

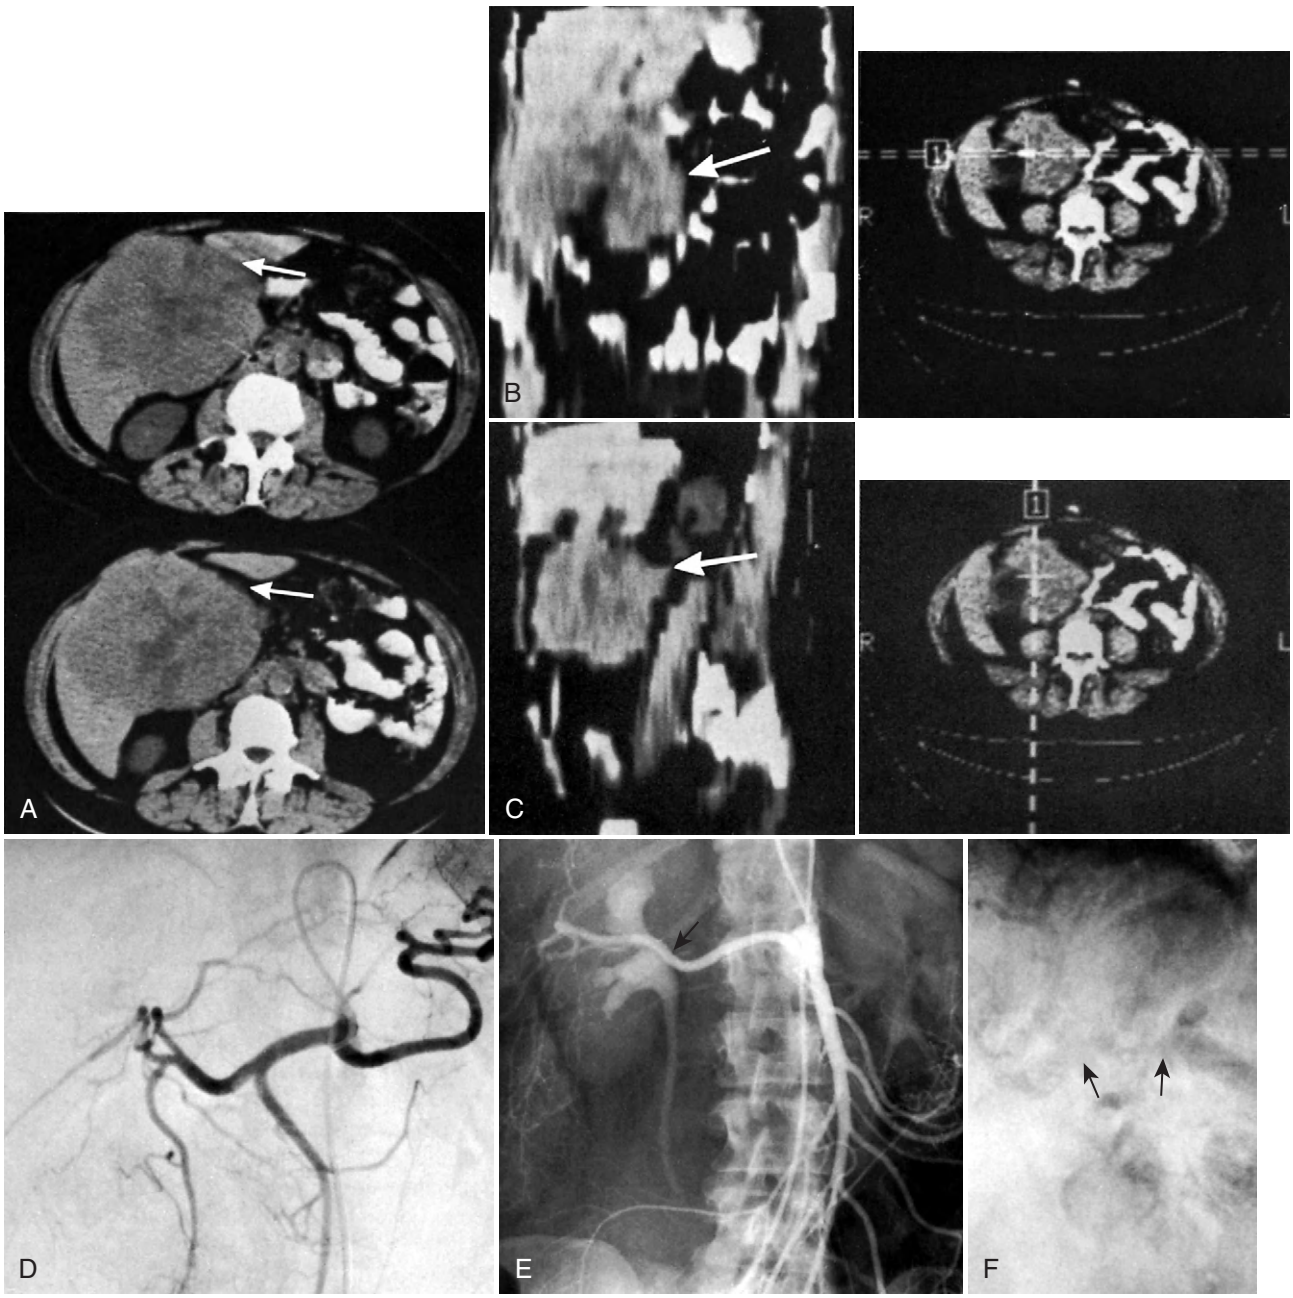

FIGURE 90B.7. **A,** Computed tomographic scan shows a large tumor apparent in the right liver and extending well into the left (*top arrow*). A gap between the tumor and segments II and III (*bottom arrow*) is apparent on the lower cut. **B,** Coronal reconstruction shows that the tumor (*arrow*) is pedunculated. **C,** Sagittal reconstruction shows the pedunculated (hanging) nature of the tumor (*arrow*), which originates from segments IV and V. **D,** Celiac axis angiogram shows the arterial supply to the tumor arising from the left hepatic artery. **E,** An accessory right hepatic artery is revealed to arise from the superior mesenteric trunk (*arrow*). **F,** Late-phase portogram obtained from selective splenic artery catheterization shows tumor involvement of the right branch of the portal vein extending to the portal venous bifurcation (*arrows*). The tumor proved to be a primary hepatocellular carcinoma, and treatment was by right lobectomy (extended right hepatectomy). *Note:* Angiographic techniques are now rarely used in diagnosis, but the images are retained for illustrative purposes.

Magnetic resonance imaging (MRI; see Chapter 17) has become increasingly valuable in the imaging of the liver before resection. Masses are well characterized, as are the presence of additional lesions sometimes not visualized on CT scan. MRI depicts major blood vessels accurately and is particularly valuable in the demonstration of the major hepatic veins and vena cava and their relationship to tumor masses (Fig. 90B.8). Compared to CT, MRI also may be more accurate in differentiating primary and secondary malignancies of the liver from benign lesions such as adenoma, focal nodular hyperplasia (FNH), or cysts.

US performