may be required, such as cases with biliary peritonitis as a result of perforation of the gallbladder; but in general, cholecystectomy in the acute phase of grade III acute cholecystitis should be avoided (Takada et al, 2007).

Cholecystectomy Technique

Choosing Laparoscopic Versus Open Techniques

For typical uncomplicated gallstone disease, laparoscopic cholecystectomy is the preferred method of removing the gallbladder (Keus et al, 2006). Since its debut, cholecystectomy rates have increased worldwide, reflecting patient acceptance of the laparoscopic technique. Because the technical aspects of this operation are covered in other chapters (see Chapters 33 and 34), this section will focus on concepts of feasibility and safety that relate to disease severity and the choice between laparoscopic and open cholecystectomy (Callery, 2006).

Laparoscopic cholecystectomy should be performed only by surgeons properly trained and proctored, and experience should be correlated to how difficult the operation may be based on disease severity. Laparoscopic cholecystectomy for severe acute and chronic inflammation is considerably more difficult and is an advanced operation. Less experienced surgeons must recognize this and seek the help they need during the operation, and conversion to open cholecystectomy may be necessary in some patients (Ishizaki et al, 2006). Biliary injuries are more likely to occur during difficult laparoscopic operations, no different than

with open operations, but at a higher incidence (see Chapter 42). When laparoscopic cholecystectomy is performed for acute cholecystitis, biliary injuries occur three times more often than during elective laparoscopic cases and twice as often compared with open cholecystectomy for acute cholecystitis.

Today, the selection of open cholecystectomy may be difficult for some. Over the past 20 years, open cholecystectomy has been far less frequently performed. Trainees during this period presumably have received valid instruction and proctoring for laparoscopic cholecystectomy but have less experience with difficult open cases (Schulman et al, 2007). The experience needed to command the laparoscopic operation potentially reduces the level of comfort with the open technique. Finally, there is the pressure related to patient expectation for rapid recovery.

Behind these two very different techniques are scenarios that might subtly account in part for static biliary injury rates (Khan et al, 2007). Because of inexperience, the surgeon ignores or resists the sensible default option to convert to the open technique, does not, and causes injury. In other instances, the surgeon overextends laparoscopic experience when disease severity warrants conversion. What can help prevent this? First, during informed consent, patients need to be made fully aware that open cholecystectomy is always a possibility. If faced with acute or chronic cholecystitis at operation, the surgeon should seek help rather than persist on marginal laparoscopic or open cholecystectomy experience. Conversion from laparoscopic to open cholecystectomy is not a defeat but rather is reflective of caution and good judgment (Jenkins et al, 2007; Wolf, 2009).

Ideally, a surgeon would suspect the likelihood of conversion on clinical grounds. The anesthesia and operative teams should be so notified and prepared. Open-case instruments need to be readily available, and trocar stab incisions should be placed along a predrawn right subcostal incision line. Unless there is need to control bleeding, the surgeon enters the RUQ deliberately and is not stressed by the decision to convert. Everyone should be ready for what lies ahead, and it should be clear to all that it will be a difficult operation.

The difficult open cholecystectomy demands adequate exposure, retraction, and identification of anatomy by dissection in the anterior and posterior aspects of the triangle of Calot, followed by dissection of the gallbladder off the liver bed. The surgeon achieves conclusive identification of the cystic structures as the only two structures entering the gallbladder, eliminating the possibility of misidentification (Callery, 2006). As with the laparoscopic technique, once the critical view is attained, the cystic structures can be occluded with ligatures and divided. Failure to achieve this critical view should prompt cholangiography to define ductal anatomy. Avoidance of ductal injury in the liver bed depends upon a combination of patience and staying in the correct plane of dissection, with meticulous technique and experience. In some cases of acute cholecystitis, the gallbladder "shells out" relatively easily from its edematous hepatic bed. In other cases, and especially in chronic cholecystitis, the dissection of the gallbladder out of the liver bed can be tedious, frustrating, and bloody. Hemostasis can take time but must be achieved, with argon beam, cautery, packing, and topical hemostatics if necessary. Subtotal cholecystectomy is always a valid option, especially in patients with cirrhosis or in those with severe inflammation that obscures the anatomy within the porta hepatis. Surgeons should indicate in operative notes for open and laparoscopic cholecystectomy precisely how they identified the cystic structures for division. For conversions, they should specify the circumstances, stressing safety and surgical judgment.

Percutaneous Cholecystostomy (See Chapter 32)

The indications for percutaneous cholecystostomy include grade II acute cholecystitis with a severe inflammatory process, grade III acute cholecystitis with associated organ dysfunction, or acute cholecystitis in patients with severe medical morbidity that limits the surgical options (Takada et al, 2007; Hirota et al, 2007; Yamashita et al, 2007; Howard et al, 2009). The technical success rate of percutaneous radiologically guided cholecystostomy is 98% to 100% with few procedure-related complications (mortality and major complications, 0% to 6.5%; minor complications, 0% to 20%) (Howard et al, 2009; Sugiyama et al, 1998).

Timing of Subsequent Operation for Cholecystitis

Once the inflammatory process has resolved, elective cholecystectomy can be performed early (within 1 to 7 days) or delayed (6 to 8 weeks) with excellent success and conversion rates as low as 3% (Akyurek, 2005). Some have reported using percutaneous cholecystostomy as definitive treatment for acute cholecystitis in high-risk, elderly, and debilitated patients. In patients who do not have subsequent cholecystectomy, recurrent biliary symptoms occur in 9% to 33% (Griniatsos et al, 2008; Sugiyama et al, 1998).

CHOLEDOCHOLITHIASIS (SEE CHAPTER 35)

The clinical clues of common bile duct (CBD) stones were recognized during the Roman Empire by Soranus of Ephesus, who described jaundice, itching, dark urine, and acholic stools. Not all common bile duct stones render such a classic clinical scenario, but they still carry risk if left unidentified and untreated. More than 85% of CBD stones originate in the gallbladder and secondarily migrate into the CBD. For patients undergoing cholecystectomy for symptomatic gallstones, the prevalence of choledocholithiasis ranges from 10% to 15%. Primary CBD stones are far less common and are typically associated with conditions of biliary infection and stasis: benign biliary strictures, sclerosing cholangitis, and choledochal cysts. Primary CBD stones are more prevalent in Asians and can relate to parasitic infections (Kaufman et al, 1989).

Silent Common Bile Duct Stones

Published reports using routine intraoperative cholangiography have found that at least 12% of CBD stones are clinically silent (Murison et al, 1993), and approximately 6% do not exhibit abnormalities in liver function tests (LFTs) or in the diameter of the CBD (Majeed et al, 1999). When prospectively followed, data suggest that more than one third of asymptomatic stones will pass spontaneously after the first 6 weeks after cholecystectomy (Collins et al, 2004).

Diagnostic Considerations

More often than not, the presence of CBD stones is uncertain. Clinicians use predictive models based on risk factors that include clinical features, abnormal LFTs, jaundice, and CBD dilation. These are very sensitive (96% to 98%) but not very

specific (0% to 70%) (Koo & Traverso, 1996). The American Society of Gastrointestinal Endoscopy (ASGE) provides a practical strategy that assigns low (<10%), intermediate (10% to 50%), or high (>50%) risk of CBD stones using relevant risk factors (ASGE Standards of Practice Committee et al, 2010).

Imaging Modalities: Why and When

Transabdominal Ultrasound

Transabdominal ultrasound (US) is an appropriate initial modality in the evaluation of CBD stones (Williams et al, 2008). US can identify bile duct dilation owing to stone obstruction, and it can visualize the actual stone (sensitivity 0.3, specificity 1.0; see Chapter 13). If the extrahepatic bile duct diameter is less than 5 mm, CBD stones are exceedingly rare, whereas a diameter greater than 10 mm with jaundice predicts CBD stones in more than 90% of cases (Abboud et al, 1996). Axial CT scans have better sensitivity (84%) for choledocholithiasis than US (see Chapter 16). Helical CT scans outperform conventional nonhelical CT, with 88% sensitivity and 73% to 97% specificity (Tseng et al, 2008). In terms of availability, cost, and radiation exposure, US prevails as the first-line diagnostic.

Magnetic resonance cholangiopancreatography (MRCP) is the most accurate noninvasive modality available (see Chapter 17). Regardless, its sensitivity decreases for small CBD stones (29% if <5 mm) (Sugiyama et al, 1998). MRCP is the standard investigation for CBD stones for patients with intermediate probability or for those who need to be investigated to exclude other differential diagnoses. MRCP is especially helpful when anatomical considerations preclude endoscopic retrograde cholangiopancreatography (ERCP; status post–Billroth II gastrectomy, Roux-en-Y biliary bypass, duodenal stenoses).

Endoscopic Retrograde Cholangiopancreatography

ERCP is still considered the gold standard diagnostic modality (see Chapter 18), although it is invasive, requires radiation, and has significant complications (Andriulli et al, 2007). Routine ERCP prior to all laparoscopic cholecystectomies is impractical and unnecessary. When overused, most cholangiograms are normal, and costs and complication rates are prohibitive. Even in patients at high risk—those with jaundice, cholestatic LFTs, CBD dilation, and a history of pancreatitis—half will not have CBD stones at the time of ERCP (Daradkeh et al, 2000), therefore ERCP is now reserved more for its therapeutic than diagnostic strength.

Endoscopic Ultrasound

Endoscopic US (EUS) is very sensitive for choledocholithiasis (see Chapter 14; Garrow et al, 2007), and a meta-analysis reveals that EUS can reduce unnecessary diagnostic ERCP (Tse et al, 2008). A systematic review reveals that patients who undergo EUS can avoid ERCP in 67% of cases, with fewer complications and less pancreatitis compared with those undergoing ERCP initially (Petrov & Savides, 2009). The diagnostic efficacy of EUS and MRCP compared with ERCP have revealed the tests to be quite comparable (Verma et al, 2006).

Real-Time Fluoroscopic Intraoperative Cholangiography

Real-time fluoroscopic intraoperative cholangiography (IOC) during cholecystectomy can accurately diagnose CBD stones and both minimize and maximize the need for ERCP (see Chapter 21). The technique can be performed safely in both open and laparoscopic approaches. Surgeons can interact with the findings, flushing the duct to clear stones or debris. Open and laparoscopic IOC can successfully be completed in about 95% of patients (see Chapter 34), with sensitivity for detecting CBD stones between 80% and 92% and specificity of 93% to 97% (Machi et al, 1999). Regardless, an ongoing debate remains whether IOC should be performed routinely or selectively during cholecystectomy. When used routinely, it has high sensitivity and specificity both for suspected CBD stones and for the 3% to 4% of stones that are not clinically suspected but may become symptomatic postoperatively. Other suggested benefits specifically relate to the prevention of bile duct injuries (Fletcher et al, 1999). No large prospective randomized trials that answer the question definitively, so most practicing surgeons perform IOC selectively.

Symptomatic Common Bile Duct Stones

The symptoms of CBD stones relate to partial or complete biliary obstruction with and without inflammatory complications such as cholangitis, hepatic abscesses, or pancreatitis. In chronic scenarios, and depending on the extent and duration of biliary obstruction (>5 years), choledocholithiasis may also lead to secondary biliary cirrhosis and portal hypertension (see Chapter 35). Because of the uncertain clinical behavior and potential harmful complications, it is currently accepted that in the great majority of situations, CBD stones should be removed, even if they are asymptomatic (Williams et al, 2008).

Definitive Treatment Approaches: Biliary Obstruction

Catheter-Based Approaches (See Chapters 27, 28, and 36)

ERCP. Before the laparoscopic era, ERCP was not commonly used, because open surgical bile duct clearance was superior to ERCP in terms of success and morbidity (see Chapters 29 and 35; Martin et al, 2006). This changed as laparoscopic cholecystectomy emerged and outpaced the abilities of most surgeons to perform laparoscopic CBD stone removal. Indeed, ERCP captured and has held its role as the first-line approach to CBD stones, being successful in more than 90% of patients (Rieger & Wayand, 1995). Although well tolerated in most, a 10% rate of complications remains constant for ERCP (Andriulli et al, 2007), with a serious morbidity rate of 1.5% and an overall mortality rate of 0.2% to 0.5% (Freeman et al, 1996). When surgical and endoscopic teams are inexperienced with CBD stones, the perceived need for preoperative ERCP increases. In this setting, ERCP allows laparoscopic cholecystectomy to be performed quickly and with confidence that CBD stones are already managed. If ERCP fails, the surgical plan will need to consider intraoperative management of choledocholithiasis. Conversely, in centers where successful sphincterotomy and stone extraction is almost assured, the rate of preoperative ERCP will be lower. If the surgeon finds a stone at operation, ERCP becomes a reliable postoperative option. Current consensus accepts the use of ERCP prior to laparoscopic cholecystectomy for patients with a high probability of choledocholithiasis. It is recommended that patients with a low or intermediate index of suspicion for choledocholithiasis undergo additional imaging techniques (MRCP, EUS, IOC) to avoid unnecessary biliary instrumentations (Tse et al, 2004; Williams et al, 2008; ASGE Standards of Practice Committee, 2010).

PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY (SEE CHAPTER 28). Compared with ERCP, percutaneous transhepatic cholangiography (PTC) is time consuming, more involved, and likely more stressful for a patient. It is usually reserved for patients in whom anatomical considerations preclude safe ERCP, such as in the case of an impossible ampullary cannulation. Experienced PTC groups have reported successful stone removal rates in more than 90% of cases, with complication rates around 5% (Garcia-Vila et al, 2004), although these are hardly the norms. PTC stone removal takes time, involving insertions of catheters that are upsized over time, before stones are actually retrieved with stone baskets. Consequently, there are many reports of attempts to make it easier. Gil and colleagues (2000) have reported the safety and utility of balloon dilation of the papilla in the clearing of CBD stones using occlusion balloon pushing. This is also gaining popularity for the laparoscopic surgeon during IOC.

Surgical Approaches: Open and Laparoscopic Techniques (See Chapters 29 and 35)

The same issues discussed in choosing open versus laparoscopic cholecystectomy are accentuated when common bile duct exploration (CBDE) is considered. Today, many trainees will graduate residency having never performed an open CBDE. Their ability to succeed with laparoscopic CBDE is quite variable, as many train with a default dependence on ERCP.

CHOLECYSTECTOMY WITH INTRAOPERATIVE CHOLANGIOGRAPHY (SEE CHAPTERS 21 AND 34). Open and laparoscopic IOC can successfully be completed in the majority of patients by the majority of surgeons (Machi et al, 1999). IOC can be performed through the direct insertion of contrast medium into the gallbladder or more often by intubating the cystic duct. Plain radiographs have largely been replaced by digital fluoroscopic imaging. IOC is common, and most surgeons receive sufficient training. Laparoscopic ultrasound cholangiography is also efficacious (Stiegmann et al, 1995) but not broadly used.

Since the introduction of laparoscopic cholecystectomy, the debate over routine versus selective IOC has been rekindled because of the increased incidence of CBD injuries and the inability to palpate the CBD during laparoscopy. IOC accurately defines the biliary anatomy and may protect against intraoperative bile duct injuries (Fletcher et al, 1999), or at least it reduces their severity (Woods et al, 1995). Opponents claim that routine IOC may lead to bile duct injury and unnecessary CBD explorations because of false positives and that it may add time and costs unnecessarily.

Selective IOC pivots upon predicting the probability of choledocholithiasis. In general, patients with a low probability (normal LFTs, normal CBD diameter) may undergo cholecystectomy with no further preoperative investigation and selective IOC. Patients with intermediate risk (isolated abnormal LFTs or CBD dilatation) may undergo further preoperative imaging (MRCP) and routine IOC at an absolute minimum. Patients with high risk (jaundice, cholangitis) warrant confirmatory/therapeutic ERCP (ASGE Standards of Practice Committee, 2010) at most centers. In fact, today many patients are triaged for this purpose, but in years past, many would undergo open CBDE. Ultimately, the choice of modality depends on local availability and expertise in minimally invasive treatments coupled with considerations of cost and convenience.

CBDE: TRANSCYSTIC VERSUS CHOLEDOCHOTOMY ACCESS (SEE CHAPTERS 29, 34, AND 35). When IOC reveals CBD stones, they can readily be removed during cholecystectomy. The open choledochotomy to allow cholangioscopy, flushing, forceps and balloon clearance, and T-tube placement is rarely performed or taught today. Instead, laparoscopic common bile duct exploration (LCBDE) has evolved as an efficient, well-accepted, and broadly utilized technique as described in other chapters. Several studies have shown LCBDE to be as efficient as preoperative or postoperative ERCP in terms of stone clearance, morbidity, mortality, and short hospital stay (Martin et al, 2006; Clayton et al, 2006) and is thus recommended for surgeons with appropiate skills and facilities. Further, for capable surgeons, LCBDE is as safe and efficient as ERCP, thus avoiding the discomfort, costs, and potential complications of an extra procedure (Martin et al, 2006).

LCBDE can be safely performed through either transcystic or choledochotomy approaches. Many prefer the transcystic approach. It is feasible in most cases, saves time, does not violate the CBD, and shows no higher morbidity than standard laparoscopic cholecystectomy alone (Hanif et al, 2010; Tinoco et al, 2008). The most consistent risk factor for failing transcystic stone clearance is the size of the stone. Once stones exceed 5 mm, the likelihood of transcystic extraction falls considerably (Stromberg et al, 2008), and laparoscopic choledochotomy becomes necessary. However, many surgeons do not have the laparoscopic dissection and suturing expertise to perform this procedure; they rely instead on ERCP, or they convert to an open operation. Experienced surgeons can remove larger or multiple CBD stones with reported success rates of up to 90% (Lien et al, 2005). A 2007 Cochrane review was not able to conclude significant differences in outcomes for primary closure of the CBD versus the routine use of T-tube drainage after open CBD exploration (Gurusamy, 2009). Similar outcomes have been reported from a recent randomized clinical trial for LCBDE through choledochotomy (Zhang et al, 2009).

Gallstone Pancreatitis

Acute gallstone pancreatitis is the most frequent form of acute pancreatitis in Western countries (see Chapter 53). The two most commonly accepted mechanisms for the pathogenesis of gallstone pancreatitis are reflux of bile into the pancreatic duct and transient ampullary obstruction caused by temporary impaction of a stone in the ampulla. The disease is mild in approximately 80% of patients, but 20% experience a more severe clinical course that includes complications such as pancreatic necrosis, multisystem organ failure, and even death (see Chapter 54; Acosta et al, 1997; Alexakis et al, 2007; NIH, 2002).

In many patients, the biliary obstruction has spontaneously resolved at the time of presentation, so biliary decompression is not needed. These patients should undergo elective cholecystectomy once the pancreatitis has resolved. At the other end of the spectrum are patients with gallstone pancreatitis and associated acute cholangitis (see Chapter 43). Clear evidence shows that endoscopic biliary drainage is beneficial in patients with acute cholangitis, thus these patients should have early biliary decompression.

A secondary question is whether patients with gallstone pancreatitis, without cholangitis, benefit from biliary decompression. Clinical and experimental studies suggest that impacted ampullary stones and persistent biliopancreatic

obstruction are associated with a more severe clinical course. In theory, early endoscopic removal of obstructing ampullary gallstones should improve outcomes (Acosta et al, 1997; Alexakis et al, 2007). Between the late 1970s and mid-1980s, urgent surgery with biliary decompression was studied as a treatment of choice for patients with acute gallstone pancreatitis, but this approach was associated with an increased mortality rate among patients with severe pancreatitis. As such, surgical treatment during the acute phase of the gallstone pancreatitis is not recommended.

The role of nonsurgical intervention, prior to definitive surgical therapy, has been examined in several prospective randomized studies in which patients with cholangitis were excluded. Integral to any interpretation of treatment approach is the severity of the gallstone pancreatitis. These studies defined *severe pancreatitis* utilizing a number of systems that included the Ranson criteria (>3), Glasgow criteria (>3), or the Acute Physiology and Chronic Health Evaluation (APACHE) II score (>8). The Ranson and Glasgow criteria have the advantage of ease of use and considerable areas of overlap (Table 37.3). A recent meta-analysis analyzed five prospective randomized studies that examined the use of early biliary decompression in cases of gallstone pancreatitis without cholangitis (Moretti et al, 2008). This study reported a significant reduction in pancreatitis-related complications in patients with predicted severe pancreatitis (rate difference of 38.5%; 95% confidence interval, –53% to –23.9%); $P < .0001$); but no advantage was seen in cases with mild pancreatitis, and no difference in mortality rate was noted.

Table 37.3

Ranson and Glasgow Criteria for Severity of Acute Pancreatitis

Criterion*	Action
Ranson	
Age >55 years	Admission
WBC count >16,000/mm^3	Admission
Glucose >200 mg/dL	Admission
AST >250 IU/L	Admission
LDH >350 IU/L	Admission
Increased BUN >8 mg/dL	48 hr
Pa_{O_2} <60 mm Hg	48 hr
Calcium <8.0 mg/dL	48 hr
Base deficit <4 mEq/L	48 hr
Fluid sequestration ≥6 L	48 hr
Glasgow	
Age >55 years	Admission
WBC count >15,000/mm^3	Admission
Glucose >200 mg/dL	Admission
AST/ALT >96 IU/L	48 hr
LDH >219 IU/L	48 hr
BUN >45 mg/dL	Admission
PaO_2 <76 mm Hg	Admission
Calcium <8.0 mg/dL	48 hr
Albumin <3.4 g/dL	48 hr

*Mortality rates: 0 to 2 = 2%, 3 to 4 = 15%, 5 to 6 = 40%, >7 = 100%
WBC, white blood cell count; AST, aspartate aminotransferase; ALT, alanine aminotransferase; LDH, lactate dehydrogenase; BUN, blood urea nitrogen

The severity of the patient's illness guides the timing of intervention. Patients whose biliary obstruction has spontaneously resolved at the time of presentation and those who have mild predicted pancreatitis should have early elective cholecystectomy once their pancreatitis has resolved. Patients with severe predicted pancreatitis and those with associated cholangitis should undergo early biliary decompression (ERCP or PTC). Among cases of escalating pancreatitis, biliary decompression should be performed within 24 to 72 hours of admission (Moretti et al, 2008). For cases with associated cholangitis, biliary decompression should occur within 24 hours of presentation. Elective cholecystectomy can then be performed once the severe illness has resolved.

Cholangitis (See Chapter 43)

Clinical findings associated with acute cholangitis include RUQ abdominal pain, jaundice, fever, and chills—also known as *Charcot's triad* (1877). Not all patients with cholangitis manifest all findings: 90% develop fever, but only about 50% to 70% of patients develop all three symptoms. *Reynolds' pentad* (1959)—Charcot's triad plus shock and altered mental status—represents a form of severe (grade III) cholangitis, which can also manifest with multiorgan dysfunction. Severe cholangitis is present in about 30% of patients with acute cholangitis (Gouma, 2003).

Cholangitis is a localized infection of the biliary tree, and an understanding of the pathophysiology of cholangitis guides treatment decisions. Research in this disease has shown that bacteria-laden gallstones are the source of infection. These bacteria exist in a bacterial microcolony (biofilm) within the pigmented matrix of gallstones (Fig. 37.2; Stewart et al, 2002). The bacteria must detach from the biofilm to cause a localized infection, and it must reflux into the cholangiovenous circulation to cause a more severe illness, including bacteremia and organ dysfunction (Raper et al, 1989; Stewart et al, 2003). Cholangiovenous reflux occurs with biliary pressures greater than 20 cm H_2O, and even at this pressure, bacterial characteristics (slime production) influence cholangiovenous reflux (see Chapter 7). In addition, bacterial breakdown by complement releases endotoxin, and this influences the induction of inflammatory cytokines that drive the septic manifestations.

The 2006 Tokyo International Consensus Meeting described three grades of acute cholangitis (Table 37.4): *grade I* is mild and responds to initial medical treatment; grade II is moderate and does not respond to initial medical treatment, but it is not associated with organ dysfunction; and grade III is severe and is associated with organ dysfunction (Miura et al, 2007). All patients with suspected cholangitis should be treated with intravenous hydration and antibiotics that cover the most common biliary organisms: *Escherichia coli*, *Klebsiella* spp., *Enterococcus*, *Enterobacter cloacae*, *Pseudomonas* spp., and anaerobic pathogens. Patients with severe grade III cholangitis also require organ support and stabilization of organ dysfunction.

The critical component of the treatment of cholangitis is biliary decompression. Because elevated biliary pressure drives cholangiovenous reflux, decompression of the biliary tree with ERCP is crucial; PTC may be used if ERCP is not available. Not only does biliary drainage prevent bacterial cholangiovenous reflux, it has also been shown to be associated with a marked decreased in bile and serum endotoxin levels. In a prospective randomized trial, Lai and colleagues (1992)

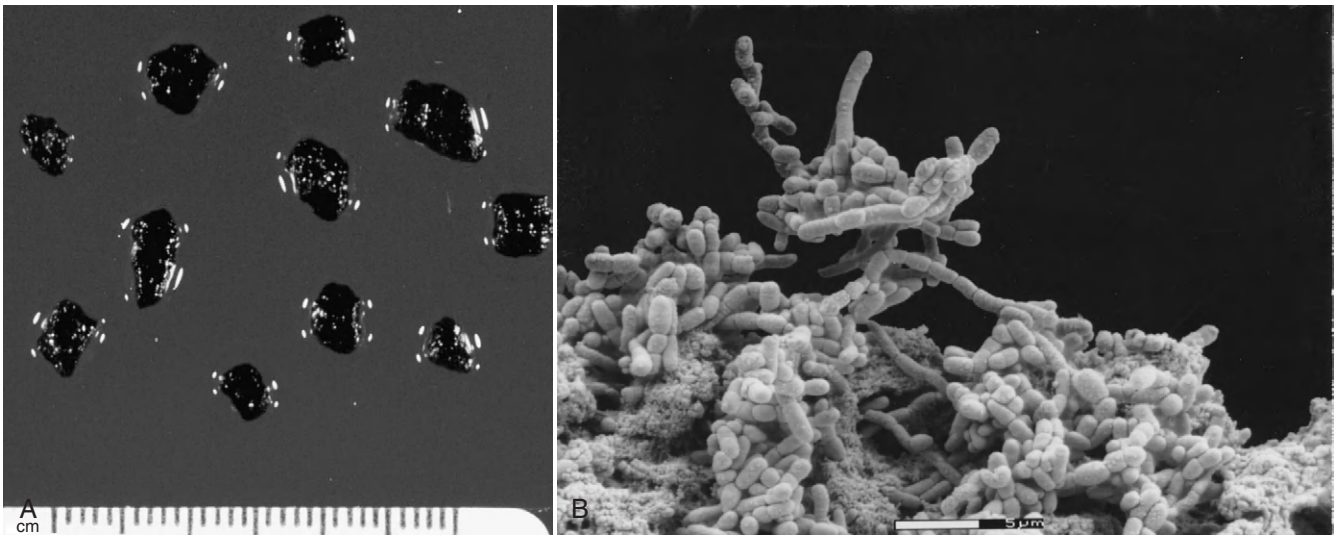

FIGURE 37.2. A, Black pigment gallstones. **B,** Scanning electron micrograph of the black pigment stones demonstrating bacterial microcolonies. Note the bacterial bridges and three-dimensional nature of the biofilm. *(From Stewart L, et al, 2002: The pathogenesis of pigment gallstones in Western societies: the central role of bacteria. J Gastrointest Surg 6:891-904.)*

demonstrated decreased mortality associated with endoscopic drainage compared with urgent surgical intervention, 10% versus 32%, respectively. A nonrandomized study by Leese and others (1986) showed similar findings. These and other studies emphasize the need for nonsurgical decompression in the setting of severe acute cholangitis.

The Tokyo Guidelines provide a useful tool for the management of acute cholangitis (see Table 37.4). Patients with grade I cholangitis who respond to medical therapy can be treated with ERCP (within 24 hours) followed by definitive surgical treatment (laparoscopic cholecystectomy), or the surgeon can proceed to laparoscopic cholecystectomy with intraoperative LCBDE after medical stabilization (Takada et al, 2007; Miura et al, 2007). Factors guiding these choices include the patient's clinical findings and the surgeon's experience with LCBDE.

By definition, patients with grade II cholangitis do not respond to medical therapy, so they require urgent biliary decompression. Patients with severe (grade III) cholangitis require urgent endoscopic or percutaneous transhepatic biliary drainage following stabilization of organ dysfunction. For patients with grade II or III cholangitis, the initial therapy should emphasize biliary decompression rather than definitive removal of all common duct stones. Prolonged procedures with excessive manipulation in an attempt to remove large stones should be avoided in patients with active infectious manifestations. Once the acute illness has resolved, early cholecystectomy can be performed within 6 weeks of biliarydecompression with no increase in postoperative complications (Li et al, 2010).

Table 37.4

Tokyo Guidelines for Acute Cholangitis

Grade	Criteria
I Mild	Responds to initial medical treatment
II Moderate	Does not respond to the initial medical treatment but is not associated with organ dysfunction
III Severe	Associated dysfunction at least in one of the following organ systems: 1. Cardiovascular system: hypotension requiring dopamine >5 μg/kg/min or any dose of dobutamine 2. Nervous system: decreased level of consciousness 3. Respiratory system: Pao_2/Fio_2 ratio <300 4. Renal system: serum creatinine >2.0 mg/dL 5. Liver: PT-INR >1.5 6. Hematologic system: platelet count <100,000/mm^3

PT-INR, prothrombin time/international normalized ratio

Need for Cholecystectomy After ERCP/Sphincterotomy

There has been considerable debate over whether cholecystectomy is required after ERCP/sphincterotomy for patients who initially present with choledocholithiasis. Retrospective studies have reported a low incidence of cholecystectomy among patients with a gallbladder in situ following ERCP/sphincterotomy managed by watchful waiting (10% to 15% over 5 to 14 years) (Schreurs et al, 2004; Sugiyama et al, 1998). Many of these studies involved older patient populations and patients with multiple medical illnesses. More recently, however, a Cochrane review of prospective randomized studies reported that elective cholecystectomy is recommended (McAlister et al, 2007). For five randomized trials with 662 participants, an increased mortality in the expectant group compared with the cholecystectomy group was noted, and patients in the observation group had higher rates of recurrent biliary pain, jaundice, or cholangitis and more need for repeat ERCP or cholangiography (McAlister et al, 2007).

CONCLUSION

In 1970, who could have predicted that the common ailments of cholecystolithiasis and choledocholithiasis would soon face historical advances in technology? Patients now benefit from improved imaging and minimally invasive endoscopic and laparoscopic techniques, especially when combined. Indeed, our treatment approaches today only occasionally resemble those of a recent but bygone era in biliary surgery.

CHAPTER 38

Postcholecystectomy problems

Satish N. Nadig and Charles M. Vollmer Jr.

OVERVIEW

Cholecystectomy for gallbladder diseases has become the most common abdominal operation in Westernized countries. Since it was first performed in 1987, laparoscopic cholecystectomy (LC) has surpassed the open approach as the gold standard operation, largely because of significant decreases in operative time, patient pain, hospital stay, and costs (Begos & Modlin, 1994; see Chapter 34). At present, approximately 750,000 LCs are performed annually in the United States, accounting for roughly 90% of all cholecystectomies (Khan et al, 2007). This minimally invasive approach has revolutionized the treatment of patients with gallbladder disease and improved outcome, and it has permitted a liberalization of indications. Patients who would have otherwise been turned away from open cholecystectomy (OC) are now undergoing LC, and the open operation is now reserved for the most complicated scenarios (Khan et al, 2007).

Although LC has some advantages for both patients and surgeons, a new set of complications has arisen. The popularity of LC, combined with its innovative technology and the decreased threshold to whom it is offered, has resulted in novel postoperative problems, such as dropped stones, port-site hernias, and unique forms of common bile duct (CBD) injuries (see Chapter 42). More disturbing is that despite the widespread acceptance of LC and increasing experience with the procedure, it has a higher *serious* complication rate than that of the open approach. Furthermore, just as with open cholecystectomy, patients with abdominal pain that masquerades as gallbladder disease may undergo LC yet continue to be persistently symptomatic after the operation. This chapter addresses the causes of postcholecystectomy problems, both biliary and nonbiliary, along with optimal diagnostic and treatment strategies. Henceforth, we will refer to *postcholecystectomy problems* (PCPs) as persistent symptoms after surgical removal of the gallbladder regardless of etiology.

INDICATIONS FOR CHOLECYSTECTOMY (SEE CHAPTERS 30 AND 31)

Gallstones that cause symptoms of epigastric and/or right upper quadrant (RUQ) pain, usually occurring after fatty meals and associated with dyspepsia and sometimes excessive flatulence, are most commonly treated with cholecystectomy. LC is successful in eliminating pain in 85% of patients with this constellation of presurgical symptoms (Tantia et al, 2008). Furthermore, patients with acute cholecystitis manifested by fevers, RUQ pain, elevated white blood count (WBC), and nausea and vomiting are also treated with LC.

A more contentious indication for cholecystectomy falls into the category of functional biliary disorders. Patients with persistent episodes of prolonged RUQ pain who lack a defined organic etiology should be evaluated for a functional biliary disorder. This condition, commonly referred to as *biliary dyskinesia*, affects approximately 2.4% of patients with biliary pain in the absence of cholelithiasis and results from the impaired physiologic contraction of the gallbladder, leading to insufficient emptying and pain (Barbara et al, 1987). Various studies suggest that patients with motility disorders of the gallbladder may benefit from LC (Westlake et al, 1990; Chen et al, 2001). However, if the physiologic derangement is downstream of the cystic duct, pain may persist even after removal of the gallbladder. This nebulous condition is termed *sphincter of Oddi dysfunction,* and it will be discussed in more detail later in this chapter. Finally, carcinoma of the gallbladder is an uncommon problem—only 9250 new cases of gallbladder cancer occurred in the United States in 2008—that is optimally treated with cholecystectomy and en bloc partial hepatectomy; but it is associated with a poor prognosis, with 5-year survival rates between 5% and 10% and an overall median survival of 3 to 6 months from diagnosis (Hueman et al, 2009). An in-depth discussion of these indications for cholecystectomy is found in Chapters 30, 31, and 49.

COMPLICATIONS OF CHOLECYSTECTOMY

Postsurgical complications may be classified by biliary and nonbiliary causes. Furthermore, biliary complications may be subdivided into *early*, *late*, and *mechanical* (Table 38.1). Despite the advantages in care offered by the laparoscopic approach, cholecystectomy should still be recognized and referred to as a *major* operation. This is emphasized by the fact that mortality rates after cholecystectomy exceed many elective operations felt to be far more significant in scope, such as cardiac bypass, colonic resection, and even pancreatectomy. In a multivariate comparison of postcholecystectomy complications studied by Jatzko and colleagues (1995), open cholecystectomy was associated with higher morbidity (7.7% vs. 1.9%) and mortality rates (5% vs. 1%) than those of LC. The incidence of pathology seen in patients who are symptomatic after having a cholecystectomy is summarized in Table 38.2.

Early Complications

The most common early biliary complications are related to intraoperative difficulties or technical considerations. By far, the most relevant of these are bile duct injuries, hemorrhage, and abscess formation.

Table 38.1

Classification of Causes of Postcholecystectomy Symptoms

Biliary	Nonbiliary
Early	Pancreatic disease
Biliary leak: minor and major	Pneumonia
Hematoma	Liver disease
Abscess	Flatulent dyspepsia syndrome
Dropped stones	Peptic ulcer
Insufficient cholecystectomy	Gastroesophageal reflux
Late	Irritable bowel syndrome
Persistent postoperative pain/ neuroma	Diverticular disease
Hernia: port site/incisional	Renal disease
Chronic inflammation	Postsurgical adhesions
Mechanical	Psychosomatic disorders
Stricture: malignant or benign	Others
Fistula	
Retained stones	
Papillary disorders	

FIGURE 38.1. Depiction of a common bile duct "tent" injury.

Biliary Injury

Despite the advantages of LC over OC, common bile duct injuries are seen more frequently in the laparoscopic approach (0.2% to 0.7%) than in OC (0.1% to 0.04%) (Konsten et al, 1993; Nuzzo et al, 2005; Soderlund et al, 2005; Ali et al, 2007; Karvonen et al, 2007). Retrospective analyses of CBD injuries reveal that the two most common factors associated with injury are acute cholecystitis, wherein the normal gallbladder and biliary anatomy is obscured or distorted because of indurated and/or edematous tissues, and misperceptions or inexperience on the part of the surgeon. A learning curve is also implicated. In a series of 350 LCs reviewed by Huang and colleagues, CBD injuries occurred more often in the first 10 to 15 operations performed by a surgeon (Huang et al, 1993). In addition to the classic direct CBD injuries caused by misidentification of the cystic and common bile ducts, clipping of the "tented" CBD may occur in cases specific to LC when applying the first clip on the cystic duct by excessive traction of the CBD into the clip itself (Fig. 38.1). These injuries can lead to stricture and obstruction of the CBD and may be avoided by placing the first clip with visualized distance from the cysticocholedochal junction (Duca et al, 2003). In a retrospective review of 10,000 patients undergoing LC in a single center by four separate surgeons with no documented CBD injuries, it was found that surgical experience, preoperative imaging, precise operative

*Periampullary diseases include papillary stenosis, choledochoduodenal fistulae, and ampullary tumors.

procedures, and conversion from LC to OC when needed are necessary prophylactic measures to prevent CBD injuries (Ou et al, 2009). In addition, regular reliance on the "critical view" technique, along with abandonment of the infundibular dissection approach, can optimize a safer dissection (Strasberg et al, 2000; Strasberg, 2002).

Minor biliary leaks from the bed of the gallbladder, so-called *Luschka leaks,* may also be troublesome intraoperatively. Often, such leaks occur as a result of errant dissection into a deep plane of hepatic parenchyma. Accessory bile ducts found in the gallbladder bed may be controlled by ligation when transection and spillage is identified, but if these leaks are not identified in the operating room, postoperative bilomas and even bilious ascites may ensue. If the drainage of these "minor" leaks exceeds 500 mL over a 24-hour period, endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy and transampullary stenting is useful in decompressing the biliary system and preventing reoperation (Pinkas & Brady, 2008; Pawa & Al-Kawas, 2009).

Hemorrhage

In a retrospective analysis of 9542 consecutive LCs by Duca and colleagues (2003), intraoperative hemorrhage occurred in 224 patients for an incidence of 2.3%. Bleeding was most commonly from the gallbladder bed and was treated with a fibrin-collagen patch. Conversion to an open procedure with suturing of the gallbladder peritoneum was required in five patients, however. It was noted that such hemorrhage from the gallbladder bed was encountered most commonly in patients with acute cholecystitis or cirrhosis. Tangential lesions of the cystic artery or, less commonly, total sectioning of the cystic artery occurred in 95 cases. In the majority of cases, the intraoperative bleeding was controlled laparoscopically with hemostatic clips, but conversion to an open procedure occurred in one patient. Damage to the hepatic artery occurred in one patient and required immediate open conversion. Finally, bleeding from the greater omentum was seen in 18 patients and was controlled laparoscopically in 16 patients.

Another source of massive intraoperative blood loss is from inadvertent incursion into a deep plane of hepatic parenchyma, where distal tributaries of the middle hepatic vein may be encountered. In fact, 10% of patients harbor large branches of the middle hepatic vein directly adjacent to the gallbladder fossa, which may lead to significant hemorrhage in instances of even minimal parenchymal dissection (Ball et al, 2006). Furthermore, postoperative hemorrhage may occur from trocar placement, or the bleeding may be from the cystic artery itself, albeit less than 1% of the time (Marakis et al, 2007). Finally, it should be recognized that management of profuse bleeding during LC, particularly when unexpected, can be fraught with significant ramifications that include major vascular ligation (hepatic artery, portal vein) and/or bile duct injury. This occurs from haphazard clip application or aggressive use of cautery in a poorly visualized field, thus conversion to open laparotomy is often the more prudent approach.

Dropped Stones

In 6% to 40% of LC procedures perforation of the gallbladder with subsequent spillage of gallstones occurs (Helme et al, 2009). These stones are usually retrieved under direct visualization, and the Morison pouch can be copiously irrigated; however, in 13% to 32% of patients these stones may be "lost" (Helme et al, 2009). This scenario contributes to postoperative morbidity 0.1% to 6% of the time, and the effects may vary in presentation and timing (Hand et al, 2006). Although such complications are infrequent, the patient may have symptoms such as fever, chronic abdominal pain, and/or intestinal obstruction. Furthermore, a meta-analysis by Zehetner and colleagues (2007) revealed that complications from "dropped stones" may present months to years after LC, most commonly as subcutaneous or intraabdominal abscesses or fistulas to less frequent manifestations such as liver abscesses or bacteremia. Additionally, stones have also been reported to erode into the chest cavity, causing empyema and broncholithiasis with expectoration (Zehetner et al, 2007). Perforation of the gallbladder during LC often occurs as the organ is dissected off of the liver by excessive retraction, direct puncture, or during omental adhesiolysis, but it may also occur as the gallbladder is being removed through trocar sites. Regular use of a retrieval bag may decrease complications from removal through trocar sites. Iatrogenic perforation of the gallbladder occurs more frequently in LC compared with OC; furthermore, spilled stones are arguably better visualized and more readily retrieved during open operations.

In a large retrospective review of more than 10,000 LCs, Schafer and colleagues reported a 6% incidence of gallbladder perforation with complications from dropped stones in 0.08% (Schafer et al, 1998). Furthermore, a 3-year prospective study by Rice and colleagues (1997) of 1059 patients who underwent LC at the Mayo Clinic revealed a perforation rate of 29% with an 11% dropped-stone rate. In this study, 2% of patients with perforated gallbladders developed subhepatic abscesses, and patients with intact gallbladders extracted had abscesses (Rice et al, 1997). In experimental studies using rabbit, rat, and dog models, the intraperitoneal introduction of gallstones resulted in a predominantly benign course without long-term complications (Welch et al, 1991; Sax & Adams, 1993; Cline et al, 1994; Cohen et al, 1994; Johnston et al, 1994; Zisman et al, 1995; Tzardis et al, 1996). Therefore, when gallbladder perforation and dropped stones are encountered, efforts should be made to retrieve stones with suctioning or forceps, and the subhepatic fossa should be copiously irrigated. Conversion to an open procedure is not necessary owing to a low rate of complications; however, it is a good policy to document the event and to inform the patient that stone spillage occurred.

Insufficient Cholecystectomy

In patients with severe acute inflamed cholecystitis, visualization of the cystic duct can be difficult, and historically this was treated with subtotal cholecystectomy. This approach has been proven to be effective and safe in open procedures. Recent reports suggest that when a critical view is impossible to obtain, laparoscopic subtotal cholecystectomy is also relatively safe (Hobbs et al, 2006; Ji et al, 2006; Sharp et al, 2009). When the triangle of Calot cannot be safely dissected, transection and oversewing of the gallbladder neck with resection of the anterior wall of the gallbladder, leaving a small strip of posterior gallbladder wall, can be an option.

Although this is a viable albeit rare approach, PCPs requiring an invasive reintervention still occur (Pernice & Andreoli, 2009). In a study from the United Kingdom of 26 cases of laparoscopic subtotal cholecystectomy over a 3-year period, five patients underwent postoperative ERCP for persistent biliary

leak (n = 4) or retained common bile duct stones (n = 1). One patient developed a subphrenic abscess and underwent reoperative laparotomy, and another patient who was critically ill before surgery died postoperatively. A completion LC was required for one patient with a gallstone in a retained pouch, and two patients developed port-site hernias (Philips et al, 2008). In cases mandating laparoscopic subtotal cholecystectomy, the procedure must be performed by experienced surgeons, a drain should be left at the level of transection, and if a posterior wall is retained, it should be coagulated. A late manifestation of "partial" cholecystectomy is a remnant gallbladder pouch with potential for retained stones or cholecystitis.

Infections

Postoperative infection after cholecystectomy is a rare event. In a 7-year study conducted by the Centers for Disease Control and Prevention, out of 54,504 patients, the rate of surgical site infections (SSIs) was significantly lower in the laparoscopic approach when compared with open surgery (0.62% vs 1.82%, $P = .001$); however, the pathogens that caused SSIs were similar in both groups (Richards et al, 2003). The pathogens identified included *Enterobacter* species, *Escherichia coli,* and *Staphylococcus aureus.* The majority of infections in the open approach were seen in superficial spaces; in the laparoscopic approach, the majority of infections were intraabdominal. As expected, the SSI rates were higher in patients taken to the operating room emergently or with an ASA of 3 or higher (Richards et al, 2003). That said, prophylactic antibiotics given preoperatively to any low-risk patient undergoing elective LC are not indicated as evidenced by several reported studies (Chang et al, 2006; Tocchi et al, 2000; Uludag et al, 2009).

Late Postoperative Complications

Months to years after undergoing a cholecystectomy, patients may be seen with abdominal pain that differs from the symptoms felt before surgery. The incidence of pain from abdominal incisions is higher in OC (9%) versus LC (5%) over a 6-month period as reported by Vander Velpen and colleagues (1993). Bile duct neuromas have also been reported as a cause of pain up to 45 years after cholecystectomy (Paquette et al, 2009). A randomized controlled study performed by Halm and colleagues with 1-year follow-up in the prelaparoscopic era demonstrated that incisional hernias complicated 2% (1 of 60) of patients undergoing OC with a transverse incision compared with 14% (9 of 63) with a midline incision (Halm et al, 2009). Muhe (1992) reported that 12% of patients developed incisional hernias or pain after OC compared with 2% after LC.

Mechanical Causes of Postcholecystectomy Problems

Common causes of mechanical obstruction of the biliary tree after cholecystectomy include benign or malignant strictures, retained stones in the common or cystic ducts, or downstream ampullary sphincter dysfunction.

Strictures (See Chapter 42)

Benign stenosis of the CBD is more common after LC, and 95% of the time, it is related to iatrogenic injury in the form of partial or total sectioning, clipping, or ligation (Kassab et al, 2006). The incidence of patients developing strictures after LC varies from 0% to 2.7% compared with 0.2% to 0.5% after OC (Deziel et al, 1993; Strasberg et al, 1996). Postsurgical benign strictures may also result from delayed thermal injury or intraoperative ischemic devascularization (Genest et al, 1986; Deziel et al, 1993). Additionally, choledochoduodenal fistula formation tends to manifest more commonly after such stricture formation. In the postoperative period, the problems caused by strictures may result in abdominal pain, fever, and jaundice. Cholestasis may lead to choledocholithiasis and recurrent cholangitis (Kassab et al, 2006). Malignant strictures after cholecystectomy should also be considered, as rare cases have been reported (Sharma et al, 2008). This indicates a misdiagnosis prior to the cholecystectomy.

Biliary strictures have historically been treated by surgical reconstruction via hepaticojejunostomy, although many studies have recently reported the safety and efficacy of endoscopic balloon dilation and/or stenting as a noninvasive method to treat such problems (Kassab et al, 2006; Gouma, 2007). Surgery is therefore reserved for major bile duct injuries or failure of endoscopic therapy. A more detailed discussion of both benign and malignant strictures can be found in Chapters 42 and 50.

Retained Stones

The remnant of the cystic duct or gallbladder (in subtotal cholecystectomy) has historically been implicated as the source of pain, nausea, and vomiting in postcholecystectomy patients (Bodvall, 1973). Several theories as to the etiology of such symptoms, characterized as the *cystic duct stump syndrome,* have been hypothesized (Garlock & Hurwitt, 1951). An increase in choledochal pressure resulting in cystic stump distension, inflammation or stone obstruction within the remnant of the cystic duct or gallbladder, and an increase in the sphincter of Oddi pressure have all served as causes of postcholecystectomy problems (Bodvall, 1973). However, various studies have confirmed that symptomatic improvement only occurs when a stone is present in the CBD or cystic duct and is subsequently removed endoscopically or via operative reintervention (Hopkins et al, 1979; Mergener et al, 1999; Tantia et al, 2008). In general, persistent symptoms following a cholecystectomy in which no cholangiogram was performed warrants analysis of the liver function profile and/or noninvasive imaging with either ultrasound or MRCP to assess for retained stones. If CBD stones are present, therapeutic ERCP is suggested (Fig. 38.2). The comprehensive management of common bile duct stones is discussed in Chapters 35 through 37.

Papillary Disorders

The apparatus responsible for directing the flow of biliary and pancreatic secretions is the sphincter of Oddi, which consists of three segments of smooth muscle: 1) the CBD segment, which is about 10 mm in length; 2) the pancreatic segment, which is roughly 6 mm in length; and 3) the segment of the confluence of both the bile duct and pancreatic duct, which is intraduodenal and close to 6 mm in length (Bistritz & Bain, 2006). When constricted, this sphincter impairs forward flow of both bile and pancreatic juices.

Sphincter of Oddi dysfunction (SOD) continues to be a diagnostic dilemma, and its management is controversial. Many entities have been reported describing this phenomenon, including papillary stenosis, sclerosing papillitis, and biliary spasm. The pathogenesis of this disorder is incompletely understood but is thought to result from an increase in basal sphincter pressure resulting in an increase in CBD pressure and stasis from obstructed biliary and pancreatic flow (Funch-Jensen et al,

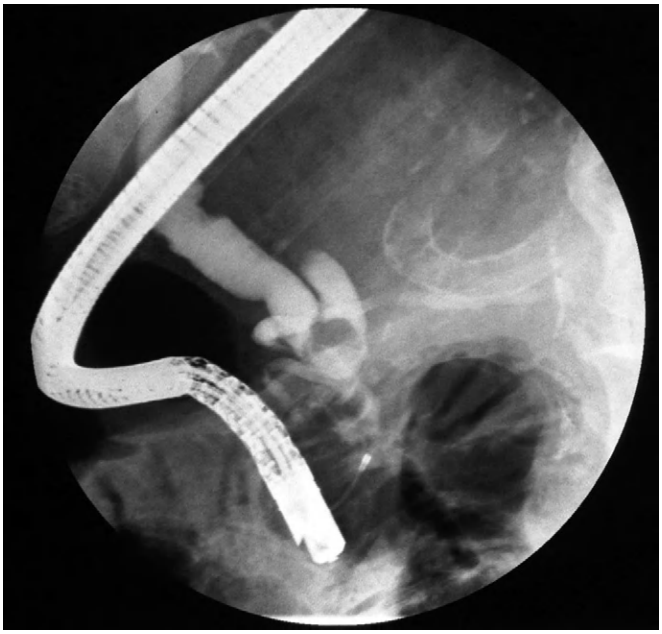

FIGURE 38.2. Depiction of a stone retained in the cystic duct stump.

2006). Microlithiasis causing transient obstruction has also been implicated as a result of stasis in the CBD from sphincter dysfunction, but this has been shown in several studies to be of little consequence in postcholecystectomy pain (Quallich et al, 2002; Rashdan et al, 2003; Bistritz & Bain, 2006). Uncoordinated spasm of the sphincter of Oddi has also been shown to produce the classic symptoms of RUQ colic with elevated liver function tests (LFTs) and has been characterized as biliary dyskinesia (Chuttani & Carr-Locke, 1993), therefore SOD may be described as two separate mechanisms: stenosis and dyskinesia.

Sphincter of Oddi Stenosis

Sphincter of Oddi *stenosis* refers to a fixed constriction or narrowing of part or all of the anatomic structures of the sphincter of Oddi. The stenosis may result from the trauma of recurrent passing gallstones, repeated attacks of pancreatitis, the effects of iatrogenic instrumentation, or other nonspecific causes. These insults result in fibrotic changes that cause a noncompliant orifice and elevated resting pressures, correlating to symptoms that fall into the category of type I biliary SOD (Bistritz & Bain, 2006). Ampullary biopsies of 43% of patients with SOD show evidence of fibrosis and inflammation (Ponchon et al, 1995). In the postcholecystectomy patient, the resulting backpressure of "papillary stenosis" is compounded by the lack of a gallbladder, which could normally serve as a reservoir for increased pressure in the CBD (Bistritz & Bain, 2006).

Sphincter of Oddi Dyskinesia

Uncoordinated contraction and relaxation of the sphincter of Oddi results in transient obstruction of biliary and/or pancreatic secretions. This leads to an elevation of intraluminal pressure with a concurrent elevation of LFTs. An increase in frequency of phasic contractions and a paradoxical response to the administration of cholecystokinin (failure of relaxation) may also occur in patients with dyskinesia (Tanaka, 2002). Interestingly, there is a significant overlap in patients with biliary dyskinesia and other intestinal motility disorders such as irritable bowel syndrome or hypertensive lower esophageal sphincter disorder (Evans et al, 1995, 1997; Chan et al, 1997).

Clinically, SOD presents in 1% of patients after cholecystectomy and in 14% to 23% of patients presenting with the postcholecystectomy syndrome (Bar-Meir et al, 1984; Meshkinpour & Mollot, 1992; Drossman et al, 1993). SOD can also manifest as recurrent pancreatitis or with recurrent acalculous RUQ pain in patients with an intact gallbladder. Patients with SOD may be classified into three types based on presentation, laboratory results, and ERCP findings. Specifically, two classification systems, shown in Tables 38.3 and 38.4, stratify patients into three clinical groups for both biliary and pancreatic symptoms and predict the outcomes of endoscopic versus surgical treatment (Hogan & Geenen, 1988; Sherman et al, 1991). Patients with type I disease have biliary pain, elevated LFTs, an increase in the diameter of the CBD (>12 mm) with a delay in contrast drainage of more than 45 minutes. Patients with type II disease present with biliary pain and one or two of the remaining criteria delineated above. Patients with type III disease are seen initially with the sole criteria of biliary-type pain (Hogan & Geenen, 1988).

When patients present with the constellation of symptoms that fall under SOD, including pain that lasts at least 30 minutes, other organic causes of RUQ pain must be ruled out with laboratory tests that include complete blood counts and LFTs with amylase and lipase measurements. Transabdominal or endoscopic ultrasonography along with nuclear hepatobiliary scans and cholangiopancreatography may aid in narrowing the diagnostic differential. Often evidence of a dilated common bile duct is seen in the setting of type I SOD and is most amenable to treatment with sphincterotomy (Rolny et al, 1993; Sugawa et al, 2001). Although no specific test is available to assess for SOD, ampullary manometry may be utilized to define

Table 38.3

Milwaukee Biliary Group Classification

Group	Biliary-Type Pain	Abnormal LFTs*	Dilated CBD†	Delayed Drainage‡
I	+	+	+	+
II	+	One or two of the above		
III	+	None of the above		

*Alanine aminotransferase and aspartate aminotransferase more than two times normal value on at least two occasions
†Dilated CBD: >12 mm on ultrasound scan or 10 mm on ERCP
‡Delayed drainage: >45 minutes on ERCP, supine position
LFTs, Liver function tests; CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography

Data from Hogan WJ, Geenen JE, 1988: Biliary dyskinesia. Endoscopy 20:179-183.

Pancreatic-Type Pain Classification

Group	Recurrent Pancreatitis and/or Typical Pain	Abnormal Enzymes*	Dilated Pancreatic Diameter†	Delayed Drainage‡
I	+	+	+	+
II	+	One or two of the above		
III	+	None of the above		

*>1.5 to 2 times the upper normal limit
†>6 mm in the head, >5 mm in the body on endoscopic retrograde cholangiopancreatography
‡>9 minutes

Data from Sherman S, et al, 1991: Frequency of abnormal sphincter of Oddi manometry compared with the clinical suspicion of sphincter of Oddi dysfunction. Am J Gastroenterol 86:586-590.

hypertensive sphincters (>40 mm Hg) or to detect an increase in the frequency of phasic contractions as well as a paradoxical response to cholecystokinin (Geenen et al, 1989; Thune et al, 1991; Smithline et al, 1993). A further discussion of the diagnostic tools and management strategies used for SOD ensues later in this chapter.

NONBILIARY CAUSES OF POSTCHOLECYSTECTOMY PROBLEMS

In 70% to 80% of patients seen with postcholecystectomy pain, the etiology is attributed to nonbiliary gastrointestinal causes including gastroesophageal reflux, peptic ulcer disease, gastritis, irritable bowel syndrome, or diverticular disease (Burnett & Shields, 1958; Bates et al, 1991). These may have been the original source of symptoms in poorly chosen patients for cholecystectomy. Discomfort in the epigastrum and RUQ is often reproduced in patients with gastric, esophageal, pancreatic, hepatic, duodenal, and even pulmonary sources and therefore must be investigated in patients with postcholecystectomy symptoms. In addition, patients with flatulent dyspepsia prior to surgery often continue to have persistent symptoms after removal of the gallbladder. Patients with RUQ pain and gallstones are often immediately offered a cholecystectomy, although other gastrointestinal sources of pain or discomfort may exist and persist subsequent to surgery, presenting as a PCP.

Postcholecystectomy diarrhea (PCD), defined as three or more loose stools per day, can occur long term in up to 12% of patients after cholecystectomy (O'Donnell, 1999). At least 5% to 8% of patients report a change in their bowel habits after cholecystectomy (O'Donnell, 1999). The etiology of PCD is incompletely understood but may relate to the malabsorption of bile acids (Merrick et al, 1985). Three categories of bile acid malabsorption have been defined. In type I malabsorption, patients have previously undergone a terminal ileal (TI) resection, as bile acids are normally reabsorbed by the TI, or they may have an ileal mucosal abnormality. Type II malabsorption is considered idiopathic, and patients with type III bile acid malabsorption have either undergone a vagotomy or cholecystectomy (Fromm & Malavolti, 1986). The pathogenesis of bile acid–induced diarrhea in patients after cholecystectomy revolves around the premise that the storage depot of bile, the gallbladder, is absent, and bile acids have the ability to flow with more ease into the colon, which allows for osmotic and electrolyte shifts as well as increased transit time. The use of diagnostic studies including a synthetic radiolabeled bile acid 23-selena-25 homocholytaurine (SeHCAT) assay may be useful in narrowing the etiology of diarrhea in patients after cholecystectomy; the retention of SeHCAT at 7 days after oral administration demonstrates normal absorption of bile acids (Ford et al, 1992). The diagnostic accuracy of SeHCAT is not convincing because of studies that reveal normal levels of fecal bile acids in patients with PCD (Fromm et al, 1987). The use of bile acid binding agents such as cholestyramine have varied effects as reported in the literature (Sciarretta et al, 1986; Arlow et al, 1987; Fromm et al, 1987), however, traditional antidiarrheals may also be used in the treatment of PCD.

Postcholecystectomy pancreatic disease may be another cause of PCPs and is often concurrent and undiagnosed, with patient complaints having led to the cholecystectomy. Some studies show, however, that cholelithiasis itself may cause pancreatic changes as seen on patients undergoing ERCP (Axon et al, 1979). Whether these concurrent pancreatic changes are the cause of pain is uncertain, as not all patients with pancreatic disease after cholecystectomy underwent ERCP at the time of cholecystectomy. Furthermore, reports of patients with pancreatic disease at the time of cholecystectomy who do not manifest postoperative problems also exist (Schofield & Macleod, 1966).

Finally, after all other organic causes of PCPs are ruled out, the diagnosis of psychosomatic pain must be entertained. Various studies have revealed a higher incidence of anxiety, depression, psychosomatic disorders, and use of psychotropic drugs in patients presenting with abdominal complaints after cholecystectomy (Hansky & Dreiling, 1963; Christiansen & Schmidt, 1971; Kakizaki et al, 1976; Talley et al, 1986; Haug et al, 1995; McMahon et al, 1995). In particular, patients with type III SOD (biliary pain only) have been shown to exhibit increased rates of depression, anxiety, and obsessive-compulsive traits (Desautels et al, 1999). However, care should be taken to thoroughly evaluate patients for biliary or other abdominal causes of pain before the diagnoses of psychosomatic disorders are entertained.

Diagnostic Studies in the Evaluation of Postcholecystectomy Problems

The evaluation of patients presenting with PCPs should be undertaken in a systematic fashion, and knowledge of the diagnostic tools available is essential. Before radiologic assessment is pursued, a full history and physical with identification of laboratory derangements, including a complete blood count and chemistry panel, and a review of any intraoperative reports and imaging must be analyzed. Thereafter, the use of ultrasonography and cholangiopancreatography can be very helpful in narrowing the differential diagnosis.

Ultrasonography (See Chapter 13)

The first imaging modality used to evaluate patients with RUQ pain is often ultrasonography, because it is inexpensive, quick, and noninvasive; however, it is highly operator dependent. With experienced technicians, ultrasonography can be used to assess for retained stones and CBD diameter and, less commonly, for sphincter of Oddi dysfunction (Funch-Jensen et al, 2006). In the early postoperative period, transabdominal ultrasonography (TUS) is particularly useful in identifying fluid collections such as bilomas, abscesses, or hemorrhage. If fluid collections are large, ultrasound-guided aspiration and culture should be performed; if the character of the collection is bilious or purulent, drainage catheters are left in place. Bile duct imaging with TUS is difficult, and the sensitivity of ultrasonography to detect stones in the distal CBD is low (Dewbury & Smith, 1983; Filip et al, 2009). Visualizing the pancreatic duct is also difficult with ultrasonography because of overlying gas from the stomach or intestines, which often obscures the acoustic windows.

The use of TUS in the detection of SOD has also been investigated. Measurements of the CBD (upper limits of normal <8 to 10 mm) can be taken after the infusion of cholecystokinin or 45 minutes after the ingestion of a fatty meal, which in the face of distal obstructive physiology, such as that of SOD, will demonstrate dilation of the diameter of the CBD over baseline (Rosenblatt et al, 2001). These diagnostic tools have not gained popularity in the assessment of SOD because of low sensitivity rates and low reproducibility (Simeone et al, 1982; Darweesh et al, 1988; Rosenblatt et al, 2001).

Endoscopic ultrasonography (EUS) is another alternative to more accurately assess the presence of CBD stones and has the ability to better visualize the stomach, duodenum, and pancreas to rule out other organic causes of postcholecystectomy syndrome (see Chapter 14). EUS is also useful in the diagnosis of chronic pancreatitis and in the detection and staging of pancreatic, ampullary, and bile duct carcinoma. In patients with suspected choledocholithiasis, EUS may also be used prior to more invasive testing, such as ERCP. In EUS the ampulla itself is not cannulated, and although not therapeutic, this method has lower complication and failure rates. Additionally, the initial use of EUS may obviate the need for ERCP in one half to two thirds of patients (Filip et al, 2009; Petrov & Savides, 2009). Limitations of EUS include the need for sedation and limited availability, and it may not be conclusive in the presence of duodenal stenosis and previous sphincterotomy and/or biliary stenting in which pneumobilia may obscure a clear view (Stewart et al, 2001). Therefore patients with an elevated serum bilirubin, with or without an elevation of alkaline phosphatase, and a CBD measurement greater than 8 to 10 mm on TUS may be candidates for EUS which, if results are negative for stones or other pathology, may obviate the need for further invasive testing such as with ERCP, thereby decreasing the risk of radiation exposure, postprocedural pancreatitis, and postsphincterotomy bleeding or perforation.

Cholangiopancreatography (See Chapter 18)

Cholangiopancreatography provides direct visualization of the biliary tree, papilla, and pancreatic duct and is highly sensitive and specific in diagnosing the causes of PCPs. The use of magnetic resonance cholangiopancreatography (MRCP; see Chapter 17) provides a noninvasive method to evaluate various biliary and pancreatic disease processes including obstructive stones. Although there is no therapeutic value to MRCP, patients with abnormal LFTs and dilated CBDs (>10 mm) after cholecystectomy with no evidence of stones or other pathology on TUS may be candidates for MRCP (Terhaar et al, 2005). MRCP has been reported to be 95% to 100% sensitive and 88% to 97% specific in detecting biliary obstructions, although it is less sensitive in detecting stones less than 6 mm in size (Terhaar et al, 2005; Tse et al, 2006).

MRCP with secretin (MRCP-S) allows for functional testing of the pancreatic duct (Mariani et al, 2003). Long-term results of MRCP-S reveal diagnostic accuracy comparable to that of ERCP and with excellent positive predictive value; however, when the test showed abnormalities, radiologists were unable to distinguish between the biliary and the pancreatic segment dysfunction of the sphincter of Oddi. Additionally, the negative predictive value of MRCP-S was poor at 64% (Testoni et al, 2008). MRCP and EUS are diagnostic tools that may be used in patients with abnormal but inconclusive first-line testing (laboratory values and TUS) to obviate the need for further invasive options. The gold standard diagnostic and therapeutic procedure in patients with biliary obstruction is ERCP. It carries a sensitivity and specificity of more than 95% in the detection of obstruction and, where pathology is seen, it may also be therapeutic, allowing for sphincterotomy, stent placement, and tissue collection (Snady et al, 1992; Palazzo et al, 1995; Prat et al, 1996; Buscarini et al, 2003). However, ERCP carries a significant risk of complications. Acute pancreatitis is the most common complication and occurs in 5% to 40% of patients. Additionally, pancreatic necrosis, duodenal or biliary tree perforation, multiorgan failure, and death may occur, albeit less than 1% of the time (Dancygier & Nattermann, 1994; Masci et al, 2001; Barthet et al, 2002; Lieb & Draganov, 2007).

In patients with postcholecystectomy pain where SOD is suspected, ERCP can also allow for concurrent sphincter of Oddi manometry (SOM), which is considered the gold standard for detection of SOD (Khashab et al, 2009). A triple-lumen catheter connected to external transducers is positioned in the sphincter of Oddi segment of both the CBD and pancreatic duct separately, and baseline pressure and phasic wave amplitude, duration, and frequencies are measured with video recording for subsequent analysis (Csendes et al, 1979; Geenen et al, 1980). SOD is a dynamic process, and a single, normal endoscopic evaluation may not be sufficient in patients with persistent symptoms (Varadarajulu et al, 2003; Khashab et al, 2009). In a study of 5352 patients who underwent SOM over a 13-year period, 1037 had SOM readings within normal limits (Table 38.5). Of these patients, 30 had repeat ERCP for persistent symptoms, and 60% of these were given the diagnosis of SOD (Khashab et al, 2009).

The most common cause of abdominal pain occurring after cholecystectomy is residual or recurrent choledocholithiasis (see Chapter 35), seen in 42% of patients undergoing ERCP in one study of more than 1000 patients with PCPs (Tondelli &

Table 38.5

Normal Sphincter of Oddi Manometric Readings

Baseline Pressure	Phasic Wave Amplitude	Wave Duration	Wave Frequency
5-15 mm Hg	100-140 mm Hg	4-6 sec	3-6 waves/min

Data from Funch-Jensen P, et al, 2006: Evaluation of the biliary tract in patients with functional biliary symptoms. World J Gastroenterol 12(18):2839-2845.

Gyr, 1983; Zhou et al, 2003). ERCP findings of biliary or pancreatic strictures are second to stones in frequency in patients with PCPs (Goenka et al, 1996; Singh et al, 1996). Furthermore, in various studies in which ERCP was performed on patients with severe PCPs manifesting as pain and/or jaundice, the diagnosis was made in over half of the patients; CBD stones comprised the majority (Ruddell et al, 1980; Hamilton et al, 1982; Carlson et al, 1992).

As noted above, bile leak from CBD injury or inadequate cystic duct stump ligation are serious complications of cholecystectomy. In this scenario, intervention via ERCP with the use of endoprosthetic stents with or without sphincterotomy is an important diagnostic and therapeutic tool (Katsinelos et al, 2006). In some cases, endoscopic access to the biliary tree is limited, such as in patients who have had diverting gastric bypass surgery, and percutaneous transhepatic cholangiography (PTC) is an alternative approach. However, a majority of patients with biliary injuries following cholecystectomy may be successfully managed initially with ultrasound or computed tomography (CT) guided percutaneous drainage of biliary collections. Patients with persistent leaks or those who present with jaundice should be considered for ERCP as a first-line diagnostic and therapeutic option (Zerem & Omerovic, 2009).

Hepatobiliary Scintigraphy (See Chapter 15)

In patients who have undergone cholecystectomy, nuclear scanning reveals rapid flow of intravenously administered ^{99m}Tc-n-(2,6,dimethylphenylcarbamoylmethyl) iminodiacetic acid (^{99m}Tc-HIDA) from the hepatocytes to the biliary canaliculi then to the CBD and ultimately to the duodenum via the sphincter of Oddi. In patients with SOD a marked delay in transpapillary transit times is seen with stasis in the intrahepatic and extrahepatic biliary system. This sort of quantitative cholescintigraphy may aid in the diagnosis of patients suspected to have SOD following cholecystectomy (Shaffer et al, 1986; Corazziari et al, 1994; Madacsy et al, 1999; Corazziari et al, 2003). It is also useful in confirming the presence of a biliary leak after cholecystectomy, although discrimination of the precise location is often not possible.

Axial Imaging

If the aforementioned techniques do not reveal the cause of PCPs, CT or magnetic resonance imaging (MRI) can be employed to rule out other sources of pain not suspected preoperatively (e.g. tumors, rib fractures, pneumonia). Postoperative complications, such as dropped stones, abscesses, hematomas, or hernias can also be detected. A scan that is inconclusive is often reassuring to the surgeon, as it can at least define that postoperative complaints are not obviously organic in nature, which can lead the workup of symptoms in other directions.

Treatment Strategies in Patients with Postcholecystectomy Problems

Early Postcholecystectomy Problems

Once the appropriate diagnostic workup is performed, various treatment strategies exist to address common PCPs. In the early days to weeks after operation, the finding of a gallbladder fossa hematoma (relatively common) should be managed with serial hematocrit values and correction of any coagulopathy. Most hematomas are asymptomatic and self-limited; however, if a patient's anemia worsens and impacts their clinical status, operative reexploration must be pursued. If an abscess is identified on diagnostic ultrasound or CT scan, percutaneous drainage is the preferred treatment, if the abscess is large enough, and if the procedure is technically feasible. Smaller or inconveniently placed collections may be successfully managed with antibiotics alone, and operative drainage is rarely necessary.

In the scenario of a biliary leak presenting as a biloma, the initial management should be aimed at percutaneous drainage to control local sepsis; however, endoscopic management may ultimately be necessary. In minor injuries, ERCP and sphincterotomy will eliminate the transpapillary pressure gradient, allowing for uninhibited flow across the papilla, thereby diminishing the extent of the leak, until it eventually ceases (De Palma et al, 2002). The endobiliary stent may also seal off the flow of bile through a physical apposition against the defect in the biliary tree, although this is less likely. External drainage of bile usually dissipates immediately, within a few days; the stent may be removed a month later, if the cholangiogram shows resolution of the leak. If external drainage does not resolve, or if it recurs in the early period, the next approach would be the serial placement of multiple endobiliary stents in a "bunched" fashion, or even deployment of a temporary covered metal stent. Should these maneuvers fail, operative repair is required and usually calls for a bilioenteric bypass. Major damage to the biliary tree can usually be salvaged by stents, but massive bile ascites causing generalized peritonitis may require an operative washout and drainage; this can sometimes be achieved laparoscopically, realizing that an open approach may ultimately be required to definitively address the damage.

Late Postcholecystectomy Problems

When patients come to the hospital months to years after having a cholecystectomy with symptoms of PCPs, a complete laboratory and diagnostic workup will guide the surgeon's management decisions. In the case of abnormal LFTs, with or without leukocytosis, and abnormal TUS findings, the patient should proceed directly to ERCP. If, however, a postcholecystectomy patient's LFTs are abnormal, but the TUS is equivocal or normal, it is reasonable to proceed with EUS or MRCP prior to ERCP. The various endoscopic management strategies regarding choledocholithiasis, strictures, and fistulae are discussed elsewhere in this textbook (see Chapters 35 and 42).

A diagnostic workup that points toward the diagnosis of SOD will alter the physician's management strategy. The goal for treatment in patients with SOD is free flow of biliary and pancreatic fluid into the duodenum. This objective may be achieved medically, endoscopically, or surgically.

Medical treatment of SOD is often attempted as a first-line management option, but results are usually poor. The utility of calcium channel blockers and oral nitrates have been plagued with poor outcomes secondary to tachyphylaxis and side effects of the medications (Staritz et al, 1985; Fullarton et al, 1992; Khuroo et al, 1992; Sand et al, 1993; Craig & Toouli, 2002; Wu et al, 2005b; Bistritz & Bain, 2006). Although controversial and underexamined, some studies reveal a decrease in sphincter of Oddi basal pressures with the use of intravenous somatostatin and its analogues (Fazel et al, 2002; Wu et al, 2005a).

Endoscopic treatment of SOD utilizes the ability to decrease transpapillary pressures with sphincterotomy. Patients with a functional obstruction resulting in SOD, as seen in type I disease in particular, benefit from sphincterotomy even when

manometry may not reveal hypertension. Symptomatic relief has been achieved at more than 2-year follow-up in patients with type I SOD with or without manometric findings of hypertension (Rolny et al, 1993; Sugawa et al, 2001). Based on these and other findings that corroborate these results, sphincterotomy without manometry is advised in all patients with type I SOD. In contrast, patients with type II SOD only benefit from sphincterotomy when basal sphincter pressures are elevated. Therefore, manometry should precede endoscopy in this patient population (Geenen et al, 1989; Toouli & Craig, 1999). In patients without objective evidence of biliary obstruction (type III), the response to sphincterotomy does not correlate well with manometric findings, thus it has been suggested that patients who carry a diagnosis of type III SOD should undergo hepatobiliary scintigraphy to gather additional objective data prior to invasive manometry or sphincterotomy (Wehrmann et al, 1996). In this patient population, botulinum toxin may also be used to avoid sphincterotomy and its resultant complications such as bleeding, pancreatitis, and perforated viscera (Wehrmann et al, 1998). Recent studies suggest that phosphodiesterase type 5 inhibitors such as vardenafil (Levitra) infused into the duodenum with endoscopy may reduce basal sphincter of Oddi pressures without significant adverse events (Cheon et al, 2009). These and other agents are under active investigation as alternatives to the more invasive approach of sphincterotomy.

Endoscopic stenting for SOD in patients without an elevated basal sphincter pressure has been attempted with poor response and a high associated risk of stent-induced pancreatitis (Goff, 1995). Additionally, stent placement has also been advocated to predict which patients would respond to sphincterotomy; although in some studies, these trials were able to detect a population of patients who would respond, this method did not gain popularity because of the risks involved and the lack of compelling evidence (Bistritz & Bain, 2006). Therefore the use of biliary stenting in the setting of SOD is not advisable.

Surgical intervention for SOD was developed before the advent of ERCP (Madura et al, 2005). Transduodenal sphincteroplasty with transampullary septectomy (TDS-TAS) was the procedure of choice at that time (Fig. 38.3). Prior to the advent of ERCP, no objective studies could accurately diagnose patients with SOD; subjective intraoperative methods, such as palpation of the sphincter through the wall of the duodenum, were used to select patients for TDS-TAS. As time progressed, various studies were developed to improve patient selection, such as the morphine–neostigmine evocative test (Nardi & Acosta, 1966). Expertise in endoscopy also continued to progress, until endoscopic sphincterotomies were standardized by the mid-1970s (Kawai et al, 1974). Advantages of the surgical approach include accurate apposition of the duodenal and ductal mucosa, as well as access to the transampullary septum, which cannot always be accomplished with ERCP (Madura et al, 2005). Endoscopic transampullary septotomy is rare, and drainage of the pancreatic duct is inadequate (Fuji et al, 1989; Rolny et al, 1989). In a series of 17 patients, pain from an unsuccessful sphincteroplasty was relieved by excision of the septum in 12 patients (Moody et al, 1990). These studies and others demonstrate the importance of a septotomy; however, both surgical and endoscopic results are not optimal owing to the vague nature of this disease (Tables 38.6 and 38.7). Patients with a suspected diagnosis of SOD should be treated by experienced surgeons and endoscopists working in concert. A treatment algorithm for patients presenting with PCP is illustrated in Figure 38.4.

POTENTIAL PITFALLS IN MODERN APPROACHES TO CHOLECYSTECTOMY

The field of hepatobiliary surgery has progressed in various ways over the years, but one of the most fascinating leaps in modern surgery is the pace at which minimally invasive methods are supplanting open operative interventions. From single incision laparoscopic surgery (SILS) to natural orifice translumenal endoscopic surgery (NOTES), the approach to cholecystectomy appears poised for further changes. To date, scant data are available regarding the outcomes of such novel approaches, but there is no doubt that these innovative methods will introduce a

host of new PCPs. In fact, an early outcomes report of 39 patients undergoing NOTES cholecystectomy, both transvaginal and transgastric, revealed NOTES-related complications such as gastric hematomas and esophageal and colonic perforations (Salinas et al, 2009). Because of safety concerns, NOTES procedures still have to be further refined prior to widespread dissemination, although SILS techniques seem to be embraced with more enthusiasm because of the ability to use existing instrumentation and the improved clinical outcomes. Clearly, additional studies are essential for the further evolution of these contemporary techniques (Kuon Lee et al, 2009).

CONCLUSIONS

Symptoms resembling those encountered prior to cholecystectomy may recur in 10% to 40% of patients undergoing either laparoscopic or traditional open cholecystectomy (Pernice & Andreoli, 2009). This occurrence is disappointing and sometimes vexing for both the patient and surgeon, therefore it is imperative that the surgeon caring for these patients rule out the most serious complications first, namely, bile duct injury, bleeding, and retained choledocholithiasis. The use of diagnostic tools and therapeutic options and the systematic approach outlined in this chapter should provide the caregiver with enough data to accurately diagnose and treat the etiology of a patient's PCPs. The vast majority of the time, these problems will be organic in nature and therefore treatable. However, we have described the diagnostic dilemma that SOD presents, and it is imperative that a stepwise, logical methodology also be applied to these patients whose outcomes are less gratifying.

CHAPTER 39

Intrahepatic stones

Yuji Nimura and Yuichi Kitagawa

OVERVIEW

Although hepatolithiasis is a rare disease prevalent only in East Asia—including China, Hong Kong, Korea, and Japan—it has increasingly been encountered in Western countries (Herman et al, 2005; Vetrone et al, 2006; Catena et al, 2006; Nuzzo et al, 2008; Al-Sukhni et al, 2008). Patients with intrahepatic stones follow a specific clinical course characterized by recurrent cholangitis with recurrent stones or liver abscess, which may cause pyogenic sepsis or liver dysfunction and result in biliary cirrhosis. Advances in hepatobiliary diagnostic modalities have allowed more precise delineation of the biliary anatomy and extent of disease, and the application of modern treatment modalities has resulted in a longer stone-free period over the past 2 decades. Intrahepatic stones include brown pigment stones (calcium bilirubinate stones), cholesterol stones, and other rare types. The majority of intrahepatic stones are brown pigment stones. Some centers, not only in Asia but also in Western countries, have reported increasing numbers of patients with primary cholesterol stones originating in the liver.

DEFINITION AND SURGICAL ANATOMY

Intrahepatic stones are defined as concretions existing in the intrahepatic bile ducts. Although the confluence of the hepatic ducts is situated outside of the parenchyma of the liver, for convenience an *intrahepatic bile duct* is defined as any bile duct proximal to the confluence of the right and left hepatic ducts. Established by the Japanese Ministry of Health, Labor, and Welfare, the Japan Research Group for the Study of Hepatolithiasis proposed a classification of patients with hepatolithiasis into two groups: *type I* patients have stones only in the intrahepatic bile duct, and *type IE* patients have stones in the intrahepatic and extrahepatic bile ducts. Patients are classified further by location of stones within the liver: right side (*type R*), left side (*type L*), right and left sides (*type LR*), and caudate lobe (*type C*) (Nimura et al, 2005).

In Japan, the proportion of type I intrahepatic stones was 20.6% from 1975 through 1979, increasing to 45.5% from 1989 through 1992 (Tanimura et al, 1994). In Hong Kong, type I constituted 51% of intrahepatic stones from 1991 to 1996 (Liu et al, 1998). In Kaohsiung, Taiwan, the percentage of type I stones was 18.3% from 1980 through 1986 (Yuan et al, 1990). In addition to the findings in East Asian countries, type I intrahepatic stones were diagnosed in 77.3% of patients between 1986 and 2003 in Bologna, Italy (Vetrone et al, 2006).

Many patients with intrahepatic stones are reported to have no stones in the gallbladder. Yuan and colleagues (1990) reported that only 62 (30.7%) of 202 patients with intrahepatic stones had stones in the gallbladder. Regarding distribution of stones in the liver, type L is reported to be dominant. In Japan, the rate was 45.5% for type L, 26.1% for type R, and 26.3% for type LR for 1989 through 1992. The distribution was 52.1% (type L), 11.5% (type R), and 31.3% (type LR) in Hong Kong and 55% (type L), 18.3% (type R), and 26.7% (type LR) for 1989 through 1992 and 71.5% (type L), 16.2% (type R), and 12.2% (type LR) from 2000 through 2005 in Taiwan (Lee et al, 2007). Similarly, it was 59.0% (type L), 18.3% (type R), and 22.7% (type LR) for 1986 through 2003 in Italy (Vetrone et al, 2006). The incidence of stones in the caudate lobe (type C) was reported to be 6.6% (Nimura et al, 1998).

Hepatobiliary radiologists, endoscopists, and surgeons should have a thorough knowledge of the segmental and subsegmental anatomy of the intrahepatic bile ducts for preoperative diagnosis of intrahepatic stones, for an understanding of the variations of the intrahepatic biliary tree, and for decision making about therapeutic approaches to difficult biliary stenosis (see Chapter 1). The subsegmental anatomy of the intrahepatic bile ducts (Fig. 39.1) was established on the basis of clinical cholangiograms (Nimura, 1997). This cholangiographic anatomy is related to the radiologic study of the intrahepatic portal branches (Takayasu et al, 1985). The left lateral segmental ducts (B2, lateral posterior branch; B3, lateral anterior branch) join just behind the umbilical portion of the left portal vein. The left medial segmental duct (B4) enters this common trunk on the right of the umbilical portion of the left portal vein and forms the left hepatic duct. Segmental ducts B3 and B4 may make a common trunk that B2 joins to form the left hepatic duct. The right *anterior* segmental branches are superimposed over the right *posterior* segmental branches and are difficult to distinguish from each other on clinical cholangiograms taken with the patient in a supine position; they are divided clearly by the right hepatic vein on cholangiograms taken with the patient in the right lateral position, the right anterior in the left cranial area, and the right posterior in the right caudal area. The right posterior segmental duct joins the left hepatic duct in 12.6% of Taiwanese patients and 16.8% of Japanese patients with intrahepatic stones. This is an important anatomic variation when considering the distribution of intrahepatic stones (Kitagawa et al, 2003).

PATHOLOGY

Intrahepatic calcium bilirubinate stones are composed mainly of bilirubin, cholesterol, fatty acids, and calcium. They are dark brown, soft, and friable. On a cut surface, a lamellar structure can be seen (Fig. 39.2). Stones are frequently located in the large bile ducts, such as the common, right, or left hepatic ducts.

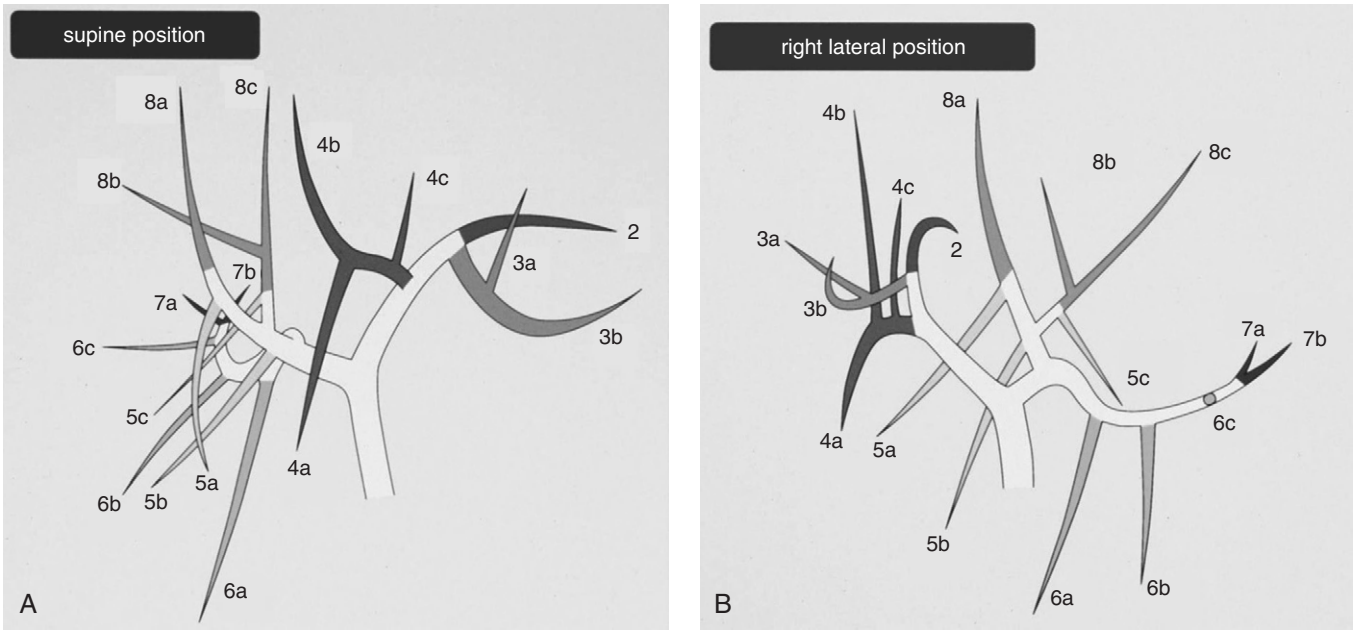

FIGURE 39.1. Cholangiographic anatomy of the intrahepatic segmental ducts according to the patient's position. Numerals refer to Couinaud's segments. *3a*, Superior branch; *3b*, inferior branch; *4a*, inferior branch; *4b*, superior branch; *4c*, dorsal branch; *5a*, ventral branch; *5b*, dorsal branch; *5c*, lateral branch; *6a*, ventral branch; *6b*, dorsal branch; *6c*, lateral branch; *7a*, ventral branch; *7b*, dorsal branch; *8a*, ventral branch; *8b*, lateral branch; *8c*, dorsal branch (Nimura et al, 1997).

Diffuse dilation of the biliary tree, chiefly of the stone-containing ducts and their merging peripheral branches, and stenosis-like ductal lesions distal to the stones are commonly noted.

The histologic changes of the bile ducts with calcium bilirubinate stones are classified as either 1) chronic proliferative cholangitis, 2) suppurative cholangitis, or 3) chronic granulomatous cholangitis (Nakanuma et al, 1981). *Chronic proliferative cholangitis* consists of extensive proliferation of fibrous connective tissue in the ductal wall, moderate to severe infiltration of the inflammatory cells (primarily lymphocytes), and proliferation of mucin-producing glandular elements in the ductal wall. *Suppurative cholangitis* is characterized by ulceration and suppurative inflammation of the ductal wall. Chronic granulomatous cholangitis is characterized histologically by prominent granulomatous changes in the ductal wall and periductal tissues.

In chronic proliferative cholangitis, histologic observation shows that most proliferative glands in the ducts have mucin-producing activity. These glands are observed to secrete a large amount of sialylated and sulfated acid mucins into the lumen (Maki et al, 1971; Sasaki et al, 1996). The affected part of the liver frequently shows atrophic changes. When the whole liver is involved, patients with intrahepatic stones may develop biliary cirrhosis and portal hypertension.

Intrahepatic cholesterol stones are composed mainly of cholesterol. They are yellow, small, and hard (Fig. 39.3). On a cut surface, a radial or crystalloid structure can been seen. Bile ducts containing cholesterol stones generally show a milder degree of fibrosis and glandular hyperplasia than ducts with calcium bilirubinate stones. Foamy cell aggregates and multinucleated giant cells are characteristic findings in patients with intrahepatic cholesterol stones.

FIGURE 39.2. Cut surface of a resected liver specimen shows dilated intrahepatic ducts filled with calcium bilirubinate stones. On the cut surface, a lamellar-like structure is seen.

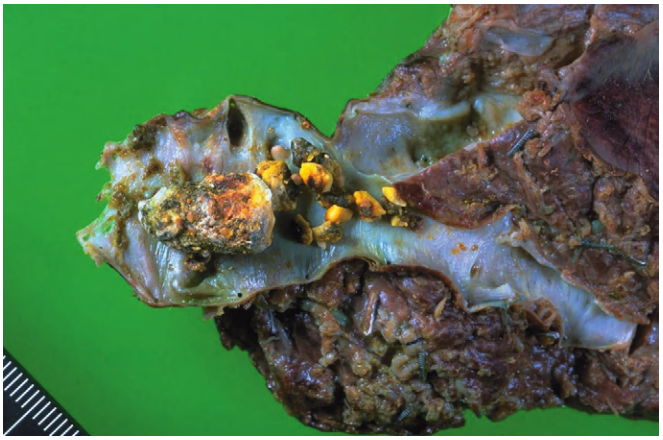

FIGURE 39.3. Resected liver specimen shows dilated bile duct with cholesterol stones.

Long-standing chronic cholangitis with biliary epithelial regeneration may be causally related to its malignant transformation, and several studies have demonstrated cholangiocarcinogenesis related to hepatolithiasis. Intraductal papillary growth of neoplastic epithelia in the liver (IPNL) is associated with hepatolithiasis and often displays variable gastroenteric metaplasia and significant intraductal spread. A continuous histologic spectrum may be observed, from papillary growths with low-grade and high-grade dysplasia to carcinoma in situ and finally to invasive carcinoma, particularly mucinous carcinoma (Chen et al, 2001). Mucin-secreting tumors of the intrahepatic biliary tract show frequent expression of *MUC2* and nuclear *CDX2*. *MUC2* expression in intestinal differentiation is closely related to the expression of *CDX2* in IPNL, and mucinous intrahepatic cholangiocarcinoma (ICC) is associated with hepatolithiasis in the same manner as intestinal metaplasia in gastric mucosa and Barrett esophagus. This suggests that a common pathway of carcinogenesis may be involved in ICC with hepatolithiasis, gastric carcinoma, and adenocarcinoma in Barrett esophagus, in which *CDX2*-dependent intestinal metaplasia develops (Ishikawa et al, 2004). Further studies revealed that two types of neoplastic lesions preceding invasive ICC were identified: a flat-type neoplastic lesion called *biliary intraepithelial neoplasia* (BilIN) and *intraductal papillary neoplasm of the bile duct* (IPNB) or IPNL. Multistep carcinogenesis has been suggested in both lesions, and immunophenotypes of *MUCs* and cytokeratins might characterize three cholangiocarcinogenetic pathways in hepatolithiasis. IPNB and increased expression of *MUC1* in BilIN are associated with tubular adenocarcinoma, and colloid carcinoma in IPNB is characterized by *MUC1*-negativity and less advanced pathologic stages (Zen et al, 2006).

Further immunohistochemical studies reveal that decreased membranous expression of β-catenin and E-cadherin is an early event in the tumorigenesis of both BilIN and IPNB lineages. However, different expression of cancer-related molecules was suggested in the progression of the BilIN and IPNB lineages in cholangiocarcinogenesis related to hepatolithiasis. The expression of matrix metalloproteinase (MMP) 7 and membrane type (MT) 1 MMT was closely associated with invasive growth of the BilIN lineage, and the *Wnt* signaling pathway may play an important role in the tumorigenesis of the IPNB lineage (Itatsu et al, 2007). The reported incidence of ICC detected at operation varies from 1.4% to 13% in Asian countries (Jeng et al, 1996; Liu et al, 1998), and it was 8.6% (three of 35 cases) in an Italian hospital (Nuzzo et al, 2008). A report from Hong Kong that assessed the long-term efficacy of hepatic resection for stone clearance in 103 patients noted cholangiocarcinoma in 10 patients (four known preoperatively) at the time of operation and in another three patients during follow-up (Chen et al, 2004). A similar report from Taiwan showed that three (2.4%) of 123 patients with intrahepatic stones had associated cholangiocarcinoma at the time of hepatectomy, and two (1.6%) had cholangiocarcinoma develop during a median follow-up of 40 months (range, 5 to 58 months) (Lee et al, 2007). Patients with retained stones or recurrent hepatolithiasis after percutaneous transhepatic cholangioscopic lithotomy have a high incidence of cholangiocarcinoma; four (17%) of 23 cases during a median follow-up of 11 years (range, 1 to 23 years; Chen et al, 2005). Intrahepatic stones associated with ICC are calcium bilirubinate stones in 89.1% of reported cases (57 of 64 cases; Sato et al, 1998). An autopsy case of intrahepatic cholesterol stones with peripheral ICC was reported, in which the causal relationship between the stones and the carcinoma remained speculative (Terada et al, 1989).

ETIOLOGY

Most intrahepatic stones appear as brown pigment (calcium bilirubinate) stones on macroscopic inspection and infrared analysis. The chemical composition of intrahepatic calcium bilirubinate stones is not identical to that of brown pigment stones in the extrahepatic bile ducts; the former contain more cholesterol and less bilirubin and bile acid and include lesser amounts of bile acids modified by bacterial metabolism (Shoda et al, 1991, 2003; Yamashita et al, 1988). The high incidence of bactibilia in patients with intrahepatic calcium bilirubinate stones suggests a relationship between bacteria and formation of stones (Maki, 1966). Among the bacteria in bile, *Escherichia coli*, *Clostridium* spp., and *Bacteroides* spp. show β-glucuronidase activity and are thought to be responsible for the hydrolysis of bilirubin glucuronide, the water-soluble form of bilirubin in bile, to free unconjugated bilirubin, which is water insoluble and combines with ionized calcium in bile to form calcium bilirubinate; this leads to stone formation. Bacterial infection alone cannot explain why intrahepatic brown pigment stones contain a higher amount of cholesterol than stones in the extrahepatic ducts. Upregulated cholesterogenesis and downregulated bile acid synthesis in the liver may be one of the causative factors responsible for the formation of hepatic bile substantially supersaturated with cholesterol, which leads to subsequent formation of cholesterol-rich stones (Shoda et al, 1995, 2003).

It is suggested that the risk factors of intrahepatic stone formation after surgery for choledochal cyst are anastomotic stricture, residual debris in the intrahepatic ducts, and dilated intrahepatic bile ducts. A Japanese surgical study reported secondary hepatolithiasis that developed after choledochal cyst excision with hepaticoenterostomy (CEHE). Although no stone formation was seen in the 145 children who had CEHE at the age of 5 years or younger, three (5.5%) of 55 children older than 5 years who underwent CEHE had intrahepatic stones develop. On the other hand, intrahepatic stones developed in five (12.5%) of the 40 adult patients with CEHE. Two of the five developed anastomotic stricture of the end-to-side hepaticojejunostomy distally to the stone at the porta hepatis with or without left intrahepatic duct dilation. The incidence of post-CEHE hepatolithiasis in children aged 5 years or younger was significantly lower than in other children and adults. In addition to the hepatolithiasis, one adult developed ICC at age 54 years, 6 years after CEHE converted from cholecystectomy performed 16 years previously (Yamataka et al, 1997). On the other hand, intrahepatic stones developed in patients with biliary atresia who had undergone hepatic portoenterostomy, and almost 100% calcium bilirubinate stones were found in bile lake in the resected liver (Tainaka et al, 2006).

A study from Taiwan investigated the possible association between biliary helminthic infestation (ascariasis or clonorchiasis) and hepatolithiasis (Huang et al, 2005). By using immunologic techniques, the authors showed a higher prevalence of ascariasis and clonorchiasis in patients with intrahepatic stones than in control subjects (33.6% vs. 17.4%; $P = .005$). However, analysis of patients with hepatolithiasis with and without evidence of helminthic infestation showed no differences in the rates of biliary stricture formation, stone recurrence, secondary biliary cirrhosis, or cholangiocarcinoma. An epidemiologic

study suggested that lower socioeconomic and hygienic status may be involved in stone formation in Taiwan (Momiyama et al, 2008). In the Kami-Goto Islands of Japan, where incidence of this disease is high, there were similar hygienic and social problems from the 1960s to the 1980s. However, there has been no new case of hepatolithiasis in the generation born after the 1970s, after improvements in the environment and economic status (Yasaka, 2008).

The most important factors for the formation of intrahepatic calcium bilirubinate stones are biliary stasis, bacterial infection, and biliary mucin produced from the covering and proliferated mucous gland epithelium of the intrahepatic bile ducts. Calcium bilirubinate and fatty acid–calcium soap occur through hydrolysis of bilirubin conjugates and lecithin by bacterial β-glucuronidase and phospholipase in bile. These salts can precipitate and form microcalculi, particularly if a nidus is present, such as desquamated epithelium or biliary mucin (Forstner & Forstner, 1975). These microcalculi coalesce to form large stones. Chronic proliferative inflammation seems to precede bile duct damage: the development of intrahepatic stones leads to biliary strictures, which promote further propagation of stones through alterations of bile flow (Nakanuma et al, 1988).

A study on the biliary dynamics of patients with intrahepatic stones revealed that the time-activity curves of technetium-99m-ethylenediaminetetraacetic acid (EDTA) were prolonged significantly in affected and apparently unaffected intrahepatic bile ducts compared with the curves in normal subjects (Takahashi et al, 1986). This result suggests a global impairment of bile flow, even when only one side of the liver is affected by stones. The curves in the intrahepatic bile ducts of the left lobe were more prolonged than those of the right lobe, even in normal liver; this prolongation could explain why involvement of the left lobe is more common.

Sphincter of Oddi motility has been analyzed in patients with intrahepatic and common bile duct (CBD) stones by percutaneous transhepatic manometry (Yuasa et al, 1994). This study disclosed no significant manometric differences among three groups—an intrahepatic stone group, a cholecystectomy group with CBD stones, and a noncholecystectomy group with CBD stones—with the exception of the higher frequencies and greater duration of burst contractions during duodenal phase III of the migrating motor complex in the cholecystectomy group with CBD stones, although this abnormality probably plays little role in the etiology of intrahepatic stones.

Indirect evidence suggests that metabolic factors play a more important etiologic role in intrahepatic cholesterol stones. Cholesterol supersaturation and microscopic cholesterol crystallization, which represent major stages in the formation of cholesterol gallbladder stones, have been observed in the hepatic bile of patients with intrahepatic cholesterol stones (Schillio et al, 1992: Strichartz et al, 1991). Activity of apolipoprotein A1, which is one of the inhibiting factors of cholesterol nucleation in bile, is reported to be decreased in the hepatic segments containing cholesterol stones (Ohta et al, 1993).

SIGNS AND SYMPTOMS

Abdominal pain, either in the right upper quadrant or in the upper abdomen, is the most frequent initial symptom observed in 70% of hepatolithiasis patients (Tanimura et al, 1994). Jaundice and fever follow and are present in 10% to 30% of cases. Other abdominal complaints, including abdominal discomfort and vomiting, are also observed. These symptoms are not pathognomonic for intrahepatic stone disease. Asymptomatic cases have increased in number to 16.1% because of advances in diagnostic imaging modalities and more frequent medical checkups. Previous biliary operations for calculous disease had been performed in 42.1% of patients with intrahepatic stones, and 22.2% had had two or more operations, indicating an intractable course of disease.

DIAGNOSIS

With the introduction of various new imaging modalities, intrahepatic stones are now diagnosed more accurately before surgery. Ultrasonography (US) is a noninvasive, reliable, and inexpensive procedure. It may reveal features of biliary obstruction, stones in the biliary system, pneumobilia, or liver abscesses. The major findings of stones on US examination are hyperechoic lesions with acoustic shadows or ductal dilation (Choen et al, 1991; Itai et al, 1980; Lim et al, 1990). Interpretation may be difficult, however, owing to the presence of pneumobilia as a result of a previous papillotomy or biliary-enteric anastomosis. In addition, intrahepatic stones that do not cast a sonic shadow may not be well visualized on US.

Computed tomography (CT) provides information regarding the location and composition of stones and generally offers more anatomic detail, which is necessary for decisions regarding definitive treatment. Round or oval high-density shadows in the dilated ducts are a sign of intrahepatic calcium bilirubinate stones (Fig. 39.4); the false-positive rate is quite low (Itai et al, 1980; Menu et al, 1985). Cholesterol stones or pigmented stones containing less calcium are hard to detect, so it is important to examine noncontrast films first (Fig. 39.5), because intrahepatic stones may be less conspicuous after parenchymal enhancement. Pneumobilia does not hinder the CT evaluation of the biliary system. In addition, CT determines the degree of atrophy of the affected part of the liver and detects the segmental or subsegmental duct involvement when cholangiography fails to visualize these ducts; CT also provides an accurate localization of liver abscesess, raises the suspicion of cholangiocarcinoma, and detects the presence of portal hypertension as a result of biliary cirrhosis. Accurate diagnosis of cholangiocarcinoma is difficult, however, because small tumors often appear as abscesses or escape detection altogether, even on high-quality helical CT scans. Park and colleagues (2006) reported several factors that were significantly associated with cholangiocarcinoma in patients with hepatolithiasis: 1) presence of periductal soft-tissue density, 2) higher enhancement of the duct than adjacent bile duct on portal venous phase images, 3) ductal thickening, 4) portal vein obliteration, and 5) lymph node enlargement.

Magnetic resonance imaging (MRI), especially MR cholangiopancreatography (MRCP), is useful for the defining stone location, obstructed intrahepatic segmental ducts, and bile duct anatomy (Kim et al, 2002; Park et al, 2004). In some cases, the bile duct diameter can be calculated for evaluation of bile duct dilation and stricture (Nimura et al, 2005).

If these modalities show intrahepatic stones only in the left lobe, no more imaging investigations for deciding the surgical intervention may be necessary. If stones are located in the right liver or are bilateral, however, percutaneous transhepatic biliary drainage (PTBD) followed by percutaneous transhepatic cholangioscopy (PTCS) should be done to determine the optimal treatment (Nimura et al, 1981, 1988). US, CT, and MRCP

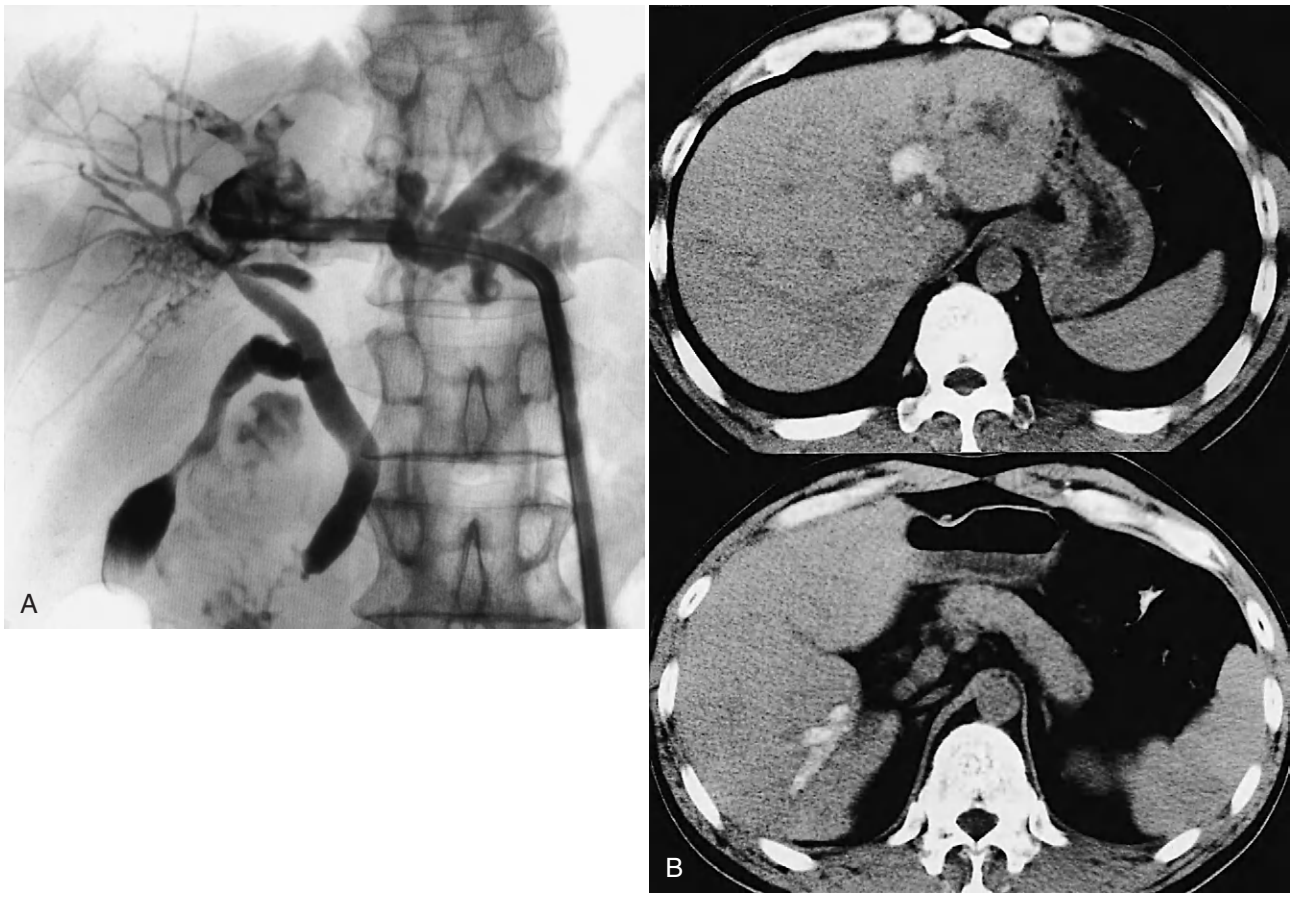

FIGURE 39.4. Intrahepatic calcium bilirubinate stones. **A,** Cholangiography through a percutaneous transhepatic biliary drainage catheter shows multiple filling defects in the dilated intrahepatic bile ducts. **B,** Precontrast computed tomography shows high-density shadows in the left lobe and right posterior sector.

provide less precise information about segmental and subsegmental anatomy of the intrahepatic bile ducts and strictures than percutaneous transhepatic cholangiography (PTC), tube cholangiograms via PTBD, or selective cholangiography by PTCS. Endoscopic retrograde cholangiopancreatography (ERCP) frequently misdiagnoses intrahepatic stones, because intrahepatic bile ducts peripheral to stones and strictures are often poorly visualized. ERCP has the other associated disadvantage of potentially causing cholangitis in patients with multiple intrahepatic stones.

With the aid of US, dilatated intrahepatic radicles can be accurately punctured and visualized by PTC, although this

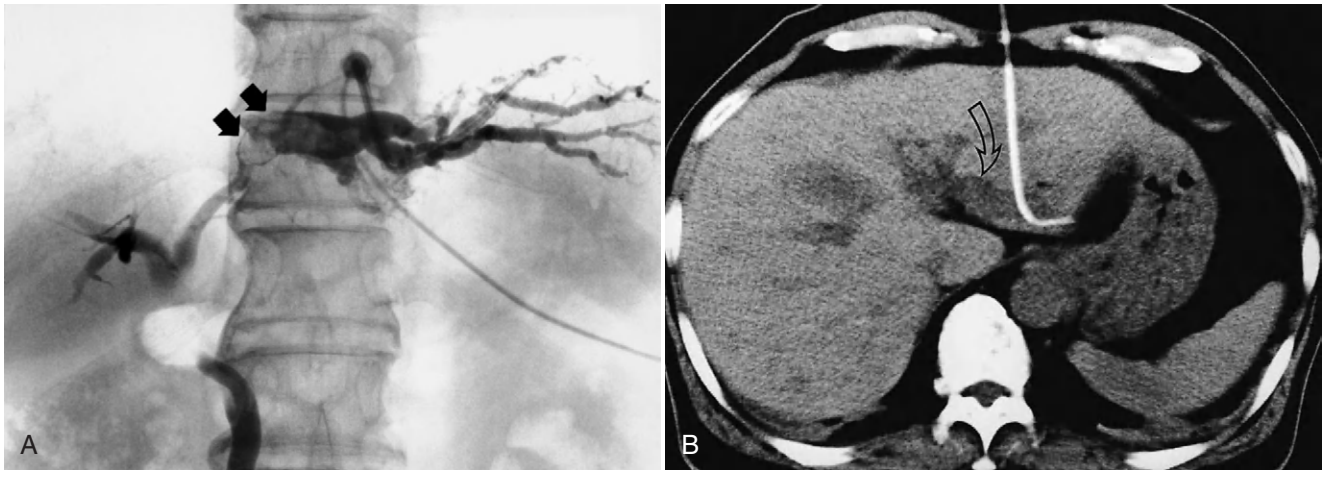

FIGURE 39.5. Intrahepatic cholesterol stones. **A,** Cholangiography through a percutaneous transhepatic biliary drainage catheter shows filling defects (*arrows*) in the dilated intrahepatic bile ducts of the left lateral posterior segment (S2). **B,** Precontrast computed tomography shows low-density shadows (*arrow*) in S2.

does not always provide sufficient biliary information, owing to impacted stones, mud, or mucin in the intrahepatic ducts. Tube cholangiography via PTBD and selective cholangiography by PTCS are more informative than PTC, because the images are obtained after biliary drainage, which decompresses the biliary tree and decreases mud or mucin around the stones thereby improving visualization. Because cholangiograms can be taken from various projections, such as right/left anterior oblique or right/left lateral positions, for defining the segmental anatomy of the intrahepatic biliary tree, PTCS makes it possible to obtain clear, selective cholangiograms before and after removal of impacted stones.

Patients with calcium bilirubinate stones seem to have more frequent biliary strictures with proximal biliary dilation on cholangiogram than patients with other types of stones, although some are false findings that disappear on cholangiograms after cholangioscopic lithotomy. A thin flow of contrast medium through the narrow space between stones and the bile duct wall may appear as a false stricture on cholangiography, but a true biliary stricture should be definitely diagnosed as a localized and unchanging diminution of the bile duct caliber. Whether biliary strictures with proximal biliary dilation cause stone formation or result from stones and repeated infections is an open question.

Making the diagnosis of associated cholangiocarcinoma is difficult, because intrahepatic stones and strictures hinder clear visualization of the intrahepatic ducts in their entirety on cholangiography. As diagnostic clues, the importance of persistent filling defects and obliteration of the involved intrahepatic ducts on cholangiography, mucobilia and mucosal changes on cholangioscopy, and gross appearance are emphasized (Chen et al, 1993).

TREATMENT

For patients with acute obstructive suppurative cholangitis, emergency PTBD is indicated and is preferable to operative and endoscopic transpapillary approaches, and local anesthesia for PTBD can alleviate much of the risk to such critically ill patients. Emergency exploration does not allow a definitive treatment and may not provide adequate biliary decompression (Cheung et al, 2005). An endoscopic transpapillary approach is an effective and safer treatment for distal bile duct stones (Cotton et al, 1998), but further studies are required to clarify the therapeutic benefit of this approach.

With the refinement of fiberoptic cholangioscopes and the development of percutaneous transhepatic approaches to the bile ducts, PTCS has allowed nonsurgical removal of intrahepatic stones (Nimura et al, 1981, 1988). The size of extractable stones is limited, however, by the caliber of the PTBD sinus tract. The presence of a biliary stricture in association with intrahepatic stones often makes stone extraction more difficult. To overcome this, laser cholangioscopy has been applied for intrahepatic stones with some success (Hayakawa et al, 1981), and electrohydraulic lithotripsy during cholangioscopy has facilitated extraction of larger stones (Matsumoto et al, 1987). Electrohydraulic lithotripsy is a unique method to disintegrate stones by means of shock waves generated by an electric discharge in a liquid medium. Under cholangioscopic control, the lithotriptor probe can be kept in contact with stones during application of discharge sparks to avoid any damage to the bile duct wall.

Hepatic resection may remove not only the stones and the strictures that led to their formation but also the consequences of repeated injury, such as cholangiocarcinoma. In general, hepatectomy is indicated when a sector or a lobe of the liver is grossly atrophic (Fan et al, 1993; Otani et al, 1999). In addition to atrophic liver, indications for hepatectomy include multiple intrahepatic strictures and cystic dilation of the peripheral intrahepatic bile duct that cannot be managed by endoscopic or radiologic intervention, particularly if the left lobe or the left liver is involved. The surgical mortality rate associated with hepatic resection in this setting is low, but morbidity rates are substantial. When PTCS shows biliary strictures involving the right or left hepatic duct or the biliary confluence, and the liver parenchyma is relatively normal, an end-to-side hepaticojejunostomy (Roux-en-Y) is performed based on the location and level of stricture. Hepatic resection with hepaticojejunostomy may be indicated when PTCS reveals a biliary stricture at the hepatic confluence in a patient with bilateral intrahepatic stones. If the function of the sphincter of Oddi deteriorates, hepaticojejunostomy is mandated.

With advances in interventional radiologic management of residual or recurrent intrahepatic stones with biliary strictures, percutaneous dilation therapy has become the initial treatment of choice for difficult biliary strictures. A wide array of devices, including balloon catheters and metallic stents, are available for possible use in dilation therapy. The clinical value of percutaneous transhepatic placement of metallic stents for benign biliary strictures must be critically evaluated, because clogging, recurrence of intrahepatic stones, and local effect of the material on the bile duct wall often greatly complicate subsequent treatment.

For patients with difficult bilateral intrahepatic stones with bilateral biliary strictures, a stepwise approach is advocated (Nimura, 1984):

1. PTBD through B3 or the left hepatic duct is performed via a direct anterior approach, which has several advantages in the management of right intrahepatic stones. The most advantageous point is easy accessibility of a cholangioscope to the right intrahepatic ducts, especially to the right posterior sectoral ducts, which are much more difficult to access via intraoperative cholangioscopy or postoperative cholangioscopy through a T-tube sinus tract or jejunal loop.
2. The PTBD sinus tract is dilated step by step. One week after the PTBD, the 6-Fr drainage catheter is replaced by a 10- or 11-Fr (PTCS) catheter (Fig. 39.6). The tract is dilated by exchanging the catheter for a larger one a few times a week, until a 16-Fr catheter can be introduced approximately 2 weeks after the initial PTBD. During this period, CT and US reveal pathologic changes of the liver. A hepatectomy is indicated in cases of unilateral atrophy of the liver as discussed earlier.
3. Cholangioscopic lithotomy is performed mainly in the hepatic sectors or lobes that will be preserved. If intrahepatic bile duct stenosis hinders the cholangioscopic lithotomy, the ducts should be dilated by introducing a 12- or 15-Fr PTCS catheter. Advances in lithotripsy technology make it possible to remove impacted stones without difficulty, and lithotripsy is warranted if the affected sectors or lobes are not atrophic. PTCS allows definition of biliary stenosis before surgical treatment. In the case of biliary stenosis at the hepatic hilus,

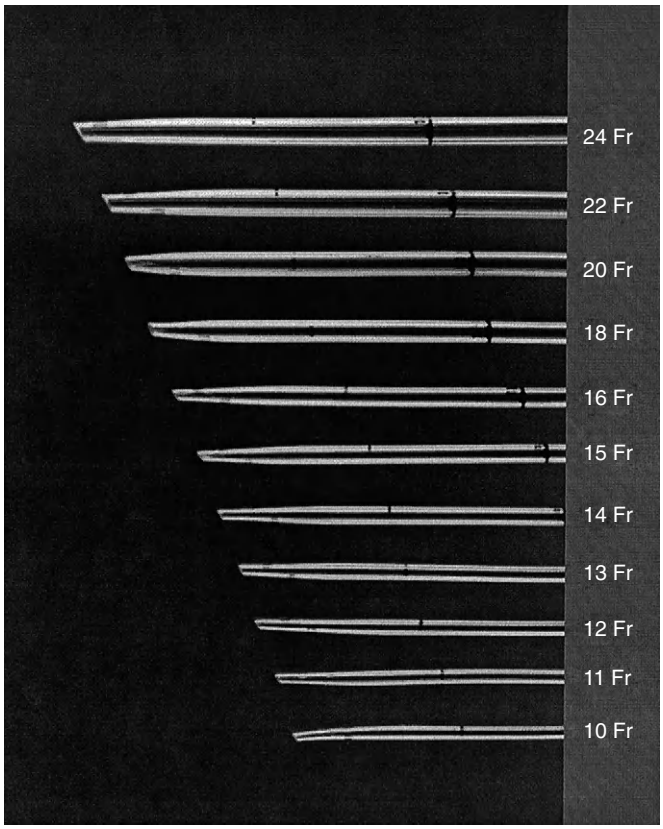

FIGURE 39.6. Percutaneous transhepatic cholangioscopy catheters. Drainage catheters in 11 sizes (10 to 24 Fr) with a tapered tip and two side holes.

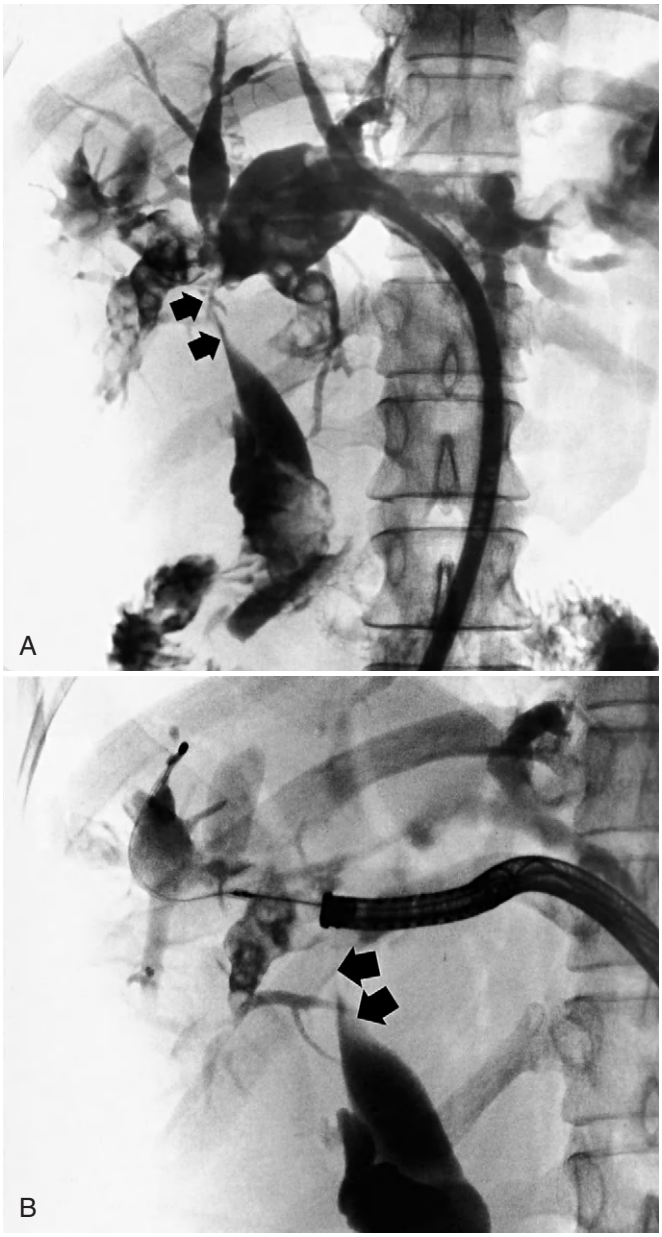
hilar bile duct resection with hepaticojejunostomy is indicated (Fig. 39.7).

4. If neither atrophy nor strictures are seen after cholangioscopic lithotomy, surgery is not recommended. Cholecystectomy may be indicated in patients with documented cholelithiasis. In cases of hepatic sectoral or lobar atrophy without biliary stricture at the hepatic hilus, cholecystectomy, hepatectomy, choledochotomy, intraoperative cholangioscopy, and T-tube placement without biliary-enteric anastomosis are recommended (Fig. 39.8). For a patient with some element of atrophy and a stricture at the hepatic duct confluence, hilar bile duct resection with hepaticojejunostomy should be performed in addition to cholecystectomy, hepatectomy, and intraoperative cholangioscopy. If a biliary stricture is defined only at the hepatic duct confluence after endoscopic lithotomy by PTCS, cholecystectomy, hilar bile duct resection, intraoperative cholangioscopy, and hepaticojejunostomy are indicated.
5. In patients subjected to surgical intervention, postoperative cholangioscopy should be performed to assess for and possibly treat residual stones and to evaluate the postoperative changes of the intrahepatic biliary strictures. If the treatment effect is insufficient, biliary stenting with a silicone catheter should be applied.

Regarding treatment of intrahepatic cholesterol stones, it is recommended to select a nonsurgical approach as the first treatment of choice (Fig. 39.9; Kondo et al, 1995). On the contrary, a high incidence (16 of 35 cases) of intrahepatic cholesterol stones was reported from a European institution, and



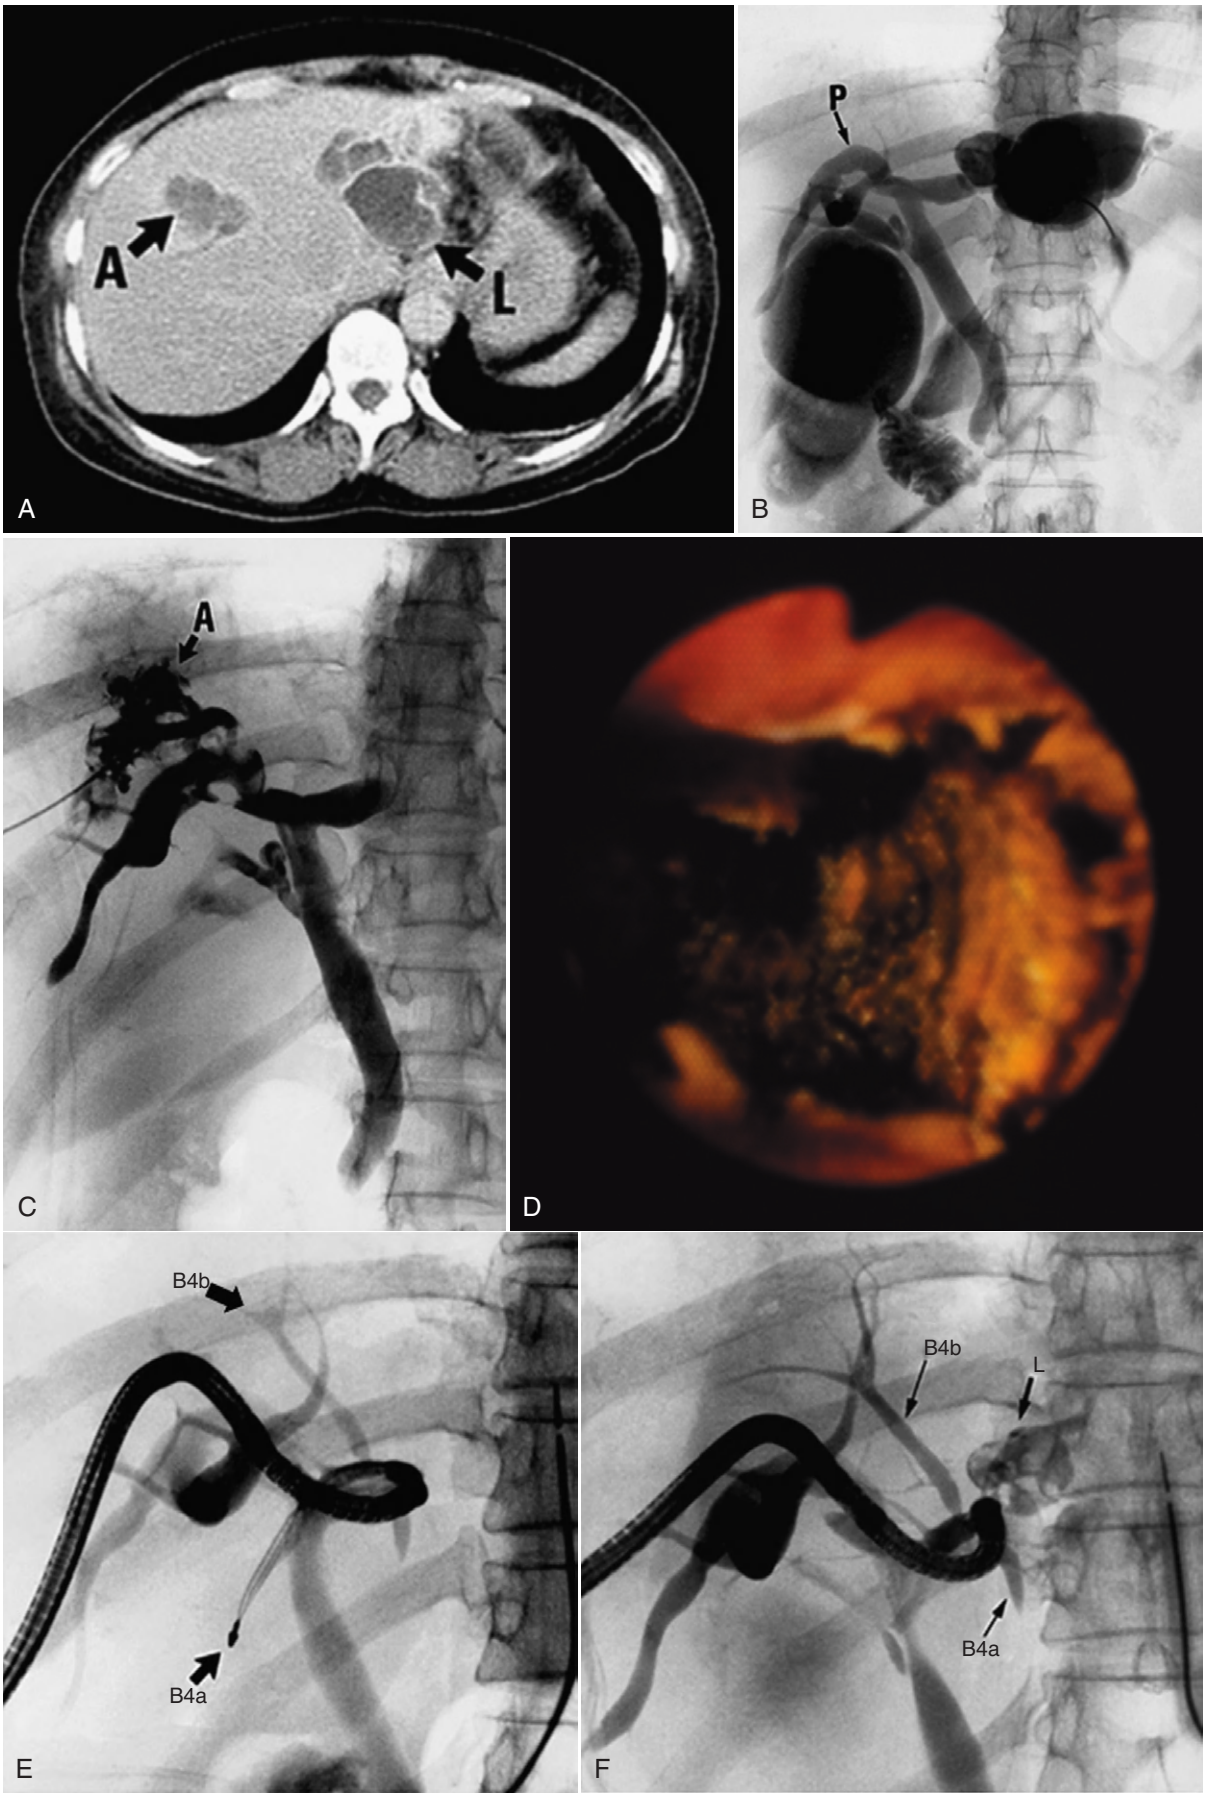


FIGURE 39.7. Bilateral intrahepatic stones with biliary stenosis at the hepatic hilus. **A,** Cholangiogram through a percutaneous transhepatic cholangioscopy (PTCS) catheter revealed severe biliary stenosis at the hepatic hilus (*arrows*). The patient had undergone biliary operations twice without any clinical improvement: first, a choledochoduodenostomy, then a choledochotomy with T-tube drainage. **B,** Cholangiogram during PTCS lithotomy showed marked proximal bile duct stenosis (*arrows*) aremaining after removing most stones in the liver, an indication for hilar bile duct resection with hepaticojejunostomy.

partial hepatectomy is recommended as a safe and effective procedure (Nuzzo et al, 2008). An ERCP approach does not seem feasible because of the generally inaccessible location of the intrahepatic stones. Extracorporeal shock-wave lithotripsy may be effective, especially in combination with dissolution therapy (Okugawa et al, 2002; Staritz et al, 1990). Improvement in bile composition has been reported after oral dissolution therapy in patients with intrahepatic cholesterol stones,

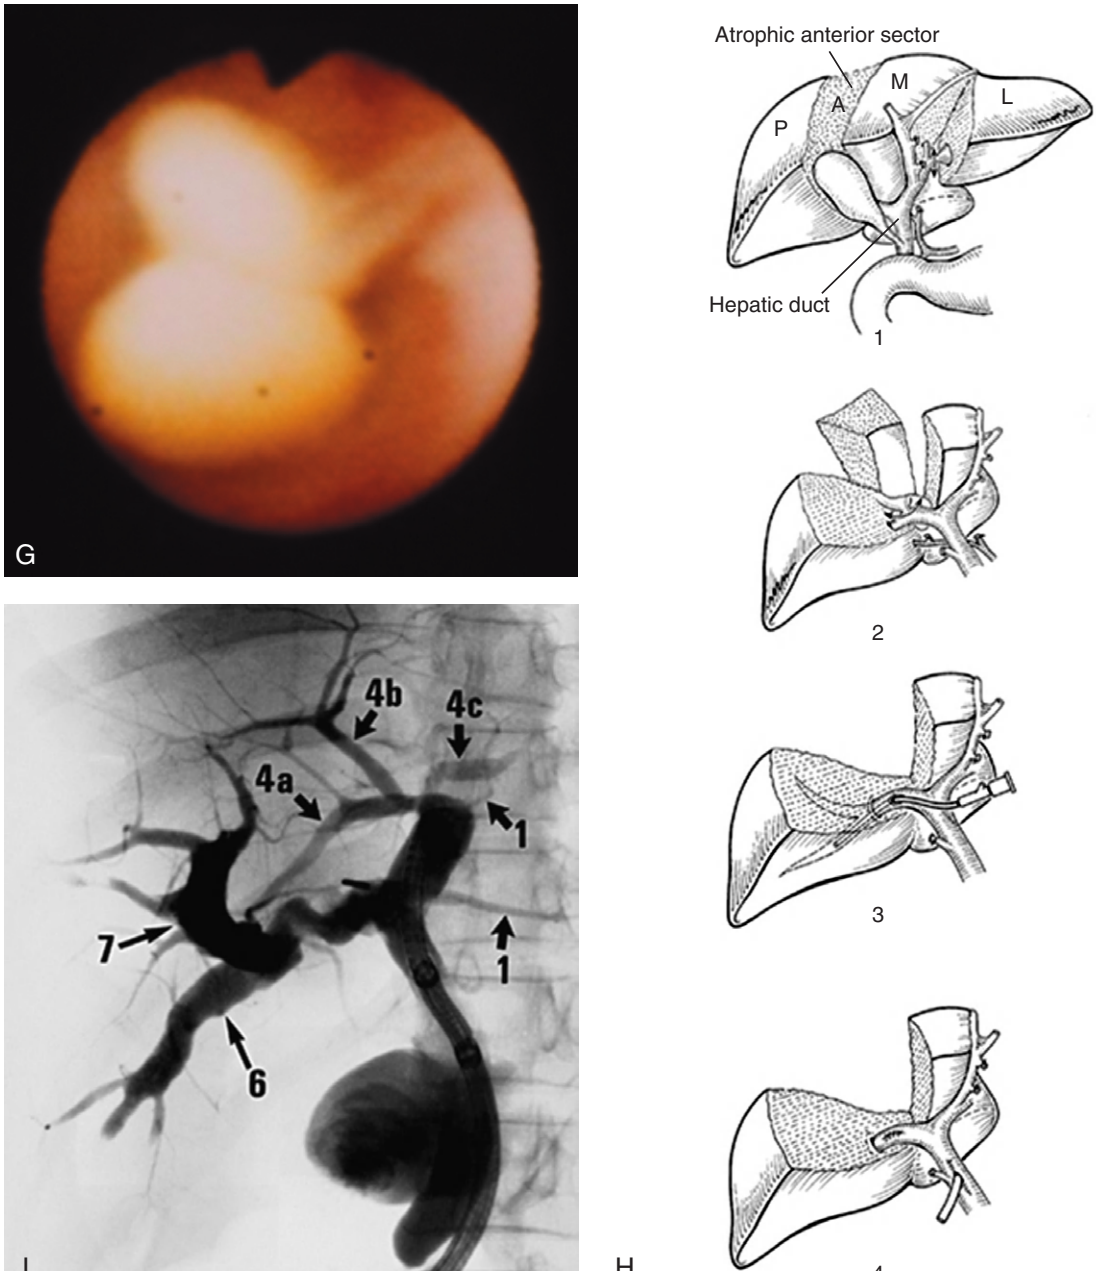

FIGURE 39.8. A case of bilateral intrahepatic stones. **A,** Computed tomography showed two low-density lesions in the left lobe (*L*) and the right anterior sector (*A*) where ultrasound (US) had revealed stones. These two parts of the liver seemed to be atrophic. **B,** US-guided percutaneous transhepatic cholangiography (PTC) revealed the dilated intrahepatic bile ducts of the left lobe. The right posterior sectoral duct (*P*) is shown, but the right anterior sectoral duct is not visualized. **C,** Selective PTC of the right anterior sectoral duct (*A*) was done under US guidance. The right anterior sectoral duct was irregularly dilated and filled with many stones, which made it difficult to make a definite diagnosis of the pathology of the right anterior sectoral duct. Post hoc, percutaneous transhepatic biliary drainage was performed into the right anterior sectoral duct to allow a precise diagnosis. **D,** Cholangioscopic lithotomy was carried out, and an impacted calcium bilirubinate stone was found at the confluence of the right anterior and posterior sectoral ducts and removed. **E,** A cholangioscope was introduced into the left hepatic duct through the right anterior sectoral duct, and selective cholangiograms of the left medial segment (*4a, 4b*) were obtained; that segment was free of hepatolithiasis. After cholangioscopic lithotomy, it became possible to introduce the cholangioscope into the right and left hepatic ducts. **F,** Selective cholangiography of the left lateral segmental ducts (*L*) showed a severe stricture and round shadow defects in the dilated left lateral segmental ducts. **G,** Cholangioscopy revealed whitish cholesterol stones in the dilated left lateral segmental duct. **H,** Scheme of the operation. *1*, A left lobectomy. The dilated left lateral segmental duct is resected proximal to the confluence of the left medial segmental (quadrate) duct. *P,* Right posterior sector; *M,* left medial segment (quadrate); *A*, right anterior sector; *L*, left lobe; *C*, caudate lobe. *2*, A right anterior sectorectomy. The dilated right anterior sectoral ducts are resected at the confluence of the right posterior sectoral duct. *3*, Intraoperative cholangioscopy was performed through the opening of the right posterior sectoral duct. *4*, A T-tube was placed through a choledochotomy. **I,** Postoperative cholangioscopic cholangiography showed no residual stones. The subsegmental bile ducts of the left medial segment (*4a, 4b, 4c*), the right posterior segments (*6, 7*), and the caudate lobe (*I*) were preserved as proposed preoperatively.

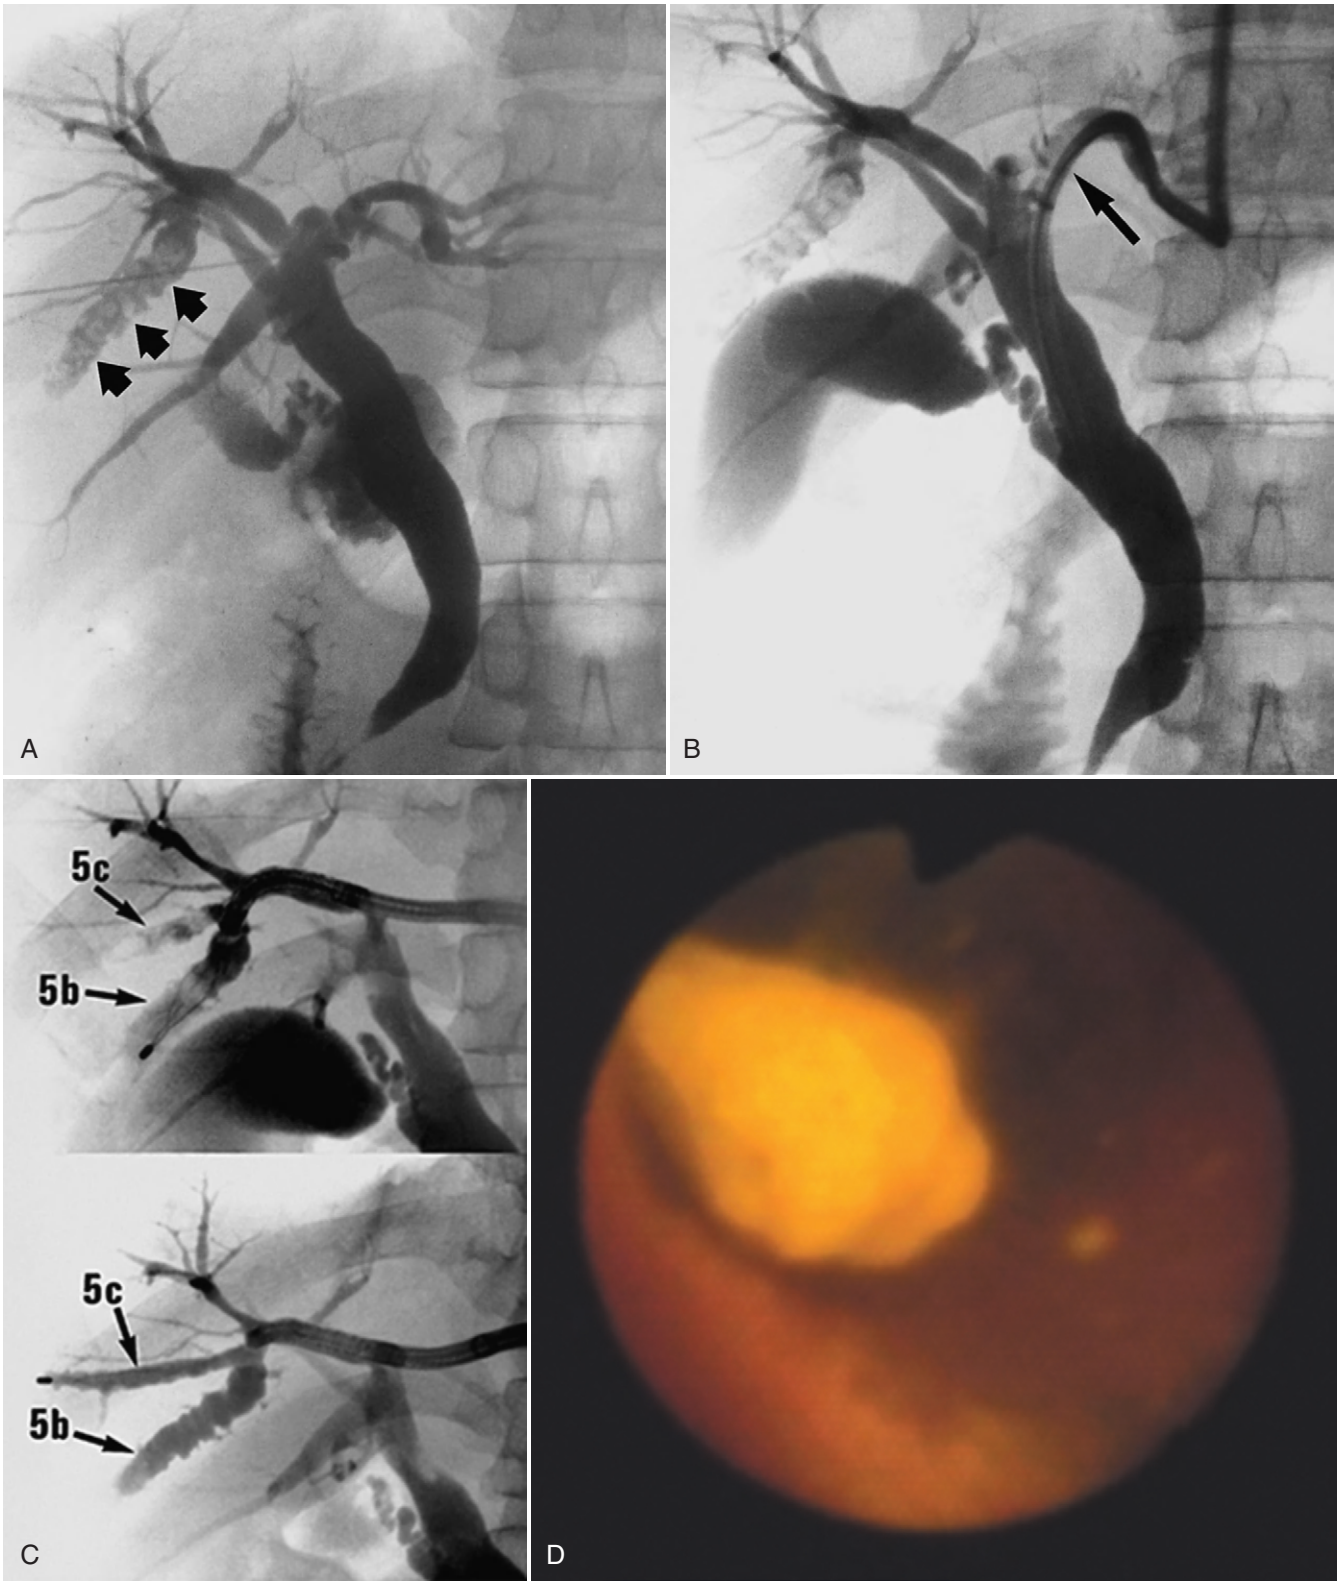

FIGURE 39.9. Intrahepatic cholesterol stones. **A,** Percutaneous transhepatic cholangiography disclosed stones (*arrows*) in the bile duct of segment 5. Note the cylindrical dilation of the stone-bearing duct. **B,** Percutaneous transhepatic biliary drainage of the left hepatic duct (*arrow*) was performed using a direct anterior approach. **C,** Percutaneous transhepatic cholangioscopy (PTCS) revealed intrahepatic stones to be cholesterol stones located only in the subsegmental ducts (5b, 5c) of segment 5. Cholangioscopic lithotomy was done easily with a basket catheter in the absence of biliary stenosis. **D,** Cholangioscopic view of a cholesterol stone.

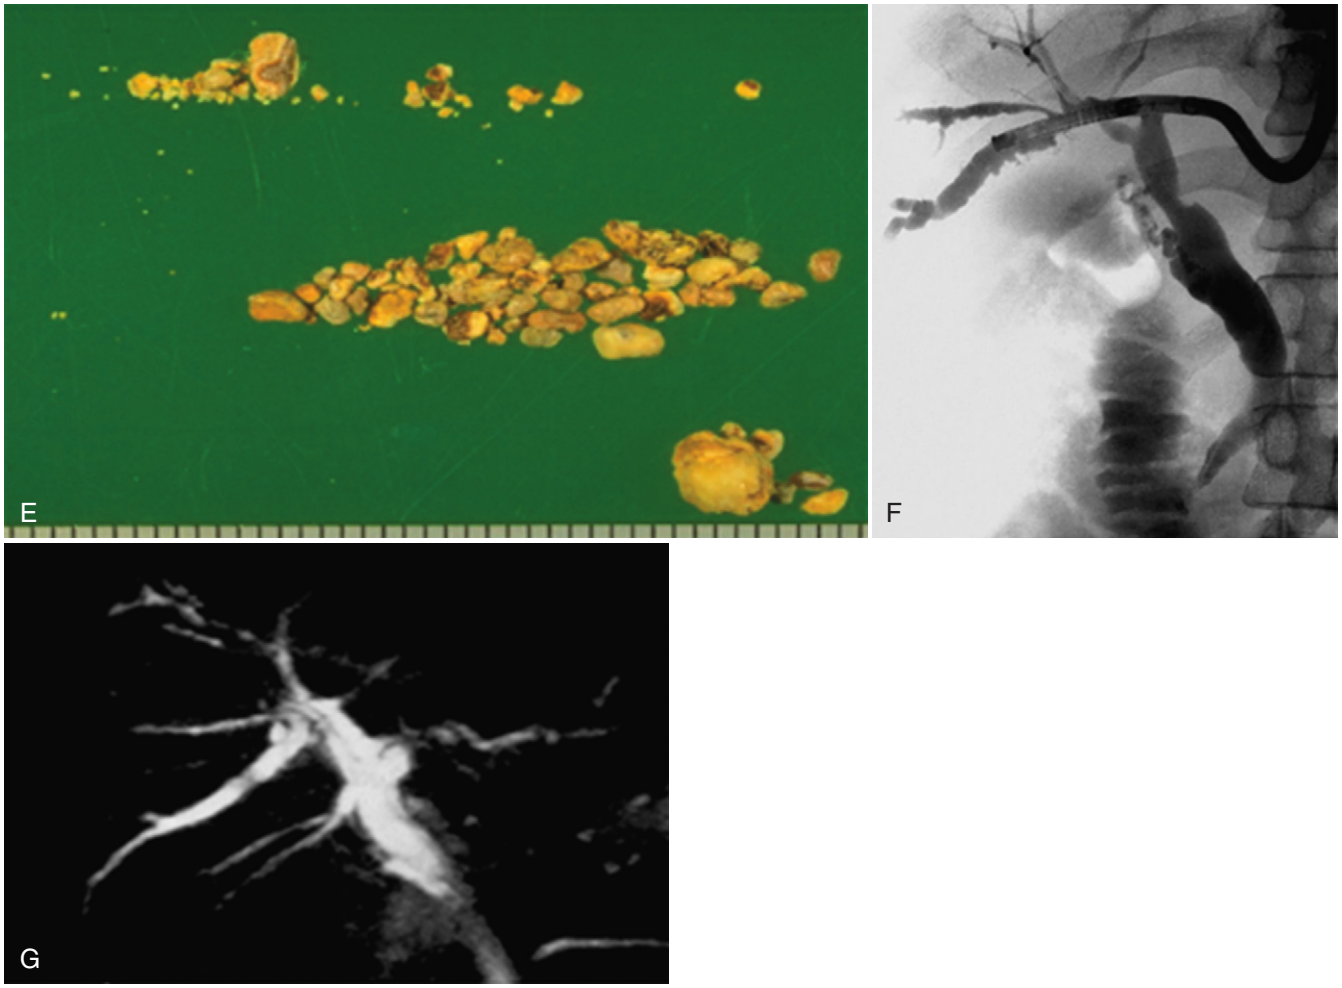

FIGURE 39.9, cont'd. **E,** All stones were removed from bile ducts of 5b and 5c in three sessions of PTCS. **F,** Selective cholangiography shows no residual stones in the subsegmental ducts of segment 5. After cholangioscopic lithotomy, the patient underwent cholecystectomy, which disclosed no stones in the gallbladder with mild cholesterosis. **G,** Magnetic resonance cholangiopancreatography (MRCP) done 17 years after the treatment showed no recurrent intrahepatic stones.

suggesting that this therapy is probably useful as a preventive adjunct (Schillio et al, 1992; Strichartz et al, 1991).

The indications for intervention in asymptomatic patients with intrahepatic stones are controversial. In a patient who has mostly cholesterol stones, treatment may not be indicated. On the contrary, if associated ICC is suspected, further evaluation and consideration for hepatectomy are mandatory. In Kami-Goto Islands of western Japan, a screening survey for intrahepatic stones was performed by US because of the high incidence of ICC in this population. This survey identified 122 asymptomatic patients with intrahepatic stones who had been followed for an average of 10 years (Furukawa et al, 1998). In this group, only 14 (11.5%) of the 122 patients had symptoms develop, and 13 of these (92.9%) had liver atrophy, whereas the incidence of liver atrophy was significantly lower (13%) in patients with no symptoms. Based on these data and other cancer-related investigations (Mori, 2008b; Tsuyuguchi, 2008), no treatment is necessary or recommended for asymptomatic patients without sectoral or lobar atrophy.

PROGNOSIS

Intrahepatic stone disease carries a high rate of recurrence. Of all cases treated in Japan in the years 1989 through 1992, the overall recurrence rate was 6.6% (119 of 1815 cases; Tanimura et al, 1994). The recurrence rate according to treatment was as follows: 5.3% (38 of 719) for hepatic resection, 8.3% (21 of 254) for choledochojejunostomy, 6.4% (40 of 624) for choledochotomy followed by cholangioscopic lithotomy, and 9.6% (20 of 208) for PTCS. The lowest reported recurrence rate is 3.1% (3 of 96) at a mean follow-up period of 26 months in patients treated in Hong Kong (Liu et al, 1998). The highest reported recurrence rate is 32.6% (43 of 132) in patients undergoing lithotomy by PTCS for a mean follow-up period of 5 years in a report from Taiwan (Yeh et al, 1995). In 2008, a nationwide survey was performed in Japan. Despite recent progress in diagnosis and treatment for hepatolithiasis, the recurrence rate was still 18.6%, and cholangiocarcinoma with hepatolithiasis was found in 5.9% of the cases (Mori, 2008a). Another report from Korea showed that 11 (5%) of 225 patients

with intrahepatic stones developed cholangiocarcinoma at 10.7 years (range, 6.6 to 19.7 years) after initial treatment of stones. The 11 cholangiocarcinoma patients consisted of six (4%) of 159 patients with complete stone removal and five (8%) of 66 patients with residual stones after treatment (Cheon et al, 2009).

The survival rate after resection of ICC associated with hepatolithiasis is quite low, primarily because most patients have advanced disease at the time of diagnosis and operation, and postoperative survival rates in 55 Taiwanese patients at 1, 2, and 4 years were 30%, 12.7%, and 3.6%, respectively (Chen et al, 1993). In Japan, 48% of patients with cholangiocarcinoma associated with hepatolithiasis died within one year of operation (Tanimura et al, 1994).

CHAPTER 40

Biliary atresia

Mark Davenport

OVERVIEW

Biliary atresia (BA) remains a somewhat elusive disease, with our understanding confined as it is to its infancy but yet with the origin of BA essentially unknown. BA is potentially fatal, certainly if left to run its natural course (Hartley et al, 2009), but it can be treated effectively with expeditious surgery in a high proportion of patients. For the remainder, liver transplantation is an option, and indeed BA remains the single most common indication for liver transplant in the pediatric population.

BA is an *occlusive panductular cholangiopathy* affecting both intrahepatic and extrahepatic bile ducts. The most common classification divides BA into three types based on the most proximal level of occlusion of the extrahepatic biliary tree (Fig. 40.1). In types 1 and 2, in which there is a degree of preservation of structure of the intrahepatic bile ducts, blunting, irregularity, and pruning occurs, and dilation may be absent, even when the duct is obstructed. In the most common type of BA, type 3, the intrahepatic bile ducts are grossly abnormal with myriad small ductules coalescing at the porta hepatis. When retrograde cholangiography is possible, this is seen as a "cloud." In approximately 5% of cases, extrahepatic formation of cysts containing clear mucus or bile can occur in the otherwise occluded biliary tree. Such cystic biliary atresia (Caponcelli et al, 2008) is distinguishable clinically and histologically from simple obstruction in a cystic choledochal malformation, where there is preservation of an epithelial lining and retention of a normal and often dilated intrahepatic biliary tree.

ETIOLOGIC HETEROGENEITY

BA is not one disease, certainly not one with a single cause. In all probability it is a phenotype resulting from a number of different etiologies. Three groups can be defined clinically: 1) biliary atresia splenic malformation (BASM) syndrome (Davenport et al, 1993, 2008), 2) cystic BA (Caponcelli et al, 2008), and 3) isolated BA (Table 40.1).

Other related entities are fewer in number, but there seems to be a relationship with other gastrointestinal anomalies, such as esophageal atresia and jejunal atresia, in a small proportion (<1% of large series); occasional cases show a defined chromosomal abnormality, such as "cat-eye" syndrome and chromosome 22 aneuploidy (Allotey et al, 2008).

Developmental biliary atresia is a term we use that includes BASM and cystic BA, for which the onset is almost certainly prenatal and is evident by the time of birth (Livesey et al, 2009). The onset of occlusion in isolated BA is much more contentious, and some authorities hold that the bile duct can be normal and patent at the time of birth and can then become occluded secondarily by virally mediated damage.

Biliary Atresia Splenic Malformation Syndrome

Although the association of BA with polysplenia had been recognized for some time, clarification of what constitutes BASM (Table 40.2) is only relatively recent (Davenport et al, 1993). The constellation of other anomalies is peculiar, and the reasons for this are still obscure. The common embryologic insult may simply be timing (30 to 35 days) rather than a specific genetic defect. Key genes are important in both bile duct development (*JAG1, HNF-6* [*ONECUT1*]; Kohsaka et al, 2002) and visceral and somatic symmetry (*INVS, CFC1;* Bamford et al, 2000; Shimadera et al, 2007), although correlation with the human condition is patchy. A possible genetic link has recently been reported by a French group, who found an increased frequency of mutations in the *CFC1* gene (on chromosome 2) compared with controls (Davit-Spraul et al, 2008).

A maternal diabetic milieu seems to predispose to BASM in the same way that it can cause transposition of the great vessels and sacral agenesis, although these are not part of the usual spectrum of defects. The macroscopic appearance of the biliary tree and liver is also somewhat different from that of isolated BA, with frequent absence of the common bile duct and a miniscule gallbladder and small proximal remnant. The liver is also usually symmetric, whatever the abdominal situs.

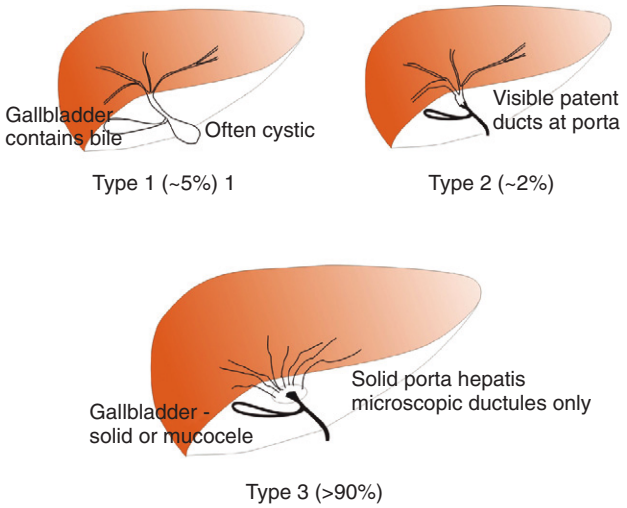

FIGURE 40.1. Classification of extrahepatic morphology in biliary atresia.

Epidemiology

A clear difference in incidence is seen across the globe. The highest is reported in Taiwan, at one in 5000 live births (Hsiao et al, 2008). In Japan, the incidence is one in 10,000 (Nio et al, 2003), with national studies from the United Kingdom and France reporting an incidence of one in 17,000 and 19,000, respectively (Chardot et al, 1999; Livesey et al, 2009; Serinet et al, 2006). Although there are no national studies in North America, smaller regional studies suggest an incidence closer to that of Europe (Yoon et al, 1997) but with some interracial variation (The et al, 2007). Significant regional differences within the United Kingdom have also been observed, again ascribed to variations in racial origin and the nature of the BA. For example, developmental BA is more common in white infants than in those of Asian origin (Livesey et al, 2009).

A distinct female predominance in seen in those with developmental BA that is not seen in the isolated BA group for unknown reasons (Davenport et al, 1993, 2006; Livesey et al, 2009). A seasonal variation in incidence has also been observed in some regionally based studies (Yoon et al, 1997; The et al, 2007), although this has not been confirmed in the larger, national studies (Chardot et al, 1999; Livesey et al, 2009).

Table 40.1

Etiologic Heterogeneity in Biliary Atresia

1. Biliary atresia splenic malformation syndrome
   - **a.** First-trimester onset
   - **b.** Other anomalies, including polysplenia, asplenia, situs inversus, preduodenal portal vein, and others
2. Cystic biliary atresia
   - **a.** First- or second-trimester onset
   - **b.** May be detected on antenatal ultrasound
   - **c.** Usually isolated
3. Isolated biliary atresia
   - **a.** Onset unclear (no clinical evidence) but possibly perinatal
   - **b.** *May* have underlying viral etiology
     - **i.** Direct, such as cytomegalovirus
     - **ii.** Indirect, such as an alloimmune attack following a viral "trigger"

Table 40.2

Spectrum of Anomalies in Biliary Atresia Splenic Malformation Syndrome

Organ System	Malformation	Notes
Splenic	Polysplenia, double spleen (95%); asplenia (5%)	No evidence of immune hypofunction
Situs determination	Inversus (50%)	
Venous	Preduodenal portal vein (40%), portosystemic shunt (<2%); vena cava absence (50%)	
Intestinal development	Malrotation (60%)	
Cardiac	Atrial septal defect, ventricular septal defect, tetralogy of Fallot, etc. (~40%)	± Dextrocardia
Liver	Mirror image, normal, or symmetrical	Position dictated by abdominal situs
Biliary appearance	Atrophic or absent gallbladder	Often noninflammatory remnants with absence of common bile duct and obvious segmental appearance
Pancreas	Annular (<5%)	
Miscellaneous	Immotile cilia syndrome, sacral agenesis	

Pathophysiology

The macroscopic appearance of the extrahepatic biliary tree ranges from being inflamed and hypertrophic yet intact to being an atrophic negligible remnant with absent parts. The histologic appearance within the liver appears more consistent with early portal tract inflammation, a mononuclear cell infiltrate, bile duct plugging, and proliferation and fibrosis giving way to overt biliary cirrhosis from about 3 months on.

The nature of the mononuclear infiltrate has assumed a degree of importance, and many authors suggest this is the specific primary destructive element of BA (Davenport et al, 2001; Mack et al, 2007). Although not necessarily uniformly applied across the spectrum of BA, the infiltrate is largely composed of CD4+ T lymphocytes, specifically Th1 (Mack et al, 2004) and CD56+ natural killer (NK) cells (Davenport et al, 2001; Shivakumar et al, 2009), which exhibit markers for proliferation (CD71+) and activation (particularly LFA-1+ but also CD25+). Infiltrating CD8+ cells appear to lack markers of activation—such as perforin, granzyme B, and Fas ligand (Ahmed et al, 2001)—in contrast to other diseases such as primary biliary cirrhosis (see Chapter 9).

Expression of cell adhesion molecules, proteins involved in cell-cell binding, is an important precursor to an immune-active cell infiltrate. Both interstitial cell adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 are important in binding circulating leukocytes by interaction with cell-surface

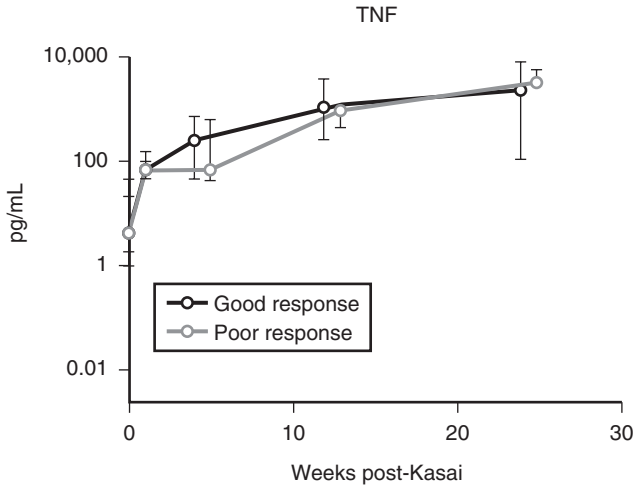

FIGURE 40.2. Postoperative plasma tumor necrosis factor (*TNF*)-α levels in biliary atresia (n = 21), showing progressive increase whether clearance of jaundice was achieved (good, n = 11) or not (poor, n = 10). *(Modified from Narayanaswamy B, et al, 2007: Serial circulating markers of inflammation in biliary atresia: evolution of the post-operative inflammatory process. Hepatology 46:180-187.)*

integrins, and they are expressed on sinusoidal and biliary epithelium of infants with BA (Dillon et al, 1997; Davenport et al, 2001).

Expression of soluble(s) ICAM-1 and sVCAM-1 in the circulation is also increased (Minnick et al, 1998; Davenport et al, 2005), as is seen in other immunologically mediated liver diseases such as primary biliary cirrhosis and sclerosing cholangitis; levels of sVCAM-1 at the time of presentation have been shown to be prognostic (Davenport et al, 2005). Increasing levels of various other cytokines (interleukin [IL]-2, tumor necrosis factor [TNF]-α, IL-18) can also be shown postoperatively (Fig. 40.2), but most discriminate poorly between patients who would clear their jaundice and those who would not; conversely, some cytokines (IL-2, interferon [IFN]-γ, IL-4, IL-10, TNF-α, and sICAM-1) were better predictors of subsequent need for early transplantation (Narayanaswamy et al, 2007).

Resident (Kupffer cells) or systemic/recruited macrophages and monocytes seem to play a dual role in BA, as both the presenters of antigenic material in the first place and as the initiating driver for fibrosis in the development of chronic liver disease. Tracy and colleagues (1996) first showed increases in resident macrophages (CD68+) with marked expression of the lipopolysaccharide receptor CD14+. Increased levels of both CD68+ cells and circulating markers of CD68+, TNF-α, and IL-18, have been shown to predict outcome post-Kasai (Kobayashi et al, 1997; Narayanaswamy et al, 2007).

Viral Hypothesis of Biliary Atresia

One suggested cause of BA is infection with hepatotropic viruses, such as rotavirus, reovirus, and cytomegalovirus, either as an indirect trigger of an abnormal immune-mediated reaction or as an actual pathologic agent. The evidence is largely based on animal models in which intraperitoneal innoculation on the first day of life is able to mimic postnatal biliary inflammation (Riepenhoff-Talty et al, 1993; Petersen et al, 1998). Subsequent translation into humans has been more problematic. Serologic evidence of viremia is contradictory (Morecki et al, 1982; Tarr et al, 1996), and isolation of both viral RNA and DNA have (Riepenhoff-Talty et al, 1996; Tyler et al, 1998; Fischler et al, 1999) and have not (Brown et al, 1988; Steele et al, 1995; Bobo et al, 1997; Jevon & Dimmick, 1999) been identified by PCR techniques.

The most recent study is one from Hannover, Germany, in which liver biopsies from 74 infants obtained at the time of portoenterostomy were tested for a panel of DNA and RNA hepatotropic viruses (Rauschenfels et al, 2009). One or more viruses was detected in about one third of infants, and the rate of detection increased with infant age, which suggested that observed viral infection was more likely to be a secondary finding rather than a specific cause.

One problem with the viral hypothesis is the lack of an explanation as to why such ubiquitous organisms only damage the biliary tree in such a small fraction of infants and children. It may be that such infants are in some way susceptible to cholangiocyte damage and require a (viral) trigger to set off an immune-mediated destructive process (Mack, 2007).

RNA gene expression studies in rotavirus-induced murine models have shown upregulation of many proinflammatory genes, among them the IFN-γ inducers *IRF7* and *IRF9* (Carvalho et al, 2005). Similar gene-expression profiling in human BA samples has also shown overexpression of immune regulatory genes and differences between isolated and syndromic forms (Bezerra et al, 2002; Zhang et al, 2004).

A number of studies have shown different but specific elements of genetic variation between patients with isolated BA and unaffected control subjects. Thus, susceptibility may be imparted by polymorphisms in a number of relevant genes. Examples of this include vascular endothelial growth factor (*VEGFA*; Lee et al, 2010), macrophage migration inhibitory factor (*MIF*, Arikan et al, 2006), and intercellular adhesion molecules (*ICAM*s; Arikan et al, 2008).

Most recently, maternal microchimerism, a novel mechanism of immune damage, has been suggested based on the observation that male infants with BA have a threefold increase in cells of maternal origin in their livers (Hayashida et al, 2007). These were later shown to be maternal-origin chimeric CD8+T cells and CD45 NK cells capable of initiating immune cholangiolar damage (Muraji et al, 2008).

CLINICAL FEATURES

The cardinal features of BA are conjugated jaundice persisting beyond 14 days of age, pale and unpigmented stools, and dark urine in an otherwise healthy, term neonate. Liver fibrosis and cirrhosis are later developments, even in infants with intrauterine BA evident at birth (Makin et al, 2009); therefore ascites and marked hepatosplenomegaly are rarely seen before 3 months. Fat malabsorption occurs by stealth, and these infants will fall behind in their growth (Livesey et al, 2009). Fat malabsorption can also cause fat-soluble vitamin K deficiency, and some infants (<3%) will be seen with a possibly catastrophic bleeding tendency and a raised international normalized ratio (INR).

A proportion of infants (approximately 5%) will be seen initially with an abnormal antenatal ultrasound (US) scan (Caponcelli et al, 2008). These will be shown to have cystic BA, with the "cyst" evident from at least 20 weeks' gestation. This has no untoward effects during pregnancy but clearly needs thorough investigation postnatally. The differential diagnosis for these

infants, if the cyst is actually recognized as of hepatobiliary origin, is that of a cystic choledochal malformation, better known as a choledochal cyst (Hinds et al, 2004).

Diagnostic Workup

Liver biochemistry will show a conjugated hyperbilirubinemia that is variable but rarely above 250 μmol/L (more than 15 mg/dL), modestly raised transaminases (aspartate aminotransferase, alanine aminotransferase), significantly raised γ-glutamyl transpeptidase (GGT), and usually normal protein and albumin levels. Hemoglobin and white cell counts are normal, although the platelet count may be raised.

The differential diagnosis of medical conditions that cause conjugated jaundice is long, and all can mimic the occluded bile duct of BA. Exclusion of TORCH infections—*Toxoplasma*, cytomegalovirus, hepatitis, and so on—α1-antitrypsin deficiency, Alagille syndrome, and cystic fibrosis should run in parallel with efforts to establish a diagnosis of BA.

US examination is a key part of the workup in order to exclude other possible surgical diagnoses (choledochal malformation, inspissated bile syndrome), and evidence of at least intrahepatic bile duct dilation should be visible (Davenport et al, 2003). Although suggestive and supportive, US is uncommonly diagnostic of BA and typically shows a shrunken, atrophic gallbladder with no evidence of filling between feeds. Some US signs do appear more reliable, such as the "triangular cord sign" (Park et al, 1997). This suggests a sonographic appearance of the proximal solid biliary remnant in front of the bifurcation of the portal vein, and advocates quote accuracy rates of greater than 80% (Humphrey & Stringer, 2007).

Radioisotope hepatobiliary imaging with technetium-labeled iminodiacetic acid derivatives has a role in some centers in showing the need for laparotomy. In BA there will be severe cholestasis and no bile excretion, but this can be seen in many cases of neonatal hepatitis and other medical conditions, depending on the severity of cholestasis. Placement of a nasoduodenal tube and aspiration over 24 hours has been used in many centers, chiefly Asian, as a simple, low-cost diagnostic measure, although this has rarely found favor in Western centers. Percutaneous liver biopsy to assess for histologic features of large-duct obstruction versus those of neonatal hepatitis is safe and well-tolerated but needs an experienced pathologist to interpret.

Direct cholangiography is becoming more prevalent in larger centers with direct access to endoscopic retrograde cholangiopancreatography (ERCP) (Shanmugam et al, 2009; Petersen et al, 2009). It requires a sufficiently small endoscope and a level of familiarity with the procedure, as failure to cannulate the bile duct are features of both BA and an inexperienced operator. Laparoscopy with or without liver biopsy offers an alternative to ERCP, and it may be the prelude to the definitive procedure. Direct puncture of the gallbladder is relatively straightforward to show presence or absence of bile and as an access point for a cholangiogram. This can be coupled with liver biopsy.

SURGERY: KASAI PORTOENTEROSTOMY

Preoperative preparation for a Kasai portoenterostomy includes normalizing the coagulopathy and possibly providing a bowel preparation regimen.* An intravenous perioperative antibiotic regimen active against aerobic and anaerobic bowel flora is standard.

Cholangiogram

The diagnosis is always confirmed initially through a limited right-upper quadrant muscle-cutting incision, allowing access to the gallbladder (does it contain bile?) and a cholangiogram if needed. It should be obvious that a cholangiogram is not always possible, simply because the gallbladder may not have a lumen. Nonetheless, this is in itself presumptive of the diagnosis. To exclude BA, the cholangiogram should demonstrate proximal intrahepatic ducts. This can be difficult, as contrast preferentially fills the distal duct and duodenum. A small, distal vascular or "bulldog" clamp should aid reflux into the more proximal biliary tree if patent.

Mobilization

The liver should be fully mobilized by dividing the falciform, coronary, and triangular ligaments such that the organ can then be everted outside of the abdominal cavity (Fig. 40.3). This allows full exposure of the porta hepatis and facilitates dissection; it also reduces venous return, and an increase in intravenous volume support is always needed, together with close communication between surgeon and anesthesiologist.

Portal Dissection

Initially the gallbladder is mobilized and the distal CBD divided (Fig. 40.4A), with the dissection consisting of elevation of the proximal pyramidal remnant from the right hepatic artery and bifurcation of portal vein (Fig. 40.4B). Small veins to the porta hepatis need division and facilitate downward traction of the portal vein and exposure of the posterior part of the portal plate and caudate lobe. On the left side, the recessus of Rex, where the umbilical vein joins the left portal vein, should be exposed; an isthmus of liver parenchyma from segment III to IV may need division by coagulation diathermy to achieve this. On the right side, remnant biliary tissue can be identified almost circumferentially around the right vascular pedicle. The division into right anterior and posterior pedicles should be visualized, and the posterior pedicle's biliary elements should also

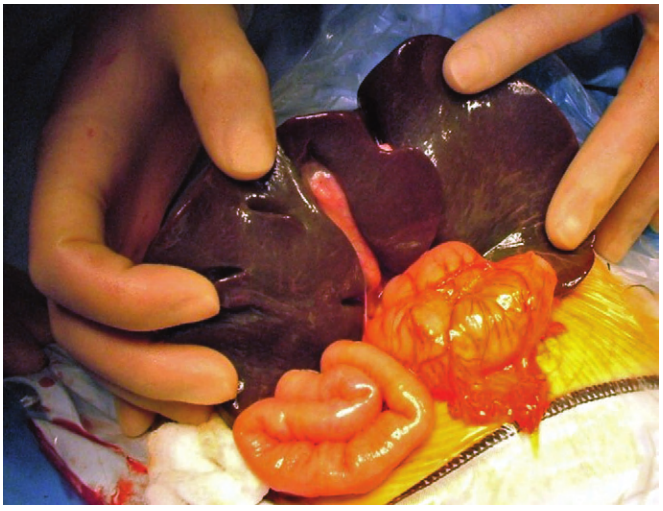

FIGURE 40.3. Operative appearance of liver in biliary atresia. The liver is relatively soft, and the gallbladder is collapsed and contains no bile, which is consistent with a type 3 biliary atresia.

*Morio Kasai (1922-2008), pediatric surgeon from Sendai, Japan, who pioneered radical excision of biliary remnants and subsequent portoenterostomy.

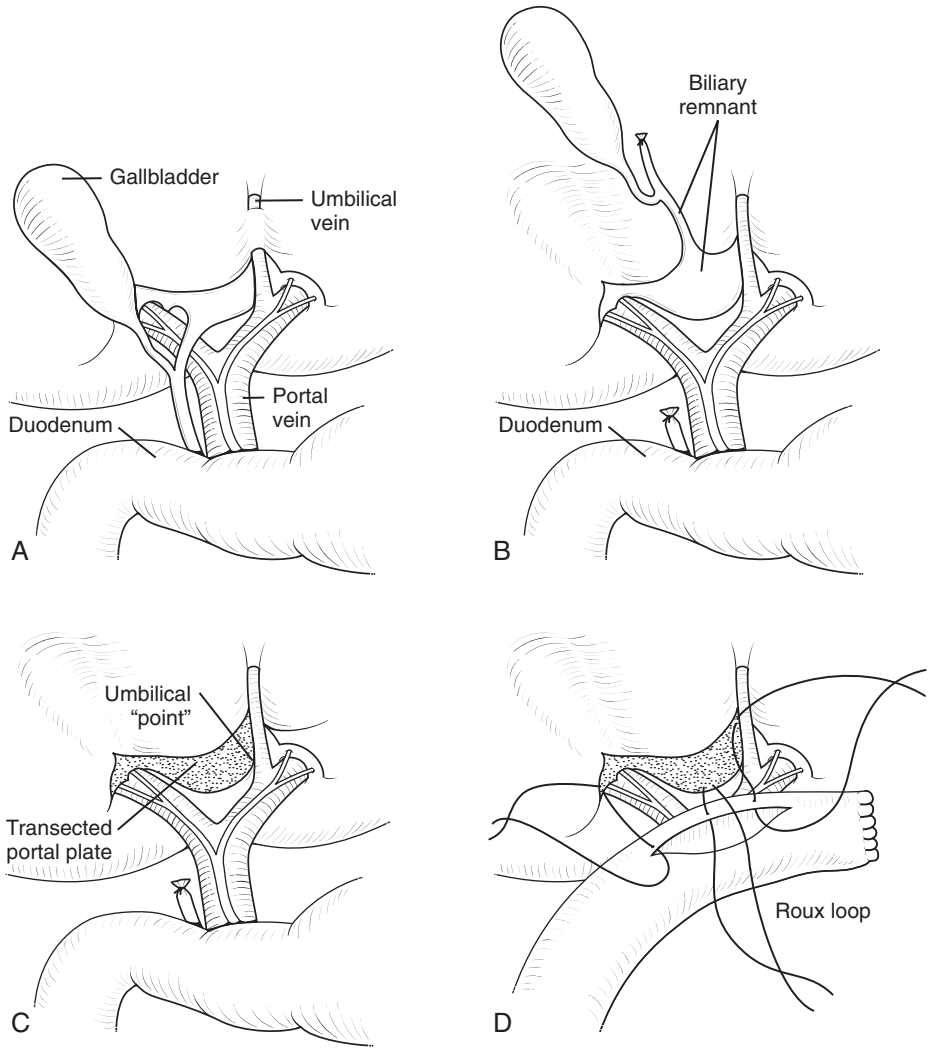

FIGURE 40.4. Schematic illustration of Kasai portoenterostomy. **A,** Mobilization of gallbladder and division of distal common bile duct. **B,** Elevation of biliary remnants and separation from vascular structures at level of porta hepatis (portal vein confluence, right hepatic arterties, and, to a lesser extent, left hepatic arteries). **C,** Transection of portal plate from umbilical "point" to around the division of right-sided (anterior and posterior) portal pedicles. **D,** Portoenterostomy with 40- to 45-cm retrocolic Roux loop.

be incorporated into the subsequent Roux loop. Excision of remnants flush with the liver capsule is accomplished by developing a plane between solid white biliary remnant and the underlying liver (Fig. 40.4C); excising liver parenchyma itself does not seem to improve bile drainage. All the denuded area of the porta hepatis needs to be incorporated into the Roux loop as the portoenterostomy. Some authors (Gittes & Koybayashi, 2007) have suggested a role for frozen section of the portal plate to determine that the observed ductules are large enough. My view is that there should be nothing left to resect from the initial dissection. Burrowing into liver parenchyma itself seems pointless, possibly because subsequent scarring obliterates any exposed ductules.

Roux Loop and Portoenterostomy

A standard retrocolic Roux loop measuring 40 to 45 cm should be constructed (Fig. 40.4D). The jejunojejunostomy should lie about 10 cm from the ligament of Treitz and can be stapled or sutured. The proximal anastomosis must be wide (approximately 2 cm), and as such, an end-to-side tension-free arrangement is preferred. Fine, precise sutures (e.g., 6-0 PDS) at the edge of the portal plate are satisfactory. Remnant ductules are concentrated in the right and left recesses, and it is important that all parts of the transected plate are incorporated.

Aftercare

Nasogastric drainage and intravenous fluids are required for 2 to 4 days postoperatively. Antibiotics, intravenous at first and then oral, are given in our institution for 1 month. All these infants, even those clearing their jaundice, have subnormal quantities of intestinal bile and to ameliorate the effects of fat malabsorption, they should have a formula rich in medium-chain triglycerides. Vitamin supplementation is standard, both enteral and parenteral, and choleretic agents, such as ursodeoxycholic acid, may have some value but only in those patients who have reestablished bile flow. The value of steroids is discussed later.

POSTOPERATIVE COMPLICATIONS AND OUTCOME

The aims of portoenterostomy are to restore bile flow and reduce bilirubin levels to normal. This is achievable in isolated BA in about 50% to 60% of infants (Davenport et al, 2004a, 2008); and should halt the progression of liver fibrosis. Table 40.3 illustrates current outcome statistics derived from national studies. Our own studies have shown that in a centralized system with experienced surgeons, the clearance of jaundice can be achieved after Kasai portoenterostomy in about 50% to 55% of patients, with translation into a 5- and 10-year native liver survival of approximately 50% and 45%, respectively. Overall survival depends heavily on the access to efficient liver transplant programs and can be approximately 90% at both 5 and 10 years (Davenport et al, 1997, 2004a, 2009). If success is achieved after either portoenterostomy or transplantation, children can grow and develop normally to adulthood with minimal medical support.

The most common complication is that the portoenterostomy does not work, and therefore it will have no effect on restoration of bile flow, and jaundice will worsen and lead to end-stage liver disease. For these infants, transplantation will be required for survival, typically within the first 2 years of life (Schneider et al, 2006; see Chapters 71 and 97A). Such infants have increasingly evident portal hypertension with splenomegaly, ascites, and variceal formation. They fail to thrive and have reduced synthetic liver function with falling levels of serum albumin and increasing evidence of a vitamin K–independent coagulopathy (DeRusso et al, 2007). This is a crucial period within which most deaths occur as a result of biliary atresia, and unfortunately most are already on a transplant waiting list.

Cholangitis

Cholangitis is presumed to occur by bacterial ascent from the Roux loop via patent biliary ductules (see Chapter 43). It is therefore uncommon in those who have no effect from Kasai surgery. Nonetheless, it may occur in 30% to 50% and is most frequent within a year of surgery (Ecoffey et al, 1987). Clinically, cholangitis is characterized by worsening jaundice, fever, and acholic stools. The diagnosis may be confirmed by blood culture or by percutaneous liver biopsy, but it is important to treat suspected cases early with broad-spectrum antibiotics effective against gram-negative organisms (e.g., ceftazidime, amoxycillin, piperacillin). Sometimes recurrent cholangitis may be problematic, which can be associated with intrahepatic cyst formation (Bu et al, 2002), presumably acting as a bacterial nidus. Most patients respond to prolonged antibiotic prophylaxis, either with intravenous broad-spectrum antibiotics via an indwelling vascular access device or with oral nonabsorbable antibiotics (e.g., neomycin). If cholangitis still recurs despite these measures, liver transplantation should be considered.

Sometimes cholangitis occurs some years after the portoenterostomy in children with otherwise good liver function. It is important in these cases to exclude a mechanical Roux loop obstruction, typically at the level of the mesocolon, because corrective surgery for obstruction is relatively simple (Houben et al, 2006). Percutaneous transhepatic cholangiography and radionuclide hepatic imaging may be useful for diagnosis.

Portal Hypertension

Elevated portal venous pressure can be shown in virtually all infants at the time of the Kasai operation (Duché et al, 2006). However, whether it persists or regresses depends on the degree of established fibrosis and, most importantly, the response to surgery (Kang et al, 1993). About 60% of children who survive to 2 years will have endoscopic evidence of esophageal varices, although only approximately half of these will ever bleed. The severity and degree of the varices themselves are not necessarily related to the original degree of liver fibrosis or to the number of episodes of cholangitis (Kang et al, 1993). Endoscopic surveillance of the upper gastrointestinal tract in children with treated biliary atresia has been suggested from about the age of 2 years because of this unpredictability of variceal formation (see Chapter 71).

The age at first hemorrhage is typically approximately 2 to 3 years, and it manifests as sudden hematemesis and melena from rupture of an esophageal varix. Ectopic intestinal variceal bleeding may also occur, usually in an older child with relatively normal liver function. The initial treatment of bleeding varices is supportive, with restoration of blood volume and correction of platelet deficiency and any coagulopathy. Drugs such as octreotide, or more recently terlipressin, may be used be used to reduce portal venous pressure. Banding has become the most efficacious technique to control varices, although it may be limited by patient size (Hall et al, 1988). For infants and small children, endoscopic sclerotherapy is still effective (Stringer et al, 1989), using sclerosants such as ethanolamine or sodium tetradecyl sulfate. Even with various pharmacologic and endoscopic alternatives, sometimes the only means of variceal control is a Sengstaken or equivalent pattern tube. Transjugular intrahepatic portosystemic shunt (TIPS) as a method of acutely reducing portal hypertension is also possible in children with BA, but it should be regarded only as a "bridge" to transplantation (Johnson et al, 1996; Cao et al, 1997), and it is not widely available.

Hepatopulmonary Syndrome and Portopulmonary Hypertension

Hepatopulmonary syndrome (HPS) is characterized by cyanosis, hypoxia, and clubbing and is due to shunting across the pulmonary vascular bed, likely caused by failure to deactivate vasoactive substances, possibly endothelin-1, by the damaged liver (Iqbal et al, 2008). Patients with HPS have higher levels of exhaled nitric oxide, presumably the final link in this chain. It is more commonly seen in those with BASM, suggesting a congenital element (Davenport et al, 2004a), and it can occur even in those who are anicteric. The diagnosis is made by arterial blood gas estimation showing significant hypoxia with no improvements seen on increasing ambient oxygen. Radionuclide lung scans with macroaggregated tagged albumin can be used to quantify the degree of shunting and can range from 4% to 50% (Al-Hussaini et al, 2010).

Portopulmonary hypertension is much less common and may share the same underlying vascular mechanism as HPS. Although it is often silent and perhaps only detected because of cardiomegaly on a chest radiograph, it can be a cause of sudden death and is associated with systolic pulmonary arterial pressures greater than 40 mm Hg. Although no real therapy is available for the pulmonary vascular anomaly, it is a definite indication for liver transplantation and is usually reversible, albeit with an increased risk of complications (Iqbal et al, 2008).

Liver Malignancy

The cirrhotic liver of treated BA is potentially premalignant, and there are several reports (Kohno et al, 1995; Iida et al, 2009; Hol et al, 2008) and a single series of three cases (Tatekawa et al, 2001). This of course may be due simply to the relatively small numbers of long-term survivors, but perhaps it implies only a modest risk. Malignant change may include hepatocellular carcinoma (Hol et al, 2008; Iida et al, 2009; see Chapter 80) or cholangiocarcinoma (Kulkarni & Beatty, 1977; see Chapter 50), but more benign changes, such as focal nodular hyperplasia (Okugawa et al, 2008), may also occur. Although the youngest reported case was diagnosed in a patient 10 months old, but most are seen during later childhood or adolescence as a nodule or mass on routine US screening of the liver. Because of the risk for malignant change, serum α-fetoprotein levels should probably be part of the routine follow-up for such children, although clearly in some, these levels will still be normal.

AREAS OF DEBATE AND CONTROVERSY IN BILIARY ATRESIA

Laparoscopy

The open technique described above requires precision, maximal exposure of the portal plate, and delicate suturing. This can be *approximated* by laparoscopic or robotic means, and small series have been reported (Esteves et al, 2002; Lee et al, 2004; Dutta et al, 2007; Ayuso et al, 2008). However, now that the first wave of enthusiasm has perhaps abated, it appears that the results are not comparable to the open technique (Wong et al, 2008). The only outcomes that matter are clearance of jaundice and preservation of the native liver; other outcomes, such as early feeding and better cosmesis, are irrelevant. In many centers, there is currently a self-imposed moratorium, until the reasons for failure become clearer or techniques improve.

Adjuvant Steroids

The inflammatory nature of BA has been emphasized above, and postoperative steroids seem a logical approach to this. In addition, most steroids have a chloretic action, although actual evidence of effect is scant. A number of small, uncontrolled studies from the United States and Japan suggesting benefit have been published (Meyers et al, 2004; Kobayashi et al, 2005). Our large, randomized, double-blind, placebo-controlled trial starting with 2 mg/kg/day showed a significant early effect at 1 month after operation with a lower bilirubin (Davenport et al, 2007), but this did not translate to a diminished need for transplantation or to a significant difference in the proportion with complete clearance of jaundice. Further studies from Germany using a higher starting dose (10 mg/kg/day) showed no difference, although their overall clearance rates were poor (27% were jaundice free at 2 years; Petersen et al, 2008).

Effect of Age at Surgery

It is axiomatic that once cirrhosis is established, the outcome will be worse. And because cirrhosis takes time to develop, it is logical to think that the earlier the surgery, the better the outcome. However, given that we do not know when biliary obliteration starts in isolated BA, trying to identify a relationship with postnatal age may be difficult. Large, multicenter series with multiple surgeons have been unable to show a statistically significant relationship (Davenport et al, 2004a).

Figure 40.5 illustrates this for isolated BA derived from a single center with only two surgeons, and it uses clearance of jaundice (<20 Umol/L) as a measure of outcome. This shows that there is no discernable difference up to 100 days, and certainly no evidence of any "cutoff." By contrast, Figure 40.6 shows the same analysis for one of the developmental forms, cystic BA, and here a relationship is obvious, with an impaired

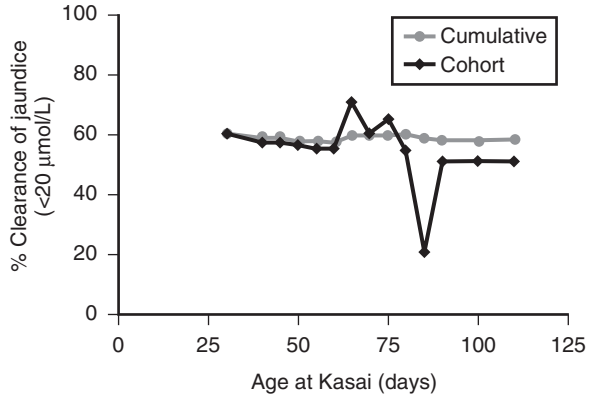

FIGURE 40.5. Relationship of age at surgery to clearance of jaundice in infants with isolated biliary atresia (n = 177). *(Modified from Davenport et al, 2008: Surgical outcome in biliary atresia: etiology affects the influence of age at surgery. Ann Surg 247:694-698.)*

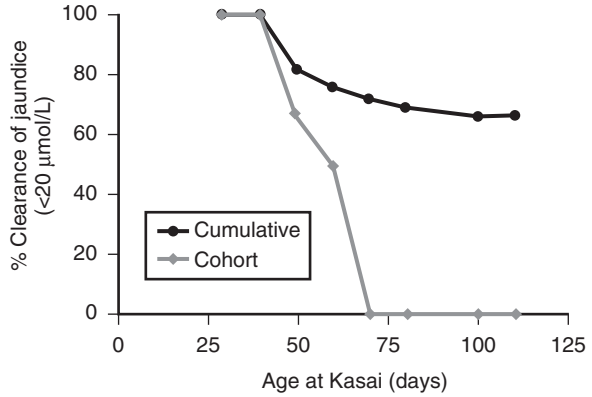

FIGURE 40.6. Relationship of age at surgery to clearance of jaundice in infants with cystic biliary atresia (n = 23). *(Modified from Davenport et al, 2008: Surgical outcome in biliary atresia: etiology affects the influence of age at surgery. Ann Surg 247:694-698.)*

outcome the older the infant is at surgery (Davenport et al, 2008).

Is there any benefit of surgery in those infants who come to surgery after 100 days? By now, this should be relatively infrequent in developed countries, but it still occurs. Such infants are much more likely to have established cirrhosis, and the prognosis is, without doubt, worse. Nevertheless, a Kasai portoenterostomy as the first step may be reasonable and has been associated with long-term jaundice-free survival in our series (Davenport et al, 2004b). The alternative is a primary liver transplant.

Kasai Variations

Although most surgeons operating today follow the original principles set out by Kasai and Suzuki (1959), most likely use a much wider portal dissection to try and incorporate as much as possible of the transected portal plate. There have been published variations in the construction of the Roux loop. Typically these were developed to reduce the postoperative incidence of cholangitis, and it included bringing the Roux loop out as a stoma and creating an antireflux valve (Tanaka et al, 1991; Nakajo et al, 1990). Hindsight suggests these have no real value and serve to impair the later transplant procedure, should it become necessary (Ogasawara et al, 2003). Use of the appendix as a conduit to the duodenum has also been described (Crombleholme et al, 1989), but again, later reports suggest no value (Lee et al, 2007; Tsao et al, 2003).

Biliary Atresia Variations

Types 1 and 2 BA may be found in up to 5% to 10% of all cases and were formerly described as "correctable," because some form of lesser procedure, such as a hepaticojejunostomy, could be done. Nonetheless, care must be taken, and a radical resection of remnant tissue back to the portal plate is now usually considered a better option with an encompassing portoenterostomy.

LIVER TRANSPLANTATION

The first ever attempt at human transplantation occurred in Denver, Colo., by Thomas Starzl on March 1, 1963 (Starzl et al, 1963; see Chapter 97). The patient was a ventilator-bound child born with BA who, because of complications related to severe bleeding, did not survive the operation; nonetheless, a milestone had been passed. Still, very few similar operations were carried out over the next 20 years, until the advent and increasing availability of cyclosporine during the 1980s made effective immunosuppression possible and transplantation a realistic option.

Currently, indications for transplantation include end-stage liver disease (usually following a Kasai portoenterostomy but less commonly as a primary procedure), recalcitrant cholangitis (despite prolonged intravenous antibiotics), severe portal hypertension, hepatopulmonary syndrome, evidence of malignant change, and failure to thrive despite maximal medical intervention.

It is still a surgically challenging procedure with reported early survival rates (1 to 3 years) from 85% to 94% and later (5 to 10 years) survival from 78% to 87% (Diem et al, 2003; Barshes et al, 2005; Fouquet et al, 2005; Cowles et al, 2008). There is, of course, the expectation of life-long immunosuppression; but in return, transplant offers the prospect of an excellent quality of life with normal liver function, and beyond the immediate postoperative period, expectation of long-term survival.

Various transplant programs have evolved in most developed countries with variation depending on cultural background. Nonetheless, all programs still have problems related to waiting-list death, lack of organ donors, and issues of size matching recipient to donor. Active living-donor programs, non–heart-beating donors, and technical advances such as organ reduction and split livers are all being pursued to try and negate these issues.

CHAPTER 41

Primary sclerosing cholangitis

Douglas L. Nguyen, Nicholas F. LaRusso, and Konstantinos N. Lazaridis

OVERVIEW

Primary sclerosing cholangitis (PSC) is a chronic, cholestatic liver disease of unknown etiology characterized by diffuse inflammatory destruction of intrahepatic and/or extrahepatic bile ducts that results in bile stasis, hepatic fibrosis, cirrhosis, and end-stage liver disease. Despite the increased awareness of PSC, the exact etiology and an effective medical therapy have yet to be identified. The disease is associated with specific human leukocyte antigen (HLA) haplotypes and has a close association with inflammatory bowel disease (IBD), which suggests that PSC is an immune-mediated disorder; but unlike other typical autoimmune diseases, there is a 2:1 male predominance. Life expectancy is reduced in PSC patients, because disease progression often results in complications of liver failure and cholangiocarcinoma (see Chapters 50A, 50B, and 50C). Among eligible candidates, surgical therapy has moved largely to orthotopic liver transplantation (OLT), as it remains the only effective, life-extending treatment for advanced-stage PSC (see Chapter 97A).

EPIDEMIOLOGY AND DEMOGRAPHICS

PSC mainly affects males during the fourth decade of life (Angulo & Lindor, 1999; Chapman, 2003). In the United States, population-based studies reported an age-adjusted incidence for PSC of 1.25 per 100,000 men and 0.54 per 100,000 women per year (Bambha et al, 2003). In the same study, the calculated prevalence of PSC was 20.9 and 6.3 per 100,000 men and women, respectively (Bambha et al, 2003). The worldwide prevalence and geographic distribution of PSC are undefined, as most epidemiologic data come from Northern Europe and the upper Midwest in the United States. Of interest is the strong association of PSC with IBD. Approximately 75% to 80% of Northern European patients with PSC suffer from IBD, with chronic ulcerative colitis (CUC) being most common, seen in about 90% (Chapman et al, 1980; Olsson et al, 1991; Wiesner et al, 1989). Conversely, only approximately 5.5% of patients with CUC have PSC (Olsson et al, 1991).

Smoking is the only environmental factor known to influence PSC susceptibility, and it is associated with a reduced risk of PSC. In a study from The Netherlands, the incidence of current smoking was 19% in patients with PSC compared with 38% in control subjects (Van Erpecum et al, 1996). Similarly, a U.S. study showed that 4.9% of patients with PSC were reported to smoke compared with 26.1% of a control population matched for age and gender. This reported difference was not attributable to the prevention of CUC (Loftus et al, 1996b). Nevertheless, smoking and alcohol consumption should be discouraged in PSC patients, because both are associated with the development of cholangiocarcinoma in this population (Bergquist et al, 1998; Chalasani et al, 2000).

Adenocarcinoma of the bile ducts appears in 8% to 15% of patients with PSC, rendering it a premalignant condition (Chalasani et al, 2000; De Groen et al, 1999; Foutch et al, 1990; see Chapters 50A, 50B, and 50C). In a recent study, 161 PSC patients without evidence of cholangiocarcinoma upon entry were followed over a median of 11.5 years. During that period, 59 patients (36.6%) died, 50 patients (31.1%) underwent liver transplantation, and 11 patients (6.8%) had cholangiocarcinoma develop (Burak et al, 2004). No association was found between the duration of PSC and the incidence of cholangiocarcinoma, and multivariate analysis revealed that variceal bleeding was the only significant risk factor for the diagnosis of cancer (risk ratio, 24.2; 95% confidence interval, 3.3% to 67%) (Burak et al, 2004).

CLINICAL PRESENTATION

PSC can affect any age group, but it is more common among men in their fourth decade of life (Wiesner & LaRusso, 1980; MacCarty et al, 1983). PSC can also occur in childhood, and children with PSC frequently have liver disease with features similar to autoimmune hepatitis (AIH) (El-Shabrawi et al, 1987; Wilschanski et al, 1995). In fact, the overlap between PSC and AIH in children can be as high as 35% (Feldstein et al, 2003). In contrast, overlap of PSC and AIH affects only about 5% of adults (Kaya et al, 2000; Van Buuren et al, 2000).

The clinical presentation of PSC varies depending on the disease stage at the time of diagnosis. PSC can be diagnosed in asymptomatic individuals who come to medical attention because of abnormal liver function tests. Approximately 15% to 40% of patients are asymptomatic at the time of diagnosis (Talwalkar & Lindor, 2005). There are no pathognomonic signs or symptoms when the disease becomes clinically apparent. The symptomatic patient may be seen initially with signs, symptoms, and complications of cholestatic liver disease or hepatic failure. In a recent study, the most common first symptoms were abdominal pain (20%), pruritus (10%), diarrhea (8%), jaundice (6%), fatigue (6%), and fever (4%) (Kaplan et al, 2007). Symptoms of bacterial cholangitis are uncommon, unless dominant biliary strictures or biliary stones are present.

Physical examination may reveal jaundice, hepatomegaly, splenomegaly, and excoriations. Ascites and peripheral edema are observed with the development of biliary cirrhosis and portal hypertension (see Chapter 70A). These findings are less common today, because PSC patients are usually evaluated before the development of end-stage liver disease. A commonly

encountered clinical scenario is a patient with CUC who presents with a cholestatic pattern of liver enzymes. Further medical evaluation results in the concurrent diagnosis of PSC. As with other chronic liver diseases, health-related quality of life is significantly impaired among PSC patients compared with healthy individuals (Younossi et al, 2001).

DIAGNOSTIC CRITERIA

The diagnosis of PSC is made based on clinical presentation, biochemical profile, and characteristic cholangiographic appearance of the bile ducts. Before the 1960s, PSC was a diagnosis of exclusion following abdominal exploration and biopsy of a suspected bile duct neoplasm (Schwartz & Dale, 1958). In the 1960s, diagnosing PSC became more frequent, when its association with IBD was recognized (Thorpe et al, 1967). With the advent of endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography (PTC) in the 1970s, the characteristic "beaded" or "pruned tree" cholangiographic appearance obviated the need for exploratory surgery to diagnose PSC and resulted in its increased recognition (Wiesner & LaRusso, 1980; see Chapter 18).

The first formal diagnostic criteria included 1) absence of previous operative trauma to the biliary system; 2) sclerosis and stenosis involving all or most of the extrahepatic bile ducts; 3) exclusion of malignant disease involving the biliary tree, such as cholangiocarcinoma; and 4) absence of calculi in the gallbladder and common bile duct (Holubitsky & McKenzie, 1964). Following the introduction of ERCP, the criteria were expanded to include a subset of PSC cases recognized to have intrahepatic bile duct involvement alone (MacCarty et al, 1983). In addition, serial ERCP examinations of PSC patients demonstrated the subsequent development of cholangiocarcinoma (Chapman et al, 1980). As such, malignancy arising in the setting of sclerosing cholangitis was eliminated as an exclusionary criterion. Imaging techniques (i.e., ERCP) have also shown biliary tract calculi in many patients with established PSC, suggesting the removal of calculi as an exclusionary criterion (Kaw et al, 1995).

The diagnosis of PSC currently relies on 1) characteristic cholangiographic abnormalities of the biliary tree; 2) compatible clinical and biochemical findings, typically of ductal cholestasis with elevated serum alkaline phosphatase level for at least 6 months duration; and 3) exclusion of other causes of secondary sclerosing cholangitis (SSC). The clinical and cholangiographic features of SSC can mimic PSC, but SSC originates from known pathologic processes. Several well-described causes of SSC are listed in Table 41.1 (Abdalian & Heathcote, 2006). Currently, the most common presentation is an asymptomatic patient with persistently elevated levels of alkaline phosphatase first noted on routine serum biochemical screening. In the proper clinical context, a characteristic cholangiographic appearance of the bile ducts is sufficient for making the diagnosis.

Liver biopsy is not always necessary for diagnosing PSC, nor does it contribute new information that affects the clinical management of patients. In a study of 79 patients with PSC who had an already established diagnosis by cholangiography, liver biopsy did not affect management (Burak et al, 2003). Thus the role of liver biopsy in PSC is to 1) exclude other causes of liver disease, 2) diagnose small-duct PSC (discussed later), and 3) define the disease stage for determining prognosis and assessing efficacy of treatment prior to entering in therapeutic trials. Small-duct PSC comprises approximately 5% of histologically confirmed PSC cases (Angulo et al, 2002) and has significantly better long-term prognosis compared with classic PSC. However, some patients with small-duct disease can progress to classic PSC (Angulo et al, 2002). Patients with small-duct PSC usually have IBD and are seen intially with a cholestatic pattern of liver enzymes but normal cholangiography. Nevertheless, liver biopsy reveals classic histologic features of PSC. In the majority of patients, the history, serum biochemical profile, and cholangiography distinguish PSC from other causes of chronic cholestatic liver disease. The differential diagnosis of PSC is presented in Table 41.2.

Table 41.1

Causes of Secondary Sclerosing Cholangitis

AIDS-associated cholangiopathy
Amyloidosis
Bile duct neoplasm (in the absence of primary sclerosing cholangitis)
Chemicals/drugs (e.g., 5-fluorouracil)
Choledocholithiasis
Congenital bile duct abnormalities (Caroli disease)
Iatrogenic biliary strictures/trauma
Recurrent pyogenic cholangitis
Autoimmune pancreatitis
Intraarterial chemotherapy
Abdominal trauma, surgical or blunt
Eosinophilic or mast cell cholangitis

AIDS, acquired immunodeficiency syndrome

Table 41.2

Differential Diagnosis of Primary Sclerosing Cholangitis

Primary biliary cirrhosis
Drug-induced cholestasis
Congenital abnormality of the biliary tract
Idiopathic adult ductopenia
Cholestasis associated with autoimmune hepatitis or alcoholic liver disease
Bile duct carcinoma (cholangiocarcinoma)
Extrahepatic obstruction
Secondary sclerosing cholangitis

BIOCHEMICAL AND SEROLOGIC ABNORMALITIES

Biochemical cholestasis of at least 6 months' duration gives reason to suspect PSC. Alkaline phosphatase remains the most commonly elevated liver enzyme, often showing a threefold to fourfold increase. Nevertheless, a normal alkaline phosphatase level does not exclude the diagnosis of PSC, because normal levels have been reported in patients with cholangiographically proven disease (Balasubramanian et al, 1988). Therefore a normal alkaline phosphatase level should not dissuade further investigation if the clinical history (e.g., presence of IBD) and other evidence suggest liver disease.

Aminotransferase levels are often modestly elevated in patients with PSC, except in children, in whom these levels can be markedly increased. On average, adults with PSC have aminotransferase levels less than three times the upper limit of normal (Lee & Kaplan, 1995). PSC patients with highly elevated aminotransferases may show concomitant serologic evidence and histologic features of AIH (Czaja, 1998).

Serum bilirubin levels are normal in 60% of patients at diagnosis (Talwalkar & Lindor, 2005), but bilirubin levels will markedly rise as PSC progresses. An abrupt, sustained rise of bilirubin may herald a dominant biliary stricture, a bile duct stone, or the development of cholangiocarcinoma; therefore it should prompt additional investigation. Serum copper and ceruloplasmin levels and hepatic and urinary copper values are often abnormal. Hepatic copper levels can be elevated to the degree seen in Wilson disease and primary biliary cholangitis (PBC) (LaRusso et al, 1984); the copper increase is a reflection of prolonged cholestasis.

No autoantibody is pathognomonic for diagnosing PSC. The prevalence of antineutrophil cytoplasmic antibodies (ANCAs), anticardiolipin antibodies, and antinuclear antibodies (ANAs) in patients with PSC is 84%, 66%, and 53%, respectively (Angulo et al, 2000). Antimitochondrial antibodies (AMAs) and anti–smooth muscle antibodies are rare in patients with PSC. Approximately 25% of patients have hypergammaglobulinemia, and immunoglobulin M (IgM) levels are the most commonly elevated component (Wiesner & LaRusso, 1980). Autoantibody testing is helpful to identify those PSC patients with concurrent AIH, but antibody titers are not important in following PSC activity.

IMAGING STUDIES

Visualization of the biliary tree is essential for establishing the diagnosis of PSC, and ERCP is the gold standard imaging technique (see Chapter 18). Typical cholangiographic findings of PSC include multifocal stricturing and beading throughout the biliary tree characteristic of alternating fibrosis and ectasia of the bile ducts (Fig. 41.1). Strictures of the bile ducts are the hallmark of the disease. They are often diffusely distributed and annular with intervening segments of dilated ducts. The classic cholangiographic findings involve both the intrahepatic and extrahepatic biliary tree. Strictures can vary in length and confluency, ranging from a bandlike appearance 1 to 2 mm in length to dense, annular strictures several centimeters in length. Approximately 25% of patients have biliary outpouchings that resemble diverticula. Similarly, 30% to 40% of patients may have mural irregularities that produce a shaggy appearance, varying from a fine brush border to frank nodularity (MacCarty et al, 1983).

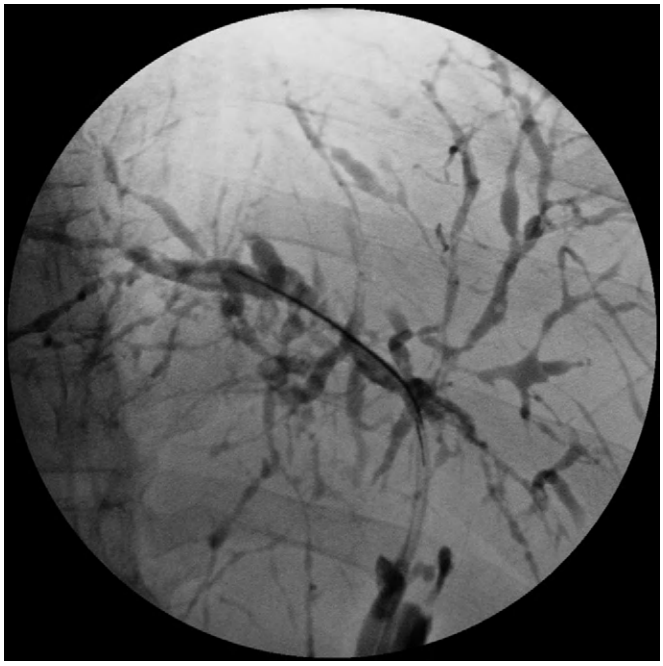

FIGURE 41.1. Endoscopic retrograde cholangiopancreatography showing the typical cholangiographic findings of primary sclerosing cholangitis: multifocal structuring and beading involves the intrahepatic bile ducts.

In a study of 86 patients with PSC, cholangiographic findings revealed involvement of the intrahepatic and extrahepatic ducts in 80 and 85 patients, respectively, when there was adequate visualization of the intrahepatic biliary tree. Involvement of only the intrahepatic and proximal extrahepatic ducts was seen in 20% of patients, and a very small number of patients had only small-duct PSC with a normal cholangiogram (MacCarty et al, 1983). Gallbladder and cystic duct involvement is less severe but is present in as many as 15% of patients (Brandt et al, 1988). ERCP should be considered in all patients suspected of having PSC. In addition to establishing the diagnosis, ERCP defines the extent and distribution of disease, identifies benign dominant strictures for endoscopic dilation or stenting, and allows brushings for cytology studies to screen for cholangiocarcinoma.

As many as 10% of cholangiocarcinomas have radiologic features that mimic PSC. Cholangiographic features that may suggest malignant degeneration of established PSC are markedly dilated biliary ducts or ductal segments, presence of a polypoid mass of 1 cm or greater in diameter, and progressive stricture formation. Nevertheless, these cholangiographic features are not specific for cholangiocarcinoma and can be seen in the absence of malignancy (MacCarty et al, 1985).

Despite the high diagnostic and therapeutic capabilities of ERCP, the procedure is invasive and is associated with clinical complications. The Mayo Clinic experience has shown that among PSC patients undergoing ERCP, the estimated rate of procedural complications requiring hospitalization is more than 10%. PSC patients undergoing ERCP are expected to have longer procedural time and a higher incidence of cholangitis compared with non-PSC patients (see Chapter 43), but the risk of pancreatitis, perforation, and bleeding are similar (Bangarulingam et al, 2009).

Magnetic resonance cholangiography (MRC) is a noninvasive substitute for ERCP (Fig. 41.2; see Chapter 17). Recent studies have estimated the sensitivity and specificity of MRC for diagnosing PSC to be between 80% to 82% and 87% to 98%, respectively (Talwalkar et al, 2004; Berstad et al, 2006). These studies concluded that MRC has diagnostic accuracy comparable to ERCP and results in cost savings when used as the initial diagnostic strategy. In another study, MRC was shown to be better than ERCP in identifying peripheral intrahepatic bile duct strictures (Vitellas et al, 2002).

In a retrospective, nonblinded study of PSC patients with known biliary tract carcinoma, MRC findings of a well-defined mass exhibiting abnormal signal intensity were classified as definite cholangiocarcinoma in six or seven patients (Vitellas et al, 2002). MRC will likely replace diagnostic ERCP, but at present it is less sensitive and does not allow for biliary biopsy and cytology or therapeutic intervention.

PTC is useful when access to the biliary tree by ERCP is not technically feasible. Abdominal ultrasonography (US) and

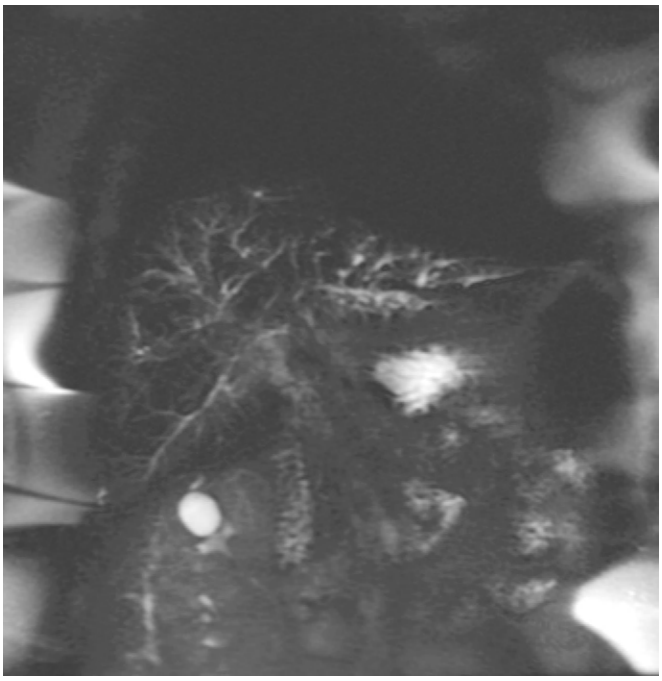

FIGURE 41.2. Magnetic resonance cholangiography images demonstrate mild dilation of numerous intrahepatic bile ducts in a segmental fashion. The findings are consistent with primary sclerosing cholangitis.

computed tomography (CT) are valuable in affirming ductal dilation and evaluating complications of PSC such as biliary stones, cirrhosis, and bile duct malignancy (see Chapters 13 and 16). US is often able to show large duct dilation and mural thickening of the common bile duct in patients with confirmed abnormalities on ERCP. It can further be used to detect gallstones or biliary tract calculi, which are important in the evaluation of bacterial cholangitis, worsening cholestasis, or jaundice.

Morphologic features of ductal abnormalities and cirrhosis can be seen on CT. Atrophy of the left lateral segment and hypertrophy of the caudate lobe may differentiate cirrhosis associated with PSC from that seen in other types of cirrhosis (Caldwell et al, 2001). CT can also complement cholangiography in the evaluation of malignancy with its ability to detect peripheral intrahepatic cholangiocarcinoma and metastatic spread within the liver parenchyma and the abdomen (Campbell et al, 1998, 2001). However, perihilar lymphadenopathy is very common in PSC with or without cholangiocarcinoma, and this finding cannot be taken as direct evidence of malignancy or metastasis.

PATHOLOGY

PSC can affect the entire biliary system. On rare occasions, it may be limited to the small intrahepatic ducts and be detectable only on histology. Small-duct PSC is thought to account for 5% of histologically confirmed PSC cases, although its true prevalence remains unknown (Angulo et al, 2002).

Liver biopsy findings alone are rarely sufficient to establish the diagnosis of PSC, which is characterized by damage to, atrophy of, and ultimately loss of bile ducts, thus sharing histologic features with other hepatobiliary diseases (Scheuer, 1998).

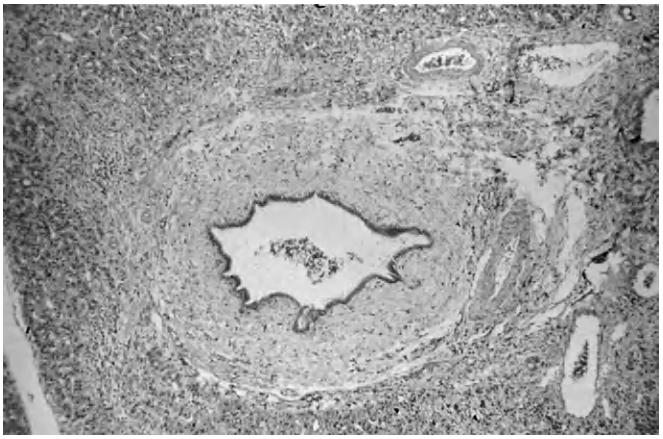

FIGURE 41.3. Histologic findings of early-stage primary sclerosing cholangitis, demonstrating prominent cholangiectasis and fibrosing cholangitis of an interlobular bile duct (hematoxylin/eosin stain ×100).

Liver biopsy specimens from patients show portal tract inflammation and sclerosis (Fig. 41.3). Afflicted bile ducts are surrounded by a cuff of lightly inflamed sheets of fibrous tissue and edema, causing the fibrotic layers to separate and form the characteristic onion skin appearance. This classic histologic finding is nearly pathognomonic, but it is seen in fewer than 10% of PSC patients (Ludwig et al, 1981). Affected bile ducts will eventually atrophy and be replaced by rounded scars.

On occasion, similar fibroobliterative cholangitis can be seen in 1) PBC, 2) mechanical obstruction of larger bile ducts, 3) ductopenic rejection following liver transplantation, and 4) after intraarterial infusion of 5-fluorouracil. Involvement of the large intrahepatic and extrahepatic ducts distinguishes PSC from PBC. Inflammation in early-stage PSC is generally milder than that of PBC, but this distinction is difficult to make (Scheuer, 1998). Granulomas, thought to be classically associated with PBC, may be seen in about 4% of biopsies from PSC patients, making the distinction between PSC and PBC even more challenging (Ludwig et al, 1995).

Distinguishing between PSC-related histopathologic features and changes as a result of simple obstruction of distal bile ducts makes the liver biopsy interpretation difficult. Canalicular cholestasis is nonspecific and can occur as a result of any cause of biliary obstruction. As PSC progresses, however, the histopathologic changes of chronic cholestasis spill into the hepatic parenchyma. The most commonly used liver histology grading system proposed by Ludwig is based on these parenchymal changes. Disease was designated as *stage 1,* portal; *stage 2,* periportal; *stage 3,* septal; and *stage 4,* cirrhotic (Table 41.3; Ludwig et al, 1986). Histologic changes in the same liver can be markedly varied from segment to segment at any given point in time. Whereas histologic staging was formerly used as an independent predictor of the disease's natural history, the revised PSC survival model does not take into account the histologic stage (Kim et al, 2000).

ETIOPATHOGENESIS

To date, the pathogenesis of PSC remains unknown. Current theories regarding the etiology of PSC encompass both genetic elements and environmental exposures. It is believed that the

Table 41.3

Staging of Primary Sclerosing Cholangitis

Portal stage (stage I)	Portal edema, inflammation, ductal proliferation; abnormalities do not extend beyond the limiting plate
Periportal stage (stage II)	Periportal fibrosis and inflammation with or without ductal proliferation; piecemeal necrosis may be present
Septal stage (stage III)	Septal fibrosis or bridging necrosis can be identified
Cirrhotic stage (stage IV)	Biliary cirrhosis evident

host–environment interaction plays an integral role in the development of PSC. Moreover, it is now known that cholangiocytes, the epithelial cells that line the bile ducts, are the target of injury in PSC.

The strong association of PSC with IBD has drawn much attention to the potential role of the inflamed colon. The hypothesis suggests that inflammation of the colon may increase permeability to various intraluminal products—toxins, bacteria, inflammatory mediators—that ultimately lead to liver disease. Bacteria or their toxic metabolic products have been considered but have not been conclusively shown to have a pathogenetic role in PSC development (Eade & Brooke, 1969; Palmer et al, 1980). However, investigators have shown that the absence of low-grade, chronic portal vein bacteremia in patients with CUC could potentially elicit the immune response that is responsible for PSC (Warren et al, 1966). Similarly, histologic evidence of bacteremia manifested as portal phlebitis is mild or absent in most PSC patients (Ludwig et al, 1981). Additional information showed that colonic bacteria might metabolize primary bile acids into toxic bile salts that are then absorbed through the ulcerated colon into the portal circulation, but no evidence of bile acid metabolism abnormalities in patients with PSC or CUC has been found (Siegel et al, 1977).

Animal models of PSC have reported that bacterial chemotactic peptides can lead to portal inflammation and histologic changes of PSC (Hobson et al, 1988: Lichtman et al, 1990). Suppression of the inflammatory response was reported in an animal model following inhibition of tumor necrosis factor (TNF). Nevertheless, in a clinical trial of PSC patients with pentoxifylline, a TNF inhibitor, no beneficial effect on symptoms or liver tests was seen (Bharucha et al, 2000). Clinical observations also cast doubt upon the role of the inflamed colonic mucosa in the development of PSC. First, PSC develops in approximately 25% of patients without evidence of IBD. Invasive screening of asymptomatic patients with PSC reveals that many have no endoscopic or histologic evidence of IBD. Second, lack of association between the severity of colonic disease and the likelihood of development and severity of PSC strengthens the skepticism that CUC may not directly cause PSC. Third, failure of proctocolectomy to modify the natural history of PSC argues against a direct causative role of CUC in PSC (Cangemi et al, 1989; Steckman et al, 1984). Thus, the putative contribution of increased colonic permeability in CUC resulting in inflammation of bile ducts remains unclear.

Genetic factors seem to play a role in the development of PSC. First, there have been reports of familial PSC among siblings (Quigley et al, 1983; Jorge et al, 1987). Second, various HLA associations with PSC have been reported, and HLA B8, DR3, DR2, and haplotype A1, B8, and DR3 have been found more frequently in patients with PSC compared with controls (Chapman et al, 1983; Donaldson et al, 1991; Schrumpf et al, 1982; Wiencke et al, 2007). PSC associated with DR4 is a more aggressive disease, although this correlation has not been universally found (Mehal et al, 1994; Olerup et al, 1995). Additional associations with DRB3*0101, DRB1*0301, DQA1*0501, DQB1*0201 and DRB1*1301, and DQA1*0103 and DQB1*0603 have been reported (Donaldson & Norris, 2002). Polymorphisms in the TNF-α receptor have been described as a possible genetic link to PSC. G to A substitution at position –308 in the TNF-α gene has been associated with susceptibility to PSC (Mitchell et al, 2001). A functional variant of stromelysin, matrix metalloproteinase 3, may also influence PSC susceptibility and disease progression (Satsangi et al, 2001). Moreover, variations in the *MICA* gene (major histocompatibility complex class I–related *MIC* gene family) have a role in PSC predisposition. Independent of other HLA haplotypes, the *MICA* 002 allele appears to significantly reduce the risk of PSC, and the *MICA* 008 allele increases the risk of developing PSC (Norris et al, 2001). Finally, the *CCR5-δ32* mutation, characterized by a 32-base pair deletion in the *CCR5* gene of T cells, has been associated with susceptibility to PSC development and severity (Eri et al, 2004).

Immune-mediated damage to cholangiocytes seems to be the most likely mechanism leading to PSC. Theoretically, certain HLA molecules and haplotypes may contribute by eliciting an immune response against antigenic epitopes present on biliary epithelia. Enhanced expression of MHC class II antigens (i.e., HLA DR) on cholangiocytes in early-stage PSC has drawn suspicion regarding its role in altered immunity in disease pathogenesis. Aberrant expression of HLA DR is also apparent in PBC and extrahepatic biliary obstruction, suggesting that expression of this antigen is an epiphenomenon rather than an implicit cause of PSC (Broome et al, 1990; Chapman et al, 1988; Van Milligen De Wit et al, 1995).

Decreased hepatic clearance of circulating immune complexes, generalized complement activation, and sharing of a specific epitope between human colonic and biliary epithelial cells have also been reported (Bodenheimer et al, 1983; Minuk et al, 1985; Das et al, 1990; Mandal et al, 1994), yet none of these observations have proven pathogenic associations with PSC. Enhanced interactions of intracellular adhesion molecule 1 (*ICAM1*) present on cholangiocytes with its cognate ligand on T lymphocytes, leukocyte function–associated antigen 1 (ITGAL), may play a role in PSC development. Genetic polymorphisms of *ICAM1* have been implicated in susceptibility to PSC. Homozygote status of the E469E allele for *ICAM1* has been associated with protection against PSC (Yang et al, 2004). Both enhanced expression on proliferating cholangiocytes and increased serum levels of ICAM1 have been reported in PSC patients (Van Milligen De Wit et al, 1995; Adams et al, 1991; Bloom et al, 1995).

ASSOCIATED DISEASES

PSC is strongly associated with IBD, most commonly CUC. PSC patients may also have biochemical, serologic, and histologic features of AIH, and a variety of other diseases have been reported to associate with PSC. Given the lack of large studies, it is unclear whether these weak associations are true or simply

Table 41.4

Celiac disease
Autoimmune hemolytic anemia
Sarcoidosis
Glomerulonephritis

coincidental. An abridged list of associated diseases is presented in Table 41.4.

Inflammatory Bowel Diseases

The close association of PSC with IBD, particularly CUC, is widely recognized. IBD is seen in approximately 70% to 80% of patients with PSC, and CUC accounts for 85% to 90% of those patients; Crohn disease is responsible for the rest (Fausa et al, 1991; Loftus et al, 1997). Patients with PSC and Crohn disease may have milder liver disease than patients with PSC and CUC, and PSC has not been seen in Crohn disease involving only the small intestine (Rasmussen et al, 1997). Typically, the diagnosis of IBD is established 8 to 10 years before the liver disease is evident, although there is no clear temporal association, and cases of IBD occurring years after diagnosis of PSC have also been reported (Chapman et al, 1980; Loftus et al, 1996a, 1998). No direct correlation has been found between the severity of bowel disease and the severity of liver disease. Furthermore, therapy of the IBD does not alter the course of the liver disease. For instance, proctocolectomy, the most aggressive treatment for CUC, has no effect on PSC natural history (Cangemi et al, 1989). Colitis is usually milder in patients with both CUC and PSC in comparison to patients with CUC alone.

PSC may play a role in the development of colorectal dysplasia in the setting of CUC, as patients with CUC and PSC show a higher risk of colonic dysplasia compared with patients who have only CUC (Broome et al, 1995a, 1995b). In a study from Sweden, the absolute cumulative risk of developing colorectal dysplasia/carcinoma in patients with PSC and CUC was 9%, 31%, and 50% after 10, 20, and 25 years of disease duration, respectively. In patients with CUC alone, the parallel risk was 2%, 5%, and 10%, respectively (Broome et al, 1995b). Subsequent studies also confirmed the observation of Broom and others, where predicted risk of colorectal carcinoma with PSC and concomitant IBD after 10 years of disease duration was up to 25% (Kornfeld et al, 1997; Claessen et al, 2009). Other investigators have reported that patients with both PSC and CUC were five times more likely to develop colonic dysplasia, based on mucosal biopsy, compared with patients with CUC alone (Brentnall et al, 1996). Whether this finding reflects the fact that PSC patients have milder pancolonic disease that remained undetected for a longer period of time is uncertain. Interestingly, a retrospective case-control study found a similar prevalence of PSC in patients with both CUC and colorectal carcinoma compared with those who had CUC but no neoplasia, that is, no carcinoma or dysplasia (Nuako et al, 1998).

Colonic dysplasia has also been reported in PSC patients without IBD (Broome et al, 1995a, 1995b). However, the risk of colorectal carcinoma in patients with PSC at 10 and 20 years of disease duration was much lower (2% and 2%) than in patients with PSC and concomitant IBD (14% and 31%). PSC patients with CUC continue to have increased risk of colorectal dysplasia and neoplasia, even after liver transplantation (Bleday et al, 1993). The increased neoplastic potential is especially critical in PSC patients following liver transplant, because of the life-long immunosuppression. Annual colonoscopy with surveillance biopsies is recommended in patients with PSC and CUC, because screening and early detection improves survival (Narumi et al, 1995; Loftus et al, 1998). Annual colonoscopy is also suggested for PSC patients without IBD.

Autoimmune Hepatitis

An overlap syndrome between PSC and AIH has been described (Gohlke et al, 1996; Luketic et al, 1997). These patients typically fulfill definite criteria for both, having elevated serum alkaline phosphatase and aminotransferases and increased IgG and antinuclear and/or anti–smooth muscle antibody titers. Liver biopsy reveals moderate to severe interface hepatitis with or without biliary damage, and aminotransferase levels are elevated beyond what would be expected for classic PSC, typically less than three times normal. IBD may also be present in patients with concurrent PSC and AIH but at a lower frequency than in PSC alone. In patients with overlap syndrome, AIH may respond to immunosuppressive therapy. Patients who are seen with AIH but do not respond entirely to immunosuppressant therapy and subsequently develop a cholestatic biochemical profile should be suspected of having concomitant PSC.

NATURAL HISTORY

PSC is an insidious and progressive disease that frequently leads to end-stage liver disease and liver failure. Patients with early-stage PSC are generally asymptomatic. Advanced-stage PSC is marked by complications of chronic cholestasis and end-stage liver disease. Prior appendectomy may delay the onset of PSC but does not affect the prevalence or severity of the disease (Florin et al, 2004). In the absence of liver transplantation, the median survival from the time of diagnosis is about 12 years. Even asymptomatic patients have decreased survival compared to age-matched controls (Wiesner et al, 1989). In a study of 45 PSC patients who were asymptomatic at the time of diagnosis, 76% had progression of PSC, and 31% had liver failure develop with a mean follow-up of 6.25 years (Porayko et al, 1990). Early diagnosis of PSC is associated with longer survival because of presumed lead-time bias (Broome et al, 1996; Okolicsanyi et al, 1996).

The progressive pattern and severe complications of PSC warrant close medical management and intervening treatment. Prognostic models for PSC have been developed to predict survival and identify the ideal timing for liver transplantation. Cox multivariable regression analysis has been widely used to define the variables for these models. The revised Mayo PSC natural history model uses six independent, reproducible parameters to estimate the survival of PSC patients. These variables include age, bilirubin, albumin, aspartate aminotransferase, and history of variceal bleeding (Kim et al, 2000). Recently the Model for End-Stage Liver Disease (MELD) has been widely used

to ensure organ allocation priority to end-stage liver disease patients with the highest mortality risk (Kamath et al, 2001).

Small-duct PSC, although rare, has a favorable long-term prognosis. In a multiinstitutional and multinational study, the 83 small-duct PSC patients were matched by age, gender, year of diagnosis, and institution to two patients with large-duct PSC. Approximately 23% patients with small-duct PSC progressed to large-duct PSC over a median of 7.4 years. Patients with small-duct PSC did not develop cholangiocarcinoma, unless the disease progressed to large-duct PSC. The same study showed patients with small-duct PSC had a statistically longer transplantation-free survival: 13 years compared with 10 years. Two patients with small-duct PSC who underwent liver transplantation did have a recurrence of small-duct PSC in the graft after 9 years (Bjornsson et al, 2008). In children with PSC who have progressive disease, the median survival despite medical therapy, and in the absence of liver transplantation, was reported to be 12.7 years (Feldstein et al, 2003).

COMPLICATIONS

Specific PSC complications include cholelithiasis, choledocholithiasis, dominant biliary strictures with or without recurrent bacterial cholangitis, cholangiocarcinoma, and peristomal varices in patients who have undergone proctocolectomy and ileostomy for CUC. Nonspecific PSC complications are related to chronic cholestasis—pruritus, steatorrhea, fat-soluble vitamin deficiency, hepatic osteodystrophy—and to complications associated with end-stage liver disease such as cirrhosis and portal hypertension.

SPECIFIC COMPLICATIONS

Cholelithiasis and Choledocholithiasis (See Chapters 30 and 35)

Although PSC is a disease affecting mainly young men, it is surprising that 25% to 30% will have calculi either in the gallbladder or biliary tree. In a study of 121 patients with PSC, 26% had gallstones, half of which were pigment stones, although the spectrum of pathology in the gallbladder is not limited to stones (Brandt et al, 1988). The same study showed that PSC directly involved the gallbladder in 15% of patients. The gallbladder can also suffer an unusual form of acalculous cholecystitis characterized by a diffuse lymphoplasmacytic infiltrate (Jessurun et al, 1998). Finally, in patients with PSC, gallbladder polyps require special attention. In a study of 102 patients with PSC, 14 patients (13.7%) had an intraluminal gallbladder mass, and eight of these lesions (57%) were adenocarcinomas (see Chapter 49). Recent case series showed that adenocarcinomas of the gallbladder can occur in polyps less than 1 cm (Karlsen et al, 2008), thus in PSC patients with gallbladder polyps, cholecystectomy is recommended (Buckels et al, 2002).

Radiologic studies have shown that intrahepatic calculi are present in approximately 8% of PSC patients (Dodd et al, 1997). Biliary calculi can serve as a nidus for the development of bacterial cholangitis in PSC patients, although this is uncommon in the absence of dominant biliary strictures or prior bile duct surgery. Evidence of bacterial cholangitis requires endoscopic evaluation to remove possible bile duct calculi and/or to dilate biliary strictures. Bacterial cholangitis commonly occurs in patients with PSC following ERCP, thus prophylactic coverage with antibiotics prior to (i.e., a single intravenous dose) and following ERCP (i.e., oral ciprofloxacin for 10 days) is recommended for PSC patients.

Dominant Biliary Strictures

Dominant strictures occur in 20% to 45% of PSC patients and present with progression of jaundice, pruritus, bacterial cholangitis, and right upper quadrant pain. ERCP is necessary to evaluate the bile ducts and allow therapeutic dilation with or without biliary stenting. In a prospective study, 12 symptomatic PSC patients with major ductal strictures were treated with repeated balloon dilation. Eight patients showed sustained improvement following an average of three treatment sessions to obtain satisfactory dilation of the affected bile ducts (Wagner et al, 1996). A retrospective study of 25 PSC patients with symptomatic dominant strictures showed that endoscopic stenting was technically successful in 21 patients (84%) and was associated with significant improvement of serum liver tests. Moreover, 12 (57%) of 21 patients with PSC remained asymptomatic with stable liver biochemistries, and four patients (19%) had clinical and biochemical relapse over a median follow-up of 29 months. All four patients with relapse responded favorably to additional endoscopic therapy (Van Milligen De Wit et al, 1996). The same investigators reported that in 16 patients with symptomatic PSC, short-term biliary stent placement (median, 9 days) was effective, with 13 patients (81%) remaining symptom free and without biochemical evidence of cholestasis after a median follow-up of 19 months (Van Milligen De Wit et al, 1997).

Despite these findings, it is unclear whether dominant biliary strictures are directly responsible for the cholestasis of PSC patients. In a retrospective study of 125 patients with PSC, 56 (45%) had dominant strictures, defined by stenosis of the common bile duct less than 1.5 mm in diameter and/or stenosis of the right or left hepatic duct less than 1.0 mm. Of interest, in PSC patients with (n = 56) or without (n = 69) dominant strictures up to 12 months after cholangiography, alkaline phosphatase and bilirubin levels were not significantly different (Bjornsson et al, 2004).

Cholangiocarcinoma

The most ominous complication of PSC is the development of cholangiocarcinoma (see Chapters 50A, 50B, and 50C), which is estimated to occur in 8% to 15% of patients during the course of the disease (Chapman, 2003; Claessen et al, 2009). In a study of 161 patients with PSC, approximately 7% had cholangiocarcinoma develop over a mean follow-up of 11.5 years (Burak et al, 2004). Among PSC patients, the estimated annual incidence of cholangiocarcinoma is approximately 1.5% (Gores, 2003). The cumulative risk of biliary tract malignancy is approximately 11.2% at 10 years from diagnosis of PSC (Kornfeld et al, 1997). Moreover, at the time of liver transplantation, approximately 10% of explanted livers have histopathologic evidence of unsuspected cholangiocarcinoma.

Patients with PSC and cholangiocarcinoma have poor survival. In a retrospective study of 30 patients with PSC, median survival was 5 months from the time of cholangiocarcinoma diagnosis. Also at the time of diagnosis, 63% had metastatic disease, and 47% considered to have localized tumors had

abdominal metastasis at surgical exploration. Also, metastasis or local extension of disease precluded curative tumor resection in all but one patient, who was cholangiocarcinoma free more than 2 years later. Unfortunately, in PSC patients who develop cholangiocarcinoma, palliative resection, chemotherapy, and radiotherapy do not prolong survival.

Cholangiocarcinoma is usually diagnosed at an advanced stage because of its insidious nature. Many of the signs and symptoms associated with cholangiocarcinoma are typical of PSC itself, making early detection of cholangiocarcinoma difficult. Suspicion for cholangiocarcinoma should be raised when a patient with PSC is seen with rapidly progressive jaundice, weight loss, or abdominal discomfort. In a study comparing PSC patients who developed cholangiocarcinoma with those who did not, the investigators found no clinical or biochemical features that could herald the onset of biliary malignancy in the year prior to diagnosis (Bergquist et al, 1998). In patients with PSC, risk factors for developing cholangiocarcinoma include age, liver histologic stage, concurrent CUC (Rosen & Nagorney, 1991), smoking (Bergquist et al, 1998), and history of variceal bleeding (Burak et al, 2004).

In PSC patients, dysplasia of the biliary epithelium is likely the greatest predisposing factor of cholangiocarcinoma. In a study from the United Kingdom, biliary dysplasia was detected in approximately 20% of liver biopsies from 26 patients with PSC and cholangiocarcinoma, but not in a single case of 60 PSC patients who were free of biliary malignancy for a follow-up period of 2 years (Fleming et al, 2001). Moreover, recognition of biliary dysplasia by three independent pathologists showed moderate reproducibility, further suggesting dysplasia as a feasible indicator of present or developing biliary malignancy (Fleming et al, 2001). Likewise, colonic dysplasia seems to be a risk factor for cholangiocarcinoma, with risk increased significantly in patients with PSC and CUC (Broome et al, 1995b); therefore detection of dysplasia in either the biliary tree or colon requires vigilant surveillance for cholangiocarcinoma and may warrant consideration for liver transplantation under certain circumstances.

Early detection of cholangiocarcinoma, and thus promise for cure, has been hampered by the low sensitivity and specificity of standard diagnostic approaches and techniques. Cholangiocarcinoma of the large bile ducts is not easily detectable by cross-sectional imaging. In this case, ERCP is perhaps the best approach to evaluate for bile duct cancer. To this end, cholangiographic features suggestive of cholangiocarcinoma have been described, but the accurate distinction between benign and malignant biliary disease is often impossible. In fact, about 10% of malignant-appearing biliary strictures are benign (Hadjis et al, 1985). Biliary brush cytology specimens and fine-needle biopsies obtained at ERCP are at best 30% to 40% sensitive for securing the diagnosis of cholangiocarcinoma. A novel test for early detection of cholangiocarcinoma is *fluorescence in situ hybridization* (FISH) on bile duct cytology specimens. In a study on detection of malignant biliary strictures, the sensitivity of FISH (34%) was better than that of standard cytology (15%, $P < .01$), but the specificity of FISH and cytology was similar, at 91% and 98%, respectively ($P = .06$) (Kipp et al, 2004). A recent study of 498 patients undergoing ERCP for pancreatobiliary stricture demonstrated that polysomy of FISH had a significantly higher sensitivity (42.9%) than routine cytology (20.1%) with identical specificity (99.6%) (Fritcher et al, 2009).

Carbohydrate antigen 19-9 (CA19-9) has been used with questionable accuracy to aid the diagnosis of cholangiocarcinoma. In patients with PSC, a cutoff serum level of 129 U/mL is estimated to have a diagnostic sensitivity of 89% and specificity of 98% for diagnosing cholangiocarcinoma (Levy et al, 2005). Similar elevations of CA19-9 can be seen in patients with pancreatic malignancies, bacterial cholangitis, and in active smokers. In PSC patients, periodic CA19-9 testing is recommended, and a sustained rise should raise suspicion for possible development of cholangiocarcinoma. Others have shown that a carcinoembryonic antigen (CEA) level greater than 5 ng/mL was 100% specific but only 38% sensitive for detection of cholangiocarcinoma (Nichols et al, 1993). Another study using an index of CA19-9 and CEA showed an 86% diagnostic accuracy for detecting cholangiocarcinoma. Although most of these patients had radiologically occult disease, and several went on to liver transplantation, the great majority still died from cholangiocarcinoma (Ramage et al, 1995). At present, we have no reliable means to detect cholangiocarcinoma early, at a curable stage, although work is underway to find dependable molecular markers for early cholangiocarcinoma detection.

Endoscopic ultrasound (EUS; see Chapter 14) is better than CT and magnetic resonance imaging (MRI) to evaluate regional lymph nodes for possible cholangiocarcinoma metastasis, including the option to obtain a biopsy of questionable lesions (Gores, 2000). Positron emission tomography (PET) is a promising tool for detection of cholangiocarcinoma in PSC (see Chapter 15), and it can detect small cholangiocarcinomas arising in the setting of PSC with 100% accuracy compared with control groups (Keiding et al, 1998). A blinded study in Sweden examined 24 pretransplant PSC patients without evidence of malignancy on CT, MRI, and US, and PET correctly identified three of three patients with explanted liver pathology showing cholangiocarcinoma. But PET failed to detect a high-grade hilar ductal dysplasia and was falsely positive in a patient with benign epithelioid granulomas (Prytz et al, 2006), therefore, further investigations are necessary to define the role of PET in the diagnosis and routine surveillance of cholangiocarcinoma.

NONSPECIFIC PRIMARY SCLEROSING CHOLANGITIS COMPLICATIONS

Many patients with PSC complain of fatigue and pruritus. The etiology of fatigue is unclear in chronic cholestatic liver diseases, including PSC, and this can affect patients' quality of life. In PSC patients, the pruritus can be debilitating; although its mechanism is not well defined, endogenous opioids and retention of other unknown factors usually excreted in the bile may play some role in its development (Bergasa & Jones, 1995; Spivey et al, 1994; Jones & Bergasa, 1990).

Patients with PSC may also suffer from steatorrhea and subsequent deficiencies of fat-soluble vitamins. In a pretransplant group of PSC patients, deficiencies of vitamins A, D, and E were present in 82%, 57%, and 43% of patients, respectively (Jorgensen et al, 1995). These deficiencies can be treated with simple vitamin supplementation. In patients with PSC and steatorrhea, consideration should be given to exclude celiac sprue or chronic pancreatitis, because either entity can coexist with PSC, and both conditions are treatable causes of fat malabsorption (Hay et al, 1988). Metabolic bone disease is also very common in PSC. Osteopenic bone disease can be severe in

advanced-stage PSC, with 50% of patients having a bone mineral density below the fracture threshold (Hay et al, 1991). Although the majority of PSC patients are males, bone biopsies revealed findings consistent with osteoporosis rather than osteomalacia.

Patients with PSC have complications of portal hypertension, just as patients with other causes of liver cirrhosis do (see Chapters 70, 74, and 75). In a study of 283 patients with PSC, 102 patients (36%) had esophageal varices, including 57 (56%) of moderate to large size. A recent study of PSC patients reported that platelet count, albumin level, and advanced histologic disease were independent predictors of esophageal varices (Zein et al, 2004), which are usually managed with endoscopic banding. If these measures are ineffective, a shunting procedure (TIPS) can be performed as a bridge to liver transplantation. Patients with advanced-stage PSC develop ascites, spontaneous bacterial peritonitis, and encephalopathy. Treatment of such complications is similar to that of other causes of end-stage liver disease, with liver transplantation considered the optimal management (see Chapters 70, 74, 75, and 97A).

TREATMENT

Medical Therapy

To date, there is no specific medical therapy for PSC. Management should focus on the treatment of specific and nonspecific complications. Clinical trials on treating the underlying hepatobiliary disease are underway.

Therapy of Specific Primary Sclerosing Cholangitis Complications

Cholelithiasis and Choledocholithiasis

Symptomatic gallbladder disease in early-stage PSC patients should be treated with cholecystectomy. In an asymptomatic patient with PSC, presence of an intraluminal gallbladder mass requires cholecystectomy. In a study of PSC patients who underwent cholecystectomy, 13.7% of patients were found to have a gallbladder mass, and 57% were adenocarcinomas (Buckels et al, 2002). Cholecystectomy is not normally advocated for polyps less than 1 cm, but it may be justified in PSC patients; adenocarcinomas have been reported in recent case series of polyps less than 1 cm (Karlsen et al, 2008).

Following the diagnosis of choledocholithiasis, the therapeutic intervention of choice is ERCP (see Chapter 27). During this procedure, endoscopic sphincterectomy is performed with removal of biliary stones and dilation of possible strictures. Temporary biliary stent placement is typically recommended but depends on the clinical circumstances.

Dominant Biliary Stricture and Recurrent Bacterial Cholangitis

Dominant biliary stricture should be evaluated by ERCP or percutaneous transhepatic cholangiography (PTC) to ensure comprehensive imaging of the biliary tree and to permit biliary brushings and biopsies of affected areas to exclude cholangiocarcinoma. The main concern is to scrutinize whether the observed biliary stricture represents cholangiocarcinoma or a benign lesion. *Dominant stricture* is defined as a common duct diameter less than 1.5 mm and a hepatic duct less than 1 mm (Stiehl et al, 2002).

The therapeutic management of dominant bile duct stricture includes a combination of biliary dilation and stenting interventions. The preferred approach, ERCP versus PTC, depends on local experience and biliary stricture characteristics, such as region and length. The majority of bile duct strictures are amenable to endoscopic cholangioplasty followed by biliary stenting. PTC is useful for cholangioplasty of biliary strictures that affect intrahepatic ducts and for cases of unsuccessful ERCP. PSC patients with frequent episodes of bacterial cholangitis should have cholangiography to evaluate patency of bile ducts. Recurrent bacterial cholangitis is not always the result of dominant biliary strictures. Edema, inflammatory exudation, and intraluminal debris can result in temporary stenosis of bile ducts and lead to obliteration and subsequent recurrent bacterial cholangitis. To this end, temporary intranasal biliary tubes and biliary lavage have been used to flush out potential irritants and keep the ducts patent. In patients with relapsing episodes of bacterial cholangitis, antibiotics can be used as prophylaxis to prevent these recurrent events, although well-designed studies to address this complication are lacking.

Therapy of Nonspecific Complications

Pruritus

Patients with advanced-stage PSC frequently complain of intense pruritus. This distressing symptom can improve using various medical therapies (Angulo & Lindor, 1999). Cholestyramine is a nonabsorbable bile acid–binding resin that decreases the intestinal absorption of bile acids and alleviates pruritus. Phenobarbital has been used in conjunction with cholestyramine to treat PSC patients with nocturnal pruritus. Ursodeoxycholic acid (ursodiol)—a hydrophilic bile acid that likely replaces hydrophobic, toxic bile acids from the bile pool—may also improve pruritus. Antihistamines, such as hydroxyzine and diphenhydramine, can be used as supplements to cholestyramine or ursodeoxycholic acid, particularly for nocturnal pruritus, because of their sedative properties. Rifampin may also improve pruritus, although its potential side effects, specifically drug-induced hepatitis, make it a second-line agent. Opiate antagonists like naloxone, nalmefene, and naltrexone are also used to alleviate pruritus (Bergasa, 2004).

Steatorrhea, Fat-Soluble Vitamin Deficiency, and Hepatic Osteodystrophy

Prolonged cholestasis causes decreased intestinal bile acid concentration. Therefore, patients with advanced-stage PSC may develop fat malabsorption and steatorrhea, although PSC patients who develop steatorrhea should first be evaluated for other coexisting causes of steatorrhea, including celiac sprue and pancreatic insufficiency (Hay et al, 1988). Because of intraluminal bile acid deficiency, steatorrhea may improve from dietary changes, such as lowering daily fat intake and substituting medium-chain triglycerides for long-chain ones.

Deficiencies of fat-soluble vitamins A, D, E, and K are treated by simple oral replacement. Special consideration must be given in advanced-stage PSC patients who have moderate to severe osteopenia. Calcium supplements, replenishment with vitamin D, and use of estrogens all have shown therapeutic value. PSC patients deficient in vitamin K have prolonged prothrombin time that usually improves with oral vitamin K supplementation.

Decompensated Cirrhosis and Portal Hypertension

Complications of decompensated cirrhosis and portal hypertension should be managed expectantly as in other end-stage liver diseases. As PSC progresses, the complications of end-stage liver disease become intractable, and liver transplantation becomes the only effective therapy.

Therapy of Hepatobiliary Disease

Over the past 2 decades, multiple medical therapies have been evaluated for the treatment of PSC. Cupruretics (D-penicillamine), immunosuppressive agents (cyclosporine, azathioprine, budesonide, silymarin), antifibrogenic drugs (pentoxifylline, colchicine), and choleretic compounds (ursodeoxycholic acid) have been used, but none so far has been shown to be effective.

A double-blind, randomized, controlled study involving 105 PSC patients and standard dose UDCA (13 to 15 mg/kg body weight/day) failed to demonstrate clinical benefit in the treatment group compared with controls over a median follow-up of 2.2 years. Subsequently, pilot studies demonstrated promise with high-dose UDCA in PSC. A small, double-blind, placebo-controlled study from the United Kingdom reported that PSC patients (n = 13) who received high-dose (20 mg/kg body weight/day) UDCA had significant improvement in liver biochemistries, cholangiographic appearance, and reduction of liver fibrosis compared with patients taking placebo (n = 13) (Mitchell et al, 2001). In a similar U.S. study, 30 PSC patients were treated with high-dose (25 to 30 mg/kg body weight/day) UDCA, with reported improvement of the Mayo PSC risk score at the end of therapy (Harnois et al, 2001). Unfortunately, two separate large, randomized, double-blind, placebo-controlled trials indexing a total of 219 and 150 patients, respectively, with extended follow-up over 5 years, showed that long-term, high-dose UDCA (17 to 30 mg/kg body weight/day) improved liver tests but did not decrease clinical end points of cirrhosis, varices, cholangiocarcinoma, liver transplantation, or death (Olsson et al, 2005; Lindor et al, 2009). In fact, Lindor and others demonstrated that adverse events were more likely to occur in the high-dose UDCA group than in the placebo group.

Although UDCA plays a limited role in slowing the progression of liver disease, it has been shown to affect the frequency of colonic neoplasia or cancer in patients with PSC and CUC. In a cross-sectional study of 59 patients with both PSC and CUC who were undergoing colonoscopic surveillance, UDCA use was associated with decreased prevalence of colonic dysplasia (Tung et al, 2001). In another randomized, placebo-controlled trial of 52 patients with concurrent PSC and CUC, use of UDCA resulted in a relative risk of 0.26 for developing colorectal dysplasia or cancer (Pardi et al, 2003). Additional, prospective, randomized controlled studies are needed to verify the proposed chemopreventive effect of UDCA in patients with PSC and CUC.

Surgical Therapy

The surgical approach to PSC has evolved tremendously in the past 3 decades. Choledochotomy with operative cholangiography and biopsy were once required for the diagnosis of PSC, but the need for these procedures has been obviated by the advent of endoscopic and percutaneous cholangiography. Similarly, palliative biliary reconstruction has largely been replaced by liver transplantation.

Reconstructive Biliary Surgery

In 1988, Cameron and colleagues reported the Johns Hopkins experience of reconstructive biliary surgery in 31 PSC patients who underwent this procedure for persistent jaundice or recurrent bacterial cholangitis (Cameron et al, 1988). This surgical approach included excision of the hepatic duct bifurcation and extrahepatic biliary tree, dilation of the intrahepatic ducts, insertion of Silastic transhepatic biliary stents, and bilateral hepaticojejunostomies. Five of 31 patients had cirrhosis. Of the 26 patients without cirrhosis, the 1-, 3-, and 5-year survival rates were 92%, 87%, and 71%, respectively. The mean bilirubin in the noncirrhotic group improved from 9.9 mg/dL to 4.3 mg/dL after 5 years. In contrast, two of the five patients with cirrhosis died after surgery, and only one survived the after the first postoperative year. The authors concluded that primary biliary reconstruction should be considered in noncirrhotic patients with severe stricturing at or near the hepatic duct bifurcation or in the distal biliary tree. Patients with cirrhosis should be referred for liver transplantation.

Over the past decade, biliary reconstructive surgery for PSC has become less common, because endoscopic techniques for bile duct dilation (see Chapter 27) and stenting, as well as outcomes with liver transplantation, have improved (see Chapter 97A). In addition, hesitation arose after several centers reported increased difficulty performing liver transplantation in patients who had previous biliary surgery. Despite this, biliary-enteric anastomosis may still be indicated in noncirrhotic patients with primarily extrahepatic disease. To compare efficacy of these different modes of therapy, Ahrendt and colleagues (1998) retrospectively reviewed 146 patients with PSC seen at the Johns Hopkins Hospital from 1980 to 1994. Of these, 50 patients underwent resection of the extrahepatic bile ducts and long-term transhepatic stenting (replaced every 2.2 months on average), 54 patients were managed nonoperatively with endoscopic balloon dilation with or without percutaneous stenting, 28 patients were treated medically, and 21 patients received liver transplantation (Ahrendt et al, 1998). Of the 50 patients managed with resection of the extrahepatic biliary tree, three patients (6%) died prior to hospital discharge, two of whom had cirrhosis. Of 21 patients, four (19%) died after liver transplant; there were no postprocedural deaths in the endoscopically managed group. In noncirrhotic patients managed with resection, bilirubin levels fell significantly from 8.2 mg/dL preoperatively to just over 3 mg/dL after 5 years. By comparison, those patients managed nonoperatively with endoscopic or percutaneous procedures had a slight lowering of their serum bilirubin levels at 1 and 3 years but returned to pretreatment levels by 5 years. Most significant, however, was the improvement in 5-year and transplant-free survival in patients managed with resection (85% and 78%, respectively) versus those managed with endoscopic dilation and/or percutaneous stenting (59% and 46%, respectively). Part of the difference in survival was due to the development of cholangiocarcinoma in three of the endoscopically managed patients. As the majority of cholangiocarcinomas occur in the perihilar region, this may explain why none of the patients who underwent resection died from this complication.

Myburgh (1994) reported on 24 patients with biliary enteric bypass without the need for transanastomotic stenting. With the Hepp-Couinaud technique, a side-to-side anastomosis 2.5 to

3.5 cm wide was performed between a Roux-en-Y loop of jejunum and the right and left hepatic ducts at their confluence. Without applying stents, the need of stent replacement, and thus the increased risk for bacterial cholangitis, was eliminated. Among the 16 noncirrhotic patients who underwent bypass, survival was 100%, and 11 remained free of jaundice with a median follow-up of 6.5 years; however, patients with cirrhosis derived minimal benefit (Myburgh, 1994).

It appears that biliary reconstructive surgery may be an effective palliative measure for selected noncirrhotic patients with primarily extrahepatic PSC. However, the association of biliary-enteric drainage surgical procedures with development of cholangiocarcinoma is a significant concern (Tocchi et al, 2001). In our practice, we refer PSC patients with dominant biliary strictures for endoscopic dilation, given the high degree of success attained by this procedure and its relative ease and low morbidity/mortality compared with biliary surgery. We recommend biliary reconstructive surgery for those few PSC patients who have persistent cholestasis but no cirrhosis; the biliary obstruction is not amenable to endoscopic treatment, and they are not candidates for liver transplantation.

Orthotopic Liver Transplantation

Orthotopic liver transplantation (OLT; see Chapter 97A) remains the most effective treatment for PSC. At the Mayo Clinic, the 1- and 5-year patient survival rates for PSC are 92% and 86%, respectively. These rates compare favorably with results of OLT for other chronic liver diseases. Wiesner and colleagues (1996) reported outcomes for patients who underwent OLT for PSC and identified risk factors that adversely affected outcome. These factors can be divided into those that influence OLT outcome and those that are specific for PSC. The former include residence in the intensive care unit or being on life support prior to transplantation, age greater than 65 years, poor nutritional status, Child-Pugh class C, and renal failure requiring dialysis prior to or after transplantation. These factors are also predictive of increased blood loss, prolonged ICU stay, and major postoperative complications. Risk factors specific for PSC are disease severity, previous biliary or shunt surgery, concurrent bile duct cancer, and presence of IBD.

Controversy surrounds the impact of prior biliary surgery on subsequent OLT for PSC. There is little doubt that prior biliary surgery increases the technical difficulty of OLT, but it is unknown whether this event affects survival. In a series of 26 patients, Farges and colleagues (1995) reported increased operative time, increased blood loss, and severe complications—including death—in 12 OLT patients who had undergone previous right upper quadrant abdominal operations. In a combined series of 216 patients from the University of Pittsburgh and Mayo Clinic, prior biliary tract and/or portal hypertensive surgery was associated with increased mortality the first 5 years after OLT, but this did not reach statistical significance (Abu-Elmagd et al, 1993). At the University of California at San Francisco, increased operative time and blood loss were reported, but not increased mortality, in PSC patients with history of prior colectomy or biliary surgery other than simple cholecystectomy (Narumi et al, 1995). Ahrendt and others (1998) reported the Johns Hopkins experience with 21 PSC patients who had undergone OLT; they found significantly increased operative time and blood loss in patients with previous biliary tract operations, as well as increased operative mortality, but this finding did not reach statistical significance. These reports suggest that prior biliary tract surgery increases the technical difficulty of OLT for PSC with a trend toward increased mortality.

After OLT, complications occur that are unique to PSC patients. Increased rates of biliary strictures have been noted in patients transplanted for PSC. This increase may not represent disease recurrence, as other factors may also cause biliary stricturing, such as ischemia related to chronic rejection or possible chronic low-grade bacterial cholangitis resulting from the Roux-en-Y anastomosis, which is performed much more frequently in patients with PSC. However, a University of Pittsburgh study found a significantly greater incidence of biliary strictures in allografts of patients transplanted for PSC versus patients who had OLT and choledochojejunostomy anastomosis for other end-stage liver disease (Sheng et al, 1993). Because cholangiographic and other clinical and biochemical criteria for recurrent disease have not been widely accepted, there is no consensus regarding incidence of recurrent PSC in liver allografts. Careful analysis at our institution concluded that 20% of patients transplanted for PSC developed recurrent disease based on characteristic cholangiographic and histologic features (Graziadei et al, 1999). PSC may recur earlier at a higher ratio after living-donor liver transplantation, particularly when the graft is from a biologically related living donor (Tamura et al, 2007). Proposed risk factors for recurrent PSC include IBD, prolonged ischemia time, number of cellular rejection episodes, prior biliary surgery, cytomegalovirus infection, and lymphotoxic cross match (Gautam et al, 2006).

Acute and chronic ductopenic rejection can be severe and steroid resistant, often resulting in graft loss. In a study of 100 consecutive PSC patients transplanted at Baylor University, it was reported that chronic rejection and disease recurrence occurred in 13% and 16%, respectively. These events adversely affected both graft and patient survival, markedly so in those patients with chronic rejection (Jeyarajah et al, 1998). Five-year graft survival rates were 33% and 65%, respectively, for patients with chronic rejection and disease recurrence compared with 76% for patients free of chronic rejection or recurrence. The authors suggested that chronic rejection and disease recurrence after transplantation for PSC are distinct entities, as evidenced by the difference in outcome, and that they should be managed accordingly.

Because many patients with PSC have CUC, concern has arisen over the possibility that OLT and attendant lifelong immunosuppression may increase the risk of colorectal carcinoma. In a study of 108 patients with PSC and concomitant IBD who underwent OLT, Loftus and others reported a fourfold, but not statistically significant, increase in colon carcinoma in the group that did not have a prior colectomy compared with the expected colon cancer in a group with comparable (pre-OLT) duration of IBD. This finding, however, did not affect patient survival (Loftus et al, 1998). Goss and colleagues (1997) also reported no difference in PSC patient survival in groups with or without a prior colectomy. Given the lack of impact on survival, we do not recommend prophylactic proctocolectomy in PSC patients with IBD who undergo OLT. Nonetheless, the risk of colonic neoplasia in these transplanted PSC patients warrants annual surveillance colonoscopy with biopsies and colectomy, even when only low-grade dysplasia is detected.

PSC patients with cholangiocarcinoma undergoing OLT merit additional discussion (see Chapter 97E). Survival after

OLT for patients with PSC and cholangiocarcinoma is dependent upon how and when the cancer is detected. Generally speaking, in PSC patients in whom cholangiocarcinoma was known preoperatively, OLT has been ineffective; indeed, recurrence of cholangiocarcinoma occurred almost uniformly. However, *incidental cholangiocarcinomas,* defined as tumors less than 1 cm in diameter discovered only at the time of pathologic sectioning of the explanted liver, portend a better prognosis. In a UCLA study, 8% of patients transplanted for PSC had an incidental cholangiocarcinoma with 5-year survival of 83%, which is not significantly different from the survival of patients undergoing OLT without incidental cholangiocarcinoma (Goss et al, 1997).

Resection of Cholangiocarcinoma

In the absence of PSC, surgical resection has been the most effective and only potentially curative treatment for cholangiocarcinoma. In patients with PSC and cholangiocarcinoma, resection is discouraged: cholangiocarcinoma is often multifocal, underlying parenchymal disease may preclude resection, and reported recurrent disease with death occurs in more than 90% of patients. This is because PSC is considered a premalignant disease. Historically, cholangiocarcinoma has been regarded as a contraindication for liver transplantation given high tumor recurrence in the transplanted organ, and disease-free and overall survival are no different from those of resection. However, selected liver transplant centers using radiation therapy, chemotherapy, and abdominal exploration prior to transplantation have shown promising outcomes for patients with hilar cholangiocarcinoma, with 5-year survival of 80% (Heimbach, 2008).

Proctocolectomy

The presence of PSC in patients with CUC affects the management of CUC. Much has already been said regarding the increased risk of dysplasia and colon carcinoma in patients with PSC. We currently recommend removal of the colon only for indications pertinent to IBD. However, the decision to perform a Brooke ileostomy or an ileal pouch–anal anastomosis (IPAA) is greatly influenced by the presence of PSC. In a retrospective analysis of patients with PSC and CUC treated with either Brooke ileostomy or IPAA, 8 (26%) of 31 patients with the ileostomy developed peristomal varices and subsequent bleeding, but none of the 40 patients who underwent IPAA developed perianastomotic varices or perineal bleeding (Kartheuser et al, 1996). The cumulative risk of pouchitis at 10 years after IPAA was 61% in patients with PSC compared with 36% in patients with CUC alone (Penna et al, 1996). Therefore in PSC patients who need proctocolectomy, we recommend IPAA and not Brooke ileostomy, because treating pouchitis is simpler than managing bleeding peristomal varices.

CONCLUSION

PSC is a cholestatic liver disease of unknown etiology that primarily affects young men and is strongly associated with IBD. The disease is characterized by a progressive, fibrous obliteration of the biliary tree leading to cirrhosis, portal hypertension, and subsequent liver failure. During the course of PSC, patients develop disease-specific and nonspecific complications. Management is challenging and requires a team approach by experts from multiple subspecialties, although to date effective medical therapy is lacking. Currently, OLT is the only curative treatment. More studies are needed to understand the pathogenesis of PSC before we can develop more effective novel therapies.

CHAPTER 42A

Benign biliary strictures

Carlos U. Corvera, Farzad Alemi, and William R. Jarnagin

OVERVIEW

Benign biliary strictures pose difficult management problems. In contrast to malignant biliary obstruction, in which short-term palliation is often the goal of therapy, benign strictures require durable repair because most patients are in otherwise good health and are expected to live for years. Many of these strictures result from iatrogenic injuries, often in young patients in the most productive years of life. Improper management has disastrous complications, such as biliary cirrhosis, portal hypertension, or recurrent cholangitis. Repeated intervention greatly reduces the likelihood of a successful outcome. It is imperative that any attempt at repair be carried out in a precise and expert manner in the setting of a specialist center. The best results are achieved through early diagnosis, mature clinical judgment, and technical expertise at the first attempt at repair.

Benign biliary strictures may affect the intrahepatic or extrahepatic bile ducts or both and may be solitary or multiple. Several causes of benign biliary strictures have been described (Table 42A.1). Iatrogenic injuries after cholecystectomy are the most commonly reported and best characterized causes, and they are emphasized in this chapter to illustrate the principles of diagnosis and management. Strictures and other injuries also may occur after common bile duct (CBD) exploration or biliary reconstruction. Other procedures in the upper abdomen may endanger the biliary tract, especially procedures involving the liver, pancreas, and stomach/duodenum. The true incidence of biliary injury after these procedures is difficult to assess, but it seems to be substantially lower than after cholecystectomy.

BILE DUCT INJURY AT CHOLECYSTECTOMY

Incidence

Because of the great frequency with which the operation is performed, cholecystectomy remains the greatest source of postoperative biliary injuries. Open cholecystectomy has long been associated with a modest incidence of biliary injuries. In a review of more than 42,000 open cholecystectomies performed in the United States in 1989, Roslyn and others (1993) documented a 0.2% incidence of biliary injuries. Strasberg and colleagues (1995) reported a 0.3% incidence of injuries in a literature review of more than 25,000 open cholecystectomies since 1980. The advent of laparoscopic cholecystectomy (see Chapter 34) has refocused attention on this issue, however, because of the significant increase in the number of injuries.

Early studies worldwide documented a marked increase in the frequency of bile duct injuries associated with the laparoscopic approach, ranging from 0.4% to 1.3% (Deziel et al, 1993; Richardson et al, 1996; Wherry et al, 1996; Adamsen et al, 1997; MacFadyen et al, 1998; Fletcher et al, 1999). In a review of nearly 125,000 laparoscopic cholecystectomies reported in the literature in the years 1991 through 1993, Strasberg and colleagues (1995) reported an overall incidence of biliary injuries of 0.85% and incidence of major injuries of 0.52%. Recent studies evaluating biliary injury rates more than a decade since the widespread introduction of the laparoscopic technique confirm a stable yet high indicence of iatrogenic injury, with the incidence ranging between 0.3% and 0.6% in larger studies (Nuzzo et al, 2005; Kaman et al, 2006; Waage & Nilsson, 2006; Tantia et al, 2008). Given the inherent difficulties in collecting data on postcholecystectomy biliary injuries, the true incidence at any one time may never be known precisely; however, the figures reported for laparoscopic cholecystectomy represent a substantial increase over historical controls reported for open cholecystectomy.

The bile duct is at increased risk of injury during laparoscopic cholecystectomy compared with open cholecystectomy for several reasons that will be discussed later. It has long been argued that surgeon inexperience is a major factor, and that with increased familiarity with the procedure, the number of injuries would decrease—the so-called *learning curve effect* (Southern Surgeons Club, 1991). Considerable evidence supports this view. Several authors have shown an inverse relationship between the incidence of bile duct injuries and the number of cases performed (Deziel et al, 1993; Gigot et al, 1997; Woods et al, 1994) and a decreased bile duct injury rate when performed by specialized hepatobiliary surgeons (Boddy et al, 2007). Also, large population-based reviews have documented a decline in injuries over time (Richardson et al, 1996; Russell et al, 1996). However, these trends have not been observed by all investigators. A recent report spanning more than 12 years showed that an initial decline in injuries was not sustained at the end of the study (Waage & Nilsson, 2006). Several other reports have suggested no change in the incidence of bile duct injuries over time (Adamsen et al, 1997; Fletcher et al, 1999; Wherry et al, 1996), and the number and complexity of cases referred for repair have remained static at some specialist units (Walsh et al, 1998). Reports of major bile duct injuries inflicted by surgeons with considerable experience continue to appear (Carroll et al, 1996; Gigot et al, 1997). Moreover, the role of hospital volume does not seem to affect the incidence of injuries (Waage & Nilsson, 2006; Csikesz et al, 2009). The data suggest that laparoscopic postcholecystectomy bile duct injuries will remain a significant problem for the foreseeable future.

Pathogenesis

Several factors are associated with an increased risk of bile duct injury at cholecystectomy, some of which are general and some

Table 42A.1

Causes of Benign Biliary Strictures

- **I.** Congenital strictures
  - **A.** Biliary atresia (see Chapter 40)
- **II.** Bile duct injuries
  - **A.** Postoperative strictures
    - **1.** Cholecystectomy or common bile duct exploration
    - **2.** Biliary-enteric anastomosis
    - **3.** Hepatic resection
    - **4.** Portocaval shunt
    - **5.** Pancreatic surgery
    - **6.** Gastrectomy
    - **7.** Liver transplantation (see Chapter 100)
  - **B.** Strictures after blunt or penetrating trauma (see Chapters 102 and 103)
  - **C.** Strictures after endoscopic or percutaneous biliary intubation
- **III.** Inflammatory strictures
  - **A.** Cholelithiasis or choledocholithiasis
  - **B.** Chronic pancreatitis
  - **C.** Chronic duodenal ulceration
  - **D.** Abscess or inflammation of liver or subhepatic space
  - **E.** Parasitic infection (see Chapters 67 and 68)
  - **F.** Recurrent pyogenic cholangitis (see Chapter 44)
- **IV.** Primary sclerosing cholangitis (see Chapter 41)
- **V.** Radiation-induced stricture
- **VI.** Papillary stenosis

Table 42A.2

Classification of Causes of Laparoscopic Biliary Injuries

Misidentification of the bile ducts as the cystic duct
Misidentification of the common bile duct as the cystic duct
Misidentification of an aberrant right sectoral hepatic duct as the cystic duct
Technical causes
Improper techniques of ductal exploration
Failure to occlude the cystic duct securely
Plane of dissection away from gallbladder wall into the liver bed
Excessive traction on cystic duct with tenting upward of common hepatic duct
Injudicious use of electrocautery for dissection or bleeding control
Injudicious use of clips to control bleeding

Modified from Strasberg SM, et al, 1995: An analysis of the problem of biliary injury during laparoscopic cholecystectomy. J Am Coll Surg 180:101–125.

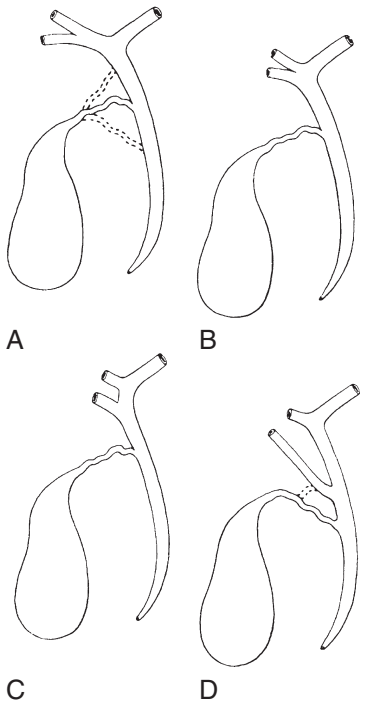

FIGURE 42A.1. Schematic representations of various junctions of the cystic duct with the main extrahepatic biliary channel. **A,** The cystic duct may join the main bile duct very high, almost at the confluence of the hepatic ducts, or it may run parallel to the common hepatic duct before entering almost at the level of the ampulla of Vater. In this illustration, the right anterior and posterior sectoral hepatic ducts join to form a main right hepatic duct. **B,** The right anterior and posterior sectoral hepatic ducts may join the left hepatic duct at a common confluence. **C,** The right anterior and posterior sectoral hepatic ducts may join the left hepatic duct independently. **D,** The right anterior or posterior sectoral hepatic duct may join the common hepatic duct at a much lower level. The cystic duct may drain into such a duct. Another variation, not shown and probably not relevant for postcholecystectomy injuries, is entry of the right anterior or posterior sectoral hepatic duct into the left hepatic duct.

unique to the laparoscopic approach. Ultimately, the final common pathway of most injuries is either a technical error or misinterpretation of the anatomy (Table 42A.2; Strasberg et al, 1995; Olsen, 1997). Many authors classify biliary injuries as major, such as transection of the CBD, or minor, such as biliary leak; but the line separating the two is often blurred. In general, major injuries are more serious and usually require reoperation to repair. Minor injuries are not always trivial, however, and they may require operative intervention. The classification of biliary injuries is discussed later.

Anatomic Variations

Any surgeon operating on the biliary tree must be familiar with the wide range of anatomic variations that may be encountered (see Chapter 1B). Anomalies of the cystic duct insertion into the common hepatic duct are most commonly seen (Fig. 42A.1). The cystic duct may join the common hepatic duct quite high, almost at the biliary confluence, or it may run parallel to the common hepatic duct for a long distance before joining it very low, occasionally at the level of the ampulla. In many patients, perhaps 25%, the right hepatic duct *per se* is absent, and the right anterior and posterior sectoral hepatic ducts join the left hepatic duct independently. In some cases, one of the right sectoral hepatic ducts, usually the anterior, may follow a prolonged extrahepatic course and enter the common hepatic duct quite low, and it may receive drainage from the cystic duct (see Fig. 42A.1D). Such unrecognized, low-entry right sectoral hepatic ducts (Bismuth type 5) are at particular risk of injury during laparoscopic cholecystectomy (Fig. 42A.2; Wherry et al, 1996).

In the future, routine use of preoperative imaging may help minimize bile duct injuries by identifying aberrant biliary anatomy. Already, some centers are examining the utility of preoperative CT cholangiography and MRI in preventing this complication (Hirano et al, 2006). Widespread adoption of this strategy will clearly be costly, but it could be justified: some

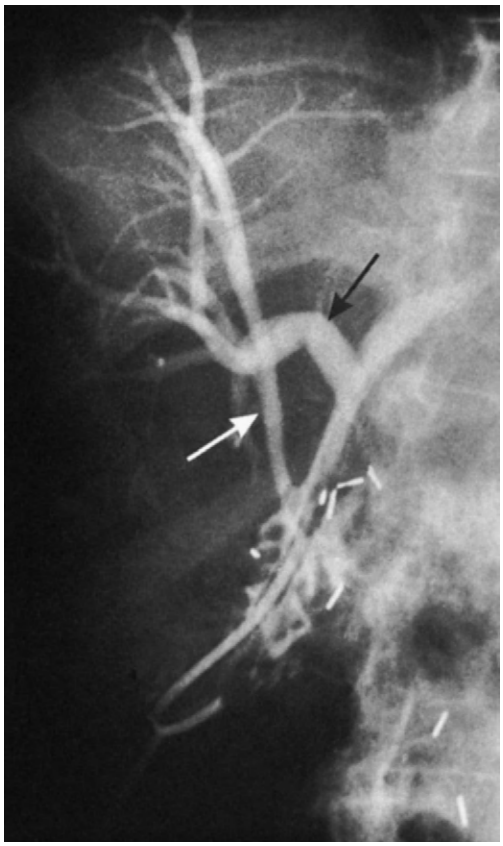

FIGURE 42A.2. The right anterior sectoral hepatic duct (*white arrow*) drains into the common hepatic duct, and the right posterior sectoral hepatic duct (*black arrow*) joins a main left hepatic duct. In this patient, cholecystectomy was accompanied by a biliary injury at the point of confluence of the common hepatic duct and the right anterior sectoral hepatic duct (Bismuth type 5). Repair has been carried out by Roux-en-Y hepaticojejunostomy.

imaging studies document right ductal aberrancy in the general population ranging from 4.8% to 8.4% (Kullman et al, 1996; Dusunceli et al, 2004). In some cases, the cystic duct is quite short, and misinterpretation of the anatomy can occur easily. Misinterpretation is especially likely if, on intraoperative cholangiography, the catheter has been advanced well into the CBD, and the proximal ducts are not visualized. The surgeon may mistake the common duct for the cystic duct, ligate it, and remove it with the attached gallbladder (Fig. 42A.3). This type of injury seems to be much more common after laparoscopic rather than open cholecystectomy and is well described (Davidoff et al, 1992). A related situation can occur in cases of long-standing cholelithiasis and chronic cholecystitis, resulting in obliteration of the cystic duct, which we will discuss later.

Vascular anomalies also are common, occurring in 20% of patients (see Chapter 1B). In the most common of these, the right hepatic arterial supply arises in part or in whole from the superior mesenteric artery. Such an aberrant vessel usually courses to the right of the portal vein, lateral and posterior to the CBD. During cholecystectomy, this vessel is prone to injury at the junction of the cystic and common hepatic ducts. Vascular injuries are not limited to patients with anatomic anomalies. The classic biliary injury during laparoscopic cholecystectomy, in which the surgeon mistakes the CBD for the cystic duct, is frequently associated with injury to the right hepatic artery, which will be discussed (Davidoff et al, 1992). This problem has been documented to occur in as many as 0.6% of patients after laparoscopic cholecystectomy and may not be apparent at the initial operation but may come to attention later as a hepatic artery pseudoaneurysm (Balsara et al, 1998; Nicholson et al, 1999). Rarely, concomitant vascular injury may involve both the right hepatic artery and right portal vein, which can be life threatening (Fig. 42A.4).

Ischemia

In the absence of overt injury, delayed biliary stricture formation may result from extensive periductal dissection and consequent interruption of the major ductal arterial supply (see Chapter 1B). Most of the arterial supply to the extrahepatic bile duct is provided by two small arteries that travel along the lateral duct borders in the 3 o'clock and 9 o'clock positions. Sixty percent of the blood supply runs upward from the major inferior vessels (retroduodenal, gastroduodenal), and approximately 38% runs downward from the right hepatic artery (Northover & Terblanche, 1979). Extensive circumferential dissection of the duct may disrupt this axial blood flow and has been proposed as a major mechanism of biliary stricture formation. Although there is no direct evidence to support this, it would seem reasonable not to pursue extensive dissection of the common duct during cholecystectomy. Also, damage to these vessels is likely to be a contributing, if not a central factor, in the formation of strictures attributed to electrocautery use.

Pathologic Factors

Patients with acute cholecystitis may have severe inflammation in the porta hepatis and triangle of Calot, which greatly distorts the anatomy. In addition, the gallbladder is often friable and difficult to grasp, and persistent oozing of blood often obscures the field. Some or all of these factors may conspire to preclude safe laparoscopic cholecystectomy. During the early era of laparoscopic cholecystectomy, acute cholecystitis was considered an absolute contraindication. However, as experience with laparoscopy grew, surgeons became more comfortable extending the indication to include acute cholecystitis. Several reports later documented that the laparoscopic approach not only is possible but also is safe in selected cases of acute cholecystitis (Kum et al, 1996; Wherry et al, 1996; Adamsen et al, 1997; Fletcher et al, 1999; Neri et al, 2003). As a result, laparoscopic cholecystectomy for acute cholecystitis is now widely practiced; in fact, the issue regarding timing of operation (early vs. delayed) has been settled (see Chapter 31; Casillas et al, 2008; Gurusamy et al, 2009). When laparoscopic cholecystectomy is performed for acute cholecystitis, studies have also revealed a greater potential for biliary injury (Kholdebarin et al, 2008). Fletcher and colleagues (1999) reported that complex cases that include patients with acute cholecystitis, cholangitis, and gallstone pancreatitis are associated with a dramatically increased incidence of bile duct injuries (1.7%), although acute cholecystitis alone is not an independent risk factor. Other authors have shown that acute cholecystitis increases the incidence of bile duct injuries twofold to threefold above baseline (Adamsen et al, 1997; Russell et al, 1996; Soderlund et al, 2005). In patients seen initially with acute cholecystitis, we recommend early operation by laparoscopic approach, even in patients with a history of prior open abdominal surgery. Given the increased risk of biliary injury in this setting, however, the

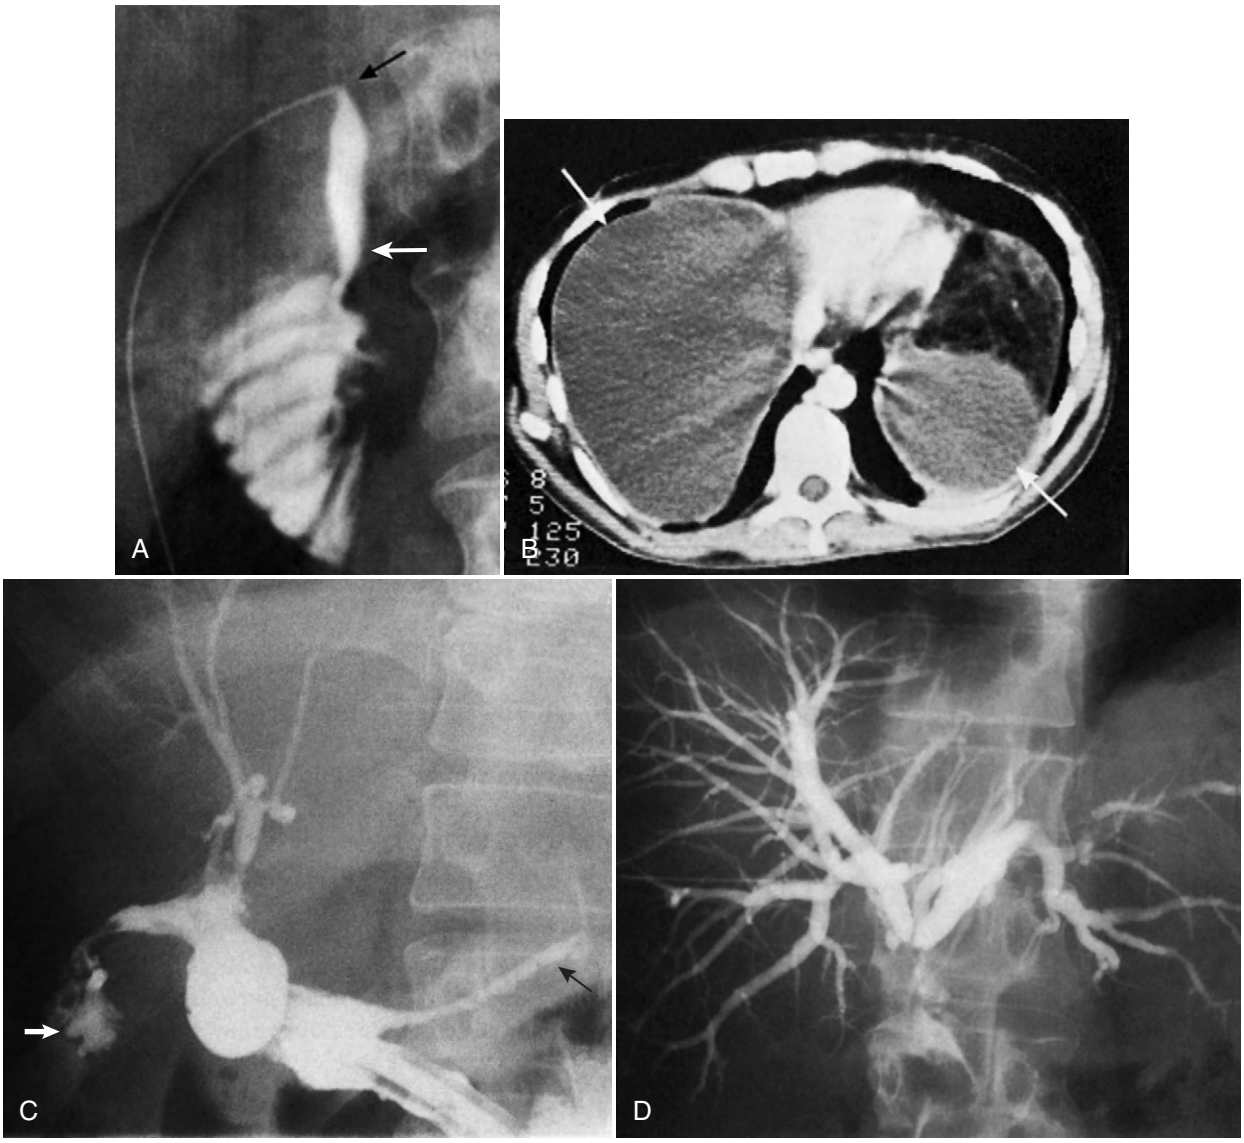

FIGURE 42A.3. **A,** Operative cholangiogram obtained after cannulation of the cystic duct. The cannula has entered the common bile duct (*black arrow*), and only the common bile duct has been outlined (*white arrow*). The common hepatic duct has not been visualized. The surgeon proceeded with cholecystectomy in the belief that he had cannulated the cystic duct. **B,** The patient became extremely ill after surgery and was referred. Computed tomographic scan revealed massive collections of intraperitoneal bile (*arrows*), which were drained. **C,** A subsequent fistulogram revealed a fistulous tract with connections to the right (*white arrow*) and left abdomen (*black arrow*). The right anterior sectoral hepatic duct also is seen. The patient, now well and free of jaundice, was monitored. **D,** Percutaneous transhepatic cholangiography obtained after the patient returned with jaundice showed that the fistula has closed, and a stricture had formed just below the biliary confluence (Bismuth type 3). Repair was performed by Roux-en-Y hepaticojejunostomy using an approach to the left hepatic duct and extending the dissection to the right.

threshold for conversion to an open procedure should always be low.

On occasion, the inflammatory reaction is so severe that even conversion to an open procedure does not clarify the anatomy. Fibrosis and inflammation within the triangle of Calot make dissection of the cystic duct particularly hazardous. In severe cases, the gallbladder neck and cystic duct may be fused to the common duct within a sheath of scar tissue. This finding should lead the surgeon away from an extensive dissection to define the cystic duct, which risks a major biliary injury. Placement of a cholecystostomy tube may be a safer approach. An alternative option is partial (subtotal) cholecystectomy with amputation of the gallbladder, well away from the cystic duct/common hepatic duct junction, and placement of a drain. This procedure is generally safe and effective, and in a review of 1100 patients, only 11.2% required operative reintervention (Soleimani et al, 2007). Moreover, centers have reported a significant decrease in the incidence of bile duct injuries since the introduction of laparoscopic subtotal cholecystectomy (Nakajima et al, 2009). In such heavily fibrosed cases, the cystic duct is nearly always obliterated, and postoperative biliary leak is infrequent.

A potentially more difficult problem is the small, contracted, fibrotic gallbladder with extensive surrounding inflammation, sometimes partially embedded into the liver and obliterating the triangle of Calot such that the gallbladder neck and cystic

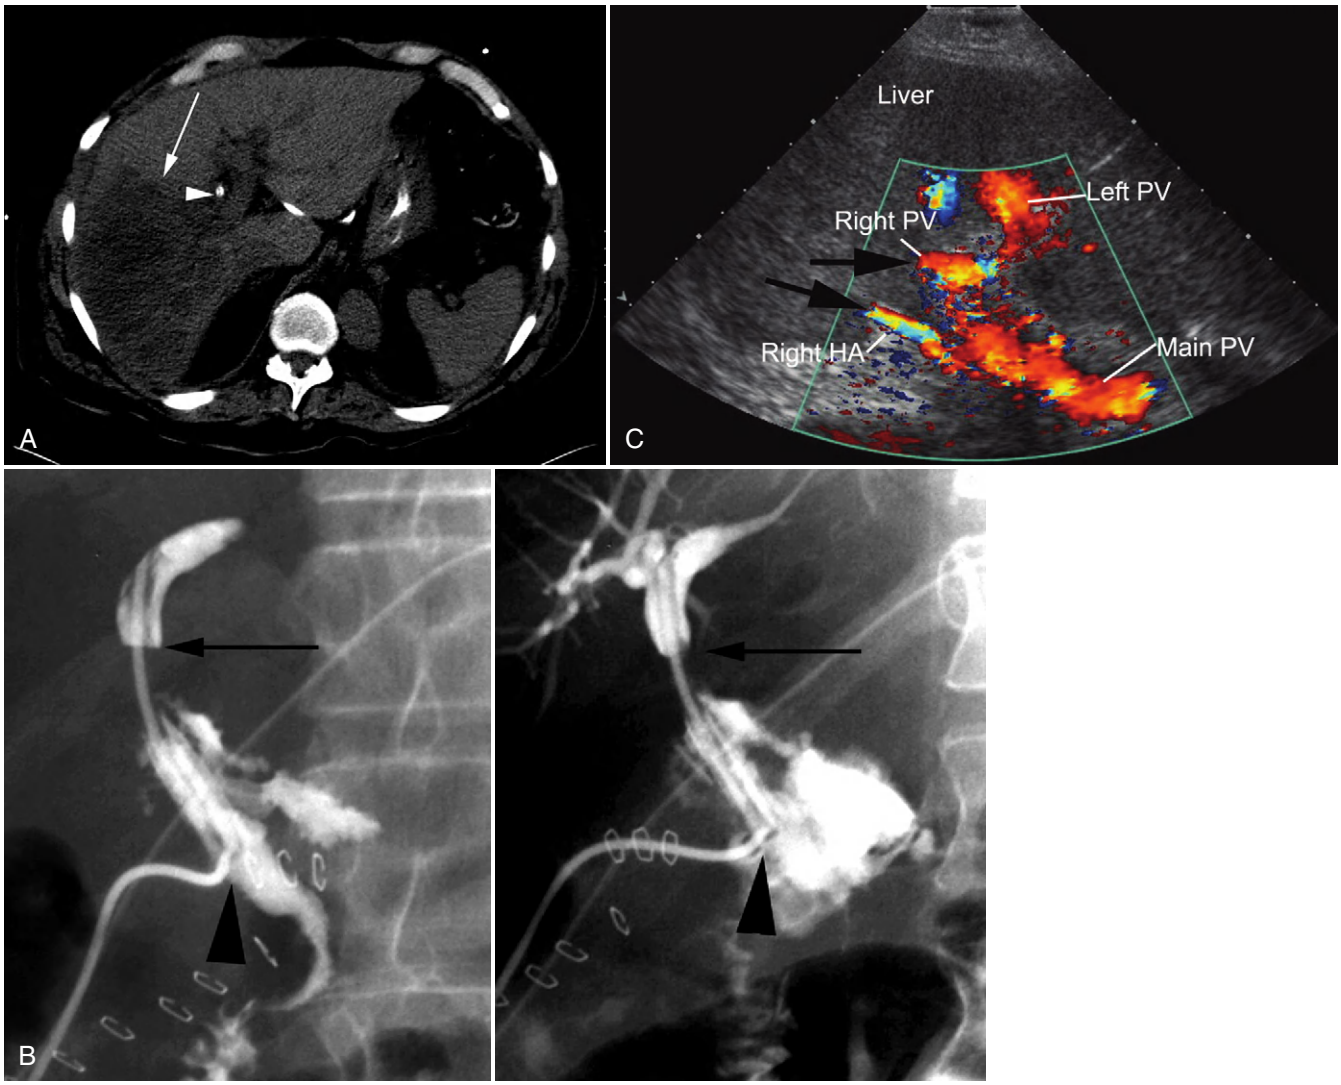

FIGURE 42A.4. A, Transaxial computed tomographic scan without intravenous contrast demonstrating the hypoperfused right lobe (*white arrow*) and an intraoperatively placed biliary tube (*arrowhead*). In this patient, the surgeon was confronted with significant bleeding during laparoscopic cholecystectomy and converted to open operation. Bleeding involved the right hepatic artery (*HA*) and portal vein (*PV*); these were suture ligated to control the hemorrhage. **B,** A tube cholangiogram demonstrates the "classic" biliary injury during laparoscopic cholecystectomy: the common bile duct was mistaken for the cystic duct, and a long section of the common duct was excised up to the common hepatic duct (*arrow*). The arrowhead points to the tube insertion site in the distal common duct. **C,** Doppler ultrasonography demonstrates lack of flow in both the right HA and PV (*arrows*).

duct are adherent to the common hepatic duct (Fig. 42A.5B). In such cases, the cystic duct is obliterated, and safe dissection in Calot's triangle is impossible. With long-standing disease, particularly associated with large impacted gallstones in the gallbladder neck, a cholecystocholedochal fistula is possible. A common hepatic duct stricture may be present, resulting from an impacted stone and the subsequent inflammatory response (Mirizzi, 1948; see Chapter 42B). A cholecystocholedochal fistula should be suspected in any patient with gallstones, jaundice, cholangitis, and imaging studies or operative findings that suggest an inflamed and contracted gallbladder. In these cases, an attempt to perform a total cholecystectomy should be abandoned, because this would lead the surgeon directly into the common hepatic duct (Sharma et al, 1998). Rather, partial cholecystectomy with extraction of the stones allows inspection of the depths of the gallbladder and is preferable. A rush of bile into the operative field at this point is strong evidence for a cholecystocholedochal fistula, because the cystic duct is nearly always obliterated. Because a biliary stricture often lies distal to the fistula, direct closure of the defect should be avoided, and it should instead be reconstructed as a cholecystocholedochoduodenostomy (see Chapter 42B and Fig. 42A.5B).

Technical Factors

General

Cholecystectomy is performed so commonly that it is easy to adopt a casual attitude toward the procedure; this is unwise, however, because some of these cases can be quite challenging. Also, although it is true that inexperienced or poorly trained surgeons cause many bile duct injuries, as we discussed earlier, even the most well-trained and experienced surgeons can cause

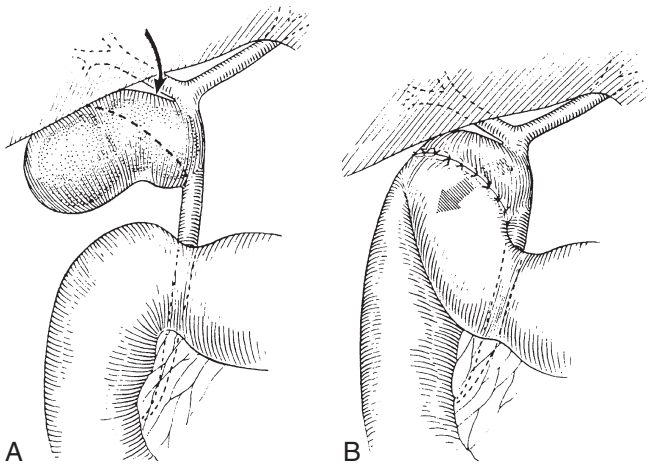

FIGURE 42A.5. A, Obliteration of Calot's triangle (*curved arrow*) by the inflammatory process accompanying severe chronic cholecystitis. The gallbladder is contracted around two large gallstones, one of which has eroded into the common hepatic duct, producing a cholecystocholedochal fistula. Such cases often present with obstructive jaundice or cholangitis. Complete cholecystectomy should not be attempted; it inevitably leads to biliary injury. Partial cholecystectomy (*dotted line*) can be performed with extraction of the calculi. **B,** Cholecystocholedochoduodenostomy can be done safely and with adequate drainage of bile.

an injury. It is imperative, therefore, that the surgeon adhere strictly to the basic tenets of cholecystectomy, either laparoscopic or open, to minimize the risk of biliary injury. Safe cholecystectomy requires clear visualization of the relevant anatomy, which demands proper exposure and modern high-resolution video equipment. Adequate assistance and retraction must be available, the incision must be adequate in length, and any trochars must be properly placed. It is imperative that no structure be ligated or divided unless its identity can be determined unequivocally.

Early reports of laparoscopic biliary injury cited bleeding and subsequent attempts to achieve hemostasis as major contributing factors to bile duct injury (Davidoff et al, 1992; Rossi & Tsao, 1994). At laparoscopy, even a small amount of blood obscures the field and hinders dissection. If necessary, an additional port should be placed for a high-powered suctioner/irrigator to precisely define the site of bleeding. Hemorrhage must be controlled, regardless of the approach, and blind placement of clips or indiscriminate use of electrocautery must be avoided. Early demonstration of the cystic artery is desirable, and it should be divided close to the gallbladder to avoid injury to the right hepatic or common hepatic artery.

Excessive traction on the gallbladder during cholecystectomy may tent the common duct upward, putting it at risk of injury if unrecognized. This mechanism does not seem to be as common at laparoscopic cholecystectomy, although other problems related to retraction may predispose to biliary injury at laparoscopy, which will be discussed later. Some authors have argued that the cystic duct–common hepatic duct junction should be precisely demonstrated before it is ligated and divided, even if this requires separating an adherent cystic duct and tracing it to its termination (Kune & Sali, 1981). We firmly believe that this is unnecessary and potentially hazardous; the risk of biliary injury with such extensive dissection is high and greatly outweighs the risk of a retained cystic duct stone.

The plane of dissection should be maintained as close to the gallbladder wall as possible to avoid entering the liver parenchyma. This is especially important when there is significant inflammation or fibrosis, and the ductal anatomy is unclear. Straying off the gallbladder wall may result in entry into the liver parenchyma and bleeding, further obscuring the field, or injury to a low-entry sectoral hepatic duct or a replaced right hepatic artery. In addition, the major right portal pedicles and branches of middle hepatic vein may be quite superficial in the liver substance with respect to the gallbladder fossa, and damage to these structures can occur if the plane of dissection is too deep. During a difficult open cholecystectomy, the advantage over the laparoscopic approach is that a finger can be inserted into the gallbladder to help define the proper plane.

The observation of bile draining from the gallbladder fossa always suggests the possibility of a biliary injury, perhaps to an aberrant right sectoral hepatic duct. It is tempting to ascribe such a finding to drainage from a subvesical duct of Lushka, a slender, 1- to 2-mm in diameter duct that passes from the right lobe in the gallbladder fossa to join the right hepatic or common hepatic duct (McMahon et al, 1995). In this situation, a major bile duct injury must be considered the leading diagnosis until disproved, and the surgeon is compelled to convert to an open procedure or to place a drain and investigate the cause postoperatively. Regarding the duct of Lushka, although some surgeons question its existence, several detailed anatomic and radiologic imaging studies have reliably identified its structure and course (Kocabiyik et al, 2009). Most patients with bile leaks attributable to a subvesical duct experience a delayed onset of symptoms and are usually seen in the first or second week following the procedure (Fig. 42A.6). In a review of nearly 10,000 patients, the incidence of bile leakage was 0.7%, of which 52% were leaks from subvesical ducts (Spanos & Syrakos, 2006).

The utility of routine cystic duct cholangiography is controversial (see Chapter 21), particularly with respect to reducing the incidence of biliary injury at laparoscopic cholecystectomy, which will be discussed later. Occasionally, operative cholangiography reveals a very small CBD with a filling defect, suggesting a small stone. In this situation, simple cholecystectomy without exploration of the common duct is probably safer than operative pursuit of a tiny stone in a small duct. Postoperative endoscopic cholangiography with stone extraction is nearly always possible if subsequently indicated. In general, exploration of a small caliber, otherwise normal-appearing common duct is frequently unrewarding, potentially dangerous, and more likely to result in postoperative symptoms than if such a stone were left in situ. Biliary strictures are more than just a theoretical concern after exploration of a small bile duct (Fig. 42A.7). Rarely, bile duct stones retained after cholecystectomy that are not removable by endoscopic means require reoperation (Fig. 42A.8; see Chapters 35 and 36). Under these circumstances, laparoscopic removal is usually possible via a transcholedochotomy approach (see Chapter 34). If this approach fails, an open exploration can often be avoided by placing a T-tube into the CBD for subsequent operative retrieval by intervential radiology techniques, which are successful in more than 95% of cases (Burhenne, 1980). When indicated at cholecystectomy or after failed attempts by other methods, open exploration of the CBD should be performed through a supraduodenal choledochotomy with careful exposure of a sufficient length of duct but without excessive dissection (see Chapters 29 and 35). Exploration must be gentle and performed only with soft bougies,

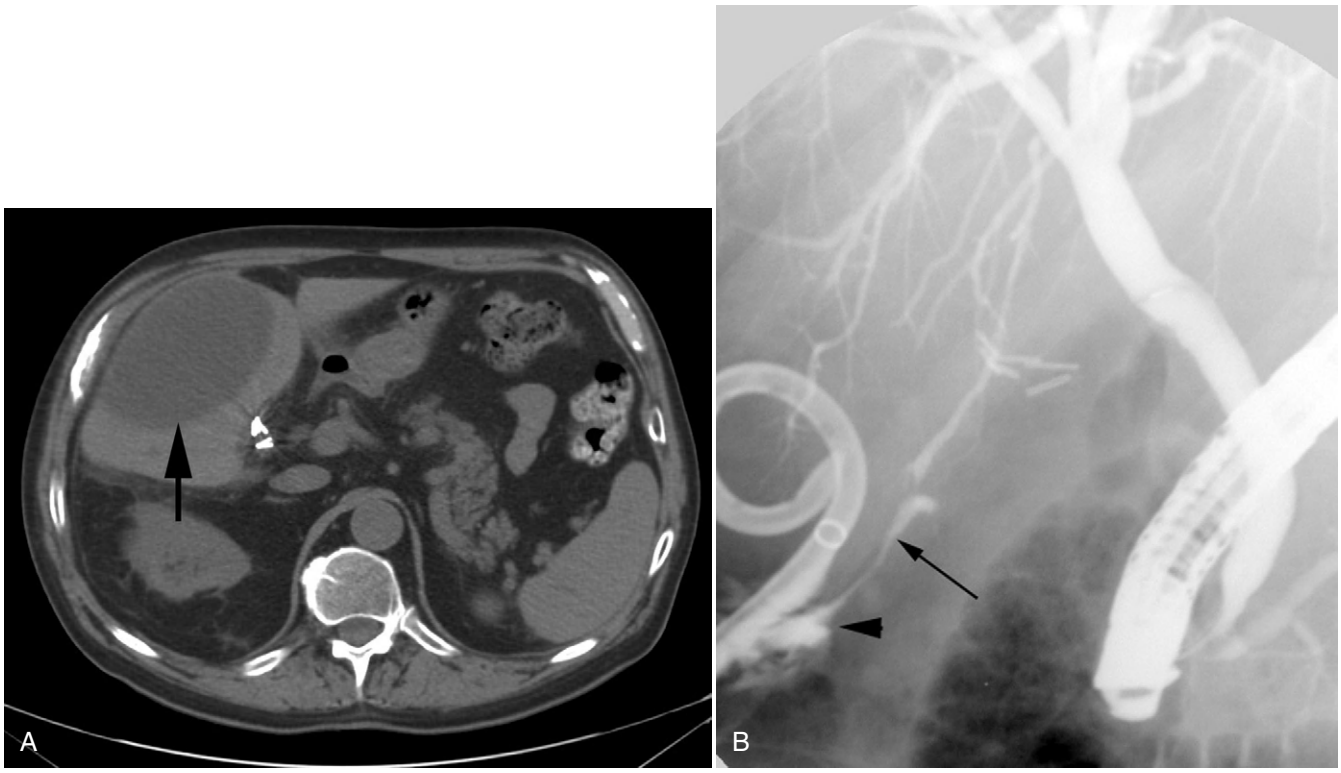

FIGURE 42A.6. **A,** Transaxial computed tomographic scan from a patient 2 weeks after elective laparoscopic cholecystectomy. The *arrow* points to perihepatic fluid collection consistent with a biloma. **B,** After percutaneous drainage of the biloma, the patient was evaluated by endoscopic retrograde cholangiopancreatography. The *arrow* points to the duct of Luschka; the *arrowhead* demonstrates contrast extravasation.

Fogarty-type balloon catheters, or a choledochoscope (rigid or flexible). Metal bougies such as Bake's dilators or stone forceps should be used with caution and should never be forced through the papilla of Vater into the duodenum; otherwise, secondary postinflammatory papillary stenosis may occur, or a false passage into the duodenum or pancreas may be created. After bile duct exploration, the choledochotomy should be closed with care, because this is also a potential source of biliary stricture (see Chapters 29 and 35).

Transduodenal sphincteroplasty probably is best reserved for patients with stones impacted in the distal bile duct (see Chapters 29 and 35). Stenosis or stricture of the distal CBD may occur after surgical or endoscopic sphincteroplasty or sphincterotomy. Side-to-side choledochoduodenostomy is an

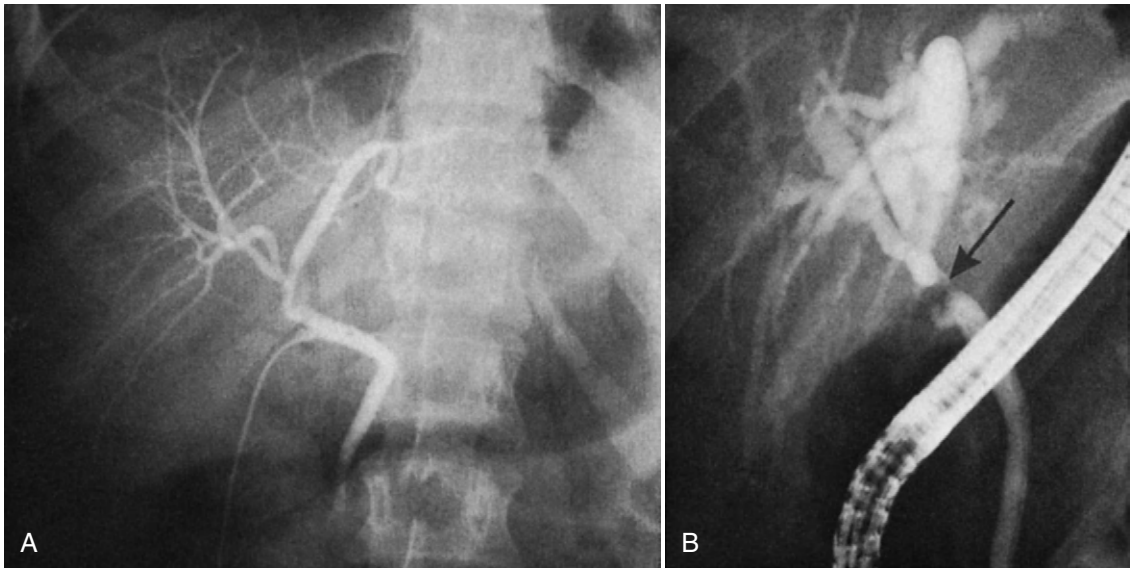

FIGURE 42A.7. **A,** Cystic duct cholangiogram obtained at cholecystectomy. A stone was suspected in a small-caliber common bile duct. Bile duct exploration was performed, but no stone was identified. **B,** Postoperatively, the patient developed recurrent attacks of cholangitis. Endoscopic cholangiogram showed a bile duct stricture at the previous choledochotomy site (*arrow*).

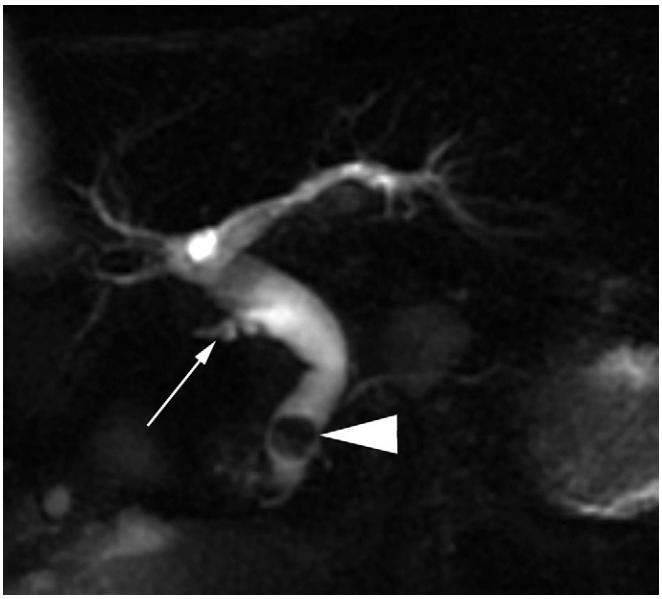

FIGURE 42A.8. Maximum intensity projection magnetic resonance cholangiopancreatographic, T2-weighed image demonstrates a large retained stone (*arrowhead*) within the common bile duct. This patient had previously undergone laparoscopic cholecystectomy and did not respond to postoperative removal by endoscopic means. The *arrow* points to cystic duct remnant.

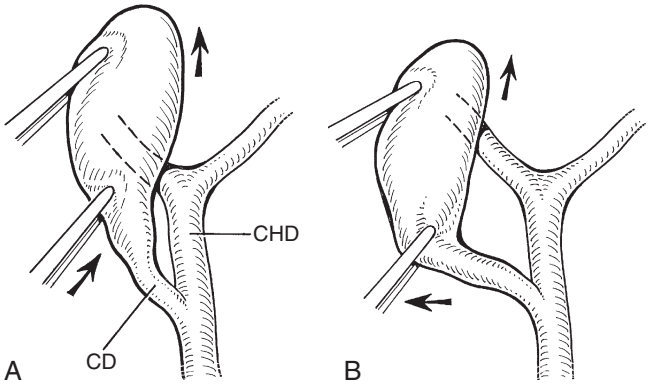

FIGURE 42A.9. Area of the triangle of Calot as it appears during laparoscopic cholecystectomy. **A,** Upward traction on the gallbladder, with insufficient lateral traction on the infundibulum, fails to open Calot's triangle adequately. This causes the cystic duct (*CD*) and common hepatic duct (*CHD*) to become aligned within the same plane. Injury to the CHD can occur during dissection of the CD because of its proximity or as a result of mistaking the CHD for the CD. **B,** Proper lateral traction on the infundibulum opens Calot's triangle, allowing safer dissection of the CD. In some cases, obliteration of Calot's triangle by dense fibrosis prevents adequate exposure of this area, even with adequate traction (see Fig. 42A.5).

option that should be considered in patients with multiple stones, primary stasis stones, or distal obstruction by stricture or papillary stenosis. The results are generally good, provided that the CBD is dilated to at least 15 mm in diameter, and a stoma of at least 2 cm can be created (Schein & Gliedman, 1981). Choledochoduodenostomy performed to a decompressed duct is more likely to result in stricture formation and cholangitis (see Chapter 29; Johnson & Stevens, 1969).

Laparoscopic-Specific Factors

Several technical factors specific to laparoscopic cholecystectomy predispose to biliary injury (see Chapter 34). Mistaking the common duct for the cystic duct is a frequent technical error (Davidoff et al, 1992; Gigot et al, 1997; Olsen, 1997). In the most common sequence of events, a long length of the common duct is excised up to the proximal common hepatic duct, which is either occluded or left to drain bile into the peritoneal cavity. This devastating injury—referred to as the "classic" laparoscopic injury, rarely seen at open cholecystectomy—also may be associated with damage to the right hepatic artery (Davidoff et al, 1992; Strasberg et al, 1995). Less severe injuries also may occur, such as lacerations of the duct wall or near-complete transections. Proper exposure is essential to avoid injuries arising from such anatomic misinterpretations. Maximum cephalad traction on the gallbladder fundus is necessary to expose the cystic duct and triangle of Calot. Concomitant lateral traction on the infundibulum is equally important, however, to open the angle between the cystic and common hepatic ducts. If lateral traction is inadequate, Calot's triangle is not opened sufficiently, and the course of the common duct is placed directly in line with that of the cystic duct (Fig. 42A.9; Rossi & Tsao, 1994; McMahon et al, 1995). The common duct may be damaged during dissection of the cystic duct because of its proximity, or because it is misidentified. Before any structures are divided, Calot's triangle must be cleared of all fatty and areolar tissue. The peritoneal reflection along the posterolateral aspect of the gallbladder should be opened to fully expose the junction of the gallbladder neck and cystic duct. At the completion of the dissection, only the cystic artery and cystic duct should be seen entering the gallbladder, and the bottom of the gallbladder fossa should be visible. The use of a 30-degree laparoscope has been advocated to improve visualization of this area (Hunter, 1991), and the resulting anatomically satisfying final view has been described by Strasberg (1995) as the "critical view of safety." The dissection should be maintained close to the gallbladder wall, and the cystic duct should be divided as close as possible to its junction with the gallbladder.

Routine intraoperative cholangiography has been advocated by many to minimize the incidence of laparoscopic biliary injuries (Way, 1992; Moossa et al, 1992; Asbun et al, 1993), but it remains controversial. In a meta-analysis encompassing more than 327,000 laparoscopic cholecystectomies, Ludwig and colleagues (2002) noted contribution of intraoperative cholangiography to incidence and outcome of CBD injuries during laparoscopic cholecystectomy and found injury rates to be halved in a routine cholangiogram group (0.21%) compared with a selective group (0.43%). A valid concern regarding the conclusions from these studies is that surgeons who use selective cholangiography do so appropriately in situations of inflammation or unclear anatomy inherently associated with increased risk of bile duct injuries. Thus, the injury rate under these circumstances can be artificially elevated, because the denominator —that is, the number cholecystectomies done without cholangiogram—is not typically included in the overall analysis. In a large review of cholecystectomies from Western Australia, Fletcher and colleagues (1999) reported that intraoperative cholangiography reduced the incidence of biliary injury twofold overall and eightfold in complex cases (acute cholecystitis, cholangitis, pancreatitis). In addition, some authors noted a strong inverse correlation between biliary injury and nonperformance

of cholangiography (Torkington et al, 1999). Cholangiography is clearly not preventive if the injury occurs after a normal study, or if the study serves only to identify an injury that already has been inflicted (Andren-Sandberg et al, 1985).

Other groups, however, have touted the lack of statistical benefit with the routine use of intraoperative cholangiography. A survey analysis of more than 184 Italian hospitals accounting for more than 56,000 operations demonstrated no significant difference between bile duct injury rate when cholangiogram was used routinely or selectively (Nuzzo et al, 2005). In contrast, several other reports have suggested that routine cholangiography may not reduce the incidence of biliary injury but may minimize injury severity and allow immediate recognition and definitive repair (Gigot et al, 1997; Woods et al, 1994; Carroll et al, 1996; Russell et al, 1996); this depends on proper interpretation of the study. In a review of 177 biliary injuries, Olsen (1997) found that only two of 32 cholangiographies were correctly interpreted, despite evidence of impending bile duct transection in most. The most common error was accepting an incomplete study as normal, without opacification of the right and left hepatic ducts. In a similar study, Stewart and Way (2003) showed that in their series of 252 bile duct injuries, cholangiograms were obtained in 43 patients, but only nine were correctly interpreted intraoperatively. They concluded that these injuries stemmed from a misperception that was often so compelling that adjunctive cholangiographic data was likewise misperceived. Failure to opacify the proximal bile ducts in their entirety should prompt the surgeon to strongly consider open conversion. Laparoscopic ultrasound has been described as an alternative to cholangiography for delineation of the cystic duct and identification of common duct calculi (Tomonaga et al, 1999). Recent studies demonstrate the efficacy of the technique as an alternative to cholangiography (Machi et al, 2009; Hublet et al, 2009), but it is not widely used.

Bile leakage occurs with greater frequency after laparoscopic cholecystectomy than after open cholecystectomy, which may be related to the use of clips rather than ties or suture ligatures (McMahon et al, 1995). Clips are less secure than sutures and may become dislodged if improperly placed or if manipulated after placement (Nelson et al, 1992; Fig. 42A.10). Reports of clip migration leading to complications such as choledocholithiasis and pancreatitis have also been reported (Raoul et al, 1992; Cetta et al, 1997; Dolay et al, 2007). Also, incomplete occlusion may occur if clips are placed across a thickened, rigid cystic duct or a cystic duct containing stones or if other tissues are included. When placing clips, it is important that the tips meet to ensure adequate occlusion. If both tips cannot be visualized as the clip is being applied, damage to adjacent structures may occur. If the clip does not fit across the entire width of the cystic duct, the surgeon must consider the possibility that the structure about to be divided is not the cystic duct but the common duct. If the anatomy is clear, and the cystic duct is simply thickened, placement of a ligature may be more appropriate (Michalowski et al, 1998). Also, using electrocautery in areas adjacent to clips should be avoided, because this may result in conduction of thermal energy to the adjacent common duct and lead to delayed biliary structure.

Location and Classification

The ease of management, operative risk, and outcome of biliary injuries vary considerably and depend on the type of injury and its location (Chapman et al, 1995). It has long been recognized that strictures involving the CBD or distal common hepatic duct are easier to repair than are more proximal injuries. The anatomic classification of Bismuth has been widely adopted in recognition of this fact (Fig. 42A.11; Bismuth & Lazorthes, 1981). In this classification scheme, five stricture types are recognized, reflecting the location with respect to the hepatic duct confluence (types 1 through 4) or the involvement of an aberrant right sectoral hepatic duct with or without a concomitant hepatic duct stricture (type 5; Table 42A.3).

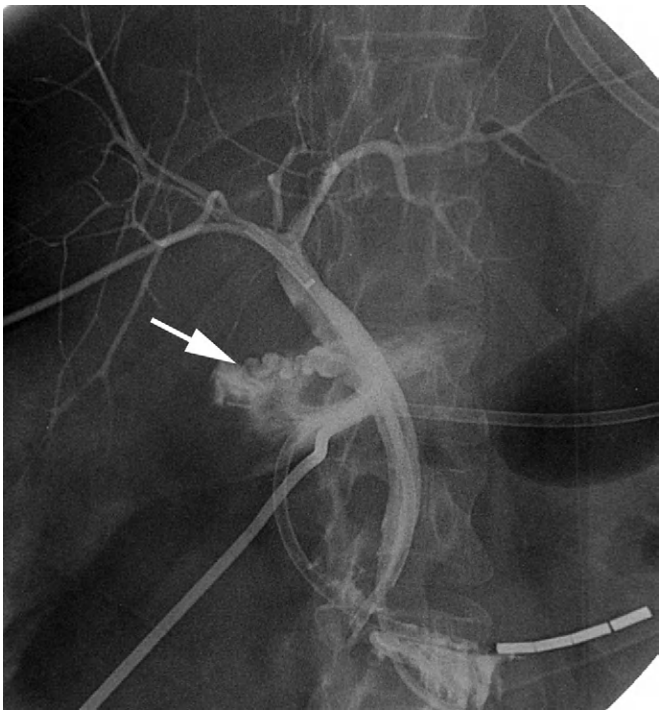

FIGURE 42A.10. Percutaneous transhepatic cholangiography on a patient who underwent laparoscopic cholecystectomy. A previously placed endoluminal stent failed to control bile leakage from the cystic duct stump (*arrow*). Note the percutaneous drain situated near the cystic duct remnant and the enteric feeding tube in the duodenum. This patient was managed nonoperatively.

The Bismuth classification is useful for localization and for prognosis after repair, but it does not encompass the entire spectrum of injuries that are possible. No provision is made for biliary leaks or major ductal injuries without stricture. Even within the group of patients with biliary leaks, there are varying degrees of severity. In an effort to fill this gap, Strasberg and colleagues (1995) proposed a comprehensive classification system that incorporates Bismuth's scheme but is much broader in scope (Fig. 42A.12). Injuries are classified as type A to type E, with the latter representing biliary strictures and further subdivided as E1 to E5 according to the Bismuth classification. *Type A* injuries are bile leaks from minor ducts still in continuity with the CBD. This encompasses the most common causes of biliary leaks seen after laparoscopic cholecystectomy—leakage from the cystic duct and from a subvesical duct of Luschka (see Figs 42A.6 and 42A.10). *Type B* injuries involve occlusion of part of the biliary tree, which for practical purposes almost always is an aberrant right sectoral hepatic duct. When this duct is transected without ligation, the injury is termed *type C*, reflecting the differences in presentation and management

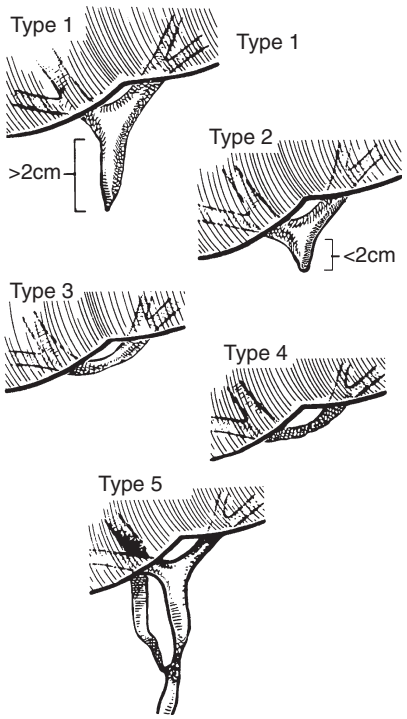

FIGURE 42A.11. Classification of bile duct strictures based on location with respect to the hepatic duct confluence (see Table 42A.3). *(From Bismuth H, 1982: Postoperative strictures of the bile duct. In Blumgart LH [ed]: The Biliary Tract: Clinical Surgery International. Edinburgh, Churchill Livingstone, pp 209-218.)*

between the two. A lateral injury to an extrahepatic bile duct is termed *type D*, which is similar to type A injuries in that the extrahepatic biliary tree remains in continuity but is classified separately to underscore the greater severity and potential need for major reconstruction (Fig. 42A.13).

The incidence of each type of biliary injury is difficult to ascertain with certainty. Most literature reports are derived from tertiary referral centers and are biased toward more severe injuries. Most surgical series focus on management of type E biliary strictures, whereas endoscopic and radiologic reports are concerned mainly with the treatment of biliary leaks. Type A injuries may be the most common, but many are managed successfully without referral and are underrepresented in reports from major centers (Strasberg et al, 1995).

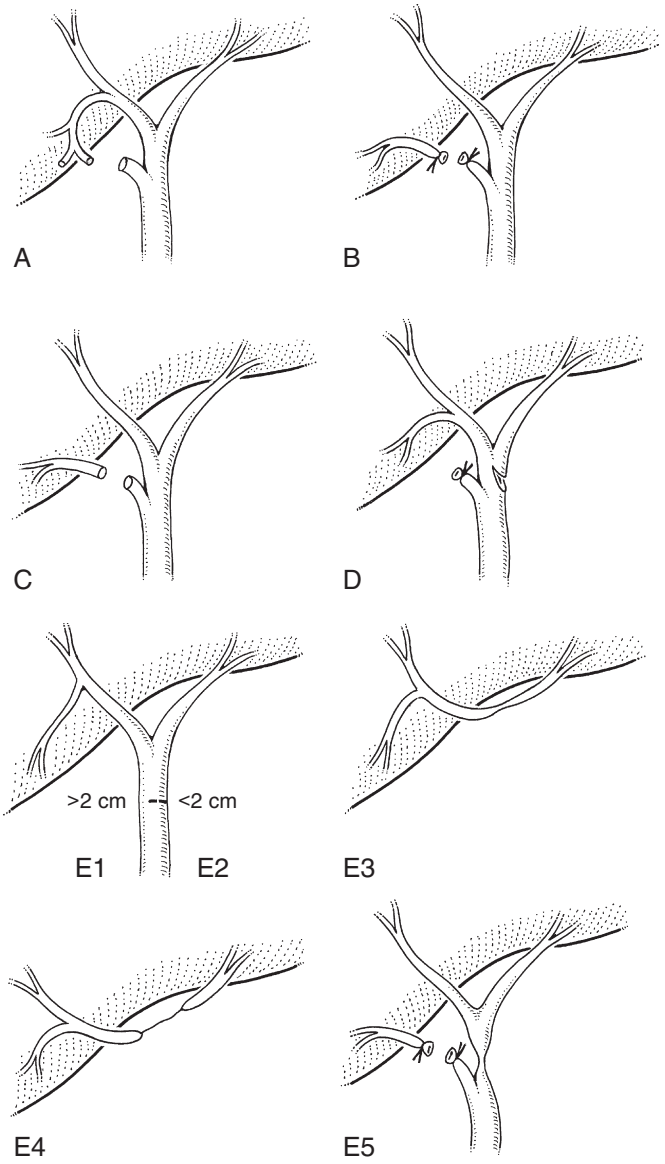

FIGURE 42A.12. Classification of laparoscopic biliary injuries according to Strasberg and colleagues (1995). Injuries are stratified from type A to type E. Type E injuries are subdivided further into E1 to E5 according to the Bismuth classification system.

Clinical Presentation

Most patients with postcholecystectomy biliary injuries, if not diagnosed at operation, come to medical attention early in the postoperative period. After open cholecystectomy, only about 10% of injuries are suspected after the first week, but nearly 70% are diagnosed within the first 6 months after operation (Pitt et al, 1982). By contrast, injuries after laparoscopic cholecystectomy seem to be recognized earlier (Davidoff et al, 1992; Lillemoe et al, 1997). This probably reflects differences in the pattern of injuries between the two approaches combined with a heightened awareness of the potential for injury at laparoscopy (Strasberg et al, 1995).

The clinical presentation depends on the type of injury; conversely, the type of injury may be inferred based on the clinical picture at presentation. Patients with significant bile leaks—types A, C, and D—generally present within the first week after operation, but some leaks may not become apparent for several weeks, and few are diagnosed intraoperatively (Strasberg et al, 1995). Most patients have abdominal pain coupled with fever

Table 42A.3

Bismuth Classification of Biliary Stricture

1. Low common hepatic duct stricture: hepatic duct stump >2 cm
2. Proximal common hepatic duct stricture: hepatic duct stump <2 cm
3. Hilar stricture with no residual common hepatic duct: hepatic duct confluence intact
4. Destruction of hepatic duct confluence: right and left hepatic ducts separated
5. Involvement of aberrant right sectoral hepatic duct alone or with concomitant stricture of the common hepatic duct

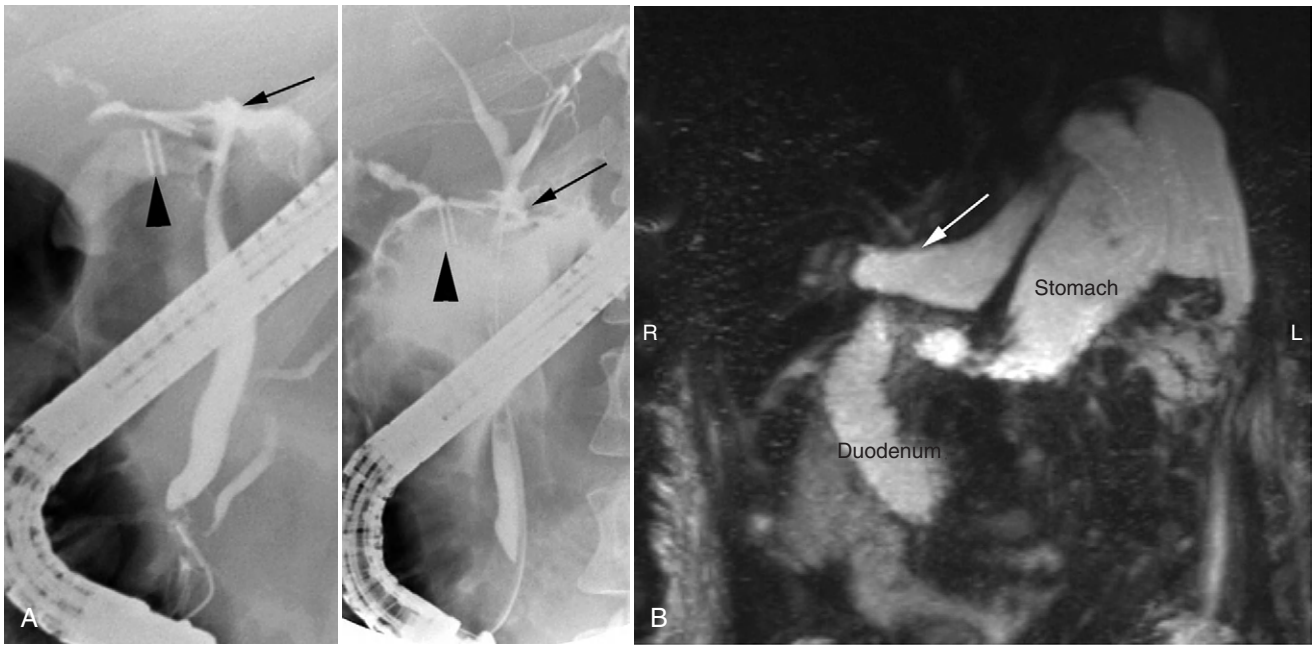

FIGURE 42A.13. A, Endoscopic retrograde cholangiopancreatography showing a Strasberg D injury. Early injection (*left*) shows contrast extravasation (*arrow*); *arrowhead* points to cyst duct clips. Higher pressure cholangiogram (*right*) shows contrast filling of the common duct and common hepatic duct. **B,** A coronal magnetic resonance cholangiopancreatography, T2-weighted image shows the biloma in the lesser sac. *Arrow* points to site of injury.

or other signs of sepsis, which is most common, or bile leakage from an incision. A few patients have none these signs and symptoms but rather have nonspecific complaints of weakness, fatigue, or anorexia. Elevated alkaline phosphatase levels are characteristic, as is mild hyperbilirubinemia, but markedly elevated serum bilirubin levels (>3 mg/dL) are uncommon (vanSonnenberg et al, 1993; Brooks et al, 1993).

Major injuries to the common duct (type E injuries) are more likely to be discovered intraoperatively, although most remain unrecognized until after operation. Similar to bile leaks, these injuries are diagnosed more often within the first few postoperative weeks, although patients with a slowly evolving stricture may not come to attention for several months (Strasberg et al, 1995), which is distinctly uncommon for patients with bile leaks. Most patients with these injuries present with jaundice often coupled with pain and occasionally sepsis. Jaundice is not always present early in the course of the illness. In some patients, the stricture may evolve slowly or cause only partial obstruction. Such patients may have nonspecific complaints, pruritus, or derangements in liver function tests (LFTs), any or all of which should prompt an investigation. In addition, patients with an isolated right sectoral hepatic duct injury (type B) or an internal biliary fistula may be seen initially with a history of unexplained fevers, pain, or general debilitation.

The findings on physical examination are often nonspecific. Jaundice, if present, is usually obvious, and there may be multiple skin excoriations from pruritus. Abdominal distension and pain may be seen in patients with bile peritonitis, whereas focal tenderness suggests a localized collection or abscess. Hepatomegaly may be seen with longstanding biliary obstruction. Splenomegaly or other signs of portal hypertension are uncommon, but if present, these should alert the surgeon to the possibility of concomitant portal venous injury or severe underlying hepatocellular damage. The presence of portal hypertension in association with a biliary stricture portends a poor outcome, and its identification is important not only for planning management but also in a medicolegal context.

Pathologic Consequences

Fibrosis

Biliary obstruction is associated with the formation of high local concentrations of bile salts at the canalicular membrane, and these initiate pathologic changes in the liver (Schaffner et al, 1971). Bile thrombi form within dilated centrilobular bile canaliculi, and secondary changes develop in adjacent hepatocytes. A complex cascade of molecular and cellular events ensues, collectively termed *fibrogenesis* (Friedman, 2008), which ultimately leads to the deposition of collagen and other extracellular matrix proteins and eventually to fibrosis and scarring around bile ducts and ductules (Maher & McGuire, 1990; Jarnagin et al, 1994; Friedman, 1997; see Chapter 6). As this process progresses, mechanical interference with bile flow develops in these intrahepatic biliary radicles and perpetuates cholestasis.

Fibrosis is accompanied by liver cell hyperplasia (Weinbren et al, 1985); this is not true in secondary biliary cirrhosis, because the lobular structure of the liver is usually well preserved (Fig. 42A.14) and the marked fibrosis that occurs in advanced cases only rarely progresses to true cirrhosis. This knowledge is important in planning therapy because many of these pathologic changes are reversible (Duffield et al, 2005). A histologic return of normal liver parenchyma is seen after relief of obstruction in both animal and human models (Sikora et al, 2008; Kirkland et al, 2009), which correlates to the return to near-normal liver function after relief of biliary obstruction (Blumgart, 1978). Fibrosis also may develop in the extrahepatic

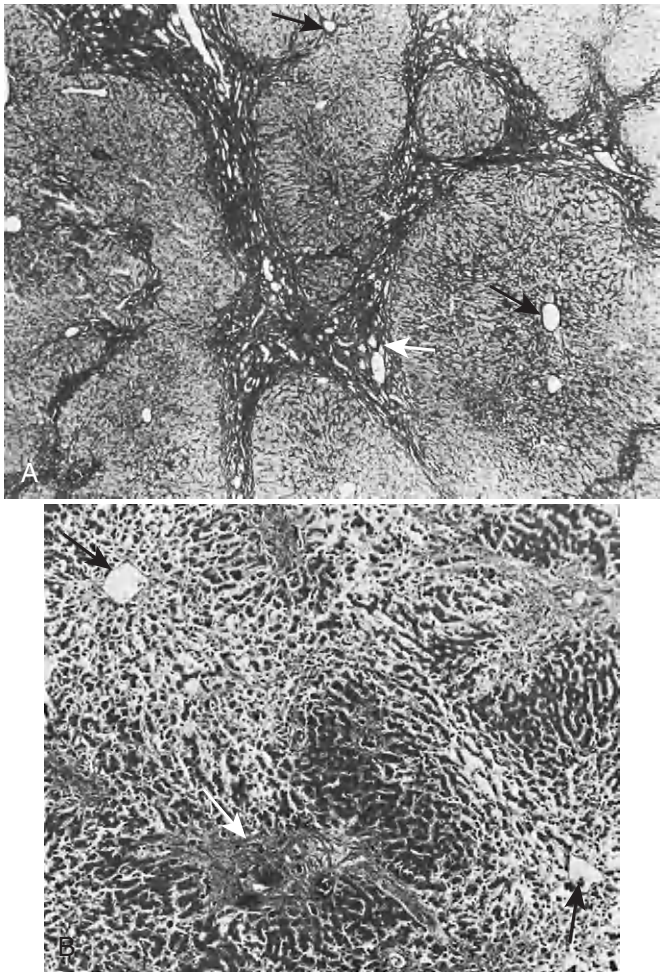

FIGURE 42A.14. A, Photomicrograph showing the effect of long-standing biliary obstruction secondary to benign biliary stricture. Hepatic fibrosis is present, but with preservation of the basic hepatic architecture, with the portal tract (*white arrow*) and hepatic venous radicles (*black arrows*) maintaining their normal relationships. The fibrosis extends between the lobules, but the pattern is not one of true cirrhosis, in which there is destruction of the basic hepatic architecture. **B,** Extensive fibrosis with a substantially normal relationship of hepatic venous radicles (*black arrows*) to portal tracts (*white arrow*) in a patient with portal hypertension. *(From Weinbren K, et al, 1985: Structural aspects of the liver in patients with biliary disease and portal hypertension. J Clin Pathol 38:1013-1020.)*

ducts proximal to the stricture, which is especially likely after biliary intubation. Upward retraction of the ducts is accompanied by a sequence of mucosal atrophy, squamous metaplasia, inflammatory infiltration, and further fibrosis in the subepithelial layers of the ducts.

It usually takes several years for liver fibrosis and portal hypertension (see Chapter 70) to become evident, although it may manifest 2 years after the development of the stricture. Major stigmata of hepatocellular dysfunction, such as spider angiomata and encephalopathy, are uncommon in benign biliary obstruction and should raise the possibility of preexisting parenchymal disease (e.g., chronic hepatitis, alcoholic liver disease). If liver biopsy reveals significant primary hepatocellular disease in association with a benign stricture, the prognosis is especially poor.

Atrophy

The distribution of liver mass is regulated by a poorly understood balance of bile flow, portal venous flow, and hepatic venous flow. Segmental or lobar atrophy may result from portal venous obstruction or bile duct occlusion in the affected area (see Chapter 5). Unilobar atrophy is associated with hypertrophy of the contralateral lobe and may present diagnostic and operative difficulties. Liver lobe atrophy and compensatory hypertrophy is frequently found in benign strictures and may be associated with asymmetric involvement of lobar or sectoral hepatic ducts, interference with portal venous blood supply, or decreased portal perfusion owing to secondary fibrosis. In benign strictures, the dilated ducts within the atrophic segments often are filled with infected bile and debris, and even though drainage of an atrophic segment would not be effective in relieving jaundice, cholangitis may continue unabated unless satisfactory drainage of the atrophic and hypertrophic segments is achieved.

The presence of significant atrophy and compensatory hypertrophy greatly influences the approach to repair. The most common situation is gross hypertrophy of the left lobe accompanied by right lobe atrophy (Czerniak et al, 1986). Anastomosis in the region of the hilum is made difficult by the rotational deformity and anatomic distortion imposed by this condition (see Chapters 5 and 29). A thoracoabdominal approach to such strictures provides more direct exposure and access for repair by allowing rotation of the liver to the left (Bismuth & Lazorthes, 1981). Recent reports verify that the presence of atrophy and contralateral hypertrophy are associated with significantly longer reconstructive operations, higher intraoperative blood loss, and greater blood transfusion requirements (Pottakkat et al, 2009). Similar problems may occur in bile duct strictures after right hepatic resection.

Portal Hypertension (See Chapter 70)

It is estimated that approximately 15% to 20% of patients with benign biliary stricture have concomitant portal hypertension (Blumgart & Kelley, 1984; Chapman et al, 1995). Patients with biliary strictures may develop portal hypertension as a result of secondary hepatic fibrosis or direct damage to the portal vein. Alternatively, portal hypertension may be due to preexisting liver disease. It is important that these patients undergo further workup, including a liver biopsy, to exclude underlying chronic parenchymal disease. Iatrogenic biliary injuries are often the subject of medicolegal proceedings, and precise documentation of all injuries is essential to provide an accurate assessment of the cause of symptoms and prognosis. The outcome of patients with biliary strictures and portal hypertension is much worse than for patients without portal hypertension, with an in-hospital mortality rate of 25% to 40% (Blumgart & Kelley, 1984; Chapman et al, 1995). It has been suggested, however, that adequate biliary drainage may be followed by some resolution of fibrosis and perhaps a reduction in portal pressure (Blumgart, 1978).

Management

Successful management of patients with postcholecystectomy bile duct injuries requires careful planning. The importance of thorough investigation and patient preparation cannot be overemphasized. Before any intervention, the surgeon must define completely the type and extent of injury and treat

life-threatening coexisting conditions—sepsis, cholangitis, ongoing biliary leakage, and abscess—that reduce the likelihood of a successful outcome. Hasty treatment decisions based on incomplete data are more likely to exacerbate an already difficult situation. Imaging studies play a central role in assessing patients with biliary injuries and should be directed at answering the following questions: Is there a subhepatic bile collection or abscess? Is there ongoing bile leakage? What is the level and extent of injury in the biliary tree? Are there associated vascular injuries? Is there evidence of lobar atrophy?

Radiologic Investigations (See Chapters 13 and 15 Through 18)

Duplex ultrasonography is an excellent, noninvasive means of showing intrahepatic ductal dilation and may reveal a subhepatic fluid collection or evidence of vascular damage. Although ultrasound may provide valuable information regarding the level of biliary injury, it is of little value in assessing the extent of a stricture and is of no value if the biliary tree is decompressed.

Computed tomography (CT) is probably the best initial study, the results of which help direct further investigations. A good quality CT scan shows a dilated biliary tree and helps localize the level of ductal obstruction in patients with strictures. In addition, CT identifies fluid collections or ascites, which may suggest the possibility of vascular damage, and it reveals lobar atrophy.

In patients with biliary strictures, complete delineation of the level and extent of injury is necessary. All branches of the right and left intrahepatic biliary tree must be outlined, particularly in cases of high bile duct stricture and recurrent stricture after previous reconstruction. Displaying the hepatic duct confluence (if intact) and the left ductal system and its branches is especially important in selecting the appropriate reconstruction. Percutaneous transhepatic cholangiography (PTC) is much more likely than endoscopic retrograde cholangiopancreatography (ERCP) to provide this information, and PTC remains the standard investigation in this setting (Fig. 42A.15).

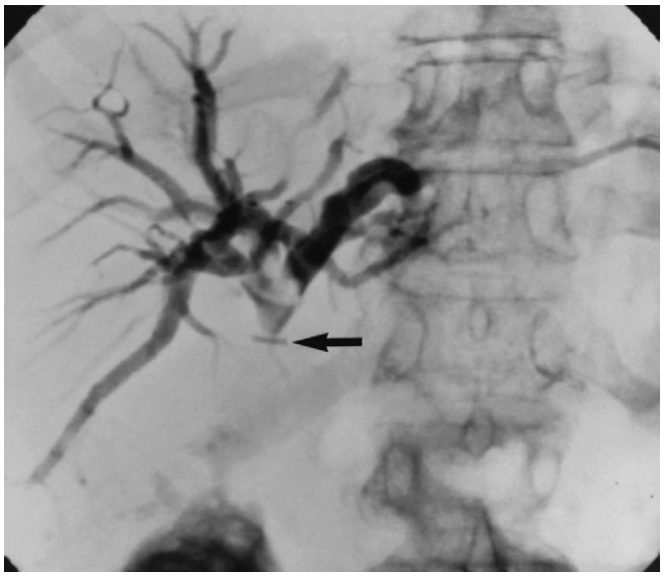

FIGURE 42A.15. Percutaneous transhepatic cholangiography showing a surgical clip occluding the common hepatic duct just below the confluence (*arrow*). All major branches of the proximal biliary tree are outlined.

Drainage catheters should be left in place following PTC if a complex injury is identified on cholangiogram, because palpation of the catheter intraoperatively often helps guide identification of ductal structures later during definitive repair. The risk of cholangitis can be reduced with prophylactic antibiotics.

Magnetic resonance cholangiopancreatography (MRCP) has emerged as a valuable tool in evaluating proximal bile duct injuries (Coakley et al, 1998). This noninvasive modality provides striking images of the biliary tree and yields anatomic information in a single study that was previously obtainable only with CT and PTC (Fig. 42A.16). Multiple studies have now confirmed the high accuracy and detailed information provided by MRCP (Bujanda et al, 2003; Jarnagin et al, 1994; Ragozzino et al, 2004). However, in some cases involving severely distorted anatomy as a result of atrophy, hypertrophy, or dense scarring, preoperative PTC and catheter placement should still be strongly considered, not only for additional cholangiographic information or intraoperative guidance but also because catheters can be easily exchanged for soft tubing to stent across worrisome small caliber anastomoses.

ERCP is seldom of value in the precise diagnosis of complete proximal bile duct strictures because there is often discontinuity of the CBD preventing visualization of the intrahepatic ductal system. ERCP may be more helpful for incomplete strictures (stenoses) and is appropriate for patients with a history of sphincteric damage at previous common duct exploration, or if there is suspicion of papillary stenosis or other periampullary pathology. ERCP also has a role in the diagnosis and treatment of patients with bile leakage from the cystic duct stump or from a laceration of the common duct (Brooks et al, 1993). These patients have evidence of an intraabdominal fluid collection on CT. After percutaneous drainage, biliary scintigraphy (e.g., hepatobiliary iminodiacetic acid [HIDA] scan) can be used to establish the presence of a persistent bile leak. ERCP may then be applied to identify the location of the leak, and placement of a stent may reduce or eliminate bile leakage; however, many bile leaks resolve with percutaneous drainage alone, and ERCP is probably unnecessary in the absence of radiographic or clinical evidence of ongoing bile drainage (Brooks et al, 1993).

Isotopic scanning techniques may be valuable in assessing bile duct strictures, particularly the functional assessment of incomplete strictures, previous biliary reconstructions, and isolated sectoral hepatic duct strictures (see Chapter 15). HIDA scanning offers a dynamic and quantitative assessment of liver function and of the clearance of bile across anastomoses and stenoses (Fig. 42A.17; McPherson et al, 1982). In patients with hepatocellular disease, HIDA scanning may be valuable in distinguishing the contribution of the biliary obstruction from that of the intrinsic liver disease to the overall biochemical and symptomatic picture. In such cases, the bilirubin level may be normal, but the alkaline phosphatase level is increased. HIDA scanning also is valuable during follow-up of patients after surgical repair. Because it can be repeated and is noninvasive, it is of particular value in showing anastomotic patency and function when no tube has been left across the anastomosis at the time of repair (see Fig. 42A.17). An isolated sectoral hepatic duct stricture is suggested by delayed clearance of isotope from a portion of the liver.

Arteriography and delayed-phase portography (see Chapter 19) can be obtained to confirm vascular injury on the initial studies, a suspicion of portal hypertension from the history and physical examination, or a history of excessive bleeding at the

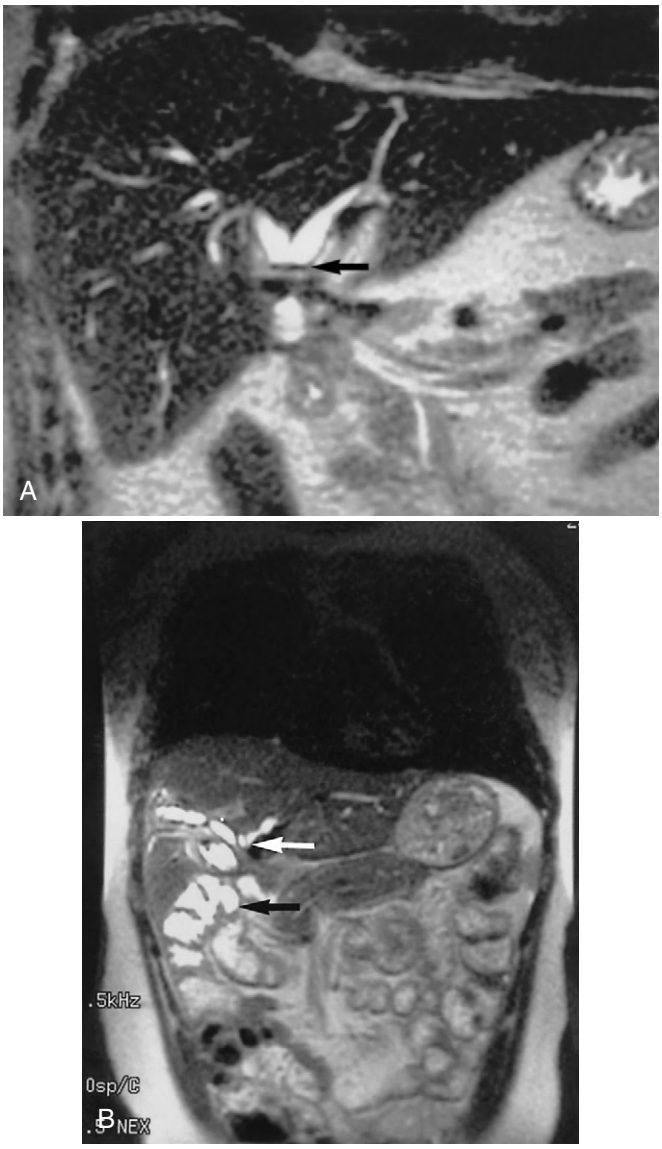

FIGURE 42A.16. A, Coronal single-shot fast spin-echo magnetic resonance cholangiopancreatography (MRCP) showing a surgical clip (*arrow*) occluding the common hepatic duct just below the confluence. **B,** Coronal single-shot fast spin-echo MRCP in a young woman with recurrent cholangitis after multiple attempts to repair a postcholecystectomy bile duct injury. The hepatic duct confluence (*white arrow*) is shown. Excess fluid was noted in the adjacent colon (*black arrow*), suggesting a fistula from the biliary tree to the hepatic flexure. Surgical findings confirmed a fistula from the right posterior sectoral hepatic duct, which had been excluded from the anastomosis. *(From Coakley FV et al, 1998: Complex postcholecystectomy biliary disorders: preliminary experience with evaluation by means of breath-hold MR cholangiography. Radiology 209:141-146.)*

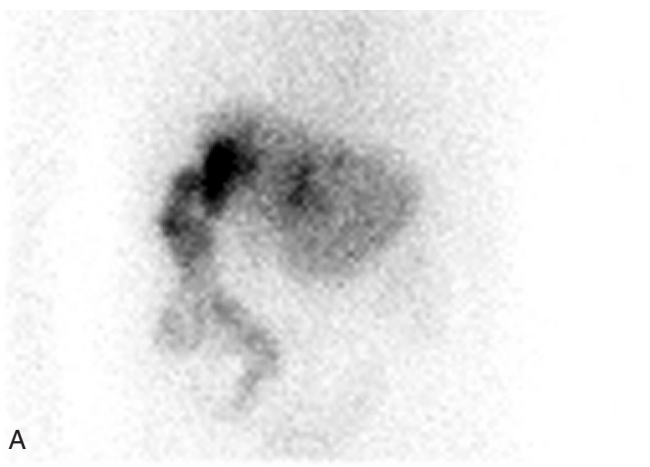
time of cholecystectomy (Li et al, 2008). A biliary injury in the setting of portal hypertension dramatically increases the morbidity and mortality of operative intervention, and its presence should redirect the management approach (Chapman et al, 1995). The combination of biliary and vascular injuries often leads to segmental or lobar atrophy, but it may also be seen with long-standing biliary obstruction alone. An atrophic lobe may be evident on the initial ultrasound or CT scan and appears as a small, often hypoperfused area with dilated, irregular, and crowded bile ducts (Fig. 42A.18). Isotopic scanning may show what appears to be a filling defect in the affected area. It is important to recognize lobar atrophy on the cross-sectional imaging studies, not only because it is an indicator of concomitant vascular injury needing further evaluation, but also because it would change the operative approach during repair (see Chapter 29). In addition, patients with combined bile duct and hepatic artery injuries seem to be at increased risk for severe complications, such as hepatic necrosis and abscess, after reconstructive surgery. A patient undergoing biliary reconstruction in the setting of hepatic artery occlusion may also be at greater risk of late stricture recurrence (Gupta et al, 1998; Schmidt et al, 2005).



Occasionally, injection of contrast material into an established biliary fistula or percutaneous drain outlines the ductal system (Fig. 42A.19). Such studies may complement information provided by formal PTC, particularly if the fistula or tube tract drains an excluded sectoral duct (see Chapter 42B). Because bacterial colonization or biliary infection is inevitable in such cases, it is wise to administer prophylactic antibiotics before and after these studies.

Preoperative Preparation

In general, operative repair of bile duct injuries need not be rushed, the exceptions being treatment of bile duct injuries recognized at the time of initial cholecystectomy or, rarely, emergency treatment of suppurative cholangitis or peritonitis. For most patients, there is ample time to treat coexisting conditions and to perform a full investigation, both of which increase the likelihood of a successful outcome (Stewart & Way, 1995; Chapman et al, 1995).

Cholangitis is a frequent occurrence in patients with bile duct strictures, especially after ductal intubation (see Chapter 43). Administration of intravenous antibiotics is important prior to surgical treatment, and the results from bile cultures obtained at PTC should be used to direct therapy. Patients with severe cholangitis and sepsis are unlikely to respond to antibiotics alone and should be submitted to percutaneous drainage before surgery. Preoperative antibiotics are usually adequate to manage milder attacks and should be used in patients with no clinical evidence of cholangitis, given the high incidence of bacterial contamination. Antibiotic regimens should take into account the frequent presence of anaerobic organisms and enterococci in patients with biliary obstruction (Thompson et al, 1990; Hochwald et al, 1999). We begin antibiotics immediately before operation and continue appropriate treatment for 5 to 7 days postoperatively if cholangitis is a preoperative feature. Although no firm data exist to guide the duration of treatment, the markedly increased incidence of postoperative infectious complications in patients with endoscopic or percutaneous stents suggests that a prolonged course of treatment is justified (Hochwald et al, 1999). These data further suggest that jaundice without evidence of cholangitis is not an indication for biliary intubation.

Anemia should be corrected, if necessary, by blood transfusion; coagulation defects, which typically manifest as a prolongation of the prothrombin time, should be treated with vitamin K or fresh frozen plasma. Patients with prolonged illness may be seen with malnutrition (see Chapter 24). Enteral feedings through a fine-bore nasal catheter may be successful in some cases but may not be tolerated in sufficient amounts, and parenteral nutrition may be necessary. Despite these measures,

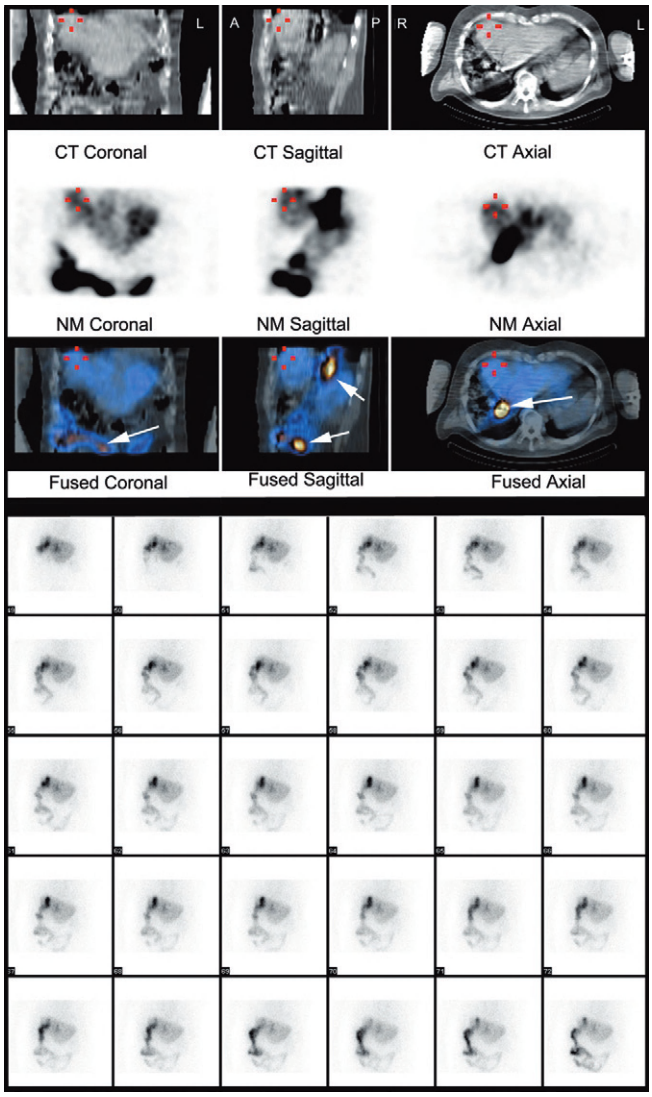


FIGURE 42A.17. A, Hepatobiliary iminodiacetic acid (HIDA) scan, anterior view of the liver 5 minutes after the intravenous injection of 5 mCi of technetium 99m–Choletec in a patient after right hepatectomy and hepaticojejunostomy for a benign stricture. This shows rapid visualization of liver with slight heterogenous distribution of the tracer throughout the liver, major bile ducts, and early filling of the Roux-en-Y limb. **B,** Additional single-photon emission computed tomography of the liver was obtained (*upper panels*). *Arrows* in the fused nuclear medicine (*NM*) and computed tomographic (*CT*) images correspond to high levels of γ-radiation emission; *lower panels* correspond to the HIDA scan with 1-minute sequential frames in the same patient.

however, weight gain is sometimes difficult to achieve, and to date no prospective randomized trials have shown a benefit from short-term preoperative nutritional support. A significant external bile fistula predisposes to excessive fluid and electrolyte loss and may lead to hyponatremia and acidosis (McPherson et al, 1982). It is imperative to correct fluid deficits and electrolyte imbalances before operation (see Chapter 24).

The preoperative management of complications of biliary injuries, such as biliary peritonitis, subphrenic or subhepatic abscess, hemorrhage from erosive gastritis or esophageal varices, or hepatic failure secondary to fibrosis, is important; usually, these must be addressed before biliary reconstruction can be considered. In general, drainage of intraabdominal abscesses and control of gastrointestinal hemorrhage takes priority; however, if systemic sepsis arises from an obstructed biliary tree, a factor that may contribute to other complications, immediate biliary drainage is essential. In such desperately ill patients, it is preferable to perform rapid percutaneous drainage to allow further resuscitative measures with intravenous antibiotics and hydration to prevent renal insufficiency. Management of portal hypertension and external bile fistula occurring in association with stricture is addressed subsequently.

Surgical Treatment

The most appropriate management of bile duct injuries depends on the injury type and whether or not the injury is diagnosed immediately or at some time after operation.

INJURY RECOGNIZED AT INITIAL OPERATION. If injury to the extrahepatic biliary tree is recognized at the time of initial cholecystectomy, the surgeon should consider his or her experience and ability to repair it immediately. The advice of a more

FIGURE 42A.18. Computed tomographic scan showing severe atrophy of the right lobe. The right lobe is hypoperfused and small and is clearly demarcated from the left lobe (*black line*). Notice the markedly increased size of segment IV and the left lateral segment (*white line*) and the dilated and crowded ducts in the small right lobe.

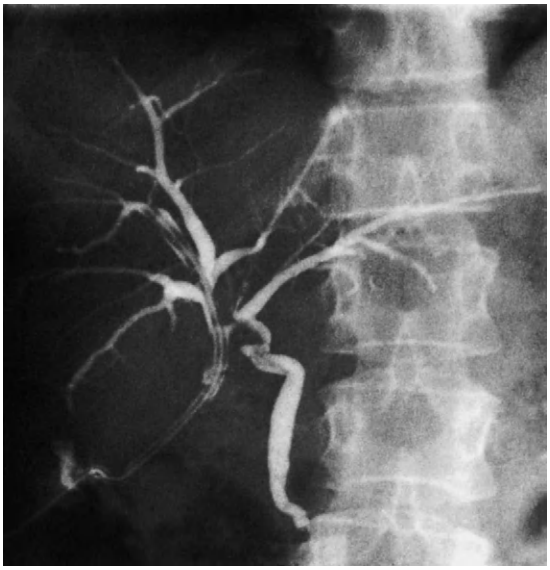

FIGURE 42A.19. Injection of contrast material into a tube that had been placed into the ductal system after a hilar ductal injury recognized at operation. The patient was referred draining approximately 200 mL of bile per day, but with normal liver function test (LFT) results and no fever. The tube was passed into the right hepatic ductal system, but filling of the entire intrahepatic biliary tree is seen with what appears to be a complete division of the common hepatic duct; a fistulous connection has developed between the left hepatic ductal system and the common hepatic duct. The tube was withdrawn and no repair was performed. Subsequent atrophy of the right liver occurred, but the patient was well and symptom free with normal LFT results over a 4-year follow-up period.

experienced surgeon should be sought if possible. The situation is not immediately desperate, and there is always time to wait a short while for another opinion and for additional assistance. Substantial evidence suggests that immediate open conversion and repair by an experienced surgeon is associated with reduced morbidity, shorter duration of illness, and lower cost (Stewart & Way, 1995; Savader et al, 1997). A recent multivariate analysis of bile duct injuries by Stewart and Way (2009) identified timing of biliary reconstruction as being insignificant when patient preoperative condition, complete cholangiography, surgical technique, and surgeon experience are optimized.

Despite the apparent ability to perform biliary reconstruction electively, several studies have cited the benefits of early referral to a tertiary center, as such institutions have specialized hepatobiliary surgeons and radiologists to diagnose and treat biliary complications in a timely fashion (Sicklick et al, 2005; Fischer et al, 2009). Each failed repair is associated with some loss of bile duct length (Tocchi et al, 1996) and greatly exacerbates an already difficult situation. This is particularly true of injuries involving the biliary confluence, in which failure of the initial repair and loss of bile duct length may result in isolation of the right and left hepatic ducts; repair becomes more difficult, and the likelihood of a successful outcome is reduced (Chapman et al, 1995). If the surgeon cannot effect a reasonable repair, and competent help is unavailable, drains should be placed to control any biliary leak, and the patient should be referred to a specialist center.

The damaged area of bile duct requires careful dissection to define the extent of injury. To accomplish this dissection without making matters worse, the laparoscopic approach must be abandoned in favor of a generous right subcostal, extended subcostal, or chevron incision. Additional assistance should be obtained to aid in exposure. Operative cholangiography may be helpful at this point to delineate the anatomy and the type of injury. Regardless of the location of the lesion, initial repair of the damage recognized at the time of cholecystectomy should have two basic aims: 1) maintenance of ductal length below the hilus without sacrifice of tissue and 2) avoidance of uncontrolled postoperative bile leakage.

The initial intervention may not be the final definitive reconstruction; this is particularly true of injury to small ducts that may be difficult to repair. The prime aims of maintaining length and preventing fistulation should guide the surgeon, rather than elaborate attempts at reconstruction under adverse circumstances. It is probably safer to provide external drainage by means of a tube inserted proximally into the bile duct and to refer the patient for specialist treatment, rather than to complicate the situation with a repair that is likely to fail and lead to further damage.

The injury in most cases involves complete transection with or without excision of a length of common duct. Occasionally, only an aberrant right sectoral hepatic duct is involved (Bismuth type 5), although this too may be associated with concomitant injury to the common hepatic duct or CBD. Durable reestablishment of biliary-enteric continuity is difficult when the ducts are small and decompressed, and referral to a specialist unit is crucial in this situation.

Two options are available for repairing a complete duct transection. The first is end-to-end repair over a T-tube. This repair is feasible only if the transected ends can be apposed without tension, which usually requires full mobilization of the duodenum and head of the pancreas. The anastomosis is created using a single layer of interrupted absorbable sutures with the T-tube brought out of the bile duct away from the anastomotic line. Silk sutures should be avoided for all biliary reconstructions, because they can promote an inflammatory reaction and act as a nidus for stone formation. End-to-end anastomoses are

associated with a high incidence of late stricture formation, up to 60% (Csendes et al, 1989; Pellegrini et al, 1984; Rossi & Tsao, 1994; Stewart & Way, 1995). Other reports support the use of end-to-end repair, because more than two thirds of the associated complications, such as stricture or leak, can be managed nonoperatively (de Reuver et al, 2007). In general, we recommend Roux-en-Y hepaticojejunostomy, which will be discussed later; this approach is more likely to give better long-term results.

An injury to the lateral duct wall may be amenable to direct suture repair, and relatively small and simple lacerations may be repaired with interrupted 4-0 or 5-0 absorbable suture. The area of injury should be adequately exposed, but extensive dissection risks further injury and late stricture formation. Some authors recommend T-tubes for all such repairs, but they are probably unnecessary for small lacerations, and their placement into a decompressed bile duct may exacerbate the injury (Rossi & Tsao, 1994). An analogous situation is primary choledochorrhaphy after CBD exploration, and several authors have reported excellent results without using T-tubes (Sheen-Chen & Chou, 1990; Sorensen et al, 1994; Tu et al, 1999). Long, lateral injuries that are not circumferential may be impossible to repair transversely without compromising the lumen, and direct repair over a T-tube is likely to result in future stenosis. Some authors have suggested that vein patches may be used to cover such defects (Ellis & Hoile, 1980), whereas others have described using the cystic duct stump or pedicled flaps of jejunum (Okamura et al, 1985).

Although these approaches may have merit in some situations, we prefer instead to use a Roux-en-Y loop of jejunum as a serosal patch (Fig. 42A.20). A T-tube is placed across the defect, and its long limb is led out through the Roux loop and exteriorized through the abdominal wall. This approach has several advantages: First, bile duct length is maintained. Second, the jejunal serosa is used to cover the defect, secured in place with fine, interrupted absorbable sutures to the bile duct wall without attempting direct approaches to the ragged edge of the damaged duct. Finally, the T-tube provides biliary decompression across the jejunum so that when it is removed, any leaking bile drains into the bowel lumen rather than the abdominal cavity. This method may be particularly useful to an inexperienced surgeon in a difficult situation.

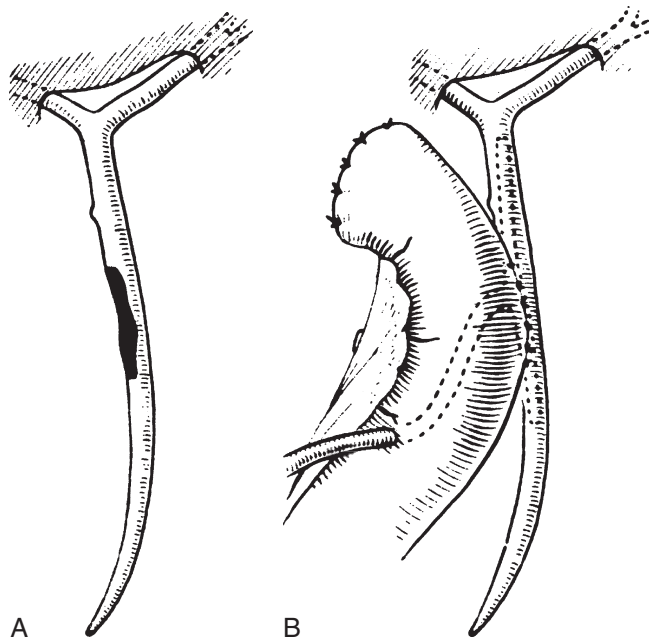

FIGURE 42A.20. Method of repair of a noncircumferential laceration to the bile duct wall. **A,** Injury is lateral with loss of ductal wall over some considerable length. **B,** A Roux-en-Y loop of jejunum is prepared and brought up. A T-tube is placed within the injured bile duct, and the long limb is led out across the jejunal loop, which is secured to the bile duct as a serosal patch over the defect.

INJURY RECOGNIZED IN THE IMMEDIATE POSTOPERATIVE PERIOD. Biliary injuries not appreciated intraoperatively may appear in the first few days after operation. The mode of presentation may be bile drainage through the wound, bile peritonitis, or progressive jaundice, depending on the injury type. In the setting of an external biliary fistula (see Chapter 42B), the essential consideration in management is to avoid early reoperation. It is wiser to take full stock of the situation, to carry out appropriate investigations as described earlier, and to keep the patient well nourished and free of infection. If fistulography or other studies reveal continuity between the biliary system and the gastrointestinal tract, a prolonged period of drainage is warranted and may result in spontaneous closure, provided that there is no distal obstruction to bile flow. This is particularly true of bile leakage from the cystic duct or a subvesical duct of Luschka (type A) or from a noncircumferential laceration (type D).

More severe lacerations or complete transections of the common duct or an aberrant right sectoral hepatic duct with ongoing bile leakage require careful consideration. Because the biliary tree is decompressed, the proximal ducts are small in caliber. Immediate surgical treatment of these injuries is difficult. Adequate repair requires exposing healthy bile duct mucosa within a sufficiently dilated proximal duct to allow precise anastomosis. In the setting of a decompressed biliary tree and significant inflammation, this exposure can be quite demanding or even impossible. A delayed approach remains the most appropriate course of action, because such fistulas also may close without operative intervention, and this may be associated with eventual proximal duct dilation and easier subsequent repair (see Fig. 42A.3). If fluid losses from the biliary fistula remain high over a prolonged period, a useful but rarely used technique is creation of a temporary internal fistulojejunostomy, with definitive repair deferred for a later date (Smith et al, 1982). Alternatively, placement of an endoscopic or percutaneous stent across the defect may reduce output from the fistula, hasten closure, and make management easier. Long-term results of such interventions have shown excellent results, and oftentimes more than 90% of patients with peripheral leaks or strictures can be treated endoscopically (Weber et al, 2009). Some authors advocate early endoscopic sphincterotomy to decrease the relative resistance of transpapillary bile drainage to promote closure (Liguory et al, 1991; Abdel et al, 1996; Inui et al, 1998; Fujii et al, 1998). Although these approaches are occasionally useful, no evidence is available to show that they provide a significant advantage, and a waiting period of 2 to 3 weeks is recommended, because most fistulas close or decrease substantially.

Patients with bile peritonitis are often desperately ill, especially if the bile is infected, although some patients with sterile bile may accumulate large volumes without overt signs of sepsis

(see Fig. 42A.3B). Drainage of the bile collection and control of ongoing bile leak is the primary objective and often requires percutaneous abscess drains in combination with percutaneous biliary catheters. Definitive repair is seldom possible initially, with the bile ducts collapsed, deeply bile stained, and friable; repair is best delayed, until the biliary leak has been controlled completely, and the patient has been fully resuscitated.

INJURY PRESENTING AT AN INTERVAL AFTER INITIAL OPERATION. Many patients seen a long time after cholecystectomy have biliary strictures. The principles of managing late bile duct stenoses and strictures include 1) exposure of healthy proximal bile ducts draining all areas of the liver, 2) preparation of a suitable segment of distal mucosa for anastomosis, and 3) creation of a mucosa-to-mucosa sutured anastomosis of the bile ducts to the distal conduit, which is almost always a Roux-en-Y loop of jejunum.

It may be necessary to consider a staged approach to stricture repair in the presence of intraabdominal infection, portal hypertension, or poor general condition of the patient. Repair attempts in the face of uncontrolled local infection, acute complications of portal hypertension, or general debilitation are doomed to fail. The initial approach in such cases should be limited to establishing external bile drainage, controlling sepsis, and treating other coexisting conditions that are life threatening. In this manner, the clinical condition of the patient may be improved before attempts at definitive repair (Cattell & Braasch, 1959). In a patient with portal hypertension, initial interventional radiologic management by percutaneously placed biliary drainage catheters is probably safer than operation, given the danger of intraoperative hemorrhage (Pellegrini et al, 1984).

Technical Approaches to Biliary Repair (See Chapter 29)

END-TO-END DUCT REPAIR. Excision of the stricture with end-to-end anastomosis was one of the earliest techniques used for reconstruction (Cattell & Braasch, 1959). This repair reestablishes normal anatomic continuity and drainage via an intact sphincter of Oddi. Such an approach has been tried even for high strictures after extensive mobilization of the duodenum and common duct. End-to-end repair is associated with a 50% to 60% incidence of long-term failure (Csendes et al, 1989; Pellegrini et al, 1984; Stewart & Way, 1995). These figures reflect the failure rates in the most favorable of cases, because patients with more extensive injuries usually were submitted to biliary-enteric anastomosis (Rossi & Tsao, 1994). These data suggest that end-to-end repair has a limited role in the surgical treatment of benign biliary strictures.

BILIARY-ENTERIC REPAIR. For most cases of bile duct transection or stricture, biliary-enteric anastomosis is the procedure of choice. For strictures of the retropancreatic or immediate supraduodenal portion of the CBD, choledochoduodenostomy is an ideal procedure. The anastomosis may be performed either side-to-side or end-to-side (see Chapter 29). This technique is appropriate only in the setting of a dilated bile duct and almost certainly would result in recurrent stricture if created to a decompressed duct. Most postcholecystectomy strictures are not amenable to choledochoduodenostomy, because such low injuries are unusual in contrast to postgastrectomy strictures, which often involve the distal bile duct. Strictures involving the common hepatic duct are more difficult to manage, especially strictures involving the biliary confluence, and they almost always require Roux-en-Y hepaticojejunostomy for reconstruction. The technical aspects of biliary-enteric anastomosis have been described (Voyles & Blumgart, 1982; Blumgart & Kelley, 1984) and are outlined in Chapter 29.

There are a variety of approaches to the proximal hepatic ducts. When the stricture is below the confluence (Bismuth type 1 or 2), a direct anastomosis to the hepatic duct stump is usually straightforward. By contrast, when the stricture encroaches on the confluence of the right and left hepatic ducts (type 3) or extends proximally so as to isolate the ducts (type 4), the problem becomes more complex, and good results are more difficult to achieve. The choice of surgical approach should be tailored to the height and extent of the lesion. The technical descriptions that follow should be read in conjunction with Chapter 29.

An important feature is early division of the falciform ligament back to the diaphragm and freeing the liver of adhesions. Dissection should begin in the right subhepatic area, and it is usually necessary to mobilize completely the hepatic flexure of the colon, starting from below and working upward and medially. The duodenum often adheres to the undersurface of the liver and to the hilar structures, particularly in the area of the stricture. The surgeon may encounter an internal bile fistula to the duodenum or may injure the duodenal wall during this portion of the dissection, either of which would require repair.

Attempts to identify the duct below the stricture are unnecessary, because the distal duct generally cannot be used for anastomosis; it is usually encased in dense scar tissue, and extensive dissection to free it risks injury to the hepatic artery and portal vein. The essential point is identification of the bile ducts proximal to the stricture, and a systematic, careful, and patient approach is necessary. Dissection in the area lateral to the hepatic artery pulsation allows identification of the common hepatic duct. Although this approach is reasonable in patients with relatively low strictures (Bismuth type 1), it is inappropriate in most cases. It is generally much easier and safer to expose the left hepatic duct by lowering the hilar plate at the base of segment IV (quadrate lobe). Often this area has not been disturbed by the previous surgeon and is likely to be relatively free of adhesions. This maneuver delivers the left hepatic duct and the biliary confluence from the undersurface of the liver and makes identification of the strictured area much easier. Adhesions posterior to a damaged duct may be dense, and extensive dissection in this situation risks injury to the underlying portal vein. It is generally unnecessary to come around the scarred area completely, provided that the posterior wall of the duct above the stricture can be elevated sufficiently for anastomosis.

Strictures at or above the level of the biliary confluence are much more challenging. Adequate exposure of the bile ducts is usually achievable by dissecting the left hepatic duct system. This approach is based on the anatomic studies of Couinaud (1953, 1955; Hepp & Couinaud, 1956) and is well described (Bismuth et al, 1978; Blumgart & Kelley, 1984). For type 2 and type 3 strictures, biliary-enteric anastomosis to the left hepatic duct provides complete drainage of the left and right ductal systems. For type 4 strictures, however, the confluence is obliterated, and it is necessary to provide drainage of the right lobe as well, often by dissection across the stricture and creation of a second anastomosis to the right ductal system. Occasionally, mobilization or even partial excision of the quadrate lobe may be necessary in some type 4 strictures.

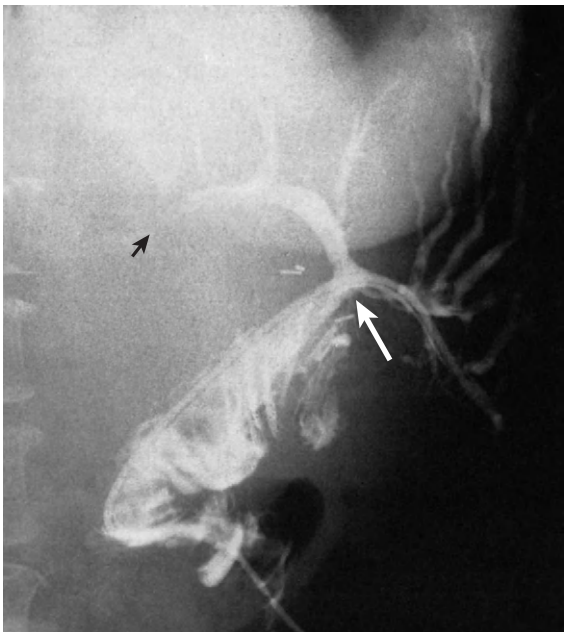

FIGURE 42A.21. Roux-en-Y hepaticojejunostomy to the segment III duct after postcholecystectomy stricture initially treated by hepaticojejunostomy, using the mucosal graft technique with a transhepatic tube through the right liver. At referral, the patient had a grossly atrophic right lobe and a high bile duct stricture (*black arrow*). At operation, the left hepatic duct was exposed using the ligamentum teres approach, and anastomosis was carried out (*white arrow*). Subsequent repeat stricture occurred 1 year later and was treated by refashioning of the anastomosis and subsequent transtubal balloon dilation with a satisfactory outcome. The patient was well and symptom free 2 years after operation.

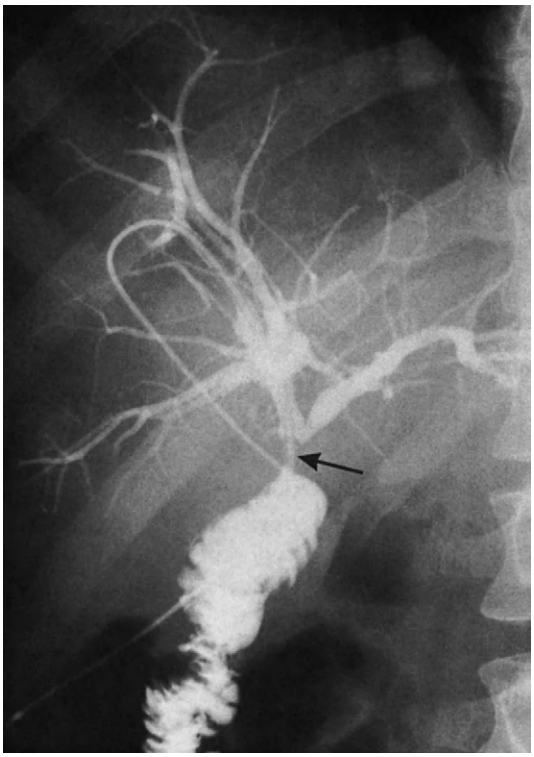

FIGURE 42A.22. Cholangiogram obtained by injection of a U-tube was used to develop a mucosal graft repair of a high bile duct stricture done 2 weeks before this radiograph was obtained. It was considered that there were no ducts visible at the hilus of the liver that would allow formal anastomosis. The mucosal graft is already widely separated from the biliary confluence (*arrow*). Repair was done by an approach to the left hepatic duct. A wide anastomosis was obtained easily, and the patient was well and symptom free with normal liver function tests 3.5 years after operation.

Although most high strictures may be approached and managed as described previously, it is occasionally difficult to expose the left hepatic duct because of adhesions or fibrosis. Excessive bleeding may be encountered, or a large, overhanging quadrate lobe may prevent access to the left duct. Occasionally, the extrahepatic length of the left duct, normally much greater than the right, is short, and access to it is difficult. In such instances, repair can be accomplished by dissection of the left duct within the umbilical fissure, known as the *ligamentum teres* or *round ligament approach* (Fig. 42A.21; Soupault & Couinaud, 1957). This approach rarely is indicated for benign strictures and should not be used unless the biliary confluence is intact, so that a left-sided anastomosis would drain the entire liver.

The mucosal graft procedure of Smith (1964, 1969) is a procedure of historical interest only. This method was introduced for treating high strictures in which hilar dissection was thought to be impossible, and the proximal ducts could not be delivered for mucosa-to-mucosa anastomosis. The object of the procedure is to use a transhepatic tube to draw the jejunal mucosa high up into the hepatic ducts and allow apposition. The procedure was claimed to be easier and quicker, because no sutures were inserted. The transhepatic tube was left in place for 2 to 6 months, occasionally longer for difficult cases. Initially hailed as an important advance in technique (Kune & Sali, 1981), it is now clear that the dome of the jejunal mucosa drawn into the hepatic ducts may block significant secondary intrahepatic ducts, occluding and isolating segments of liver tissue (Blumgart, 1978; Blumgart et al, 1984). In addition, the mucosa may slip away postoperatively, and the jejunal loop may become detached (Fig. 42A.22). Recurrent stricture at the site of previous mucosal grafting is common (Blumgart & Kelley, 1984). This technique fell out of favor after several series of complex biliary strictures documented good to excellent long-term results using biliary-enteric anastomotic techniques without using the mucosal graft approach (Schol et al, 1995; McDonald et al, 1995; Chapman et al, 1995; Stewart & Way, 1995; Nealon & Urrutia, 1996; Tocchi et al, 1996; Lillemoe et al, 1997).

LIVER SPLIT AND LIVER RESECTION. To expose the bile ducts for repair, it is sometimes necessary to open the liver tissue as a hepatotomy (Blumgart, 1980). The most frequent situations involve opening the umbilical fissure to obtain access to the segment III duct or extending the subhepatic approach to expose the origin of the right hepatic duct. This latter approach involves opening the liver in the line of the gallbladder fossa. Upward mobilization of the entire quadrate lobe by this maneuver combined with opening the umbilical fissure facilitates access for selected type 4 strictures, especially when approaching the right hepatic ducts is difficult. Fiddian-Green and colleagues (1988) described a similar approach. Resection of the lower parts of segments IV and V to obtain exposure to the hilar plate has been described for Strasberg E3 injuries; in this setting, the surgeon must be diligent to stay away from the hepatoduodenal ligament (Sirichindakul et al, 2009). Division

of liver tissue in this setting must be accomplished patiently, because it may be accompanied by significant hemorrhage. These techniques are unnecessary if approaches to the left duct are possible. Actual liver resection is rarely necessary for exposure of the bile ducts in benign postcholecystectomy strictures. Most often, excision of the anterior portion of the quadrate lobe is done if exposure of the umbilical fissure and incision in the gallbladder bed are insufficient to expose the ducts in difficult type 4 strictures.

More rarely, benign strictures may be treated by means of an intrahepatic hepaticojejunostomy as described by Longmire and Sandford (1948, 1949), which involves resection of a portion of the left lateral segments (II and III) and anastomosis to ducts exposed on the cut surface of the liver. In general, this procedure is difficult and potentially dangerous, because the liver is often fibrous, and resection is met by a fair degree of hemorrhage. The bleeding vessels are generally in close proximity to the ducts needed for anastomosis. The use of this procedure is limited to cases in which there is left-sided hypertrophy (Czerniak et al, 1986), and it is rarely the only option available to secure access to the bile ducts.

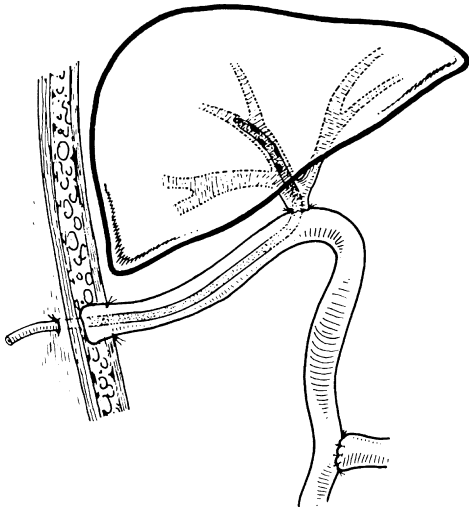

FIGURE 42A.23. Hepaticojejunostomy with a long, defunctionalized Roux limb with the end secured subcutaneously or subperitoneally to allow access for future diagnostic or therapeutic studies.

ISOLATED SECTORAL HEPATIC DUCT INJURIES. Injuries to aberrant or "low entry" right sectoral hepatic ducts can be particularly difficult to diagnose and manage. Patients with a stricture but no bile leak (type B) may remain asymptomatic for months or years after the injury and only then present with pain or evidence of cholangitis. Some patients may remain essentially asymptomatic and come to attention because of abnormal LFTs. These injuries are not associated with jaundice, unless concomitant stricture of the common hepatic duct (type E5) is present. Long-standing obstruction may result in atrophy of the corresponding hepatic sector drained by the occluded duct (right anterior or right posterior). Some of these patients will have had ERCP in the course of their evaluation that was interpreted as normal, but in retrospect, it is found to actually show partial nonfilling of the right biliary tree. Biliary drainage to a Roux-en-Y loop of jejunum should be done in symptomatic patients. In patients with symptoms, especially recurrent cholangitis, and evidence of liver atrophy, drainage alone may be insufficient, and resection of the atrophic sector may be required. Asymptomatic patients may not require intervention, especially if the injury was remote, and significant atrophy is already evident; however, patients with a relatively recent injury and no atrophy probably are best served with operative drainage to prevent future problems (Strasberg et al, 1995).

Patients with sectoral hepatic duct injuries associated with biliary leak (type C) are a particularly difficult group to manage. After appropriate initial investigation, control of biliary leak, and resuscitation, reconstruction to a Roux-en-Y jejunal loop should be performed. Because the transected duct is small and decompressed, achieving good results is difficult even in experienced hands, and restenosis is common. It has been suggested that percutaneous transhepatic drainage of the affected duct before operation (Lillemoe et al, 2000; Strasberg et al, 1995) and prolonged postoperative anastomotic stenting are crucial for successful management (Lillemoe et al, 2000). We believe that neither of these maneuvers is necessary as a matter of routine, but they may be helpful in selected cases.

COMBINED MODALITY APPROACHES. The standard surgical techniques of biliary reconstruction described previously are suitable for most cases. In the most complex and difficult strictures, and especially in the presence of intrahepatic strictures and stones, even optimal surgical management is met with a disappointingly high incidence of postoperative intrahepatic stone formation, cholangitis, and recurrent stricture. Interventional radiologic and endoscopic techniques, used as primary therapy in this setting, are similarly unsuccessful because of recurrent cholangitis associated with stent occlusion or recurrent stricture after balloon dilation. Often, nonoperative techniques are technically impossible because of limited access.

Under such adverse circumstances, when the risk of recurrent stricture or stone formation is believed to be high, hepaticojejunostomy may be performed over a transjejunal tube brought to the exterior across the blind end of the Roux limb. The defunctionalized Roux limb is deliberately left long, and the end is secured subcutaneously or subperitoneally (Fig. 42A.23); this allows easy subsequent access for cholangiography, cholangioscopy, dilation, or stone removal. The blind end of the Roux limb may be reaccessed by percutaneous puncture under fluoroscopic guidance or via a small incision made under local anesthetic for late diagnostic or therapeutic procedures long after the transjejunal tube has been removed. In our experience, this approach is rarely necessary but can provide an improved chance of excellent outcome in difficult cases and may spare the patient the need for repeated major surgical intervention months or years later (Schweizer et al, 1991; McPherson et al, 1998). It is generally unnecessary to add the morbidity of a formal stoma, although such an approach has been reported (Barker & Winkler, 1984).

HEPATIC RESECTION. Patients who have undergone prior unsuccessful repairs or have concomitant vascular injury or long-standing cholangitis often develop sectional duct strictures or interruptions between the right-sided and left-sided biliary tree, effectively precluding biliary-enteric revision. Such patients may require formal liver resection to eliminate atrophied liver or the biliary duct confluence. The surgical aim in such instances is to create a more functional biliary-enteric anastomosis using the remnant liver. Although mostly described as isolated cases

(Uenishi et al, 1999; Heinrich et al, 2003), Laurent and colleagues (2008) reported their experience with 18 cases of formal resections (14 right hepatectomies, 3 left hepatectomies, and 1 left trisectionectomy) for benign biliary stricture (see Chapter 90B). At a median follow-up of 8 years, 94% of patients had good or excellent results. Another report described eight patients who underwent either right hepatectomy or left lateral sectionectomy, and it demonstrated similar, excellent results (Thomson et al, 2007). Hepatic resection remains an important option in the treatment of refractory benign bilary stricture, especially in patients suffering from recurrent bouts of cholangitis or sepsis.

LIVER TRANSPLANTATION. Transplantation for iatrogenic biliary injury can be performed acutely but is usually done because of a devastating combined vascular and biliary injury (Felekouras et al, 2007; Zaydfudim et al, 2009). Only rarely does secondary biliary fibrosis resulting from longstanding biliary obstruction progress to true cirrhosis (see Chapter 97A). In such cases, orthotopic liver transplantation should be considered as an alternative to biliary reconstruction. Thomson and colleagues (2007) reported their series of 14 patients who either underwent hepatic resection or transplantation for secondary biliary cirrhosis. Of the five patients who ultimately required transplant for survival, two were deemed unsuitable for the procedure, one died awaiting an organ, and two underwent the procedure. Even in experienced transplantation centers, surgical reconstruction is preferred for most patients with benign strictures.

PORTAL HYPERTENSION AND BILIARY STRICTURE. Patients with coexisting portal hypertension and biliary stricture are an especially difficult group to manage (see Chapter 70). This combination has been reported in 10% to 20% of patients at the time of referral (Blumgart & Kelley, 1984; Chapman et al, 1995). Portal hypertension may result from secondary biliary fibrosis or direct injury to the portal vein, or coincident hepatocellular disease may be evident from alcohol abuse, chronic hepatitis, or other causes. The presence of splenomegaly or a history of gastrointestinal bleeding in a patient with biliary stricture should prompt further investigation with esophagogastroduodenoscopy and angiography with delayed-phase splenoportography. Bleeding esophageal varices, particularly if accompanied by hypersplenism or ascites, render the overall prognosis far worse (Chapman et al, 1995; Way & Dunphy, 1972). Collateral venous channels in the subhepatic region and within adhesions make dissection difficult and bloody. Patients with portal hypertension often have a proximal stricture, and some have had multiple previous attempts at repair, further reducing the likelihood of a successful outcome.

In seriously ill patients with jaundice and portal hypertension, it is preferable to attempt nonoperative stenting or balloon dilation than to proceed to immediate definitive repair (Fig. 42A.24; Toufanian et al, 1978; Molnar & Stockum, 1978; Teplick et al, 1980; Schwarz et al, 1981; Pellegrini et al, 1984). In the face of severe gastrointestinal bleeding, initial measures must be directed at stopping the hemorrhage and resuscitating the patient (see Chapters 75A and 75B). If bleeding continues, consideration should be given to immediate splenorenal or transjugular intrahepatic portosystemic shunting (TIPS; see Chapter 76) to achieve control, with bile duct reconstruction deferred until a later date. Occasionally, successful biliary-enteric reconstruction can be done under these circumstances with no need to create an intraoperative vascular shunt (Perakath et al, 2003; Agarwal et al, 2008). The best and most convenient form of operative shunt is the splenorenal shunt (see Chapter 76C). TIPS has a limited patency, and such shunting is used most often as a bridge to transplantation. The risk of biliary injury and subsequent biliary-venous fistula is high in the setting of a dilated biliary tree and seems to be a major mechanism of early shunt failure (Jalan et al, 1996; Saxon et al, 1998). TIPS is unlikely to play a major role in the management of these patients; instead, percutaneous drainage or balloon dilation may be used along with the measures described earlier.

If hemorrhage is encountered during stricture repair, hepaticostomy drainage may be performed as an initial measure, and a splenorenal shunt may be undertaken at a later date. Bile duct stricture repair done at the time of the shunting procedure can be extremely difficult and in any event is unwise at a time of severely compromised liver function. Occasionally, patients present with variceal hemorrhage after an otherwise successful stricture repair (Fig. 42A.25). In these instances, portosystemic shunting may be indicated as an emergency measure or, preferably, after initial conservative management. Injection sclerotherapy may control the bleeding successfully and obviate the need for operative intervention (see Chapter 75B).

RESULTS OF BILIARY RECONSTRUCTION. Given the wide spectrum of injuries that are possible at laparoscopic cholecystectomy, it is difficult to assess fully the results of operative repair. Most surgical series report results of repair of biliary strictures (type E) and do not address operative intervention for other injury types. In addition, many patients are subjected to immediate repair at the time of initial injury; the more difficult cases and the failures generally are referred to specialist units, but the long-term outcome of the other cases is often not reported. As a result, most literature reports—generated from tertiary referral centers—include significant numbers of patients requiring difficult reconstructions or with multiple previous repair attempts, which may underestimate the overall success rate. Relatively few reports with sufficient follow-up focus on the results of repair of laparoscopic injuries alone (Table 42A.4). It remains to be determined whether the results of repair of bile duct strictures after open cholecystectomy or other procedures can be extrapolated to repair of laparoscopic injuries. It has been suggested that laparoscopic bile duct injuries may have a less satisfactory outcome because of the more complex nature of many of these injuries and the frequent inflammation and fibrosis secondary to bile leakage (Lillemoe et al, 1997).

OPERATIVE MORBIDITY AND MORTALITY. Several studies have suggested significant morbidity associated with repair of benign strictures (Blumgart et al, 1984; Kune & Sali, 1981). The most common postoperative complications seen were intraabdominal abscess, wound infection, cholangitis, sepsis, biliary fistula, postoperative hemorrhage, and pneumonia. The perioperative mortality rate in many series ranged from 5% to 8% (Cattell & Braasch, 1959; Warren et al, 1982; Way & Dunphy, 1972); however, since the 1990s, several authors have documented a considerable decline in mortality, with many citing no perioperative deaths (see Table 42A.4). These figures generally do not take into account patients who die as a result of biliary tract–related sepsis while awaiting definitive treatment. Factors frequently associated with perioperative death include advanced age, significant comorbid medical conditions,

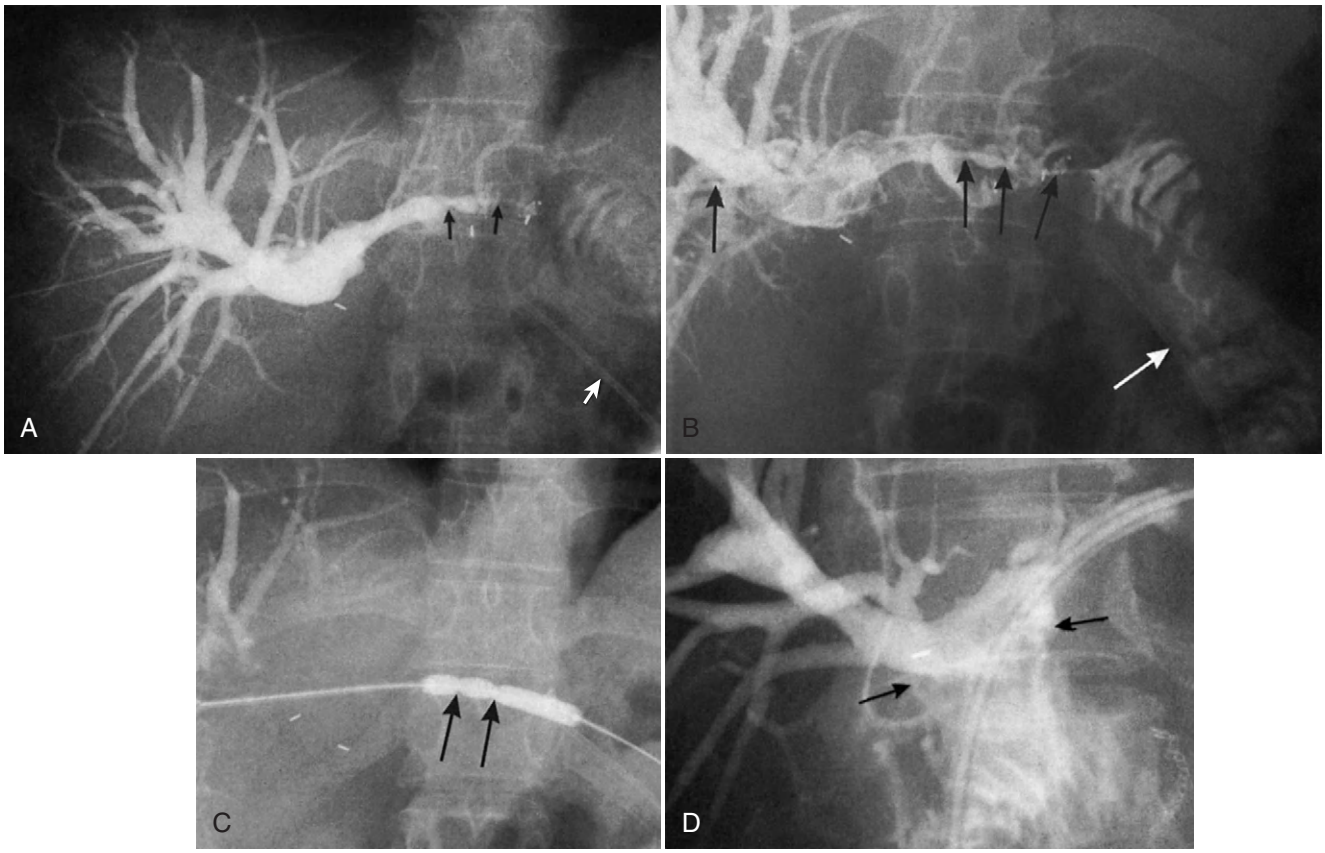

FIGURE 42A.24. A, Percutaneous transhepatic cholangiography showing a high (type 3) postcholecystectomy biliary stricture in a patient after cholecystectomy, during which there had been excision of the entire common hepatic duct. This was followed by two attempts at a mucosal graft repair and a left-sided hepaticojejunostomy by the Longmire-Sandford procedure. After failure of this operation, percutaneous intubation of the biliary ductal system was undertaken from the right side with attempted balloon dilation of the hepaticojejunostomy on three consecutive occasions. The radiograph shows the area of the hilus, marked by a surgical clip, and two strictures in the left hepatic ductal system, one just proximal to and the other at the hepaticojejunostomy (*black arrows*). A free endoprosthesis is seen (*white arrow*) lying in the jejunum. **B,** Cholangiogram obtained during attempted balloon dilation of the stricture reveals the passage of the catheter (*black arrows*) and the biliary system full of clot. The guidewire crosses the stricture, and a free endoprosthesis lies within the jejunal loop (*white arrow*). This procedure was followed by a severe episode of hemobilia requiring blood transfusion. **C,** Radiograph obtained during balloon dilation clearly shows the two strictures (*arrows*). **D,** Roux-en-Y hepaticojejunostomy was performed by the left hepatic duct approach, and a wide anastomosis was obtained (between the *arrows*). The previous hepaticojejunostomy to the left lobe was dismantled, and the new anastomosis was splinted by a tube passed through the left hepatic ductal system. The tube was removed 2 months later, and the patient was well and symptom free with normal liver function test results 2 years after operation.

and biliary sepsis. Significant underlying liver disease is perhaps the most important predictor of adverse outcome. Chapman and colleagues (1995) reported a perioperative mortality rate of 23% in patients with biliary strictures and portal hypertension subjected to any operative procedure.

A significant proportion of patients in many reports were referred after one or more repair attempts. Failed repairs nearly always render subsequent attempts more difficult and have a negative impact on the ultimate outcome. The reported morbidity and mortality rates reflect this point and underscore the serious nature of these injuries. Nevertheless, in experienced hands, operative repair of biliary strictures is a relatively safe procedure, and this fact must be considered when comparing surgery with nonoperative techniques.

LONG-TERM RESULTS AND FOLLOW-UP. Several factors must be considered when analyzing the long-term results of biliary reconstruction. First, there is no consistently used algorithm for postoperative investigation. Likewise, the measures used to assess outcome vary considerably. Approaches to follow-up range from simple observation and measurement of LFTs to performance of cholangiography or HIDA scans. Consistency in analyzing long-term results is important and should include an assessment of symptoms, LFTs, and radiographic studies. Such a triad of criteria is useful for clarifying the results and is the only way to compare accurately the results from various series or interventions (Table 42A.5; Schweizer et al, 1991). In addition, long-term follow-up is crucial in analyzing the final results of any series and when comparing different treatment modalities. Pitt and colleagues (1982) reported that two thirds of recurrent strictures were apparent within 2 years, but 20% were diagnosed 5 or more years after the initial repair. Similarly, Tocchi and colleagues (1996) observed that 40% of restrictures were identified more than 5 years after the initial operation. Complete and accurate assessment of the results of surgery or any other intervention requires a minimum follow-up of 5 years, but probably longer (Bismuth, 1982).

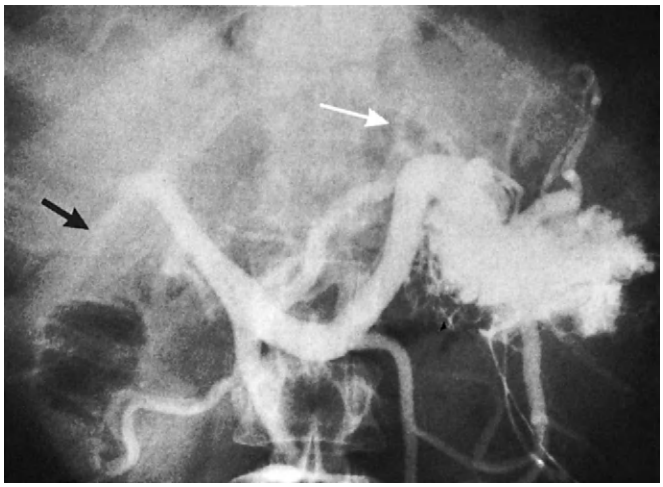

FIGURE 42A.25. Splenoportography in a patient with benign bile duct stricture and a history of vascular injury at the initial operation. The patient presented with portal hypertension and bleeding esophageal varices. Only a portion of the right portal venous vasculature is outlined (*black arrow*). Note varices in the area of the gastric fundus (*white arrow*). Percutaneous transluminal cholangiography revealed a stenosis near the biliary confluence, but not a complete obstruction, and liver biopsy showed hepatic fibrosis. Biliary reconstruction was not undertaken; instead, the patient was managed with a splenorenal shunt and has remained well for several years, and repair of the stricture has never been necessary.

Numerous studies assessing the impact of postcholecystectomy bile duct injuries on quality of life (QoL) in long-term follow-up have reported mixed results. Three studies showed significant impairment in several measured QoL categories (Boerma et al, 2001; Moore et al, 2004; de Reuver et al, 2008), whereas three others showed minimal (Melton et al, 2002) or no difference (Sarmiento et al, 2004; Hogan et al, 2009) compared with a matched cohort. Tornqvist and colleagues (2009) analyzed more than 374,000 laparoscopic cholecystectomies over 40 years' time in Sweden and identified 1386 injuries requiring reconstructive surgery; of note, injured patients had a fourfold increase in the risk of death from liver disease and a signficantly decreased overall survival. However, differences in study design and in the QoL instrument used make direct comparisons between studies difficult. In addition, pending litigation, which is common in such cases, is a potential confounding variable that likely has some influence on the results. Nevertheless, QoL measurement adds another dimension to the assessment of long-term outcome.

Several specialist centers reported satisfactory outcomes in 80% to 90% of patients reconstructed with Roux-en-Y biliary-enteric anastomosis, (see Table 42A.4). Many of these studies also identified factors associated with an adverse outcome (Table 42A.6). Chapman and colleagues (1995) found that long-term failure and the need for reintervention were significantly greater in patients with injuries involving the biliary confluence and those subjected to three or more repair attempts before referral. Tocchi and colleagues (1996) observed that the best results correlated directly with the degree of biliary ductal dilation, independent of stricture location. A report from Schmidt and colleagues (2005) confirmed that a repair in the presence of uncontrolled infection, a concomitant hepatic arterial injury, and injury location (i.e., at or above the bifurcation) were independent predictors of the development of major biliary complications. Surgeon experience and the type of repair also are important determinants of outcome. In the series reported by Stewart and Way (1995), primary end-to-end repairs over a T-tube were always unsuccessful when the duct had been completely transected.

Many authors have advocated the use of anastomotic stents (Smith, 1969; Crist et al, 1987; Lillemoe, 1997), but the impact

Table 42A.4

Selected Series Reporting Outcome After Repair of Benign Biliary Strictures

Reference	No. Patients	Mechanism of Injury	Previous Repair Attempt	Morbidity/ Mortality	Successful Outcome	Follow-up
Chapman et al, 1995	122	OC (all)	80 (66%)	NR/1.8%*	76%	86 mo
McDonald et al, 1995	45	OC, 26 LC, 16 Other, 3	11 (24%)	36%/0	95%†	55 mo
Stewart & Way, 1995	45	LC (all)	27 (60%)	4%/0	94%	NR
Tocchi et al, 1996	84	OC, 60 CBDE, 4 Trauma, 4 Other, 16	4 (5%)	21%/2.2%	83%‡	108 mo
Lillemoe, 1997	59	LC (all)	15 (25%)	NR/0	92%‡	33 mo
Frilling et al, 2004	40	LC (all)	10 (25%)	NR/5%	82.5%	16 mo (median)
Schmidt et al, 2005	54	LC and OC, 22	41%	NR/1.9%§	92.6%	61.9 mo (median)

Most repairs were performed as hepaticojejunostomy or choledochojejunostomy (Roux-en-Y). *Previous repair attempt* refers to the number and percentage of patients referred after at least one attempt at repair. *Successful outcome* refers to the percentage of patients requiring no further intervention after initial, definitive surgical management at the reporting institution; most series reported salvaging some of the initial failures with interventional radiologic or further surgical intervention.

*Postoperative deaths in two patients subjected to mucosal grafts; no deaths occurred in patients submitted to direct biliary-enteric repair.

†Includes some asymptomatic patients with mild elevations of liver function tests.

‡Includes patients with excellent or good outcomes.

§A total of five deaths occurred during the follow-up period with one perioperative death.

CBDE, common bile duct exploration; LC, laparoscopic cholecystectomy; NR, not reported; OC, open cholecystectomy

Table 42A.5

Suggested Criteria for Assessing the Late Results of Biliary Stricture Management

Classification	Symptoms	Biochemistry*	Radiology†
Excellent	None	Normal	Normal
Good	None	Elevated	Abnormal
Fair	Improved	Elevated	Abnormal
Poor	Persistent/worse	Elevated	Abnormal

*Serum bilirubin and alkaline phosphatase
†Hepatobiliary iminodiacetic acid scan or cholangiography or both

Table 42A.6

Factors Associated with Stricture Recurrence or Poor Outcome After Operative Reconstruction

Proximal stricture (Bismuth types 3 and 4)
Multiple prior attempts at repair
Portal hypertension
Hepatic parenchymal disease (cirrhosis or hepatic fibrosis)
End-to-end biliary anastomosis
Surgeon inexperience
Intrahepatic or multiple strictures
Concurrent cholangitis or hepatic abscess
Intrahepatic stones
External or internal biliary fistula
Intraabdominal abscess or bile collection
Hepatic lobar atrophy
Advanced age or poor general health

of such stents on long-term patency is questionable. We and other authors rarely use stents, and we get excellent results (Bismuth, 1982; Bismuth et al, 1978; Stewart & Way, 1995; Tocchi et al, 1996). Transanastomotic stents seem to have little impact on outcome and probably should not be used routinely. Although stents may be useful in selected cases, they cannot prevent the inevitable failure of a poorly constructed anastomosis.

The results of surgical reconstruction for injuries other than those involving the main extrahepatic bile duct have not been reported in great numbers and are not known precisely. Lillemoe and colleagues (2000) reported the results of 9 cases of reconstruction for isolated sectoral hepatic duct strictures over an 18-year period. All patients in this series incurred injuries to aberrant right sectoral hepatic ducts at laparoscopic or open cholecystectomy, and all had associated bile leaks. After Roux-en-Y hepaticojejunostomy, six (66.6%) of the nine patients had a successful outcome, whereas three patients developed late strictures that required reintervention. Colovic (2009) likewise analyzed 19 patients with isolated segmental, sectoral, and right hepatic duct injuries over a 26-year period. Twelve patients underwent surgical reconstruction, and the rest were managed expectantly or with percutaneous drainage with good to excellent results.

Patients with recurrent strictures after reconstruction at a specialist unit may be salvaged with further intervention, either anastomotic revision or balloon dilation. Several authors have reported some measure of success with surgical revision in these patients (Chapman et al, 1995; Lillemoe et al, 1997; Stewart & Way, 1995; Tocchi et al, 1996; Walsh et al, 2004). The likelihood of a good outcome is less than with the initial reconstruction, however. In the series reported by Chapman and colleagues (1995), 11 of 22 operative failures were treated a second time successfully and had satisfactory outcomes, but this was substantially lower than the nearly 80% success rate after the initial repair. Other groups have reported nearly equivalent surgical outcomes for reoperated patients when compared with primary repairs at the same institution (Pottakkat et al, 2007). As discussed previously, the loss of bile duct length associated with a failed repair is a major factor that limits the success of subsequent interventions.

Duodenal ulceration has been reported in 10% of patients after Roux-en-Y biliary-enteric reconstruction and constitutes an additional cause of late morbidity (McArthur & Longmire, 1971; Sato et al, 1982). Most patients respond to antiulcer medication, but some may develop significant hemorrhage.

NONOPERATIVE APPROACHES. Advances in interventional radiology have resulted in a broader application of nonoperative approaches to bile duct stricture (see Chapter 28). The largest reported experience has been with percutaneous balloon dilation. With this technique, the biliary tree is accessed percutaneously, and a guidewire is passed through the stricture. The stricture is dilated with an angioplasty-type balloon catheter, after which a transhepatic stent is left in place for follow-up cholangiography and repeat dilation. In most cases, multiple dilations and prolonged biliary intubation are required. Early results have been encouraging, with several authors reporting good results in 55% to 85% of patients (Vogel et al, 1985; Mueller et al, 1986; Williams et al, 1987; Moore et al, 1987; Pitt et al, 1989; Lillemoe, 1997).

These results must be viewed with considerable caution, however. First, the mean follow-up in most of these studies was less than 3 years, which is insufficient to make a definitive comment regarding long-term efficacy. However, Cantwell and colleagues (2008) reported their long-term results with balloon dilation of 85 patients with benign postoperative biliary stricture and reported that most patients (61.9%) were successful after the first dilation, and 75% of patients had clinical patency after multiyear (mean, 8 years) follow-up. Second, balloon dilation is limited in its application to patients in whom biliary continuity is intact or has been restored by a previous attempt at repair; it has no role for strictures at or above the confluence and cannot be used if the bile duct has been transected (Lillemoe et al, 1997). Third, complications related to balloon dilation or to the percutaneous catheter are frequent and include hemobilia, bile leak, and cholangitis in 20% of patients.

Another nonoperative approach used is endoscopic stenting. With this technique, multiple plastic or metallic stents are placed across the stricture endoscopically, necessitating removal at a later date. Kassab and colleagues (2006) reported their experience with 88 patients with benign biliary stricture after

cholecystectomy who underwent endoscopic stenting during ERCP. They reported that 69.1% of patients were successfully treated, with a mean of 1.6 stents placed for an average duration of 14 months and no stricture recurrence at a mean follow-up of 28 months after stent removal. Other groups have reported higher success rates, albeit at shorter follow-up intervals (Kuzela et al, 2005; van Boeckel et al, 2009). As with balloon dilation, the results of stenting are tempered with caveats of short follow-up periods and no randomized studies.

Comparing the results of balloon dilation or endoscopic stenting with operative reconstruction is difficult because of differences in the types of injuries selected for each type of treatment, inconsistencies in defining successful outcomes, and differences in reporting complications and length of follow-up. To date, no randomized studies have compared these techniques. In two retrospective analyses, biliary reconstruction was more likely to result in a successful outcome: 89% versus 52% (Pitt et al, 1989), 92% versus 64% (Lillemoe et al, 1997), and 94% versus 58% (Misra et al, 2004). Because balloon dilation requires multiple readmissions and repeat interventions, the overall cost and morbidity seem to be similar to that of operatively treated patients (Pitt et al, 1989). The data suggest that, in most cases, biliary-enteric anastomosis is more effective and provides more durable relief of symptoms than balloon dilation, although balloon dilation is preferable in patients who otherwise would not tolerate an operation; it may be tried as an initial treatment in patients with biliary anastomotic strictures, for which the success rate seems to be greater than for primary bile duct strictures (Millis et al, 1992).

BILE DUCT INJURY AFTER OTHER OPERATIONS

Nontraditional Cholecystectomy

The advent of novel surgical technologies has ushered in a new potential for causation of iatrogenic biliary stricture. Natural orifice translumenal endoscopic surgery (NOTES)—a technique to obtain intraabdominal access via transgastric, transvaginal, transvesical, or transcolonic routes—has been recently applied for cholecystectomy. Multiple groups have described both the feasibility and safety of the technique (Chamberlain & Sakpal, 2009) as well as the ability to achieve Strasberg's critical view of safety (Auyang et al, 2009). However, hepatic complications, including bile leak and hepatic injury (Zornig et al, 2009; Salinas et al, 2010; Chow et al, 2009), have occurred in addition to other NOTES-specific complications such as gastric hematoma, abdominal sepsis, and esophageal perforation.

Another recent surgical trend is single-incision laparosopic surgery (SILS) to perform cholecystectomy via a single port at the umbilicus. Similar to NOTES, complications include hepatic injury, cystic artery hemorrage, and biliary leakage (Palanivelu et al, 2008; Tacchino et al, 2009). As with any new technology, initial results are tempered by the anticipated learning curve. An important limitation for both SILS and NOTES for cholecystectomy is inadequate retraction and maneuverability of the gallbladder to achieve critical views. Percutaneous large-bore–needle T-fasteners inserted into the gallbladder for retraction are fragile and may increase the likelihood of bile leakage. The effect on iatrogenic biliary injury remains to be seen with these techniques. On the other hand, the implementation of robotic technologies in theory gives the ability for more refined movement and views. Groups have already reported using robotic surgical platforms as a salvage mechanism for completion cholecystectomy, as it is believed the increased precision allows for better visualization and dissection in a hostile abdomen than that provided by traditional open or laparoscopic approaches (Kohn & Martinie, 2009). These new techniques need further careful safety evaluations before they should be widely accepted. The authors believe that the minor cosmetic benefit of these procedures does not outweigh the unknown potential harmful affects when compared with the standard laparoscopic approach.

Biliary Reconstructive Operation

Postoperative stricture or fistula can complicate procedures that require biliary-enteric anastomoses, such as reconstruction after pancreaticoduodenectomy, bile duct resection for mid–bile duct tumors, and excision of choledochal cysts. Typically, these procedures involve choledochoenteric or hepaticoenteric anastomosis. Late strictures after such procedures are most likely to occur when enteric anastomosis is performed to a normal caliber duct, or when the duct itself is diseased, as in cases of choledochal cysts. When biliary-enteric anastomosis has been performed for longstanding biliary obstruction, the duct is dilatated and thickened. In these cases, the anastomosis is usually easy to construct, and late stenosis is uncommon (Tocchi et al, 1996). In most cases, stricture of a biliary-enteric anastomosis after resection for malignancy is the result of cancer recurrence. However, in a retrospective study of 1595 patients, no difference was apparent in postoperative stricture rate (2.6%) between benign and malignant indications for resection following pancreaticoduodenectomy (House et al, 2006). Only 9% of strictures were caused by recurrent malignant disease, and preoperative biliary drainage and postoperative biliary stenting were the only risk factors for stricture.

Late stricture may also occur after side-to-side choledochoduodenostomy performed for choledocholithiasis or as a bypass procedure for chronic pancreatitis. This complication is rare if the anastomosis is performed to a sufficiently dilated duct (at least 1.5 cm), and the final diameter of the anastomosis is at least 2 to 2.5 cm (Schein & Gliedman, 1981; Escudero-Fabre et al, 1991). The so-called sump syndrome after choledochoduodenostomy—in which particulate matter, stones, and food debris accumulate and stagnate in the distal, "blind" end of the common duct—is an occasional cause of recurrent cholangitis that can result in anastomotic stricture (Matthews et al, 1993; Venerito et al, 2009). Endoscopic management, consisting of sphincterotomy with or without balloon dilation of the anastomosis or even placement of an occlusion device, has been reported for this condition (Baker et al, 1985; Ell et al, 2006). This approach may not be adequate, however, to remove the thick, infected debris that is often densely adherent to the wall of the inflamed distal CBD, and restricture of the anastomosis is common. We prefer reoperation, with end-to-side hepaticojejunostomy, Roux-en-Y, to prevent persistent regurgitation of intestinal contents and to remove the "sump" permanently (Matthews et al, 1993). When dissection in the hilus is rendered hazardous because of dense scarring, an alternative maneuver is to perform a pyloric exclusion and gastrojejunostomy, which accomplishes the same objective of preventing reflux of intestinal contents into the biliary tree.

Recurrent cholangitis after biliary-enteric anastomosis almost invariably is attributed to anastomotic stricture; however, this assumption has been questioned (Goldman et al, 1983). Some patients develop repeated episodes of cholangitis despite apparently free drainage of bile through the anastomosis in the absence of a clear stricture. In these cases, there may be an overlooked intrahepatic stricture or intrahepatic stone disease (Matthews et al, 1993) or even parasitic infection (Mercado et al, 2006).

Gastric Resection

Injury to the bile duct at gastrectomy is particularly likely when the pyloric region and duodenal bulb are severely distorted or inflamed (Florence et al, 1981). The most common situation is biliary injury during Billroth II gastrectomy. Patients may be seen with jaundice or biliary fistula in the postoperative period, which may be mistakenly attributed to a duodenal stump leak. Less commonly, bile duct injury occurs during gastrectomy (Fig. 42A.26), which can result in biliary stricture. Chronic inflammation from a duodenal ulcer or deeply placed sutures for management of hemorrhage can present with a delayed distal bile duct stricture or papillary stenosis (Fig. 42A.27).

Repair of the damaged bile duct after gastrectomy is usually not difficult. The stricture typically lies close to the proximal, divided end of the duodenum, and it is a simple matter to identify the biliary tree and perform a direct anastomosis at or near the duodenal stump. Occasionally, the entire first and second portion of the duodenum has been disconnected from the pancreatic head. One approach to such cases is repair with a retrocolic Roux-en-Y segment and envelopment of the pancreatic head in the open end of the jejunum.

Hepatic Resection

Biliary injury during hepatic resection is uncommon in experienced hands, but it can occur, particularly when resection is done for lesions near the hilus. In such instances, we recommend that the bile duct be freed from the tumor by careful dissection of hilum and clear identification of the right and left main ducts. Special care should be exercised when using the pedicle ligation and stapler technique to prevent inadvertent injury or complete occlusion of the left bile duct in right-sided resections (Fig. 42A.28). If there is a suspicion of iatrogenic ductal injury that cannot be readily identified, or if the biliary anatomy is unclear, intraoperative cholangiography should be performed; deliberate choledochotomy with passage of fine bougies into the right and left ducts may assist identification. If a choledochostomy has been performed, a T-tube usually is inserted.

The management of injuries that occur after partial hepatectomy can be extremely difficult (Johnson et al, 1979; Smith et al, 1982; Matthews et al, 1991). The problems are similar to

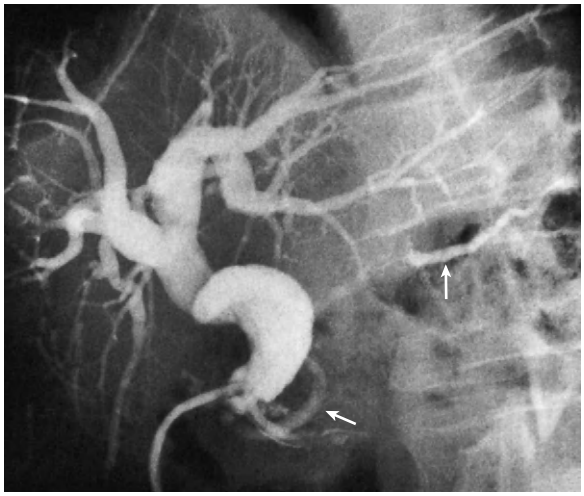

FIGURE 42A.26. A patient with ampullary disconnection that occurred during Billroth I gastrectomy. The duodenal loop was completely detached from the periampullary area. A fistulogram obtained through a T-tube that had been left in situ shows the biliary tree and the pancreatic duct (*arrows*). *(Courtesy Dr. H. Gooszen, University of Leiden, The Netherlands.)*

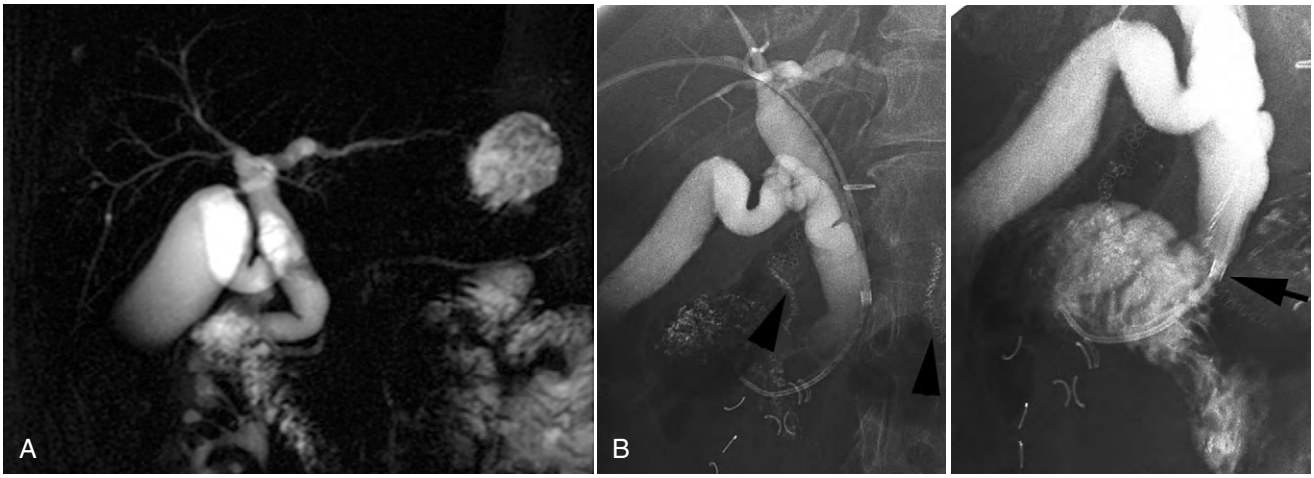

FIGURE 42A.27. A, Magnetic resonance cholangiopancreatographic (maximum-intensity projection), T2-weighted images demonstrating diffuse dilation of the common bile duct. The patient had undergone a gastrectomy with a Billroth II reconstruction for bleeding ulcer disease 15 years prior and presented with abdominal pain and normal liver function tests. A postgastrectomy bile duct stricture was suspected, but intraoperative findings showed papillary stenosis with a pinpoint opening. **B,** Percutaneous transluminal cholangiography (*right*) shows distal bile duct coming to a point at the level of the ampulla (*arrow*) and staple lines (*arrowheads, left*) from prior gastrectomy.

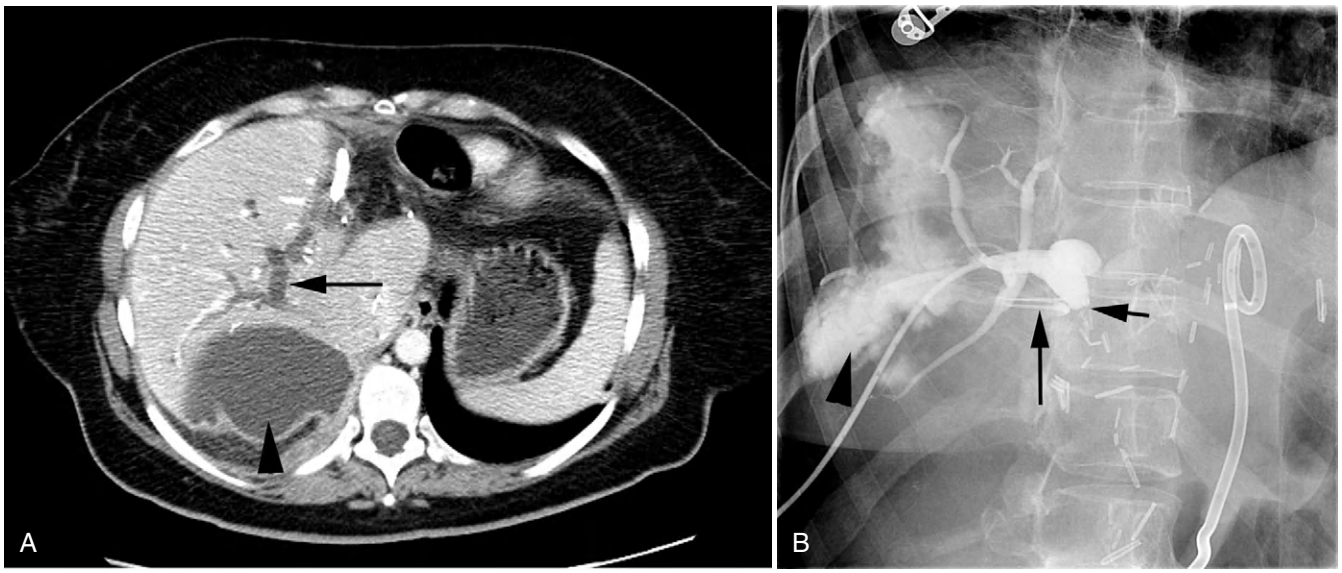

FIGURE 42A.28. A, Transaxial computed tomographic scan showing dilatated intrahepatic bile ducts (*arrow*) and biloma (*arrowhead*). This patient had undergone a right hepatectomy and segment II resection for metastatic colorectal cancer. A large tumor deposit was located at the bifurcation, and the bile duct was divided using a vascular stapler, which incorporated the left bile duct and resulted in complete biliary obstruction. **B,** Percutaneous transluminal cholangiography shows the obstruction of the bile duct at the hilum (*short arrow*). Contrast extravastion is seen (*long arrow*), resulting in biloma (*arrowhead*).

those encountered with liver atrophy discussed earlier. A biliary fistula after liver resection should be treated expectantly for a long time, because many resolve spontaneously. Operative repair should be undertaken only for persistent fistula despite continued observation or for jaundice or recurrent episodes of cholangitis.

Other Procedures

Late biliary stenosis may follow any other procedure requiring dissection in or near the porta hepatis, such as portocaval shunt or lymphadenectomy (Ishizuka et al, 1998). Biliary strictures also have been described after external-beam radiation therapy (Schmets et al, 1996) and after endoscopic injection of sclerosant into a bleeding duodenal ulcer (Luman, 1994). Bile duct strictures also may complicate orthotopic liver transplantation (see Chapter 98A), although their frequency seems to have decreased (Calne, 1976; Colonna et al, 1992; Vougas et al, 1996; Macfarlane et al, 1996; Lemmer et al, 1997; Wojcicki et al, 2008). Direct end-to-end choledochostomy has been the preferred method of reconstruction, but Roux-en-Y choledochojejunostomy also is used (Lopez-Santamaria et al, 1999). The use of T-tubes after biliary reconstruction, once considered essential, has been shown to offer no significant benefit (Vougas et al, 1996), and their routine use has been discontinued in many centers (Macfarlane et al, 1996; Vougas et al, 1996; see Chapter 35). Hepatic artery thrombosis is an uncommon but well-recognized cause of biliary stricture after liver transplantation (Colonna et al, 1992; Orons et al, 1995; Sanchez-Urdazpal et al, 1993; see Chapter 100). Late stricture is seen in 10% to 15% of cases (Macfarlane et al, 1996; Vougas et al, 1996), which is much lower than the reported rate of recurrent stricture after direct anastomosis for bile duct injuries. Many of these patients require operative revision, but some may be managed successfully with endoscopic or interventional radiologic approaches (Colonna et al, 1992; Lemmer et al, 1997; Macfarlane et al, 1996). In addition, the burgeoning of living donor transplantation has exposed the potential for significant biliary injury to the donor, a problem that seems to be uncommon in experienced hands (see Chapters 98B and 100; Lo, 2003; Liu et al, 2005).

BILE DUCT INJURY RESULTING FROM BLUNT OR PENETRATING INJURY

Hepatic, pancreatic, and biliary injuries from trauma are discussed more fully in Chapters 102, 103, and 104. The gallbladder or biliary tree may be damaged by blunt (Fig. 42A.29) or penetrating abdominal injuries. The CBD is susceptible to disruption from deceleration injuries, usually at the level of the pancreaticoduodenal junction, where it is relatively fixed compared with the more proximal duct. Delayed common duct stricture has been reported after blunt abdominal trauma (Yoon et al, 1998; Horiguchi et al, 1998). Late problems also may arise after hepatic trauma, in which prolonged fistulization occurs from a segment of liver isolated by the injury, particularly when bile drains from a large portion of the liver through the fistulous tract.

Management of ductal injuries depends on the extent of associated injuries. Major hemorrhage and other life-threatening injuries take priority, and in this setting, external diversion of bile flow through a tube passed proximally into the duct prevents bile leak and allows for later definitive repair. Roux-en-Y biliary-enteric reconstruction is the preferred approach for complete ductal transections (Degiannis et al, 2001). Traumatic strictures are probably also best approached in this manner, although successful dilation has been reported (Horiguchi et al, 1998). Management of persistent bile leak after liver injury is a much more difficult problem, because the fistula may persist even after prolonged observation. The possibility of an associated distal stricture, which perpetuates bile drainage, should be excluded. One approach to management is

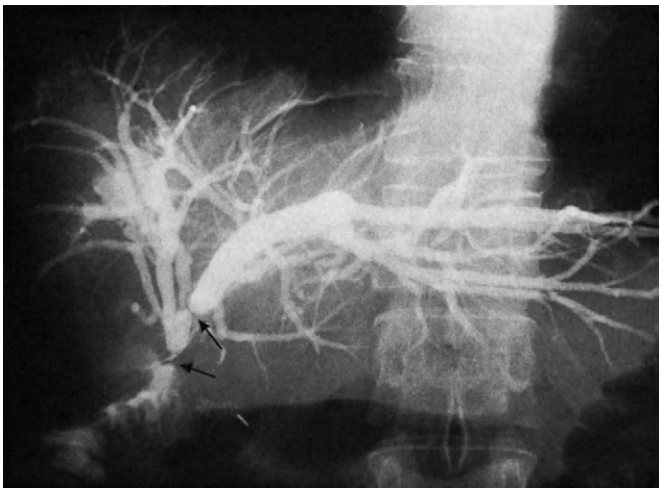

FIGURE 42A.29. Percutaneous transluminal cholangiography in a young man with recurrent attacks of cholangitis 1 year after repair of a biliary stricture at the site of damage to the common hepatic duct associated with a liver injury that necessitated right hepatectomy. Two strictures are present: one at the site of previous hepaticojejunostomy and the other in the main left hepatic duct (*arrows*). Rotation of the liver had made an approach to the left duct difficult. Hepaticojejunostomy was refashioned in the area of the confluence, and the stricture within the left hepatic duct was treated by subsequent balloon dilation with a good result.

by anastomosis of a well-developed fistula tract to a loop of jejunum (fistulojejunostomy) or to the gallbladder. Fistulojejunostomy may yield a permanent cure, although late stenosis or stricture still may develop, for which secondary repair must be performed (Smith et al, 1982). Resection of an isolated segment of liver that is the source of the drainage is difficult and seldom warranted, and direct oversewing of the fistula is rarely successful.

POSTINFLAMMATORY BILIARY STRICTURES

Longstanding Cholelithiasis

Repeated attacks of cholecystitis may result in progressive fibrosis and shrinking of the gallbladder, which ultimately obliterates the triangle of Calot, as described earlier. The inflammatory process may spread to involve the common hepatic duct, causing inflammatory stenosis and resulting in jaundice and cholangitis (Mirizzi, 1948; see Chapter 42B). The presentation may be associated with a history of acute or chronic cholecystitis, and an overt stricture may be present at the time of cholecystectomy. Intraoperative cholangiography may be difficult to obtain, and inadvertent bile duct injury may ensue during attempts to remove the gallbladder. A large stone in the region of the Hartmann pouch may erode into the common hepatic duct and cause a cholecystocholedochal fistula (see Fig. 42A.5). In such cases, attempts to remove the gallbladder result in injury to the common hepatic duct or removal of a portion of the duct. Patients with long-standing gallstones and jaundice should never be submitted to operation without preliminary percutaneous or endoscopic cholangiography.

Patients with inflammatory strictures of the common hepatic duct in association with chronic cholelithiasis may be seen with radiologic features that are indistinguishable from cholangiocarcinoma (see Chapter 50B); this possibility must be considered in all patients suspected to harbor a tumor at the biliary confluence with coincident choledocholithiasis (Hadjis et al, 1985; Standfield et al, 1989; Wetter et al, 1991). Biliary cytology and percutaneous biopsy generally are not helpful, because a benign result never excludes a malignancy; the diagnosis usually is established at operation.

Chronic Duodenal Ulcer

Chronic duodenal ulcer can cause inflammation and fibrosis in the entire periampullary area and result in distal biliary stricture or choledochoduodenal fistula. The presentation is typically that of jaundice and cholangitis in a patient with a long history of duodenal ulcer. The advent of acid-reducing agents has greatly reduced the incidence of complications related to peptic ulcer disease, and such problems are now rarely seen.

Recurrent Pyogenic Cholangitis

Recurrent pyogenic cholangitis is addressed in detail in Chapters 39 and 40. This condition is seen mainly in Southeast Asia and is associated with intrahepatic calcium bilirubinate stones and intrahepatic strictures (Ong, 1962; Maki et al, 1972; Choi et al, 1982; Chen et al, 1984). Recurrent episodes of cholangitis and sepsis are the major threat to life in these patients, along with a significantly increased risk of cholangiocarcinoma (Sato et al, 1995, 1998; Chijiiwa et al, 1995; Chu et al, 1997). Hepatic resection combined with Roux-en-Y biliary-enteric reconstruction is effective in relieving symptoms and clearing stones. This is particularly true if the disease is unilateral, but even patients with bilateral disease may benefit from a combination of resection and postoperative balloon dilation and stone extraction (Jeng et al, 1996). Because of the high incidence of recurrent stricture and stone formation, a team approach that includes experienced surgeons, interventional radiologists, and gastroenterogists is required to obtain the best results (Kim et al, 1998). Careful operative planning is important, and the operation can be tailored to help provide future access to the biliary tract. For example, we have sucessfully used a Roux-en-Y biliary-enteric reconstruction that not only includes the long-segment limb anchored to the abdominal wall for interventional radiology access, but a jejunogastrostomy is also constructed, using the proximal end of the Roux limb, for easy endoscopic access in patients at high risk for recurrent stones (Fig. 42A.30). Some authors have reported success using balloon dilation combined with transhepatic choledochoscopic lithotripsy, either as initial therapy or for recurrent stones after surgery (Yoshida et al, 1998; Sheen-Chen et al, 1998). Numerous patients have advanced parenchymal disease at presentation and die as a result of related complications despite aggressive intervention (Chijiiwa et al, 1995).

Chronic Pancreatitis (See Chapter 55)

Chronic pancreatitis is a well-known cause of distal bile duct stenosis and stricture. The incidence of biliary stricture in these patients is difficult to know with certainty, but it has been reported in 30% of patients (Sarles & Sahel, 1978). The characteristic lesion is a long, narrow stricture involving the retropancreatic portion of the CBD (Fig. 42A.31), but other variants

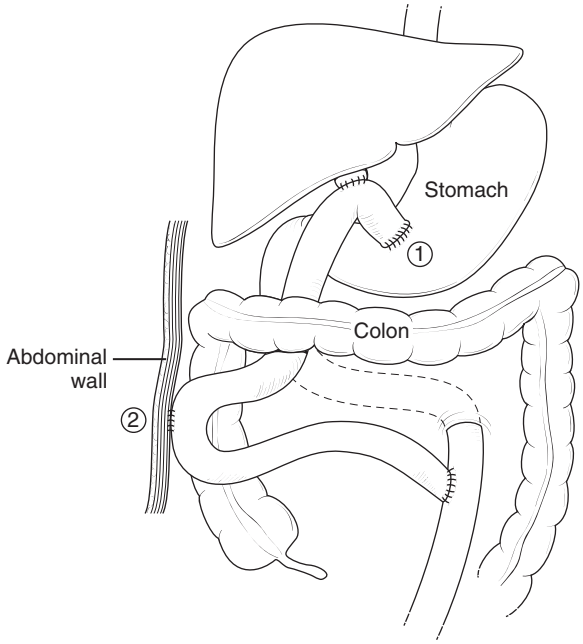

FIGURE 42A.30. Surgical reconstruction option for patients with recurrent pyogenic cholangitis. Note the jejunogastrotomy (*1*) constructed from the proximal end of the Roux limb to the antrum for easy endoscopic assess. A long-segment jejunal Roux limb is used and is anchored to the abdominal wall (*2*) for interventional radiology access for future therapeutic or diagnostic studies in patients at high risk for recurrent stones.

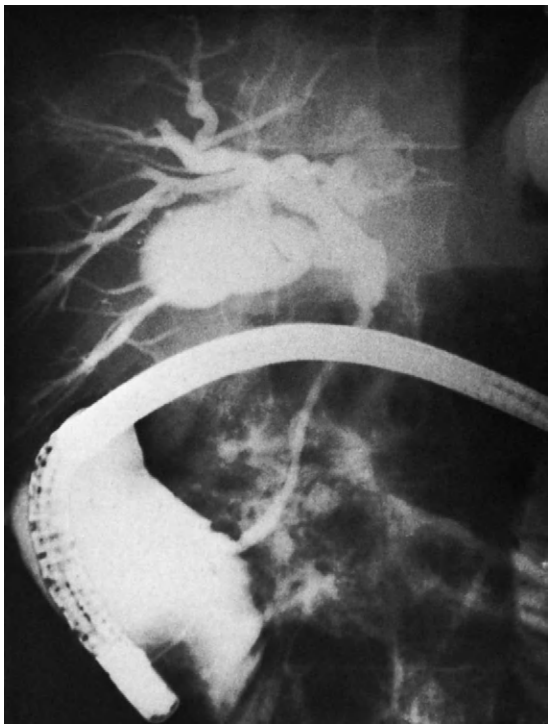

FIGURE 42A.31. Retrograde cholangiography in a patient with biliary stricture related to pancreatitis. Note the long stricture in the common bile duct as it passes through the head of a calcified pancreas. The stricture is a result of pancreatitis from alcohol ingestion, and the patient's symptoms were of intermittent attacks of jaundice and pain. The pancreatic duct could not be delineated; management included laparotomy and choledochojejunostomy.

have been described (Sarles & Sahel, 1978; Barthet et al, 1994). Although more common in association with alcohol-related chronic pancreatitis, it may occur in chronic pancreatitis unrelated to alcohol use. In addition to jaundice, pain is common, which may be intermittent and similar to biliary colic; cholangitis and fever are less frequent (Stabile et al, 1987; Kalvaria et al, 1989; Barthet et al, 1994).

The diagnosis of bile duct stricture usually is made by MRCP. The radiologic appearance is typically a long stenosis of the retropancreatic portion of the CBD. The fibrotic process also may affect the proximal duct gradually over a prolonged period so that it is relatively nondistensible, and the proximal duct may exhibit little dilation, as one would expect from a stricture from other causes. Occasionally, the stenosis is shorter in length, however, or it may involve only the immediate papillary area. Contrast medium usually, but not always, traverses the stenosis and flows into the duodenum. Differentiating a stricture related to pancreatitis from malignant obstruction may be difficult. Although the long, tapering, narrow stricture of the bile duct is characteristic of chronic pancreatitis, especially when associated with demonstrable pancreatic ductal abnormality on ERCP, carcinoma still may be present, and one must use extreme caution to avoid an erroneous diagnosis.

The presence of a bile duct stenosis or stricture in association with chronic pancreatitis is not an indication for therapy. Quite severe stenosis may be found in the presence of absolutely normal LFTs and in patients who have never had jaundice. If cholestasis or cholangitis occurs, however, biliary bypass becomes necessary. Occasionally, operation is necessary in the management of chronic pancreatitis, and if it is known that a high-grade biliary stricture is present, biliary bypass may be performed concomitantly. In a series of 240 patients with chronic pancreatitis, 39 of whom came to operation, nine had symptomatic biliary obstruction, and 13 were subjected to some form of biliary-enteric anastomosis, either alone or associated with excisional surgery for pancreatic disease. Most patients with CBD stenosis associated with chronic pancreatitis can be managed without biliary bypass (Kalvaria et al, 1989; Smits et al, 1996). Temporary endoscopic biliary stenting may be useful in some cases and may be definitive therapy in 10% to 25% (Barthet et al, 1994; Itani & Taylor, 1995; Smits et al, 1996).

For patients requiring biliary bypass, side-to-side choledochoduodenostomy may be used, but this is often not the best option, because the surrounding inflammatory reaction may render the duodenum rigid and less mobile. Also, the CBD may be involved in periductal fibrosis and may be only minimally dilated. Roux-en-Y choledochojejunostomy is the preferred reconstructive approach. Cholecystojejunostomy should not be used, and transduodenal sphincteroplasty is generally not suitable because of the great length of the stricture. Biliary-enteric anastomosis generally affords excellent long-term relief of obstruction, but relief from chronic pain associated with the pancreatitis itself is unusual (Barthet et al, 1994; Stabile et al, 1987).

PART 5: Biliary Tract Disease

SECTION I: Inflammatory, Infective, and Congenital

C. Biliary Infection and Infestation

CHAPTER 43

Cholangitis

Cherif Boutros and N. Joseph Espat

OVERVIEW

Cholangitis, or bile duct inflammation, is generally associated with infection in the presence of biliary obstruction. It should be considered a clinical emergency that requires urgent multidisciplinary care comprising intravenous (IV) fluids, broad-spectrum parenteral antibiotics, and, most importantly, biliary decompression. The most common cause for cholangitis, as we have defined it, is choledocholithiasis and pathologies that similarly result in the obstruction of the biliary tree. For "true" cholangitis to develop, obstruction of bile flow contaminated by bacteria or fungi is necessary. As such, in the absence of both of these conditions, cholangitis is uncommon.

Approximately 80% of patients with cholangitis will clinically improve with IV fluids and antibiotics; however, definitive biliary decompression is still likely necessary. Patients who fail to improve or those who deteriorate within 12 hours of instituting medical therapy should undergo emergent biliary decompression by either endoscopic or percutaneous drainage procedures. The specific procedure selected for decompression should be based upon the type and suspected location of the obstruction. In general terms, a low biliary obstruction is best decompressed endoscopically, but obstruction proximal to the bifurcation or from biliary-enteric anastomoses should be decompressed percutaneously.

Procedures to achieve a goal beyond decompression—such as papillotomy, balloon stricture dilation, or biliary tract debris clearance—should be avoided in the setting of recent or present sepsis. Emergent operative exploration and decompression of the bile duct is rarely indicated and is associated with high mortality. Operative biliary decompression should be reserved only for those patients who fail nonoperative decompression. The extent of operative biliary decompression should, in most cases, be limited to T-tube type decompression of the common bile duct (CBD) with deferred definitive management of the biliary obstruction, until the sepsis has resolved, and the patient's condition has improved. Continuation of antibiotic therapy should be guided by the persistence of residual biliary obstruction because of the increased risk of recurrent cholangitis.

CHOLANGITIS

Cholangitis is not a single disease with a well-defined clinical appearance but rather a spectrum of disease that presents variably with a wide range of severity. The appearance and course of cholangitis ranges from mild, intermittent, and recurrent episodes of abdominal pain, jaundice, fever, and chills as described by Charcot in 1877 to a rapidly progressive systemic illness that results in shock, coma, and death as described by Reynolds and Dargan (1959).

The development of cholangitis requires the presence of three factors: 1) obstruction of bile flow, 2) colonization of the bile with bacteria (bactobilia) or fungi, and 3) elevation of intraductal biliary pressure. The most common causes of biliary obstruction associated with cholangitis are calculi, benign and malignant strictures, obstructed stents, and parasites (Table 43.1; see Chapters 7 and 11). The management of cholangitis should follow three principles: 1) vigorous resuscitation and hemodynamic support, 2) broad-spectrum parenteral antibiotics, and 3) relief of biliary obstruction (decompression). Figure 43.1 provides a suggested management algorithm for patients with cholangitis.

All patients being treated for cholangitis should be aggressively resuscitated, administered appropriate IV antibiotics, and closely monitored. Most patients (85%) will clinically improve over the ensuing 12 to 24 hours, after which time semielective imaging of the biliary tree by ultrasound (US), computed tomography (CT), and/or magnetic resonance cholangiography (MRC) is indicated to diagnose the location and cause of the underlying biliary obstruction. However, it cannot be overstated that the definitive treatment for cholangitis is biliary decompression.

Table 43.1

Causes of Cholangitis

1. Biliary stones
   - a. Choledocholithiasis
   - b. Hepatolithiasis
   - c. Mirizzi syndrome
2. Benign biliary strictures
   - a. Biliary surgery
   - b. Chronic pancreatitis
   - c. Primary sclerosing cholangitis
   - d. Orthotopic liver transplantation
   - e. Cholangiography in patients with AIDS
3. Malignant biliary obstruction
   - a. Pancreas
   - b. Bile duct/gallbladder
   - c. Ampulla
   - d. Duodenum
4. Nonsurgical biliary interventions
   - a. ERCP
   - b. PTC
   - c. Biliary stents
5. Parasitic infection
6. Miscellaneous

AIDS, acquired immunodeficiency syndrome; ERCP, endoscopic retrograde cholangiopancreatography; PTC, percutaneous transhepatic cholangiography

Modified from Bornman PC, et al, 2003: Management of cholangitis. Hepatobiliary Pancreat Surg 10:406-414.

Pharmacologic Treatment for Cholangitis

The pharmacologic treatment of cholangitis differs from that of acute cholecystitis in the need for more specific and broader antimicrobial therapy dictated by the patient's underlying pathology and clinical condition. Culture-identified bacteriology of the biliary tree has changed over the past 40 years. Previously, the gram-negative aerobes *Escherichia coli* and *Klebsiella,* gram-positive aerobes, and enterococci were the most common isolates identified from patients with cholangitis (Helton, 1987). More recently, infections have been polymicrobial in 30% to 80% of cases (Westphal & Brogard, 1999). In some studies, anaerobes have been detected in more than 15% of patients but rarely as the sole isolate. *Bacteroides* and *Clostridium* species are the most frequently cultured anaerobes, and anaerobic bacteria are commonly isolated from biliary tract specimens from patients who have a history of biliary surgery, especially those with a biliary-enteric anastomosis or chronic biliary tract infection and the elderly. Cholangitis arising from anaerobic organisms is reported to be associated with a more severe clinical illness compared with purely aerobic infections (Csendes et al, 1996; see Chapter 11).

Bacteremia in acute cholangitis has been demonstrated to be the result of increased bile duct pressure that favors the reflux of bacteria into the blood and lymphatic circulation (Csendes et al, 1995); it has been reported in 21% to 71% of patients with cholangitis (Cotton et al, 1991; Csendes et al, 1996; see Chapter 7). The organisms isolated reflect a similar distribution to that of biliary cultures, except for anaerobes and enterococci, which are infrequently found in blood cultures.

A variety of antibiotic regimens and combinations have been compared in prospective randomized clinical trials to establish efficacy, safety, and toxicity profiles. Monotherapy with broad-spectrum agents, such as a third- and fourth-generation cephalosporins (cefotaxime, cefipime), and a ureidopenicillin (mezlocillin, piperacillin) combined with a β-lactamase inhibitor (ticarcillin-clavulanate, piperacillin-tazobactam) or quinolone (ciprofloxacin) have been reported to be as effective in treating patients with cholangitis as metronidazole or clindamycin in combination with an aminoglycoside or a third-generation cephalosporin and ampicillin (Sung et al, 1995; Thompson et al, 1993).

In a multicenter comparative study of cefepime versus broad-spectrum antibacterial therapy in moderate and severe bacterial infections (Badaro et al, 2002), cefepime was demonstrated to achieve a higher cure rate compared with broad-spectrum combination therapy as an initial empiric treatment for hospitalized patients with moderate to severe community-acquired infections.

Carbapenems, ureidopenicillins, and fluoroquinolones offer good coverage for gram-negative aerobes (Mazuski et al, 2002), but piperacillin offers the advantage of gram-positive coverage, including enterococci, as well as anaerobic coverage (Thompson et al, 1990). Tazobactam, a β-lactamase inhibitor, extends the spectrum to cover organisms that have acquired resistance. These regimens are sufficient for most patients presenting with de novo cholangitis who have not yet been hospitalized, operated upon, or instrumented (Table 43.2). Again, it is emphasized that although hydration and antibiotics may improve the clinical condition in up to 80% of patients with acute cholangitis, 20% with clinical sepsis will require urgent biliary decompression.

For patients with a previously instrumented biliary tract (endoscopic retrograde cholangiopancreatography [ERCP], placement of a biliary stent), a previous biliary operation, or prolonged hospitalization, the cholangitis is likely to be associated with resistant flora such as *Pseudomonas* or *Serratia* species. Liver transplant patients who develop cholangitis have been observed to have *Candida* and/or *Enterococcus* in the biliary tree. Interestingly, vancomycin-resistant enterococci (VRE) are common in liver transplant patients (Schlitt et al, 1999). When *Candida* and/or *Enterococcus* are cultured, these should be treated with amphotericin and one of the streptogramins (quinupristin/dalfopristin [Synercid] or oxazolidinone linezolid [Zyvox], respectively). For all hospitalized patients, antibiotic coverage should always take into consideration the local resistance patterns ("antibiotic-gram") of specific pathogens.

Duration of Antibiotic Therapy for Cholangitis

No randomized clinical trials have firmly established the duration of antibiotic therapy for the treatment of cholangitis. However, general guidelines are for antibiotic therapy to continue until biliary obstruction is completely relieved, biochemical liver function tests have improved or normalized, and the patient is afebrile for at least 48 hours. After successful biliary drainage by ERCP, a retrospective study comparing short-duration antibiotic therapy (3 days) with longer antibiotic coverage showed that 3 days of antibiotic therapy appears sufficient when adequate drainage has been achieved and fever is abating (van Lent et al, 2002).

Patients at risk for recurrent cholangitis, such as those with residual calculi or incompletely relieved obstruction

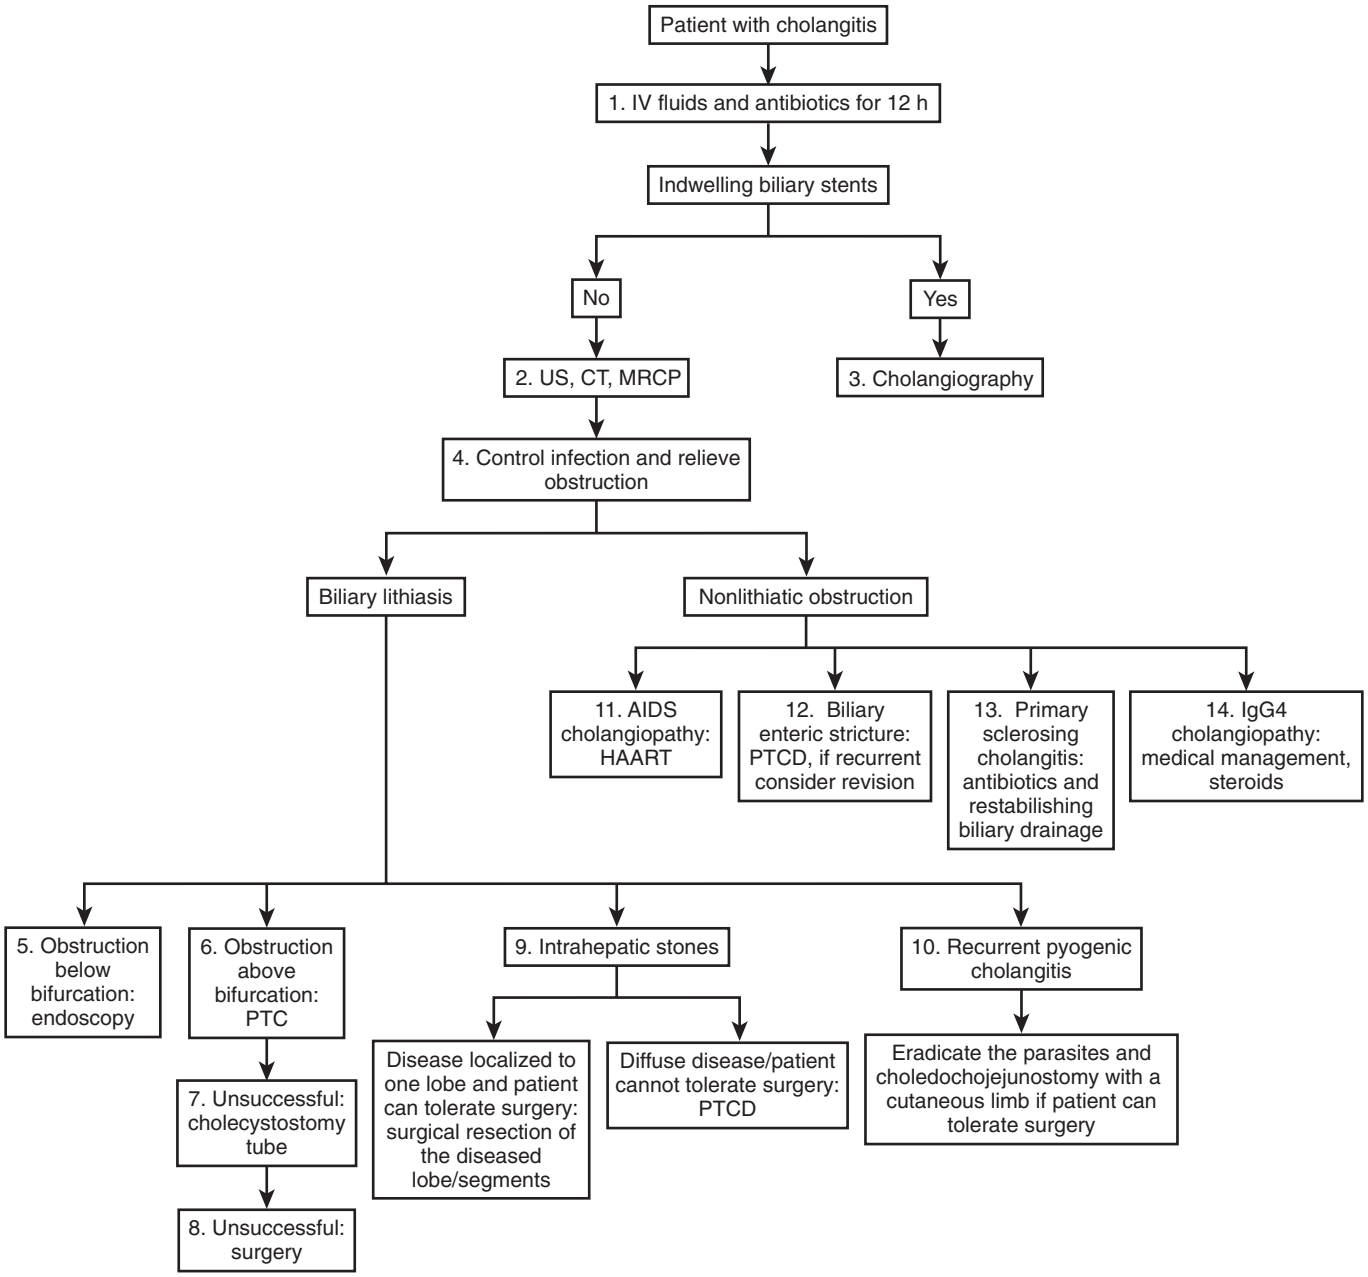

FIGURE 43.1. Suggested algorithm for management and interventions in the treatment of cholangitis. AIDS, acquired immunodeficiency syndrome; CT, computed tomography; HAART, highly active antiretroviral therapy; IgG4, immunoglobulin G4; IV, intravenous; MRCP, magnetic resonance cholangiopancreatography; PTC, percutaneous transhepatic cholangiography; PTCD, percutaneous transhepatic cholangiography and drainage; US, ultrasound.

Pharmacologic Parameters Relevant to Antibiotic Therapy or Prophylaxis of Biliary Sepsis

					CLINICAL RELEVANCE OF THE PARAMETERS FOR		
	THERAPEUTIC CLASS						
PARAMETER	Aminoglycosides	Quinolones	Penicillins	Cephalosporins	Treatment of Acute Infections	Prophylaxis	Maintenance Therapy
Oral bioavailability	No	++	+/++	+/++	No	Yes	Yes
Distribution in tissues	+	+++	++	++	Yes	Yes	More or less
Ratio of concentration to MIC for *Escherichia coli*							
In blood	+++	+++	++	+++	Yes	Yes	More or less
In bile	+	+++	++*	+/+++†	Yes	No	Yes

*Ureidopenicillins

†Anionic cephalosporins with molecular weight >500 (e.g., cefpiramide, cefoperazone, ceftriaxone, cefotetan, cefixime)

MIC, minimum inhibitory concentration

From Westphal JF, Brogard JM, 1999: Biliary tract infections: a guide to drug treatment. Drugs 57(1):81-91.

from any cause, should remain on oral antibiotics until the biliary obstruction is completely relieved. Acceptable oral antibiotics for these types of patients include trimethoprim/sulfamethoxazole and levofloxacin or ciprofloxacin alone or in combination with metronidazole.

Diagnostic Imaging Studies

Various noninvasive modalities are available to image the biliary tree and gallbladder: transabdominal ultrasonography (TUS), radionuclide imaging (e.g., hepatoiminodiacetic acid [HIDA]), CT, MRC, and CT cholangiography.

Transabdominal Ultrasound

TUS (see Chapter 13) is the least expensive and most universally available imaging modality to evaluate the biliary tree and gallbladder. As such, it is the preferred first diagnostic test when evaluating a patient with acute cholecystitis and/or cholangitis. US can reliably demonstrate intrahepatic and extrahepatic biliary dilation, but this can be absent in the case of an acute obstruction. In the presence of gallstones less than 10 mm in size and dilation of the CBD greater than 10 mm, CBD obstruction by gallstones is likely (Abboud et al, 1996). The sensitivity of US to detect CBD stones varies between 20% and 75%, with increased sensitivity in the case of multiple large stones within a dilatated CBD and less sensitivity in the case of stone impaction in the retropancreatic segment of the CBD.

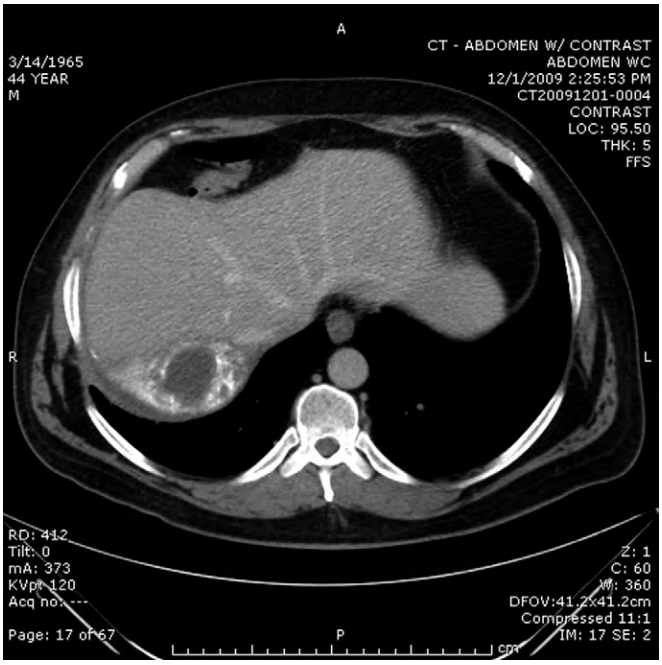

FIGURE 43.2. Abdominal computed tomographic scan demonstrating a hepatic abscess involving the right hepatic lobe with surrounding inflammatory changes.

Computed Tomography

Non–contrast-enhanced CT scan (see Chapter 16) overcomes the technical limitations of US, as it can detect impacted stones in the retropancreatic CBD segment; when performed with 2- to 3-mm slices, its sensitivity for detecting small stones is reported to range between 65% and 80% (Neitlich et al, 1997). However, because up to 25% of gallstones will have the same density as bile, the sensitivity of noncontrast CT does not exceed 80%.

In the case of cholangitis, intravenous (IV) contrast–enhanced CT scan can reveal inflammation and demonstrate thickness of the bile ducts. The arterial phase should reveal peripheral or periductal hypervascularization (Arai et al, 2003). Another important role for CT is to detect the complications of cholangitis, such as hepatic abscess (Fig. 43.2) and pylephlebitis (suppurative thrombosis of the portal vein). Finally, CT can reveal etiologies of biliary obstruction, other than a CBD stone, such as a tumoral mass; however, contrast material is associated with a risk of hypersensitivity or induced renal toxicity, particularly in underresuscitated patients or in the presence of hemodynamic instability.

Magnetic Resonance Cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP; see Chapter 17) provides imaging in a noninvasive manner that allows visualization by emphasizing the hyperintensity of stationary liquids, thus the use of this modality precludes the need for contrast injection to fully visualize the biliary system. Images obtained by MRCP are similar to those obtained by cholangiogram: stones appear as hypointense defects (lacking liquid) within the biliary system. However, MRCP cannot differentiate stones from air bubbles, sludge, or blood clots—all these lack liquid. A further limitation of MRCP is that it cannot detect stones less than 3 mm in size, nor can it detect impacted stones in the ampulla, which require evaluation of T1 images before and after gadolinium injection. The overall sensitivity of MRCP to detect CBD stones is 80% to 100%, and its specificity is excellent, varying between 90% and 100% (Hakansson et al, 2002; Kondo et al, 2001; Soto et al, 2000). It is important to recall that MRCP is purely a diagnostic modality, it is not therapeutic.

Endoscopic Ultrasound

Endoscopic ultrasound (EUS; see Chapter 14) is an invasive procedure that requires sedation or general anesthesia. Once it has been passed through the stomach and into the duodenum, the US probe is in close relationship to the CBD; by using a high US frequency (7.5 to 12 MHz), the resolution of EUS is exceptional (<1 mm), making it the gold standard in the detection of small gallstones or other obstructive etiologies. The major limitations of EUS are that it cannot be performed in patients with altered anatomy, such as those with a prior distal gastrectomy or gastric bypass, or in the presence of a significantly calcified pancreas or hilar biliary pathology.

Direct Cholangiography

Although historically considered the reference radiologic modality, direct cholangiography (see Chapter 18) for purely diagnostic purposes has been supplanted by less invasive cross-sectional imaging alternatives, which also provide additional anatomic detail related to adjacent organs to allow a more complete assessment. Retrograde or percutaneous cholangiography is largely limited to the first step of a therapeutic procedure (Gallix et al, 2006).

In addition to its inferior image quality, there are various complications associated with the use of direct

cholangiography, including biliary infection, pancreatitis, and hemorrhage (Vidal et al, 2004).

MANAGEMENT OF CHOLANGITIS

Extrahepatic Biliary Stone Obstruction: Procedures for Biliary Decompression

When performed in a timely manner, biliary decompression and successful drainage are the cornerstones of acute cholangitis treatment. Several techniques can be used to ensure effective biliary drainage. A review of these techniques with the Tokyo guidelines was recently published (Tsuyuguchi et al, 2007).

The preferred method and route to relieve biliary obstruction, and the ultimate success of biliary drainage, depends upon a number of factors that include availability of the technique (endoscopic, percutaneous, or operative), local expertise, etiology, location and severity of obstruction, and the presence of comorbid medical conditions. Patients who do not respond to initial medical treatment within 12 to 24 hours should undergo emergent, nonoperative decompression of the biliary tract. When the obstruction is believed to be below the bile duct bifurcation, the preferred initial approach is endoscopic (Kumar et al, 2004).

Endoscopic Biliary Decompression (See Chapters 27 and 36)

ERCP and biliary decompression should be performed only after patients have been resuscitated and given systemic antibiotics, although an exception can be made for patients who do not respond to initial medical therapy or those who clinically deteriorate within 12 hours of beginning treatment. If the patient has mild to moderate cholangitis and is stable, an effort can be made to definitively clear the duct of calculi. However, if the patient is septic with hemodynamic instability, or if there is purulence within the duct, efforts to clear the duct completely should be deferred to another time, when the patient is more stable, and sepsis has resolved.

The procedure should be carried out in a monitored setting (endoscopy lab, intensive care unit, or operating theater) under either conscious sedation or general anesthesia. A side-viewing scope is used to visualize and cannulate the ampulla of Vater. Contrast is injected into the CBD under real-time fluoroscopy only in an amount that allows the level of the obstruction to be visualized, and a guidewire is passed across the obstruction. In acutely ill or septic patients, biliary decompression should be obtained with the least amount of manipulation and effort, and extended maneuvers to remove calculi or perform sphincterotomy should be avoided. A convenient method of decompression is with external nasobiliary drainage (ENBD), a drainage procedure done by placing a 5- to 7-Fr tube using a guidewire technique. ENBD has the advantage of being an effective drainage tool, without the need of a sphincterotomy, and it provides access for biliary cultures.

Another biliary drainage modality is internal drainage using a 7- to 10-Fr plastic stent in the bile duct, using a guidewire after selective cannulation of the bile duct. Two stent shapes are available: a *straight type* with flaps on both sides and a *pigtail type* to prevent dislocation. Advantages of this approach include minimal or absent discomfort and limited electrolyte or fluid shifts relative to transnasal biliary drainage. Disadvantages include the potential for stent clogging or loss of patency, risk of dislodgement, and the technical disadvantage for a sphincterotomy when a stent larger than 7 Fr is inserted.

In cases of difficult biliary cannulation, an endoscopic sphincterotomy (EST) may be performed. A common EST technique is to perform a high-frequency electric surgical incision of the duodenal papilla, using a sphincterotome selectively inserted into the bile duct. In contrast to EST for stone removal, when performed for drainage, only a limited incision is necessary. Bleeding, retroduodenal perforation, and pancreatitis are the most common complications after ERCP and sphincterotomy. Morbidity and mortality rates are much higher with sphincterotomy than with nasobiliary catheter drainage when patients are critically ill (Boender et al, 1995; Chawla et al, 1994; Leese et al, 1986). Complications commonly reported with EST are hemorrhage (2% to 3%) and pancreatitis (1.9% to 5.4%), and mortality rate is 0.4% to 1.3% (Cotton et al, 1991; Freeman et al, 1996).

Contraindications

Sphincterotomy is contraindicated in the presence of coagulopathy, systemic sepsis, and hemodynamic instability, with the exception of those patients who have clinically deteriorated after initial medical therapy.

As stated, emergent sphincterotomy to decompress the bile duct should be avoided in septic patients, and especially in elderly patients, because of potentially high mortality rates (18.8%). In the elderly, endoscopic drainage alone has been observed to result in lower morbidity (16.7%) and mortality (5.6%) rates than surgical (87.5% and 25.0%, respectively) or percutaneous drainage (36.4% and 9.1%, respectively) (Boender et al, 1995; Sugiyama & Atomi, 1997). It is important to emphasize that once control of sepsis has been achieved, sphincterotomy and more optimal biliary imaging can be obtained, thus defining the underlying obstruction and enabling definitive treatment for either a stone, tumor, or stricture (Lee et al, 2002).

Percutaneous Transhepatic Cholangiography and Drainage (See Chapters 28, 32, and 36)

Retrospective analyses and prospective randomized trials have shown that urgent endoscopic drainage is an effective treatment for suppurative cholangitis and results in a better clinical outcome than surgical drainage (Hui et al, 2002); however, in an unstable patient, ERCP should not be performed; percutaneous transhepatic decompression is a better alternative, despite the limitation of not treating the cause of the obstruction (Gould et al, 1985; Kadir et al, 1982).

Percutaneous transhepatic cholangiography and drainage (PTCD) is especially valuable in the presence of a hilar obstruction (Nomura et al, 1997), having been reported to be useful in cases of malignant biliary obstruction, particularly when used in combination with definitive decompressive adjuncts, such as expandable metallic stents. In a series of 233 patients with malignant biliary obstruction requiring biliary drainage, with decompression achieved by PTCD and placement of metallic stents and/or plastic tubes, improvement in survival was reported after either chemotherapy, radiotherapy, or brachytherapy at 1, 3, 6, and 12 months of 97.96%, 95.92%, 89.80%, and 32.59%, respectively. Most notable was the observation that the patency rates for biliary stents at 1, 3, 6, and 12 months were 97.96%, 93.86%, 80.93%, and 56.52%, respectively.

These results strongly suggest that for patients with malignant biliary obstruction, biliary decompression with PTCD, using internalized stents for biliary patency, approaches the duration of patient survival (Qian et al, 2006).

Standard Procedure

Deciding which side of the liver to drain initially depends on the underlying pathology and the location of the obstruction within the biliary tree. Therefore, US and/or CT of the liver should be obtained to assess anatomy, liver lobe atrophy, distribution of dilated intrahepatic ducts, and to identify the likely cause and location of the obstruction. When the left hemiliver is punctured, it is preferable to enter into the segment III or IV bile duct through the left lateral segment or the umbilical fissure. When the right hemiliver is punctured, an intercostal approach is often used, preferably aimed toward the main segment VI duct. A Chiba needle is used under real-time fluoroscopy, and contrast is slowly injected, until a biliary division is entered. It is important to remember not to inject contrast under pressure into the biliary tree to avoid cholangiovenous reflux of bacteria and endotoxin. Once the biliary tree is accessed, a guidewire is placed, passed, and advanced distally to traverse the point of obstruction. If the point of obstruction cannot be traversed, a locking pigtail catheter is placed to decompress the biliary system proximal to the point of obstruction. In the septic or unstable patient, it is not recommended to attempt complete clearance of the biliary tree—the goal is decompression.

Although no studies directly compare percutaneous to endoscopic drainage in the setting of acute cholangitis, PTCD should applied to those patients who are not candidates for, or who have failed, endoscopic drainage. PTCD is potentially more morbid, with known complications that include intraperitoneal hemorrhage (2.5%) and biliary peritonitis (1.2%) with a mortality rate as high as 1.7%. In patients with proximal biliary obstruction, percutaneous drainage is clearly preferred, especially in an ill patient (Paik et al, 2009).

Complications from PTCD can be severe and may require additional procedures. The most frequently encountered complications are catheter dislodgement, hemobilia, catheter obstruction, cholangitis, hemoperitoneum, and choleperitoneum (Gazzaniga et al, 1991). The spillage of infected bile into the subdiaphragmatic and perihepatic space may lead to peritonitis and prolonged fever and may eventually require operative drainage.

Mortality rates are substantial after unsuccessful endoscopic drainage of cholangitis from hilar obstruction (Ducreux et al, 1992). Hence, rather than endoscopic drainage, PTCD is indicated for such lesions. If PTCD is unsuccessful or unavailable, the patient should undergo emergent percutaneous cholecystostomy tube decompression, if the cystic duct is patent, and the obstruction is below the cystic duct–CBD union. Because of its high mortality rate (>30%), emergency laparotomy and CBD decompression via a T-tube should only be used as a last resort, when nonoperative modalities are unavailable or unsuccessful (Lai et al, 1992).

Contraindications

PTCD should not be performed in the hemodynamically unstable or otherwise seriously ill septic patient, except in those who have clinically deteriorated after initial aggressive medical therapy. PTCD should be used only if endoscopic drainage fails for lower bile duct obstruction, and it should not be used as the primary means of decompression in the patient with ascites.

Open Common Bile Duct Exploration (See Chapters 29 and 35)

Patients with acute cholangitis are preferentially treated with noninvasive drainage procedures, such as endoscopic drainage or PTCD; only the minority should be candidates for open surgical drainage. However, open drainage may be indicated for patients who cannot undergo such noninvasive drainage procedures, most commonly for anatomic reasons that may include a prior Roux-en-Y choledochojejunostomy or gastric bypass procedure. In open drainage, the goal is to decompress the biliary system as quickly and effectively as possible. Simple procedures such as T-tube placement without choledocholithotomy are recommended, because prolonged operations should be avoided.

During open CBD exploration, exposure should be obtained along the free border of the lesser omentum, above the duodenum. When dense adhesions are encountered, or the anatomy is unclear, aspiration with a fine needle facilitates the localization of the CBD. Once identified, an anterior vertical incision is made parallel to the long axis of the duct on the distal CBD, with stay sutures placed on either side. It is important to emphasize that a vertical, rather than horizontal, incision should be performed; a horizontal incision is limited in extension, yields a stenotic area when closed, and may interrupt the axial arterial blood supply of the CBD, which courses along the 3 o'clock and 9 o'clock positions along the lateral aspects of the bile duct. A T-tube should be placed in the CBD above the level of the obstruction to externally decompress the biliary system and enable bile duct closure. The benefits of T-tube placement and decompression are maintenance of biliary ductal patency in the setting of edema and allowance of subsequent access to the biliary tract. Usually, the T-tube is kept in place for 4 to 6 weeks and is removed after a normal cholangiogram (Verbesey & Birkett, 2008).

Intrahepatic Biliary Stone Obstruction (See Chapters 39 and 44)

Patients with complex hepatolithiasis represent a difficult problem, as intrahepatic stones are more difficult to access and remove endoscopically and are often associated with intrahepatic biliary strictures. The resulting cholangitis is characterized by high treatment failure and high recurrence rate. In the past, surgical management consisting of hepatic resection and/or hepaticojejunostomy was the only option for patients with complex hepatolithiasis, with the goal of preventing recurrent cholangitis. Currently, a nonsurgical approach consisting of PTCD followed by cholangioscopy, biliary stricture balloon angioplasty, and lithotripsy is preferred to avoid the morbidity and mortality associated with surgical treatment, especially in debilitated elderly patients with significant comorbidities (Chiang et al, 1994). For patients whose intrahepatic stones have been successfully removed, compared with those whose removal failed, the recurrence of cholangitis is delayed (Cheung, 1997; Yeh et al, 1995).

When the percutaneous approach is unsuccessful, and the patient can tolerate a major operation, hepatic resection should

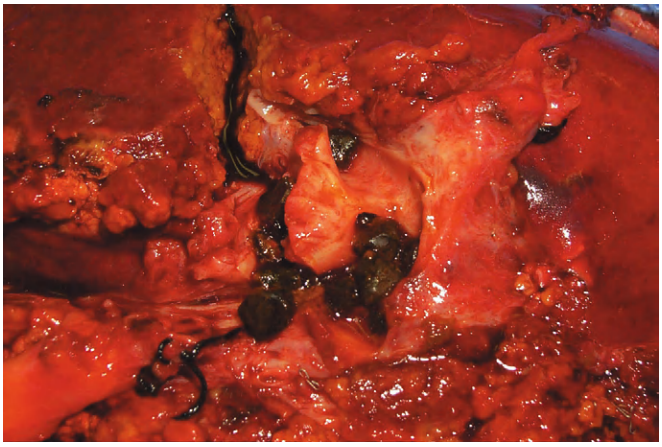

FIGURE 43.3. Intraoperative picture of intrahepatic biliary stones with strictures and microabscesses.

still be offered (Yeh et al, 1995). In a selected group of patients with disease localized to one lobe or a few segments, hepatic resection removes the stones and the associated pathologic changes, including ductal stricture, fibrosis, and microabscess (Fig. 43.3). In a series of 174 patients with intrahepatic stones treated with liver resection or percutaneous choledochoscopy (Cheung & Kwok, 2005), the overall success rate in the surgical group was 98.0%, and the 5-year cholangitis recurrence rate was 13.3%. For the percutaneous choledochoscopic–treated group, the overall success rate was 70.5%, and the 5-year cholangitis recurrence rate was 43.2% and 26.4% for those with and without stricture, respectively. Bilateral stones, the presence of stricture, and the presence of hepatic parenchymal atrophy were demonstrated to be significant risk factors for a poor long-term outcome after stone removal alone.

It is generally acceptable to offer liver resection to patients with associated atrophy of the involved segments, mostly those in whom the left lobe was involved, because of the reduced operative risk. Resection of nonatrophic stone-bearing segments is more controversial. In patients with biliary stricture, liver resection can reduce the reported high rate of restenosis; regardless of whether dilation of the stricture was successful, the associated rate of recurrent cholangitis has been reported to be upward of 35% (Jan & Chen, 1995). In patients without stricture yet with numerous stones, resection may be considered to eliminate the risk of future cholangiocarcinoma, which is reported in 5% to 16% of patients (Chen et al, 1993; Chijiiwa et al, 1993; Liu et al, 1998).

Two additional nonsurgical approaches for the treatment of intrahepatic stones are discussed, namely, the transhepatic percutaneous intracorporeal electrohydraulic shock-wave lithotripsy (ICSWL) and yttrium-aluminum-garnet (YAG) laser lithotripsy. In ICSWL, PTCD is placed, and the infection is allowed to resolve. At separate settings, the PTCD catheter is exchanged for larger biliary catheters to enable the formation of a well-formed tract. Once the tract is a sufficient size (at least 14 Fr), downstream stones can be crushed with mechanical lithotriptors or contact shock-wave lithotripsy under direct endoscopic visualization. When stone debris is removed, distal strictures can be traversed with an angioplasty balloon catheter and dilated. As such, multiple treatment sessions are required to successfully and safely clear the duct to avoid sepsis (Bonnel et al, 1991).

Although an important procedure in the armamentarium, fragmentation with ICSWL requires additional therapies for removal of stone fragments in 50% of patients (Bland et al, 1989). It requires general anesthesia or regional blocks that may be avoided with percutaneous techniques. The most obvious advantage is avoidance of the percutaneous biliary catheter, which gives some patients discomfort. When combined with endoscopic removal, ICSWL can achieve stone clearance for 94% to 96% of patients (Harz et al, 1991; White et al, 1998).

A more recent nonsurgical approach involves laser application. This technique consists of percutaneous access to the biliary tree with percutaneous holmium: YAG laser lithotripsy ablation of bile duct stones (Hazey et al, 2007). Depending on the location of the stones and anatomic considerations, the left, right, or both systems may be accessed via percutaneous transhepatic cholangiography (PTC) techniques. The catheter is upsized to 12- or 14-Fr over several weeks to allow for passage of a videocholedochoscope. Passage of an endoscope and direct visualization of the calculi is all that is required to pass energy via the laser and fragment the stones. Once the stones are fragmented, the debris is flushed out the access catheter, or it may pass through the sphincter of Oddi into the duodenum. Frequently, the sphincter has been rendered incompetent by a previous endoscopic sphincterotomy.

The medical literature is replete with studies outlining percutaneous access and removal of primary hepatolithiasis using YAG laser therapy in Asian patients, with clearance rates of 76.8% to 100% (Chen et al, 2005; Cheung et al, 2003; Shamamian & Grasso, 2004). Primary intrahepatic stones have frequently required more treatments (average, 3.9) than secondary intrahepatic calculi (average, 2.6) (Shamamian & Grasso, 2004). The clearance rates diminished significantly for patients with intrahepatic strictures: 58% in the presence of stricture versus 100% in cases with no stricture (Huang et al, 2003). Similarly, presence of stricture is associated with a high recurrence rate of 51.6% (Jan & Chen, 1995) to 63.2% (Huang et al, 2003).

In the Western literature, fewer YAG laser applications for hepatolithiasis are reported. In a relatively small series, Hazey and others (2007) reported that all patients (n = 13) undergoing percutaneous holmium:YAG laser lithotripsy and ablation of their biliary calculi were successfully treated; the average number of treatments required for stone clearance was 1.6 (range, 1 to 3), no patients required more than three treatments, and 3 of the 13 patients were treated solely as outpatients.

Recurrent Pyogenic Cholangitis (See Chapter 44)

Recurrent pyogenic cholangitis (RPC), previously called *oriental cholangiohepatitis,* was first described in 1930 by Digby. This clinical entity is most common among Southeast Asians and is characterized by recurrent episodes of bacterial cholangitis that occur in association with bile duct strictures, segmental biliary dilation with bile stasis, recurrent episodes of obstructive jaundice and ascending cholangitis, pigmented biliary calculi, and biliary cirrhosis.

A possible association between biliary helminthic infection and hepatolithiasis has been suggested (Huang et al, 2005; see Chapter 45). *Ascaris lumbricoides, Clonorchis sinensis, Opisthorchis viverrini, O. felineus,* and *Fasciola hepatica* are pathogens that

often lead to the initial epithelial damage (Abdalian & Heathcote, 2006). *Ascaris lumbricoides,* a round worm, is a common cause of cholangitis in tropical and subtropical countries. Mature adult worms lodged in the biliary system are responsible for a variety of disease processes that include cholangitis, cholecystitis, gallstone formation, and pancreatitis. In the case of cholangitis secondary to *Ascaris* infection, the worms are located in the CBD in 95% of cases, and they can be seen in 86% of cases during endoscopic examination (Sandouk et al, 1997).

The goal of treatment is to eradicate the parasites with mebendazole and eliminate all biliary stones and strictures. As optimal management of stones and strictures will often require multiple treatment sessions, it is usually advised that patients be capable of tolerating a major operation, which may include choledochojejunostomy or hepaticojejunostomy with a biliary access procedure, so that the biliary tree can be readily accessed to clear recurrent stones and to dilate recurrent intrahepatic strictures.

Choledochojejunostomy with a cutaneous limb offers a number of distinct advantages over previous approaches in the management of RPC (see Chapter 29). Following standard cholecystectomy, a portion of the common duct is isolated for choledochoenteric anastomosis. A 60- to 70-cm segment of bowel is used for the Roux-en-Y limb, and a side-to-side choledochojejunostomy is then constructed 10 to 15 cm from the end of the jejunal limb. The blind limb of the jejunal access loop is then brought through the fascia of the abdominal wall in the right upper quadrant at a point that will allow straight access to the biliary tree. Lateral placement of the bowel, just below the skin, will help ensure that the interventional radiologist's hands and instruments are not in the fluoroscopy beam. Although gross stones are removed, no attempt is made at complete clearance of the CBD or hepatic radicles. After closure of the abdomen, the stoma is matured in a "turn-back" fashion. The availability of the cutaneous stoma greatly facilitates subsequent treatment of the residual stones and strictures. After completion of radiologic treatment, the stoma is mobilized, closed, and left buried in the subcutaneous tissues for future access (Gott et al, 1996).

The treatment described above is far less radical with less morbidity and mortality than hepatic resection previously offered to patients with RPC, without sacrificing hepatic parenchyma that can potentially recover subsequent to biliary decompression. At the same time, the bypass provides effective initial biliary drainage of the biliary tree and alleviates any immediate biliary sepsis.

Clearance of residual stones and dilation of strictures is easily accomplished on an outpatient basis. The treatment of recurrent stones or strictures is greatly simplified by access to the cutaneous jejunal limb, and it avoids the need for high-risk reoperative biliary procedures (Gott et al, 1996).

Nonlithiatic Biliary Obstruction

As previously mentioned, biliary stones are responsible of *most* cases of biliary obstruction; other less frequent causes can produce either an extrahepatic obstruction, as in AIDS cholangiopathy or cholangitis as a result of stricture of a biliary enteric anastomosis, or a mixture of hepatic and extrahepatic obstruction, as in the case of primary sclerosing cholangitis (PSC) and immunoglobulin G4 cholangitis.

AIDS Cholangiopathy

First described in 1986 (Margulis et al, 1986), AIDS cholangiopathy occurs in patients with advanced HIV infection. It occurs with acalculous cholecystitis, focal distal biliary stricture at the papilla of Vater, or multifocal biliary strictures similar to what is seen in primary sclerosing cholangitis. These patients are often colonized with cryptosporidia or microsporidia, but it is not clear whether treatment directed at these organisms with albendazole makes any short- or long-term difference in their outcome (Bird et al, 1995).

AIDS cholangiopathy typically occurs in patients with very low CD4 lymphocyte counts (median, 26.5 × 106/L). It is very unusual to see cholangiopathy in patients with CD4 lymphocyte counts greater than 100, because most of the opportunistic infections typical of this disorder occur only in late stages of the disease.

The prognostic factors in patients with AIDS cholangiopathy have been studied by Ko and colleagues (2003). In this retrospective analysis, the authors evaluated 94 patients with AIDS cholangiopathy who were diagnosed at the San Francisco General Hospital between 1983 and 2001. Patient outcome (death) was subsequently correlated with a number of collected variables via multivariable logistic regression. Mean survival was 9 months in those patients with cholangiopathy, with those on highly active antiretroviral therapy (HAART) having a significantly prolonged duration of survival. The presence of opportunistic infections and an elevated alkaline phosphatase level (>1000 U/L) were negative prognostic indicators of survival. Interestingly, endoscopic sphincterotomy, the type of cholangiopathy, and CD4 lymphocyte counts did not correlate with survival.

ERCP in patients with AIDS cholangiopathy is helpful as a diagnostic tool; however, therapeutic ERCP is helpful only in reducing pain, not in extending survival. Additionally, as a result of the advances in HIV management, this disorder is becoming a rarity, and ERCP should only be considered in those patients with very low CD4 lymphocyte counts after other noninvasive diagnostic modalities have been exhausted. The presence of opportunistic infections and a very low CD4 count are markers of advanced disease, and the emphasis should be on the HIV disorder, not on the AIDS cholangiopathy.

The goal of therapy of both is directed toward elevating the CD4 count and decreasing the viral loads, which can only be obtained by HAART. A multidisciplinary approach to this disorder is critical, particularly because the disease rapidly changes, depending on therapy. With the changing modalities of treatment, it is hoped that AIDS cholangiopathy might become a disorder of historical interest only (Enns, 2003).

The overall prognosis of patients with AIDS cholangiopathy is poor, because the disease itself is believed to be a manifestation of advanced HIV. As previously mentioned, the survival of patients is not affected by endoscopic therapy (Cello & Chan, 1995). Survival rates were low, with 1- and 2-year survival as low at 14% to 41% and 8%, respectively, with a mean reported survival of 7 to 12 months (Bouche et al, 1993; Cello & Chan, 1995). For survivors, an association with subsequent cholangiocarcinoma has also been reported (Hocqueloux & Gervais, 2000).

Biliary-Enteric Strictures

Patients with a history of a previous Roux-en-Y hepaticojejunostomy or choledochojejunostomy who are seen with

cholangitis present a complex situation. Initially, a PTCD and balloon dilation of the stricture should be performed, as it is a simple and effective procedure. However, the incidence of long-term restenosis (follow-up period of 5 to 7.5 years) is high—up to 45% (Jan et al, 1994). In the case of recurrent cholangitis after PTCD dilation, every consideration should be given to operative revision of the biliary enteric anastomosis, provided that the patient can safely undergo operation.

Primary Sclerosing Cholangitis

PSC (see Chapter 41) is an idiopathic inflammatory process that affects the biliary tree, resulting in patchy areas of fibrosis and obstruction that are often associated with biliary infection. The diagnosis of PSC is based on selection and exclusion criteria. A persistent twofold or threefold elevation of the alkaline phosphatase level is typical (Gordon, 2008). Protoplasmic-staining antineutrophil cytoplasmic antibodies are present in 80% of cases of PSC, but this finding is not specific (Mulder et al, 1993). The radiologic inclusion criteria include the presence of diffusely distributed strictures of the biliary system seen on cholangiography and characteristic hepatic histology. The histology, classified by Ludwig and colleagues (1981), includes four stages: 1) periportal hepatitis, 2) periportal hepatitis and fibrosis, 3) fibrosis extending beyond the limiting plate, and 4) biliary cirrhosis.

Various diseases are associated with PSC: inflammatory bowel disease (IBD), celiac sprue, sarcoidosis, chronic pancreatitis, rheumatoid arthritis, retroperitoneal fibrosis, thyroiditis, and vasculitis. Patients with PSC also have a substantial predisposition to develop cholangiocarcinoma.

The mainstay of treatment for PSC consists of providing appropriate antibiotic coverage for the bactobilia and reestablishing biliary drainage to the intestinal tree. Long-term antimicrobial prophylaxis is necessary in many patients because of multiple intrahepatic partial biliary strictures; however, no medical therapy is available that can halt the progression of the disease or prevent the development of cholangiocarcinoma. The only effective treatment for advanced PSC is orthotopic liver transplantation (OLT), which in the absence of cholangiocarcinoma has a 5-year survival of up to 89%. Patients with cholangiocarcinoma who undergo OLT have a high risk of recurrence and a dramatically worsened survival if this occurs; therefore the identification of patients with deterioration in liver function sufficient to warrant OLT before they develop cholangiocarcinoma remains a central goal in the management of PSC.

Current management of PSC includes medical therapy with the use of choleretic immunosuppressive and antifibrinogenic agents, surgical management for reconstruction of the biliary tract and colon resection in patients with ulcerative colitis, with liver transplantation reserved for end-stage PSC (Gordon, 2008).

Immunoglobulin G4–Associated Cholangitis

Although the systemic diseases associated with immunoglobulin G4 (IgG4) have been recognized since the 1960s (Sarles et al, 1961), the credit for the first description IgG4 cholangitis belongs to Montefusco and colleagues (1984), who described a series of case reports of patients with combined pancreatic and extrapancreatic disease associated with IgG4. The predominant extrapancreatic feature noted was sclerosing cholangitis with PSC-like features.

In the largest reported cohort to date, which includes 53 patients, Ghazale and colleagues (2008) described the most frequent clinical signs and symptoms at presentation of IgG4 cholangitis: jaundice (77%), weight loss (51%), mild to moderate abdominal pain (26%), steatorrhea (15%), and new-onset diabetes (8%). The diagnostic criteria for IgG4 cholangitis are either having a previous diagnosis of IgG4-related pancreatic/biliary disease or two or more of the following: elevated serum IgG4, other manifestation of a systemic disease, or bile duct biopsy showing more than 10 IgG4-positive cells per high-powered field (HPF) with a documented response after 4 weeks of steroid therapy (Ghazale et al, 2008).

Cholangiographic studies do not reveal pathognomonic findings; they show either a picture of intrahepatic bile duct involvement similar to PSC and/or extrahepatic biliary strictures similar to those found with cholangiocarcinoma and pancreatic cancer. As it is difficult to differentiate IgG4-associated cholangitis from PSC, many studies have investigated the clinical and laboratory findings that correlate with the diagnosis of IgG4. A recent review (Alderlieste et al, 2009) reported significant differences between IgG4 and PSC in the age at onset, occurrence of diabetes mellitus and IBD, salivary gland swelling, and elevated serum IgG4 levels (Table 43.3). Liver or biliary biopsy can help to differentiate IgG4 cholangitis from PSC or pancreatic or biliary cancer. Liver histology in IgG4-associated cholangitis is characterized by lymphoplasmacytic infiltrates within and around bile ducts and obliterative phlebitis and fibrosis leading to sclerosis of the bile ducts. Numbers of IgG4-bearing plasma cells, mainly found in the portal tracts, are significantly higher than in patients with other hepatopathies—including PSC, primary biliary cirrhosis, autoimmune hepatitis, and chronic viral hepatitis—and correlate to serum IgG4 levels, decreasing on

Table 43.3

PSC and IAC: Differences in Clinical Presentation, Immunopathologic Features, and Treatment Response

	PSC	IAC
Age (yr)	25 to 45	65
Male gender	65%	80%
Response to steroids	–	+++
Association with IBD	+++	–
Association with cholangiocarcinoma	+++	?
Other organ involvement	?	+++
Histologic findings	Obliterative cholangitis and cirrhosis	Abundant IgG4-positive plasma cells
Dominant cholangiographic findings	Bandlike strictures with a beaded appearance	Segmental strictures and distal bile duct strictures
Elevated serum IgG4	7% to 9%*	~70%

*As the authors of this table suggest, within their cohort of PSC patients, some of the patients with elevated IgG4 levels may be misdiagnosed IAC patients.

IBD, inflammatory bowel disease; IgG4, immunoglobin G4; IAC, immunoglobulin-associated cholangitis; PSC, primary sclerosing cholangitis

From Alderlieste YA, et al, 2009: Immunoglobulin G4–associated cholangitis: one variant of immunoglobulin G4–related systemic disease. Digestion 79(4):220-228.

corticosteroid treatment (Kamisawa, 2008; Umemura et al, 2007). Endoscopic biopsy specimen of biliary epithelium revealed more than 10 IgG4-positive cells/HPF in 88% of 16 patients with IgG4 cholangitis who underwent biopsy (Ghazale et al, 2008). Accurate diagnosis is of utmost importance to prevent unnecessary surgery and avoid delayed diagnosis of a potentially fatal malignancy.

CHOLANGITIS AND INTRAABDOMINAL HEPATIC ABSCESS

Inadequately managed cholangitis can be complicated by liver, gallbladder, and subphrenic abscesses (see Chapter 66). In general, these abscesses should be treated following standard surgical principles of drainage and broad-spectrum antibiotics, until the fever resolves and liver function tests return to normal (Rintoul et al, 1996).

Untreated pyogenic liver abscesses are almost uniformly fatal. Traditionally, treatment consists of antibiotic administration and drainage of purulent collections. Although this remains the standard approach to the patient with hepatic abscess, some investigators have advocated the use of antibiotics alone in selected patients (Pearce et al, 2003).

Over the past decade, percutaneous aspiration of pyogenic liver abscess without catheter drainage has also gained increased attention. Retrospective series have reported percutaneous aspiration success rate in combination with antibiotic therapy to be in the range of 58% to 88%, which is comparable to the results of catheter drainage (Barakate et al, 1999; Johannsen et al, 2000; Seeto & Rockey, 1996). However, it is important to mention that no randomized trial comparing percutaneous aspiration and catheter drainage of liver abscesses has been performed.

Antibiotics should be started as soon as possible, once the diagnosis of pyogenic liver abscess is suspected. Blood specimens for culture should be obtained before initiating empiric therapy, but delaying therapy until abscess material is obtained is potentially dangerous and ill advised. The suspected origin of infection should be considered when choosing initial antimicrobial therapy, because it will predict the most likely pathogens. Pyogenic liver abscesses that arise in a patient with biliary disease often include enterococci and enteric gram-negative bacilli. Pyogenic liver abscesses from a colonic or pelvic source are more commonly the result of coliforms and anaerobes. Metronidazole should be included in the initial therapy for most cases of pyogenic liver abscess to empirically treat both anaerobes, especially *Bacteroides fragilis* and *Entamoeba histolytica,* while the specific etiology is being evaluated. Once microbiologic data are obtained, antibiotic therapy should be tailored to the organisms isolated and their respective antibiotic susceptibility profiles (Johannsen et al, 2000).

Pyogenic liver abscesses are usually treated initially with parenteral antibiotic therapy for 2 to 3 weeks, and patients subsequently complete a 4- to 6-week course of oral antibiotics (Pitt, 1990). In general, abscesses completely resolve after a full course of therapy. On occasion, a residual cavity persists despite prolonged therapy; if the size of this cavity is stable on serial imaging studies, and the patient is asymptomatic, antibiotics can be stopped and the patient observed closely for the development of recurrent fevers or abdominal pain. In these situations, a follow-up CT scan is recommended 1 to 2 months after cessation of therapy.

SUMMARY

Cholangitis is not a single clinical process but rather a wide spectrum of disease that presents variably with a broad range of severity. In the setting of acute cholangitis, intervention should begin with resuscitation, parenteral antibiotics, and biliary decompression. The imaging and procedural modalities used in the treatment of affected patients requires a thorough understanding of the etiology and should be tailored to the specific causation. It cannot be overemphasized that untreated cholangitis-associated sepsis is almost universally fatal, and the potential for the progression from mild to moderate to severe cholangitis can be rapid and irreversible.

CHAPTER 44

Recurrent pyogenic cholangitis

See Ching Chan, Sheung Tat Fan, and John Wong

OVERVIEW

Recurrent pyogenic cholangitis (RPC) is characterized by repeated bacterial infections of the biliary tract as a result of stones and bile duct strictures (see also Chapters 7, 11, 39, and 43). This condition was first described in Hong Kong by Digby in 1930, and the name *recurrent pyogenic cholangitis* was first coined by Cook in 1954. RPC has many synonyms, including *Oriental cholangiohepatitis* (Stock & Fung, 1962), *Hong Kong disease* (Mage & Morel, 1965), *intrahepatic stones* (Wen & Lee, 1972), *hepatolithiasis* (Nakayama et al, 1980), *primary cholangitis* (Choi et al, 1981), and *Oriental infestational cholangitis* (Seel & Park, 1983). It is prevalent in East Asia (Balasegaram, 1972; Chang & Passaro, 1983; De & Acharya, 2001; Maki et al, 1964; Nakayama et al, 1980; Ong, 1962; Seel & Park, 1983). With ease of travel and increasing migration from Asian countries, RPC is being encountered more frequently in Western countries, particularly in cities where Asian emigrants congregate (Al-Sukhni et al, 2008; Harris et al, 1998; Nguyen et al, 2009). RPC should not be regarded as a curiosity peculiar to Asia but rather as a disease that may affect Asians wherever they live.

RPC affects the young and the elderly of those who were of the lower socioeconomic classes growing up. There is no gender difference in incidence. In the past, RPC was one of the most common surgical emergencies, but the incidence has declined in recent years, particularly in urban centers (Nakayama, 1982). The overall incidence of RPC has decreased in Japan, from 50% of the cases of biliary stones in the pre–World War II years to 20% (Nakayama et al, 1980) despite advances in diagnostic techniques. In Hong Kong today, 12% of biliary stone cases are due to RPC (Fan et al, 1991a).

ETIOLOGY AND PATHOGENESIS

The exact etiology of RPC continues to be elusive and is probably multifactorial. The likely initiating event is the establishment of infection by bowel microorganisms in the small biliary radicles (see Chapter 43). Experimental and clinical studies (Nakayama et al, 1980; Ong, 1962) indicate that the organisms isolated from portal vein blood, common duct bile, and liver biopsy specimens are predominantly of bowel origin (see Chapter 11). Although bowel organisms may reach the liver under ordinary circumstances, clinical infection does not occur except when bowel infection is severe, the organism is of particular virulence, or the host defense in the liver is compromised. In RPC, numerous organisms may enter the portal vein during a serious attack of enteric infection, which was previously common in Asia. As this condition often affects the lower socioeconomic classes, malnutrition and perhaps infection by flukes and worms may reduce the capacity of the liver to clear enteric bacteria effectively.

Once the organisms are established in the liver, infection begins in the cholangioles and subsequently involves the rest of the portal triads. If the infection is severe, the hepatocytes show vacuolation and may undergo necrosis, hence the name *cholangiohepatitis.* Hepatocellular damage is usually mild, if the infection is confined to the cholangioles. If cholangiolitis spreads to the larger intrahepatic ducts and to the common bile duct (CBD), hepatocellular damage is severe. Resolution of infection in the early phases restores normal morphology, but more intense or repeated infection may result in fibrosis of intrahepatic ducts or cholangitic liver abscess formation.

Whether stones or strictures develop first is not clear (see Chapter 39). Endoscopic retrograde cholangiopancreatography (ERCP) of the bile ducts in RPC (Lam et al, 1978) suggests that structural changes may occur in the ducts before stones are demonstrable, and strictures are often seen at cholangiography in the absence of stones. Conversely, stones are also found in the intrahepatic ducts when no significant narrowing of the ducts is discerned. In advanced cases, strictures are associated with extensive formation of stones, which can fill the ducts throughout the liver. Cisternal dilation of a duct may not be associated with very tight stenosis, and the cavernous ducts do not contain many stones; perhaps some ball-valve mechanism is responsible for these changes. In some patients with acute attacks, stones are not found, but infected, viscous bile permeates the entire biliary tree, which may represent the early stages of precipitation of bile before discernible stones are formed (see Chapter 7). Whatever the sequence of development, repeated or severe infection leads to transmural inflammation of the ducts and results in stenosis in the larger ducts, forming weblike strictures, and in the smaller peripheral ducts, showing more tubular narrowing. As a result of obstruction, together with parenchymal damage to the adjoining liver, the rest of the ducts dilate.

The calculi formed in RPC are pigmented bilirubinate stones (see Chapter 39). Infection in the bile duct changes the bile from a supersaturated solution to an insoluble precipitate. It is postulated that β-glucuronidase, derived from *Clostridium perfringens* and *Escherichia coli,* splits the bilirubin diglucuronide into free bilirubin, and the ionized unconjugated bilirubin together with ionic calcium precipitates to form insoluble calcium bilirubinate, which with time coagulates and consolidates into stones (Leung et al, 2001; Maki, 1966; Nakayama et al, 1980).

Although positive bile cultures are commonly obtained in patients with Western-type stones lodged in the CBD, when the stones are confined to the gallbladder, the incidence of infection is low. In contrast, regardless of whether the stones are located

in the gallbladder or the CBD, the incidence of positive bile cultures in RPC is high (Suzuki et al, 1984; Tabata & Nakayama, 1981), a finding that favors infection as the primary step in the etiology of RPC. It also has been shown that in affected intrahepatic ducts, the number of mucous glands in the epithelial lining is increased (Nakanuma et al, 1988; Terada & Nakanuma, 1988). The integrated role of bacteria and mucus in the lithogenesis of hepatolithiasis was shown in a study by Zen and colleagues (2002), who found that lipopolysaccharide could induce overexpression of gel-forming apomucin (MUC2 and MUC5AC) in biliary epithelial cells via synthesis of tumor necrosis factor (TNF)–α and activation of protein kinase C. Mucin hypersecretion contributes to more stone formation by impeding bile flow and creating a nidus for pigment deposition (Sasaki et al, 1998). Augmented expression and secretion of trefoil factor family protein, a mucin-associated protein important for mucosal defense and repair, together with gel-forming apomucin may play a role in lithogenesis (Sasaki et al, 2004).

Once formation has started, the stones enlarge; where they finally reside depends on whether they can pass through existing strictures. When the stones are larger than the strictures, they are trapped proximally and increase in size as layers of calcium bilirubinate become encrusted on their surface. If the stones are small, they may pass into the common duct and egress through the ampulla into the duodenum, or they may be held in the common duct and enlarge. At any site, stones trapped in the liver or the common duct perpetuate infection and cause further inflammation and scarring of the duct wall.

An association with infection by *Clonorchis sinensis* and *Ascaris lumbricoides* has been implicated in the past (Fung, 1961) and is still commonly regarded as causally significant (see Chapter 45; Rana et al, 2007). However, in countries where clonorchiasis is absent, such as the Philippines, RPC remains prevalent; and in Japan, where clonorchiasis is endemic, RPC is on the decline. Other evidence against clonorchiasis as a causal factor is that *Clonorchis* ova are isolated from the stools of only 25% of patients with RPC, and ascariasis is present in only 5% (Ong, 1962). It is indisputable that clonorchiasis is a serious infection that may cause structural changes in the intrahepatic and extrahepatic bile ducts (Hou, 1956). Although the cholangiographic changes of clonorchiasis are distinctly different from the changes of RPC (Choi et al, 1984), in that the terminal ducts are dilated rather than narrowed, the predominant and more severe changes are seen in the left duct. This occurrence corresponds to the distribution of RPC, a finding that still defies explanation.

Even if clonorchiasis and ascariasis are merely coincidental infections, they may become a nidus for stone formation (Teoh, 1963). Ascariasis probably plays no role in RPC except as a source of foreign bodies, and clonorchiasis may be a contributory factor in countries where RPC is endemic.

PATHOLOGY

The primary pathologic changes are infection and fibrosis with strictures and stone formation in the bile ducts, with other changes being consequences of these main events. The consequences of repeated infection are progressive biliary epithelial and hepatocellular damage, as discussed previously. Suggested sequential changes in the bile ducts in RPC have been documented in detail by Lam and others (1978). These changes include loss of parallelism of duct walls, excessive branching, abrupt termination or "arrowhead" formation of smaller ducts, and development of strictures (Fig. 44.1).

FIGURE 44.1. Endoscopic retrograde cholangiopancreatography showing early recurrent pyogenic cholangitis changes with extensive branching and dilation of the left intrahepatic ducts proximal to the intrahepatic ductal strictures.

Strictures may be found anywhere in the biliary tree but are more common in the major hepatic duct branches, especially in the left liver and in the intrahepatic ducts. When in the extrahepatic ducts, strictures are weblike, situated toward the lower end; if the obstruction is severe, proximal dilation is marked (Fig. 44.2). Strictures in the hepatic ducts also extend over a short distance and are usually intrahepatic, but they may extend to the extrahepatic portion (Fig. 44.3). In the smaller intrahepatic ducts, the strictures are longer, and there may be a pattern of tubular narrowing over a length of duct (Fig. 44.4; also see Fig. 44.1).

The left duct is more frequently and severely affected than the right. Left duct involvement alone is found in 40% of cases of intrahepatic disease, right duct involvement alone is found in 20%, and involvement of both ducts is found in 40%. No satisfactory explanation has been offered for this finding, but it has been suggested that the left duct is more horizontal, and bile in the left duct may not drain as well as bile in the right duct. On the right side, one would expect the incidence of intrahepatic stones to be higher, if the right posterior hepatic duct joins the left hepatic duct at a sharp angle; however, a detailed study of the confluence patterns of segmental hepatic ducts did not show a causal relationship (Kitagawa et al, 2003).

Proximal dilations behind the strictures are an expected secondary phenomenon. These dilations sometimes can be so large as to be called *cisterns* (Maki et al, 1964), and little liver parenchyma remains in such affected segments (Fig. 44.5). In these dilated ducts, relatively fewer stones are found (Fig. 44.6). Dilated segments taper toward the strictures, which are thick and fibrous; when operative plastic repair of such strictures is attempted, restenosis is common as a result of ongoing fibrotic changes in the diseased ductal tissues, and failure can be expected in most cases.

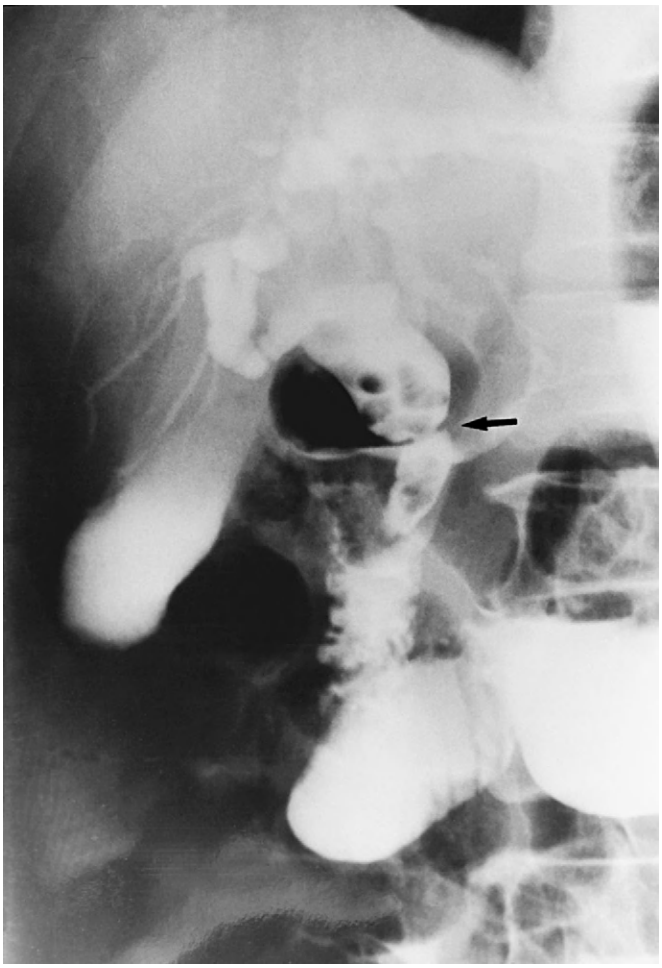

FIGURE 44.2. Stricture of the distal common bile duct in recurrent pyogenic cholangitis (*arrow*). It is weblike, and proximal dilation is seen, with stones above and below the stricture. The gallbladder is unremarkable.

FIGURE 44.3. T-tube cholangiogram shows tight strictures at the confluence of the left and right hepatic ducts and the common hepatic duct.

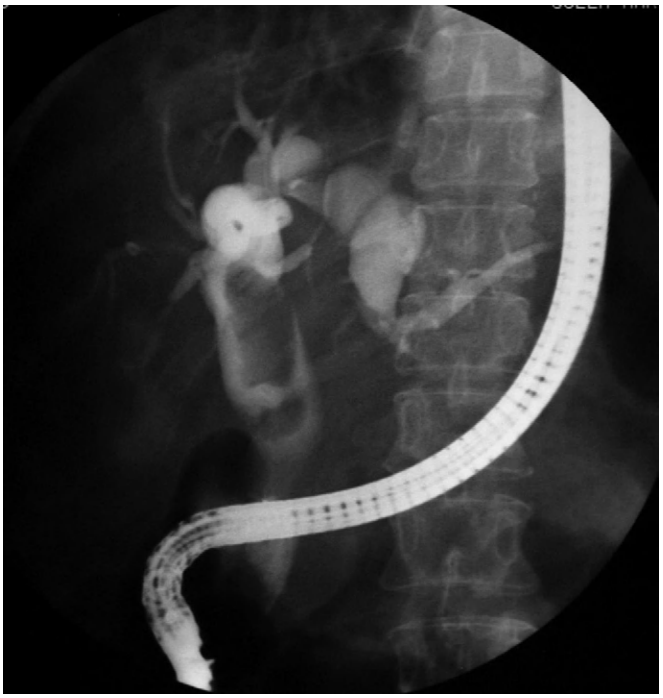

FIGURE 44.4. Recurrent pyogenic cholangitis affecting the extrahepatic and, bilaterally, the intrahepatic ducts. Many stones are present in the liver proximal to the strictures.

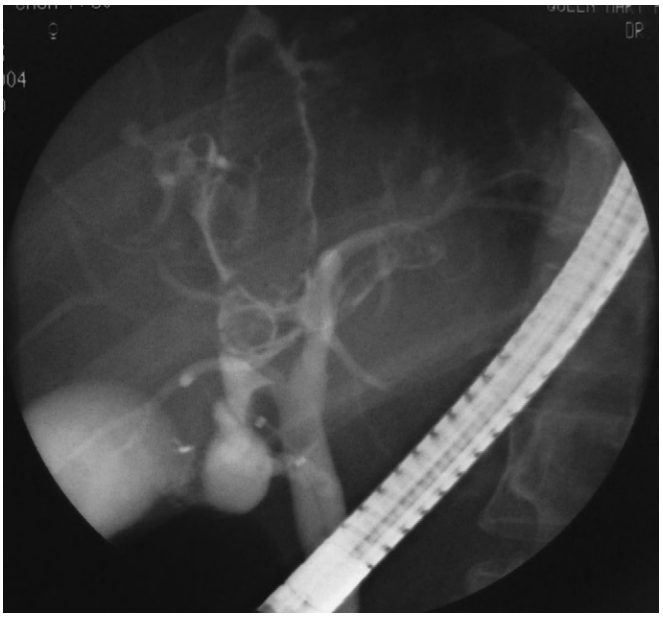

FIGURE 44.5. The right segmental duct is obstructed, and the proximal ductal system has become grossly dilated to form cisterns. Few stones are seen within the duct. The resected specimen is shown in Figure 44.6.

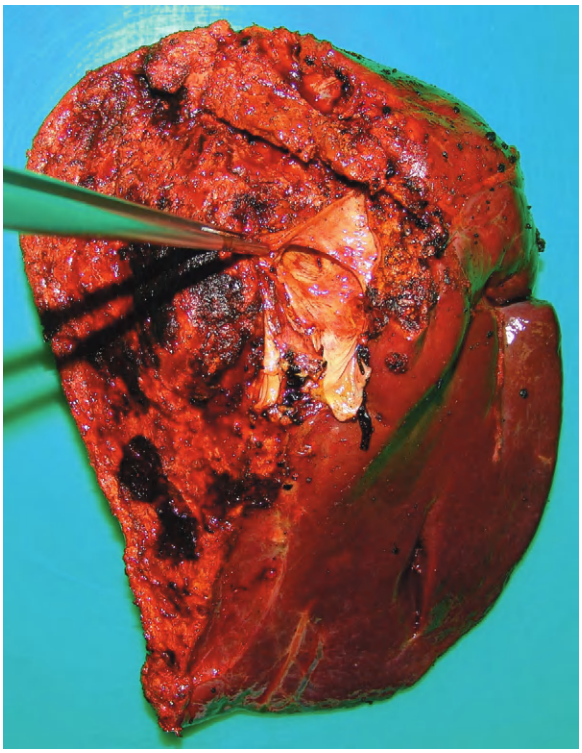

FIGURE 44.6. Resected specimen of the right segmental duct (endoscopic retrograde cholangiopancreatography is shown in Fig. 44.5) showing saccular enlargement of the intrahepatic ducts with stones. The surface is hemorrhagic, and the duct walls are thick.

The gallbladder is diseased in approximately 20% of patients with RPC, but in many patients with extensive ductal disease, the gallbladder is normal (see Figs. 44.2, 44.17A, and 44.19). When stones are found in the gallbladder, disease is invariably present elsewhere. In the acute attack, and when common duct obstruction is severe, the gallbladder may be grossly distended, and empyema, gangrene, or perforation may develop. When a normal gallbladder is left behind after drainage procedures to the common duct, the risk of developing a complication arising from the gallbladder that would require operation is small. When an operation is performed for patients with RPC, it is justified, although perhaps not recommended, to leave an apparently normal gallbladder when stones are found only in the bile duct.

All stones recovered in RPC patients are bilirubinate stones: soft, pigmented, earthy stones that are very friable and crumble when pressed between the fingers. Application of forceps to these stones leads to fragmentation, and the small pieces usually left behind can be flushed out with saline (Fig. 44.7). The stones are irregular in shape and conform to the configuration of the bile duct in which they reside; when packed together, some may have facets. Their size varies from greater than 4 cm to almost microscopic, and in a single patient, a continuum in size may be seen, in contrast to the stepwise size change observed in Western-type mixed stones (Fig. 44.8).

In the fresh state, the stone surface is covered with mucus or a film of viscous bile. In some stones, the outer color may be almost black from prolonged exposure to bile; in others, it is orange or green. Flakes of more recently deposited bile debris are separated from the surface when gently scraped, exposing a lighter colored interior, which may appear laminated. Some stones show no organized structure and disintegrate with slight compression into irregular, powdery clumps. A nidus may sometimes be identified, and microscopic examination of this area may show dead parasites or clumps of bacteria or cells (Teoh, 1963).

In approximately 10% of patients, stones are absent, and the bile duct is filled with biliary debris, termed *biliary mud*. This debris is composed of mucus, pus, parasites, altered bile products, microcalculi, and desquamated epithelium, all mixed to form a thick, porridge-like material that exudes from the duct when it is opened. This material may also coexist with stones. In an acute attack, this soft, infected material with or without stones is more commonly encountered.

At operation for an acute problem, the liver appears "cholangitic": congested, bile stained, soft, and prone to bleeding easily. In the quiescent phase, avascular adhesions are found between the surface of the liver and the parietal peritoneum—evidence of previous, resolved acute episodes. In long-standing cases, the adhesions are dense and vascular and contain pockets of pus, which are due to rupture of cholangitic liver abscesses into the peritoneal cavity. Scars on the liver surface indicate previous attacks and dilated bile ducts and may appear prominently, especially from the undersurface of the left lobe (Fig. 44.9). When the left lobe is atrophic, compensatory hypertrophy of the right lobe is seen. Conversely, in the rare situation of severe right lobe disease, the left lobe may be massive, and the liver hilum anatomy may be grossly distorted (Fig. 44.10). Even when the external appearance is normal, intrahepatic disease may be extensive, and stones are easily palpable through the surface.

Biliary cirrhosis and liver failure are possible complications (Jeng et al, 1989) and usually follow long-standing severe disease that has failed to improve with multiple operations, some of which may be associated with stricture of the biliary-enteric anastomosis (see Chapters 29 and 42A). When cirrhosis has developed, portal hypertension and bleeding esophageal varices may ensue. Further corrective biliary surgery is feasible only after decompression by portosystemic shunting (see Chapter 76).

Stones at the lower end of the CBD may cause two additional complications in addition to biliary obstruction: choledochoduodenal fistula and acute pancreatitis. Choledochoduodenal fistula is not serious, but it may be confusing to the endoscopist and the radiologist. Acute pancreatitis is an important potential consequence of RPC. In Hong Kong, acute pancreatitis was once associated with RPC in approximately half of all patients (Ong et al, 1971), and in approximately 20% of patients with RPC, a high serum amylase level was recorded, although many cases were clinically silent.

Although rare, abscesses in the left liver may rupture into the pericardial cavity and cause cardiac tamponade (Fan & Wong 1997). Abscesses in the right liver may rupture to form a pleurobiliary or bronchobiliary fistula (Wei et al, 1982). These abscesses also may bleed into the abscess cavity (Fig. 44.11) or bile duct (Joo et al, 2003), rupture into the abdominal cavity or into adjacent hollow viscera, or extend into the subphrenic or subhepatic spaces.

A chronic abscess may be indistinguishable clinically, at operation or on contrast studies, from cholangiocarcinoma, and it may be identified as such only through detailed histologic

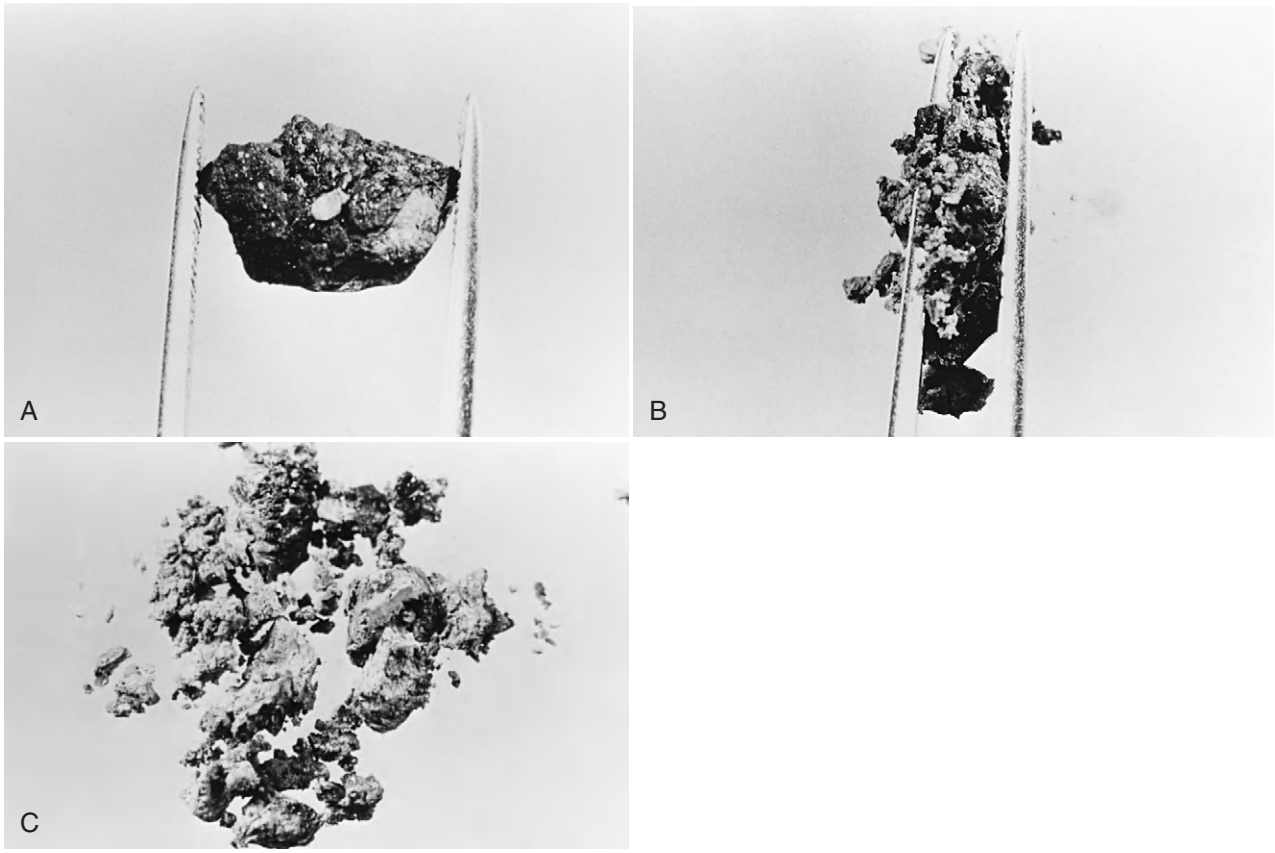

FIGURE 44.7. A, Recurrent pyogenic cholangitis stone is placed between tissue forceps. **B,** The stone is crushed easily by gentle pressure. **C,** Stone fragmenting into soft amorphous masses.

examination after resection. As with hepatolithiasis, an increased incidence of cholangiocarcinoma owing to clonorchiasis has been noted (see Chapter 50; Hou, 1956; Ohta et al, 1984).

Whether cholangiocarcinoma is coincidental or etiologically related to RPC is controversial. The nearly constant presence of severe clonorchiasis in patients with cholangiocarcinoma supports a cause-and-effect relationship (Belamaric, 1973). Cholangiocarcinoma is found in 2% to 13% of patients with intrahepatic stones (Chen et al, 1989; Chu et al, 1997; Ohta et al, 1984, 1988). Autopsy studies suggest that recurrent cholangitis can induce progressive changes, leading to atypical epithelial hyperplasia and cholangiocarcinoma (Ohta et al, 1984). The tumor may take the form of a nodular or papillary growth, and stones may be found within the tumor mass or within the ductal lumen with tumorous invasion (Fig. 44.12). Cholangiocarcinoma should be suspected whenever a mass lesion is seen on imaging studies (Fig. 44.13); however, inflammatory pseudotumor (see Chapter 48) is also present in patients with RPC (Yoon et al, 1999). The imaging characteristics are nonspecific; only resection and pathologic examination can reliably differentiate the two conditions.

FIGURE 44.8. Gradation of sizes of irregular recurrent pyogenic cholangitis stones. The surfaces are bile stained, but the interior is lighter in color. The shape of the stones molds to the contours of the intrahepatic ducts.

Thrombophlebitis of major portal vein branches may develop when adjacent large biliary ducts are affected by RPC, causing extensive periductal inflammation (Fig. 44.14). The degreee of portal vein obstruction correlates well with the degree of liver atrophy (Kusano et al, 1991; see Chapter 5). When the hepatic veins become thrombosed, pulmonary emboli may develop; in rare instances, this can lead to pulmonary hypertension (Lai et al, 1968). Microscopically, the portal triads are infiltrated with inflammatory cells, and the cholangioles are filled with pus. In severe attacks, neutrophils are also seen in the sinusoids of the lobules, and adjacent hepatocytes undergo vacuolation. The larger bile ducts show acute inflammatory changes initially, but with repeated attacks, the ducts

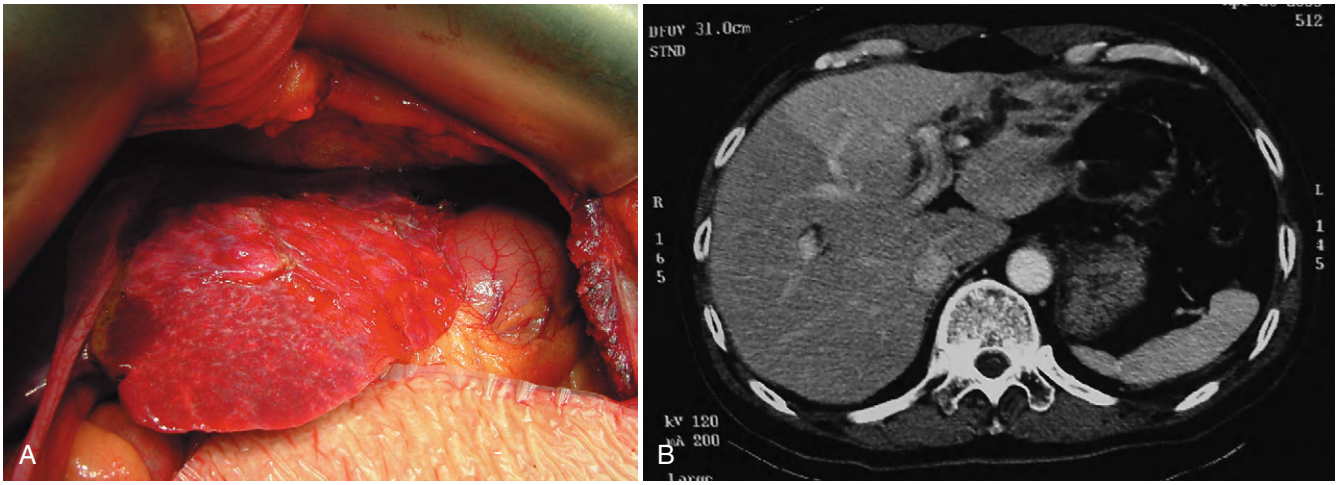

FIGURE 44.9. **A,** At laparotomy, the left lateral segment appears cholangitic with scars, and dilated ducts are seen on the surface. Stones may be palpable in the dilated ducts through the atrophic liver parenchyma. **B,** Computed tomographic scan of the same patient shows the typical features of this condition.

FIGURE 44.10. Computed tomographic scan of a patient with recurrent pyogenic cholangitis shows right lobe atrophy and shifting of the liver hilum toward the right side. Stones are located within the right duct.

FIGURE 44.12. Right hepatectomy specimen of the same patient as in Figure 44.13, showing tumor mass (*arrowheads*) growing within the dilated bile duct; a black stone is seen within a branch of the bile duct (*arrow*).

FIGURE 44.13. CT scan of a patient with recurrent pyogenic cholangitis shows a dilated right duct with a soft tissue mass within (*arrowheads*).

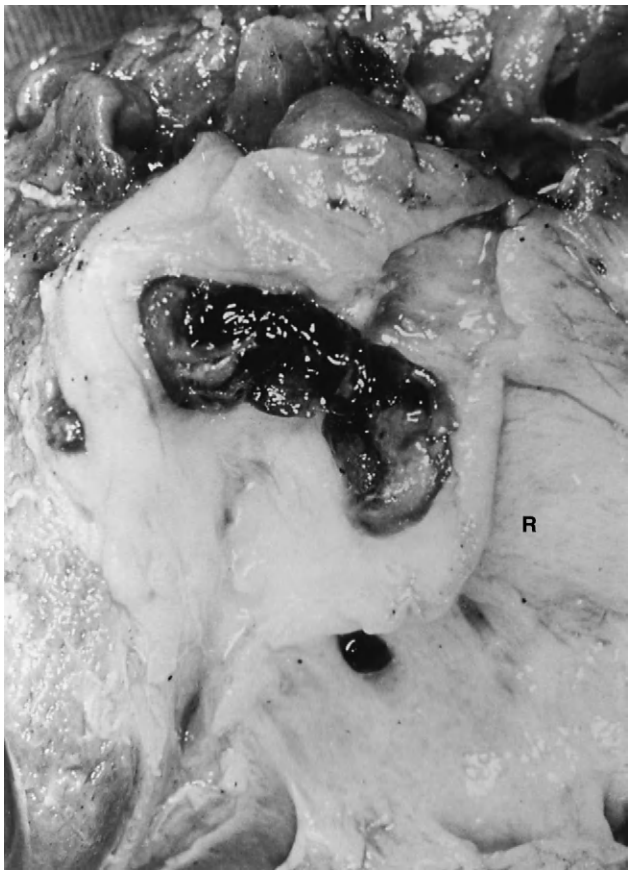

FIGURE 44.14. Thrombophlebitis of the right branch of the portal vein in severe recurrent pyogenic cholangitis affecting the right hepatic duct (*R*). The vein wall is thickened with white fibrous tissue.

FIGURE 44.15. Photomicrograph of a large intrahepatic duct affected by recurrent pyogenic cholangitis. The wall is thick and fibrosed, the epithelial lining in the duct lumen is denuded, and glandular proliferation extends into the depths of the thickened duct wall (hematoxylin and eosin stain, ×67.)

become thickened, surface mucosal lining is lost, and marked glandular proliferation advances into the thickened duct wall and beyond (Fig. 44.15). With repeated attacks, many of the glands undergo metaplasia, and fibrosis may extend far beyond the already thickened duct wall into the adjoining liver parenchyma, which undergoes degeneration and necrosis.

CLINICAL FEATURES

In contrast to biliary calculous diseases seen in Western countries (see Chapter 30), RPC affects men and women equally, with a predilection for the lower socioeconomic classes. In Hong Kong today, with improved socioeconomic conditions, there are fewer new cases and fewer young patients with RPC. In a survey, the median age of patients with RPC was 59.5 years, and 56% had previous biliary operations for biliary stone disease (Liu et al, 1998).

The symptoms of RPC are not in themselves distinctive and are characteristic of acute cholangitis: pain, fever, and jaundice (Charcot's triad; see Chapter 43). The pain is right hypochondrial or epigastric, and it may be distending, sharp, gnawing, or cutting, with frequent radiation to the back. It is constant, seldom colicky, and lasts for hours. Nausea is common, but vomiting is unusual. If the body temperature is elevated, septicemia or liver abscess must be suspected; the temperature chart often shows spikes rather than a continuous fever. Jaundice is seldom marked and may be just clinically perceptible, indicating incomplete obstruction. Pruritus is rarely a complaint, and the patient does not note pale stools. More typically, the patient is aware of the passage of tea-colored urine.

Physical examination in the acute attack reveals a restless patient, slightly jaundiced, and unwell. The abdomen may bear the scars of previous surgery. Tenderness is elicited in the epigastrium or right hypochondrium, and there is guarding. The liver is enlarged in 60% of patients, but this may be masked by guarding. Similarly, a distended gallbladder may not be palpable. The spleen is enlarged in 25% of patients.

Should the abdominal signs deteriorate, indicating worsening peritonitis, or if generalized peritonitis is present, emergency operation or nonoperative intervention is mandatory. In elderly patients, abdominal signs may be minimal, even in septicemic patients, and reliance on physical findings alone may delay a decision to operate until the patient is in shock. Even when shock is present, there still may be a reluctance to operate on these elderly patients for lack of convincing abdominal signs. A transient increase in blood pressure in a patient with acute cholangitis may be a prelude to shock and must be regarded as a sign of impending deterioration rather than a positive response to treatment. In between attacks, there are few if any significant clinical features. Recent weight loss in elderly patients known to have RPC should raise the suspicion of development of cholangiocarcinoma, and it should also be suspected during follow-up when a patient's serum alkaline phosphatase increases markedly (Kim et al, 2003), or when intrahepatic stones involving both lobes have not been completely cleared in previous operations (Jan et al, 1996).

INVESTIGATIONS

Routine hematologic and biochemical tests are consistent with bacterial infection of an obstructed bile duct and do not distinguish patients with RPC from patients with infectious processes from other causes. Leukocytosis is present, and liver function tests show an obstructive picture with a moderate elevation of

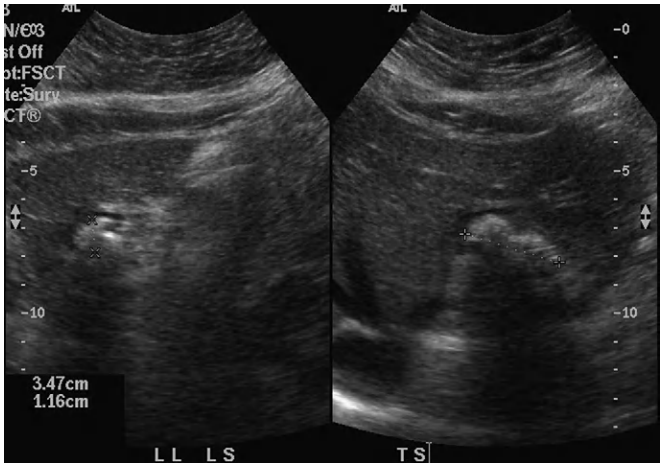

FIGURE 44.16. Ultrasound of a patient with recurrent pyogenic cholangitis. The intrahepatic stone produces an acoustic shadow, a feature not always demonstrable.

the bilirubin level and high serum alkaline phosphatase and γ-glutamyltransferase (GGT) levels. Occasionally, patients with RPC have completely normal liver biochemistry, even during an acute attack.

Imaging studies are important for the diagnosis of the disease, evaluation of the extent of involvement, and formulation of treatment plans for eradication of stones and strictures. Ultrasonography (US), computed tomography (CT), cholangiography, and magnetic resonance imaging (MRI) are complementary to each other in achieving such goals (see Chapters 13, 16, and 17).

When applied optimally, US diagnoses the size of the common and intrahepatic ducts and the location of stones. It also shows liver abscesses, biloma, or tumor if any of these are present. Color Doppler US is useful in studying portal vein hemodynamics. Intrahepatic stones are readily identified if they cast sonic shadows (Fig. 44.16), but some stones found in RPC are isoechoic and may be isoechoic with respect to the surrounding tissue (Federle et al, 1982). This fact, combined with the propensity of these stones to form biliary casts, may lead to failure of US to identify intrahepatic stones in some cases (Chau et al, 1987). Another deficiency of US in the imaging of this disease is related to pneumobilia, which may produce highly reflective echoes and acoustic shadowing that simulates stones (Federle et al, 1982). Pneumobilia is a common finding in patients with RPC who have undergone biliary-enteric drainage procedures. In 30% of patients with RPC, prominent periportal echogenicity is found (Chau et al, 1987). These changes could represent pericholangitis and periportal fibrous thickening found in advanced stages of RPC, a finding that should prompt the ultrasonographer to search for other evidence of RPC.

CT is more expensive than US, but it provides imaging that is largely free from observer bias and operator-dependent interpretation. In addition to providing the information offered by US, it can accurately differentiate intrahepatic stones from pneumobilia, which may be confusing on US, and can provide accurate topographic localization for drainage of liver abscess (Fan et al, 1990). In RPC, some stones may become less conspicuous on postcontrast scans against the contrast-enhanced hepatic parenchyma (Fig. 44.17), and examination of a noncontrast scan is mandatory to avoid a false-negative interpretation. On CT scan, volumetric and contour alteration of the liver can be readily seen; liver lobe atrophy, hypertrophy, and rotation of the liver hilum are present in longstanding cases (see Fig. 44.10), and parenchymal changes can also be detected. During an acute attack, persistent segmental enhancement is observed in 36% of patients (Chan et al, 1989), representing parenchymal suppuration analogous to the angiographic finding of diffuse hypervascularity and arteriovenous shunting described for the disorder (Freeny, 1980).

US and CT are complementary examinations to cholangiography (see Chapter 18), which provides clear delineation of the ductal anatomy. The pattern of ductal disease can be so diverse in IPC that detailed delineation of the entire biliary tract is essential. ERCP and percutaneous transhepatic cholangiography (PTC) are the direct cholangiographic methods of choice

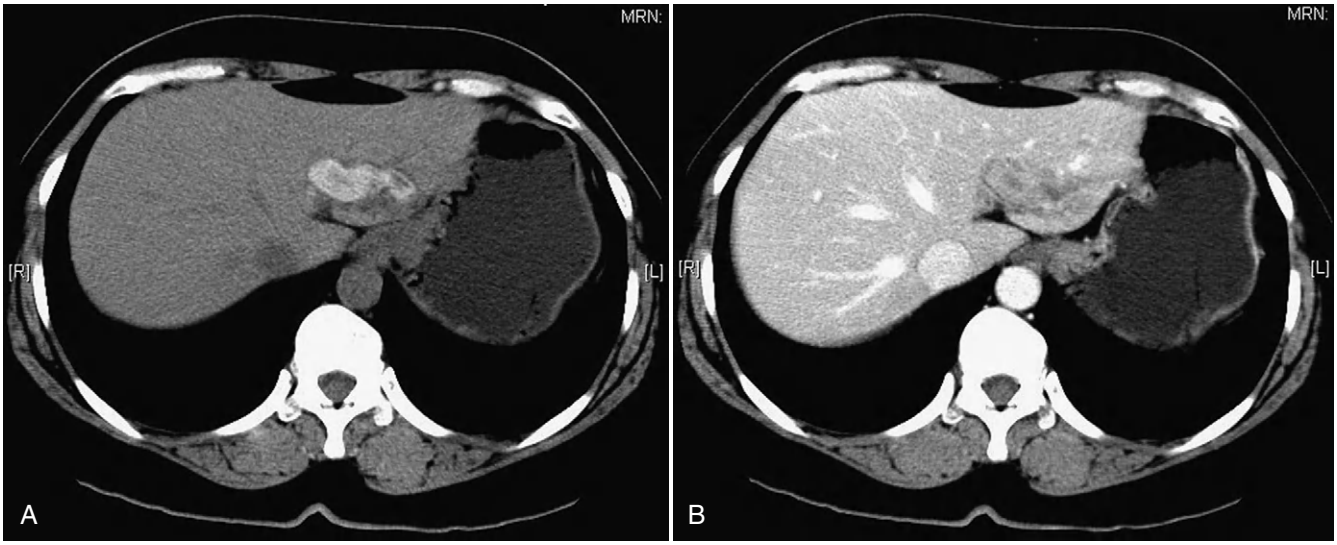

FIGURE 44.17. A, Computed tomographic (CT) scan shows obvious intrahepatic stones on a noncontrast film. **B,** CT scan shows the stones being masked by parenchymal contrast enhancement.

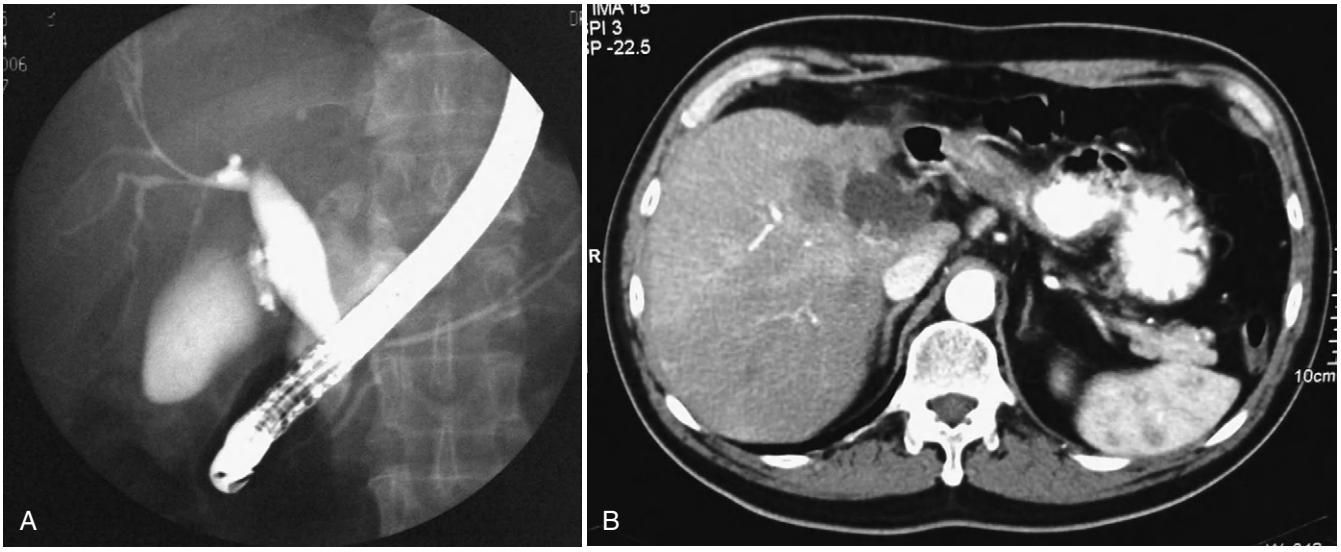

FIGURE 44.18. A, Endoscopic retrograde cholangiopancreatography shows an apparently normal cholangiogram. On closer examination, a lack of intrahepatic ductal filling is present on the left side. **B,** Computed tomographic scan of the same patient shows that the absent intrahepatic filling is due to stricture of the left duct leading to cisternal dilation. Multiple stones are present inside the dilated duct.

for RPC. We generally prefer to perform ERCP first, because the extrahepatic ducts, which are affected in more than 50% of patients with RPC, are better visualized. PTC is preferred when there has been a hepaticojejunostomy or choledochojejunostomy and when a stone or stricture located at a confluence of bile ducts prevents filling of the intrahepatic ducts. US can be useful in this instance by guiding percutaneous puncture of the targeted bile duct and by offering greater safety (Nakayama & Koga, 1984). On interpreting cholangiograms obtained in patients with this condition, care should be exercised in looking for missing segmental ducts, especially with a paucity of intrahepatic filling (Fig. 44.18). Correlation with US or CT may yield useful information in defining the cause of repeated attacks of cholangitis in patients who apparently have cleared all stones.

Similar to CT and US, MRI is a sensitive modality for showing the volume and contour changes in RPC. Contrast-enhanced T1-weighted MRI can show acute suppurative changes by enhancement of the ductal walls and parenchyma. Periportal inflammation is seen on MRI as an intermediate signal between that of the liver and bile on T2-weighted images (Chan et al, 1997). T2-weighted images are best for showing ductal dilation and stones, because bile appears with high signal intensity, whereas stones (without free protons) are signal void and appear as an intraductal filling defect (Fig. 44.19). Compared with US and CT, MRI is slightly better in detecting intrahepatic stones, ductal dilation, and strictures (Kubo et al, 1995), however, the presence of pneumobilia, which is also signal void, may adversely affect the stone detection rate. Three-dimensional display of the biliary system by MRI cholangiography (see Chapter 17) is indicated when ERCP cannot be performed, and it may supplant direct cholangiography for diagnostic purposes (Fig. 44.20; Soto et al, 1996). MRI cholangiography is more sensitive than ERCP in detecting intrahepatic stones, because intrahepatic stricture inhibits filling of intrahepatic branches by contrast material in ERCP, and MRI cholangiopancreatography may replace ERCP in situations in which a therapeutic procedure is not mandatory (Kim et al, 2002).

MANAGEMENT

Most patients present with an acute attack, which is often not their first. The acute attack usually resolves with antibiotic and surgical or endoscopic treatment, and the patient undergoes detailed radiologic examination. In particular, the site of the strictures, location of stones, size of the ducts, volume of the liver parenchyma involved, and any associated complications

FIGURE 44.19. Magnetic resonance imaging shows coronal plane of a patient with recurrent pyogenic cholangitis. Cisternal dilation of intrahepatic ducts and stone (*arrow*) are seen, whereas the common bile duct (*CBD*) is normal in caliber. *(Courtesy Dr. F.L. Chan.)*

can be ascertained before a decision is made regarding the need for or type of operation to be performed. Definitive treatment by liver resection is often indicated. Patients for whom liver resection is not recommended are few, and those generally include frail patients who have minimal ductal strictures and in whom stones are absent and also the rare patients whose bile ducts are filled with *C. sinensis* and whose attack of cholangitis is presumably due to bacterial infection on top of a heavy infection by flukes.

Acute Attack

The goal of treatment of an acute attack is to provide noninvasive conservative measures. This phase of treatment is regarded as preoperative or preinterventional. Intravenous fluids, broad-spectrum antibiotics, and analgesics are given, and the gastrointestinal tract is rested. Antibiotics must cover gram-positive and gram-negative organisms, particularly *E. coli, Klebsiella* species, and anaerobes, especially in patients with a previous biliary-enteric anastomosis (Sheen-Chen et al, 2000). Patients who come to medical attention in shock or whose condition is unstable must receive surgical or nonsurgical intervention without delay.

Conservative treatment for an acute attack fails in about 30% of patients. Complications occur in approximately 35% of the patients who required emergent operative, endoscopic, or radiologic procedures (Chen et al, 1984; Fan et al, 1991b). A retrospective analysis suggested that failure of conservative treatment is more likely to occur with obstruction of the entire biliary tract by stones or strictures in the common duct than when the biliary obstruction involves an isolated segment only. In other words, sepsis involving the entire biliary tract seems to be more serious than sepsis with segmental involvement. Factors such as age, incidence of comorbidities, previous surgery, bacteremia, bacterial strains resistant to antibiotics, and multiplicity of bacterial cultures seem to be less important determinants (Fan et al, 1991b).

Failure of conservative treatment is evidenced by persistent fever, mental obtundation, spreading signs of peritonitis, tachycardia, oliguria, and hypotension. Urgent biliary decompression is required before the patient lapses into irreversible shock and death. This is achieved by an endoscopic, radiologic, or operative approach.

Surgical Treatment During an Acute Attack

In an acute attack, the operation is aimed at saving the patient's life by decompressing the obstructed bile duct and providing free biliary drainage. The standard approach is exploration of the CBD through a choledochotomy and insertion of a large-bore T-tube. The common duct is often a few centimeters in diameter and very thick walled. When the CBD is extremely large and fibrosed, the normal anatomy is distorted; in this situation, recognition may not be straightforward, especially with a history of previous operation. When the duct is opened, thick, infected biliary mud or pus exudes. After this material has been aspirated, stones within the duct are removed with forceps gently, to avoid fragmentation; a scoop is useful in retrieving soft stones and thick mud (see Chapters 29 and 39).

Intrahepatic strictures and stones are not dealt with definitively at the emergency operation, but intrahepatic ductal infection must be relieved by dilation of strictures with graduated sounds. When tight strictures are dilated, a gush of infected bile emerges from the duct. To establish the drainage and decompression of the intrahepatic segmental ducts, a transhepatic tube can be inserted on the same principle as a percutaneous transhepatic biliary drain inserted by radiologic means (Fan & Wong, 1996). During exploration of the CBD, irrigation of the bile duct with warm saline solution must be done gently, because syringing at high pressure may induce bacteremia. For this reason, among others, choledochoscopic examination of the intrahepatic duct should not be performed. Choledochoscopy can be done for the lower end of the CBD, provided that the choledochotomy is large and allows free egress of saline.

After the common duct is cleared, patency of the lower end can be established by gently passing a biliary Fogarty catheter. Inflation of the Fogarty catheter without choledochoscopic guidance is not recommended, because inflation of the balloon at the sphincter of Oddi may damage the sphincter or induce acute pancreatitis. Similarly, blind passage of a biliary sound is not recommended, because it may create a false passage or damage the sphincter of Oddi. Digital exploration also is helpful to detect stones and strictures in the CBD and the proximal hepatic ducts, but it is not reliable in ascertaining complete clearance of stones.

After bile flow from both lobes of the liver is established, a large-bore T-tube is inserted in the CBD, and the choledochotomy is closed with absorbable sutures. This T-tube allows debris to pass unimpeded, and because residual stones are found in more than 30% of patients after emergency exploration, it affords a large tract for percutaneous manipulation after operation.

Whether additional procedures are required depends on the presence of concomitant pathology and the condition of the patient. Cholecystectomy and cholecystostomy are not routinely performed, unless the condition of the patient is satisfactory; acute cholecystitis, empyema, or gangrene of the

gallbladder is present; or the gallbladder is extremely distended. When the condition of the patient is not satisfactory, the presence of stones in an otherwise normal gallbladder is not an indication for cholecystectomy during operation for an acute attack. Palpable liver abscesses are drained externally. Smaller, multiple abscesses should resolve with adequate biliary drainage and antibiotics. If the cardiovascular condition of the patient is stable, hepatic resection can be performed safely for multiple liver abscesses in a destroyed left lateral segment (Fan et al, 1993a).

A stone impacted at the lower end of the CBD that cannot be extracted via a choledochotomy is left in situ, if there is no associated acute pancreatitis. In the presence of acute pancreatitis, removal through a transduodenal sphincteroplasty is mandatory, because pancreatitis may progress (see Chapter 35). This operation can be performed with low risk (Ong et al, 1979). Although it may be argued that such an impacted stone may be left for endoscopic removal, this strategy entails further intervention in the immediate postoperative period, using a procedure that is not without risk; in addition, it does not offer the assured success of surgical removal at the same operation. The patient may lose a large volume of bile in the postoperative period, leading to hyponatremia, hypokalemia, metabolic acidosis, and dehydration. An alternative to transduodenal sphincteroplasty for an impacted stone at the lower end of the CBD is fragmentation of the stone using electrohydraulic lithotripsy (Fan, 1989). In experienced hands, this procedure is safe and quick, and transduodenal sphincteroplasty can be avoided.

Postoperatively, the patient's improvement is usually dramatic. Patients who undergo operation for septic shock may need a prolonged convalescence in the intensive care unit to recover from hepatic and renal dysfunction; temperature, pulse rate, and blood pressure may take some time to return to normal levels. Some of these critically ill patients remain in shock and subsequently die of multiple organ failure, sepsis, and generalized bleeding secondary to coagulation defects.

Patients with heavy *C. sinensis* infections may pass large volumes of thin bile through the T-tube despite demonstrated patency of the lower end of the CBD. The mechanism for this choleresis is unknown. Praziquantel should be given to eradicate the infection, and adequate fluid and electrolyte replacement must be given to avoid complications.

Nonoperative Treatment of an Acute Attack

Biliary decompression can be achieved by endoscopic papillotomy (see Chapters 27, 36, 37, and 39) and nasobiliary catheter or large-bore endoprosthesis insertion (Lam, 1984). Biliary decompression has the advantage of immediate relief of biliary obstruction if the site of obstruction is within the CBD, but it is not beneficial if the disease is mainly intrahepatic. In this situation, percutaneous transhepatic biliary drainage (see Chapters 28 and 32) of the obstructed segmental ducts under US guidance may be helpful (Heffernan et al, 2009; Huang & Ker, 1988). The drainage tubes used in these procedures are small, and the lumen is even smaller; these can be blocked easily in the presence of thick, infected bile and soft stones (Takahashi et al, 1990). Because multiple strictures are often present inside and outside the liver, a single drain is inadequate in affording total decompression.

Careful assessment of the clinical condition after endoscopic or radiologic biliary decompression is necessary. If the patient's condition does not improve, further imaging is necessary to identify the location of sepsis. Possible causes of ongoing sepsis may include empyema of the gallbladder with perforation and bile peritonitis, one or more undrained segmental ducts, liver abscess, and blockage of the lumen of a previously placed drainage tube by thick bile. Regardless of the cause of sepsis, prompt surgical intervention is indicated.

In the past, biliary decompression was performed when a patient's condition deteriorated or failed to improve after conservative treatment. The mortality of this approach is about 10% and is unacceptable. With the availability of emergency endoscopic service, we advocate emergency ERCP and endoscopic decompression within 24 to 48 hours of admission, hoping to avoid surgical intervention at the time of an unfavorable physiologic condition. ERCP is the best initial step, because the pathology leading to failure of conservative treatment usually resides in the CBD (Fan et al, 1991a, 1991b), and adequate decompression can be achieved by the use of a large-bore endoprosthesis. With this approach, there is almost no hospital mortality for an acute attack (Liu et al, 1998); however, the condition of the patient must be meticulously observed. If a sign of immediate improvement is not apparent, the patient must be considered for surgical intervention.

Definitive Surgery

The goals of elective definitive surgery are to clear the biliary tract of stones, to bypass or enlarge the strictures, to provide adequate biliary drainage, and, where necessary, to provide percutaneous access to the biliary tract. Because the disease affects the biliary tract at different sites and with varying degrees of severity, many procedures have been developed to deal with the different circumstances. These procedures include common duct exploration, hepatotomy, partial hepatectomy, hepaticocutaneous jejunostomy, and stricturoplasty. A complete and exact imaging study to outline the location of stones and strictures and the degree of segmental liver atrophy is mandatory in planning elective definitive treatment.

In general, RPC can be arbitrarily divided into simple and complicated cases depending on the absence or presence of intrahepatic strictures. For simple cases, cholecystectomy, exploration of the common duct, and choledochoscopy with or without hepaticojejunostomy suffice. For complicated cases, hepaticocutaneous jejunostomy, stricturoplasty, and partial hepatectomy are additional procedures needed to circumvent intrahepatic ductal strictures and to eradicate impacted stones.

Approach to the Biliary Tract

Similar to the operations performed for an acute attack, a choledochotomy or hepaticodochotomy is made for initial exploration of the bile duct. In patients with predominantly intrahepatic involvement, the hepaticodochotomy can be extended up into the right or left duct. By such an extension, pathology located at the confluence involving the main right or left duct can be readily approached. The orifice of the right posterior sectoral duct, especially when it joins the left duct, can be exposed for removal of an impacted stone. If a stricture is found at this orifice, dilation or stricturoplasty (Fan & Wong, 1996) can be performed.

Exposure of the CBD is sometimes difficult when it is obscured by dense adhesions as a result of previous operations or by a pericholedochal venous plexus related to portal vein thrombosis or portal hypertension. On occasion, the CBD

becomes posterior to the portal vein as a result of left lobe hypertrophy and right lobe atrophy (see Chapters 1B and 5; Czerniak et al, 1986). In these situations, the biliary system can be approached by extraperitoneal mobilization of the duodenum followed by transduodenal sphincteroplasty (see Chapter 35; Choi et al, 1982) or dissection of the left duct (Blumgart & Kelley, 1984) or the segment III duct (see Chapters 29 and 42; Dudley et al, 1979). Sometimes, dilated intrahepatic ducts with or without impacted stones are palpable on the surface of the liver, or they can be located by intraoperative US. In this situation, access to the intrahepatic ducts can be achieved by direct hepatotomy (Zhang et al, 1997). This method causes little bleeding if the parenchyma is thin but massive bleeding if the stones are deeply seated. Careful Doppler and US assessment must be done before a decision is made to proceed with direct hepatotomy.

Removal of Stones During Laparotomy

When the biliary tract is opened, stones can be readily removed by forceps, scoops, a Fogarty catheter, or saline flushing. Intraoperative flexible choledochoscopy (see Chapter 21) is mandatory to discover and remove additional stones, and extraction of stones can be difficult when they are impacted, situated behind strictures, or positioned within sharply angulated ducts, such as the right posterior sectoral or segment IV ducts (Fan et al, 1991a; Jeng et al, 1994; Mahadeva et al, 2003). The difficulty can be circumvented by electrohydraulic lithotripsy (Fan et al, 1989), which involves introduction of an electrohydraulic probe through the working channel of a flexible choledochoscope. Under direct visual control, the probe is brought into contact with the stone, which is disintegrated by sparks generated by the electrohydraulic lithotripter. The lithotripter should be applied cautiously, because a probe in contact with the ductal wall may damage the wall and lead to hemobilia. A holmium:yttrium-aluminum-garnet laser (Uchiyama et al, 2002) and a new-design plasma shock-wave lithotripter (Xu et al, 2002) may be viable alternatives, because they do not damage the ductal wall, and they work to clear intrahepatic stones in almost 100% of cases.

Cholecystectomy

Emergent cholecystectomy has been recommended by some authors only when gallbladder disease is present. This approach is justified, because a normal gallbladder left in situ has only rarely required subsequent removal for acute complications, it might act as a sentinel of distal obstruction in the bile duct, and it may be used for further biliary operation should the need arise. For RPC, these reasons are not compelling, therefore it is prudent to remove the gallbladder at the first opportunity in an elective situation.

Biliary Drainage Procedures

Additional drainage procedures, such as transduodenal sphincteroplasty (see Chapter 35) and choledochojejunostomy or hepaticojejunostomy (see Chapters 29 and 42), are carried out when specific indications are present. For sphincteroplasty, these indications include stenosis at the ampulla of Vater or distal common duct, a stone impacted at the lower end, or residual small stones in the intrahepatic ducts. In addition, the duct wall should not be thickened. Transduodenal sphincteroplasty is performed in the standard manner (Chapter 35). An extraperitoneal approach for this operation has been described (Choi et al, 1982) and is particularly useful for patients who have had multiple previous operations. A high transverse incision is used, and the duodenum is identified by its anterior relationship to the kidney. After the sphincteroplasty has been completed, the common duct is explored from below, and residual stones are extracted. Although a supraduodenal choledochoduodenostomy suffices for some of the indications listed, and the anastomosis allows passage of an endoscope for diagnosis or therapy, the disadvantage is possible development of the sump syndrome and liver abscess, because food debris may reflux into the partially obstructed segmental duct (Rumans et al, 1987). Conversion from choledochoduodenostomy to hepaticojejunostomy may be required in these situations. Choledochojejunostomy or hepaticojejunostomy (see Chapter 29) is carried out most commonly for a stricture in the intrapancreatic portion of the CBD or for a dilated thickened CBD that has lost its elasticity. It is performed with the hope that newly formed stones may pass into the bowel. In this instance, sphincteroplasty may not suffice, because the common duct may act as an inert sac and may drain inadequately.

Hepaticojejunostomy is also required when a stricture is present in the common hepatic duct. When the stricture involves the common hepatic duct at or near the confluence, biliary-enteric anastomosis to the left hepatic duct or segment III duct is necessary. When stricture involves the right and left ducts simultaneously in their immediate extrahepatic portion, the difficulty in treatment is increased (see Fig. 44.20); it may be possible to resect the strictures and to perform a bilateral hepaticojejunostomy (Figs. 44.21 and 44.22).

Hepaticocutaneous Jejunostomy

Hepaticojejunostomy is constructed with the hope of providing adequate drainage to the biliary tract for unimpeded passage of newly formed intrahepatic stones. Intrahepatic strictures proximal to the hepaticojejunal anastomosis impede free drainage of bile and passage of stones. Reoperation for recurrence of stones after hepaticojejunostomy becomes increasingly difficult and hazardous. Percutaneous access to the biliary tract may be achieved by flexible choledochoscopy, if the Roux-en-Y limb of the hepaticojejunostomy can be extended to the cutaneous level and opened as a stoma (see Chapter 29; Fan et al, 1993b; Fang & Chou, 1977). Via the stoma, it is possible to perform unlimited sessions of choledochoscopy, until all stones are removed, and all strictures are adequately dilated (Figs. 44.23 to 44.25). The stoma is closed and buried under the skin, so it may be reconstructed as a stoma for diagnostic and therapeutic purposes when recurrence of disease is suspected.

The operative procedure of hepaticocutaneous jejunostomy is simple, but it is imperative to construct a relatively straight and short loop from the skin to the biliary-enteric anastomosis; choledochoscopy through a redundant loop of small bowel is difficult, and access to the intrahepatic branches may be impossible. A variety of methods are effective for construction of a hepaticocutaneous jejunostomy (Hutson et al, 1984). In patients with RPC and numerous abdominal operations, a simpler attachment of a part of the circumference of the long limb of the jejunal loop to the abdominal wall is possible (see Fig. 44.25D).

Postoperative Choledochoscopy and Extraction of Stones

During the definitive operation, intraoperative choledochoscopy is performed, and as many stones as possible are extracted. Complete clearance of stones is sometimes impossible because

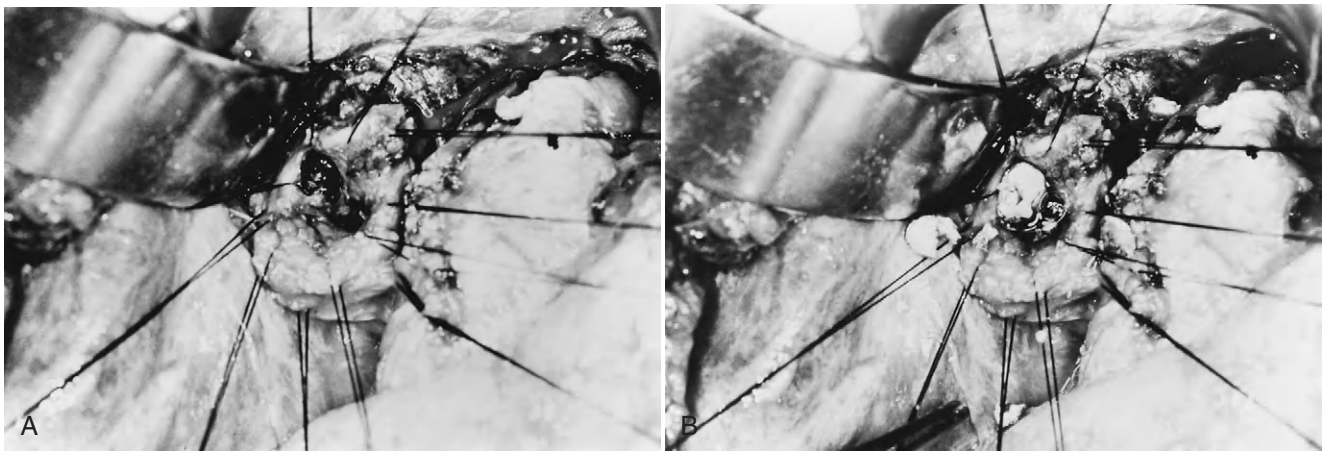

FIGURE 44.21. A, Stricture of the right hepatic duct at the porta hepatis. A stone can be seen within the stricture. **B,** Application of forceps on the stone results in fragmentation, showing the paler interior of the stone.

of the presence of a huge number of stones, or because many more stones are discovered only on postoperative cholangiogram. Postoperative choledochoscopy is required via the T-tube tract, or a cutaneous stoma is required. With numerous sessions of choledochoscopy aided by electrohydraulic lithotripsy, complete stone clearance can be achieved in 90% of patients (Table 44.1; Fan et al, 1991a). A similar complete stone-clearance rate can also be achieved by choledochoscopy via a percutaneous transhepatic biliary drain (PTBD) tract, which is favored by some authors (Cheung et al, 2003; Huang et al, 2003; Lee et al, 2001; Pitt et al, 1994).

The merits of choledochoscopy via a cutaneous stoma or PTBD tract are compared in Table 44.2. Generally, choledochoscopy via a cutaneous stoma is preferred for patients with many stones and strictures, because introduction of the choledochoscope is not painful, approach to the orifices of the segmental ducts is direct, extraction of stones from intrahepatic ducts is not limited, and lost access is not a concern. Bile may induce excoriation of skin, however, especially when the stoma adhesive cannot be applied properly. The location of the stoma has to be planned carefully before the operation to avoid scarred areas. On the contrary, bile leakage is not a major problem with PTBD, but the presence of the drainage tube can be a nuisance. Finally, creation of a PTBD pathway is less cumbersome than hepaticocutaneous jejunostomy but not entirely free of serious complications, such as injuries to the hepatic artery and portal vein. Despite the pros and cons, the two routes of access should not be considered mutually exclusive, but rather complementary, for complete clearance.

Choledochoscopic extraction of stones is generally effective, but occasional large stones may prove difficult and may defy fragmentation by electrohydraulic lithotripsy. Extracorporeal shock-wave lithotripsy (ESWL) is an alternative, and resultant stone fragments may either be extracted endoscopically or passed spontaneously (Adamek et al, 1999; Sackmann et al, 2001).

ERCP has been advocated as a sole modality for eradication of intrahepatic stones (Okugawa et al, 2002). With the aid of the "mother-baby" endoscope system, the complete stone removal rate is about 64%. Considering cost and efficacy, ERCP is considered supplementary to PTBD in difficult situations and is the treatment only in patients who are unfit for surgery.

Access to the biliary tract using the gastroscope via choledochoduodenostomy or interposition duodenojejunostomy has

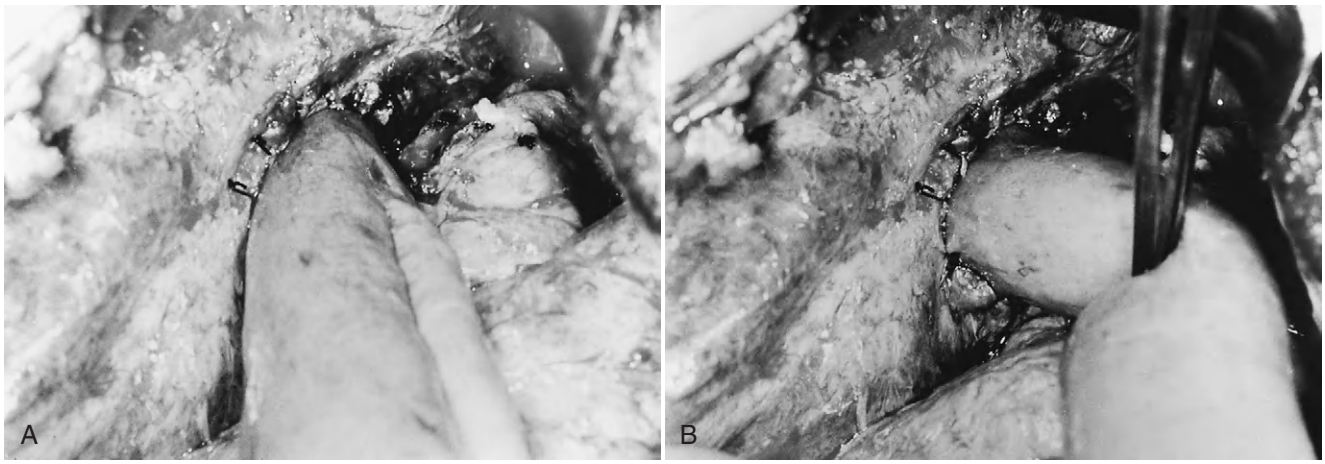

FIGURE 44.22. A, Hepaticojejunostomy performed after the stricture shown in Figure 44.21 had been excised and stones had been cleared from the intrahepatic duct. **B,** Posterior aspect of the hepaticojejunostomy shows the anastomosis is essentially intrahepatic.

FIGURE 44.23. **A,** Percutaneous transhepatic cholangiography of a patient who had undergone six previous operations for recurrent pyogenic cholangitis, including a left hepatectomy, a choledochojejunostomy, and a hepaticojejunostomy. The right duct is packed with stones proximal to an intrahepatic duct stricture, and the enteric anastomosis is patent. **B,** Postoperative appearance of the abdomen of the same patient. The end of the right intrahepatic duct was anastomosed to the side of a jejunal loop, the proximal end of which was brought out as a cutaneous stoma for permanent access to the intrahepatic duct.

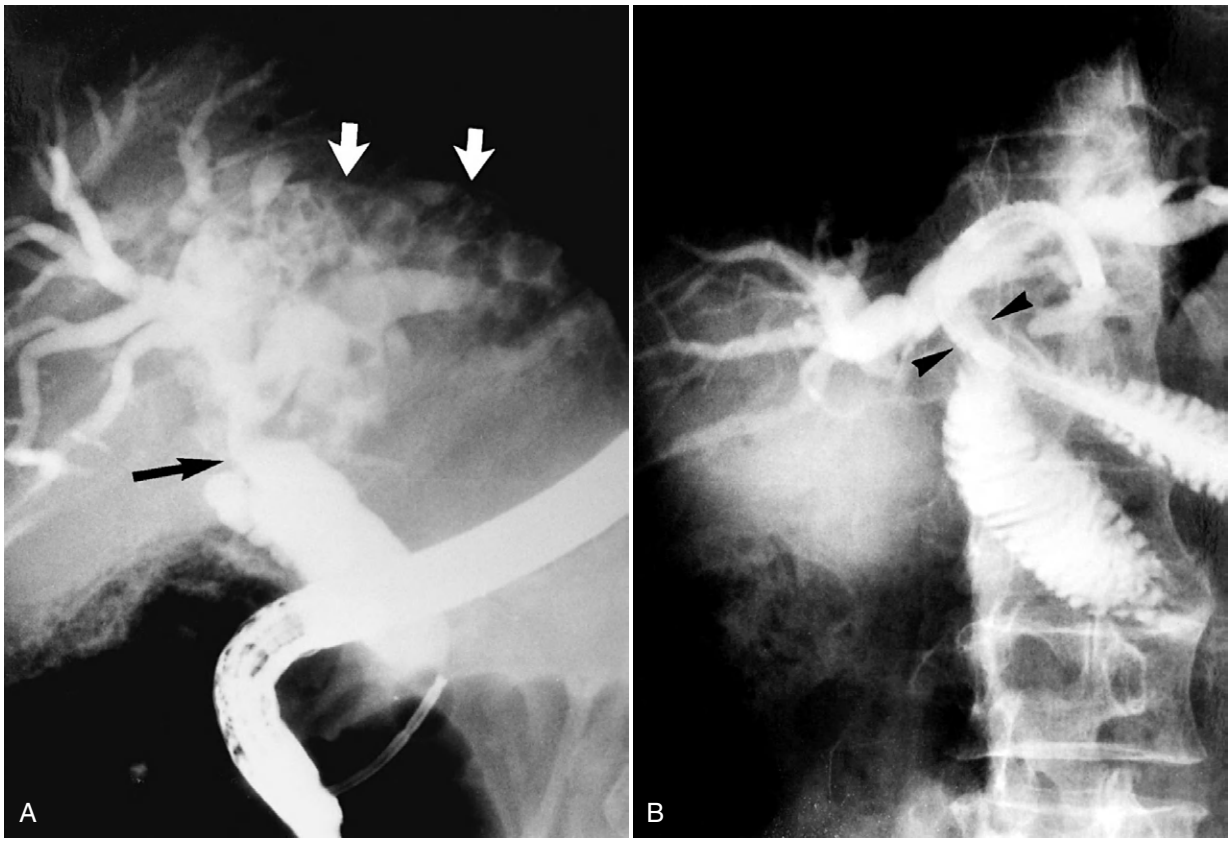

FIGURE 44.24. **A,** Cholangiogram of a patient with stricture at the common hepatic duct (*black arrow*) and numerous stones inside dilated left ducts (*white arrows*). **B,** Hepaticojejunostomy is constructed at segment III duct (*arrowheads*), and a flexible choledochoscope is shown passing through the anastomosis deeply into peripheral branches of left ducts. All stones have been cleared.

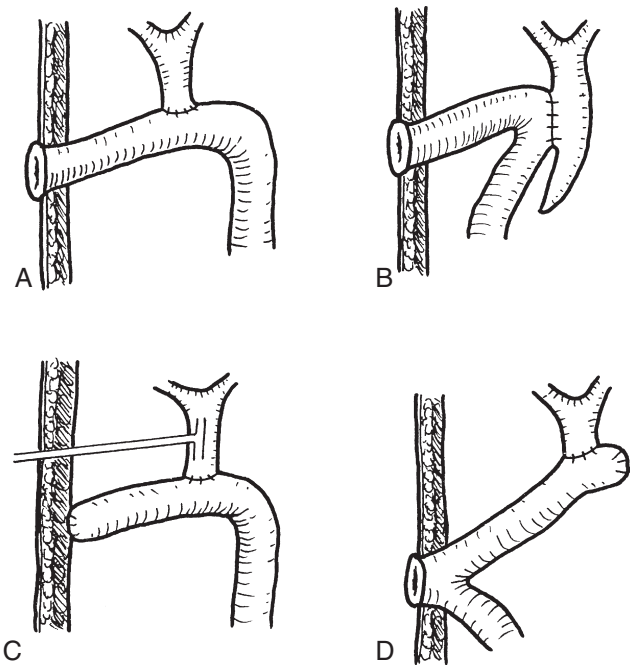

FIGURE 44.25. Diagram showing the standard operation of hepaticocutaneous jejunostomy (**A**) and modifications in selected circumstances (**B** through **D**). Method **B** is used when separation of the common bile duct from the portal vein is dangerous. Method **C** is used when a stoma is not required immediately after the operation. Method **D** is used when the patient has had a previous choledochojejunostomy (see Chapter 35).

been considered (Cunha et al, 2002; Ramesh et al, 2003). Although these techniques have the advantage of having no cutaneous stoma or percutaneous tube, both have the disadvantage of poor access to the small intrahepatic ducts by the gastroscope. With stenosis, food reflux into the intrahepatic duct cannot return freely to the duodenum, and the incidence of ascending cholangitis and liver abscess may be higher in these cases.

Hepatic Resection

Partial hepatectomy is indicated for destroyed liver segments, multiple cholangitic liver abscesses, and concomitant cholangiocarcinoma (see Chapter 90B; Cheung & Kwok, 2005; Fan et al, 1993a; Jeng et al, 1996; Otani et al, 1999). In the past, hepatic resection for RPC was confined largely to left lateral segmentectomy and occasionally left hepatectomy, because intrahepatic stones are located mainly in the left intrahepatic ducts. More recently, left hepatectomy instead of left lateral segmentectomy has been recommended, because ductal strictures are usually near the confluence of the right and left ducts. After hepatectomy, the ductal stricture is dilated, and the left ductal stump and the right and common ducts are explored for removal of intraductal stones. Thorough clearance of stones reduces the need for exploration of the CBD separately (Hwang et al, 2008). Right hepatectomy was once rarely performed, considered too dangerous and undesirable for a nonmalignant condition. However, with improved surgical technique and anesthetic care (see Chapter 22), more and more right hepatectomies are performed safely for RPC associated with impacted stones, an atrophic right lobe, or concomitant cholangiocarcinoma

Table 44.1

Comparison of Patients Treated in 2 Decades at Queen Mary Hospital

	1984-1989*	1991-1996†
No. patients	137	96
Age (median)	56	59.5
Intrahepatic strictures	46 (33.6%)	31 (32.3%)
Emergency ERCP	1 (0.7%)	61 (63.5%)
Partial hepatectomy	44 (32.1%)	55 (57.3%)
Hepaticocutaneous jejunostomy	19 (13.9%)	70 (72.9%)
Right hepatectomy	1 (0.7%)	5 (5.2%)
Stone clearance rate	114 (83.2%)	96 (100%)
Hospital mortality	4 (2.9 %)	1 (1.0%)
Stone recurrence rate	18 (13.1%)	3 (3.1%)

*Fan et al, 1991a
†Liu et al, 1998
ERCP, endoscopic retrograde cholangiopancreatography

(Table 44.2 and Fig. 44.26; also see Table 44.1 and Fig. 44.12) (Hung & Lin, 1997; Liu et al, 1998).

The technique of partial hepatectomy for RPC is not different from the standardized procedures (see Chapters 90 to 93). Modification is needed, however, when difficulty is encountered. When right hepatectomy is indicated for an atrophic right lobe, a thoracoabdominal approach may be indicated (see Fig. 44.10). If the inflow and outflow vascular dissection is difficult because of previous operation or infection, it may be wise to proceed to parenchymal transection directly and to achieve vascular control within the liver parenchyma. Furthermore, mobilization of the right liver can result in bacteremia; therefore the anterior approach is preferred (Liu et al, 2003). Adhesion of the left lateral segment to the adjacent viscera owing to repeated infection and rupture of liver abscess may predispose to injury to the vagus nerve, diaphragm, and the phrenic veins and to a higher incidence of postoperative septic complications (Fan et al, 1993a). The complication rate of hepatectomy for RPC is approximately 40%, half of which are of wound infections (Cheung & Kwok, 2005; Lee et al, 2009), and good correlation

Table 44.2

Comparison of Choledochoscopy via PTBD vs. Hepaticocutaneous Jejunostomy

	Via PTBD Route	Via Jejunal Loop
Choledochoscopy	Painful at skin entry site	Painless
Stone extraction	Stone fragments possibly too large for the tract	No limitation
Approach to intrahepatic duct by choledochoscope	Difficult to bend over angulation into segmental ducts	Theoretically easy
Loss of access	Tract disruption after repeated use	Redundant loop
Wound complication	Granuloma around skin entry site	Skin excoriation by bile

PTBD, percutaneous transhepatic biliary drain

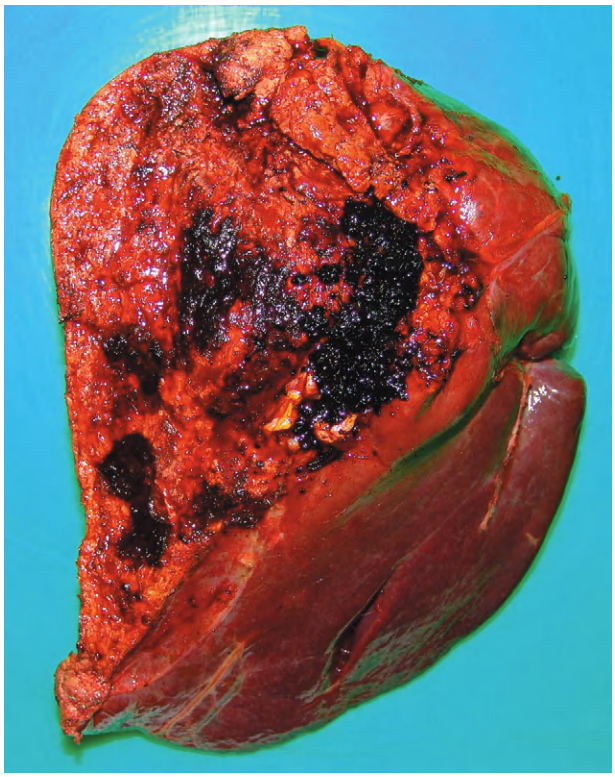

FIGURE 44.26. Resected specimen of the right lobe in which the ducts are packed with stones. Despite a significant residual functional parenchyma, the frequency and severity of symptoms of recurrent pyogenic cholangitis necessitated resection.

is found between the preoperative or intraoperative bile culture and wound infection culture (Lee et al, 2009). An appropriate choice of antibiotic and wound protection during the operation may lower the incidence of wound infections. With advances in the laparoscopic surgery technique, left lateral segmentectomy and even left hepatectomy could be performed in selected patients with an atrophic segment using a hand-assisted device (see Chapter 90E; Chen et al, 2004; Tang & Li, 2003). Such an approach is generally feasible for patients who have not undergone multiple operative procedures and without excessive perihepatic infection and adhesions, although with increasing experience, even these patients are potentially amenable to a laparoscopic resection. Longer follow-up is needed, however, before laparoscopic resection can be considered a standard technique for RPC.

Treatment for Intrahepatic Duct Strictures

Strictures located in the extrahepatic bile duct may be treated or circumvented by hepaticojejunostomy performed proximal to the stricture (e.g., at the confluence, left hepatic duct, or segment III duct; see Chapters 29 and 42). Intrahepatic duct strictures associated with liver atrophy or numerous cholangitic abscesses are best treated by partial hepatectomy. If significant thickness of the liver parenchyma is still present, the stricture is best treated by instrumental dilation (Cheng et al, 2000). After adequate dilation and removal of stones, however, such strictures may recur, and the stoma of the hepaticocutaneous jejunostomy, if present, has to be reopened for repeat dilation. Intrahepatic duct strictures have been treated by self-expanding metallic stents with a reported patency rate of approximately 60% (Jeng et al, 1999; Tsukamoto et al, 2004; Yoon et al, 1997). However, the use of such stents for benign biliary stricture is still controversial. For patients who have refractory intrahepatic biliary strictures and who refuse surgery, self-expanding metallic stents are a potential option, but at present, these should be considered only as a secondary alternative when surgery is impossible.

Liver Transplantation

Bilateral and extensive presence of intrahepatic stones far out into the peripheral ducts may not be amenable to resection and endoscopic treatment. Established secondary biliary cirrhosis, which results in liver failure and bleeding esophageal varices, is an indication for the ultimate treatment of RPC by liver transplantation. The possibility of the development of cholangiocarcinoma with time needs to be addressed, and vascular adhesions from previous operations and portal hypertension renders total hepatectomy of the native liver difficult and potentially hazardous (Strong et al, 2002).

RESULTS OF TREATMENT

Short-Term Results

The short-term results of the treatment of RPC is measured by the mortality, stone clearance, and stone recurrence rates. The outcome depends on the level of scrutiny for residual stones by various types of imaging and on the experience of the team, especially in choledochoscopy. The best results are achieved after good imaging studies, selection of the appropriate procedure for the individual case, and vigilant postoperative choledochoscopy before removal of the T-tube or closure of the cutaneous stoma. Our series indicate that the increasing use of aggressive treatment—such as partial hepatectomy, hepaticocutaneous jejunostomy, and diligent postoperative choledochoscopy—can lead to a 100% stone clearance rate and 3% stone recurrence rate after a median follow-up period of 26 months, with a mortality rate of only 1% (see Table 44.1).

Long-Term Results

The long-term result is best measured by the reappearance of stones and strictures after 5 years of follow-up and by the occurrence of portal hypertension, bleeding esophageal varices, ascites, liver failure, and cholangiocarcinoma. With respect to the location of the disease, patients with simple disease patterns can be expected to do well in the long-term with drainage procedures, whereas patients with complicated disease patterns are expected to have a 30% recurrence of symptoms (Chijiiwa et al, 1995; Jan et al, 1996). Along with recurrence of stones and strictures, progressive liver damage leads to portal hypertension, liver failure, and cholangiocarcinoma. About 10% to 20% of patients may eventually die of the disease, and the occurrence of complications is related to the failure to eradicate stones completely at the time of treatment (Jan et al, 1996).

Treatment is difficult in cases of RPC complicated by liver failure and portal hypertension. Liver transplantation is the only way to salvage these patients, but it is problematic because of the presence of dense perihepatic vascular adhesions resulting from previous infection, multiple abdominal operations, and cholangitic liver abscesses rupturing into the perihepatic

region. Torrential bleeding on mobilization of the liver may occur. This hemorrhage, together with the underlying sepsis, results in a much higher risk than in other patients undergoing liver transplantation. The number of patients with RPC having liver transplantation is small, and the hospital mortality rate has been reported to be 33% (Krissat et al, 1998). If liver transplantation is performed before multiple biliary procedures, the outcome seems to be acceptable (Chen et al, 2008; Strong et al, 2002).

CONCLUSION

To achieve optimal results in treating RPC, a judicious choice of a combination of treatment modalities by a dedicated multidisciplinary team is mandatory. Although it may not be possible to prevent recurrence of stones and strictures in all patients, the construction of a permanent percutaneous access to the biliary tract can facilitate the overall management and reduce the magnitude of subsequent procedures. For less complicated cases, complete removal of the stones and dilation or bypass of all strictures combined with vigilant follow-up can prevent disease recurrence. In the case of establishment of secondary biliary cirrhosis and liver failure, an early decision on liver transplantation must be made before the operative risk has become excessively high.

CHAPTER 45

Biliary parasitic disease

Luis A. Marcos, Angélica Terashima, and Eduardo Gotuzzo

PARASITIC INFECTIONS

Parasitic infections of the biliary tract are a common cause of biliary obstruction in tropical developing countries and less frequently in developed countries. These infections are important, because they can lead to serious complications such as cholelithiasis (see Chapters 30, 35, and 39), recurrent pyogenic cholangitis (Chapter 44), cirrhosis (Chapter 70), pancreatitis (Chapter 53), and cholangiocarcinoma (Chapters 50A and 50B). The most common parasites of the biliary tract reported in humans are *Fasciola*, *Opistorchis*, *Clonorchis*, and *Ascaris* species. They have a wide geographic distribution, complicated life cycles, and various clinical manifestations with several diagnostic options available to detect them and multidisciplinary treatments. Millions of people are infected by these parasites, and surgical complications occur quite often.

Fascioliasis

Fascioliasis, or distomatosis, is a zoonosis caused by *Fasciola hepatica* or *F. gigantica* (Trematoda: Fasciolidae). The infection is distributed globally on all continents, but *F. hepatica* predominates in temperate zones, whereas *F. gigantica* is found in most tropical regions. In approaching a patient with suspected fascioliasis, epidemiologic (Table 45.1), clinical (Table 45.2), and imaging features (Table 45.3) can provide clues for the diagnosis before ordering a diagnostic test to confirm the infection. An algorithm for diagnosis and management is recommended and summarized in Figure 45.1.

Epidemiology

F. hepatica infection was first documented in the Gallo-Roman period (Da Rocha et al, 2006). Today, the estimated number of human infections ranges from 2.4 million to 17 million, and 91.1 million are at risk of infection around the world (Keiser & Utzinger, 2005). In the past, fascioliasis was limited to specific and typical geographic areas, but it is now widespread throughout the world. According to the reported cases, *F. hepatica* transmission has increased in Europe, the Americas, and Oceania, and in Africa and Asia, where *F. gigantica* and *F. hepatica* overlap. The geographical distribution is determined by the intermediate host (*Lymnaea* spp.) and certain other conditions such as climate, alimentary behaviors, and poverty.

Examples of countries with estimates of the infected population include 830,000 in Egypt, 742,000 in Peru, 360,000 in Bolivia, 37,000 in Yemen, 20,000 in Ecuador, and 10,000 in Iran (Haseeb et al, 2002). Furthermore, other countries that have reported a significant number of cases in years include Argentina (Kleiman et al, 2007), Venezuela (Incani et al, 2003), Chile (Llanos et al, 2006), Ecuador (Trueba et al, 2000), Mexico (Cruz-Lopez et al, 2006), Turkey (Kaya et al, 2006; Turhan et al, 2006), Thailand (Aroonroch et al, 2006), Japan (Inoue K, et al, 2007), Korea (Lee & Kim, 2006), the United States (Fullerton et al, 2006; Graham et al, 2001), Tunisia (Khelifi et al, 2006), and Lebanon (Birjawi et al, 2002), among others. The majority of reported cases in these countries are related to complications from the infection, and the current number of cases is undoubtedly underestimated. On the other hand, globalization and migration of populations from rural areas to large cities have led to a number of cases of fascioliasis in nonendemic areas. In fact, because of clinicians' lack of familiarity with this parasitic infection in nonendemic areas, the diagnosis can be delayed, which increases the rate of complications (Kang, 2008).

Fascioliasis is distributed globally, with the most affected area in the world being the Andean region of South America. In fact, more than half of the population may carry the infection in some selected regions, with prevalence ranging from 6% to 68% (Marcos et al, 2005b, 2007a; Parkinson et al, 2007). New evidence has shown that proximity of medium- to high-income industrialized cities to rural areas creates a potential source of infection in nonendemic areas because of the importation of contaminated vegetables to the high-consuming markets of big cities. Thus it is not uncommon to see cases of fascioliasis in nonendemic areas. Another factor that contributes significantly to the dissemination of the infection to new areas is the highly adaptable capacity of both the parasite and the lymnaeid snail hosts to challenging meteorologic conditions (e.g., 4200 meters above sea level, Andean Altiplano). Paleoparasitologic studies have shown that the introduction of *F. hepatica* and its snail host from Europe into the Americas has been relatively recent. Today, fascioliasis as a result of *F. hepatica* is the vector-borne disease with the widest latitudinal, longitudinal, and altitudinal distribution known. These key factors explain the wide geographical distribution of the disease (World Health Organization [WHO], 2007).

The epidemiologic pattern of transmission of fascioliasis can be classified as follows (Mas-Coma et al, 1999): 1) cases imported to areas where neither human nor animal fascioliasis is transmitted; 2) autochthonous, isolated, nonconstant cases of sporadic infection in areas where animal fascioliasis is present; 3) endemic fascioliasis (hypoendemic ≤1%, mesoendemic 1% to 10%, hyperendemic ≥10%); 4) epidemic fascioliasis (i) in animal endemic areas and (ii) in human endemic areas. Epidemiology is an important determinant of the initial evaluation of a patient with probable fascioliasis.

Life Cycle

The adult *F. hepatica* flukes are large, flat, brown, and leaf shaped with a broad anterior portion covered with scalelike spines. Flukes measure approximately 25 to 30 mm by 10 to 15 mm, although *F. gigantica* can measure up to 75 mm. The

Table 45.1

Table 45.3

Clinical Manifestations, Laboratory Data, and Imaging in Fascioliasis

Clinical Picture	Imaging and Laboratory Results
Acute	
Prolonged fever (weeks or months)	Eosinophilia (any cell count)
Abdominal pain (mostly upper abdomen)	Anemia
Hepatomegaly	Anicteric hepatitis
Weight loss	Biliary hemorrhage or hemobilia
Urticaria	Subscapular hematoma or hepatic rupture (seen on CT)
Ectopic lesions*	Hepatic abscesses
	Tracklike lesions on CT
Chronic	
Abdominal pain in right upper quadrant	Eosinophilia (sometimes)
Biliary colic	Cholestasis
Nausea and vomiting	Hepatic abscesses
Recurrent or intermittent jaundice	Liver fibrosis and ultimately cirrhosis
Uritcaria	Necrotic granuloma (increased ALT and AST levels)
	Cystic tumors
	Cholangitis caused *by Klebsiella, Escherichia coli, Enterococcus* spp.
	Choledocolithiasis
	Eosinophilic cholecystitis
	Achalcolous cholecystitis

*Ectopic migration and other clinical manifestations. Acute stage: migratory nodule under the skin or peritoneal cavity, arthralgias, lymphadenopathies, hemolytic anemia, seizures, pleural effusion. Chronic stage: subcutaneous nodules and gastric nodules.
CT, computed tomography; ALT, alanine aminotransferase; AST, aspartate aminotransferase

adult fluke lives in the common and hepatic bile ducts of the human or animal host, and animals susceptible to becoming reservoir hosts for *Fasciola* species include mainly cattle, sheep, pigs, buffaloes, and donkeys, although it has been also reported in horses, dogs, goats, llamas, alpacas, dromedaries, and camels. The eggs are oval, yellowish brown, and measure approximately 130 to 150 by 60 to 90 µm (Fig. 45.2).

The life cycle begins when the parasite eggs in stools are deposited in tepid water (22° C to 26° C); miracidia appear, develop, and hatch in 9 to 14 days. These miracidia then invade many species of freshwater snails, in which they multiply as sporozoites and redia for 4 to 7 weeks. They leave as free-swimming cercaria that subsequently attach to watercress, water lettuce, alfalfa, mint, parsley, or khat. Free-swimming cercaria may remain suspended in water and encyst over a few hours, and infection of the human host begins after consumption of plants or water contaminated with the metacercariae. In the first week, the larvae excyst in the duodenum and migrate through the bowel wall and peritoneal cavity; after 4 weeks, the juvenile larvae penetrate the liver through the Glisson capsule to initiate the acute larval, hepatic, and invasive stages of human infection.

Sometimes the larvae deviate to other locations; these are called *extrahepatic forms* or *ectopic infections.* Maturation from juvenile larvae into adult flukes takes approximately 3 to 5 months, during which time the larvae mature and migrate through the liver into the large hepatic and common bile ducts (Fig. 45.3). Mature flukes consume hepatocytes and duct epithelium and reside for years in the hepatic and common bile ducts and occasionally in the gallbladder. Adult fluke worms produce eggs within 4 months after infection (range, 3 to 18 months); these eggs traverse the sphincter of Oddi and intestine and then continue the cycle of infection. Of note, acute and chronic stages can overlap; this is commonly seen in endemic areas, and it is not unusual to find eggs in the stool samples of patients with acute infection.

Table 45.2

Epidemiology of Human Fascioliasis

Geographic Area	Risk Factors	Population at Risk
Latin America (Andean region)	Watercress	Children in endemic areas
Europe	Drinking alfalfa juice	Travelers
Africa	Green vegetables	Women
Asia	Contaminated water	Vegetarians
Australia	Travel to endemic areas	
	Living close to irrigation canals	
	Eating salads	

Risk Factors

The main source of infection is the consumption of metacercariae-contaminated raw vegetables—such as watercress, lettuce, alfalfa juice, and mixed green salads—or

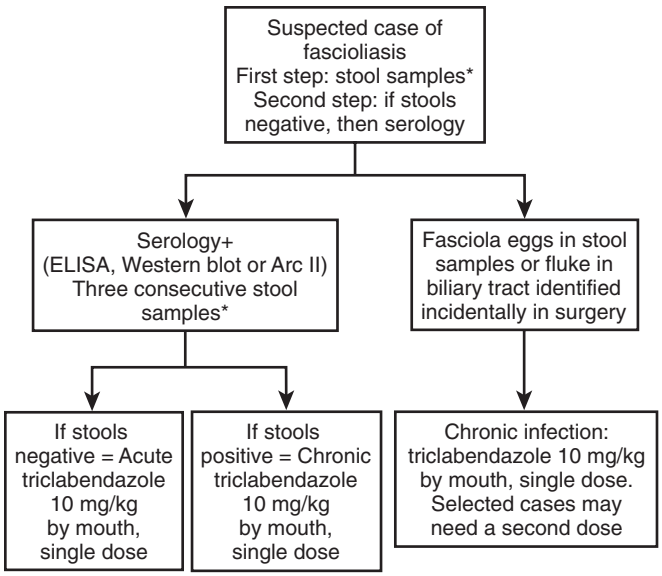

FIGURE 45.1. Summary of management and treatment of a suspected patient with fascioliasis. *Three consecutve stool samples must be examined by a sedimentation technique (Lumbreras, 1962) before ruling out the infection. Stool examination is preferred over serology because of cost effectiveness and availability. In highly suspected cases, a trial of triclabendazole is warranted. Single-dose triclabendazole 10 mg/kg has a cure rate greater than 90%. A second single dose may be used in selected cases (e.g., high intensity of infection in feces, large numbers of parasites in surgery, refractory cases). ELISA, enzyme-linked immunosorbent assay.

contaminated water from man-made irrigation channels (Marcos et al, 2004, 2005a). Because of epidemic obesity, alimentary habits have changed; for example, higher consumption of green vegetables has led to an increase in the risk for fascioliasis, because it requires vegetables imported from endemic areas (Marcos et al, 2007b). The infection has been also seen in people who have eaten salads in luxury restaurants or hotels in endemic countries, and watercress has traditionally been the

FIGURE 45.2. Adult egg of *Fasciola hepatica* in microscopic examination of stools by the rapid sedimentation technique.

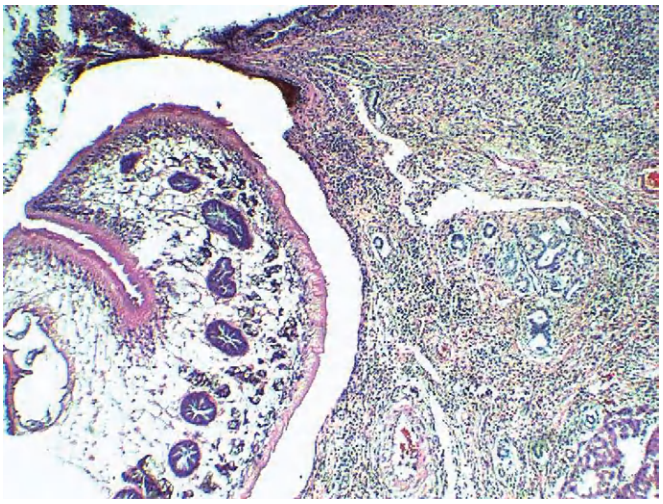

FIGURE 45.3. Liver biopsy of an infected rat with *Fasciola hepatica*, adult parasite in a bile duct.

most common known source of infection. Nonetheless, a large variety of plants have been described in recent years, such as *Medicago sativa* (alfalfa in juice) in Peru; *Taraxacum dens leonis* (dandelion leaves), *Valerianella olitoria* (lamb's lettuce), and *Mentha viridis* (spearmint) in France; green leafy *Nasturtium* spp. and *Mentha* spp. in Iran; *Juncus andicola* and *J. ebracteatus* (Juncaceae), *Mimulus glabratus* (Scrophulariaceae), and *Nostoc* species (Cianofitas) in the Bolivian Altiplano (Bjorland et al, 1995; Mas-Coma et al, 1999).

More women are affected than men, with higher prevalence rates, more severe infections, and with more reported liver or biliary complications (Marcos et al, 2006). Although, the differences are not well understood, alimentary habits, immunologic factors, and proximity to contaminated sources may play a role; for example, children are affected more than adults (Marcos et al, 2007c) likely because of alimentary habits. Reinfection is commonly seen in highly endemic areas, and the parasite can live in the biliary tract for a long time—between 9 and 13.5 years.

Epidemiologic studies have been carried out in endemic areas to measure the impact of alimentary habits on the acquisition of infection. Drinking beverages made from watercress or alfalfa leaves, called *emollients,* and living close to irrigation channels were found to be risk factors in a multivariate analysis in the Andean region (Marcos et al, 2004). Eating salads is the common factor among infected families, and it carries a 3.3-fold increased risk of acquiring the infection (Marcos et al, 2005b). In a logistic regression analysis, an age- and gender-matched case-control study comparing 60 infected children found that drinking alfalfa juice carries a 4.5-fold increase in the risk of acquiring fascioliasis, and familiarity with aquatic plants carries a 4.3-fold increased risk (Marcos et al, 2006). Therefore aquatic plants—watercress, alfalfa, and others—and the irrigation channels that carry the metacercariae play a key role in the transmission of fascioliasis in Andean endemic areas. Hypothetically, exportation of plants or other products could lead to transmission in nonendemic areas. Treatment of contaminated plants with high doses of potassium permanganate decreases metacercariae viability and could be used to prevent infection (Ashrafi et al, 2006), although its impact in endemic

areas has not yet been tested. A summary of risk factors with studies reporting odds ratios is presented in Table 45.4.

Clinical Manifestations

Fascioliasis has two distinct clinical phases: acute and chronic. Signs and symptoms depend on the worm burden, duration, and phase of infection. In general, the *chronic infection* is usually diagnosed in epidemiologic studies in endemic areas as a cause of biliary obstruction or in routine stool tests for other reasons. On the other hand, the *acute infection* has a more florid clinical picture that brings the patient to the emergency room. The clinical manifestations are so variable that mild right upper quadrant pain may call for a step-by-step workup that can lead to the final diagnosis of fascioliasis (Behar et al, 2009).

ACUTE INFECTION

The first acute or invasive phase lasts from 3 to 5 months and is caused by the migration of the immature larvae from the duodenum to the liver. Finally reaching the bile ducts, parasites migrate through the liver parenchyma and digest hepatic tissue, causing intense inflammation and hemorrhage proportionate to the number of worms. Migration tracks can be observed in histologic sections, and flukes sometimes die, leaving cavities filled with necrotic debris; these are eventually replaced by scar tissue. Symptoms include prolonged fever, hepatomegaly with abdominal pain, and mild eosinophilia (early infection) or hypereosinophilia (mid- or late-acute infection). Multiple hypodense lesions can be seen on CT scan, similar to metastases (MacLean & Graeme-Cook, 2002). Of note, one of the most frequent manifestations in this acute phase is hypereosinophilia, which is seen in almost all cases. If no eosinophilia is detected at the initial visit, it may be too early in the acute infection; a repeated cell blood count 3 to 5 days later will detect a significant increase in the eosinophil count. Absence of persistent eosinophilia reduces the suspicion for acute infection. In summary, acute fascioliasis is a clinical syndrome similar to acute cholecystitis with significant eosinophilia.

The acute phase presents itself with subcapsular hematomas, hepatic cysts, residual hepatic calcifications, and severe anemia. Hyperbilirubinemia is absent in the acute phase (Marcos et al, 2008b), which distinguishes it from other forms of acute hepatitis. Other manifestations are anorexia, weight loss, nausea, vomiting, cough, diarrhea, urticaria, lymphadenopathies, and arthralgias (Marcos et al, 2005c). Occasionally, the juvenile larvae reach other anatomic locations, such as the subcutaneous tissue, pancreas, eye, brain, and stomach wall, among others (Rana et al, 2007).

CHRONIC INFECTION

The chronic phase begins approximately 3 to 6 months after the consumption of the metacercariae, when the parasite reaches the bile ducts. By macroscopic examination, the liver has large, dilated, thick-walled, and calcareous bile ducts with yellowish brown bile. By microscopic examination, the bile ducts have a thickened hyperplastic wall with marked fibrosis (Haridy et al, 1999; Marcos et al, 2007c). Symptoms usually reflect biliary obstruction with colicky pain in the right upper quadrant, epigastric area, or upper abdomen (Rana et al, 2007; Maco et al, 2003; Jimenez et al, 2001). It can also be a silent, potential threat: the parasites can survive for longer than 10 years, and infection is commonly asymptomatic (Marcos et al, 2004).

Liver function tests during this phase are consistent with an extrahepatic cholestasis syndrome (Dobrucali et al, 2004) that can lead to surgery to treat the biliary obstruction (Jimenez et al, 2001). Moreover, an increase in liver enzymes can be present with minimal symptoms in endemic areas. In Egypt, it was found that patients with fascioliasis had significant liver enzyme abnormalities: elevation of alanine aminotransferase in 21.5% of the patients, aspartate aminotransferase in 21.9%, total bilirubin in 16.5%, gamma-glutamyltransferase in 80.6%, and alkaline phosphatase in 76.4% was reported. Excluding viral liver infections, *F. hepatica* infection is a significant cause of cholestasis in endemic areas ($P < .05$) (El-Shazly et al, 2005).

Imaging abnormalities were also found on ultrasound (US), including hepatomegaly, splenomegaly, periportal fibrosis, thickened gall bladder wall, dilated common bile duct, parasites in the gallbladder and common bile duct, stones in the gallbladder, stones in bile duct, cystic lesions in the liver, focal lesions in the liver, and ascites (El-Shazly et al, 2001).

Fasciola may also cause acute eosinophilic cholecystitis (Umac et al, 2006) along with pruritus and intermittent jaundice (Umac et al, 2006; Marcos et al, 2002). The parasites appear as small intrahepatic cystic lesions (Aroonroch et al, 2006) or as a large, multiloculated cyst that causes abscesses. On imaging parasites may appear very similar to echinococcosis (Maeda et al, 2008). Bacterial superinfection of *Fasciola* cysts is a complication of the chronic phase. Recent studies in a rat model have shown a significantly increased risk of bacterobilia in the chronic infection (Valero et al, 2006) and with gallstones (Valero et al, 2003). Even after successful treatment, abdominal pain and weight loss may still be present in approximately 2% to 4% of patients for several months (Rondelaud et al, 2006), and morbidity in these patients is significant.

Eosinophilia is absent in approximately half of the chronic cases. Upon admission to a tertiary health center, 47% of 277 complicated cases had eosinophilia (Blancas et al, 2004). A similar percentage was found in 101 chronic cases from the Andean region and other endemic areas: 48% had eosinophilia above normal levels, and only 14% had more than 1000

eosinophils/mL (Alban et al, 2002). In another study, about half of a group of 61 children in the Peruvian Altiplano with chronic fascioliasis had eosinophilia (Marcos et al, 2002). In Turkey, two (11%) of 18 subjects with fascioliasis had eosinophilia (Turhan et al, 2006).

Eosinophilia is present in a minority of cases of fascioliasis in the chronic phase. If present, it is generally mild (Gil-Gil et al, 2006). Few cases in the chronic phase have high-grade eosinophilia, in contrast with the acute phase, which presents with hypereosinophilia in almost all cases. Finally, a wide variety of other infectious agents are associated with eosinophilia, such as *Strongyloides stercoralis, Ascaris lumbricoides,* and hookworms or other helminths. Despite the fact that these are the most common parasitic causes of eosinophilia, they do not typically cause hepatic lesions, nor do they reach the high levels that we observe in patients with acute fascioliasis.

Another presentation of the chronic infection is hemobilia as a result of ulcerative lesions in the biliary tract caused by the adult parasite (see Chapter 105; Bahçecioglu et al, 2007). A granulomatous chronic inflammation may also be triggered by parasite ova in the liver or in other anatomic locations (Marcos & Terashima, 2007; Naresh et al, 2006). New data developed in an animal model have demonstrated a persistent immune suppression in advanced chronic infection (Gironès et al, 2007), suggesting that the infected host may be susceptible during the chronic phase to any Th2-suppression–dependent infection. Hence, a chronic immunosuppression may predispose to bacterial infection that can be life threatening.

An association exists between fascioliasis and liver fibrosis. It appears that hepatic fibrosis may evolve in some susceptible hosts, depending on the time and burden of infection. For instance, almost 50% of cattle infected chronically by fascioliasis had cirrhosis (Marcos et al, 2007c). In addition, hepatic cirrhosis has been reported in infected children (Almendras-Jaramillo et al, 1997; Marcos et al, 2005a) and adults (Heredia et al, 1984; Sanchez-Sosa et al, 2000), especially those with high-density infections. New data on the pathogenesis of hepatic involvement associated with *F. hepatica* infection have implicated cathepsin L1 and its collagenolytic function associated with tissue-invasion (Stack et al, 2007), with proteolytic activity leading to collagen type I expression and ultimately to hepatic fibrosis. The chronic infection can also have a negative impact on the nutrition and health of children in endemic areas.

Imaging Studies

The most common imaging findings in fascioliasis are summarized in Table 45.3.

ABDOMINAL ULTRASOUND. Findings in the acute phase include focal areas of increased echogenicity, multiple nodular or irregular lesions of variable echogenicity, or a single, complex mass in the liver that resembles malignancy mimicking malignancy (Cosme et al, 2001, 2003). In frequent travelers, an abnormal liver US showing a complex cystic lesion warrants a workup for fascioliasis or other parasitic disease, such as echinococcal infection. In the chronic phase, US is even less specific, although the adult parasites can be visualized in the gallbladder (Bonniaud et al, 1984; Kabaalioglu et al, 1999; Gonzales-Carbajal et al, 2001). Overall, the detection rate is extremely low if used as the sole diagnostic tool. For instance, of 76 subjects with chronic fascioliasis evaluated by means of abdominal US, only 11 patients (14%) had visualized parasites, and in only two cases (2.6%), the parasites were spontaneously moving into the gallbladder. Therefore, the detection-rate of *F. hepatica* chronic infection by US is disappointingly low (Richter et al, 1999) and not specific (Turhan et al, 2006).

COMPUTED TOMOGRAPHY. The most common computed tomography (CT) findings include multiple hepatic metastasis-like lesions that change in position, attenuation, and shape over time (Marcos et al, 2008). Initial lesions may be easily confused with hepatic metastases. Other findings are hepatomegaly, tract-like hypodense lesions with subcapsular location, subcapsular hematoma, and cystic calcifications (Marcos et al, 2008; Loja et al, 2003). The hepatic lesions correlate with the time of infection. Early infection is associated with contrast enhancement of the Glisson capsule as a result of inflammation stimulated as the juvenile parasite penetrates the liver capsule. This occurs in the early stage of the acute infection (first month of infection). In the intermediate stage (after the first month), multiple hypodense nodular areas (abscesslike lesions) or low-density serpiginous, tortuous, tunnel-like branching lesions that range from 2 to 10 mm are created by parasite migration through the liver and are typically visualized in the subcapsular region (MacLean & Graeme-Cook, 2002; Gonzalo-Orden et al, 2003). In the late stage (≥3 months), a necrotic granuloma is seen that appears as a single, non–contrast-enhanced hypodense irregular mass in the liver parenchyma, more central than peripheral (Kim KA et al, 1999; Noyer et al, 2002). Finally, part of the differential diagnosis of liver calcification is fascioliasis, which generally means an old infection of at least 6 months' duration. Although the characteristics of these cyst calcifications seem to be unique to fascioliasis, this finding adds a new agent to the list of infectious diseases associated with tissue calcifications, such as echinococcosis, paragonimiasis, histoplasmosis, toxoplasmosis, and others.

MAGNETIC RESONANCE IMAGING (MRI). Only a few cases visualized on MRI imaging have been reported. T2-weighted turbo spin-echo MRI showed a homogeneous hyperintense area in a subcapsular location containing multiple hypointense areas. A T1-weighted three-dimensional gradient-echo image displayed homogeneous contrast enhancement (Orlent et al, 2007). The hypodense lesions observed in the CT scan are of hypointense signal in T1-weighted imaging and hyperintense in T2 (Kabaalioglu et al, 2000; Aksoy et al, 2006).

Diagnosis

The diagnosis of the acute phase of fascioliasis is confirmed by serology or response to therapy. Accurate identification of early disease has been difficult because of the lack of a confirmatory test; the serologic test that requires medium-high technology is not available in most endemic areas. Nonetheless, if the pretest probability or clinical suspicion is unequivocally high, an antiparasitic trial is warranted. Diagnostic criteria are significant clinical improvement and decreasing levels of eosinophils in the 3 to 5 days after a trial of triclabendazole (Marcos, 2008b). The results of the serology and stool sampling, the possible stage of the infection, and the clinical significance are illustrated in Figure 45.4.

ACUTE PHASE. Among the serologic tests developed in the last few years, an enzyme-linked immunoabsorbent assay (ELISA) detects the antibodies against cathepsin L1 and is highly

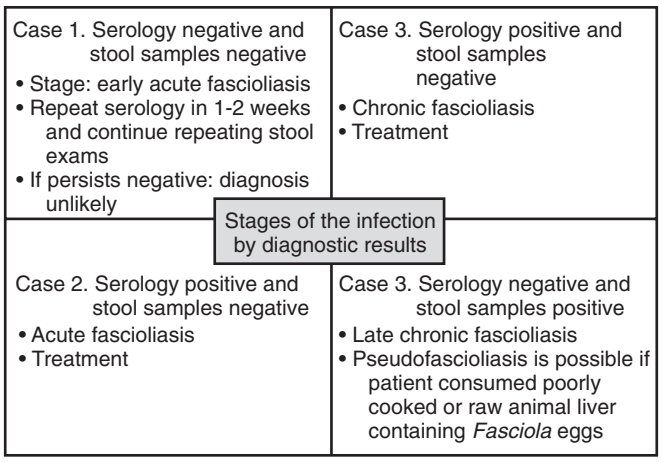

FIGURE 45.4. Most common possible scenarios of diagnostic results in fascioliasis. Cases 2 and 3 are the most common found in clinical practice. Cases 1 and 4 are uncommon.

sensitive and specific for the acute phase of fascioliasis. It is also called *Fas2-ELISA* (cathepsin L1–based antibody), and it is more specific than Western blot and Arc II (Espinoza et al, 2005, 2007). This ELISA has been tested in 634 infected children from endemic areas in Peru and has been found to have a sensitivity of 92.4% and a specificity of 83.6%, with a negative predictive value of 97.2% (Espinoza, 2007). Acute *F. hepatica* infection must be considered in patients with eosinophilia, prolonged fever, abdominal pain, multiple hepatic abscesses, or metastases-like lesions in the peritoneum or liver before starting multiple diagnostic tests. Recognizing the clinical scenario early may allow timely and noninvasive identification of this infection.

CHRONIC PHASE. The gold standard test for the chronic infection is the visualization of the parasite eggs in the stool of the host. A serologic test is used when an adequate stool test is persistently negative despite a high pretest probability. A sedimentation technique must be performed on serial stool specimens (at least three) from different days to increase the likelihood of detecting the eggs in the stools, and an experienced technician is required. The intermittent deposition of parasite ova in the biliary duct can decrease the sensitivity of the sedimentation technique. Again, a high pretest probability warrants a trial of triclabendazole. The sedimentation technique that can be performed in any laboratory in the world is the rapid sedimentation technique (RST) described by Lumbreras and colleagues (1962) in Peru. This test is inexpensive, easy to perform, and highly sensitive, with a higher sensitivity than the ether-formalin concentration method (Marcos et al, 2007a). The Kato-Katz technique may be used to measure the intensity of infection (Katz et al, 1972), and it can be also helpful for the diagnosis.

***Fasciola* and Liver Fibrosis.** *F. hepatica* infection causes bile duct hyperplasia (Hamir & Smith, 2002), increased levels of proline (Campbell et al, 1981; Wolf-Spengler & Isseroff, 1983), and type I and III collagen in the liver (Mark & Isseroff, 1983); these anomalies are similar to the progression observed in cirrhosis and other pathologic conditions, including wound healing. However, few studies have attempted to identify factors associated with liver fibrosis, which is a significant clinical outcome of the infection (Marcos et al, 2007c; Perez et al, 1999; Phiri et al, 2006; Shirai et al, 2006). In addition, liver cirrhosis has been reported in both children and adults with fascioliasis (Almendras-Jaramillo et al, 1997; Heredia et al, 1984; Marcos et al, 2005a; Sanchez-Sosa et al, 2000). In cirrhotic patients in an endemic country, 9.1% were positive for Fas2-ELISA (Marcos et al, 2009b). In conclusion, the chronicity of the infection can lead to liver fibrosis.

DIAGNOSIS OF FASCIOLIASIS BY SURGERY. In the cases reported in the literature, the majority that underwent a surgical or invasive procedure were patients in the chronic phase of the infection whose initial clinical problem was biliary obstruction and choledocholithiasis (Kim et al, 2006). The detection rate of the adult parasite in operations of the biliary tract is low. In a series of 162 cases of cholecystectomy in an endemic area, only 1.2% had *F. hepatica* in the gallbladder (Alban et al, 2002); however, several cases have been diagnosed in the operating room incidentally.

Because the chronic phase may be seen with or without very mild eosinophilia, a high level of suspicion should always be maintained in cases of biliary obstruction in endemic areas or in immigrants or travelers from endemic areas. Nine cases have been diagnosed and managed by endoscopic retrograde cholangiopancreatography (ERCP), and only two had mild eosinophilia (Bahçecioglu et al, 2008; Diaz Fernandez et al, 2005; Gulsen et al, 2006). A single dose of triclabendazole must be given after the procedure to ensure elimination of any parasites missed by endoscopy or remaining in other anatomic locations. The adult parasite can also be found during an elective laparoscopic cholecystectomy (Bulbuloglu et al, 2007).

Even in highly endemic areas, the diagnosis can be missed initially, and cases of parasites accidentally obstructing percutaneous biliary drainage catheters have been reported (Maco et al, 2003). Clinical judgment is mandatory when biliary obstruction is associated with cholangitis that requires surgical intervention. In cases of biliary obstruction, both surgical intervention to manage the obstruction and antiparasitics are the cornerstones in the treatment when clinically indicated.

Interestingly, fascioliasis can be misdiagnosed as echinococcal because the former may have a strong cross-reactivity in the ELISA. Patients may end up with surgical intervention to remove the pseudocyst of *Echinococcus*, when parasites of *F. hepatica* were causing an intrahepatic cyst (Das et al, 2007). In other situations, adult parasites were found when trying to remove a possible malignancy or metastasis-like lesion from the colonic wall (Makay et al, 2007), neck (Marcos et al, 2009a), epidural space (Vatsal et al, 2006), eye (Dalimi & Jabarvand, 2005), and breast (Naresh et al, 2006).

When fascioliasis affects the pancreatic duct (Parsak et al, 2007), the management, either surgical or conservative, should be individualized. However, when indicated, drainage can be a reasonable approach, followed up by a trial of triclabendazole with antispasmodics to reduce the severe abdominal pain experienced after the death of the parasite. Complications such as pancreatic duct obstruction and consequent pancreatitis may be life threatening, but they are rare (Echenique-Elizondo et al, 2005).

In cases of cholangitis (Ait Ali et al, 2002), emergent percutaneous drainage is recommended, because despite the antiparasitic medication, the dead parasites will remain in the biliary duct for a few days before being released, thus interrupting the

drainage through the ampulla of Vater. The most common organisms identified in an animal model were *Escherichia coli* (45%), *Enterococcus faecalis* (45%), and *Klebsiella pneumonaie* (10%) (Valero et al, 2006). No data in humans are available, but the fact that *E. faecalis* is present in almost half of the cases of bacterobilia in the animal model should be taken with special consideration for antibiotic choice. It is recommended that a single antibiotic be given, such as a β-lactam/lactamase inhibitor for mild to moderate infection or a carbapenem for severe infection. A combination therapy of cephalosporin or fluoroquinolone is also acceptable. Ideally, antimicrobial therapy should be adjusted according to the organism identified, with susceptibilities to common antimicrobials.

The literature reveals several diagnoses of fascioliasis that have been made in the operating room. Although an uncommon presentation in a nonendemic area, lack of familiarity by the clinician can underestimate the impact of fascioliasis.

In summary, a patient who comes from endemic areas and who presents with a clinical picture similar to acute cholecystitis, normal US, or abscesslike lesions by imaging, the diagnosis of fascioliasis should be considered. Furthermore, during a diagnostic laparoscopy, metastatic-like liver lesions with eosinophilia are strongly suggestive of acute fascioliasis.

Treatment

Triclabendazole is the treatment of choice for both phases of *Fasciola* infection (Keiser & Utzinger, 2007a). The cure rate exceeds 90% for acute stages after a single dose of 10 mg/kg (Marcos et al, 2009), and similar results have been obtained in the therapy of chronic infection (Apt et al, 1995; Talaie et al, 2004; El-Tantawy et al, 2007). This drug has a better absorption with a fatty meal, and the most frequent adverse event is biliary colic caused by the passage of dead or dying parasites through the bile ducts. Triclabendazole was introduced in the early 1980s for the treatment of *F. hepatica* infections in livestock, and it has been placed on the WHO List of Essential Medicines (http://www.who.int/medicines/publications/essentialmedicines/en/) because of its efficacy and cost effectiveness.

Treatment of fascioliasis with triclabendazole was shown to reduce the prevalence significantly, from 5.2% to 1.2% in 7 years (Abdussalam et al, 1995). However, the intensive use of triclabendazole has resulted in the development of resistance in animals (Mottier et al, 2006; Alvarez-Sanchez et al, 2006). On the other hand, in places where triclabendazole for humans is not available, the veterinary form can be effective as well. In Peru, a single dose of 10 mg/kg cured 96%, whereas 10 mg/kg for 2 days cured 100% with no major adverse effects registered (Terashima et al, unpublished data). The most important adverse effect was abdominal pain or biliary colic during the first week of treatment. This pain is likely caused by the passage of dead or dying parasites through the bile ducts (Millan et al, 2000; Richter et al, 1999). Antispasmodics may decrease or completely alleviate the transitory episodes of abdominal pain and should be used in most cases at the beginning of the therapy or even before the first dose.

A single dose of triclabendazole is effective and tolerable, without major side effects, and it may also be used as a diagnostic tool (Marcos et al, 2007c). However, given the unlikelihood of any new drugs against *F. hepatica* being developed in the foreseeable future, the emergence of resistance represents an important threat (Alvarez-Sanchez et al, 2006), although resistance in humans has not been reported.

Many years ago, parenteral dehydroemetine at doses of 1 mg/kg for 10 days was used. Then, bithionol was applied at doses of 30 to 50 mg/kg every third day for a total of 10 to 15 doses, although it is cardiotoxic and very expensive. Other drugs, such as nitazoxanide, have been evaluated for fascioliasis, but cure rates have been disappointingly low. Adult patients who received a 7-day course of nitazoxanide had a cure rate of 60%, but the rate was only 40% in children (Favennec et al, 2003). Because of this, and because of the increasing triclabendazole resistance in animals, new drugs have been evaluated and tested in animals with fascioliasis. For instance, artesunate, artemether, and OZ78 have fasciocidal properties in animals, and they are promising drugs for the near future, should resistance to triclabendazole become a problem (Keiser et al, 2007a, 2009). Albendazole, metronidazole, and praziquantel are not recommended for fascioliasis treatment.

Future Directions and Vaccines

Because fascioliasis constitutes a major economic impact, development of effective vaccines would be an important advance. Preliminary studies in animals have reported significant advances (McManus & Dalton, 2006; Spithill & Dalton, 1998). Cysteine proteinases released by *F. hepatica* play a key role in parasite feeding and migration through host tissues and in immune system evasion. A recombinant cysteine proteinase (CPFhW) expressed as inclusion bodies in *E. coli* was used for enteral vaccination of rats against fascioliasis. In that study, oral vaccination reduced the parasite burden by 78% to 80% after a challenge with metacercariae (Kesik et al, 2007). The glutathione transferase superfamily (GST) from liver fluke plays phase II detoxification and housekeeping roles and has been shown to contain protective vaccine candidates (Chemale et al, 2006). Promising future research will yield meaningful immunologic targets to prevent the infection, especially in the well-recognized endemic areas and particularly in children, but so far the vaccines are targeted only to animals.

Clonorchiasis and Opisthorchiasis

Liver fluke infection caused by trematodes belonging to the family Opisthorchiidae—*Opisthorchis viverrini*, *O. felineus*, and *Clonorchis sinensis*—is a major public health problem in many parts of the Far East, Southeast Asia, and Eastern Europe. Clonorchiasis is an infection caused by *Clonorchis sinensis*, the Chinese or Oriental liver fluke, whereas opisthorchiasis is caused by *O. viverrini* and *O. felineus* (class Trematoda). Migration and global tourism are responsible for cases diagnosed in areas where the disease is not endemic.

C. sinensis and *O. viverrini*, small Asian liver flukes 8 to 15 mm in length, are very similar in adult morphology and genetics but differ in geographic distribution (Park, 2007). There are 601 million and 79.8 million people at risk of infection with *Clonorchis* and *Opisthorchis*, respectively, and *C. sinensis* is endemic in northeast China, southern Korea, Japan, Taiwan, northern Vietnam, and the far eastern part of Russia (Rim, 2005), and *O. viverrini* is endemic in Laos, Thailand, Vietnam, and Cambodia. *O. felineus* infection is the most prevalent foodborne liver fluke infection of humans in Russia, Ukraine, and Kazakhstan. In Thailand, approximately 6 million people are infected with *O. viverrini* (Kaewpitoon et al, 2008). In China, *Clonorchis* infections have more than tripled over the last decade, with 15 million people infected in 2004 (Lun et al, 2005).

Similar to fascioliasis, the geographic pattern of these small flukes is not uniform. For instance, in Thailand, the greatest prevalence of opisthorchiasis is in the north (19.3%) and northeast (15.7%) compared with the central (3.8%) and southern regions (0%). In general, the infection is acquired by eating raw or uncooked cyprinoid fish products in rural areas or dishes such as koi-pla (Sayasone et al, 2007). Some cases are commonly documented in North America, mainly imported by Asian immigrants.

Life Cycle

Fish-borne trematodes have a complicated life cycle with two intermediate hosts. Starting from a human host, the adult worms deposit fully developed eggs; the eggs are then passed to the environment through the feces, and they must get into water to hatch and to infect their first intermediate host, a freshwater snail. After being ingested by a suitable snail, the eggs release miracidia, which undergo several developmental stages in the snail: as sporocysts, redia, and cercaria. The snail intermediate hosts for *Opisthorchis* are *Bithynia goniompharus, B. funiculata, and B. siamensis. Parafossarulus manchouricus* often serves as a first intermediate host for *C. sinensis,* and snail hosts also include other *Bithynia*, *Tarebia*, *Alocinma,* and *Bulimus* species. Once inside the snail's body, the miracidium hatches from the egg and parasitically grows inside of the snail, where it develops into a sporocyst that houses the asexual reproduction of redia, the next stage. The redia themselves house the asexual reproduction of free-swimming cercaria. This system of asexual reproduction allows for an exponential multiplication of cercaria individuals from one miracidium. Once the redia mature, having grown inside the snail body until this point, they actively bore out of the snail body into the freshwater environment and seek out fish. Cercariae are released from the snail and then penetrate freshwater fish—the second intermediate host (*Cyclocheilichthys* and *Puntius* spp., *Hampala dispar*), encysting as metacercariae in the muscles or under the scales. Once inside the fish muscle, the cercaria creates a protective metacercarial cyst with which to encapsulate their bodies. This protective cyst proves useful for when the fish muscle is consumed by a human or other host, such as a cat, dog, pig, or any other fish-eating mammal. The acid-resistant cyst enables the metacercariae to avoid being digested by the gastric acids and allows them to reach the small intestine unharmed.

Reaching the small intestine, the metacercariae navigate toward the human liver—the final habitat. In contrast with the larger *F. hepatica* fluke, metacercariae of *Opisthorchis* and *Clonorchis* migrate through the ampulla of Vater after excysting in the duodenum; they then travel into the bile ducts, where they mature into adult worms within 4 weeks and deposit yellow, operculated eggs. The parasites may live for up to 45 years in the liver of a human host, producing 1000 to 2500 eggs per day. The adult flukes, measuring 10 to 25 mm by 3 to 5 mm, reside in medium-sized and small intrahepatic bile ducts and, occasionally, in the extrahepatic bile ducts, gallbladder, and pancreatic duct.

Clinical Manifestations

Clonorchiasis and opisthorchiasis infections are associated with a number of hepatobiliary diseases but mainly with disease in the biliary tract, because these flukes do not penetrate the liver parenchyma as they do in fascioliasis. The frequency and types of pathology and clinical disease seem to differ for *C. sinensis* and *O. viverrini*. For example, cholelithiasis is one of the more serious complications of clonorchiasis but is a rare complication of opisthorchiasis. In both species the prominent inflammatory process within the biliary tract is the main pathologic characteristic of these infections that can sometimes lead to cholangiocarcinoma, especially with *O. viverrini*.

Flukes can occasionally gain access to the pancreatic tract, where they can cause obstruction and pancreatitis. The pathologic and clinical consequences of opisthorchiasis are related to the intensity and duration of cumulative infections. Because adult flukes are long lived, they can produce eggs and symptoms long after the human host has emigrated from the area. Most people with these Asian fluke infections have no symptoms, and only 5% to 10% of those heavily infected have nonspecific chronic symptoms such as right upper quadrant abdominal pain, flatulence, and fatigue. Cholangiocarcinoma is a known complication.

***Clonorchis sinensis*.** Acute infection by *C. sinensis* is usually asymptomatic, but some patients may have fever, rash, malaise, and right upper quadrant abdominal discomfort. Chronic infection reflects the worm burden and may appear as recurrent pyogenic liver cholangitis (see Chapters 43 and 44), cholecystitis (see Chapter 31), obstructive jaundice, hepatomegaly, cholecystitis, multiple hepatic tumours (Liao et al, 2006), and cholelithiasis (Park & Son, 2008; Stunell et al, 2006). An association between clonorchiasis and cholangiocarcinoma has also been reported (Choi et al, 2006). Severe *C. sinensis* infection is a significant risk factor for malignant changes in bile ducts and surrounding liver tissues occurring as a result of direct contact with *C. sinensis* worms and their excretory-secretory products.

***Opisthorchis viverrini*.** In acute *O. viverrini* infection, only 5% to 10% of heavily infected patients have nonspecific symptoms, such as right upper quadrant abdominal pain, flatulence, fatigue, and a hot sensation over the abdomen. In the chronic phase, mild hepatomegaly occurs, mainly in more heavily infected patients (egg counts >10,000 eggs/g). Jaundice and splenomegaly are not observed, but intrahepatic duct stones and recurrent suppurative cholangitis are common manifestations of opisthorchiasis. Whenever jaundice and ascending cholangitis are detected, fluke-related cholangiocarcinoma should be suspected.

***Opisthorchis felineus*.** Infection with *O. felineus* usually follows consumption of raw, slightly salted, and frozen fish ("stroganina"). Acute symptoms occur 2 to 4 weeks after eating raw fish. These include high-grade fever, nausea, vomiting, abdominal pain, malaise, arthralgias, lymphadenopathy, and skin rash (Tselepatiotis et al, 2003). Peripheral eosinophilia is a common finding, especially during the first 2 to 6 weeks of the infection, together with raised liver enzymes. In chronic infection, eosinophilia is usually milder, but patients may present with suppurative cholangitis and liver abscess as a result of biliary obstruction.

Consequences of Chronicity of Infection

Carcinogenesis associated with helminth infections is a complex process that may involve several different mechanisms, but chronic inflammation is a key feature. The human liver fluke *O. viverrini* infects millions of people throughout Southeast Asia and is a major cause of cholangiocarcinoma, or cancer of the

bile ducts. The mechanisms by which chronic infection with *O. viverrini* results in cholangiocarcinogenesis are multifactorial, but one such mechanism is the secretion of parasite proteins with mitogenic properties into the bile ducts, driving cell proliferation and creating a tumorigenic environment. A possible pathway for the development of cholangiocarcinoma is the presence of Ov-GRN-1, a major growth factor present in *O. viverrini* excretory-secretory products that induces proliferation of host cells, which supports a role for this fluke protein to establish a tumorigenic environment.

In general, these flukes cause inflammation around the biliary tree that leads to severe hyperplasia of epithelial cells, metaplasia of mucin-producing cells in the mucosa, and progressive periductal fibrosis. There are clear associations between *O. viverrini* infection and cholangiocarcinoma in the context of the intensity of infection, parasite-specific antibody response, and abnormalities of the biliary tract.

The higher the intensity of anti–*O. viverrini* antibody titers, the higher the risk for cholangiocarcinoma (Honjo et al, 2005). The International Agency for Research on Cancer recognizes this parasite as a category I carcinogen. The lesions that predispose to malignant changes in *O. viverrini* are evident as a dilation of subcapsular medium and large bile ducts with a prominent fibrotic wall, periductal inflammatory cell infiltration, goblet cell metaplasia, epithelial and adenomatous hyperplasia, and periductal fibrosis. The pathogenesis of *O. viverrini*–mediated hepatobiliary changes may be due to mechanical irritation or to its metabolic products (Sriamporn et al, 2004). Several N-nitroso compounds and their precursors occur at low levels in fermented food, such as preserved mud fish paste (*pla ra*), a condiment ubiquitous in the cuisine of northeastern Thailand and Laos (Sripa et al, 2007). The study of *O. viverrini* genes should expedite molecular studies of cholangiocarcinogenesis and accelerate research focused on developing new interventions, drugs, and vaccines that might help in controlling *O. viverrini* and related flukes (Laha et al, 2007). Similarly, recent studies show a strong association between *C. sinensis* and the development of cholangiocarcinoma (Choi et al, 2006). For instance, a recent epidemiologic study in Korea correlates the prevalence of *C. sinensis* and the incidence rate of cholangiocarcinoma: *C. sinensis* prevalence was 2.1% in Chuncheon, 7.8% in Chungju, and 31.3% in Haman; cholangiocarcinoma incidence rate was 0.3, 1.8, and 5.5 per 100,000 population, respectively (Lim et al, 2006). Hepatocellular carcinoma also has been associated with clonorchiasis, along with hepatitis B virus and alcohol consumption as cofactors (Tan et al, 2008). It seems plausible that cholangiocarcinogenesis associated with clonorchiasis is the cumulative end result of a multifactorial carcinogenic mechanism, although the mechanisms involved are not completely understood.

Improving diagnosis with new serologic tests may be helpful, but such tests cannot distinguish between recent or past infection. Currently, the Ov-CP-1–based ELISA shows a sensitivity of 95% and specificity of 96% in serum coinfected with hookworm, minute intestinal fluke, *S. stercoralis*, *Taenia* spp., *Giardia lamblia,* and *E. coli* infection (Watthanakulpanich et al, 1997). The sensitivity and specificity are similar to other studies using an ELISA based on recombinant trematode cysteine protease such as *C. sinensis* (sensitivity 81.3% to 96%, specificity 92.6% to 96.2%) (Nagano et al, 2004; Zhao et al, 2004).

Human clonorchiasis and opisthorchiasis are primarily diagnosed by the detection of eggs in feces. The Kato-Katz method is accepted as the best for fecal examination, although sometimes the eggs may not be detected because of biliary obstruction or intermittent egg excretion similar to that encountered with fascioliasis. In light infections, with less than 10 adult worms in the biliary tract, a polymerase chain reaction (PCR) detecting the DNA of the adult parasite in stools may be helpful (Duenngai et al, 2008). Intrahepatic duct dilation is the most common finding on US imaging (76% of patients), and increasing periductal echogenicity and gallbladder sludge are seen only in patients with heavy infection (Choi et al, 2005). Recently, Ruangsittichai and colleagues (2006) reported high sensitivity and specificity using a recombinant eggshell protein with potential for the serodiagnosis of human opisthorchiasis. However, detection of *O. viverrini* DNA is expensive and requires skillful personnel.

Treatment

Praziquantel, a derivative of pyrazino isoquinoline, is the drug of choice for *O. viverrini*, *O. felineus,* and *C. sinensis* treatment. For *O. viverrini*, a single dose (40 to 50 mg/kg) of praziquantel treatment is indicated, with a cure rate between 91% and 97%. For clonorchiasis, the recommended dose of praziquantel is 25 mg/kg three times at 5-hour intervals in 1 day (total dose 75 mg/kg), with a cure rate of 83% to 85% (Rim, 2005).

Future Directions

Opisthorchis and *Clonorchis* are medically important foodborne trematodes endemic in Asian countries, and infection is associated with cholangiocarcinoma and other hepatobiliary diseases. The epidemiology is found in some rural areas because of the tradition of eating raw or uncooked fish products.

Other Parasitosis of the Biliary Tract

Ascaris lumbricoides infections are endemic in tropical countries. *A. lumbrocoides* may occasionally migrate from its normal habitat in the small bowel to other locations, such as the biliary tract or pancreatic duct. Because of the high intensity of infection in endemic areas, *A. lumbrocoides* is more often seen as a clinical picture of jaundice, abdominal right upper quadrant pain, and fever, although it can occasionally cause biliary obstruction and result in obstructive jaundice or pancreatitis.

Occasionally, ERCP may diagnose parasitosis of the biliary tract. For example, of 3548 ERCPs performed for extrahepatic cholestasis, cholangitis, and choledocolithiasis (see Chapters 31, 43, and 44) in a moderate endemic area in Eastern Europe, only 24 (0.66%) were found to show biliary parasitosis, such as hydatid cystic disease (n = 16; see Chapter 68); in addition, 8 showed partial obstruction of the biliary tract, and 8 had ruptured cysts; *F. hepatica* (n = 4) and *A. lumbricoides* (n = 4) were also found. Endoscopic sphincterotomy was performed, after which the choledochus was examined carefully using a balloon catheter and basket procedure. ERCP is very useful in the therapy of biliary parasitic infections. The treatment for *Ascaris* in the biliary tract is elimination of the adult parasite through the endoscope, followed up by a single, oral dose of albendazole (400 mg).

Hepatic hydatid cyst rupture into the biliary tree occurs in 5% to 25% of patients and constitutes the most common complication of hepatic echinococcal cysts (see Chapter 68). In this setting, ERCP plays a pivotal role in the therapeutic management of the disease, even as a definitive therapy in some cases.

However, oral albendazole (400 mg) twice a day can be started prior to the procedure. Typically, the ERCP will show a global dilation of the biliary tree with several laminated defects occupying the distal common bile duct with multiple white germinative membranes; a sphincterotomy will help eliminate the membranes causing the obstruction. The treatment of choice for hepatic echinococcosis usually involves antihelmintic therapy and surgical resection or percutaneous aspiration. However, when hydatid material, comprising daughter cysts and hydatid membranes, is released into the biliary tree through a fistulous tract, an ERCP is mandatory before surgery to ensure the retrieval of hydatid biliary material to treat or prevent biliary obstruction complications, mainly acute cholangitis. Regardless of management, antihelmintic drugs should always be started prior to endoscopic or surgical therapy to inactivate intracystic material and minimize allergic disorders or postoperative recurrence.

CHAPTER 46

Bile duct cysts in adults

Saboor Khan and David M. Nagorney

BILE DUCT CYSTS

Bile duct cysts typically are a surgical problem of infancy or childhood (Altman, 1994); however, in nearly 20% of patients, the diagnosis is delayed until adulthood. Although clinically similar, the presentation and therapeutic strategies for bile duct cysts in adults may differ substantially from those of younger patients. In contrast to the pediatric experience, adult patients have an increased rate of associated hepatobiliary pathology (Nagorney et al, 1984a; Powell et al, 1981; Rattner et al, 1983), and they often are first seen with complications of previous cyst-related procedures (Gigot et al, 1996; Nagorney et al, 1984a; Ono et al, 1982; Todani et al, 1984a). The surgical management of bile duct cysts in adults is thus complicated by coexisting hepatobiliary disease and the added technical difficulties of reoperative biliary surgery. Despite the heterogeneity of the disease and the absence of clinical trials, a consensus on the management of extrahepatic bile duct cysts has been established: excision is best. However, the management of intrahepatic bile duct cysts remains problematic, and the method of choice for reestablishing bilioenteric continuity after excision is debatable. This chapter examines the spectrum of hepatobiliary pathology encountered in adults with bile duct cysts and describes the alternative surgical approaches for managing such patients.

DIAGNOSIS

Classification

Bile duct cysts are classified on the basis of site, extent, and shape of the cystic anomaly of the ductal system. Although the term *choledochal cyst* is often used, *bile duct cyst* is semantically more appropriate because cystic dilation can occur anywhere throughout the biliary ductal system, not just in the common bile duct (choledochus). The first coherent classification of extrahepatic bile duct cysts was proposed by Alonso-Lej and colleagues in 1959. Cysts were classified into three types: *type I* is a fusiform or saccular dilation of the common hepatic and common bile duct, *type II* is a supraduodenal diverticulum of the common hepatic or common bile duct, and *type III* is an intraduodenal diverticulum of the distal common bile duct or choledochocele. Although this classification did not include intrahepatic bile duct cysts, this simple and practical scheme has provided the basis for all other classification systems.

The recognition of intrahepatic bile duct cysts prompted modification of the Alonso-Lej classification system, and in 1958, Caroli and colleagues described the entity of multiple intrahepatic bile duct cysts in the absence and presence of extrahepatic cysts. Although initially described as an entity of multiple saccular dilations of only the intrahepatic ducts, the term *Caroli disease* has been broadly applied to describe any patient with intrahepatic bile duct cysts, regardless of the presence of extrahepatic bile duct cysts or the shape of the intrahepatic cysts (Dayton et al, 1983). Caroli disease represents a spectrum of diseases that may include such variants as cysts with congenital hepatic fibrosis or Grumbach disease (see Chapter 70A; Grumbach et al, 1954). Todani refined the classification system of bile duct cysts by combining the Alonso-Lej classification and the variants of Caroli disease (Todani et al, 1977). The comprehensive Todani classification system is shown in Fig. 46.1.

Matsumoto also modified the Alonso-Lej classification system based not only on the location of the cyst but also on the configuration of cysts (Matsumoto et al, 1977a). To date, clinical management of bile duct cysts is dictated by cyst location, not configuration; therefore there is little clinical rationale for adoption of the more detailed classification scheme (Kamisawa et al, 2005; Komi et al, 1992; Matsumoto et al, 1977b), although further additions to the Todani classification have been suggested (Calvo-Ponce et al, 2008; Conway et al, 2009).

ETIOLOGY

Multiple theories have been proposed to explain the origin of bile duct cysts. The most widely accepted hypothesis is that cystic dilation of the bile ducts is related to an anomalous arrangement of the pancreaticobiliary ductal junction (Babbitt,

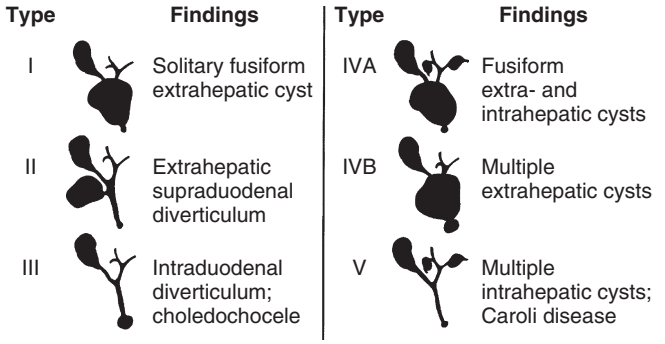

FIGURE 46.1. Classification of bile duct cysts.

1969; Cheng et al, 2004; Komi et al, 1992; Okada et al, 1990; Todani et al, 1984b; Wiedmeyer et al, 1989). The pancreaticobiliary junction is proximal to the sphincter of Oddi (Fig. 46.2) (Nagata et al, 1986). An anomalous pancreaticobiliary junction is often associated with a long common channel that predisposes to reflux of pancreatic juice into the biliary tree, leading to inflammation, ectasia, and, ultimately, to dilation. This postulate has been supported by biliary manometric studies (Iwai et al, 1986), high concentrations of pancreatic enzymes in cyst fluid (Todani et al, 1990), and histopathologic studies of ductal epithelial hyperplasia, round cell infiltration, and marked ductal fibrosis (Oguchi et al, 1988). Moreover, experimental canine studies of pancreaticocholecystostomy and pancreaticocholedochostomy have resulted in cystic dilation of the extrahepatic bile duct (Oguchi et al, 1988; Ohkawa et al, 1981). Pancreaticobiliary maljunction, or *anomalous union*, defined as union of the pancreatic and biliary duct outside of the duodenal wall, has also been implicated in biliary tract cancer even in the absence of a biliary cyst (Funabiki et al, 2009; Horaguchi et al, 2005).

Reports of choledochal cysts of the same type in family members suggest that a hereditary factor may contribute, albeit rarely, to bile duct cysts (Iwafuchi et al, 1990). Finally, oligoganglionosis in the distal neck of the cyst may account for some bile duct cysts. The reduction in ganglion cells in the narrow portion of the cyst wall may be the biliary equivalent of Hirschsprung disease of the colon (Kusunoki et al, 1988).

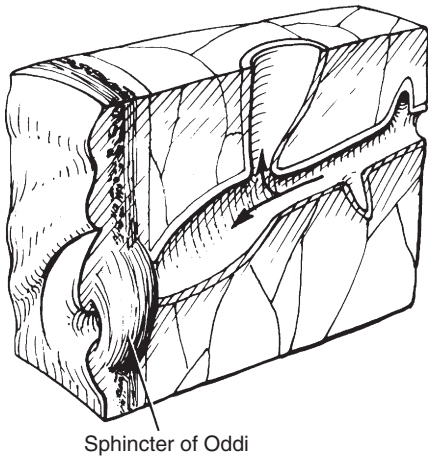

FIGURE 46.2. A long common channel, as shown in this figure of the pancreaticobiliary ductal confluence, is the most accepted cause of choledochal cysts.

DEMOGRAPHICS

Bile duct cysts are an uncommon finding, with fewer than 4000 cases reported (Flanigan, 1975; Powell et al, 1981; Yamaguchi, 1980). Estimates of the actual clinical incidence range from one in 13,000 to one in 2 million patients (Olbourne, 1975), and biliary cysts account for approximately 1% of all benign biliary disease (Saxena et al, 1988). The estimated prevalence of bile duct cysts by type (Todani classification), based on a review of the current literature, is shown in Table 46.1. The true prevalence of bile duct cysts by current classification schemes is underestimated here because classification is often not detailed. The frequency of bile duct cyst in decreasing order is the type I choledochal cyst (79%), followed by type IV (13%), then type III, or choledochocele (4%), and type II (2.6%). Multiple intrahepatic bile duct cysts without an extrahepatic component (Caroli disease) occur in fewer than 1% of all patients with biliary cystic disease. The distribution of cyst types encountered in adults is similar to that in infants and children (Gigot et al, 1996; Nagorney et al, 1984a; Ono et al, 1982), except type IV cysts are more frequent in adults (Todani et al, 1978, 1984a).

A marked population prevalence has been seen in Japan (Flanigan, 1975; Powell et al, 1981; Yamaguchi, 1980), where more than one third of reported cases have occurred. Although the number of reported cases has increased recently, this finding probably reflects advances in diagnosis through improvements in hepatobiliary imaging rather than a true increase in incidence.

A female preponderance among patients with bile duct cysts is well known, regardless of cyst type. In Flanigan's (1975) collected series of 820 cases, 81% of the patients were female. A similar female/male ratio has been found in adults (Powell et al, 1981). Current theories on the pathogenesis of bile duct cysts have not implicated sex hormones or congenital intrauterine endocrine disturbances as possible factors.

CLINICAL FEATURES

Choledochal cysts may remain asymptomatic for many years. Initial clinical presentation in adulthood (age >16 years) occurs in fewer than 20% of all patients with common duct cysts (Flanigan, 1975). Diagnosis may be an incidental finding on imaging studies for unrelated processes. If symptomatic, bile duct cysts usually present with symptoms mimicking calculous biliary tract disease, regardless of cyst type. Symptoms are typically intermittent, recurrent epigastric or right hypochondrial pain, abdominal tenderness, fever, and mild jaundice—the most common initial findings. The pain may radiate to the right infrascapular region or to the mid back, and it generally persists for hours. Abdominal pain or discomfort is often overshadowed by fever and rigors, which may occur repeatedly for several days. An abdominal mass is uncommon in adults; however, if a mass is present, cyst-associated malignancy must be strongly suspected. Biliuria heralds the onset of clinical jaundice. Nausea, vomiting, and anorexia may accompany other symptoms; if cholangitis persists, the jaundice deepens and overt signs of sepsis may evolve.

Approximately 15% of adults with common duct cysts present with overt evidence of cirrhosis or hepatic fibrosis from

chronic biliary obstruction. Such patients typically have had multiple operations for complications of type I or IVA cysts or Caroli disease. Hepatomegaly and splenomegaly are common in patients with cirrhosis and portal hypertension. Hematemesis, melena, and ascites may accompany portal hypertension; however, cholangitis remains the most common initial symptom complex in adults, whether or not cirrhosis is present. Interestingly, other signs of chronic liver disease—muscle wasting, fatigue, spider angiomas, and pruritus—are uncommon. Liver failure is seen late in Caroli disease.

Clinical pancreatitis is present in nearly 30% of patients with choledochal cysts (Nagorney et al, 1984a). In contrast to patients with cholangitis, patients with pancreatitis have more intense and prolonged epigastric pain and vomiting. Fever and jaundice are less prominent. Weight loss, although unusual, is noteworthy because nearly 70% of adults with this finding will harbor an associated bile duct malignancy (see Chapter 50B).

IMAGING

Accurate preoperative diagnosis can be achieved by using the routine diagnostic armamentarium for patients with suspected biliary tract disease: abdominal ultrasonography (US), computed tomography (CT), percutaneous transhepatic cholangiography (PTC), endoscopic retrograde cholangiopancreatography (ERCP), and magnetic resonance cholangiography (MRC) (Fig. 46.3). Current reviews of the diagnostic imaging modalities of bile duct cysts with representative images are referenced (Kim et al, 1995; Savader et al, 1991a, 1991b). Although hepatobiliary scintigraphy has also been useful in identifying bile duct cysts, its value is limited because the information is functional and not anatomic; it is therefore only complementary to US, CT, and direct cholangiography. In general, bile duct cysts are typically recognized serendipitously in adults, unless a past diagnosis had been established before adulthood.

The noninvasiveness and accuracy of US, combined with its ability to image adjacent viscera, support its use as the initial investigative procedure (see Chapter 13). Real-time US is favored because of its speed and ease of application. Moreover, the ability of real-time US to scan multiple planes adds a distinct advantage in defining the extent of the dilation. The sonographic features of choledochal cysts have been well defined for type I choledochal cysts and the variants of Caroli disease (Bass et al, 1977; Morgan et al, 1980; Todani et al, 1978; Young et al, 1990). US of type I cysts simply shows an irregular hypoechoic segmental dilation of the extrahepatic bile duct. Focal duct wall thickening or nodularity should arouse suspicion for cancer in an adult. Stones within the cyst can also be identified by typical

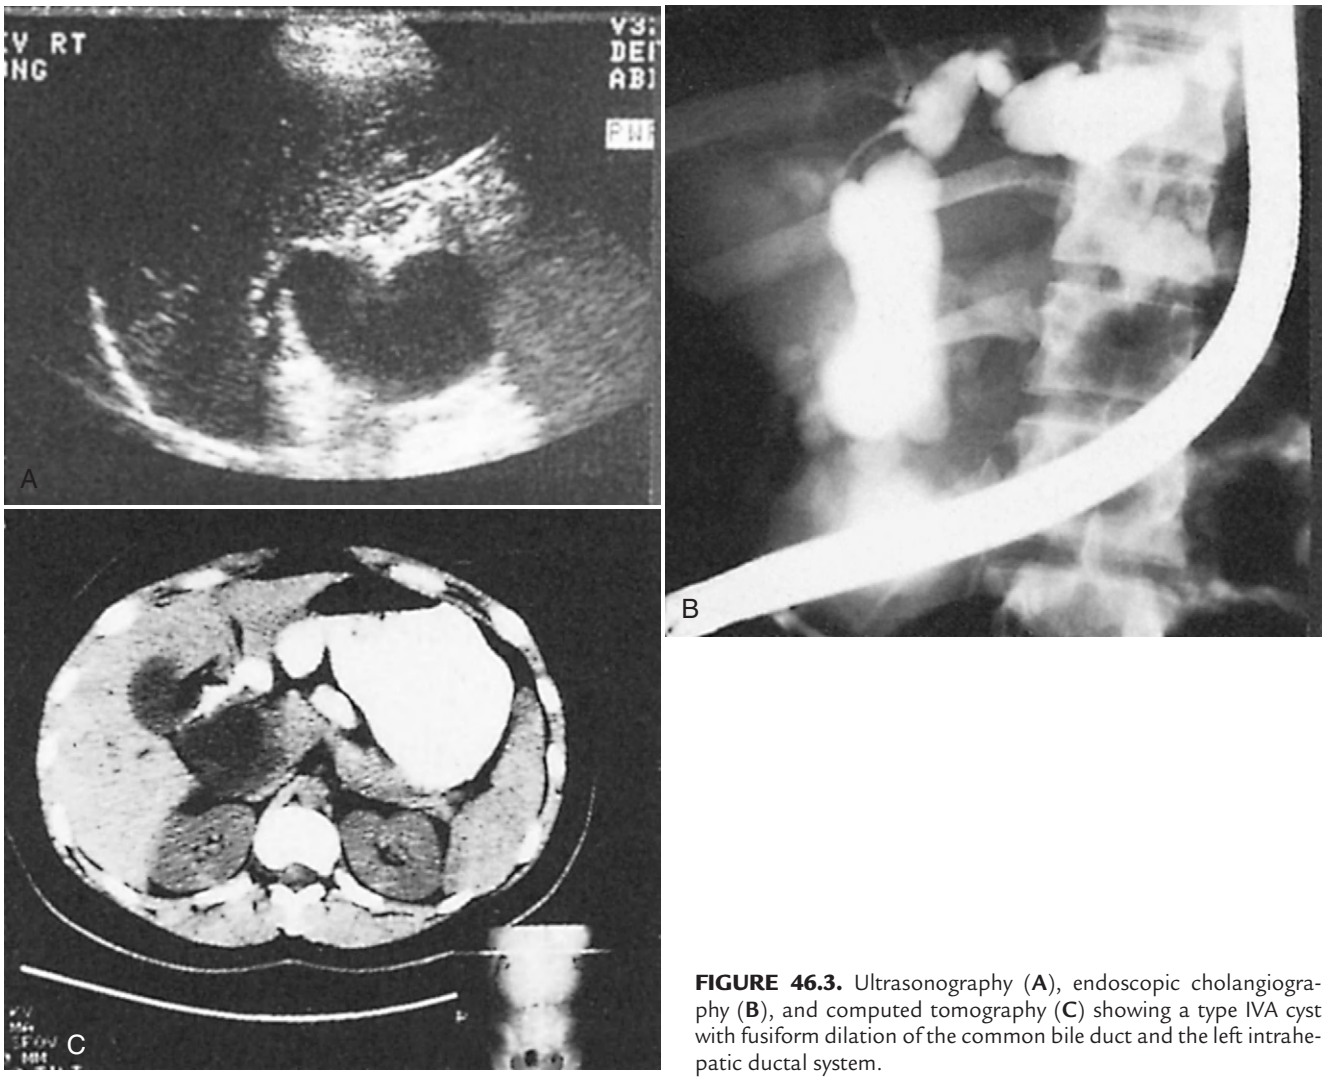

FIGURE 46.3. Ultrasonography (**A**), endoscopic cholangiography (**B**), and computed tomography (**C**) showing a type IVA cyst with fusiform dilation of the common bile duct and the left intrahepatic ductal system.

echogenic features and acoustic shadowing. The absence of septations on US will distinguish choledochal cysts from extrahepatic biliary tumors, such as cystadenomas (Nagorney et al, 1984b). Although the sensitivity of US is excellent for cysts involving the bile duct proximal to the pancreas, US is limited in adults in identifying choledochoceles because of the small size of these cysts and the frequency of bowel gas overlying the terminal common bile duct.

Caroli disease is clinically recognized by multiple cysts adjacent to the major intrahepatic bile ducts on US (Bruneton et al, 1983). Cysts may be unilobar or bilobar, and confirmation of communication of the intrahepatic cysts to the bile ducts can be confirmed by scintigraphy (Sty et al, 1978) or using CT with biliary contrast medium (Musante et al, 1982).

CT combined with intravenous cholangiography is useful for demonstration of cyst communication with the biliary tract (see Chapter 16; Hoglund et al, 1990). Intravenous cholangiography is performed 2 hours before abdominal CT scanning. The sensitivity of CT allows for accurate identification of accumulated contrast material within the cyst, if communication is present, and for accurate definition of the bile duct cyst (Tohma et al, 2009).

Direct cholangiography is the preferred diagnostic modality for accurate definition of the type of choledochal cyst (see Chapter 18). Indeed, cyst classification is based on cholangiographic features (Matsumoto et al, 1977a; Todani et al, 1977). All bile duct cysts communicate with the ductal system. Direct cholangiography is a prerequisite to operation because it has the advantage of being able to define the configuration and extent of the cyst; it also can identify ductal strictures, stones within the biliary and pancreatic ducts, and polypoid filling defects that suggest ductal malignancy. In addition, direct cholangiography is essential in defining the relationship of the distal bile duct in the type I cyst or the extrahepatic component of type IVA cyst to the pancreatic duct. The base of the extrahepatic choledochal cyst typically joins the pancreatic duct 2 to 4 cm proximal to the duodenum (Fig. 46.4), resulting in a long common channel (ampulla) (Jona et al, 1979; Komi et al, 1992; Ono et al, 1982; Rattner et al, 1983). The angle of fusion between the distal bile duct and pancreatic duct varies widely and has led to subclassifications of cyst type (Komi et al, 1992). Anatomic definition of the pancreatic biliary ductal junction is of key importance to avoid intraoperative damage of the pancreatic duct during cyst excision, recognize stones impacted within

FIGURE 46.4. Endoscopic retrograde cholangiopancreatogram shows the most frequent anomaly of the bile duct, cyst, and pancreatic duct anatomy with perpendicular fusion of the distal bile duct or cyst to the pancreatic duct and the presence of a long common channel.

the common channel or junction, and exclude distal tumors. Regardless of method, complete cholangiographic visualization of the entire biliary and pancreatic ductal systems is essential in patients with choledochal cysts because failure to recognize pancreatic duct anomalies or segmental areas of dilation within the liver parenchyma may lead to sepsis, subsequent cholangitis, pain, pancreatitis, and eventual reoperation.

There are advantages and disadvantages of PTC and ERCP for assessing choledochal cysts. Regardless of method, large volumes of radiographic contrast may be required for complete visualization of the bile ducts. Adults without previous cystenterostomy are probably best evaluated by ERCP because it provides better visualization of an abnormal pancreaticobiliary ductal junction (Savader et al, 1991b; Komi et al, 1992). Carcinoma can be excluded by biopsy or brush cytology, and intracystic stones can be extracted after papillotomy to relieve severe cholangitis before surgery. Endoscopy also allows visualization of the esophagus and stomach to exclude signs of portal hypertension. The endoscopist should attempt to examine the ductal bifurcation and the lining of the cyst, if a patent cystoduodenostomy allows introduction of the endoscope into the biliary tree. Endoscopically directed biopsy of intracystic masses should be performed to exclude malignancy. Obstructing balloons should be available to ensure that complete radiographic filling of the biliary tree is possible, especially in patients with prior cystoduodenostomy. Endoscopy of the cyst through a cystenterostomy may also permit diagnosis of intraductal stenoses by membranes or septa at the confluence of the major bile ducts in patients with type IVA cysts (Ando et al, 1995). The procedure of choice for type III cysts or choledochoceles is ERCP because endoscopic papillotomy is potentially therapeutic (Sarris & Tsang, 1989; Venu et al, 1984).

PTC is an effective alternative to ERCP in the diagnosis of choledochal cysts. Because of endoscopic limitations imposed by the Roux-en-Y jejunal limb, PTC is particularly advantageous in patients with previous Roux-en-Y cystenterostomy and in patients with type IV bile duct cysts, in whom ductal strictures or tumors prevent complete visualization of intrahepatic cysts by ERCP (Savader et al, 1991b). The major diagnostic disadvantage of PTC is occasional failure to clearly define the pancreaticobiliary junction. Percutaneous biliary drainage (PBD) may be performed after PTC when indicated for control of biliary sepsis or to aid surgical reconstruction. PTC is particularly limited in patients with a widely patent cystenterostomy or huge extrahepatic cysts, because intracystic contrast is often superimposed over the pancreaticobiliary junction and obscures its radiographic definition.

MRC provides a noninvasive method of imaging the bile ducts and its anomalies (see Chapter 17), and it has been shown to provide an accurate anatomic definition of bile duct cysts in neonates, infants, and young children (Fitoz et al, 2007; Miyazaki et al, 1998). In a recent study, MRC reliably diagnosed biliary cystic disease in 74 (96%) of 76 patients with an accuracy of 86% for ductal anomalies (Park et al, 2005); however, it was less effective in detecting minor ductal anomalies and small cysts (Shaffer, 2006). MRC application to adults can be anticipated because image acquisition in adults is not hindered by the technical difficulties met when performing these studies in children. The limitation of MRC for bile duct cysts has related to its inability to clearly define the pancreaticobiliary junction (diagnostic accuracy, 69%) and its lack of therapeutic capability.

ASSOCIATED HEPATOBILIARY PATHOLOGY

Additional hepatobiliary pathology is frequently associated with bile duct cysts in adults. Cystolithiasis, hepatolithiasis, calculous cholecystitis, pancreatitis, cholangiocarcinoma, intrahepatic abscess, and cirrhosis with portal hypertension are potential problems that may either precipitate or complicate treatment. Although spontaneous perforation of bile duct cysts has been reported in infants and children, that complication has not been recognized in adults (Ando et al, 1998). Studies in adults suggest that nearly 80% of adults with bile duct cysts have complications from one or more of the conditions listed above (Nagorney et al, 1984a; Ono et al, 1982). A recent study suggests that complications in adults may decrease if excision is used routinely in infants and children (Gigot et al, 1996).

Cystolithiasis is the most frequent accompanying condition in adults with bile duct cysts. In contrast to the low prevalence of cystolithiasis in pediatric patients (Flanigan, 1975; Matsumoto et al, 1977a, 1977b; Rattner et al, 1983), the prevalence of intracystic stones has ranged from 2% to 72% in adults (Chijiiwa & Koga, 1993; Nagorney et al, 1984a; Todani et al, 1988). Although their composition has not been analyzed biochemically, most intracystic stones have been described as soft, earthy, and pigmented in appearance, thus supporting bile stasis as a primary etiologic factor (Matsumoto et al, 1977a, 1977b). These stones typically are associated with thick, viscous bile that may form bile duct or cyst casts. Cystolithiasis frequently complicates anastomotic strictures after previous

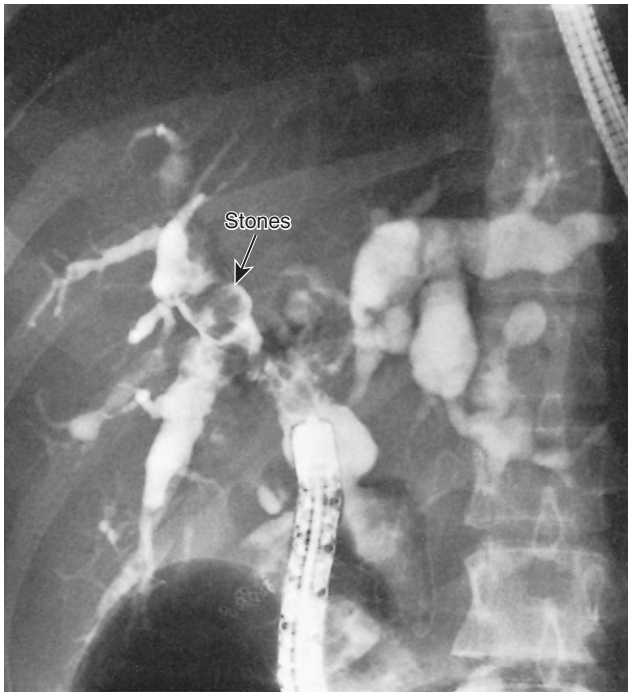

FIGURE 46.5. Endoscopic retrograde cholangiogram of a type IVA bile duct cyst showing multiple intrahepatic stones and a patent choledochoduodenostomy.

cystoenterostomies, which suggests that stasis and infection are major factors contributing to the pathogenesis of these stones.

Hepatolithiasis has been recognized with increasing frequency with long-term follow-up and may occur with or without evidence of anastomotic stricture (Fig. 46.5) (see Chapter 7; Deziel et al, 1986; Gigot et al, 1996; Uno et al, 1996). Some patients will have a complete or partial stricture of the cystenteric anastomosis, and hepatolithiasis develops as a consequence of proximal bile stasis or migration of intracystic stones. Hepatolithiasis usually occurs in type IV bile duct cysts. A recent study has shown that more than 80% of type IV bile duct cysts are associated with either a membranous or septal stenosis of the major lobar bile ducts near the confluence (Ando et al, 1995). Stenosis of the major ducts should be assessed in all patients with hepatolithiasis. Intrahepatic stones may be sequestered in segmental ducts, leading to further localized intrahepatic ductal dilation or subsequent intrahepatic abscess formation.

Gallbladder disease is a frequent complication for patients with bile duct cysts. Gallbladder disease can occur de novo, leading to the incidental discovery of bile duct cysts, or it can evolve after treatment for bile duct cysts. In particular, a gallbladder that is not excised as part of the initial treatment for symptomatic bile duct cysts is frequently a subsequent source of biliary tract disease. Both acute and chronic cholecystitis, with or without stones, has been recognized in these patients. Similar to stones within cysts, stones in noncystic portions of the bile duct are typically bilirubinate in appearance. Stasis is probably the primary etiologic factor in such cases.

The association of pancreatitis with choledochal cysts is a well-recognized entity, particularly in adults (see Chapter 53). The prevalence has ranged from 2% to 70% (Lipsett et al, 1994; Nagorney et al, 1984a; Okada et al, 1990; Rattner et al, 1983; Swisher et al, 1994). The true incidence of pancreatitis is difficult to determine because the diagnosis is based on the clinical findings of epigastric pain, nausea and vomiting, and hyperamylasemia. Another clinical condition, the common channel syndrome (Jona et al, 1979) or pseudopancreatitis (Todani et al, 1990), may mimic these findings completely, thus overestimating the true incidence of pancreatitis. Whether differentiation between these two entities has clinical or therapeutic significance is unclear. Pancreatitis associated with bile duct cysts typically is mild. The pattern of pancreatitis is acute and often relapsing, but objective pancreatic dysfunction seldom occurs. Chronic pancreatitis associated with bile duct cysts is rare.

The pathogenesis of pancreatitis in patients with choledochal cysts is primarily related to the anomalous pancreaticobiliary ductal anatomy and the presence of cystolithiasis or cholelithiasis. Several authors have confirmed that the base of the extrahepatic cyst or distal common bile duct in type I or IV cysts joins the main pancreatic duct more proximally than normal, resulting in a long common channel (Jona et al, 1979; Nagorney et al, 1984a; Ono et al, 1982; Rattner et al, 1983; Swisher et al, 1994). Obstruction of the pancreatic duct at the pancreaticobiliary junction or distally in the common channel (ampulla) by stones is postulated as the precipitating factor. A few studies (Nagorney et al, 1984a; Rattner et al, 1983) have shown an association between biliary tract stones in patients with choledochal cysts and pancreatitis, and stone impaction within the pancreaticobiliary junction may cause pancreatitis (Fig. 46.6). An alternative mechanism for pancreatitis is bile reflux into the pancreatic duct (Okada et al, 1983; Swisher et al, 1994); although the anatomy of the pancreaticobiliary ductal system is conducive to bile reflux, little evidence is available to support this theory. Some patients with bile duct cysts and pancreatitis have normal pancreaticobiliary anatomy (Swisher et al, 1994), and some patients with choledochoceles also may have recurrent acute pancreatitis (Martin et al, 1992; Masetti et al,

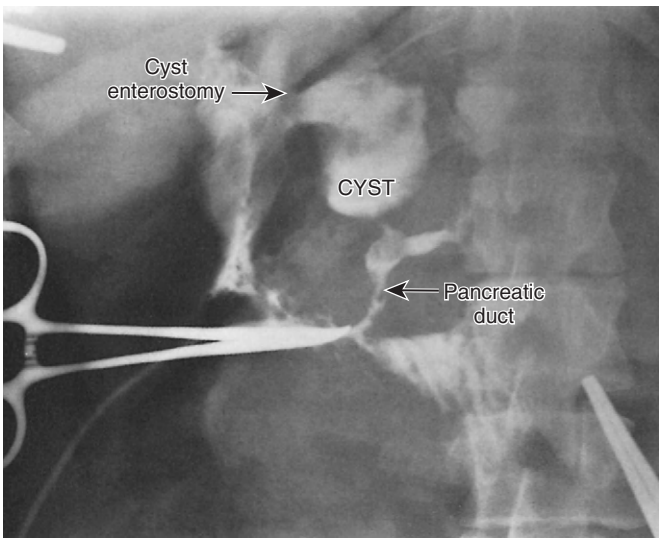

FIGURE 46.6. Intraoperative cholangiopancreatography in a patient with clinical pancreatitis and a type I cyst shows a stone impacted in the anomalous junction of the distal common bile duct and pancreatic duct. Previous cystenterostomy is also identified.

1996). Thus pancreatitis associated with bile duct cysts has multiple potential causes.

A significant association between bile duct cysts and hepatobiliary malignancy is well established (Dayton et al, 1983; Fieber & Nance, 1997; Flanigan, 1977; Komi et al, 1989; Rossi et al, 1987; Todani et al, 1979; Tsuchiya et al, 1977). The incidence of cancer associated with bile duct cysts ranges between 2.5% and 28% (Fieber & Nance, 1997; Flanigan, 1975; Ono et al, 1982). Hepatobiliary malignancies arising within or associated with bile duct cysts have included cholangiocarcinoma or adenocarcinoma, adenocanthoma, squamous cell carcinoma, anaplastic carcinoma, bile duct sarcoma, hepatocellular carcinoma, pancreatic carcinoma, and gallbladder carcinoma (Fieber & Nance, 1997; Ono et al, 1982; Todani et al, 1979, 1987; Tsuchiya et al, 1977). Cholangiocarcinoma is the most common malignancy associated with bile duct cysts (see Chapter 50), and its incidence is approximately 20 times greater than the incidence of bile duct carcinoma in the general population (Flanigan, 1975). The incidence of cyst-associated malignancy is age related, increasing from 0.7% in the first decade of life to more than 14% after age 20 years (Voyles et al, 1983). The mean age of patients with cancer associated with bile duct cysts is 32 years (Ono et al, 1982). These findings underscore the necessity for a high index of suspicion of carcinoma in adults with biliary cystic disease.

Malignancies associated with bile duct cysts may arise within the cyst or elsewhere within the liver or pancreaticobiliary tract. Indeed, only 57% of tumors are intracystic (Fig. 46.7) (Flanigan, 1977), and they may occur after cyst excision (Ishibashi et al, 1997; Nagorney et al, 1984b). Malignancies may be associated with any type of bile duct cyst, although the prevalence of cancer is significantly greater in type I and IV cysts. Caroli disease (type V) is also associated with an increased incidence of carcinoma (Dayton et al, 1983).

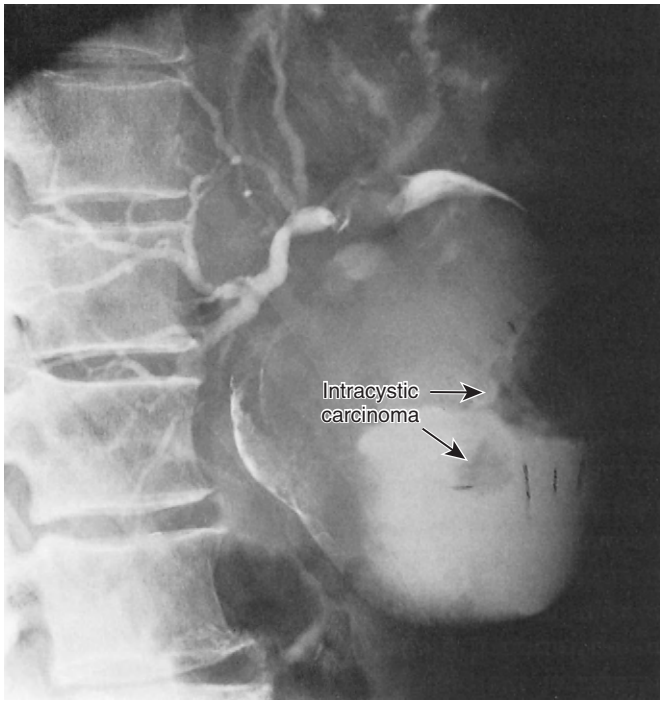

FIGURE 46.7. Percutaneous transhepatic cholangiography of a type I choledochal cyst with a polypoid intracystic cholangiocarcinoma.

The etiology of cyst-associated malignancies is unknown. Bile stagnation with the development of intrabiliary carcinogens leading to epithelial malignant degeneration is postulated as the most likely mechanism (Flanigan, 1977; Todani et al, 1979). Unconjugated deoxycholate and lithocholate have been associated with biliary metaplasia and mutagenicity, which may lead to neoplasia. Secondary bile acids have been found in bile duct cysts with cancer (Reveille et al, 1990), although neither their relative or absolute concentration in patients with bile duct cysts has differed in the presence or absence of cancer (Chijiiwa et al, 1993), thus suggesting other factors as primary carcinogens. An association between cystolithiasis and malignancy has not been established, although stasis and bacterial overgrowth associated with stones may lead to secondary bile acid formation. Long-term survival of patients with bile duct cysts and malignancy is rare. Delayed diagnosis, advanced stage of disease, intraabdominal seeding from previous operations, and tumor multicentricity generally preclude curative resection. Whether primary prophylactic excision of cysts in childhood can reduce the incidence of malignancy is unknown (Ono et al, 1982; Voyles et al, 1983).

Rare hepatobiliary problems arising in adults with common duct cysts include intrahepatic abscess and portal hypertension. Both conditions usually result from recurrent cholangitis and biliary obstruction after strictures of prior cystenterostomies. Large solitary hepatic abscesses represent an end stage of obstructive cholangitis and are usually completely obstructed, pus-filled intrahepatic cysts (see Chapters 43 and 66). These intrahepatic abscesses occur predominantly in the left intrahepatic duct (Mercadier et al, 1984; Ramond et al, 1984) and may be related partly to angulation of the left main duct. Adjacent liver parenchyma is fibrotic and atrophic and may harbor miliary abscesses within the peripheral bile duct radicles.

Portal hypertension associated with choledochal cysts may be due to secondary biliary cirrhosis or fibrosis, portal vein thrombosis, or Caroli disease with congenital hepatic fibrosis (see Chapter 70A; Kim, 1981; Martin & Rowe, 1979; Ono et al, 1982). Portal hypertension in adults generally is preceded by numerous operations for cyst drainage (Chaudhary et al, 1997; Hewitt et al, 1995; Lipsett et al, 1994). Portal hypertension in patients with bile duct cysts is manifested clinically by hepatosplenomegaly, hematemesis, melena, or ascites. Portal hypertension causes a hypervascularity of the hepatoduodenal ligament with prominent pericholedochal varices. Hepatic functional reserve deteriorates progressively, and hepatic coma and renal failure may be precipitated by recurrent cholangitis.

TREATMENT

General Principles

The surgical management of adults with bile duct cysts is based on cyst type and the presence of associated hepatobiliary pathology. The aims of preoperative management are complete cholangiographic definition of the extent of the cystic process and associated ductal pathology and control of biliary infections. Any patient with recurrent symptoms after prior cyst-related operations must be evaluated for anastomotic stricture, ductal stones, biliary tract malignancy, cirrhosis, and portal hypertension. Broad-spectrum antibiotics concentrated in bile and effective against proximal enteric bacteria are preferred for control of biliary infections. When sepsis fails to resolve with

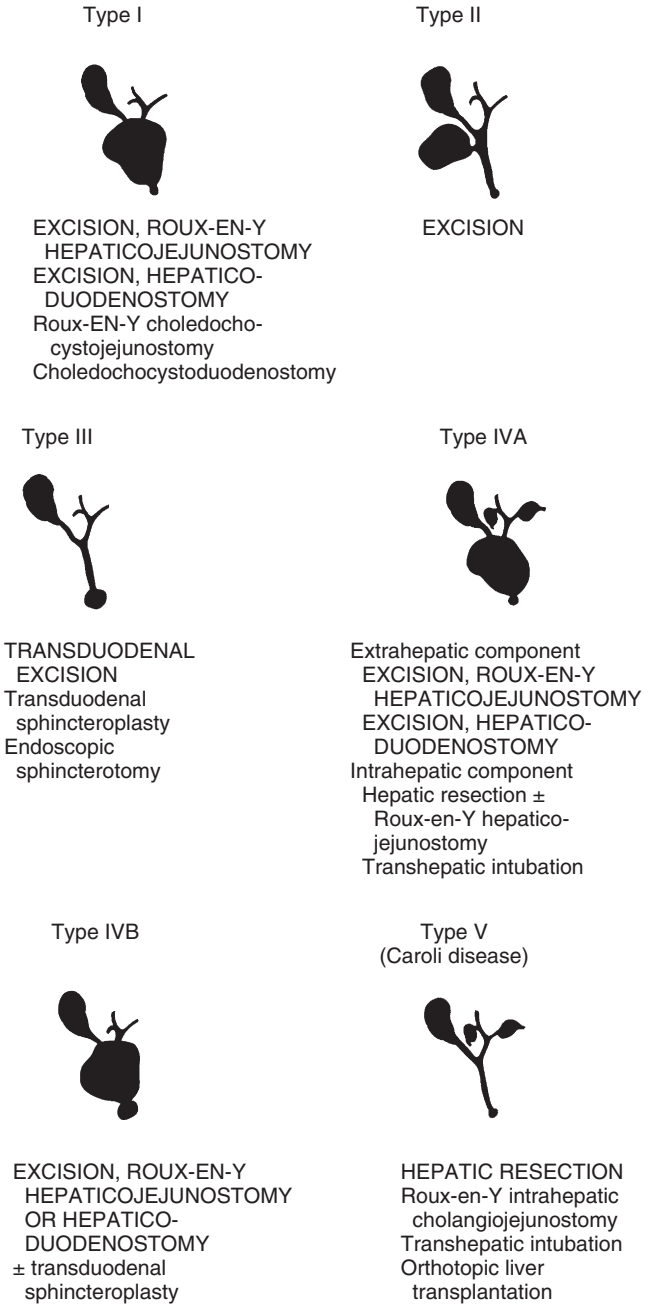

FIGURE 46.8. Surgical options for treatment of choledochal cysts. The preferred treatment appears in capital letters.

intravenous antibiotics, percutaneous or endoscopic drainage of infected bile duct cysts usually controls the infections before definitive operation.

The definitive treatment of bile duct cysts is surgical (Todani et al, 1978). The therapeutic alternatives for the treatment of each type of bile duct cyst are shown in Fig. 46.8. In general, all bile duct cysts should be excised and bile flow reestablished by mucosa-to-mucosa bilioenteric anastomosis (see Chapter 29). If complete excision is not feasible, partial cyst excision and Roux-en-Y cystojejunostomy to an epithelial-lined portion of the cyst remnant is preferred; external drainage alone has no role in the management of bile duct cysts. Cholangioscopy can be used in adults to exclude retained ductal stones and ductal malignancy (see Chapter 21). Finally, long-term follow-up must be maintained in adults because of the age-related risk of malignancy and the frequency of late anastomotic strictures in patients treated without cyst resection.

Type I Cyst

The treatment of choice for type I choledochal cysts in adults is total cystectomy and Roux-en-Y hepaticojejunostomy. Cyst excision eliminates the primary site of bile stasis and permits a bilioenteric anastomosis of normal jejunum and epithelial-lined proximal bile duct. The theoretical advantages of this approach include a reduced incidence of anastomotic stricture, stone formation, cholangitis, and intracystic malignancy. The advantages of a mucosa-to-mucosa anastomosis have been extrapolated from similar biliary reconstructions for other biliary tract problems: benign strictures, common bile duct stones, and suppurative cholangitis (see Chapter 42A).

Reduction in risk of malignancy is based on three presumptions: 1) the potential carcinogenic effect of pancreatic secretions is eliminated because of total diversion from the biliary tract; 2) the production of mutagenic secondary bile acids are reduced because bacterial overgrowth in the bile is less frequent; and 3) abnormal cyst epithelium is excised. The clinical results of cyst excision and Roux-en-Y hepaticojejunostomy have been excellent. Morbidity and mortality rates of excision have not been greater than that of drainage by Roux-en-Y choledochocystojejunostomy (Flanigan, 1975; Nagorney et al, 1984a; Ono et al, 1982; Rattner et al, 1983; Stain et al, 1995; Todani et al, 1978). Moreover, most reports with late follow-up have confirmed that the majority of patients remain asymptomatic following excision (Chen et al, 1996; Chijiiwa et al, 1993; Gigot et al, 1996; Nagorney et al, 1984a; Ono et al, 1982; Rattner et al, 1983; Uno et al, 1996), although recurrent cholangitis from anastomotic strictures occurs in 10% to 25% of patients (Chijiiwa & Tanaka, 1994; Gigot et al, 1996; Ono et al, 1982; Rattner et al, 1983; Uno et al, 1996).

Although reduction of malignancy by cyst excision has been suggested (Todani et al, 1987), cancer has developed after cyst excision (Nagorney et al, 1984a; Yamamoto et al, 1996). Previous cystenterostomy predisposes to ongoing risk of malignancy, and although such procedures are inadequate therapy for biliary cystic disease, they do not preclude definitive cyst excision (Gigot et al, 1996; Ono et al, 1982; Todani et al, 1988). Although morbidity is increased, low mortality rates and excellent long-term functional results can be achieved in adults with previous cystenterostomy, and reoperation and cyst excision should generally be undertaken. Bilioenteric continuity can be reestablished by hepaticoduodenostomy after cyst excision, although this method has been used infrequently in adults (Todani et al, 1981). An advantage of hepaticoduodenostomy is that the residual biliary epithelium is partially accessible to direct visualization by endoscopy (Todani et al, 1988). Technical factors influencing choice of hepaticoenterostomy (Roux-en-Y hepaticojejunostomy vs. hepaticoduodenostomy) include aberrant hilar ductal anatomy, ductal strictures, ductal size, and hilar arterial anatomy (Todani et al, 1998). Mobility of the duodenum is an important factor and may limit its use in some patients.

Cyst excision in adults differs technically from the approach generally advocated for pediatric patients (Altman, 1994; Lilly,

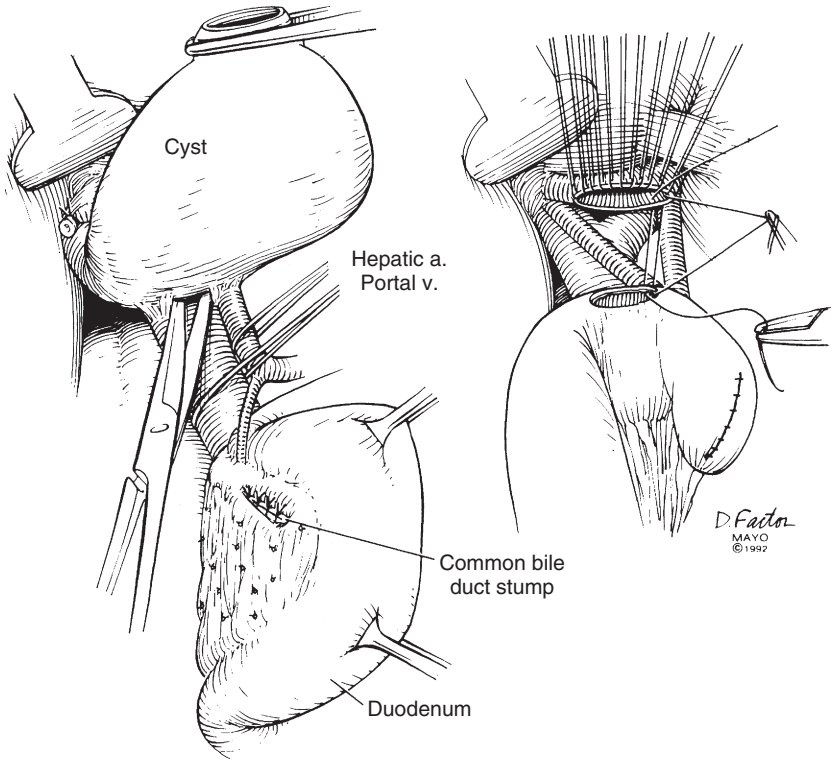

FIGURE 46.9. Isolation of vascular structures, complete excision of the cyst with closure of the distal stump, and bilioenteric reconstruction with hepaticojejunostomy with a Roux-en-Y loop. a., artery; v., vein.

1979). Most adults have had prior cyst drainage procedures, which may result in dense subhepatic adhesions. Recurrent cholangitis may result in epithelial degeneration or ulceration that can obscure or mimic malignancy, and regenerative epithelium may be densely adherent to the cyst wall. Although the vascularity of the pericholedochal tissue may increase, hypervascularity is most often limited to the ductal wall. In contrast to reports in pediatric patients (Lilly, 1979), complete dissection of the intracystic epithelium from the posterior cyst wall after excision of the anterior wall may be difficult. Because of the age-related incidence of cancer and its often occult operative and radiographic manifestations, total cyst excision to remove all intracystic epithelium is essential in adults. Only extensive hypervascularity from portal vein thrombosis or secondary biliary cirrhosis with portal hypertension would preclude excision.

Technically, cyst excision in adults can be accomplished by initially mobilizing the gallbladder from its bed to dissect the cyst away from the hilar structures. The portal vein is identified. Isolation and proximal control of the hepatic artery before dissection of the posterior cyst wall can be very helpful, especially if hypervascularity and dense adhesions are encountered. Before division of the cyst, the distal cyst is dissected from the pancreas to identify the pancreaticobiliary ductal junction (Ando et al, 1996). The intrapancreatic portion of the cyst is separated from the pancreas along the loose areolar plane between these structures. Meticulous fine suture ligature of collateral vessels will prevent potentially troublesome postoperative hemorrhage. Knowledge of the anatomy by preoperative cholangiography becomes particularly important to avoid damage to the pancreatic ducts. The cyst is transected distally within the head of the pancreas, and the distal bile duct is ligated carefully to prevent narrowing of the pancreatic duct. The cyst is mobilized proximally to the ductal confluence. After confirmation of the ductal confluence, the proximal cyst is transected, and the cyst is removed. Bilioenteric flow is reestablished through a wide mucosa-to-mucosa Roux-en-Y hepaticojejunostomy at the level of the hilum (Fig. 46.9) or with a hepaticoduodenostomy. If a previous cystenterostomy has been performed, the same technique is used for excision after the cystenterostomy has been divided. An existing Roux loop can be reused for the new anastomosis. Hepatic arteries should be positioned posterior to the cystenterostomy to reduce potential injury in case of reoperation.

Portal hypertension secondary to biliary cirrhosis and inflammatory adhesions from severe pancreatitis or past drainage procedures may preclude cyst excision. In these circumstances, Roux-en-Y choledochocystojejunostomy is the preferred alternative treatment for type I choledochal cysts. Preoperative morbidity and mortality rates are similar to that of cyst excision. Adequate long-term functional results from Roux-en-Y cyst drainage can be expected in 60% to 70% of patients (Nagorney et al, 1984a; Ono et al, 1982; Rattner et al, 1983). Long-term results are improved by partial cyst excision in an effort to ensure a mucosa-mucosa bilioenteric anastomosis (Gigot et al, 1996). When either excision or Roux-en-Y drainage is performed, intraoperative choledochoscopy to exclude retained ductal stones and to biopsy the abnormal epithelium to exclude malignancy is advised. In patients with recurrent acute pancreatitis and unresectable cysts, intracystic closure of the base of the cyst proximal to its junction to the pancreatic duct or concurrent transduodenal sphincteroplasty

should be used to prevent further episodes of pancreatitis (Rattner et al, 1983; Nagorney et al, 1984a). Careful long-term follow-up is essential because of the late development of malignancies, recurrent ductal stones, and anastomotic stricture (Chijiiwa & Tanaka, 1994; Fieber & Nance, 1997; Todani et al, 1998; Uno et al, 1996).

Portal decompression may be required before biliary reconstruction in patients who develop portal hypertension (Nagorney et al, 1984a). Preoperative assessment of these patients should include hepatic arteriography and portography. In general, central splenorenal shunts are preferred because portal decompression can be performed in an area distant from the subhepatic pericystic inflammation. In general, drainage is undertaken 6 to 12 weeks after portosystemic shunting. Alternatively, transjugular intrahepatic portosystemic stenting (TIPS) could be used for preoperative portal decompression (see Chapter 76E).

Type II Cyst

The treatment of choice for type II bile duct cysts is excision (Flanigan, 1975; Powell et al, 1981). Due to the low incidence, however, experience is limited, although reported results after excision have been excellent (Kouraklis et al, 1996; Lopez et al, 1991; Nagorney et al, 1984a; Powell et al, 1981). Technically, excision of type II bile duct cysts is similar to that of cholecystectomy. Depending on the size of the neck of the cyst at its junction with the common duct, the neck can either be closed primarily, or closure can be achieved via T-tube decompression of the common duct. Excision with Roux-en-Y hepaticojejunostomy has also been successful but has no clinical advantage over excision alone (Benhidjeb et al, 1994).

Type III Cyst (Choledochocele)

Choledochoceles are true cysts of the distal bile duct protruding into the duodenum. Patients are seen with biliary colic, cholangitis, or pancreatitis (Masetti et al, 1996). Choledochoceles are typically small (≤2 cm), and a classification scheme for them has been proposed (Sarris & Tsang 1989). Until recently, transduodenal cyst excision with or without sphincterotomy was the treatment of choice (Flanigan, 1975; Powell et al, 1981; Venu et al, 1984), but endoscopic sphincterotomy and cyst unroofing have now become the preferred treatment (Ladas et al, 1995; Martin et al, 1992; Masetti et al, 1996). The excellent long-term results with endoscopic treatment coupled with the diagnostic advantage of ERCP in defining the terminal pancreatic biliary anatomy clearly favor the endoscopic approach. Although transduodenal excision eliminates the risk of malignancy, the fact that only three cases of carcinoma in choledochoceles have been documented confirms that the risk of cancer alone is sufficiently low to justify endoscopic treatment as an alternative to surgery (Masetti et al, 1996).

Damage to the major pancreatic duct is the major source of operative morbidity and mortality. Identification of the duct of Wirsung is paramount before transduodenal cyst excision or sphincteroplasty because of numerous pancreatic biliary ductal variations (Komi et al, 1989, 1992). The pancreatic duct of Wirsung may enter the posterior wall of the choledochocele, or it may enter normally into the duodenum at the inferior aspect of the major papilla adjacent to the choledochocele (Sarris & Tsang, 1989). Before cyst excision or sphincteroplasty, the pancreatic duct orifice must be identified at the papilla to avoid damage to the duct. If the major pancreatic duct empties normally into the duodenum, it should be left in situ and not transected during choledochocele excision. If the pancreatic duct enters into the posterior wall of the cyst, the distal common bile duct and the duct of Wirsung should be implanted separately into the duodenal mucosa after cyst excision (Powell et al, 1981).

Type IV Cyst

The treatment of choice for type IV bile duct cysts is excision of the extrahepatic cyst and Roux-en-Y hepaticojejunostomy (Mercadier et al, 1984; Nagorney et al, 1984a; Todani et al, 1984a). The extrahepatic component of type IVA and IVB cysts is approached as a type I bile duct cyst. Transduodenal sphincteroplasty and Roux-en-Y hepaticojejunostomy complete the treatment of type IVB cysts, which have a choledochocele component. Type IVA cysts require more selective management because of the wide range of problems associated with the intrahepatic component of these cysts (Ando et al, 1997; Chijiiwa & Tanaka, 1994; Nagorney et al, 1984a; Todani et al, 1984a; Uno et al, 1996). When type IVA cysts are not complicated by hilar or intrahepatic ductal strictures, intrahepatic stones, intrahepatic abscess, or malignancy, bilioenteric continuity should be restored by a wide Roux-en-Y hepaticojejunostomy at the bile duct confluence (Todani et al, 1988, 1998). In addition, the hepaticojejunostomy must take into account anomalous ductal anatomy. In patients with stones sequestered within the intrahepatic cysts, refractory ductal strictures distal to the intrahepatic cysts, or intrahepatic abscess due to chronic cholangitis, the abnormal hepatic segment should be resected. Bile flow is restored by Roux-en-Y hepaticojejunostomy, and lobar hepatic resection is usually required to eliminate the complicated unilobar intrahepatic cystic component. In addition to the hepaticojejunostomy at the hilus, Roux-en-Y cholangiojejunostomy incorporating the segmental bile duct of the resected segment may further optimize intrahepatic bile drainage. In patients with type IVA cysts and an intrahepatic component involving both lobes of the liver or complicated by cirrhosis, transhepatic tubes can be added to the Roux-en-Y hepaticojejunostomy for access to the biliary tree for diagnosis and treatment.

The results of the treatment of type IVA cysts have been reviewed by several centers (Gigot et al, 1996; Todani et al, 1998; Uno et al, 1996; Ando et al, 1997). Although treatment varies widely because of the spectrum of pathology associated with these cysts, the results of cyst drainage alone without excision of either the intrahepatic or extrahepatic cystic components were considered satisfactory or good in fewer than 50% of patients (Todani et al, 1984a). In contrast, 90% of patients who had excision of the extrahepatic component of the type IVA cyst had good results, whether or not the intrahepatic component was resected. Although these findings suggest that adequate treatment of the extrahepatic component in these patients may provide effective prophylaxis for progression of the problems associated with intrahepatic cystic disease, the results of some studies (Ando et al, 1997; Todani et al, 1998) emphasize the importance of addressing the presence of variant ductal anatomy and stenoses at the hilum. If intrahepatic ductal stenosis or aberrant ducts are not recognized and addressed during extrahepatic cyst excision, subsequent reoperation will often be necessary. Both membranous or bridgelike stenoses should be

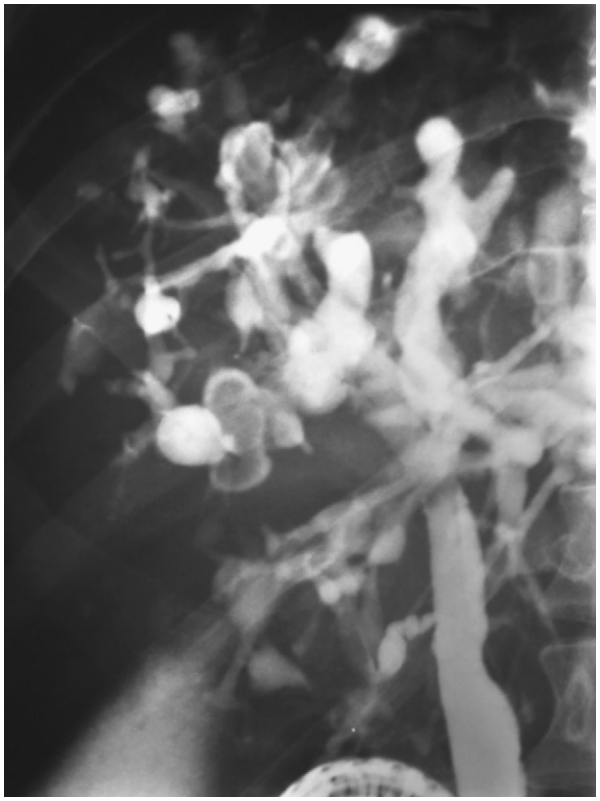

FIGURE 46.10. Endoscopic retrograde cholangiogram of Caroli disease and multiple saccular cysts of only the intrahepatic bile duct with intrahepatic stones.

excised circumferentially to their base. The long-term results of the treatment of type IVB cysts in adults are similar to those of type I choledochal cysts. Although patients with type IVA cysts and portal hypertension may be approached by proximal splenorenal shunts before cyst drainage, liver transplantation may provide a more durable solution. Resection of intrahepatic cysts in cirrhotic patients is associated with an increase in morbidity and mortality rates and is generally contraindicated.

Caroli Disease

The treatment of Caroli disease depends on the extent of the intrahepatic bile duct cysts and the presence of congenital hepatic fibrosis, secondary biliary cirrhosis, or carcinoma. Caroli disease in adults may present in a localized form, limited to one hepatic lobe or segment, or a diffuse form, involving the entire intrahepatic biliary tree (Fig. 46.10) (Barros et al, 1979; Dayton et al, 1983; Mercadier et al, 1984; Witlin et al, 1982). Most adults with Caroli disease have a unilobar fusiform dilation of the intrahepatic ducts, most commonly involving the left ductal system (Mercadier et al, 1984; Ramond et al, 1984). Hepatic resection, with or without Roux-en-Y cholangiojejunostomy, remains the treatment of choice in patients with Caroli disease limited to one lobe of the liver without the presence of concurrent cirrhosis or hepatic fibrosis. Cyst removal by hepatic resection provides the simplest solution to the recurrent problems of cholangitis, stone formation, and intrahepatic cancer (Mercadier et al, 1984; Todani et al, 1984a). Resection is always preferable to drainage if the liver parenchyma surrounding the cyst is atrophic. Indeed, segmental fibrosis and atrophy from complications of the underlying cyst are irreparable with drainage, which mandates segmental resection. Morbidity and mortality associated with hepatic resection for localized Caroli disease have been minimal, and functional results have been good, although follow-up has been limited (Bockhorn et al, 2006; Mercadier et al, 1984; Ramond et al, 1984). Alternative approaches to localized intrahepatic Caroli disease have included external T-tube biliary decompression or internal drainage via choledochoduodenostomy, Roux-en-Y choledochojejunostomy, or Roux-en-Y hepaticojejunostomy. These alternatives are often ineffective because ductal drainage is distal to the intrahepatic cysts (Witlin et al, 1982). In general, recurrent cholangitis, hepatic abscess formation, intrahepatic stone formation, and carcinoma eventually complicate these approaches. If resection in patients with localized Caroli disease is not feasible, Roux-en-Y intrahepatic cholangiojejunostomy to the intrahepatic cyst is preferable (Mercadier et al, 1984).

The results of the treatment of Caroli disease involving both lobes of the liver, or associated with portal hypertension from congenital hepatic fibrosis or secondary biliary cirrhosis, remain poor (Barros et al, 1979; Dayton et al, 1983; Mercadier et al, 1984). Most patients with diffuse Caroli disease have chronic recurrent cholangitis and portal hypertension with variceal bleeding, and their deaths are secondary to liver failure or carcinoma. Long-term medical therapy including antibiotics, analgesics, and litholytic agents may improve symptoms, but it does not permanently eliminate them. In selected patients with diffuse intrahepatic Caroli disease but with dominant unilobar disease, extended hepatic resection has been advocated, although long-term benefit remains unproven (Mercadier et al, 1984). Long-term transhepatic decompression using bilobar silicone tubes has been successful in the management of recurrent cholangitis (Witlin et al, 1982); however, to date, the treatment of diffuse Caroli disease remains disappointing.

In light of the natural history of Caroli disease—cirrhosis, variceal bleeding, and liver failure—hepatic transplantation offers the best chance of success. Orthotopic liver transplantation has been successfully used for Caroli disease (see Chapter 97A; De Kerckhove et al, 2006; Habib et al, 2006; Scharschmidt, 1984). If the diagnosis of bilobar Caroli disease is made, nonoperative medical treatment should be used until the patient is considered a transplant candidate. Avoidance of numerous ineffective operative procedures will reduce the technical risk of transplantation.

LAPAROSCOPIC ADVANCES IN SURGICAL MANAGEMENT

Minimally invasive approaches are increasingly used in most visceral procedures, and outcomes consistently suggest patient advantages over conventional approaches with regard to pain, wound complications, length of hospital stay, and recovery time. A laparoscopic approach in the management of bile duct cysts was first described in 1995 in a pediatric patient with a type I choledochal cyst (Farello et al, 1995), and several case reports and small series have been reported since (Abbas et al, 2006; Chokshi et al, 2009; Laje et al, 2007; Sun et al, 2009). Although feasibility has been demonstrated, the small numbers of patients in these reports has limited the assessment of outcomes, and comparisons with open procedures are needed. Only four contemporary series include more than 12 patients

ND, no data available

(Table 46.2), three of which included only pediatric cases. Palanivelu and colleagues (2008) recently reported the largest series to date of laparoscopic treatment of bile duct cysts. In this series of 35 patients, 16 were adults. Conversion to laparotomy was performed in three patients for suspicion of malignancy, and complete cyst excision was performed in 28; in five patients, an incomplete resection was performed as a result of extension of the cyst proximal to the hepatic duct confluence. Postoperative complications occurred in 14%, with no perioperative mortality.

One of the major advantages of the laparoscopic approach in choledochal cyst surgery is the superior visualization of the structures around the cyst and within the hepatic hilum. The magnification conferred by the laparoscope helps assess neovascularity around the cyst, separation of the posterior cyst wall from the portal vein, and dissection and anastomosis in the hilar area. It also may aid dissection and identification of the narrow intrapancreatic bile duct close to the anomalous pancreatobiliary junction because of the magnified laparoscopic view. However, it must be emphasized that laparoscopic excision of choledochal cysts is technically challenging and requires experience in both complex biliary operations and advanced laparoscopic surgery.

Recent large series have established the feasibility of laparoscopic cyst excision with hepaticojejunostomy. Although the outcomes appear favorable, a formal comparison has not been made to open approaches, and the expected advantages of minimally invasive approaches—reduced pain, fewer wound complications, shorter hospital stay, and faster recovery—have not been confirmed.

SECTION II Neoplastic

A. General

CHAPTER 47

Tumors of the biliary tree: pathologic features

David S. Klimstra and N. Volkan Adsay

OVERVIEW

The biliary tract is lined by simple columnar epithelial cells of foregut origin (Fig. 47.1; Frierson, 1989; 1997). Most biliary neoplasms are related to this cell type and hence show major similarities to other foregut tumors, particularly those of pancreatic ductal origin. By far the most common neoplasm of the biliary tract is adenocarcinoma, which is referred to collectively with pancreatic ductal adenocarcinoma as a *pancreatobiliary-type* adenocarcinoma (Figs. 47.2 through 47.5), reflecting the similarities between these two neoplasms.

Tumors arising from the gallbladder and the different segments of the bile ducts have overlapping histologic characteristics; therefore their pathologic classification is also very similar (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003). On the other hand, the risk factors, clinical findings, and biologic behavior may vary (see Chapters 49, 50A, and 50B). For instance, although gallstones are the main risk factor for gallbladder adenocarcinoma, adenocarcinomas of proximal bile ducts have a much stronger association with primary sclerosing cholangitis (PSC) (see Chapter 41) or anomalous pancreatobiliary duct junction (see Chapter 46). This variability also is partially reflected in the molecular alterations, which although not specific for the histologic subtype of the tumor, may affect the management and prognosis (see Chapter 8B). The different presentations of biliary adenocarcinoma also influence the mode by which a specimen is obtained for pathologic examination. For example, many gallbladder adenocarcinomas are currently identified in "routine" cholecystectomy specimens in primary care facilities, performed with a preoperative diagnosis of chronic cholecystitis or cholelithiasis, whereas extrahepatic bile duct lesions are seldom resected without a strong preoperative suspicion of carcinoma, and this is usually performed in tertiary care facilities.

This chapter discusses the pathologic aspects of biliary tract neoplasia, with special emphasis on adenocarcinomas. The tumor types are discussed by viewing the biliary system as a whole; site-specific characteristics are mentioned only when pertinent to pathologic classification. For the details of clinical findings, risk factors, and site-specific management, the reader is referred to other chapters of this book (see Chapters 49, 50A, and 50B).

INVASIVE CARCINOMAS OF THE BILIARY TRACT

Most "biliary tract cancers" are conventional adenocarcinomas (pancreatobiliary type), which are morphologically very similar to pancreatic ductal adenocarcinoma (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003). This tumor is referred to as *gallbladder adenocarcinoma* in the gallbladder, *cholangiocarcinoma* in the intrahepatic biliary tract, and *adenocarcinoma of the extrahepatic bile ducts* in the extrahepatic biliary tract. As in adenocarcinomas of other organs, these are usually tumors of the elderly. The association of biliary adenocarcinomas with preceding chronic inflammation has been well established (Herzog & Goldblum, 1996; Sheth et al, 2000), mostly by epidemiologic data showing the high incidence of gallbladder cancer in areas with a high prevalence of gallstones and by the pathologic observation that many individual carcinomas have associated gallstones or cholecystitis (see Chapter 49). Also, the risk of adenocarcinoma is relatively high in patients with PSC and indirectly in those with ulcerative colitis (see Chapter 41). The association of biliary cancers with parasites (see Chapter 45; Carriaga & Henson, 1995) and choledochal cysts (see Chapter 46) is also presumably related to the potential for chronic inflammation from constant epithelial injury and repair that leads to neoplastic alterations (Parkin et al, 1993).

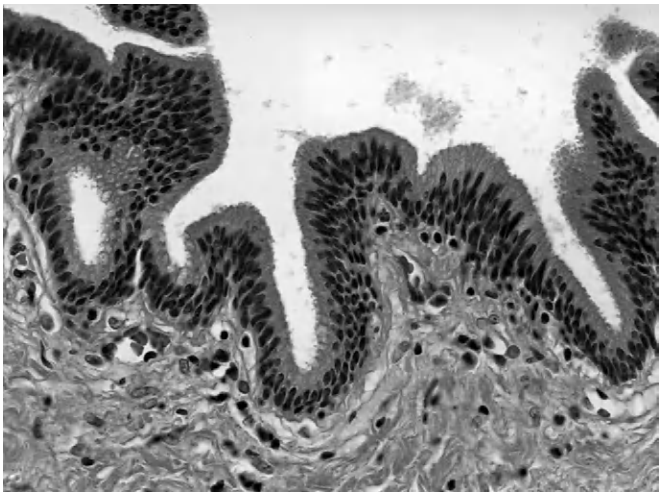

FIGURE 47.1. Benign epithelium. The biliary epithelium is composed of a layer of columnar cells with acidophilic cytoplasm.

FIGURE 47.2. Macroscopic appearance of an adenocarcinoma. The cut surfaces of adenocarcinomas of the biliary tract and gallbladder typically have a firm, white, sclerotic appearance because of the abundance of desmoplastic stroma.

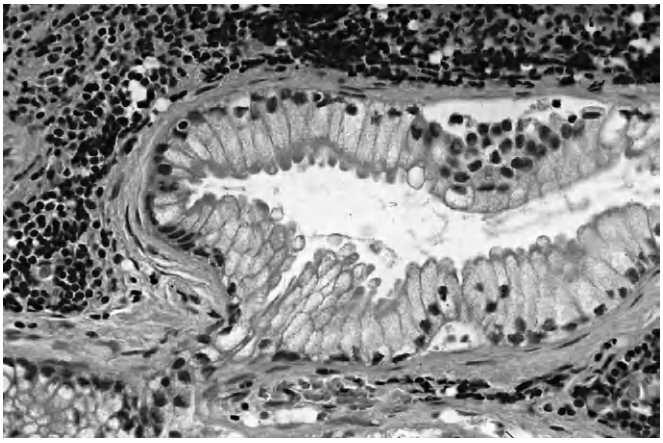

FIGURE 47.3. Well-differentiated adenocarcinoma. Most adenocarcinomas of the biliary tract are the tubular, pancreatobiliary type, characterized by simple tubular units with well-polarized, deceptively bland-appearing cells.

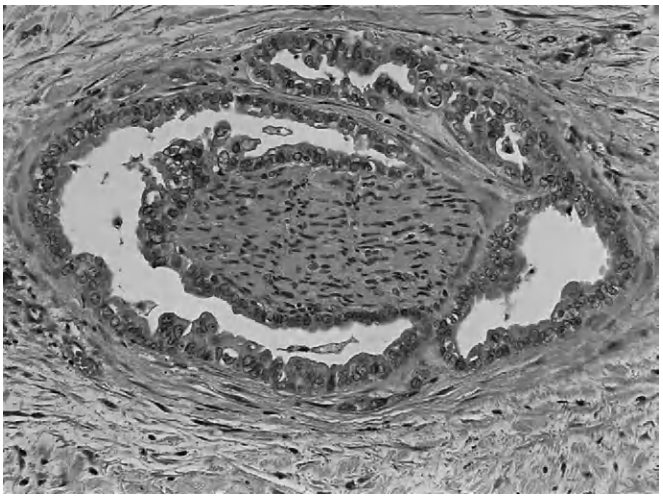

FIGURE 47.4. Adenocarcinoma with perineural invasion. Carcinoma cells wrapping around nerves is a very common finding in biliary adenocarcinomas.

Growth Patterns and Macroscopic Features

Based on their macroscopic growth pattern, biliary carcinomas have been divided into four types: 1) polypoid, 2) nodular (nodular-sclerosing), 3) schirrous-constricting, and 4) diffusely infiltrative (Albores-Saavedra et al, 2000a; Todoroki et al, 1980; Van Heerden et al, 1967; Weinbren & Mutum, 1983). Polypoid growth typically is found in carcinomas with an associated component of intraductal papillary neoplasm (IPN), previously designated *noninvasive papillary carcinoma* (Albores-Saavedra et al, 2010), which are associated with a better prognosis. The nodular and schirrous types have a propensity to infiltrate surrounding tissues and are therefore difficult to resect. The diffusely infiltrating type tends to spread linearly along the ducts. The constricting and diffusely infiltrative patterns may be difficult to differentiate from chronic inflammatory conditions, especially PSC and autoimmune cholangitis (Corvera et al, 2005). Significant histologic overlaps occur among these different growth patterns, so their utility in tumor classification is limited.

On cut sections, the intraluminal components of biliary carcinomas, especially those with a polypoid gross appearance,

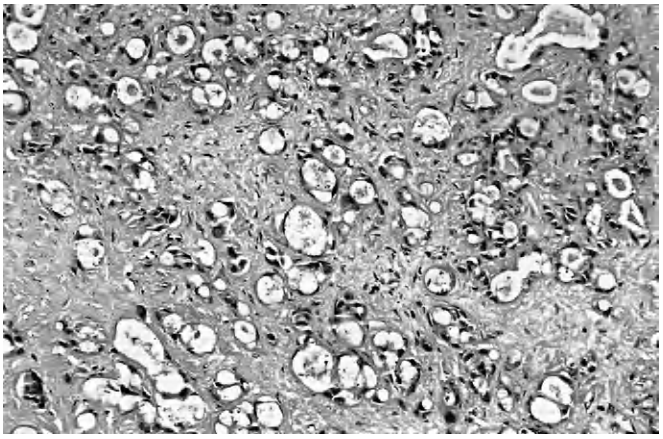

FIGURE 47.5. Adenocarcinoma with mucin. Intracytoplasmic and intraluminal mucin often are present in biliary adenocarcinomas. In this example, the granular material in the lumina represents mucin admixed with necrotic debris.

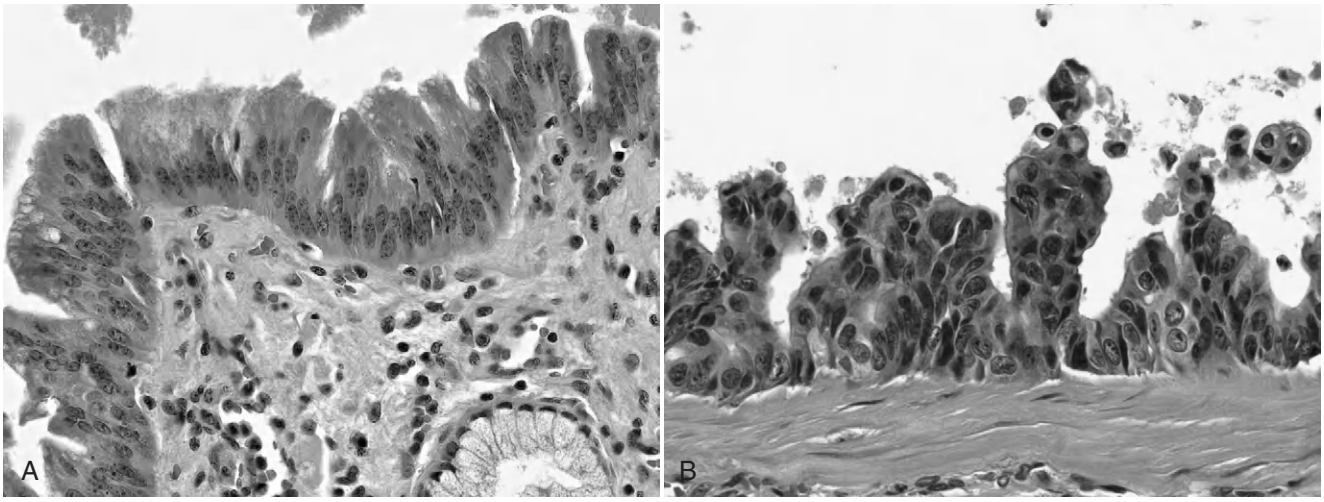

FIGURE 47.6. Dysplasia (biliary intraepithelial neoplasia). Loss of polarity of the cells is associated with nuclear atypia, including enlargement, hyperchromatism, and pleomorphism. **A,** Low-grade dysplasia. **B,** High-grade dysplasia.

may appear more friable, soft, and tan; this reflects the presence of intraductal papillary neoplasm elements growing into the lumen, and ulceration and necrosis may be evident in larger tumors. The infiltrating components of adenocarcinomas are more schirrous (scarlike) with a firm, white, gritty appearance (see Fig. 47.2) because of the abundance of desmoplasia, a fibrotic tissue reaction associated with infiltrating carcinoma. Necrosis may also be evident.

When adenocarcinoma invades into the adjacent liver, the growth pattern often becomes more expansile, and the liver-carcinoma interface appears deceptively well demarcated. This allows easier detection of the boundaries of these carcinomas in hepatic resections. In contrast, the boundaries of carcinomas invading the hilar soft tissue are typically poorly defined and difficult to appreciate. Gallbladder carcinomas are often associated with gallstones. In patients with porcelain gallbladder (Stephen & Berger, 2001), the wall of the gallbladder may be entirely calcified.

Microscopic Features

Most adenocarcinomas of gallbladder and bile ducts show the characteristic features of a pancreatobiliary-type adenocarcinoma (see Figs. 47.3 to 47.5): both simple and complex, irregularly shaped glands mixed with small clusters of cells, often with associated stromal desmoplasia (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003). The glands often are well formed, lined by cuboidal cells, and show dilated lumina. Often the nuclear grade is unexpectedly high for the degree of glandular differentiation, and marked variation in nuclear size, shape, and intracellular location occurs between different cells within the individual glands. The cytoplasm may be acidophilic and granular in some cases and pale or clear in others. Variable amounts of intracytoplasmic and intraluminal mucin are present; in some cases, mucin is readily evident by routine histologic examination; in others, it is demonstrable by special stains.

Perineural (see Fig. 47.4) and vascular invasion are common, and carcinoma cells may have a deceptively well-differentiated appearance, even when they invade these structures. In fact, the distinction of a well-differentiated adenocarcinoma from a benign reactive process in this region is one of the more challenging differential diagnoses in surgical pathology.

Dysplasia, or biliary intraepithelial neoplasia (BilIN; Fig. 47.6), is often present in the adjacent biliary epithelium (Zen et al, 2007). Sometimes the intraepithelial component comprises a papillary neoplasm (Fig. 47.7). In such cases, the noninvasive and invasive components of the tumor should be evaluated separately, and the extent of invasion should be quantified because those with "minimal invasion" have a better prognosis (Albores-Saavedra et al, 2000b).

Tumors that infiltrate the adjacent liver may acquire a more trabecular pattern, presumably by growing along the sinusoidal backbone of the liver parenchyma. Entrapped reactive bile ductules and hepatocytes are often present within the tumor; these may create a diagnostic problem in biopsy specimens.

Anatomic Variations

For therapeutic and prognostic purposes, tumors of the extrahepatic biliary tract are separated by their anatomic distribution into *upper third* (above the cystic duct junction, including the

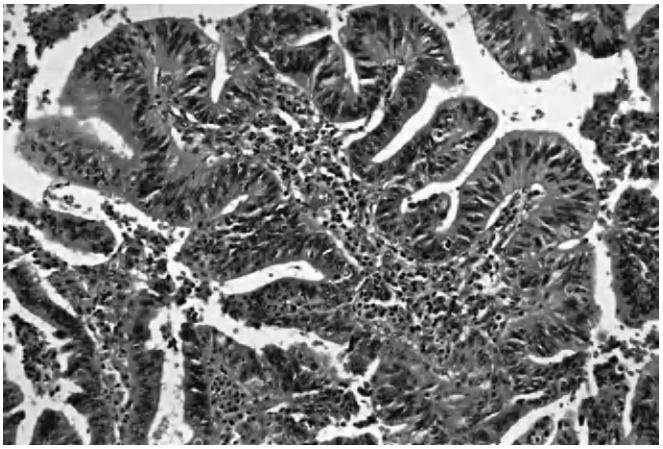

FIGURE 47.7. Intraductal papillary neoplasm. This polypoid lesion shows papillary fronds lined by neoplastic cells.

both hepatic ducts, common hepatic duct, and the cystic duct), *middle third* (upper half of the common bile duct [CBD]), and *lower third* (distal half of the CBD) (Klatskin, 1965; Tompkins et al, 1981; Van Heerden et al, 1967; Weinbren & Mutum, 1983). The distinctive clinical characteristics of adenocarcinomas occurring in different segments of the biliary tract are discussed in other chapters of this book, and only a few issues pertinent to pathologic aspects are mentioned here. Most carcinomas arise in the upper third of the bile ducts and tend to be the schirrous-constricting and diffusely infiltrative types. Recent studies have shown that many originate within 5 mm of the cystic duct junction or within the cystic duct itself. Hilar carcinoma, located at the confluence of the right and left hepatic ducts, sometimes referred to as a *Klatskin tumor* (Bosma, 1990; Klatskin, 1965), has distinctive clinical features. Klatskin tumors usually grow into the liver rather than distally toward the duodenum (see Chapter 50B; Hayashi et al, 1994), and the component that invades the liver is often well demarcated. Carcinomas in the middle third tend to be the nodular-sclerosing type—thickened along a long segment, with a narrow lumen and inflammatory changes in the surrounding tissues; hence these are difficult to differentiate from sclerosing cholangitis. They have a very high propensity for perineural invasion and involvement of radial surfaces, making curative resection difficult (Bhuiya et al, 1993). Those in the distal third have the best prognosis, partly because of their resectability by pancreatoduodenectomy and partly because many, especially those close to the ampullary region, are composed predominantly of noninvasive papillary neoplasmic elements (Adsay, 2004; Albores-Saavedra et al, 2000a; Lack, 2003).

Pathologic Differential Diagnosis

The difficulty at the clinical level of distinguishing biliary adenocarcinomas from benign inflammatory conditions, such as sclerosing cholangitis, is also problematic at the microscopic level (Ludwig, 1989; Ludwig et al, 1992). Reactive changes in the accessory biliary ductules in the wall of the bile ducts can mimic adenocarcinomas, although nonneoplastic ductules may retain a lobular configuration, and they lack the density of cellularity of a carcinoma. As also discussed in Chapter 56, pancreatobiliary adenocarcinomas can be deceptively benign appearing, composed of well-formed glandular elements lined by fairly organized, cytologically bland glandular cells (see Figs. 47.3 and 47.4). The distinction of reactive changes in the surface epithelium from dysplasia (BilIN) often proves to be even more challenging, especially because any injury to the biliary epithelium, including instrumentation and stent placement, has a tendency to induce marked cytologic atypia that mimics the appearance of high-grade dysplasia (Fig. 47.8). Marked nuclear enlargement or irregularity, hyperchromasia, loss of polarity, mitotic figures, apoptotic cells, and intraluminal necrosis are findings in favor of a neoplastic process (see Fig. 47.6); however, overlaps are common, and at times this distinction may not be possible on the basis of biopsies or frozen sections.

Biliary carcinomas that grow into the liver must be distinguished from primary hepatocellular carcinomas (see Chapter 78). The presence of true glandular elements and mucin are common findings in biliary carcinomas and typically are lacking in hepatocellular carcinomas. In contrast, hepatocellular carcinomas may have intracellular bile and generally lack significant stromal fibrosis and desmoplasia. Other distinctive features of hepatocellular carcinomas—the solid and trabecular growth pattern, centrally located nuclei with prominent nucleoli, and abundant eosinophilic cytoplasm—usually are identifiable; immunohistochemical demonstration of hepatocellular differentiation with markers such as hepatocyte-1 or glypican-3 can be used in problematic cases.

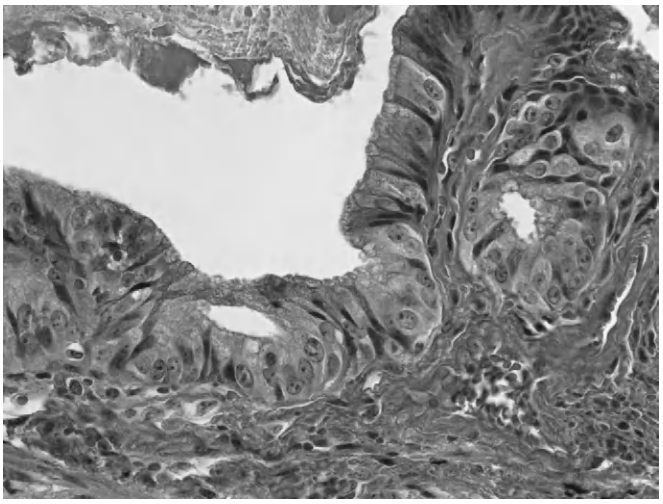

FIGURE 47.8. Reactive atypia. Injury to the bile duct epithelium—whether from a primary inflammatory process, such as sclerosing cholangitis, or to instrumentation from endoscopic retrograde cholangiopancreatography or stent placement—often induces remarkable atypia that may mimic carcinoma.

Differentiation between ampullary and duodenal neoplasms and CBD tumors can be difficult because carcinomas of these sites often infiltrate neighboring structures in close proximity. In such cases, the correct classification of the tumor greatly depends on determining where it is centered, which often can be achieved only by close correlation of the radiographic and macroscopic findings. In addition, any dysplasia or other preinvasive features may be an important clue to the site of origin. In this complex region, the origin of the tumor (by site) should be evaluated separately from the type of the carcinoma, such as ampullary carcinomas of the pancreatobiliary type. Intestinal-type carcinomas in this region are more likely to be of either ampullary or duodenal origin.

Biliary carcinomas metastatic to other sites may mimic the primary tumors of those organs. In particular, metastases to the ovary often become cystic and are mistaken for primary ovarian mucinous cystic neoplasms (Young & Hart, 1989), and lung metastases can resemble mucinous bronchioloalveolar carcinomas. Metastases to the peripheral liver from biliary carcinomas can be nearly impossible to distinguish from metastatic pancreatic ductal adenocarcinoma.

Immunohistochemical and Molecular Characteristics

By immunohistochemistry, biliary adenocarcinomas typically express CK7, CK19, CA19-9, CEA , MUC1 (Fig. 47.9), and MUC5AC (Adsay, 2004; Albores-Saavedra et al, 2000a; Lack, 2003). On occasion, these markers can be helpful in distinguishing certain other carcinomas that do not express these markers, such as hepatocellular carcinoma. However, none of

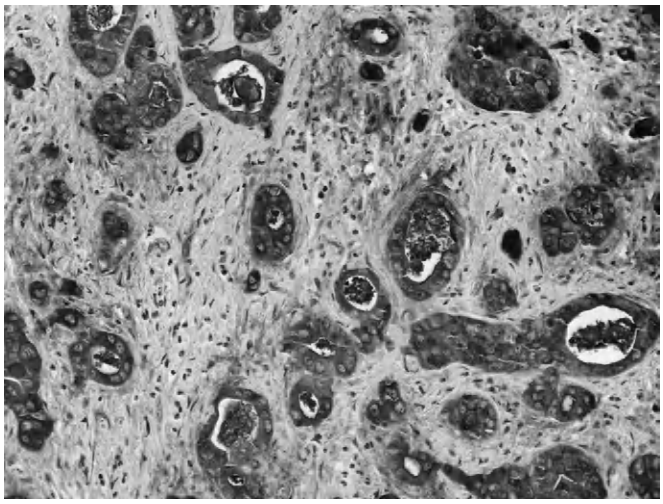

FIGURE 47.9. MUC1 in adenocarcinoma. Immunohistochemical studies may be useful in the differential diagnosis of biliary neoplasia. In this example, carcinoma cells show expression of MUC1, which often is negative in intestinal-type adenocarcinomas.

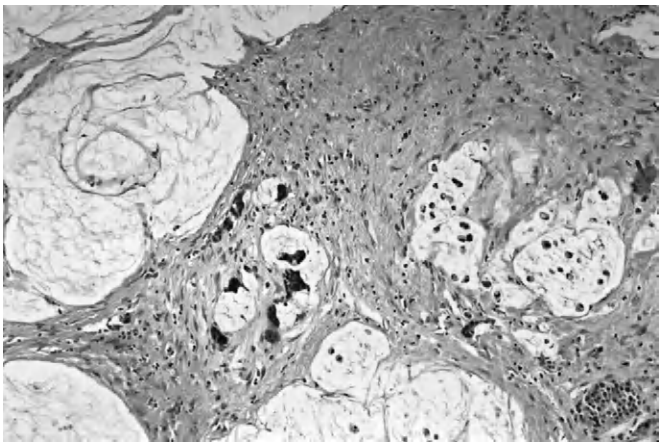

FIGURE 47.10. Mucinous carcinoma. Rarely, a biliary adenocarcinoma may be associated with abundant stromal mucin deposition. In this example, scant carcinoma cells are floating within the mucin pools.

these markers is specific enough to prove biliary origin for an adenocarcinoma when a metastasis from another organ is under consideration. Biliary adenocarcinomas generally lack expression of CK20 and CDX2 typically found in intestinal adenocarcinomas; TTF1 and napsin, found in pulmonary primaries; and hormone receptors. Mutations at codon 12 of the *KRAS* oncogene, seen in more than 90% of pancreatic ductal adenocarcinomas, are much less common in biliary adenocarcinomas (Rashid et al, 2002); the frequency of *KRAS* mutation appears to decrease from distal to proximal along the biliary tree. Similarly, loss of *SMAD4* is also less common in biliary than pancreatic adenocarcinomas (Argani et al, 2001). More than half of the cases have abnormal expression of TP53 and loss of heterozygosity at 8p, 9q, and 18q; amplification of *ERBB2* is also reported in more than half.

Other Types of Carcinomas in the Biliary Tract

Other carcinomas of glandular epithelial origin, in the gallbladder and biliary tract are classified separately from pancreatobiliary adenocarcinomas (Adsay, 2004; Albores-Saavedra et al, 1996, 2000a, 2010; Lack, 2003). *Intestinal-type adenocarcinomas* (Albores-Saavedra et al, 1986) are morphologically similar to their counterparts in the gastrointestinal tract. *Signet ring cell carcinomas* are characterized by a diffusely infiltrative pattern of individual cells, often with signet ring morphology because of intracellular mucin; a cordlike growth pattern may also occur in the biliary tract but is exceedingly uncommon. *Mucinous adenocarcinomas* may be seen in some cases, with extensive mucin production associated with stromal mucin deposition (Fig. 47.10), usually mixed with conventional adenocarcinomas; this subtype can occur with intraductal papillary neoplasms. Some studies suggest that the prognosis of mucinous adenocarcinomas may be more favorable than that of conventional pancreatobiliary-type adenocarcinoma (Bosma, 1990). *Adenosquamous carcinomas* (Nishihara et al, 1994) are rare tumors in which a mixture of glandular and squamous differentiation is seen in variable amounts. *Clear-cell carcinomas* (Vardaman & Albores-Saavedra, 1995) are described, in which the morphologic features resemble those of renal cell carcinoma.

Some patterns of biliary carcinoma lack gland, mucin, or papilla formation. *Undifferentiated* (Fig. 47.11) and *sarcomatoid* carcinomas (Appelman & Coopersmith, 1970; Nishihara & Tsuneyoshi, 1993; Suster et al, 1987) probably represent the least differentiated end of the spectrum of adenocarcinomas, in which glandular differentiation is no longer detectable; these patterns can coexist with conventional adenocarcinomas, pointing to the close relationship of these tumor types. In sarcomatoid carcinomas the cells acquire mesenchymal characteristics, including a spindle shape; in some cases "heterologous" elements, such as bone and cartilage, occur. In the absence of a more epithelioid or glandular component or preinvasive neoplasia within the bile ducts, these tumors may be difficult to distinguish from true sarcomas. Some examples of undifferentiated carcinomas are associated with abundant osteoclast-like giant cells and are referred to as *undifferentiated carcinoma osteoclastic-like giant cells* (Haratake et al, 1992; Husek, 1990; Ito et al, 1992). It has been well documented that these giant cells are in

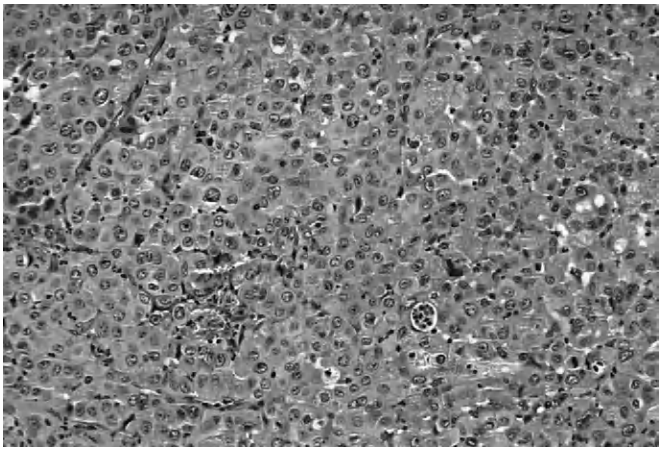

FIGURE 47.11. Undifferentiated carcinoma. This carcinoma is characterized by a diffuse, sheetlike growth pattern of large cells with prominent nucleoli.

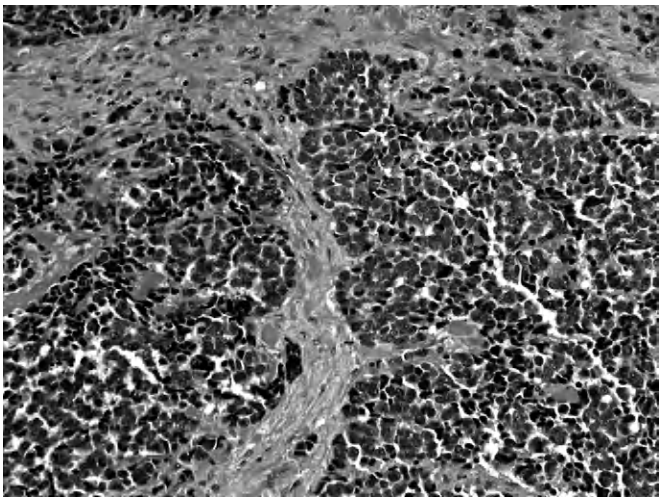

FIGURE 47.12. Small-cell carcinoma. The cells have very high nucleus/cytoplasm ratio with only minimal cytoplasm. Molding of nuclei is apparent, and the chromatin pattern is finely granular.

fact of histiocytic origin, and the malignant cells in this tumor are the mononuclear cells in the background.

Small-cell carcinoma (Komminoth et al, 2010; Maitra et al, 2001; van derWal et al, 1990) also occurs in the region of biliary tree, predominantly in the gallbladder or distal CBD. Small-cell carcinomas (Fig. 47.12) are defined by the same histologic criteria applied to their counterparts in the lung, including high nucleus/cytoplasm ratio, molding of nuclei, diffuse chromatin pattern, and absence of nucleoli. Small-cell carcinomas are high-grade neuroendocrine carcinomas; therefore neuroendocrine markers such as chromogranin, synaptophysin, and CD56 are often detectable by immunohistochemistry. *Large-cell neuroendocrine carcinomas* may also occur in this region (Komminoth et al, 2010; Papotti et al, 2000).

Pathologic Evaluation of Biliary Specimens with Carcinomas

Clinically Relevant Pathologic Parameters in Biliary Carcinomas

TUMOR TYPE. Whether the tumor is a conventional pancreatobiliary invasive adenocarcinoma or another type of neoplasm is important (Bivins et al, 1975). For instance, intraductal papillary neoplasms with focal microinvasion have a significantly better prognosis, and undifferentiated carcinoma has a worse outcome.

INVASIVE VERSUS NONINVASIVE COMPONENTS. For carcinomas with predominantly intraluminal growth (intraductal papillary neoplasms are discussed later), the extent of the noninvasive and invasive components should be considered separately. In fact, cases of biliary adenocarcinomas associated with an unusually protracted clinical course are often predominantly intraductal papillary neoplasms.

PATHOLOGIC STAGE. The size and depth of the tumor are the most important aspects of pathologic staging of biliary carcinomas (Choi et al, 2010; Greene et al, 2002; Hong et al, 2007). There are, however, pitfalls in establishing the depth of the tumor in some parts of the biliary tract, where unlike other sites, such as the gastrointestinal tract, the layers that constitute the duct walls are not well defined. In particular, in parts of the CBD the interface of the mucosa with the muscular layer and the interface of the muscle with the perimuscular tissue are highly irregular, which hinders the accurate evaluation of tumor depth. Similarly, in the intrapancreatic segment of the common bile duct, the demarcation of the common bile duct from pancreatic lobules is highly variable, and how to evaluate invasion into the pancreas is controversial (Hong et al, 2005).

GRADING. The grading scheme advocated by the World Health Organization (WHO) (Albores-Saavedra et al, 2000c) is based on the percent of the tumor showing glandular differentiation, specifically, tubule formation. If more than 95% of the tumor is composed of tubules, it is well differentiated; 40% to 95% is moderately differentiated, and 5% to 39% is poorly differentiated. Those without any glandular differentiation are regarded as undifferentiated.

PERINEURAL AND VASCULAR INVASION. Although the prognostic significance of perineural and vascular invasion has not been fully established, these are nevertheless regarded as components of the pathologic evaluation, especially in resection specimens.

ASSESSMENT OF SURGICAL MARGINS. Proper orientation of the specimen with identification of the margins by the surgical team using sutures or dyes often proves very helpful for accurate evaluation of the surgical margins, especially in complex specimens. The status of the resection margins is an important factor predictive of recurrence (Weber et al, 2001). Bile duct margins typically are amputated from the specimen and submitted *en face,* whereas hepatic and soft tissue margins are inked and sections are submitted perpendicular to the margin.

NONINVASIVE EPITHELIAL NEOPLASIA

Dysplasia (Biliary Intraepithelial Neoplasia)

Dysplasia, also called *biliary intraepithelial neoplasia* (BilIN; see Fig. 47.6), can be seen in mucosa adjacent to invasive biliary carcinomas and, on occasion, as an incidental finding in specimens obtained for other reasons (Albores-Saavedra et al, 1980; Laitio, 1983; Ojeda et al, 1985; Suzuki et al, 1989; Yamagiwa, 1989; Zen et al, 2007). In general, it is a radiographically and grossly occult process characterized by cytoarchitectural atypia of the biliary epithelium, including nuclear enlargement, irregularities, loss of polarity, and mitotic activity. Based on the degree of atypia, dysplasia is graded as *low, intermediate,* or *high grade* or *BilIN1, BilIN2,* and *BilIN3,* respectively (Zen et al, 2007); the high-grade category has been historically referred to as *carcinoma in situ*. Among biliary organs, dysplasia is most common and best studied in the gallbladder, where high-grade dysplasia has been reported in up to 3.5% of routine cholecystectomy specimens (Chan, 1988; Ojeda et al, 1985); this figure is reported to be higher in geographic regions with a higher prevalence of gallbladder carcinoma. The incidence of dysplasia in surgical specimens in the remainder of the biliary tract appears to be much lower. However, when hepatic explants for cirrhosis resulting from alcohol abuse or hepatitis C are systematically evaluated, dysplasia—particularly the low to intermediate grade—is found in more than half of the cases (Wu et al, 2009).

However, the diagnostic criteria for dysplasia are highly subjective, and reactive atypia in the biliary epithelium as a result of inflammation or stenting is very difficult to distinguish from dysplasia, rendering the intraoperative frozen section evaluation of bile duct margins challenging. On the other hand, in patients with invasive carcinoma, dysplasia may be difficult to distinguish from retrograde mucosal involvement by invasive carcinoma, a phenomenon referred to as *colonization* of the surface epithelium. For these reasons, the true frequency of dysplasia in the biliary tract is difficult to determine. It should also be noted that the concept of BilIN, proposed in analogy to pancreatic intraepithelial neoplasia (PanIN) in the pancreas (Zen et al, 2007), is thus far largely based purely on morphologic findings in the biliary epithelium. Molecular alterations supporting the neoplastic nature of all these lesions, analogous to the frequent clonal mutations in the *KRAS* oncogene found in PanINs, have yet to be documented.

In the gallbladder, dysplasia associated with invasive carcinomas appears to have no bearing on the prognosis. Cases of gallbladder dysplasia detected incidentally in the absence of invasive carcinoma appear to be clinically silent and have no documented clinical consequences, provided that the gallbladder has been extensively examined histologically to exclude occult foci of invasive carcinoma. However, data from the Surveillance Epidemiology and End Results (SEER) program of the National Cancer Institute show that one third of the patients with high-grade dysplasia (carcinoma in situ) of the gallbladder died of carcinoma in 10 years, although all were alive at 5 years, suggesting that either a small invasive carcinoma was missed or the patients developed a second malignant neoplasm elsewhere in the biliary system (Albores-Saavedra et al, 2000a). Extrapolating from these observations, a "field effect" phenomenon may occur in some cases, and patients with high-grade gallbladder dysplasia, especially if it is extensive, probably should have some surveillance to screen for subsequent invasive biliary carcinoma. In the bile ducts, high-grade dysplasia rarely is detected in the absence of invasive carcinoma, so the clinical significance of isolated dysplasia is unclear. Such patients would presumably also have an increased risk of developing invasive bile duct carcinomas, and careful examination of the biliary tree to exclude a synchronous, discontinuous focus of invasive carcinoma would seem prudent.

Mass-Forming Intraepithelial Neoplasms

Exophytic, mass-forming neoplasms that project into the lumina of the gallbladder or bile ducts include a family of related entities that have been designated by different terms depending on the location of the tumor, its architecture, and the cell types it comprises. Most of these neoplasms are predominantly formed of papillary structures or tubular glands and some cases have a mixture of both. In the gallbladder, the term *adenoma* is used for localized, generally small tumors that may be tubular, papillary, or tubulopapillary and are further subdivided into pyloric gland, intestinal, foveolar, and biliary types based on the morphology of the epithelium (O'Shea et al, 2002). Pyloric gland adenoma (tubular adenoma, pyloric gland type) is by far the most common type and typically is found as an incidental polyp less than 1 cm composed of tightly packed, cytologically bland pyloric-type cells in routine cholecystectomy specimens (Albores-Saavedra et al, 2010). Exophytic gallbladder neoplasms composed of complex biliary-type epithelium with more marked atypia, a predominantly papillary architecture, and more diffuse involvement of the gallbladder mucosa are regarded as *intracystic papillary neoplasms* (Albores-Saavedra et al, 2010). Most have high-grade dysplasia, which should be graded on the basis of the most severe focus. These tumors have also been designated *noninvasive papillary carcinoma* when high-grade dysplasia is present (Albores-Saavedra et al, 2000a).

Adenomas are uncommon in the bile ducts, and most exophytic bile duct tumors are collectively designated *intraductal papillary neoplasms*, including cases previously reported as *papillomatosis* (Albores-Saavedra et al, 2010; Gouma et al, 1984; Sagar et al, 1993; Taguchi et al, 1993). Most intraductal papillary neoplasms of the bile ducts have high-grade dysplasia (see Fig. 47.7) and were previously designated *noninvasive papillary carcinoma* (Albores-Saavedra et al, 2000b). In contrast to dysplasia or BilIN, intraductal papillary neoplasms can be identified grossly as soft, polypoid tumors within the bile duct lumen. Most are relatively localized within a segment of the bile duct, although multicentric or diffuse involvement can occur, as in so-called *papillomatosis* (Gouma et al, 1984; Sagar et al, 1993; Taguchi et al, 1993). Cystic dilation of the bile ducts may occur (Zen et al, 2006), and some cases exhibit mucin hypersecretion (Shibahara et al, 2004). The epithelial cell types in intraductal papillary neoplasms include pancreatobiliary, gastric, intestinal, and oncocytic (Albores-Saavedra et al, 2010; Ji et al, 2008; Martin et al, 2002; Shibahara et al, 2004; Tanaka et al, 2009), similar to the spectrum of intraductal papillary mucinous neoplasms (IPMNs) of the pancreas. Some authors have referred to these tumors as *biliary IPMNs* (Abraham et al, 2003; Chen et al, 2001; Kim et al, 2000; Shibahara et al, 2004; Tamada et al, 2002). However, differences in the frequency and types of associated invasive carcinoma, as well as the morphology and staining, are significant (Klimstra, 2002). Accumulating data suggest regional geographic differences in the proportion of intraductal papillary neoplasms with the different cell types, perhaps related to varying etiologic factors in different parts of the world (Shibahara et al, 2004). In Asian patients, for example, an association of intraductal papillary neoplasms with *Clonorchis* infection has been reported (see Chapter 45; Jang et al, 2008).

Exophytic intraepithelial neoplasms of the biliary tree are biologically benign when no invasive carcinoma is present, so the detection of a component of invasive carcinoma is key to the pathologic evaluation of these tumors. Small gallbladder adenomas may display high-grade dysplasia, but invasive carcinomas are very rare. In contrast, intracystic papillary neoplasms of the gallbladder and intraductal papillary neoplasms of the bile ducts have associated invasive carcinomas in more than half of all cases (Choi et al, 2010; Paik et al, 2008; Shipov & Aizikov, 1992). Conversely, in some patients with invasive adenocarcinomas, a focal, residual, intraductal papillary neoplasm component is identifiable; in fact, many adenocarcinomas with a polypoid gross appearance represent this latter group. Intraductal/intracystic papillary neoplasms have an excellent prognosis if they can be completely resected, and patients with minimally invasive carcinoma also have a favorable prognosis (Albores-Saavedra et al, 2000b). Once there is a significant amount of invasive carcinoma, however, the prognosis approaches that of biliary adenocarcinomas that do not arise from papillary precursors. Most invasive carcinomas arising in intraductal papillary neoplasms are conventional tubular adenocarcinomas, similar to other bile duct carcinomas. Some cases have a mucinous

(colloid) pattern, usually when the intraductal neoplasm is of the intestinal type. Undifferentiated carcinoma and high-grade neuroendocrine carcinoma have also been reported (Albores-Saavedra et al, 2010).

One lesion to be distinguished from intraductal papillary neoplasms of the bile ducts is biliary mucinous cystic neoplasm, also know as *hepatobiliary cystadenoma* (Albores-Saavedra et al, 2010; Devaney et al, 1994; Wheeler & Edmondson, 1985). Biliary mucinous cystic neoplasms are analogous to mucinous cystic neoplasms of the pancreas and are also regarded as a type of mass-forming preinvasive neoplasm. They form multilocular cystic lesions that occur predominantly in adult women and exhibit pathognomonic hormone receptor–expressing ovarian-type subepithelial stroma (Grayson et al, 1996). The lining epithelium is composed of cuboidal to columnar cells, sometimes with abundant apical mucin. Papillary projections may be identified in the cyst lumen. Although most biliary mucinous cystic neoplasms show benign cytoarchitectural features, some may harbor foci of high-grade dysplasia or invasive carcinoma. Carcinoma can be focal; for this reason, thorough histologic examination is warranted.

NEUROENDOCRINE NEOPLASMS

Carcinoid tumors (Fig. 47.13), also known as *well-differentiated neuroendocrine tumors,* may occur in any part of the biliary tract but tend to be more common in the gallbladder and CBD (Barron-Rodriguez et al, 1991; Ferrone et al, 2007; Kommi-noth et al, 2010; Maitra et al, 2000; Modlin & Sandor, 1997). They are seen predominantly in young or middle-aged adults. Most cases are nonfunctioning and patients present with signs and symptoms of biliary obstruction. Rare examples may be associated with von Hippel–Lindau syndrome (Sinkre et al, 2001). Grossly, carcinoid tumors form relatively well-demarcated nodules and may be polypoid and mucosa covered. They are fleshy, firm, and homogeneous on cut sections. Microscopically, carcinoid tumors are characterized by distinct nests separated by a fibrovascular stroma and strands of cells with round, uniform nuclei, coarsely granular chromatin, and abundant cytoplasm. Rarely, the cytoplasm may exhibit clear-cell, oncocytic, or signet ring–like changes, and a goblet cell variant has also been described. In general, carcinoid tumors are low-grade malignancies with an indolent clinical course. Rare carcinoid tumors mixed with adenocarcinoma (composite adenocarcinoma-carcinoid; Olinici & Vasiu, 1991) behave more like standard adenocarcinomas.

Focal neuroendocrine differentiation and carcinoid-like patterns may be seen in other neoplasms of the biliary tract that should *not* be classified as carcinoids. Rarely, paraganglioma (Caceres et al, 2001), a tumor that also displays neuroendocrine differentiation, may occur in the biliary tract.

OTHER TUMORS

Mesenchymal Tumors

Among the extremely rare mesenchymal tumors of the biliary tree (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003), the one that warrants specific attention is *embryonal (botyroid) rhabdomyosarcoma* (Davis et al, 1969; Lack et al, 1981) because it is relatively more common and well characterized in this region. These are predominantly seen in children 3 to 4 years old and constitute 1% of all rhabdomyosarcomas. The tumor consists of a conglomerate of soft, mucosa-covered polyps filling the lumen. Sizes range from 3 to 14 cm, and the most common site is the CBD. Beneath the surface layer of flattened biliary epithelium is a dense zone of primitive spindle cells, representing the cambium layer. Cytoplasmic cross-striations may be seen, and skeletal muscle differentiation is demonstrable by immunohistochemical staining for actin, desmin, or myoD1. Although the prognosis is poor, multimodal therapy has resulted in long-term survival in some cases. Metastases occur in 40% of cases, but death usually is caused by the local effects of the tumor.

Granular cell tumor (Fig. 47.14) is another mesenchymal tumor that occurs in this region (Eisen et al, 1991), predominantly in the CBD. It is characterized by cells containing abundant acidophilic granular cytoplasm with occasional larger

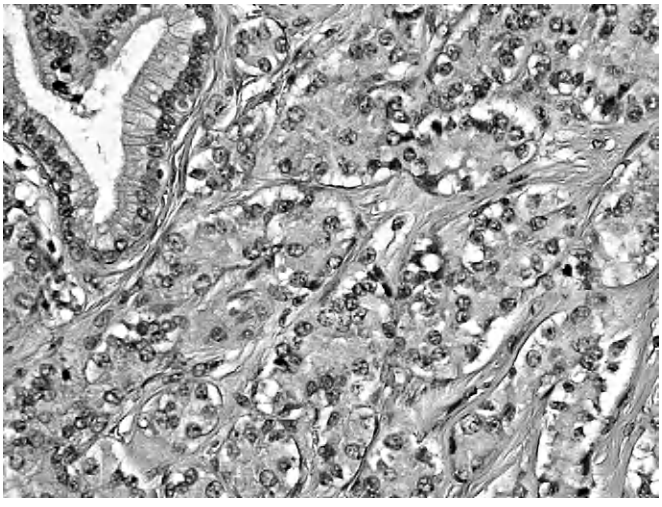

FIGURE 47.13. Carcinoid tumor (well-differentiated neuroendocrine tumor). Carcinoid tumors are characterized by relatively uniform cells with round nuclei and abundant cytoplasm, usually arranged in nests separated by prominent, delicate vasculature.

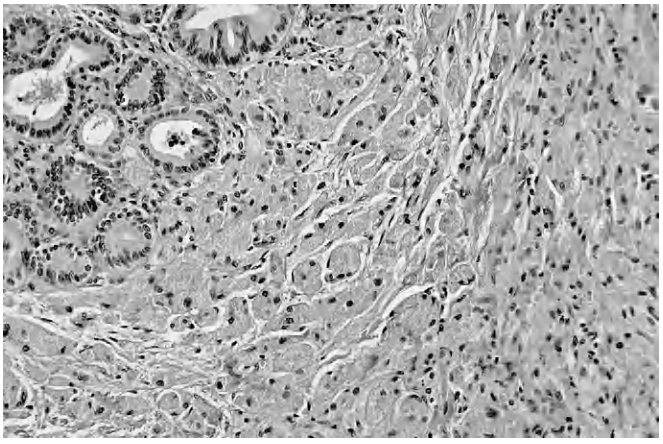

FIGURE 47.14. Granular cell tumor. The cells have small nuclei; abundant granular cytoplasm, occasionally with larger globules; and no nuclear atypia, necrosis, or mitoses.

globules. This tumor is of uncertain origin, but most evidence, including expression of S-100 protein, points toward a relationship to Schwann cells. Although it has an infiltrative appearance, it is a benign tumor with only minimal recurrence potential, even when incompletely excised.

A variety of other mesenchymal tumors have been documented in the biliary tree, both benign (neurofibroma, hemangioma, lipoma, lymphangioma, leiomyoma, ganglioneuroma, myofibroblastic tumors) and malignant (peripheral nerve sheath tumor, leiomyosarcoma, Kaposi sarcoma, angiosarcoma, fibrous histiocytoma, etc.), mostly as case reports (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003). Before a case is classified as sarcoma, the possibility of a sarcomatoid carcinoma must be carefully considered.

Secondary Tumors

The biliary tree may be involved by a variety of carcinomas originating in other organs—especially the pancreas, stomach, colon, kidney, and breast—either by metastasis or direct invasion (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003). Among these, metastatic renal cell carcinoma is notorious for mimicking a primary tumor because it may form a polypoid lesion, and the history of the primary tumor may be too remote to be appreciated in the preoperative clinical evaluation. Similarly, melanomas (Fig. 47.15) may also form polypoid lesions and mimic primary tumors, and often the history of melanoma may not be apparent. Metastases from primary colorectal cancer to the biliary epithelium have also been described (Povoski et al, 2000).

Hematopoietic Malignancies

The biliary tree may be involved by hematopoietic malignancies (lymphoma, myeloma, or leukemia) as a part of systemic disease; rarely, this may be the initial presentation (Adsay, 2004; Albores-Saavedra et al, 2000a, 2010; Lack, 2003). Primary tumors of the mucosa-associated lymphoid tissue type also have been reported.

TUMORLIKE LESIONS

In addition to sclerosing cholangitis, a few other nonneoplastic conditions of the biliary tract may present as tumors (see Chapters 42 and 48). Rarely, heterotopic tissue, especially pancreatic tissue (Inceoglu et al, 1993), may form a mass. Traumatic, or "amputation," neuroma (Sano et al, 1985), which is an exuberant regenerative proliferation of transected nerves, may form a tumor-like nodule, typically in the cystic duct stump, that may mimic a carcinoma. These are very rare and may be seen with obstruction-related signs and symptoms, sometimes several years after the intervention.

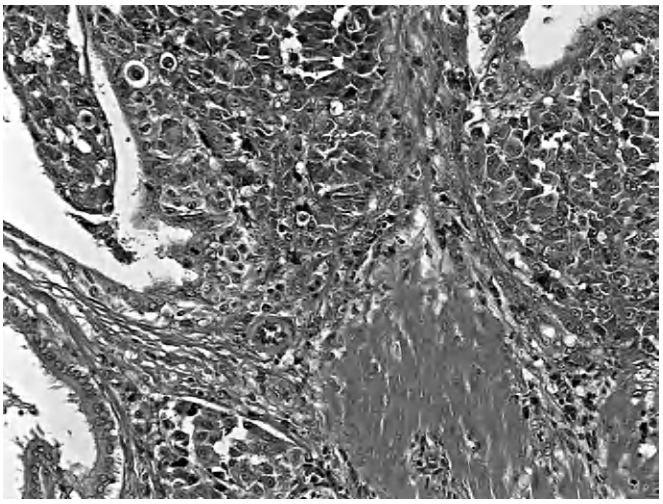

FIGURE 47.15. Melanoma. Metastatic melanomas may mimic primary carcinomas in the gallbladder and biliary tract, sometimes even forming polypoid tumors.

Certain types of tumorlike lesions occur rather frequently in the gallbladder but not often in the remainder of the biliary tree. Nonneoplastic polyps of various kinds may be seen, including cholesterolosis, lymphoid polyps, inflammatory (fibrous, granulation tissue) polyps, and hamartomatous polyps (Albores-Saavedra et al, 1993). Cystic change in Rokitansky-Aschoff sinuses and adenomyomas (Levesque et al, 1964) also commonly form pseudotumors in the gallbladder; however, these are not seen in the bile ducts.

Autoimmune sclerosing disorders related to autoimmune pancreatitis may affect the bile ducts and gallbladder. As in the pancreas, these are characterized by a dense, subepithelial lymphoplasmacytic inflammatory infiltrate; dense fibrosis, often with a storiform pattern; and obliterative venulitis. There is an association with elevated levels of immunoglobulin G4 in the serum, and immunoglobulin G4–expressing plasma cells can be found in large numbers within the lesions by immunohistochemistry (Kamisawa & Okamoto, 2008). These processes form a tumorlike mass that can be mistaken for carcinoma on imaging studies (Corvera et al, 2005). Some cases are associated with autoimmune pancreatitis (Wang et al, 2009), whereas others present with disease limited to the gallbladder or bile ducts, sometimes called *autoimmune cholangitis* (Deshpande et al, 2009).

CHAPTER 48

Benign tumors and pseudotumors of the biliary tract

Adeel S. Khan and David C. Linehan

OVERVIEW

Painless jaundice is most frequently caused by obstruction of the extrahepatic bile duct by malignant periampullary neoplasms, but benign tumors and pseudotumors of the biliary tract, although rare, should be included in the differential diagnosis. Benign biliary tumors are clinical rarities that in the past have been the subject of infrequent case reports, usually combined with a review of the literature. In previous series, benign bile duct tumors have been reported in 0.1% of all biliary tract operations and have constituted only 6% of all extrahepatic bile duct neoplasms (Burhans & Myers, 1971). To date, fewer than 300 cases of benign bile duct tumors have been reported in the English literature. As shown in Table 48.1, benign neoplasms are derived from the epithelia or from nonepithelial structures that make up the normal bile duct (Levy et al, 2002). Similarly, pseudotumors or tumorlike lesions of the bile duct or other periampullary tissues can cause biliary tract obstruction and jaundice. When pseudotumors or nontraumatic inflammatory strictures of the extrahepatic bile duct are included, the incidence increases, with some surgical series reporting up to a 10% to 25% incidence of benign biliary pseudotumors (Corvera et al, 2005; Koea et al, 2004). Importantly, these series demonstrate that with current preoperative staging tools, it is often impossible to distinguish between benign and malignant etiologies for biliary obstruction, so preoperative tissue confirmation does not often alter management in resectable patients.

As a result of their rarity, benign tumors of the bile ducts are seldom considered in the differential diagnosis of obstructive jaundice. Symptoms may be present for a few days to several years, whereas the clinical presentation may mimic cholecystitis; biliary calculi; or ampullary, pancreatic, or bile duct cancer, all of which are much more common. In addition, true benign bile duct neoplasms must be differentiated from a number of inflammatory conditions they mimic, not only in presentation but in cholangiographic features and even appearance at laparotomy. Indeed, preoperative diagnostic and laboratory studies often cannot distinguish malignant from benign etiologies of bile duct obstruction, so preoperative biopsy in resectable patients usually is not indicated.

This chapter, after a discussion of biliary tract anatomy and embryology, addresses the clincial presentation and diagnostic workup of patients with benign tumors and pseudotumors of the biliary tract. Biliary lesions resulting from benign neoplasms or other benign conditions presenting as localized masses and causing biliary obstruction are classified in the following general categories: 1) papilloma and adenoma, 2) granular cell tumor, 3) neural tumors, 4) leiomyoma, 5) neuroendocrine tumors, and 6) pseudotumors (idiopathic benign biliary stricture or heterotopic tissue).

Biliary cystadenoma is not covered in this chapter because the lesion usually presents as an intrahepatic cystic neoplasm, which is difficult to differentiate from cystadenocarcinoma (see Chapter 79B). Indeed, benign and malignant epithelium frequently coexist, and histologic diagnosis is extremely difficult (Ishak et al, 1977; Marsh et al, 1974; Moore et al, 1984; Woods, 1981).

EMBRYOLOGIC AND ANATOMIC FACTORS

Benign tumors of a variety of histologic types have been observed in the extrahepatic ductal system. The embryology and anatomy of the region account for this to a large degree (see Chapter 1A). Embryologically, the extrahepatic biliary tree develops in close relationship to the liver, arising from a thickened area of endoderm on the ventral surface of the primitive gastrointestinal (GI) tract at the junction of the foregut and hindgut in the 3-mm human embryo during the fifth week of intrauterine life. This small outpouching is the anlage of the liver, extrahepatic biliary ducts, gallbladder, and the ventral bud of the pancreas.

Sclerosing cholangitis
Heterotopic tissue

Modified from Levy AD, et al, 2002: Benign tumors and tumor-like lesions of the gallbladder and extra-hepatic bile ducts: radiologic–pathologic correlation. Radiographics 22:387-413.

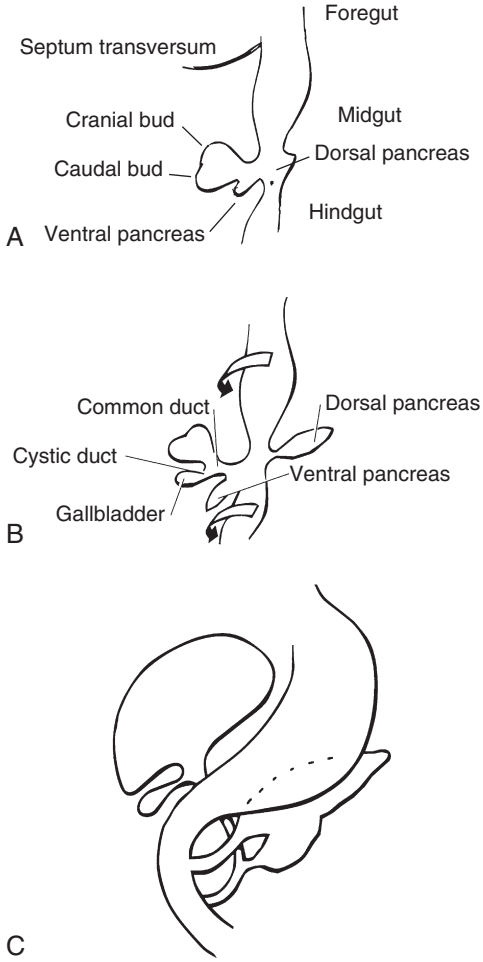

FIGURE 48.1. A, At approximately the fifth week of intrauterine life, a diverticulum evolves near the junction of the midgut and hindgut and grows into the ventral mesogastrium. The ventral pancreatic bud develops from the superior surface as the cranial sacculation and pushes cephalad into the septum transversum. **B,** The gallbladder and extrahepatic ducts develop from the caudal bud, and the liver develops from the cranial bud. The ventral pancreas evolves in close relationship to the developing common bile duct. **C,** At the 7-mm stage, left-to-right rotation occurs, resulting in subsequent fusion of the pancreas, gallbladder, duodenum, and extrahepatic bile ducts in their normal anatomic relationship.

A diverticulum evolves from this thickened area, which divides into a superior and inferior bud as it grows into the ventral mesogastrium (Fig. 48.1A). The ventral pancreatic bud develops from the superior surface of the diverticulum, proximal to the enlarging terminal sacculations. The cranial sacculation, the larger of the two, pushes ventrally and cranially into the septum transversum, which separates the thoracic from the celomic cavity. Composed of a solid mass of endodermal cells, it spreads out into the substance of the septum transversum, eventually forming the right and left lobes of the liver. Cephalad growth and extension of the cranial sacculation results in stretching of the endodermal cell mass from the duodenum to the liver, which eventually evolves into the extrahepatic biliary tree. At approximately the seventh week of intrauterine life, vacuolization takes place within the solid mass of cells of the primitive extrahepatic biliary tree and results in the development of a ductal lumen.

Before the 7-mm stage, the common bile duct (CBD) is attached to the ventral surface of the duodenum close to the ventral pancreatic bud. At the 7-mm stage, left-to-right rotation of the ventral pancreas and duodenum takes place so that the CBD eventually enters on the posteromedial surface of the duodenum (Fig. 48.1B and C). The gallbladder and cystic duct develop concurrently from the caudal portion of the primitive hepatic diverticulum during the same period (Lindner & Green, 1964).

The CBD lies in the right border of the hepatoduodenal ligament between serosal surfaces. The ductal wall is composed of mucosa, fibrous tissue, and serosa. Rare smooth muscle fibers may be found in the duct wall, but muscular tissue is not a prominent component. Thickness of the duct wall varies from 0.8 to 1.5 mm, with an average of approximately 1.1 mm (Mahour et al, 1967). The terminal end of the duct is invested with muscle fibers, as elegantly described by Boyden (1957). At this point the CBD usually joins with the major pancreatic duct, but they may fail to unite and enter the duodenum separately (Dowdy et al, 1961).

The mucosa lining the extrahepatic biliary tree consists of a single layer of columnar epithelium and a tunica propria containing mucous glands. Scattered chromogranin-positive cells can be formed in glands of the normal gallbladder neck, and rare cells immunoreactive for somatostatin have been found between the lining epithelium of the hepatic duct in patients with biliary disease (Dancygier et al, 1984). It has been observed that chronic inflammation of the biliary tract may result in intestinal metaplasia of the mucosa, which seems to result in an increase in the number of argentaffin cells (Kulchitsky cells). Barron-Rodriguez and colleagues (1991) have suggested that these changes may be the basis for the development of carcinoid tumors of the biliary tree. The epithelial surface of the duct is

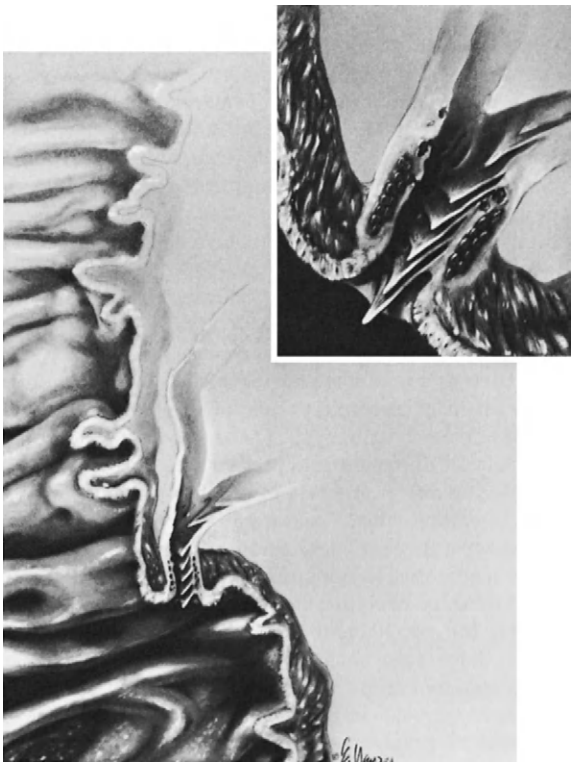

FIGURE 48.2. Artist's representation of the macroscopic anatomy of the choledochoduodenal junction, depicting the transverse valvules described by Brown and Echenberg (1964), which probably serve to prevent reflux from the duodenum.

generally flat except for tiny pits in the mucosa known as *sacculi of Beale,* which are luminal openings for the intramural mucous glands. As the duct penetrates the wall of the duodenum, the mucosa appears to become thickened and the surface roughened by longitudinal folds of mucosa, or *valvules,* particularly at the terminal end of the duct. According to Boyden (1936), the valvules were first described in the *Fabrica of Vesalius* (1543), followed later by a more detailed description by Santorini (1724). Brown and Echenberg (1964) described a more frequent occurrence of transversally oriented flaps or valvules that face the duodenal lumen and probably function to prevent reflux of duodenal contents into the biliary tree and pancreatic ducts (Fig. 48.2). Baggenstoss (1983) has also reported that free folds of ductal epithelia in the form of papillary processes may extend 2 to 3 mm beyond the Vaterian orifice.

Microscopically, a definite transition exists between the mucosa of the duct within the ampulla and the surrounding duodenal mucosa. The ductal mucosa exhibits numerous papillary processes much larger than the adjacent duodenal villi.

CLINICAL PRESENTATIONS AND DIAGNOSIS

Patients with benign biliary tract tumors, and often those with inflammatory masses masquerading as neoplasms, invariably present with clinical manifestations of jaundice. The onset of icterus may be insidious or intermittent, with few other symptoms. On the other hand, the presentation may be sudden and associated with colicky epigastric pain, referred to the back or shoulder, along with nausea and vomiting. There is seldom any significant weight loss, unlike patients with pancreas cancer or cholangiocarcinoma, who frequently present with jaundice, poor appetite, and weight loss (see Chapters 50B and 58B). Because these tumors are relatively slow growing, some of the clinical symptoms may be intermittent or gradually progressive over an extended period only to culminate with obstructive jaundice. No clinical symptoms are apparent that can help the physician differentiate a benign biliary tract tumor from other, more common causes of biliary tract obstruction.

Physical findings are likewise nonspecific: liver enlargement, a palpable gallbladder, tenderness to palpation in the right hypochondrium, and jaundice. Indeed, because of the lack of characteristic symptoms and physical findings, benign biliary tumors usually are not diagnosed preoperatively or antemortem (Chu, 1950).

Reports since the early 1970s have emphasized the usefulness of percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) in the establishment of a preoperative diagnosis of extrahepatic obstruction and in distinguishing between calculus and tumor as a cause (see Chapter 18; Kittredge & Baer, 1975). Noninvasive imaging of the biliary tree with magnetic resonance cholangiopancreatography (MRCP) and high-quality computed tomography (CT) also now play a significant role in the diagnosis of these lesions. In their report of a patient with granular cell myoblastoma, Jain and colleagues (1979) suggested that an eccentric, short stenosis might be associated with a benign biliary tumor. However, obstructive changes identical to those seen in malignant neoplasms are not uncommon and indeed may be produced by inflammatory masses (Hadjis et al, 1985; Stamatakis et al, 1979). Although PTC and ERCP cannot distinguish between a benign tumor and a malignant process, adequate visualization of the ductal system can provide vital information concerning tumor location, extension, and size as well as the status of the intrahepatic ductal system. However, no preoperative diagnostic study is capable of reliably distinguishing benign from malignant tumorous obstruction of the biliary ducts. Endobiliary brush cytology has a high positive predictive value but, unfortunately, the negative predictive value is too low for clinical usefulness, particularly in the setting of a resectable tumor. Similarly, molecular study of cytology specimens, such as K-ras mutational analysis, has not shown improved diagnostic accuracy (Sturm et al, 1999). Newer minimally invasive tissue-acquisition techniques that include endoscopic, ultrasound-guided methods may improve diagnostic accuracy, although negative biopsy results still offer no assurances because of the suboptimal negative predictive value. Therefore these tests often do not often alter clinical management in the resectable patient (Byrne et al, 2004; Eloubeidi et al, 2004).

PAPILLOMA AND ADENOMA

The most common variety of benign tumor of the extrahepatic biliary tree is that arising from the glandular epithelium lining the ducts. Roughly two thirds of the benign neoplasms reported fall into the category of either *polyp, adenomatous papilloma,* or *adenoma.* Chu (1950), in his classic review of benign biliary neoplasms, found that 26 out of 30 cases studied were either papillomas or adenomas. A similar observation was made by Dowdy and colleagues (1962), when 36 of the 43 reviewed cases were noted to be either papillomas or adenomas. Since

1962, 58 additional patients have been added to the English literature (Bahuth & Winkley, 1966; Short et al, 1971; Sull & Brown, 1972; Archie & Murray, 1978; Lukes et al, 1979; Bergdahl & Andersson, 1980; Austin et al, 1981; Gouma et al, 1984; Van Steenbergen et al, 1984; Thomsen et al, 1984; Byrne et al, 1989; Loh et al, 1994; Chae et al, 1999; Fletcher et al, 2004; Kunisaki et al, 2005; Boraschi et al, 2007; Akaydin et al, 2009). Presently, we have traced a total of 120 patients reported in the English literature with benign polyps, adenoma, or cystadenoma.

A slight female predominance (1.3:1) in the incidence of these lesions has been noted, and although the average age at diagnosis is 58 years, the youngest recorded occurrence was in a 3-year-old child (Wardell, 1969). Leriche (1934) reported a massive papillomatous tumor weighing 750 grams, arising from the CBD of a 4-year-old child.

The anatomic distribution of papillomas or adenomatous lesions reported to date appears in Figure 48.3. The majority are found either in the ampulla or in close proximity to the Vaterian system (47%), and the CBD (27%) is the second most frequent site.

The onset of symptoms may vary from a few weeks to 35 years. Jaundice, a presenting symptom in more than 90% of patients (McIntyre & Pay-Zen, 1968), occurs intermittently in approximately 40% of patients. Most patients complain of right upper quadrant pain associated with the jaundice. Wright (1958) reported a patient with relapsing pancreatitis who was cured by excision of a CBD polyp that had prolapsed into the ampulla of Vater. Gallstones or biliary calculi are reported in only 20% of patients found to have benign extrahepatic ductal tumors. Cattell and Pyrtek (1950) suggest that recurrence of symptoms following cholecystectomy should suggest the possibility of a tumor in the ampullary area rather than biliary dyskinesia.

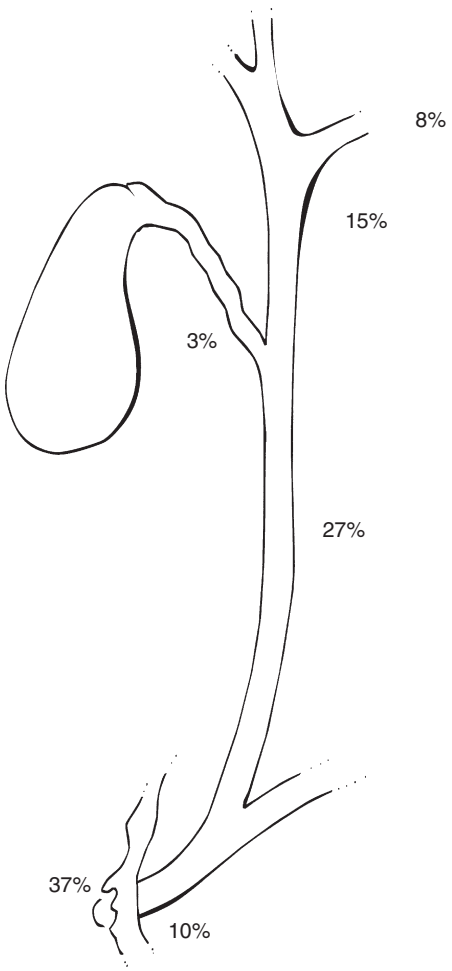

FIGURE 48.3. Location and frequency of papillomas and adenomas reported between the hepatic duct confluence and the ampulla of Vater.

A benign adenomatous tumor should be included on the differential list in all secondary operations performed for obstruction of the biliary tree. Interestingly, Kunisaki and colleagues (2005) described the case of a 54-year-old man who showed up with abdominal pain and jaundice 3 years after a cholecystectomy for cholecystitis and choledocholithiasis. ERCP revealed impingement of the common hepatic duct (CHD) at the level of the cystic duct, without filling of the cystic duct remnant. Reexploration for a presumed diagnosis of retained cystic duct stone revealed a 2-cm papillary adenoma of the cystic duct remnant, compressing the CBD (Mirizzi syndrome; see Chapter 42B) and causing symptoms. These lesions are generally soft, difficult to palpate, and present little or no resistance to exploring ductal probes; thus they are difficult to detect at operation and are more frequently detected by intraoperative cholangiography, ultrasonography, or choledochoscopy (see Chapter 21).

The radiographic features of extrahepatic bile duct adenomas are often difficult to distinguish from cholangiocarcinomas and even ampullary cancers (see Chapters 50B and 59; Figs. 50B.2 and 50B.8). Ultrasound typically reveals a nonshadowing intraluminal mass, sometimes with a visible pedicle or stalk but more often with a sessile architecture. ERCP will show a lobulated intraluminal filling defect that is often obscured by mucin accumulation in mucin-producing adenomas. Lesions developing in the lower CBD near the ampulla may actually protrude through the papilla and be visible endoscopically, and we have seen such a case. In contrast, malignant lesions developing in the ampullary area tend to be infiltrative and are usually larger, firmer, and more likely to be ulcerated at presentation. Initial symptoms related to bleeding in association with benign adenomatous polyps of the bile ducts are exceedingly rare, although Teter (1954) recorded a death due to massive hemorrhage secondary to such a lesion.

Kozuka and colleagues (1984) suggested that most polypoid or papillary cancers of the extrahepatic duct arise from preexisting adenomas (see Chapter 50B). In a review of 43 carcinomas of the extrahepatic tree, they identified an adenomatous residue in nine (21.4%). Gouma and colleagues (1984) reported a case of intrahepatic bile duct papillomata associated with changes of nuclear atypia and reviewed the literature, suggesting that it is reasonable to regard these lesions as having low-grade malignant potential. Pathologic review of the specimens often show foci of carcinoma in situ, atypia, or dysplasia; these may point to a premalignant nature, but the rarity of such lesions makes definitive conclusions difficult.

Although it has been suggested that biliary adenomas may be the result of a focal reactive process to injury, the exact etiology remains uncertain. Miyano and colleagues (1989) demonstrated that these lesions could be produced experimentally by performing a choledochopancreatostomy in puppies, a model for anomalous choledochopancreatic ductal junction. After

several years, mucosal hyperplasia was observed in 100% of the dogs, and almost half had bile duct adenomas.

Austin and colleagues (1981) reported two patients who presented with obstructive jaundice and solitary, nonparasitic liver cysts. At reoperation, the first was found to have a papillary adenoma in the CHD, which was excised; the second had an obstructing polypoid cystadenoma of the left hepatic duct compressing the right biliary system.

A possible association was proposed between solitary, nonparasitic liver cysts and adenomas of the ductal system (Austin et al, 1981), and the clinical course of these two underscores the difficulty in detection of soft adenomatous tumors obstructing the extrahepatic biliary tree. An association between nonparasitic cystic biliary disease and the development of cholangiocarcinoma has also been described in the literature (Schiewe et al, 1968; Jones & Shreeve, 1970; Gallagher et al, 1972; Dayton et al, 1983; Nasu et al, 1971; Leroy et al, 1979). However, any association between these overt malignancies and the presence of preexisting adenoma or papilloma within biliary cysts is difficult to prove.

TREATMENT

In 1962, Dowdy and others reviewed the literature and detailed the operative procedures for 37 patients with papillomas or adenomas. They reported that four out of the five recognized tumor recurrences were in patients who had had local tumor excision as primary therapy. Since that time, 41 additional patients have been reported in whom both the operative procedure and follow-up data are available: 15 underwent local excision, presumably including the stalk and/or base of the polyp, and two of these (13%) had recurrences that necessitated reoperation. Also, 14 patients with lesions in or near the ampulla had local excision by way of transduodenal papillotomy without a recorded tumor recurrence, and in three other patients, curettage of a polypoid tumor was accomplished without recurrence. In addition, 4 patients had local resection of the duct, one had local resection of the duct wall without recurrence, and four underwent pancreaticoduodenectomy for a low-lying tumor initially thought to be malignant.

Based upon reported experience, it appears that the choice of operative procedure is dependent upon the patient's age, medical condition, and the location of the tumor; any procedure should include total resection of the lesion, preferably with some duct wall. Lesions arising in the ampulla can successfully be managed by wide local excision in most instances.

MULTIPLE BILIARY PAPILLOMATOSIS

Multiple biliary papillomatosis (MBP) is a rare disease characterized by the presence of numerous mucin-secreting papillary adenomas within the extrahepatic and/or intrahepatic biliary tree. It is generally considered a low-grade malignancy with a propensity for local recurrence after resection. Histologically, these papillomas consist of fibrovascular stalk covered by a single layer of epithelial cells with apical mucin and minimal pleomorphism (Tsui et al, 2000). The etiology and pathogenesis of MBP remain unclear. One hypothesis includes induction of mucosal metaplasia or hyperplasia in response to chronic biliary inflammation by stones, infection, or pancreatic juice. Terada (1991) and Cheng (1999) suggested a relationship between MBP and Caroli disease that may indicate a congenital etiology. Most of the reported cases are from Asia, which may reflect a racial or geographic predeliction, but such an association has not yet been established.

Most patients with intrahepatic papillomatosis are initially seen with obstructive jaundice that is frequently intermittent and often complicated by cholangitis. This complication is a result of partial and intermittent obstruction of the bile duct by tumor fragments, mucus plugs, or blood clots. In some patients, however, the only symptom has been abdominal pain. The history may extend for more than 20 years and may be associated with anemia as a result of bleeding. In only two cases have associated cholelithiasis and choledocholithiasis been reported. If left untreated, the disease ultimately results in death from sepsis or liver failure.

Preoperative diagnosis is made radiologically and may be made more frequently now, since the advent of widespread availability of endoscopic retrograde cholangiography (ERC), MRCP, and direct cholangioscopy. The endoscopic examination of the papilla of Vater often shows a widely open orifice with mucin drainage. Direct or noninvasive cholangiography shows multiple intraluminal filling defects that typically do not move with vigorous catheter irrigation and hence can be differentiated from mucin or stones. The lesions can be intrahepatic, extrahepatic, or both (D'Abrigeon, 1997). Tompkins and colleagues (1976) have emphasized the value of intraoperative endoscopy in the evaluation of the biliary tree for multiple lesions. Several studies have suggested that endoscopic ultrasound (EUS) can be at least as accurate as ERCP in diagnosing MBP, with the additional advantage of visualizing invasion of the duct wall or adjacent vessels and metastasis to locoregional lymph nodes in the presence of malignancy (Mukai, 1995; Ma, 2000; Lai, 2002).

Caroli and colleagues (1959) first reported the occurrence of diffuse papillomatosis in both the intrahepatic and extrahepatic ducts of a 42-year-old male. Although the presenting symptoms were of abdominal pain and jaundice, the patient was also noted to be anemic secondary to hemobilia. A T-tube was placed in the biliary tree, through which 10 L of mucoid secretions were drained in the first 24 hours following surgery. The patient died 48 hours later. It was noted that the biliary secretions had a high potassium content, which the authors postulated might be analogous to the mucoid diarrhea and hypokalemia associated with villous adenoma of the colon. In the same report, a second patient presented with cholangitis and was reported to be cured following a left hepatectomy for papillomatosis confined to the left intrahepatic ducts.

Since Caroli's first report in 1959, an additional 87 cases of MBP have been reported in the English literature. A review of 78 cases by Yeung and colleagues (2003) showed a male/female ratio of approximately 2:1, with a mean age at presentation of 63 years (range, 6 to 83 years). The most common symptoms at the initial visit were abdominal pain and jaundice. Almost half of the patients (42%) had diffuse intrahepatic and extrahepatic disease, and 27% had only intrahepatic disease; another 27% had only extrahepatic disease, and two patients had involvement of the gallbladder. Malignant transformation was seen in 42% of the patients at the time of presentation. Only 55% of the patients were candidates for a curative resection, and the remainder were palliated in various ways, including choledochoscopic laser ablation, iridium-192 intraluminal therapy, percutaneous cholangioscopic electrocoagulation, and

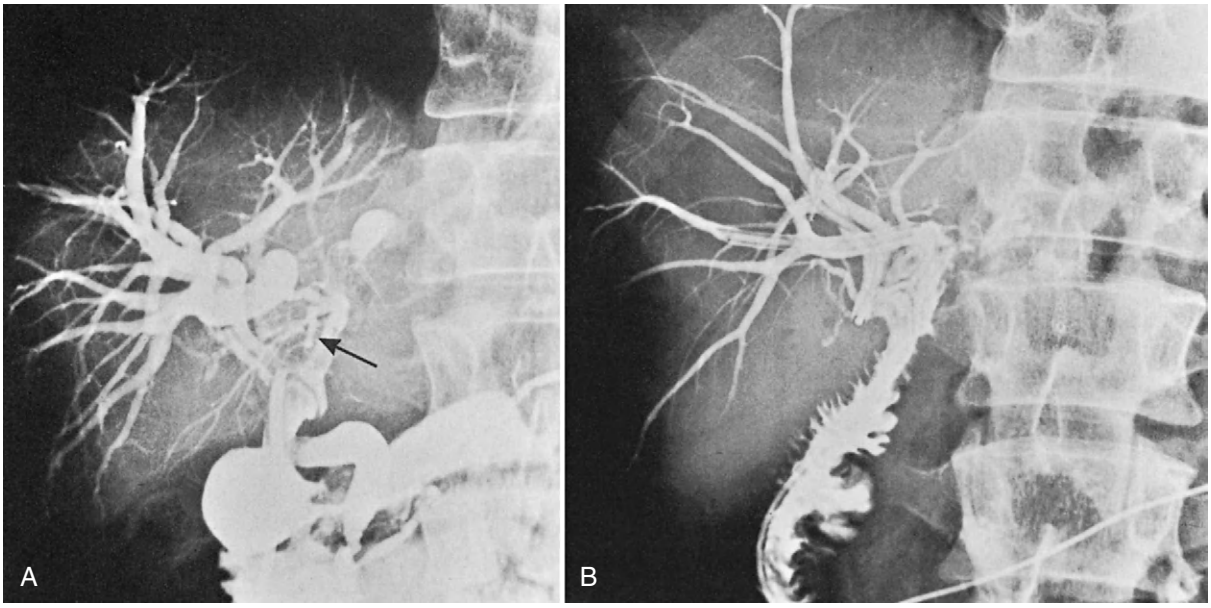

FIGURE 48.4. A, T-tube cholangiogram obtained after initial choledochotomy in a patient who presented with intermittent attacks of jaundice. At operation, loose tumor particles were found in the common bile duct and proved to be fragments of papilloma. The T-tube enters the main right hepatic duct, and a residual filling defect is seen in the left ducts (*arrow*). **B,** Tube cholangiogram following subsequent left hepatic lobectomy and reconstruction by hepaticojejunostomy Roux-en-Y. The anastomosis is widely patent. The tube was removed, and the patient was alive and well 4 years later. *(Reproduced with permission from Gouma DJ, et al, 1984: Intrahepatic biliary papillomatosus. Br J Surg 71:72-74.)*

combined cholangioscopic laser ablation and external beam radiotherapy.

The low-grade malignant potential of MBP has been the subject of many studies. Cattell and colleagues (1962) suggested that these lesions had a low-grade malignant potential after reporting recurrence of obstructive jaundice in a patient within a year of undergoing successful placement of a T-tube. Indeed, risk of malignant transformation with nuclear atypia or carcinoma in situ is significant, and it is commonly observed in papillary lesions. Ohta and others have reported point mutations of the *KRAS* gene in benign papillary lesions (Ohta et al, 1993). Padfield and colleagues (1988) documented basement membrane discontinuities in three patients consistent with patterns accompanying malignant tumors; they cautioned that papillary neoplasms, although histologically benign, should be considered premalignant. Gouma and others (1984) reported a similar case, in which intrahepatic bile duct papillomata (Fig. 48.4A) were associated with changes of nuclear atypia. The patient was treated by left hepatic resection that included the base of the papillomatous lesions, and biliary-enteric continuity was established by hepaticojejunostomy to the residual right liver (Fig. 48.4B). The patient was symptom-free and without recurrence 4 years after surgery.

The authors concur with Cattell's view that it is reasonable to regard these lesions as having low-grade malignant potential. A further patient has been reported who lived approximately 5 years before dying of cholangitis (Madden & Smith, 1974). Treatment had included partial hepatic resection, choledochoduodenostomy, and weekly courses of carmustine (BCNU). Some decrease in the amount of tumor was observed following therapy, and although cellular atypia was reported, no malignant changes could be documented at autopsy. Of the two recently reported patients, an 80-year-old male died after choledochoduodenostomy because of variceal bleeding, but the second, reported by Gertsch and colleagues (1990), was reported alive and well 15 months after curettage (Hubens et al, 1991).

The extent, distribution, and secondary obstructive changes induced by these soft lesions present management challenges. If the lesions are limited and confined to one liver lobe, liver resection should be strongly considered, although attempted radical surgery by means of hepatic lobectomy has been reported in only five cases: One of these was alive and well at 4 years (Gouma et al, 1984). One further case was reported alive 6 months after surgery with no evidence of recurrence, and one died 6 years after resection with diffuse malignant tumors in the right lobe of the liver after initial left hepatic lobectomy. The remaining two patients had multiple papillomatoses, apparently localized to the left hepatic duct at operation; both had recurrence in the common and right hepatic duct 6 months and 3 years after lobectomy and died 5 and 6 years, respectively, after the first operation. It seems clear, therefore, that even major resectional surgery for this lesion has a high recurrence rate; Gouma and colleagues (1984) were able to trace 12 patients for whom adequate follow-up figures were available and found mean survival to be 28 months. It should be noted, however, that although no patient survived more than 6 years, the only 5-year survivals were in three cases submitted to radical surgery.

A report by Helling and Strobach (1996) documents a 67-year-old female patient with papillomatosis and high-grade dysplasia occluding the left hepatic duct who was successfully managed by a left hepatic lobectomy. The patient was disease free 20 months following resection. The authors reviewed the literature and commented on three important features of this lesion: 1) a high recurrence rate, with approximately 50% of patients requiring reoperation; 2) copious mucin production

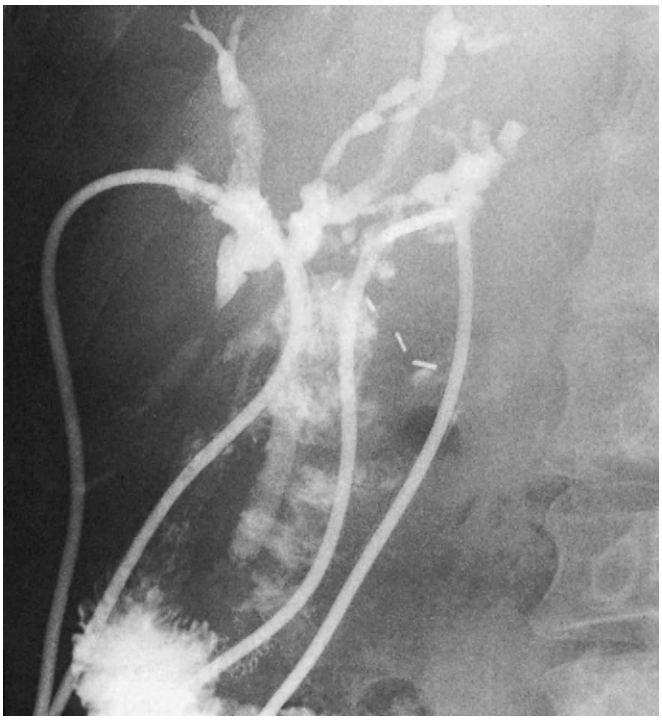

FIGURE 48.5. Bilateral U-tubes placed through hepaticojejunostomy to the right and left hepatic ducts in a patient with multiple intrahepatic biliary papillomatoses. The patient, a middle-aged woman, presented with chronic iron deficiency anemia followed by the onset of jaundice. At initial operation, papillomata at the orifice of the right and left hepatic ducts were curettaged, and bilateral U-tubes were placed. Satisfactory palliation of jaundice was obtained for 18 months, but malignancy supervened; the patient died of recurrent biliary obstruction and liver failure.

that may lead to fluid electrolyte imbalances, and 3) malignant transformation, which is observed in a significant percentage of patients (Helling & Strobach, 1996). Since this report, five additional extrahepatic benign papillary lesions have been recorded (Loh et al, 1994; Lam et al, 1996; Meng et al, 1996; Khan et al, 1998; Yeung et al, 2003).

An intubational approach to papillomatosis affecting the entire biliary tree has been described (Fig. 48.5). Employment of the approach described by Hutson and colleagues (1984) and by Barker and Winkler (1984) seems reasonable: a Roux-en-Y hepaticodochojejunostomy is fashioned in such a manner as to allow a jejunal fistula for access to the biliary tree postoperatively and permit repeated curettage or intubation. Meng and colleagues (1996) reported on the use of holmium: YAG laser therapy via choledochoscopy and successful ablation after curettage; after four sessions of choledochoscopy and laser therapy, all tumor was ablated, and there were no signs of tumor recurrence at 6 months. Lastly, consideration might be given to chemotherapy, especially with agents excreted by the liver. Recently Beavers and colleagues (2001) reported the case of a 59-year-old patient with recurrent cholangitis from diffuse biliary papillomatosis that persisted even after a left hepatectomy and hepaticojejunostomy. Because of deteriorating liver function, she was placed on the list for liver transplantation and underwent successful orthotopic liver transplantation (OLT) with a Roux-en-Y hepaticojejunostomy. She was alive and asymptomatic 9 months following the surgery. Similarly, Dumortier and colleagues (2001) reported their results for a 61-year-old patient with recurrent symptoms from diffuse MBP who underwent an OLT and pancreatoduodenectomy. Her final pathology revealed three foci of invasive carcinoma limited to the biliary wall. After 22 months of follow-up, the patient remained asymptomatic, without evidence of tumor recurrence or metastasis.

In summary, a reasonable approach to this rare condition includes preoperative and operative cholangiographic diagnosis, early choledochotomy, and assessment of the intrahepatic biliary tree by choledochoscopy. If the tumor is bulky, curettage is performed to identify the sites of origin within the bile duct. Care must be taken to perform choledochoscopy of as many intrahepatic ducts as possible. When the papillomatosis appears to be confined to one lobe, it is reasonable to perform a radical resection consisting of partial hepatectomy that includes excision of all involved ducts. Although this does not guarantee freedom from recurrence, it offers good palliation and carries the best possibility of long-term cure. In cases of papillomatosis involving both the right and left ductal system, radical surgery is not applicable. It seems best to avoid long-term external drainage as a preliminary palliative procedure, and curettage or internal bypass is indicated. Some form of hepaticojejunostomy may be helpful, as it allows percutaneous access to the biliary tract. Recent results with OLT seem promising and should be considered in patients with diffuse disease who are not candidates for any other curative procedures. The prognosis should be regarded as poor if complete removal of the tumor is not possible.

GRANULAR CELL TUMORS

Granular cell tumor (GCT) is a very rare benign tumor of uncertain etiology occasionally encountered in the extrahepatic biliary tree. First desribed in 1926 as *granular cell myoblastoma,* recent debate has ensued about the cell of origin. Levy and colleagues (2002) suggest that, rather than myoblasts, the tumor may originate fom Schwann cells, evidenced by its immunohistochemical staining with antibodies to S-100 protein normally found in the central nervous system or in Schwann cells in the peripheral nervous system. Honjo and colleagues (2003) recently reported a case of extrahepatic biliary Schwannoma, basing this diagnosis on S-100 positivity on immunohistochemistry. Similarly, Altavilla and colleagues (2004) described reactivity to S-100 and neuron-specific enolase antibodies in GCT of the intrapancreatic portion of the CBD.

GCTs constitute less than 10% of all benign tumors of the extrahepatic biliary tree (Dursi et al, 1975). Although reported in anatomic locations as varied as the pituitary and appendix, the lesions are most commonly encountered in the tongue, breast, and subcutaneous tissues, with less than 1% of GCTs occurring in the extrahepatic biliary tree (Paskin et al, 1972; Dursi et al, 1975). The most frequent sites of occurrence of extrahepatic biliary GCTs are the CBD, cystic duct, and gallbladder. The average age of patients with this tumor is 34.5 years. More than 80% of documented cases have occurred in females, 66% of whom are black, and 15% of patients have multiple lesions (Vance & Hudson, 1969).

Since Coggins' original autopsy report in 1952, 67 additional patients have been reported with GCTs of the

extrahepatic biliary tree; 33 had lesions arising from the common hepatic or CBD, 19 from the cystic duct, 5 from the cystic duct and CHD, and 4 from the hepatic duct (Kittredge & Baer, 1975; Mauro & Jacques, 1981; Cheslyn-Curtis et al, 1986; Lewis et al, 1993; MacKenzie et al, 1994; Yazdanpanah et al, 1993; Ferri Romero et al, 1994; Foulner, 1994; Karakozis et al, 2000; Pongtippan et al, 2000; te Boekhorst et al, 2000; Altavilla et al, 2004; Lochan et al, 2006). In addition, one patient had lesions involving the cystic duct and the hepatic duct (Sanchez & Nauta, 1991); two had lesions involving the cystic duct, gallbladder, and CBD (Aisner et al, 1982; Martin et al, 2000); and two had cystic duct, CHD, and CBD lesions (Balart et al, 1983; Butler & Brown, 1998). GCT arising from the ampulla of Vater has only been reported once (Khalid et al, 2005).

The fact that extrahepatic ductal granular cell myoblastomas are found more commonly in black females is attested to in the literature: 38 of 54 females recorded are black, 10 are Caucasian, 3 are Asian, and 5 are of unspecified racial origin. Three black males and a single male child of unspecified race have been reported. Multiple tumors within the extrahepatic biliary tree have been reported in seven patients (Kittredge & Baer, 1975; Mauro & Jacques, 1981; Aisner et al, 1982; Sanchez & Nauta, 1991; Cheslyn-Curtis et al, 1986; MacKenzie et al, 1994; Martin et al, 2000). Multifocal tumors have been noted in seven patients with bile duct lesions, two patients with separate gastric tumors, four with synchronous skin lesions, in one individual with lesions in the mesentery and trachea, and in one patient with simultaneous lesions in the trachea and CHD (Mulhollan et al, 1992; LiVolsi et al, 1973; Whisnant et al, 1974; Assor, 1979; Manstein et al, 1981; Orenstein et al, 1984; Yang & Ortiz, 1993). Clinical symptoms associated with granular cell myoblastoma arising in extrahepatic bile ducts tend to be those of painless jaundice, and a presentation of upper abdominal pain and colic is more commonly associated with lesions arising in the cystic duct. Other described symptoms include anorexia, weight loss, nausea, and vomiting. Granular cell myoblastoma might be included in the differential diagnosis of obstructive jaundice seen in a black female, especially if she has a tumor nodule in the tongue, breast, or subcutaneous tissue, but such a clinical presentation would be extraordinarily rare.

The majority of tumors have been described as firm to palpation, localized, confined to the wall of the CBD or cystic duct, and generally less than 3 cm in diameter. Because granular cell tumors are typically small, they may not be visible on US or CT scan, and only intrahepatic and extrahepatic biliary dilation are seen. ERCP often reveals a short, focal, annular stricture, and MRCP may show similar findings. Usually these tumors do not invade surrounding structures, and the mucosa overlying the tumor has generally been intact and histologically normal. On cut section, granular cell myoblastoma is yellowish white, and microscopically it consists of fibrous tissue diffusely infiltrated by large, elongated polygonal cells or cells containing small, dark nuclei and an abundant eosinophilic granular cytoplasm on a hematoxylin and eosin stain. The cytoplasmic granules are markedly positive with the periodic acid-Schiff reaction (Fig. 48.6), and frozen-section diagnosis has been shown to be adequate for delineating these lesions. Although this tumor usually does not metastasize, local recurrence may occur, especially if excision is incomplete.

The histogenesis is uncertain and is marked by controversy. The tumor was initially termed *granular cell myoblastoma,*

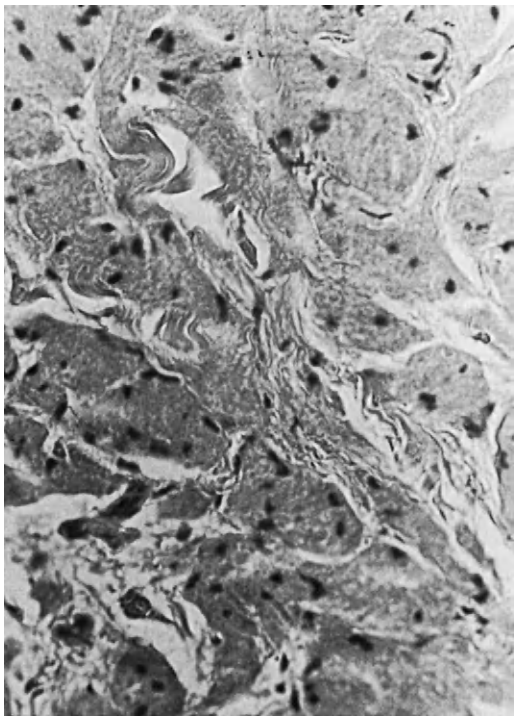

FIGURE 48.6. Granular cell myoblastoma excised from the common bile duct showing large polygonal cells with indistinct cell borders. Also typically demonstrated are uniform, small, round nuclei surrounded by finely granular, eosinophilic cytoplasma. (Hematoxylin and eosin, ×120.)

because it was thought to be derived from "myoid cells." Indeed, characteristics of the cells in tissue culture suggest a myogenic origin (Murray, 1951). Moreover, it is now generally regarded that granular cell tumors arise from the Schwann cell in that the tumor cells react to antibodies with S-100 protein, normally found in the central nervous system and in peripheral Schwann cells (Armin et al, 1983). Treatment should consist of total excision of the bile duct segment containing the lesion with reconstruction by Roux-en-Y choledochojejunostomy or hepaticojejunostomy for lesions arising in the CHD (Manstein et al, 1981; MacKenzie et al, 1994). Altavilla and colleagues (2004), Karakozis and colleagues (2000), Chandrasoma and Fitzgibbons (1984), Manstein and colleagues (1981), and Raia and colleagues (1978) have reported successful management of lesions occurring in the intrapancreatic bile duct by pancreaticoduodenectomy. Two local recurrences were documented, and three patients required second procedures because of incomplete local excision (Dursi et al, 1975; Manstein et al, 1981; Butler & Brown, 1998; Khalid et al, 2005). To date, malignancy has not been observed in any reported extrahepatic glandular cell tumor.

NEUROENDOCRINE TUMORS

Endocrine tumors of the extrahepatic bile ducts are exceedingly rare. The only endocrine cells that have been normally demonstrated in the extrahepatic ducts are somatostatin-containing D cells (Dancygier et al, 1984). However, it has been postulated that metaplastic changes in the biliary epithelium, perhaps resulting from inflammation, may lead to the development and appearance of argyrophile cells (Barron-Rodriguez et al, 1991).

Because the biliary system is derived embryologically from the foregut, it is not surprising that cells immunoreactive for gastrin, serotonin, and somatostatin have been demonstrated in the biliary tree (Angeles-Angeles et al, 1991). Only a handful of cases have been reported, most of which have been hormonally nonfunctional. Reported tumors fall into one of three categories: carcinoid, gastrinoma, or somatostatinoma. A clinical picture of obstructive jaundice is the usual presentation, although a carcinoid was found incidentally in the unobstructed CBD of an explanted cirrhotic liver following OLT (Hao et al, 1996). To date only one patient has been recorded as having a functioning endocrine tumor, a 52-year-old female with a 2-year history of recurrent duodenal ulcer whose peptic disease was cured when her gastrinoma was excised from the CBD (Mandujano-Vera et al, 1995).

Since Davies' original report in 1959, an additional 61 documented cases of carcinoid tumors arising in the extrahepatic bile ducts have been reported in the literature (Felekouras et al, 2009). In the cases reviewed, jaundice was the most common presenting symptom (two thirds of patients), and a third had right upper quadrant abdominal pain. Other symptoms included back pain, weight loss, nausea, and vomiting. Analysis also indicates an increased incidence of extrahepatic carcinoid tumors in younger people along with a slight female predominance (1.9:1). There have been 35 reported cases of biliary carcinoids arising in the CBD, 14 of tumors originating in the hilum, 7 in the cystic duct, and 5 arising in the CHD (Davies, 1959; Bumin et al, 1990; El Rassi et al, 2004; Nesi et al, 2006; Felekouras et al, 2009). A recent report from Memorial Sloan–Kettering Cancer Center (MSKCC) documented a case of isolated carcinoid arising from the right hepatic duct (Ferrone et al, 2007; Fig. 48.7A and B). The clinical course is indolent, and endoscopic or percutaneous biopsy or brush cytology tends to be notoriously nondiagnostic, which makes preoperative diagnosis difficult. Most small neuroendocrine tumors of the CBD are found incidentally during biliary tract operations performed for other indications, and the final diagnosis is made postoperatively, after histologic and immunohistochemical examination. Although some patients with carcinoid tumors of the extrahepatic bile ducts may have slightly elevated levels of urinary 5-hydroxyindoleacetic acid, none of the published cases have reported carcinoid syndrome. Biliary neuroendocrine tumors have an indolent biologic behavior and exhibit limited propensity for metastatic disease, which has been reported only in a third of the patients at presentation. Most patients are candidates for curative resection, with excellent long-term results.

The choice of operation depends on the location of the tumor and the extent of disease. Hilar, CHD, and proximal CBD neoplasms can be treated with regional lymphadenectomy, Roux-en-Y hepaticojejunostomy (Jutte et al, 1986; Bumin et al, 1990), and en bloc resection of the tumor and adjacent bile ducts. In the uncommon situation of carcinoid tumors arising at or above the biliary confluence, distinguishing this diagnosis from cholangiocarcinoma prior to operation is nearly impossible; an approach to resection that includes en bloc partial hepatectomy is required for cholangiocarcinoma (see Chapter 50B; Ferrone et al, 2007; see Fig. 48.7A and B). Patients seen initially with tumors of the distal bile duct are generally managed with pancreatoduodenectomy, or Whipple procedure (Vitaux et al, 1981; Nesi et al, 2006). There have been three reported cases of patients with cystic duct tumors treated with a simple cholecystectomy (Goodman et al, 1984; Hermina et al, 1999; Nahas et al, 1998). Long-term disease-free survival up to 20 years has been reported, even in the presence of distant metastases (Davies, 1959; Little et al, 1968; Hao et al, 1996; El Rassi et al, 2004).

No absolute histologic criteria are available by which to judge the malignant potential of biliary endocrine tumors. Larger tumors are thought to be more aggressive with respect to metastatic potential; however, metastases with very small carcinoid tumors of the cystic duct have been reported (Hermina et al, 1999). Ki-67 cell index greater than 5% also does not

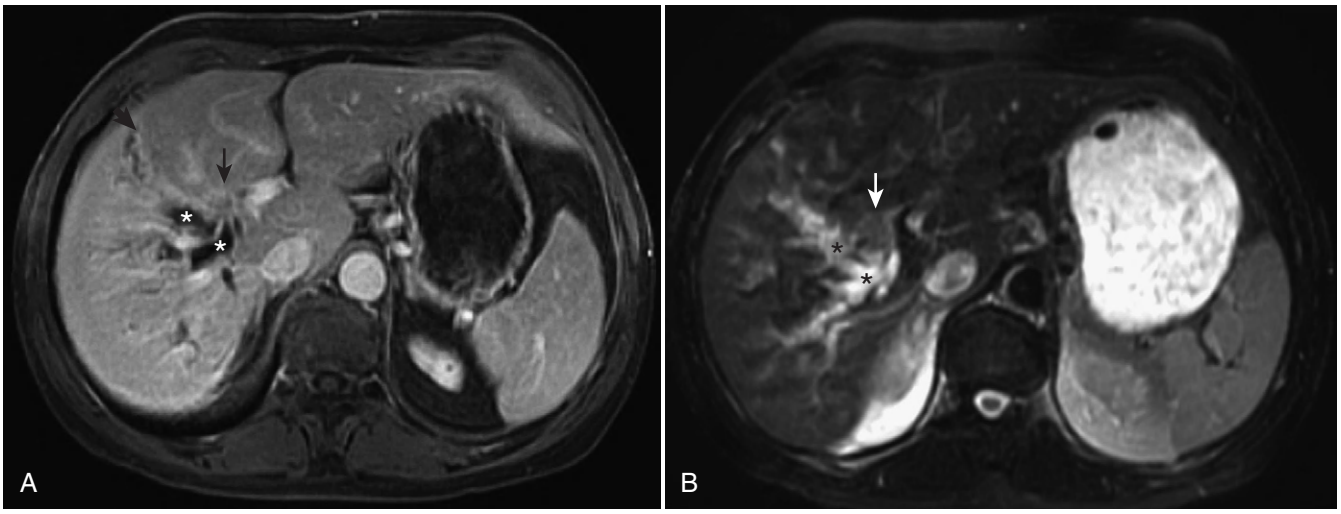

FIGURE 48.7. Magnetic resonance cholangiopancreatogram (MRCP) showing a carcinoid tumor arising from the right hepatic duct. **A,** Contrast-enhanced axial T1 sequence. The tumor (*arrow*) is located at the confluence of the right anterior and posterior sectoral ducts, which are dilated (*asterisks*). Despite the absence of vascular inflow involvement by tumor, a notable difference in perfusion was found between the right and left hemilivers (*arrowhead*) with hypertophy of the left side, the apparent result of long-standing biliary obstruction. **B,** Axial MRCP image of the same patient. The tumor (*arrow*) at the confluence of the dilated right and left anterior sectoral ducts (*asterisks*), which appear white in this sequence.

necessarily predict aggressive behavior (Ligato et al, 2005). Given the good long-term results with surgical resection, it is generally agreed that curative surgical resection is the most relevant prognostic factor in management of endocrine tumors of the extrahepatic biliary ducts.

NEURAL TUMORS

The incidence of neural tumors would appear to be lower than expected, when the abundant network of neural tissue that normally surrounds the extrahepatic bile ducts is considered. In 1955, Oden reported the occurrence of a neuroma in a 40-year-old woman who presented with jaundice and mild epigastric discomfort. At operation, a cystic tumor was found displacing the CBD medially. The cyst was extirpated, but the wall contiguous to the CBD was left in situ. Several common duct stones were also removed.

Neurofibromas of the bile duct are extremely uncommon, although they have been reported in patients with type 1 neurofibromatosis (NF). Because GI involvement occurs in approximately 25% of patients with NF, biliary involvement is more commonly secondary to obstructing duodenal or periampullary neurofibromas (Mendes, 2000). Although bleeding, perforation, and obstruction as a result of intussusception, volvulus, and stenosis have been reported, only one other instance of obstructive jaundice secondary to visceral neurofibromatosis has been recorded in the literature. Curry and Gray (1972) reported the autopsy finding of a submucosal nodular tumor 25 mm in diameter protruding into the duodenum around the ampullary opening.

Sarma and colleagues (1980) reported a hilar tumor arising in the left hepatic duct and surrounding the right hepatic duct that was deemed unresectable. The biopsy submitted at that time was interpreted as poorly differentiated carcinoma. A tube was placed through the lesion, and the patient was readmitted with cholangitis several times over the next 7 years. A second exploration revealed total obstruction of the left hepatic duct, partial obstruction of the right hepatic duct, and cystic degeneration of the left lobe of the liver. Another tube was placed through the tumor into the right hepatic duct, and the cystic left liver lobe was drained by a Roux-en-Y jejunal loop. Review of the fresh biopsies and the original material were each interpreted as paraganglioma. Although these tumors commonly arise in the adrenal gland as pheochromocytoma, extraadrenal lesions are more commonly found in the neck, the mediastinum, and around the aorta. Paragangliomas have been observed in the gallbladder, GI tract, and the genitourinary tract; this appears to be the first lesion reported in the extrahepatic biliary tree.

LEIOMYOMA

Leiomyomas are the most common benign tumors of the esophagus, stomach, and small intestine; in the extrahepatic biliary tree, they are among the least common. The scanty presence of muscle fibers in the normal CBD probably accounts for the fact that only seven such lesions have been reported. Each of these patients presented with progressive jaundice, itching, nausea, vomiting, and weight loss. The first case was reported in a 31-year-old female with a 2-cm tumor confined to the intrapancreatic segment of the CBD, which was locally excised, along with some of the overlying pancreatic tissue; the duct of Santorini was also ligated, and the proximal bile duct was anastomosed to the jejunum. This patient was reported well 3 years following surgery (Archambault & Archambault, 1952). Fernandez and Gonzales-Bueno (1974) recorded a leiomyoma occuring at the ampulla of Vater. A third patient, reported by Kune and Polgar (1976), was a 49-year-old male treated by pancreatoduodenectomy for a 4-cm tumor in the intrapancreatic segment of the CBD, which was assumed to be a pancreatic carcinoma at surgery. Microscopically, the lesion was observed to arise from the bile duct wall, and the patient was well 28 months after operation. The fourth patient died of septicemia following ERCP demonstration of a tumor obstructing the lower part of the CBD, seemingly as a result of external compression. Autopsy examination revealed an angioleiomyoma of the CBD; the mucosa overlying the tumor was observed to be intact (Ponka et al, 1983). Mandeville and Stawski (1991) reported a fifth patient in whom a leiomyoma of the hepatic duct bifurcation was treated with excision and hepaticojejunostomy. Yamaoka and colleagues (1993) described the case of a 49-year-old male with distal common bile duct leiomyoma who was treated with pancreatoduodenectomy. Recently, Goo and colleagues (2006) described a seventh case of biliary leiomyoma in a 39-year-old woman who underwent a pylorus-preserving pancreatoduodenectomy for a distal CBD stricture. Final pathology disclosed leiomyoma of the CBD accompanying severe fibrosis.

PSEUDOTUMORS

Nonmalignant lesions may cause obstruction of the extrahepatic biliary ductal system and closely resemble neoplasms at investigation and even at laparotomy; they occur frequently enough to be seriously considered in the differential diagnosis of any lesion suspected to be a bile duct tumor. In a recent large series of 132 consecutive patients undergoing resection for a suspicious hilar lesion, 20 (15%) had a histopathologically proven benign tumor diagnosed as chronic fibrosing or erosive inflammation, sclerosing cholangitis, or a granular cell tumor (Gerhards et al, 2001). Similarly, the incidence of benign pseudotumors is approximately 10% to 20% in several recently published large series of surgically treated patients with proximal biliary obstruction (Corvera et al, 2005; Koea et al, 2004; Binkley et al, 2002). Interestingly, all of these published series show that preoperative diagnosis is difficult, and resection remains the only reliable way to rule out malignancy. In a more recent study of 171 patients with a presumptive diagnosis of hilar cholangiocarcinoma, benign strictures were ultimately identified in nine (5.3%; Are et al, 2006). In this study, the combination of vascular involvement and lobar atrophy were much more common in patients with cholangiocarcinoma (38%) than in those with other diagnoses (3.3%, $P < .001$; see Chapter 50).

The possibility of a benign diagnosis, although uncommon, must always be kept in mind. Lesions should not be assumed to be neoplastic without histologic proof, and certainly a presumed diagnosis of neoplasm should not be the signal for incomplete drainage procedures carried out surgically, percutaneously, or endoscopically. Such maneuvers are inevitably followed by infection that necessitates stent exchange, and they are likely to complicate subsequent curative surgery.

Primary sclerosing cholangitis (PSC) should be strongly suspected in a patient with biliary stricture in the setting of ulcerative colitis; the prevalence may be as high as 90% when routine

rectal and sigmoid biopsies are obtained (Tung et al, 1996; see Chapter 41). Diagnosis can be established by demonstration of characteristic multifocal stricturing and dilation of the intrahepatic or extrahepatic biliary tree on cholangiography (Lee & Kaplan, 1995). Untreated disease almost always leads to complications of hepatic failure and cholestasis, and liver transplantation is the treatment of choice for patients with advanced disease. Five-year survival rates as high as 85% have been described after liver transplantation for patients with PSC (Langnas et al, 1990; Graziadei et al, 1999).

INFLAMMATORY TUMORS

Stamatakis and colleagues (1979) reported the occurrence of a benign inflammatory mass of the CBD in a 13-year-old girl who presented with obstructive jaundice and abdominal pain. PTC demonstrated complete obstruction of the CHD with intraluminal shouldering, suggesting a tumor. At operation, a 3-cm spherical mass was found to be closely applied to the porta hepatis, necessitating excision of the confluence, CHD, and CBD with reconstruction by Roux-en-Y hepaticojejunostomy. Pathologic examination demonstrated nearly complete obstruction of the CHD and CBD by an encapsulated yellowish-brown mass. Microscopically, the encased bile duct exhibited loss of muscular coat, loss of ductal epithelium, and replacement by collagenous fibrous tissue. Scattered throughout the fibrous tissue were foci of acute inflammatory cells. These authors concluded that the mass represented an excessive inflammatory reaction to some local chemical or infective irritant and further speculated that the lesion might represent a form of localized sclerosing cholangitis. The child was reported fit and active 1 year after treatment.

Haith and colleagues (1964) reported a somewhat similar clinical occurrence in a 6-year-old boy with a lesion located in the distal CBD, treated successfully by pancreatoduodenectomy. A similar case was reported by Golematis and colleagues (1982) of a 23-year-old man who presented with obstructive jaundice and a lesion at the confluence of the hepatic ducts. The lesion was successfully resected and histologically appeared to represent a localized area of sclerosing cholangitis. One other such case has been reported by Heuser and Polk (1983).

Standfield and colleagues (1989) reported an interesting group of 12 patients with localized strictures of the extrahepatic biliary system. No patient had a history of trauma, gallbladder stones, or antecedent diseases generally associated with sclerosing cholangitis. All patients were found to have histologic evidence of chronic inflammation, fibrosis, and epithelial ulceration. These authors felt that this entity was distinct from sclerosing cholangitis in that the mucosa remains intact in sclerosing cholangitis.

At the Hammersmith Hospital, London, Hadjis and colleagues (1985) showed eight out of 104 patients submitted to surgery with a clinical diagnosis of malignant obstruction at the confluence of the bile ducts to have benign disease. The benign nature of the lesion was not certain in 6 of these patients even at the time of laparotomy. Comprehensive investigation had failed to give an accurate preoperative diagnosis, although biliary obstruction was accurately shown in all patients, and preoperative assessment using cholangiographic and angiographic data indicated that all were potentially resectable. For this reason, and in light of the safety of local excisional surgery and excellent quality of life obtained (Beazley et al, 1984; Blumgart et al, 1984), palliation by intubational methods was not attempted. In all patients, the obstructing lesion was removed, biliary reconstruction was by means of Roux-en-Y hepaticojejunostomy, and liver biopsy was obtained.

Microscopic examination of the biopsies taken from the bile ducts of these patients showed an extensive increase of fibrous tissue in all instances. Subepithelial mucous glandular proliferation was evident in all patients, but not in every specimen, and the glandular cells were always well differentiated with elongated to round nuclei showing normal polarity. Most glands were surrounded but not replaced by fibrous tissue. In some instances, glands appeared to be distorted by fibrous tissue coursing between acini. Striking nerve trunks were observed in four of the patients but not in all the specimens, some of which were very small. Accumulations of lymphocytes were present in most specimens and were sometimes perivascular, sometimes perineural, but not diffusely infiltrating the wall of the bile duct, with little adventitial inflammation. Sections of associated lymph nodes and of the gallbladder were unremarkable, and no vascular changes were identified. In no specimen was evidence of dysplastic, neoplastic, or preneoplastic cytologic change found. Nuclei were normal, no single epithelial cells were encountered within connective tissue, and no pools of mucin were found. Similar changes were reported by Ikei and colleagues (1989).

One patient with overt signs of peritonitis following previous laparotomy underwent emergency exploration and was found to have a loculated intraabdominal bile collection and a subhepatic abscess, which was drained; renal function was impaired at the time of laparotomy, and the patient subsequently died of multiple system failure. No tumor was found at the hilum of the liver, but a sclerotic lesion was confirmed together with proximal large duct obstruction.

No operative deaths were recorded in the eight patients submitted to elective surgery, and seven were alive and asymptomatic from 16 to 46 months after operation. One patient required reoperation for a further stricture and remained reasonably well for 2 years, at which time she developed recurrent episodes of cholangitis with cholangiographic evidence of progression of intrahepatic sclerosing cholangitic lesions; she died 30 months after a second operation.

Although the cholangiographic picture of diffuse sclerosing cholangitis is usually characteristic (see Chapter 41), this is not necessarily true of the localized form of the disease. The diagnostic difficulty is compounded in that cholangiocarcinoma has been described in association with, or as a complication of, PSC. It is important to emphasize that in the presence of a localized high bile duct stricture, and in the absence of angiographic involvement, it is impossible, without specific biopsy or cytology, to make a definitive diagnosis in this situation. The marked desmoplastic reaction that even small hilar cholangiocarcinoma often excites, together with the ductal and glandular hyperplastic changes consequent of long-standing obstruction and severe secondary cholangitic changes, comprise the main pathologic factors responsible for histologic difficulty in differentiating benign from malignant disease (Weinbren & Mutum, 1983). Indeed, some believe that cases of sclerosing cholangitis localized at the hilum may be instances of slow-growing sclerosing carcinoma, and that it is only a matter of time before such a lesion declares its malignant potential. However, extensive studies at the Royal Postgraduate Medical School have demonstrated characteristic features of malignant biliary disease (see

Table 48.2

Malignant Masquerade Tumors of the Extrahepatic Biliary Tree Reported Since 1987

Reference	Number	Location	Etiology	Treatment
Schroyens et al (1987)	1	CBD	Sclerosing cholangitis	Liver transplant
	1	CBD	Sclerosing cholangitis	Autopsy
Standfield et al (1989)	12		Nontraumatic inflammatory strictures	Excision Roux-en-Y (7)
				Hepaticojejunostomy (3)
				Intubation (2)
Wetter et al (1990)	2		Mirizzi syndrome	
	3		Granuloma	
	3		Focal stenosis	
Tsunoda et al (1991)	1	Confluence	Sclerosing cholangitis	Partial hepatectomy
Oren et al (1991)	1	CHD	Sclerosing cholangitis	Stent and liver transplant
Gerhards et al (2001)	20	Hilus	Fibrosis, granular cell tumor	
				Resection
Binkley et al (2002)	4	Hilus	Fibrosis	Resection
Koea et al (2004)	12	Hilus	Idiopathic benign biliary stricture (10)	Resection
			Stone disease (2)	
Corvera (2005)	22	Hilus	Lymphocytic sclerosing cholangitis (2)	Resection
			PSC (3)	
			Granulomatous process (3)	
			Idiopathic benign biliary stricture (8)	
			Stone disease (6)	

For data prior to 1987, see text.
CBD, common bile duct; CHD, common hepatic duct; PSC, primary sclerosing cholangitis

Chapter 47; Weinbren & Mutum, 1983), and these were found to be absent in all cases in the series reported by Hadjis and colleagues (1985). Six patients remained symptom free with normal liver function at a mean follow-up period of 28.3 months.

In a more recent series, Koea and colleagues (2004) presented a New Zealand experience of 49 consecutive patients who presented with obstructive jaundice as a result of a stenosing lesion at the hepatic hilus. The final tissue diagnosis in 12 of these patients was benign (idiopathic benign biliary stricture in ten and stone disease in two). MRI, US, CT scan, and cholangiography were performed in all patients. At least half of the benign lesions had radiologic features suggestive of malignancy. Routine measurement of serum CEA and CA19-9 was also performed. Marked elevation of CA19-9 was shown to have a high positive predictive value, but five of 32 patients with malignancy had a normal CA19-9, and CEA was not found to be useful. The authors concluded that current diagnostic modalities do not reliably distinguish malignant and benign disease, and therefore definitive resection should remain the gold standard. Interestingly, Koea and others point out that frozen section performed intraoperatively did not guarantee an accurate tissue diagnosis, as these were negative in two patients with subsequently confirmed cholangiocarcinoma.

Gerhards and colleagues (2001) reported 20 cases of suspicious hilar lesions that ultimately proved to be benign. Interestingly, of the 16 patients who had ERCP, 13 were considered to have radiographic characteristics suspicious for malignancy (irregular eccentric stenosis or blunt ending). Brush cytology revealed no malignant cells in nine patients, atypical cells in four, and carcinoma in a single patient, again attesting to the poor accuracy of this test.

Similarly, in the report by Corvera and colleagues (2005), 22 of 275 patients treated at MSKCC for proximal biliary obstruction had a final histologic diagnosis of benign fibroinflammatory stricture despite preoperative radiologic assessment suggestive of malignancy, a feature termed "malignant masquerade" by the authors. The etiology of obstruction in these cases is listed in Table 48.2. No preoperative clinical or diagnostic features were identified in this series that could reliably distinguish between benign and malignant causes of bile duct stricture, leading the authors to conclude that the treatment approach should continue to be resection for presumed malignancy.

Lymphoplasmacytic sclerosing pancreatitis and cholangitis (LPSPC) is a rare inflammatory cause of pancreatitis that can be indistinguishable from pancreatic cancer and may result in biliary obstruction (see Chapter 55). The hallmark of this diagnosis is an exuberant inflammatory process characterized histologically by fibrosis and a large population of plasma cells, and in many patients it is associated with elevated serum IgG4 levels (Yoshida et al, 1995). Patients usually are seen with painless jaundice and a pancreatic mass. Radiographic studies show biliary obstruction due to the pancreatic mass, which shows characteristics indistinguishable from pancreatic cancer (see Chapter 58b). Weber and colleagues (2003) published a series of patients presumed to have pancreas adenocarcinoma who were subsequently determined to have LPSCP. The pathologic characteristics of this inflammatory tumor includes 1) lymphoplasmacytic infiltration of the pancreas, 2) interstitial fibrosis, 3) periductal inflammation, and 4) periphlebitis. Some have reported on the effectiveness of pancreatoduodenctomy in the treatment of this disease (Weber et al, 2003; Hardacre et al, 2003), but others have argued that preoperative diagnosis by

evaluating serum IgG4 levels may avoid unnecessary pancreatic resection in these patients, who can often be successfully treated with systemic corticosteroids (Hughes et al, 2004).

It is now recognized that a similar process may involve the biliary tract without concomitant pancreatic disease (Ghazale et al, 2008). Such cases of IgG4-associated cholangitis are extremely difficult to distinguish from sclerosing cholangitis. In a recent report of 10 patients with this diagnosis, compared with 17 with PSC, the former had higher portal and lobular inflammatory scores (Deshpande et al, 2009).

As termed by Hadjis and colleagues in their original report in 1985, *malignant masquerade* has since been observed by many others. Table 48.2 records the reports in the literature since 1987 related to benign inflammatory lesions occurring in the extrahepatic biliary tree. The authors draw attention to the fact that these lesions should not be allowed to masquerade in the guise of malignant tumors, but it is equally important that bile duct malignancies are not mistaken for benign tumors.

HETEROTOPIC TISSUE

Symptomatic heterotopic tissue arising in the biliary tree is exceedingly rare. In 1967, Whittaker and colleagues first observed heterotopic gastric mucosa in a cystic duct that had obstructed the gallbladder. Welling and colleagues (1970) have since recorded a similar mucosal mass obstructing the CBD at the level of the cystic duct. Kalman and colleagues (1981) reported a 1-cm papillary tumor arising in the CHD, which on microscopic examination demonstrated gastric fundal mucosa replacing the full thickness of the bile duct wall.

Heterotopic gastric mucosa occurring at the ampulla of Vater was observed to be the basis for biliary tract obstruction by Blundell and colleagues (1982). Although occurrence elsewhere in the GI tract is well documented, this appears to be the first documented ampullary obstruction secondary to heterotopic gastric mucosa. A more recent report documented a case of heterotopic gastric tissue causing biliary tract obstruction that was clinically indistinguishable from cholangiocarcinoma (Quispel et al, 2005).

Kalman and colleagues (1981) cite two hypotheses for the etiology of heterotopia: First, metaplasia with heterotopic differentiation is suggested. Several authors have described metaplastic gastric replacement of the gallbladder mucosa in cases of chronic cholecystitis; usually the metaplastic glands resemble pyloric and Brunner glands, whereas specialized chief and parietal cells are absent. A second, perhaps more tenable theory is one based upon the observation that embryologically, the epithelial lining of the foregut together with parenchyma of the liver and pancreas all arise from the same primitive endoderm, as discussed previously. Kalman states that because of the "common origin of these structures lined by multipotential cells capable of differentiation along several cell lines, it is not unreasonable to conclude that the heterotopic gastric replacement may have resulted from congenitally replaced tissue."

Heterotopic pancreatic tissue has been observed to occur from the stomach to the ileum, as well as in the omentum, spleen, gallbladder, and CBD. Seven cases have been reported in which heterotopic pancreatic tissue was found in the CBD or ampulla of Vater (Barbosa et al, 1946; Weber et al, 1968; Sabini et al, 1970; Laughlin et al, 1983). Al-Shraim and colleagues (2010) recently reported a case of ectopic pancreatic tissue in the gallbladder associated with chronic cholecystitis.

CHAPTER 49

Cancer of the gallbladder

T. Peter Kingham and Michael I. D'Angelica

OVERVIEW

Gallbladder cancer is rare and traditionally has been considered an incurable disease with an extremely poor prognosis. The pessimism and nihilism that historically have been associated with gallbladder cancer stem from its commonly late presentation, often with disseminated disease, its overall dismal prognosis, and lack of effective therapy. The quote that sums up this sentiment best comes from Blalock, who stated in 1924, "In malignancy of the gallbladder, when a diagnosis can be made without exploration, no operation should be performed, inasmuch as it only shortens the patient's life." Although it is clear that gallbladder cancer has a tendency to spread early via lymphatic, hematogenous, and peritoneal metastases, it also has the unique ability to implant along biopsy tracts and wounds. Gallbladder cancer is often discovered incidentally after cholecystectomy performed for presumed benign disease; unfortunately, this operation is incomplete except for the earliest stage of disease.

Pessimistic attitudes about gallbladder cancer have persisted from its original description in 1778 (Kato et al, 1994) to more recent times and are supported by reports of overall 5-year survival of 5% and median survivals of less than 6 months. For advanced, untreated gallbladder cancer, the median survival is generally 2 to 5 months, and long-term survival is exceedingly rare (Perpetuo et al, 1978; Piehler & Crichlow, 1978). Systemic chemotherapy remains limited in its effectiveness, but with major improvements in systemic chemotherapy in other diseases, these benefits may begin to extend to patients with gallbladder cancer. The role of definitive resection, however, has now been shown to be effective in properly selected patients. Complete surgical removal of gallbladder cancer is the only potentially curative therapy. With improvements in imaging, staging, and hepatic and biliary resection, there is now hope for patients with nonmetastatic gallbladder cancer. Effective adjuvant therapy is lacking, however, and this represents a significant limitation of current treatment options.

All surgeons who treat gallbladder disease must understand the natural history, biology, imaging, staging, and proper surgical treatment of gallbladder tumors. It is crucial to make proper treatment decisions early rather than after an incomplete, noncurative cholecystectomy. For surgeons whose specialty includes gallbladder cancer, it is important to understand the outcome and limitations of surgical resection so that a complete understanding of the risks and benefits can be analyzed and presented to the patient and result in a rational treatment strategy.

EPIDEMIOLOGY

The incidence of gallbladder cancer varies by racial group, and it has been reported that internationally, incidence varies 20-fold based on geographic region (Randi et al, 2006). The highest incidence of gallbladder cancer is found in women living in India (21.5 cases per 100,000 population annually), Pakistan (13.8 per 100,000), and Ecuador (12.9 per 100,000). Approximately 9760 cases of gallbladder and other biliary cancers are diagnosed annually in the United States, with 3320 deaths annually (Jemal et al, 2010). In North America, high incidence rates are found among Native Americans and Hispanic women (Barakat et al, 2006). The annual incidence of gallbladder cancer in the United States is approximately 2 per 100,000 women and 1 per 100,000 men. In North America and Western Europe, urban areas and areas of lower socioeconomic status harbor higher rates of gallbladder cancer (Diehl, 1980; Zatonski et al, 1993). In these areas, limited access to health care delays and decreases the rate of cholecystectomy for gallstone disease (see Chapter 30) may lead to higher rates of gallbladder cancer (Serra et al, 1996). In the United States overall, gallbladder cancer is the most common cancer of the biliary tract and the fifth most common gastrointestinal cancer (Carriaga & Henson, 1995).

Across all populations that have been studied, women are approximately three times more likely to develop gallbladder cancer than are men (Lazcano-Ponce et al, 2001). This ratio is as high as 5:1 in countries such as Pakistan and Colombia (Randi et al, 2006). Although rare, reports of children (<21 years old) developing gallbladder cancer do exist (Rudolph & Cohen, 1972; De Aretxabala et al, 1994); it is generally a disease of advancing age, with the incidence steadily increasing to a

plateau after age 60 years (Nakayama, 1991). Rare reports of familial gallbladder cancer exist but probably account for only a small percentage of cases (Trajber et al, 1982; Fernandez et al, 1994). Throughout the world, no consistent trend in the incidence of gallbladder cancer has been found, with decreases and increases reported in different countries. From 1978 to 1997, the incidence generally stabilized or declined in North America and Western Europe, but in Japan and South America, the incidence increased (Randi et al, 2006).

Obesity is now associated with increased death rates from many cancers. In a prospective cohort study of 900,000 U.S. adults, the relative risk of death from gallbladder cancer in women with a body mass index (BMI) of 30 to 34.9 was 2.13 compared with women with a BMI of 18.5 to 24.9. In men, the relative risk of death from gallbladder cancer with an elevated BMI was also significant at 1.76 (Calle et al, 2003). Other rare associations with gallbladder cancer include inflammatory bowel disease, primary sclerosing cholangitis (Lewis et al, 2007), and polyposis coli (Willson et al, 1987).

ETIOLOGY

The most consistently implicated etiologic factor in the development of gallbladder cancer is cholelithiasis and chronic inflammation. Of gallbladder cancer cases, 75% to 90% occur in the setting of cholelithiasis (Lazcano-Ponce et al, 2001; Serra & Diehl, 2002; Wanebo & Vezeridis, 1994). In one case-control study, the relative risk of gallbladder cancer was 10.1 in patients with stones larger than 3 cm (Diehl, 1983). Similar results were reported in another case-control study that compared gallstones in patients with gallbladder cancer with gallstones in patients with benign gallbladder disease (Roa et al, 2006). There were significantly more stones, heavier stones, and increased stone volume in the patients who had gallbladder cancer. The epidemiology of gallstones often parallels that of gallbladder cancer (Zatonski et al, 1997; Shrikhande et al, 2010); however, most patients with gallstones never have cancer develop, and a definitive cause-and-effect relationship has not been established. It is possible that stones and cancer share similar risk factors (see Chapter 8B), or stones may simply prompt a radiologic workup or cholecystectomy, increasing recognition in this group of patients.

There appears to be an association between cholesterol metabolism gene polymorphisms and a combined risk of gallbladder cancer and stones (Xu et al, 2010). Although nearly 90% of gallbladder cancer specimens contain stones, the incidence of gallbladder cancer in the population of patients with stones is 0.3% to 3%, which is low when considering this as the only risk factor. The other epidemiologic associations such as biliary-enteric fistulae, typhoid infection, and pancreaticobiliary maljunction also represent conditions in which the mucosa of the gallbladder is exposed to the effects of chronic inflammation. Although a true cause-and-effect relationship has never been proven, most epidemiologic data point to a significant relationship between chronic inflammation of the gallbladder and the development of neoplasia.

The presence of calcification in the wall of the gallbladder, otherwise known as *porcelain gallbladder,* is also a condition associated with a higher risk of gallbladder cancer. The calcification is probably the result of long-standing inflammation. The risk of malignancy within a porcelain gallbladder was previously reported to be extremely high (10% to 50%); modern series, however, have shown a much lower incidence (<10%) (Berk et al, 1973; Kim et al, 2009; Kwon et al, 2004; Stephen & Berger, 2001). The type of calcification seems to be associated with the degree of risk, with stippled calcification of the mucosa apparently representing a higher risk than diffuse intramural calcification.

Chronic inflammatory conditions of the gallbladder, such as cholecystoenteric fistula and chronic infection with typhoid bacillus, also have been associated with a risk for gallbladder cancer (Welton et al, 1979). Because bacterial colonization often accompanies chronic cholecystitis, bacteria has been proposed to play an important role in carcinogenesis. The argument against this etiology is that gallbladder cancer occurs in the setting of bacterial infection without stones and commonly occurs in the setting of stones without infection. The presence of an anomalous pancreaticobiliary junction with a long common channel between the pancreatic and bile duct also has been associated independently with gallbladder cancer risk and may be related to chronic inflammation (Chijiiwa et al, 1993). It has been difficult in experimental models, however, to induce gallbladder carcinoma with chronic inflammation. Fortner and Randall (1961) placed gallstones from patients with and without gallbladder carcinoma into the gallbladders of 126 cats. After 4 to 5 years, they found carcinoma in three cats, one of whose stones came from a patient without carcinoma. Despite these data, it is likely that chronic inflammation, regardless of cause, at the least predisposes to gallbladder carcinoma.

In patients with chronic inflammation as a predisposing factor, one hypothesis is that one or more carcinogenic exposures are required for carcinoma to develop. In numerous animal experiments, rates of gallbladder cancer were dramatically higher when inflammation was combined with known carcinogenic agents compared with exposure to the carcinogen alone (Enomoto et al, 1974; Kowalewski & Todd, 1971; Piehler & Crichlow, 1978). The composition of bile in patients with gallbladder cancer has been studied in attempts to identify carcinogenic agents. Higher concentrations of free radical oxidation products (Shukla et al, 1994) and secondary bile acids (Shukla et al, 1993) were found in gallbladders harboring cancer compared with gallbladders with gallstones alone. Some chemicals have been implicated in gallbladder carcinogenesis, including methyldopa (Broden & Bengtsson, 1980), oral contraceptives (Broden & Bengtsson, 1980), isoniazid (Lowenfels & Norman, 1978), and occupational exposure in the rubber industry (Mancuso & Brennan, 1970). None of these associations has been definitively proved (Pandey, 2006).

There is some suggestion of an adenoma-carcinoma progression in the development of gallbladder cancer. Severe dysplasia and carcinoma in situ are often adjacent to gallbladder carcinomas (Lazcano-Ponce et al, 2001). Unlike colorectal cancer, however, the association of polypoid gallbladder tumors and gallbladder cancer is rare. In fact, in patients with multiple gallbladder polyps, no increased risk of malignancy was found (Ito et al, 2009; Zielinski et al, 2009). Kubota and colleagues (1995) found that 11% of cholecystectomy specimens with gallbladder polyps had malignancies, and 88% of these polyps were larger than 1 cm. Yang and colleagues (1992) reported similar results with an 8% incidence of gallbladder cancer in gallbladder specimens with polyps, all more than 1 cm in size. Based on these studies, current practice recommendations are to perform cholecystectomy for gallbladder polyps larger than 1 cm.

ANATOMIC CONSIDERATIONS

It is important to understand the anatomy of the gallbladder, biliary tree, liver, and hepatic hilum to manage tumors of the gallbladder properly. The anatomy of the gallbladder is reviewed in Chapter 1, but a few specific comments are worthy of review. The gallbladder is a partially intraperitoneal structure that lies attached to the undersurface of the liver on segments IVb and V. On the side of the gallbladder that is attached to the liver, there is no peritoneal covering; a fibrous lining known as the *cystic plate* occupies this space. When a simple cholecystectomy is performed, the plane between the muscularis of the gallbladder and the cystic plate is dissected, which is an inadequate resection for a malignancy involving this portion of the gallbladder. This fact makes a simple cholecystectomy inadequate for most gallbladder cancers. Because the body and fundus of the gallbladder generally lie at a distance from the major inflow structures to the liver, a limited segmental resection (segment IVb/V) is adequate to resect most tumors arising from this area of the gallbladder. The infundibulum and cystic duct encroach into the porta hepatis, however, and tumors of this area often involve the porta. The surgeon must be prepared to perform bile duct resections or major hepatic resections for tumors of the lower part of the gallbladder because major inflow structures are commonly involved.

The lymphatic drainage of the gallbladder has been extensively studied (Shirai et al, 1992c); it is crucial to understand this drainage when radiologically or surgically staging patients with gallbladder cancer. The principal lymphatic drainage of the gallbladder as studied by dye injections is shown in Figure 49.1. When injected into the lymphatics of the gallbladder, the dye never ascends into the proximal porta hepatis lymphatics. The channels lead to the cystic and choledochal nodes first. From these nodes, the primary drainage areas are the retroportal and posterior-superior pancreaticoduodenal nodes. Progressing from these lower portal areas, the lymphatics course to the celiac, superior mesenteric, and interaortocaval nodes. An important finding was that some lymphatic material seemed to drain directly from the pericholedochal nodes to the interaortocaval nodes in the retropancreatic space. These connections may offer an explanation for the often advanced nature of gallbladder cancer at diagnosis and highlight the importance of analyzing the retropancreatic area radiologically and with a full Kocher maneuver at operation to stage patients with gallbladder cancer properly.

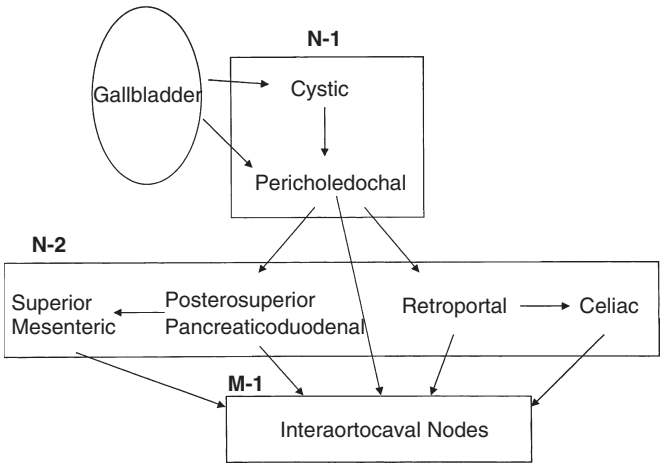

FIGURE 49.1. Schematic representation of lymphatic drainage routes for gallbladder cancer as reported by Shirai and colleagues (1992c). Note the direct route from N-1 pericholedochal lymph nodes to M-1 interaortocaval nodes.

PATHOLOGY

Preneoplastic Lesions

Similar to many gastrointestinal malignancies, progression from dysplasia to carcinoma in situ to frank invasive carcinoma is seen in gallbladder epithelium (Albores-Saavedra et al, 1986; Kozuka et al, 1982). When surrounding mucosa is sectioned in cases of gallbladder cancer, more than 90% of the cases harbor high-grade dysplasia or carcinoma in situ. Although chronic inflammation of the gallbladder can cause cellular atypia, it is generally easy to differentiate this from dysplasia and carcinoma in situ (Fig. 49.2). Carcinoma in situ may appear in the Rokitansky-Aschoff sinuses and may be mistaken for invasive carcinoma. Although it is impossible to know definitively the time course between dysplastic changes and invasive carcinoma, estimations have been made. In one series, the rate of progression of precursor lesions to invasive carcinoma was estimated to be approximately 15 years based on the mean ages of patients at each stage (Roa et al, 1996). Another study found a 5-year difference between the mean ages of patients with dysplasia and those with carcinoma in situ, and a 10-year difference was found between the mean ages of patients with carcinoma in situ and those with invasive carcinoma (Albores-Saavedra et al, 1986).

The precancerous nature of gallbladder polyps is more controversial; however, it provides some evidence that an adenoma-adenocarcinoma progression exists. Gallbladder polyps have been noted in 3% to 6% of patients undergoing ultrasonography (US). Most are cholesterol polyps with no malignant potential (Choi et al, 2008; Zielinski et al, 2009). The incidence of carcinoma in nonadenomatous polyps—cholesterol polyps, inflammatory polyps, and hyperplastic polyps—is close to zero

Light micrograph of gallbladder carcinoma in situ after peroxide antiperoxidase and carcinoembryonic antigen antibody staining. *(From Albores-Saavedra J, Henson DE, 1986: Tumors of the gallbladder and extrahepatic bile ducts. In Atlas of Tumor Pathology, Second Series. Bethesda, MD, Armed Forces Institute of Pathology.)*

(Canturk et al, 2007; Choi et al, 2008; Ito et al, 2009). Approximately 1% of cholecystectomy specimens contain adenomatous polyps (Aldridge & Bismuth, 1990; Fong & Malhotra, 2001). In another series of 123 gallbladder polyps, 21 (17%) were found to be adenomatous, and seven (6%) were found to harbor malignancy. Risk of malignancy was associated with increasing age, size greater than 1 cm, and the presence of a single polyp (Yeh et al, 2001). Ito and colleagues (2009) reviewed 417 patients with gallbladder polyps found on US. Only 7% of patients had polyps larger than 1 cm. Among the 80 patients who underwent cholecystectomy, neoplastic (adenomatous) polyps were found in 10%, and one patient had a carcinoma in situ (in a 14-mm polyp). No patient was found to harbor an invasive malignancy.

Kozuka and colleagues (1982) described seven adenomas showing histologic progression into malignancy and showed that 19% of invasive carcinomas had adenomatous components. In a series of 182 resected gallbladder polyps, 13 (7%) were found to harbor a malignancy, which was related to the size of the polyp (Yang et al, 1992). One report described a higher incidence of malignancy in gallbladder polyps arising in the face of primary sclerosing cholangitis (Buckles et al, 2002).

Benign adenomatous polyps do not have the same association with cholelithiasis that invasive carcinomas do, and it is unlikely that most gallbladder cancers arise from adenomatous polyps. It may be that some tumors arise in this manner, although the specific percentages would be difficult to estimate.

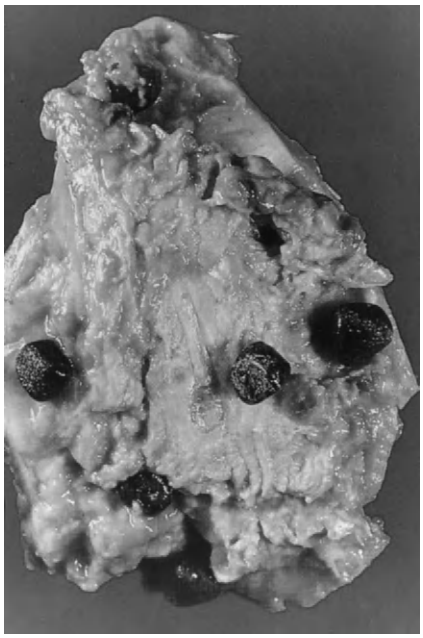

FIGURE 49.3. Giant cell adenocarcinoma of the gallbladder. This tumor has an infiltrative nature, but it fills most of the lumen of the gallbladder. *(From Albores-Saavedra J, Henson DE, 1986: Tumors of the gallbladder and extrahepatic bile ducts. In Atlas of Tumor Pathology, Second Series. Bethesda, MD, Armed Forces Institute of Pathology.)*

Gross Morphology

Early-stage gallbladder cancers are difficult to distinguish from the findings typical of chronic cholecystitis because they both often present as a thickened gallbladder wall in the face of inflammation. This similar presentation accounts for the frequent discovery of gallbladder cancer incidentally in a cholecystectomy specimen. The overall incidence of gallbladder cancer discovered during cholecystectomy for presumed benign disease is less than 1% (Bazoua et al, 2007). As gallbladder tumors progress, they can present in numerous ways. The gallbladder may become distended with tumor, or it may become contracted and collapsed. Approximately 60% of tumors originate from the fundus, 30% from the body, and 10% from the neck of the gallbladder (Albores-Saavedra et al, 1986; Daines et al, 2004; Rajagopalan et al, 2004). Tumors in the lower end of the gallbladder may obstruct the neck or cystic duct, leading to hydrops. Advanced tumors of the neck, infundibulum, or cystic duct may infiltrate the porta hepatis and result in major vascular invasion, jaundice, and even hepatic atrophy. This presentation is often indistinguishable from a hilar cholangiocarcinoma.

Gross descriptions of gallbladder cancer have been grouped into infiltrative, nodular, combined nodular-infiltrative, papillary, and combined papillary-infiltrative forms (Albores-Saavedra et al, 2005; Sumiyoshi et al, 1991). Most tumors have an infiltrative pattern as part of their presentation, which causes thickening and induration of the gallbladder wall (Fig 49.3). These types of tumors seem to spread in a subserosal plane and can invade the whole gallbladder wall and even invade into the porta hepatis, causing jaundice from diffuse biliary involvement. These types of tumor can also diffusely invade the liver. Nodular types of tumors tend to grow as a more circumscribed mass. Despite invasion into the liver, these lesions are more easily resected because they are less diffuse in their invasive pattern. Papillary tumors of the gallbladder are polypoid lesions with frondlike extensions that give a cauliflower-like appearance (Fig. 49.4). Despite the fact that papillary tumors can grow quite large, they tend to have a better prognosis than the other gross types; this is likely related to the less invasive nature of these tumors. Even at large sizes, papillary gallbladder tumors may have minimal invasion into the gallbladder wall (Albores-Saavedra et al, 2005).

HISTOLOGY (SEE CHAPTER 47)

Table 49.1 shows the classification of malignant gallbladder tumors, and Table 49.2 summarizes the relative incidence of the various histologic types of gallbladder cancer. Over a 10-year period at Memorial Sloan-Kettering Cancer Center (MSKCC), 391 (90%) of the 435 patients with gallbladder cancer had adenocarcinomas. Additional diagnoses were squamous/adenosquamous carcinoma (4%), neuroendocrine carcinoma (3%), sarcoma/adenosarcoma (1.6%), unspecified carcinoma (1.1%), and melanoma (<1%) (Duffy et al, 2008). Most gallbladder tumors can be characterized histologically, but more than one histologic pattern is commonly found in each tumor. The only histologic subtype that seems to have prognostic significance is the papillary tumor. Papillary adenocarcinomas of the gallbladder tend to have a better prognosis than the other subtypes (Albores-Saavedra et al, 2005; Carriaga & Henson, 1995). This improved prognosis is likely related to the tendency of this tumor to be noninvasive or minimally invasive. When this tumor becomes invasive, however, it can metastasize and have a prognosis typical of the pathologic stage (Albores-Saavedra et al, 2005).

FIGURE 49.4. Papillary adenocarcinoma of the gallbladder: this tumor has a cauliflower-like appearance and protrudes into the lumen with minimal invasion of the gallbladder wall. These tumors have the best prognosis. *(From Albores-Saavedra J, Henson DE, 1986: Tumors of the gallbladder and extrahepatic bile ducts. In Atlas of Tumor Pathology, Second Series. Bethesda, MD, Armed Forces Institute of Pathology.)*

are extremely rare. Other reported uncommon gallbladder cancers include carcinosarcoma, carcinoid, lymphoma, melanoma, and metastatic tumors to the gallbladder. Although reports have suggested a poorer outcome for oat-cell carcinomas (Henson et al, 1992) and adenosquamous carcinomas (Yamaguchi & Enjoji, 1988), these conclusions are based on small numbers, and comparisons of such rare tumors are impossible.

Gallbladder cancers also have been grouped into metaplastic and nonmetaplastic types based on metaplastic changes in the tumors; this is similar to the classification of gastric cancers into intestinal and diffuse types. The two predominant types of metaplasia that are precursors to malignancy in the gallbladder mucosa are *pseudopyloric* and *intestinal* (Duarte et al, 1993). The intestinal type has a higher rate of carcinoma. The progression from metaplasia to carcinoma in situ to carcinoma is evident in that patients with invasive cancer are 15 and 5 years older than patients with dysplasia and carcinoma in situ, respectively (Roa et al, 1996).

Histologically, gallbladder cancers are graded into four categories that range from well differentiated to poorly differentiated. This differentiation does not have a significant impact on prognosis except for the observation that most papillary tumors are well differentiated, which may account for the better prognosis seen in these types of tumors. Most gallbladder cancers are poorly differentiated at presentation. DNA ploidy has been studied in gallbladder tumors and corresponds to the histologic grade but does not correlate with prognosis (Baretton et al, 1994). Although it is clear that gallbladder cancers can be differentiated based on histologic type and grade, the most important prognostic factor is the stage at presentation, making grade and type prognostically unimportant.

Molecular Biology (See Chapter 8B)

The precise pathway linking different genetic mutations responsible for gallbladder cancer is not clear; however, multiple genetic defects are known to be associated with gallbladder cancer (Lazcano-Ponce et al, 2001; Rashid, 2002; Sasatomi

Table 49.3

Genetic Mutation in Gallbladder Cancer

Gene	Gene Type	Mutation	Expression in Gallbladder Cancer (%)	Comments
Oncogenes	*KRAS* (Ajiki et al, 1996a)	Activation	40-50	Higher percent with anomalous pancreaticobiliary duct
	CDKN1A (Puhalla et al, 2007)	Activation	28	Survival lower when coexpressed with *TP27* and *TP53*
	ERBB2 (Kim et al, 2001)	Activation	10-46.5	Survival lower if mutation present
Tumor suppressor	*TP53* (Ajiki et al, 1996b)	Inactivation	27-70	Present at high stage of disease
	CDKN2A (Quan et al, 2001)	Inactivation	50	Survival worse with mutation
	FHIT (Koda et al, 2003)	Inactivation	100	Potentially involved in early initiating events
PG pathway	*COX2* (Asano et al, 2002)	Increased expression	70	Survival worse with mutation
Angiogenesis	*VEGFA* (Tian et al, 2006)	Increased expression	Unknown	Increased expression with higher stages
Inflammatory mediator	*NOS2* (Zhang et al, 2003)	Increased expression	71	Common with chronic gallbladder inflammation
Telomerase subunit	*hTERT* (Itoi et al, 2000)	Increased expression	93	Expressed in premalignant tumors
Adhesion molecules	Cadherins (Choi et al, 2004), catenins (Yanagisawa et al, 2001)	Decreased expression	14-40	Present early in tumor progression and with metastases
	MSI (Yanagisawa et al, 2001)	Presence	10	Found in 83% of dysplastic lesions
	DNA methylation (Roa et al, 2006)	Presence	Unknown	Prognosis worse when some genes (*FHIT, TP73*) are methylated

et al, 2000). Tumor suppressor genes, oncogenes, microsatellite instability, and DNA repair genes all participate in the initiation of gallbladder cancer (Table 49.3) (Goldin & Roa, 2009). Several of these genetic mutations have been identified in case-control studies and have been combined into risk scores. For example, Srivastava and colleagues (2010) compared genetic variations in three DNA repair genes—*ERCC2, MSH2,* and *OGG1*—among 230 patients with gallbladder cancer and 230 control subjects. They found that patients with more than six of the variant alleles that were studied had a fourfold increased risk for developing gallbladder cancer.

Serologic biomarkers can potentially be useful to identify groups of patients at increased risk for gallbladder cancer. When used together, polymorphisms CA242 and CA125 have been associated with high sensitivity and specificity for differentiating between cholelithiasis and gallbladder cancer (Shukla et al, 2006). Several other serum markers may identify patients at high risk for developing gallbladder cancer, regardless of the presence of cholelithiasis. These markers include the NAT2 slow acetylator phenotype, the X(+), D haplotype of apolipoprotein B, and the D allele of lipoprotein receptor–associated protein (LRPAP1) insertion/deletion polymorphism (Pandey, 2006; Pandey et al, 2007a, 2007b).

Pattern of Spread

Gallbladder cancer spreads via lymphatics, hematogenously, and notoriously into the peritoneal cavity or along biopsy or surgical wound tracts. Cancers of the gallbladder seem to invade and metastasize relatively early, which may be attributable to the anatomy of the gallbladder; the wall is thin, contains a narrow lamina propria, and is only a single muscular layer with no serosal covering between it and the liver. Tumors invade into the liver at such a thickness that a second muscular layer would be encountered in many organs, and the thin wall of the gallbladder may be conducive to early hematogenous and lymphatic spread. Gallbladder tumors, once through the muscular layer, have access to major lymphatic and vascular channels, providing these tumors with early opportunities for dissemination.

An autopsy study showed a 94% incidence of lymphatic metastases and a 65% incidence of hematogenous dissemination (Kimura et al, 1989); however, autopsy studies represent the end stage of disease, with sufficient time for extensive metastases to develop. It has been postulated that hematogenous metastases originate from small veins extending directly from the gallbladder into the portal venous system of the gallbladder fossa. These connections can lead to segments IV and V of the liver or via larger veins to the portal venous branches of segments V and VIII (Boerma, 1994). A review of the incidence of regional invasion and metastases at the time of diagnosis and treatment is summarized in Table 49.4.

It is also important to understand the patterns of spread after complete resection because these facts can help guide approaches to adjuvant therapy. Autopsy studies have shown widely disseminated disease, including liver metastases, in greater than 90%; abdominal lymph node metastases in greater than 80%; and peritoneal metastases in 60% of patients (Perpetuo et al, 1978). The only common extraabdominal site of distant metastases is the lung, but lung metastases are rarely seen in the absence of advanced intraabdominal disease. In an attempt to define sites of first recurrence after complete resection, Jarnagin and colleagues (2003) found that only 15% of patients had locoregional recurrence as the only site of

Table 49.4

Incidence of Regional Invasion and Metastasis at the Time of Diagnosis and Treatment Based on a Literature Review

Pathologic Finding	Relative Incidence (%)
Confined to gallbladder wall	10
Liver invasion	59
Common bile duct infiltration	35
Lymphatic invasion and regional lymphatic metastases	45
Gallbladder vein infiltration	39
Portal vein or hepatic artery invasion	15
Adjacent organ invasion (excluding liver)	40
Perineural invasion	42
Liver metastasis	34
Distant metastasis (excluding liver)	20

Data from Boerma EJ, 1994: Towards an oncological resection of gall bladder cancer. Eur J Surg Oncol 20(5):537-544.

recurrence, and most (85%) had recurrence involving a distant site. This finding shows the minimal potential utility of adjuvant locoregional strategies and underscores the importance of effective adjuvant systemic therapies.

CLINICAL PRESENTATION

Three clinical scenarios are common for gallbladder cancer: 1) final pathology after routine cholecystectomy identifies gallbladder cancer; 2) gallbladder cancer is discovered intraoperatively; and 3) gallbladder cancer is suspected before surgery (Miller & Jarnagin, 2008). The clinical presentation varies depending on geographic location, rates of gallbladder cancer, and referral patterns. In a study of 435 patients with gallbladder cancer treated at MSKCC during a 10-year period, 47% had cancers discovered incidentally at the time of routine laparoscopic cholecystectomy (Duffy et al, 2008), and 53% were initially seen with advanced (16%) or disseminated (37%) disease. Given the high percentage of patients diagnosed with gallbladder cancer after routine cholecystectomy for presumed benign gallbladder disease, it is appropriate for the surgeon to inspect the gallbladder mucosa at the completion of the resection if there are any concerns. Frozen-section analysis should be used to examine any suspicious areas.

Gallbladder cancer is notorious for being asymptomatic in its early stages. When symptoms do occur, however, gallbladder cancer tends to present in a similar manner to biliary colic or chronic cholecystitis. Careful history taking often shows a history of constant right upper quadrant pain rather than the typical episodic crampy pain of biliary colic. The diagnosis of gallbladder cancer should be considered in an elderly patient with constant right upper quadrant pain with weight loss, anorexia, or both because weight loss, anorexia, and jaundice in particular are signs of advanced disease (Duffy et al, 2008). The presence of a palpable mass is also an ominous finding that predicts a high rate of unresectability and advanced disease (Thorbjarnarson & Glenn, 1959). The presence of jaundice is an especially ominous finding. In a report by Hawkins and colleagues (2004), 82 (34%) of 240 patients presented with jaundice. Of these 82 patients, only six (7%) were resectable, and all had recurrence or died of disease within 2 years. The median survival in jaundiced patients was 6 months compared with 16 months in patients presenting without jaundice.

The incidence of symptoms and signs at presentation is summarized in Table 49.5. A report from New York Hospital reviewed their experience with gallbladder cancer from 1915 through 2000 (Grobmyer et al, 2004). Throughout the years, the presentation was remarkably similar in that most patients had advanced disease at presentation. Over time, however, a decrease was reported in the percentage of patients who presented in the more recent era with weight loss (95% vs. 42%), palpable mass (50% vs. 9%), and nausea/vomiting (97% vs. 70%). The percentage of patients presenting with abdominal pain and jaundice was similar (approximate 85% and 50%, respectively).

Laboratory examination generally is not helpful except to identify the typical signs of advanced disease, such as anemia, hypoalbuminemia, leukocytosis, and elevated alkaline phosphatase or bilirubin levels (Grobmyer et al, 2004; Thorbjarnarson & Glenn, 1959). The only tumor markers studied that are of any potential value are carcinoembryonic antigen (CEA) and carbonin anhydrase 19-9 (CA19-9). An elevated CEA tends to be specific for gallbladder cancer (90%), but it lacks sensitivity (50%) when used as a screening test in cancer patients compared with patients who have benign gallbladder diseases (Strom et al, 1990). CA19-9 is more consistent as a marker for gallbladder cancer, with sensitivities and specificities of approximately 75% at a level greater than 20 U/mL (Ritts et al, 1994). Overall, serum tumor markers are of minimal clinical value compared with clinical awareness, a heightened level of suspicion in appropriate cases, and good-quality imaging studies. As is typical of the utility of serum tumor markers, they can be helpful in following a patient for recurrence, if they are elevated before treatment and normalize after treatment.

Weight loss	42%	7%	28%	77%
Anemia	NR	NR	8%	NR

NR, not reported

RADIOLOGIC INVESTIGATION

In the era before the availability of routine real-time US and computed tomography (CT), gallbladder cancer was rarely diagnosed preoperatively. With the development of rapid and more widely available imaging modalities, patients who have suspected or incidentally diagnosed gallbladder cancer should have high-resolution cross-sectional imaging for adequate staging. Because most patients present with advanced disease, it is important to try to establish the diagnosis and extent of disease with imaging to minimize the number of patients who have to undergo a nontherapeutic surgical exploration. Except for the earliest stage of disease, this should now be possible in most patients. In addition to the modalities available for examining the gallbladder and liver, chest radiographs or CT scan should be obtained during the complete staging workup to rule out pulmonary metastases. It is rare, however, to find pulmonary metastases without locally advanced or intraabdominal metastatic disease (Lee et al, 2010).

US is an excellent imaging modality for the gallbladder. Findings such as discontinuous mucosa, echogenic mucosa, and submucosal echolucency are more common in early malignancy compared with benign gallbladder disease. Doppler assessment of blood flow through areas of mucosal abnormalities can help to differentiate early malignancy from benign disease, and newer contrast-enhanced US techniques may improve detection confidence even further (Sato et al, 2001). In one study, a polypoid mass was present in 27% of cases, and a gallbladder-replacing or invasive mass was present 50% of the time (Wibbenmeyer et al, 1995). US is a good modality for evaluating the direct extension of gallbladder cancer. One retrospective study reported that in 203 patients with gallbladder cancer, a mass was identified in 177 patients (87%) on preoperative US (Pandey et al, 2000). US was limited, however, in identifying lymph node metastases in pericholedocal and peripancreatic nodes. Because most cases are advanced, the most typical findings in gallbladder cancer are an inhomogeneous mass replacing all or part of the gallbladder (Bach et al, 1998; Franquet et al, 1991). Diffuse thickening of the gallbladder wall also is a common finding on cross-sectional imaging and on US, but it can be difficult to differentiate from benign inflammatory changes.

Cross-sectional imaging with CT or magnetic resonance imaging (MRI) is an important part of the preoperative assessment of gallbladder cancer (see Chapters 16 and 17). These techniques provide crucial information about the local extent of disease and show whether distant metastases are present. The most common finding on CT is a mass involving all or part of the gallbladder. Extension into local organs, particularly the liver, usually can be discerned. In one study of patients with gallbladder masses, asymmetric wall thickening was found in 45% of patients, a mass replacing the gallbladder was found in 35%, and an intraluminal mass was found in 20% (Fig. 49.5) (Kalra et al, 2006). Assessment of regional and distant lymph nodes is important and can be done with CT. With criteria of size greater than 1 cm and a ringlike heterogenous enhancement, accuracy rates greater than 80% have been reported (Ohtani et al, 1993). Although large lymph nodes replaced with tumor are relatively easy to identify with CT, false-negative examination results continue to be a problem because many involved lymph nodes can be small, with minimal tumor. CT is 71% to 84% accurate in staging

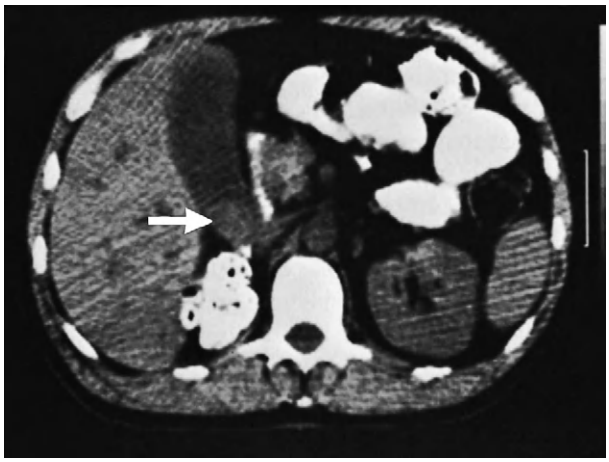

FIGURE 49.5. Computed tomography scan showing a filling defect in the neck of the gallbladder (*arrow*) representing an early carcinoma.

gallbladder cancer. In one study of 118 patients with gallbladder cancer, CT was 79% accurate for differentiating T1 versus T2 tumors, 93% accurate for differentiating T2 versus T3 tumors, and 100% accurate for differentiating T3 versus T4 tumors (Kim et al, 2008). The overall accuracy improved from 72% to 85% when multiplanar reconstructions were added to conventional axial imaging.

The utility of MRI for evaluating patients with gallbladder cancer has increased in recent years. Improvements in MRI technology over the last 2 decades has been dramatic, with wider availability of MRI cholangiography and angiography. Invasive diagnostic cholangiography has largely been replaced by MRI cholangiography in most high-volume centers (Schwartz et al, 2002). Likewise, the use of diagnostic angiography has been replaced by CT/MRI angiography, and such modern equipment can provide detailed imaging of the related vessels at the hepatic hilum. Analyses of MRI for the assessment of gallbladder cancer have shown sensitivities of 70% to 100% for hepatic invasion and 60% to 75% for lymph node metastases (Kim et al, 2002; Schwartz et al, 2002). It is unclear whether MRI adds to the results obtained from CT scan. In one study of 25 patients with gallbladder cancer, MRI/MRCP did not change the preoperative stage as determined by CT scan (Rao et al, 2005).

The development and use of fluorodeoxyglucose (FDG) positron-emission tomography (PET) has resulted in superior staging and diagnosis of many tumors. Most gallbladder cancers are visible on PET scan; theoretically, PET imaging could help differentiate between benign and malignant tumors and can help diagnose extrahepatic spread (Petrowsky et al, 2006). PET, however, is limited in differentiating between benign inflammatory states, such as postcholecystectomy, and malignancy (Corvera et al, 2008). PET appears to be more accurate in diagnosing metastatic disease than is CT scan. In a study of 61 patients with biliary tract malignancies, PET/CT had a sensitivity of 100% compared with 25% for CT alone ($P < .001$), and PET alone changed surgical management in 17% of cases (Petrowsky et al, 2006). PET is more useful for evaluating primary gallbladder cancer than it is for evaluating recurrent disease. In 41 patients with gallbladder cancer at MSKCC, PET results altered surgical management in 23%

Table 49.6

Imaging Modalities Used to Diagnose Gallbladder Cancer

Imaging	Accuracy	Pros	Cons
US*	87%	Cost effective Better than CT for diagnosing cholelithiasis Detailed view of gallbladder wall, polyps No radiation exposure	Difficult to evaluate regional nodes and CBD Operator dependent
CT	Overall: 71% to 84%†‡ T1 vs. T2: 79%‡ T2 vs. T3: 93%‡ T3 vs. T4: 100%‡	Cost effective Evaluation of regional nodes Diagnosis of extrahepatic disease More anatomic information vs. US	Difficult to differentiate between inflammation and malignancy Low sensitivity for diagnosing peritoneal implants
MRI	Hepatic invasion: 67% sensitivity, 89% specificity§ Vascular invasion: 100% sensitivity, 87% specificity§ CBD invasion: 100% sensitivity, 89% specificity§ Nodal involvement: 56% specificity, 89% sensitivity	Detailed images of CBD and vascular involvement No radiation MRA and MRCP images provide more detail than CT scan	Expensive Low sensitivity for diagnosing peritoneal disease
PET	Sensitivity: 75% to 86‖ Specificity: 78% to 87%‖ Management changed in 17% to 23% of cases‖	Clarifies suspicious findings on CT or MRI Diagnosis of extrahepatic disease	Expensive Difficult to differentiate between inflammation and malignancy Not proven to enhance CT or MRI findings

*In patients with biopsy-proven gallbladder cancer, US demonstrated mass in 87% of patients (Rodriguez-Fernandez et al, 2006).
†CT is 71% to 84% accurate in diagnosing gallbladder cancer T stage (Kalra et al, 2006; Kim et al, 2008).

§Sensitivity and specificity of MRI for diagnosing T stage of gallbladder cancer (Kim et al, 2002).
‖Sensitivity and specificity of preoperative PET scan in diagnosing gallbladder cancer (Koh et al, 2003; Corvera et al, 2008).
US, ultrasound; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography; CBD, common bile duct; MRA, magnetic resonance angiography; MRCP, magnetic resonance cholangiopancreatography

during preoperative staging (for either the initial operation or reresection after an incidental finding of cancer after cholecystectomy) compared with 10% in patients evaluated for recurrent disease (Corvera et al, 2008). In one study from Japan, 16 patients with mass lesions of the gallbladder were evaluated with PET. Eight of the tumors were histologically proven to be malignant, and PET had a sensitivity and specificity of 75% and 88%, respectively. The false-positive case was in a patient with xanthogranulomatous cholecystitis (Koh et al, 2003).

The usual first test for gallbladder symptoms is US, and it is crucial always to consider the diagnosis of gallbladder cancer when abnormalities are found in the wall of the gallbladder. Duplex US adds information in terms of vascular tumors and helps assess local hepatic vasculature. When gallbladder carcinoma is proven or suspected preoperatively, good-quality cross-sectional imaging with CT or MRI should provide adequate data on local extent of tumor to help assess for metastases. PET can also be a valuable adjunct in searching for metastatic disease or when CT or MRI provides limited information about the primary tumor (Table 49.6).

Gallbladder cancer presenting with jaundice is relatively common; this diagnosis must be in the differential diagnosis for any malignant-appearing, mid–bile duct stricture. Gallbladder cancer must also be considered when the diagnosis of Mirizzi syndrome has been made (Redaelli et al, 1997). To help plan therapeutic procedures, the level of obstruction can be assessed by CT or MRI cholangiography with reasonable accuracy. Stricturing, distortion, or nonfilling of the segment V or VI bile ducts can be caused by gallbladder tumors without effect on the rest of the biliary tree (Fig. 49.6) (Collier et al, 1984). Invasive cholangiography is indicated only when a therapeutic intervention, such as stenting, is anticipated. According to the level of obstruction, a judgment can be made regarding the best approach for biliary stenting (endoscopic retrograde vs. transhepatic cholangiography). As discussed later in this chapter, this can be a crucial part of the palliation of advanced gallbladder cancer.

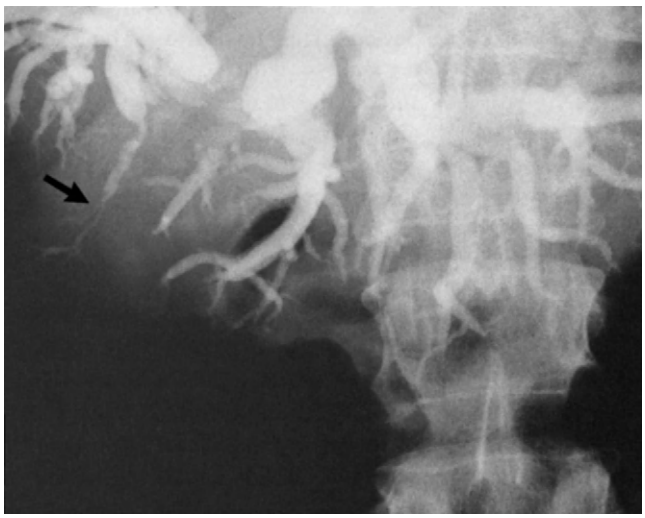

FIGURE 49.6. Percutaneous transhepatic cholangiogram showing malignant obstruction of the bile duct confluence and stricturing and distortion of the duct draining the segment V area of the liver (*arrow*). This is due to a gallbladder cancer directly invading segment V.

PREOPERATIVE PATHOLOGIC DIAGNOSIS

If gallbladder cancer is suspected on clinical and radiologic grounds, preoperative histologic diagnosis is unnecessary in

patients who are potentially resectable. Gallbladder cancer has a tendency to seed the peritoneum, biopsy tracts, and surgical wounds (Fong et al, 1993; Hu et al, 2008; Merz et al, 1993), and unnecessary biopsies simply increase this risk. Although a positive biopsy result may make the surgeon feel more justified in the operative approach, a negative biopsy result cannot be trusted because of significant false-negative rates. If the diagnosis is suspected, the surgeon and patient must be prepared for a definitive operation. If concern for gallbladder cancer is significant, it is unwise to perform a cholecystectomy to make the diagnosis because the same risk of tumor spillage applies. The surgeon and patient also must be prepared for the possibility of performing a liver resection for benign disease. In experienced hands, a limited liver resection should be safe, and the risk of this procedure should be less than the risk of multiple biopsies or noncurative operations. For a patient with unresectable or metastatic disease, a percutaneous biopsy has an accuracy of nearly 90%, and the false-positive rate is negligible (Akosa et al, 1995).

Bile cytology has been proposed as a less risky way of making the diagnosis of gallbladder cancer without risking peritoneal seeding. Although it is reasonable to check bile cytology if the patient needs to undergo endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC), for the reasons stated earlier, a deliberate attempt to make the diagnosis this way is unwarranted. Sensitivity of bile cytology has been reported to be approximately 75% (Akosa et al, 1995; Arora et al, 2005; Mohandas et al, 1994; Naito et al, 2009).

STAGING

Over the years, a variety of staging systems for gallbladder cancer have been proposed based on prognostic clinical and pathologic factors. Historically, the American Joint Committee on Cancer (AJCC) system, the Japanese Biliary Surgical Society system (Onoyama et al, 1995), the Nevin system (Nevin et al, 1976), and the modified Nevin systems (Donohue et al, 1990) were all used. These staging systems are summarized in Table 49.7. The AJCC tumor-node-metastasis (TNM) staging of gallbladder cancer was adopted in 2002 as the standard reporting mechanism for gallbladder cancer studies in the literature, and it is the preferred staging system clinically (Table 49.8).

The AJCC uses tumor depth (T), nodal status (N), and the presence of metastases (M) to place patients into four stages according to pathologic and radiographic findings. The sixth edition of the AJCC system divided T1 tumors into two groups: T1a tumors invade the lamina propria of the gallbladder, and T1b tumors invade the muscular layers; T2 tumors spread through the muscular layers into, but not beyond, the connective tissue layers. Anatomically, this translates to spread into the gallbladder serosa or cystic plate but not into the liver parenchyma. T3 lesions spread through the gallbladder serosa and invade the liver, extrahepatic bile ducts, or perihepatic organs. T4 lesions invade multiple extrahepatic organs and/or major vessels and generally reflect locally unresectable disease. The seventh edition of the AJCC system includes the cystic duct in the classification scheme and reclassifies locally unresectable T4 tumors as stage IV.

The N stage is either N0 (no nodal metastases) or N1 (positive regional nodal disease) in the AJCC sixth edition. Regional nodal metastases can be found in the porta hepatis, retroduodenal nodes, and the gastrohepatic region. Disease outside this area, for example in aortic or celiac nodes, is considered M1 disease. The AJCC seventh edition now distinguishes between hilar nodes (N1) and regional nodes (N2). The T, N, and M scores are then arranged into stages. Stage I includes node-negative T1 (stage Ia) and T2 (Ib). Stage II includes node-negative T3 (IIa) and node-positive T1 through T3 (IIb). Stage III includes any T4 lesions with no metastatic disease, and stage IV consists of any T or N score with metastatic disease. The AJCC seventh edition has changed so that N1 disease is now stage IIIb, and N2 disease is now stage IVb.

The seventh edition was issued in 2010 with stage groupings that were changed to correlate with resectability and patient outcome. Locally unresectable T4 tumors were classified as stage IV, and the N classification was changed. N1 nodes are lymph nodes adjacent to the cystic duct, bile duct, hepatic artery, and portal vein. Regional nodes are celiac, periduodenal, and peripancreatic nodes. Lymph node metastasis is now classified as stage IIIb (N1) or stage IVb (N2) disease.

Fong and colleagues analyzed the sixth edition AJCC scoring system in more than 7000 patients in the United States National Cancer Database (NCDB). They reported that stage III should be segregated into IIa from the T3N0M0 patients and that IIIb would consist of T1 through T3N1M0 patients. The justification for this change was the belief that nodal metastases indicate a different cancer biology, and the presence of nodal metastases may call for other therapies, such as radiotherapy. Stage IVa and

III	T4	N0, N1	M0
IV	Any T	Any N	M1

*Sixth edition of the AJCC manual
The seventh edition has reclassified locally unresectable T4 tumors as stage IV. In addition, lymph node metastases are now classified as stage IIIb (N1) or stage IV (N2).

IVb were also regrouped to T4N0M0 for stage IVa and IVb and included anyone with nodal metastases.

SURGICAL MANAGEMENT

Benign Polyps

Benign polypoid lesions of the gallbladder are common and are best assessed by US, although definitive diagnosis is often difficult. The only polypoid lesions that have malignant potential and are associated with a significant rate of harboring malignancy are adenomatous polyps. Other benign lesions—fibromas, lipomas, hemangiomas, cholesterol polyps, inflammatory polyps, and adenomyomas—are not known to be associated with malignant potential. *Adenomyomatosis,* defined as extension of Rokitansky-Aschoff sinuses through the muscular wall, is common and often diagnosed by US criteria (Stunell et al, 2008). Cholesterol polyps are the most common gallbladder polyp, but they are not easily differentiated from other lesions of the gallbladder wall without pathologic analysis. The relevant clinical question is which lesions mandate a cholecystectomy in an asymptomatic patient.

Numerous clinical reviews have identified factors associated with malignancy in gallbladder polyps. The most consistent predictors are single polyps, size greater than 1 cm, and age older than 50 years (Shinkai et al, 1998; Yeh et al, 2001). Although some clinicians have recommended cholecystectomy for any patient with fewer than three polyps (Shinkai et al, 1998), we generally recommend cholecystectomy for any polyp greater than 1 cm because the risk of malignancy for smaller polyps, regardless of their number, is exceedingly low. In a study from MSKCC of 417 patients with polypoid lesions of the gallbladder discovered on US, 10% had neoplastic/adenomatous polyps (Ito et al, 2009). Polyp growth was found in only 6% of patients on follow-up. Eighty patients underwent cholecystectomy, and a single patient had carcinoma in situ with a 13-mm gallbladder polyp. The exception to this recommendation of resection only for polyps larger than 1 cm is for those arising in the setting of primary sclerosing cholangitis. These polyps are more likely to be neoplastic, and the threshold for cholecystectomy probably should be lower in this patient population (Buckles et al, 2002).

US is the diagnostic modality of choice to measure and characterize gallbladder polyps (see Chapter 13), but if there is any suspicion of malignancy, cross-sectional imaging with contrast-enhanced CT or MRI is essential. For gallbladder polyps found in the context of abdominal symptoms, another cause of the pain should be sought. Most polyps are asymptomatic, and if no other cause is found to explain the abdominal symptoms, a cholecystectomy should be performed. Patients with polyps smaller than 1 cm who are asymptomatic should be followed up with serial US to rule out the possibility of a growing adenomatous polyp. Long-term follow-up of stable polyps does not seem warranted according to a multiinstitutional registry of approximately 70,000 patients who had gallbladder US. A prevalence

of gallbladder cancer with polypoid lesions of the gallbadder equal to 0.08% was reported in white patients (Aldouri et al, 2009). Conversely, Kubota and colleagues (1995) reported that on periodic US 4 to 12 months after the original US, polyps grew 1.4 to 4 times larger. Thus our recommendation is for US follow-up at 6- to 12-month intervals for 2 years; if polyp size is stable, routine surveillance can be stopped. Additional studies should only be performed in the setting of new clinical findings or symptoms.

For polyps mandating cholecystectomy (>1 cm) without obvious evidence of malignancy on imaging, whether an open or laparoscopic cholecystectomy should be performed has been considered controversial. Our practice originally was to perform an open cholecystectomy for 1-cm polyps. More recently we have adopted a policy of laparoscopic cholecystectomy when there is no obvious US concern for malignancy, with the caveat that all such lesions must be examined by frozen-section histology, the threshold to convert to an open procedure should be low, and definitive resection must be performed if invasive cancer is suspected. The reasons for this policy are due to the overall low risk of malignancy, the fact that simple cholecystectomy is curative for T1a tumors, and that laparoscopically resected early-stage tumors do not seem to have a dramatically worse outcome if a definitive resection is ultimately performed and the gallbladder is not perforated. Laparoscopic US may be helpful to locate the tumor, and every patient undergoing a cholecystectomy for polyps should be carefully counseled regarding the risk of malignancy and the possibility of needing a liver resection and lymph node dissection at the same sitting.

Incidentally Discovered Gallbladder Carcinoma During or After Routine Cholecystectomy

Gallbladder cancer is found in 0.27% to 2.1% of all laparoscopic cholecystectomies (Darmas et al, 2007; Frauenschuh et al, 2000; Kwon et al, 2008). If the diagnosis of gallbladder cancer is made by frozen-section analysis in the operating room, the operating surgeon should prepare for a curative resection with possible liver and bile duct resection. If the surgeon is not comfortable with this extent of surgical resection, no further dissection should be performed and the patient should be transferred to an experienced hepatobiliary surgeon. This strategy does not appear to affect outcomes; a retrospective study at MSKCC reported that outcomes after prior noncurative resection were similar to outcomes from primary curative resections (Fong et al, 2000). However, these findings are subject to selection bias because the majority of patients diagnosed with gallbladder cancer after routine cholecystectomy have early-stage tumors. Ouchi and colleagues (2002) reported on 498 patients diagnosed with gallbladder cancer after laparoscopic cholecystectomy. They found that 34% had T1a, 14% had T1b, 41% had T2, 8% had T3, and 2% had T4 tumors.

Once the diagnosis is made, all patients should undergo a complete staging workup, as previously described. If patients have resectable disease with no contraindications to additional surgery, a second operation should be considered. With T1a tumors, if margins are negative, standard cholecystectomy cures 85% to 100% of patients (Shirai et al, 1992; Yamaguchi & Tsuneyoshi, 1992); thus no additional resection or treatment is indicated. For tumors staged as T2 and above, additional resection is indicated. Controversy surrounds treatment of T1b tumors. Principe and colleagues (2006) demonstrated a 50% 1-year survival in patients with T1b gallbladder cancers after simple cholecystectomy (Shirai et al, 1992a). Other series, however, report cure rates for T1b tumors that are 90% to 100% at 5 years (Kang et al, 2007b). A multiinstitutional study of 115 patients reported residual disease at any site in the abdomen during re-resection for 38% of T1, 57% of T2, and 77% of T3 tumors (Pawlik et al, 2007). Residual invasion of the liver parenchyma in the gallbladder bed was found in 0% of T1, 10% of T2, and 36% of T3 tumors.

When a patient who has undergone noncurative cholecystectomy is referred, careful workup is required. Reviewing the precholecystectomy US and any other imaging is prudent to try to pinpoint the location of the tumor. It is also wise to personally discuss the case with the operating surgeon to assess the specific intraoperative findings, and the specimen should be carefully re-reviewed pathologically to assess T stage and margins.

Given the results discussed above, re-resection is recommended for all patients who are medically fit with T1b or greater level of invasion. Although the role of re-resection in patients with T1b tumors has been the subject of some controversy, data from several centers now support reoperation and definitive resection in this setting. If the cystic duct stump is positive or the margin is a specific concern, a bile duct resection and reconstruction are generally required. In highly selected cases, a re-resection of the cystic duct stump with frozen-section assessment can be considered. Routine resection of the bile duct has not been globally associated with improvements in survival in all patients, but it is generally required for a complete resection in cases with a positive cystic duct stump margin (Pawlik et al, 2007; Sakamoto et al, 2006).

Staging Laparoscopy

Staging laparoscopy is an important consideration when operating on intraabdominal malignancy. Because most gallbladder cancer patients do not require palliative operations, and because incidence of occult metastatic disease is high, staging laparoscopy makes sense for this disease. The benefits of discovering occult metastases at laparoscopy compared with laparotomy are obvious and include less pain, less morbidity, quicker hospital discharge, more rapid resumption of normal activity, and earlier start of other therapies. The yield for staging laparoscopy in gallbladder cancer is high, and this examination should be routinely used. Of 44 cases in which staging laparoscopy was used, Weber and colleagues (2002) reported a 48% yield, and these patients all were spared a laparotomy. Despite this high yield, the examination still missed an additional 15 malignancies, suggesting room for further improvement. Even in patients who have had a prior noncurative cholecystectomy, the yield is still generally approximately 20% and is justified in this patient group.

Extent of Resection by Stage

An early description of a rational approach to the surgical treatment of gallbladder cancer was provided by Glenn and Hays in 1954. They recommended a wedge resection of the gallbladder bed and regional lymphadenectomy of the hepatoduodenal ligament. The late presentation and generally poor prognosis, compounded by the rarity of the disease, have resulted in significant controversy and confusion about the best surgical approach to gallbladder cancer since that time. For the same

stage of disease, surgeons have recommended varying operations, from a simple cholecystectomy to combined hepatectomy, bile duct resection, and pancreatoduodenectomy. A survey of gastrointestinal surgeons from the early 1990s showed that 49% recommended lymph node dissection and 64% recommended some form of liver resection for stage T2 through T4 disease (Gagner & Rossi, 1991). No such consensus was reached on the optimal extent of resection. In recent years, however, much has been learned and consistent radical approaches have been met with some success. Despite the lack of definitive evidence, a rational approach to gallbladder cancer can be devised and should depend on the stage of the disease, location of the tumor, margin status (if previous cholecystectomy), and whether a prior, noncurative cholecystectomy has been performed. When considering extensive operations, the morbidity must be weighed carefully against the long-term outcome data.

Despite the confusion about the extent of resection for gallbladder cancer, strong evidence supports the use of liver resection and regional lymphadenectomy for T2 and T3 tumors without distant metastases. The modest improvements in survival over time probably reflect the better surgical resections applied to this overall minority of patients (Grobmyer et al, 2004). In a study from Toronto, two separate periods were analyzed and showed improved survival in completely resected patients; median survival increased from 9 to 17 months. In the second period, liver resection and regional lymphadenectomy were used more often, and the authors attributed the improved survival to this strategy (Dixon et al, 2005). In general, we recommend the following principles based on the literature and our own data. T1a tumors can be treated with a simple cholecystectomy. T1b tumors, although associated with good long-term survival after simple cholecystectomy, are associated with a higher locoregional recurrence rate and, in most patients, liver resection and lymph node dissection should be performed. A negative cystic duct margin must be ensured, and a bile duct resection to obtain a negative margin for a T1 tumor is recommended. In general, for T2 and T3 tumors, a complete resection of the tumor en bloc with segments IVb and V of the liver should be carried out to ensure complete clearance. If the tumor extent is such that invasion of hepatic inflow vascular structures is documented or suspected, an extended right hepatectomy may be necessary to clear all tumor; this is appropriate in a healthy patient with no evidence of distant disease. A negative margin at the cystic duct should be assessed and, if necessary, a bile duct resection should be performed. A lymph node dissection of the hepatoduodenal ligament also should be carried out. It is important to stage the patient carefully at operation, and major resections should be abandoned if distant nodal (retropancreatic or celiac) or other metastases are found. A diagrammatic representation of the extent of operation in a typical extended cholecystectomy is shown in Figure 49.7.

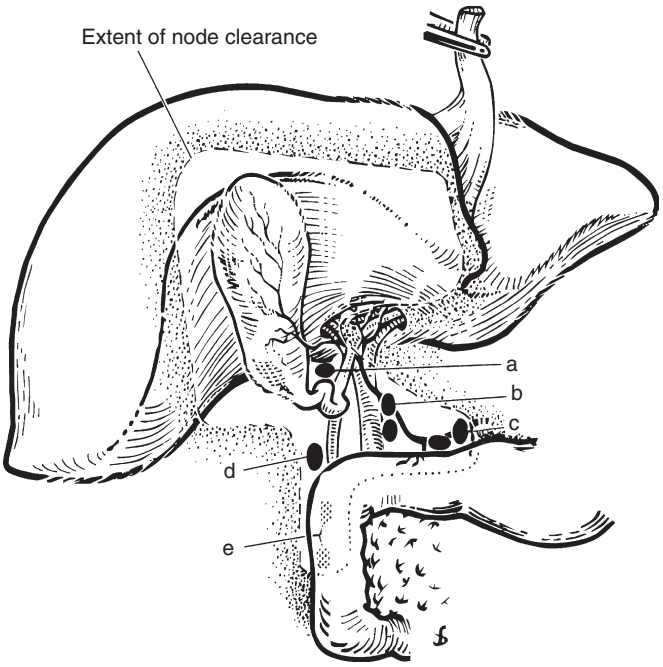

FIGURE 49.7. Diagrammatic representation of the extent of dissection in an extended cholecystectomy. *a-e*, lymph node field.

Liver Resection (See Chapter 90B)

It is now accepted that some degree of liver resection is appropriate to treat gallbladder cancers beyond the very early T1a stage. Recommendations have ranged from a limited 2-cm wedge resection of the gallbladder bed to a routine extended right hepatectomy. The goal of the liver resection is to ensure a margin of resection of approximately 1 to 2 cm because there is no serosal surface on the liver side of the gallbladder. Although a wedge resection may be sufficient for a clear margin, it is a nonanatomic approach that may compromise the safety of the operation related to bleeding or bile leakage or both. It also may result in a closer margin than anticipated. We generally recommend an anatomic resection of segments IVb and V. Intraoperative US can be helpful in delineating vascular anatomy and guiding the resection. The inflow pedicles to segments IVb and V generally are taken within the liver substance, but the segment IVb pedicles can be dissected in the umbilical fissure and divided before parenchymal dissection. Major bleeding can occur from the distal branches of the middle hepatic vein, and these must be carefully controlled. Care must be taken to avoid injury to the main right anterior sectoral pedicle and the segment VIII pedicles.

If a segment IVb/V resection would result in an inadequate margin, an extended right hepatectomy may be required. This may be the case for large tumors invading the right portal pedicle or tumors of the lower end of the gallbladder encroaching on the porta hepatis. In the latter situation, a bile duct resection is usually required. Isolated invasion of local organs (stomach, duodenum, colon) in the absence of distant metastases requires a local resection, which is reasonable to perform to ensure tumor clearance. In patients who have had a prior noncurative cholecystectomy, the preoperative US should be reviewed to find the tumor; this can guide the resection. The cystic duct margin also should be reanalyzed. Typically, a segment IVb/V resection is adequate if no obvious tumor is present and the tumor was present in the body or fundus. It often is impossible to differentiate scar from tumor in the porta hepatis at the time of operation, forcing the surgeon to perform a bile duct resection and extended right hepatectomy; this is appropriate in well-selected patients. Reddy and colleagues (2007) described 11 patients with stage I and II gallbladder cancer who underwent extended hepatectomy for either large

tumors, positive cystic duct margins, preoperative jaundice and biliary obstruction, known node-positive disease, or significant inflammation in the triangle of Calot. Morbidity and survival were similar when compared with historic controls treated with extended cholecystectomy (Reddy et al, 2007). In a series of 104 patients from MSKCC, however, morbidity and mortality increased with more extensive resections without any improvement in survival (D'Angelica et al, 2009). In this series, 20% of patients had direct invasion of other organs and concurrent en bloc resections. The principal finding of this analysis was that the stage of the tumor, rather than the extent of resection (given a margin-negative resection), was the overwhelming determinant of long-term survival. Thus current practice is to perform only the extent of hepatic resection necessary to achieve tumor clearance.

Lymph Node Dissection

Studies of the lymphatic drainage of the gallbladder have been performed and were reviewed earlier in this chapter (Shirai et al, 1992c). As in the extent of liver resection, there has been wide variability in the recommendation for the extent of lymphadenectomy, ranging from excision of the cystic duct node to a complete portal clearance combined with pancreatoduodenectomy (Matsumoto et al, 1992). Groups from Japan have reported some success for the treatment of extensive gallbladder cancer with hepatopancreatoduodenectomy even in the face of extensive nodal metastases (Sasaki et al, 2002). The recommendation for these extensive procedures is based on the fact that early lymph node metastases to the retropancreatic and interaortocaval nodes are common, and a pancreatic resection presumably improves the ability to clear these nodes. The more important question is whether the increased risk of such an approach is justified by the outcome. In general, the outcome for patients with nodal disease, in particular in patients with distant nodal disease, is so poor that this approach is not generally recommended. Given the importance of identifying lymph node metastases outside the "extended cholecystectomy" field, the first maneuver in the operating room is mobilization of the duodenum to assess the aortocaval and retropancreatic lymph nodes. The celiac lymph nodes should also be assessed early on; suspicious nodes are sent for frozen-section analysis and, if positive, the procedure is terminated.

Whether lymph node dissection improves outcome is unknown; given the rarity of this disease, this question will probably never be tested in a randomized trial. Lymph node dissection does provide important diagnostic information, however, and it may provide further regional control. Regional lymphadenectomy for gallbladder cancer includes removal of nodes in the porta hepatis, gastrohepatic ligament, and retroduodenal space (all N1 nodes). In patients with T1b or greater tumors, regional lymphadenectomy is associated with improved survival in retrospective studies when compared with extended cholecystectomy alone (Frauenschuh et al, 2000; Kwon et al, 2008). The rate of positive nodes with T1b to T3 tumors in these studies ranges from 16% to 30%. Despite these data, a study that used the epidemiology and Surveillance and Epidemiology End Results (SEER) database to track gallbladder treatment trends found that an adequate lymphadenectomy (three or more nodes) was only reported in 5.3% of patients treated surgically for gallbladder cancer (Coburn et al, 2008). The year of resection (after 1988, hazard ratio [HR] = 1.20; 95% confidence interval [CI] 1.14 to 1.26) and T1 stage (compared with T2, HR = 0.48; 95% CI, 0.27 to 0.83) were associated with adequate lymphadenectomy. Only 6% of patients with T2 or T3 tumors underwent lymphadenectomy. In addition, the majority of T3 tumors (75%) were treated with inadequate lymphadenectomies (up to two nodes). Although this study suggests that the majority of patients with gallbladder cancer did not receive appropriate surgical treatment, the limitations of the SEER database may be responsible for overestimating this trend.

Controversy surrounds the question of whether a routine bile duct resection is necessary for an adequate lymph node dissection. Although there is no question that excising the extrahepatic bile duct can make a lymph node dissection easier, it also increases the morbidity of the operation (Bartlett et al, 1996). However, no differences are reported in the numbers of lymph nodes harvested in regional lymphadenectomy with or without a bile duct resection (Sakamoto et al, 2006; Pawlik et al, 2007; D'Angelica et al, 2009). In general, a bile duct resection should not be necessary unless there is suspicion of infiltration into the porta hepatis. One study from Japan reported on patients with T2 or T3 tumors who underwent routine bile duct resection (Shimizu et al, 2004). Histologic spread of tumor in 30 of 50 specimens into the hepatoduodenal ligament was documented; some represented direct spread of tumor, and others represented lymph node metastases. It is unknown whether this resection would have any impact on outcome, especially in patients with lymph node metastases. In a study from MSKCC of 109 patients undergoing surgical resection for gallbladder cancer (D'Angelica et al, 2009), 68 patients (65%) had common bile duct resections, with 36 the result of clinical involvement and 32 with empirical resections. Bile duct resection was not associated with clinical or pathologic variables. The 5-year survival of patients without bile duct involvement was 49%, which was significantly higher than for those with bile duct involvement (20%). This study, combined with the data from Sakamoto and others, reinforces the point that stage of disease, not extent of surgery (assuming an R0 resection), determines survival in patients who undergo resection of gallbladder cancer.

Bile duct resection combined with regional lymphadenectomy requires a Kocher maneuver, division of the bile duct at the level of the duodenum, and complete dissection of all the associated soft tissue. This tissue should be swept superiorly, skeletonizing the porta hepatis vasculature. Reconstruction is with a Roux-en-Y hepaticojejunostomy (see Chapter 50B). Malignant invasion of the bile duct with jaundice would necessitate a bile duct resection, but the surgeon must consider the overwhelmingly poor prognosis in these patients and the low likelihood of a complete resection (Hawkins et al, 2004); a palliative approach may be best in this patient population.

PORT SITE RECURRENCES

There is a theoretical risk of port site seeding after laparoscopic cholecystectomy for what is eventually diagnosed as gallbladder cancer. This problem may be exacerbated by spillage of bile or stones inside the peritoneal cavity (Winston et al, 1999). One study looked at 409 patients who underwent laparoscopic cholecystectomy for presumed benign gallbladder disease but were diagnosed with gallbladder cancer on final pathology (Paolucci et al, 1999). Seventeen percent of patients at a median of 180 days were diagnosed with laparoscopic port site recurrences. As

a result of this high percentage, some surgeons recommend port site excision during reoperation for gallbladder cancer. It is important to note, however, that it is rare for port site recurrences to occur as the sole site of disease (Povoski et al, 2004; Shoup & Fong, 2002). Given that it is more a marker of aggressive disease than a single site of resectable disease, our general practice does not include empirically resecting prior port sites during reexploration for gallbladder cancer.

RESULTS

The overall picture of gallbladder cancer is slowly improving but is still a dismal one. Historically, more than two thirds of patients are initially seen with disease beyond the scope of surgery; even including patients who are lucky enough to make it to resection, the overall survival is poor. The overall 5-year survival is consistently less than 5%, with a median survival of 5 to 8 months. Older large reviews (Perpetuo et al, 1978; Piehler & Crichlow, 1978) documented a 5-year survival of 4% to 5% and a median survival of 5 months. One-year survival was 12%. Approximately 25% of the patients were resected for cure, and in this select group, 5-year survival was only 17%. Studies published in Europe and Australia in the 1990s report overall median survivals of approximately 3 months and 5-year survivals of approximately 5% (Carty & Johnson, 1991; Cubertafond et al, 1994; Wilkinson, 1995). Survival results from MSKCC for patients treated from 1995 to 2005 show some improvements compared with older studies (Duffy et al, 2008). Of the 435 patients studied, 36.6% presented with AJCC stage IV disease. Median overall survival for the entire patient cohort was 10.3 months (95% CI, 8.8 to 11.8 months) with a median follow-up of 26.6 months. For patients with stage Ia through stage III disease, median survival was 12.9 months (95% CI, 11.7 to 15.8 months) compared with 5.8 months (95% CI, 4.5 to 6.7 months) for those with stage IV disease. Median survival for patients who had an incidental diagnosis of gallbladder carcinoma after laparoscopic cholecystectomy was 15.7 months (95% CI, 12.4 to 18.4 months). Of this subset of patients, those who were reexplored had a median survival of 72 months (95% CI, 34/not reached); for patients with no pathologic evidence of residual disease, median survival was 19 months (95% CI, 12.9 to 28 months) if an R0 resection was done and 12.7 months (95% CI, 8.2 to 15.7 months) for an R1 or R2 resection ($P < .0001$). Of these patients, 104 were analyzed in a separate study (D'Angelica et al, 2009) that showed T and N stage to be strong independent predictors of outcome along with histologic differentiation and bile duct involvement.

Refinements in hepatobiliary surgery have made safe and rational approaches to malignancy more broadly applicable. As presented below, there is now mounting evidence that in selected patients without distant disease, an aggressive surgical approach can provide the potential for long-term survival. Given the rarity of this disease, prospective data are lacking and decision making relies on the analysis of imperfect retrospective analyses. Because most operable gallbladder cancer is incidental, and surgical decisions are based on T stage from a resected gallbladder or from imaging, the approach to the three potentially resectable T stages and their outcomes are outlined.

T1 Tumors: Confined to the Muscular Coat

T1 tumors are typically diagnosed incidentally in cholecystectomy specimens because they are usually not obvious on imaging studies. By definition, they do not penetrate the muscular layer, and because a simple cholecystectomy dissects the perimuscular layer, this operation theoretically should be curative. These tumors are rarely associated with lymph node metastases. In the uncommon circumstance that a T1 tumor is detected intraoperatively, the surgeon should palpate lymph nodes and sample any that are suspicious. It is crucial to obtain negative margins, and the cystic duct margin always should be reviewed to ensure this. It is sometimes necessary to resect the common bile duct to obtain this negative margin. Overall, the cure rate is 85% to 100% with a simple cholecystectomy (Table 49.9). Of the small number of patients with T1 gallbladder cancer that recurs, they are commonly found to have submucosal spread involving the cystic duct margin (Shirai et al, 1992b). T1b tumors also seem to be at a higher risk of recurrence, as previously described; because of this, an extended cholecystectomy is recommended in patients with T1b tumors who can tolerate the procedure.

T2 Tumors: Invading into the Subserosal Layer

T2 tumors are most likely to benefit from an extended resection of the lymph nodes near the liver and porta hepatis. Results from modern series are listed in Table 49.10. Because these tumors are difficult to diagnose preoperatively, they also are

Table 49.9

commonly diagnosed incidentally at cholecystectomy. The dissection plane of a simple cholecystectomy in the subserosal plane is often involved with tumor, resulting in a positive margin for many T2 tumors (Yamaguchi et al, 1992). In addition, approximately one third of patients with T2 tumors have nodal metastases, reinforcing the need for a regional lymphadenectomy for diagnostic and potentially therapeutic purposes (Chijiiwa et al, 2001). Although based on multiple retrospective reviews, the data indicate that survival is significantly improved in patients undergoing an extended cholecystectomy compared with patients undergoing a simple cholecystectomy. What is striking from these series is that long-term survival generally is achieved in 60% to 100% of patients undergoing an extended resection, depending on the stage, compared with less than 50% with simple cholecystectomy.

T3 and T4 Tumors: Locally Advanced

The most controversial aspect of the surgical treatment of gallbladder cancer involves patients with nonmetastatic locally advanced tumors (T3 and T4 tumors). Table 49.11 summarizes representative studies in this patient group. Historically, these patients were documented to have extremely poor survival, and surgical extirpation was thought to be futile. Since the 1990s, however, numerous small series have documented that with varying levels of extended resections, long-term survival is possible in highly selected patients. In a series from MSKCC, 15% to 20% of patients with locally advanced disease were long-term survivors (Fig. 49.8) (D'Angelica et al, 2009).

Numerous series from Japan, in particular, have shown the possibility of long-term survival in these patients. Japanese surgeons liberally use extensive surgical procedures, including

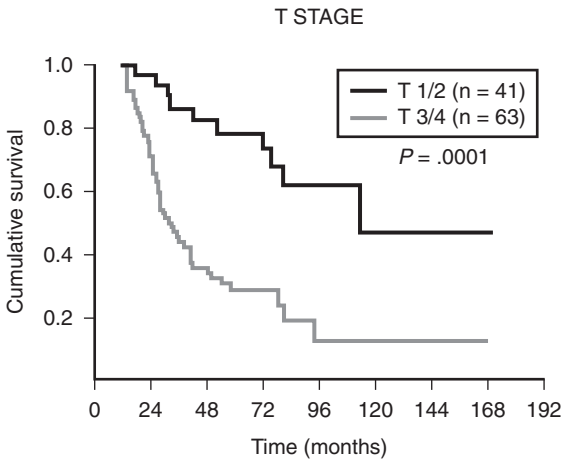

FIGURE 49.8. Disease-specific survival for 104 patients with gallbladder cancer stratified by T stage. *(From D'Angelica M, et al, 2009: Analysis of the extent of resection for adenocarcinoma of the gallbladder. Ann Surg Oncol 16[4]:806-816.)*

vascular resection, bile duct resection, extended hepatectomy, and hepatopancreatoduodenectomy (Nakamura et al, 1989; Onoyama et al, 1995; Shirai et al, 1992b). In general, extensive lymph node dissections are routinely performed, and survival results may be a reflection of stage migration and better staging. Western series also have begun to show similar results with an aggressive surgical approach (Gall et al, 1991). These data must be interpreted in the proper context, however; overall, most patients with locally advanced disease have metastatic disease, and resection is often impossible. The most important associated prognostic factor in every series is the status of lymph nodes. Long-term survival rarely accompanies distant lymph node disease, and it is uncommon with hepatoduodenal lymph node metastases. The uncommon patient with a locally advanced tumor and no lymph node metastases probably benefits the most from an extensive operation. Patients with locally advanced gallbladder tumors should be carefully evaluated to rule out distant metastases. In general, patients with lymph node metastases outside the hepatoduodenal ligament should not undergo resection. In carefully selected patients, however, extended radical resection provides the only chance for long-term survival.

Regional Lymph Node Positivity

Nodal status was found to be an independent predictor of outcome in multiple studies. Although the number and location of positive nodes can affect survival, the presence of any nodal disease is associated with poor survival. In a study of 104 patients with gallbladder cancer at MSKCC, for example, the 34 patients with N1 disease had a significantly worse 5-year survival (17%) compared with patients with N0 disease (51%; P = .0002) (D'Angelica et al, 2009). Endo and colleagues (2006) reported a similar difference in survival, with 5-year survival rates of 77% with node-negative disease and 33% with one positive lymph node. These findings also apply to patients who had gallbladder cancer discovered incidentally after cholecystectomy. Pawlik and colleagues (2007) examined nodal status in patients diagnosed after surgical resection and found a 5-year survival of 73% with node-negative disease compared with a 5-year survival of 27% in patients with node-positive disease (Endo et al, 2006). The number of positive nodes has also been described as a predictor of outcome. Patients with a single lymph node metastasis had a higher 5-year survival rate (33%) compared with patients who had two or more lymph node metastases (0%; $P < .05$) (Endo et al, 2006).

Gallbladder Cancer Discovered Incidentally After Laparoscopic Cholecystectomy

The surgical approaches to patients who have undergone a prior noncurative cholecystectomy have been previously outlined. When a patient is seen after a noncurative cholecystectomy with no evidence of disseminated disease, a repeat resection is warranted in most cases. For patients who undergo definitive operation, the outcome seems to be similar to that of patients who undergo primary resection; this seems to be true stage for stage (Fong et al, 2000).

Significance of Jaundice on Presentation

The presence of jaundice is a troubling sign; it suggests porta hepatis involvement with tumor. In 240 patients at MSKCC who presented with gallbladder cancer, 82 (34%) were jaundiced and were more likely to have advanced stage disease; only six patients underwent resection with curative intent, and only four had an R0 resection (Hawkins et al, 2004). The median disease-specific survival of patients with jaundice was 6 months, significantly worse than those without jaundice (16-month disease-specific survival; $P < .0001$), and none from the jaundiced group survived 2 years. A retrospective study by Varma and colleagues (2009) reported that although jaundice was associated with a higher stage at presentation, it did not preclude resection. Half of those patients who presented with jaundice underwent R0 resections. Survival differences, however, were not reported between jaundiced and nonjaundiced patients. Thus curative resection can be attempted in select patients with gallbladder cancer and jaundice, but the expectations of the surgical team and patient should be tempered.

ADJUVANT THERAPY

The rarity of gallbladder cancer has traditionally precluded large randomized trials, and the literature abounds with small case series and retrospective comparisons that attempt to address whether adjuvant chemotherapy and/or radiation therapy are beneficial after complete resection. In a study from MSKCC, 85% of recurrences included distant sites as part of the recurrence pattern (Jarnagin et al, 2003), highlighting the importance of systemic therapies. Reports of small series with fewer than 10 patients from the 1970s and 1980s suggested a small benefit to adjuvant chemotherapy compared with historic controls (Morrow et al, 1983; Oswalt & Cruz, 1977). Chao and Greager (1991) reported on 15 patients who received some form of chemotherapy or radiation or both after resection and found no difference compared with patients who had not received adjuvant therapy. Similarly, studies of adjuvant radiation therapy over the last few decades have suggested modest benefits (Bosset et al, 1989; Hanna & Rider, 1978; Todoroki et al, 1991).

A recent retrospective review of 123 patients who underwent resection of gallbladder cancer with adjuvant therapy (n = 24; 66% of patients with chemoradiation, 34% of patients with chemotherapy alone) or without (n = 99) showed no difference in

overall survival between the groups; however, patients treated with adjuvant therapy had a higher rate of incomplete resections, higher stage of disease, and more positive lymph nodes (Duffy et al, 2008). A recent SEER database analysis of 4000 patients with gallbladder cancer found a survival benefit with adjuvant radiotherapy in patients with positive nodal disease or T2 or greater tumors (15 months vs. 8 months). This difference was significant on multivariate analysis (HR = 1.46; 95% CI, 1.07 to 1.98; $P = .014$) (Wang et al, 2008).

Three randomized, controlled trials have included patients with gallbladder cancer. Takada and colleagues (2002) reported a phase III multiinstitutional trial of adjuvant chemotherapy performed in Japan. This trial included 508 patients with biliary and pancreatic cancers. On subset analysis, this study included 140 gallbladder cancer patients who were randomized to receive surgical resection alone or resection plus adjuvant mitomycin C and 5-fluorouracil (5-FU). When considering the gallbladder cancer patients only, the actuarial 5-year disease-free survival favored the adjuvant chemotherapy group (20.3%) compared with the surgery-alone group (11.6%, $P = .02$). Data regarding the extent of surgical resection and histologic staging were lacking, making the results difficult to interpret. More recently, gemcitabine-based regimens, often combined with a platinum agent, have become the drug of choice for treating gallbladder cancer. Much of the data for the adjuvant setting has been extrapolated from the metastatic setting. A recently published randomized, phase III study of palliative gemcitabine compared with gemcitabine and cisplatin for metastatic biliary cancers offers information that may be useful in the adjuvant setting (Valle et al, 2010). With overall survival as the primary end point, 410 patients with locally advanced or metastatic gallbladder cancer, cholangiocarcinoma, or ampullary cancers were randomized; 149 patients had gallbladder cancer. After a median follow-up of 8.2 months for all patients in the trial, a significant difference in overall survival was reported, with an HR of 0.61 (CI, 0.42 to 0.89) favoring the gemcitabine-cisplatin combination. There were, however, more neutropenic events in the gemcitabine-cisplatin group. It remains to be seen whether this new trial will change clinical practice in the adjuvant setting, but it continues to reinforce gemcitabine-based regimens as the standard chemotherapy for gallbladder cancer. Another smaller randomized, controlled trial of gemcitabine combined with oxaliplatin (GEMOX) showed a similar benefit when the gemcitibine regimen was compared with 5-FU or best supportive care in patients with unresectable or metastatic gallbladder cancer (Sharma et al, 2010). Median overall survival was 9.5 months in the GEMOX group (n = 27), compared with 4.6 months in the 5-FU group (n = 28; $P = .039$).

In light of the available data, it is reasonable to consider patients with high-risk lesions (T4 tumors, at least one positive lymph node, R1 resection) for adjuvant therapy and to offer consultation with an oncologist to discuss treatment options. However, it must be emphasized that treatment efficacy in the palliative setting may not translate into better disease control when used as an adjuvant to resection.

PALLIATIVE MANAGEMENT

Most treatment options in patients with gallbladder cancer are palliative because most patients are unresectable by the time they come to medical attention. The most common symptoms to palliate include pain, jaundice, and bowel obstruction.

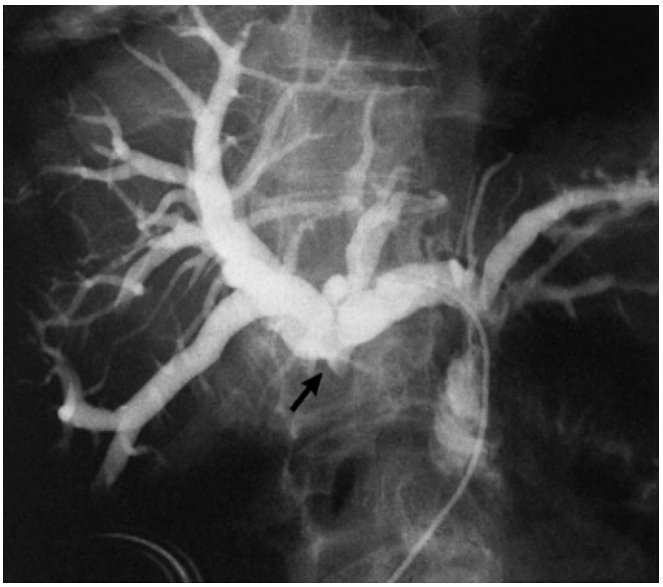

FIGURE 49.9. Tubogram showing a segment III hepaticojejunostomy. The anastomosis is well away from the malignant obstructing lesion in the liver hilus (*arrow*).

Palliation of jaundice in gallbladder cancer can be complex and depends on the location and extent of biliary obstruction. The outcome for these patients is poor, and chemotherapy often offers little in terms of prolongation of life. In the past, operative approaches provided the most effective relief of obstruction in well-selected patients. Operations such as the segment III bypass (Fig. 49.9) (Bismuth & Corlette, 1975; Kapoor et al, 1996) and the Longmire operation (Longmire et al, 1973) have become less common with the development of interventional percutaneous stenting techniques. In patients who have symptoms from obstructive jaundice, endoscopic or percutaneous interventions are the preferred approach for palliation and minimalization of morbidity (Lung et al, 2009; Naitoh et al, 2009; Togawa et al, 2008).

In general, patients in need of palliative procedures for symptomatic gallbladder cancer have high complication rates after such procedures. A prospective study from MSKCC included 109 patients undergoing percutaneous biliary drainage for malignant biliary obstruction. A 58% rate of major complication and two procedure-related deaths were reported, and the 8-week postprocedure mortality rate was 28%. These palliative procedures were successful in alleviating pruritus, but no improvement was reported in measures of quality of life (Robson et al, 2010). The high risk of morbidity and mortality precludes recommending these treatments in the absence of symptoms or a specific reason to treat jaundice, such as to allow the administration of chemotherapy. Saluja and colleagues (2008) randomized 44 patients with gallbladder cancer and obstructive jaundice to percutaneous or endoscopic stenting. They found that successful stenting occurred in 89% of patients in the percutaneous group compared with 41% in the endoscopic group ($P < .001$). Cholangitis was also significantly higher (48%) in the endoscopic stent group compared with the percutaneous group (11%; $P = .002$). The mortality rates were similar between the two groups, but percutaneous stenting in this trial offered better palliation than endoscopic stenting. The

Table 49.12

Treatment Recommendations for Gallbladder Cancer Diagnosed After Cholecystectomy

T Stage	Recommended Surgical Procedure	Notes
Ia	Simple cholecystectomy	85% to 100% of patients cured
Ib, II	Extended cholecystectomy with resection of segments IVb and V with en bloc regional lymph node dissection Bile duct resection if bile duct margin positive	
III	Hepatic resection (segments IVb, V) with major hepatectomy as necessary	More commonly involves bile duct and right-sided vascular structures, requiring major liver resection
IV	Same as stage III if resectable	Often unresectable because of hilar vascular invasion

choice between endoscopic and percutaneous interventions often depends on local resources and personnel. Intestinal bypass can also be performed in patients with symptomatic bowel obstructions. Percutaneous feeding tubes or drains and endoscopic stents are favored over surgical bypass because of the extremely poor prognosis.

Chemotherapy has been used to palliate unresectable disease but often offers little benefit. Historically, regimens have included 5-FU, leucovorin, mitomycin C, doxorubicin, and methotrexate. Response rates in these studies generally range from 10% to 20% (Hejna & Zielinski, 2001). More recently, however, phase II trials with gemcitabine and oxaliplatin have showed improved response rates ranging from 40% to 50% (Andre et al, 2008; Harder et al, 2006; Verderame et al, 2006). Radiation therapy may be an effective palliative therapy for locally advanced disease; it is generally well tolerated, may have an impact on local symptoms, and is usually combined with chemotherapy (Lin et al, 2005; Valle et al, 2010).

SUMMARY

Although the overall picture of gallbladder cancer is a dismal one, we have come a long way since Alfred Blalock's quote in 1924, which summarized the nihilism of the day. Localized gallbladder cancer can be cured with an extended resection, and although most patients who are cured had early-stage disease, there is some hope for patients with locally advanced tumors. Perhaps the most important lesson is to recognize abnormalities of the gallbladder wall as possibly malignant at an early stage because primary resection remains the best chance of a good outcome. General surgeons who treat gallbladder disease should critically review the results of preoperative imaging in patients with presumed benign gallstone disease, particularly the US findings, and the possibility of a malignant process must always be considered when abnormalities of the gallbladder wall are reported.

Cancers incidentally discovered at cholecystectomy are common, and this is sufficient treatment for most T1 cancers (Table 49.12). Exceptions are patients with positive cystic duct margins, who should undergo a definitive complete resection, and patients with T1b tumors, who should also be considered for reoperation and definitive resection. For T2 through T4 tumors, patients should undergo reexcision as described throughout this chapter. In general, patients with distant nodal metastases are not able to be cured and probably do not benefit from reoperation. Preoperative imaging and surgical staging are crucial because of the high incidence of metastatic disease. Tumors recognized before cholecystectomy should be resected with an en bloc liver resection and portal lymphadenectomy as described. Even large, locally advanced tumors are potentially curable, albeit the likelihood of such is low. In well-selected, otherwise healthy patients, an aggressive approach is warranted in the absence of distant metastases, including distant nodal disease. For the rare patient with a locally advanced, node-negative tumor, complete resection offers a significant chance for long-term survival. This is probably also true for patients with limited nodal disease in the hepatoduodenal ligament.

The proper operation to treat gallbladder cancer has been extensively discussed and involves a liver resection to encompass the tumor and achieve a negative margin. This is generally a resection of segments IVb and V, but if invasion of inflow structures to the liver mandate it, an extended hepatectomy is warranted. Bile duct resection is indicated to obtain negative margins if necessary, but it should not be routine; however, a complete lymphadenectomy of the hepatoduodenal ligament is an important part of the treatment. Extensive operations to clear distant nodal disease, including a pancreatoduodenectomy, have been described but cannot be advocated in most patients because the risk generally outweighs the benefit. Despite this relative optimism, the overwhelmingly more common issue is the treatment of advanced, metastatic, or recurrent disease. New randomized trials have helped reinforce gemcitabine-based chemotherapy regimens as the most effective, but the development of additional effective systemic agents is crucial.

The surgeon's role is often to facilitate palliative treatments to improve the quality of life for patients with advanced gallbladder cancer. In the past few decades, surgeons have proven that resection for localized gallbladder cancers can be performed safely. Because of the often advanced nature of gallbladder cancer at presentation, efforts should be focused on diagnosing biliary malignancies earlier and developing more effective systemic agents. It is not reasonable to screen an entire population for gallbladder cancer given its rarity; however, gallbladder cancer may be detected at earlier stages with better education to raise awareness so physicians will consider the diagnosis in patients who present with signs or symptoms of gallbladder disease.
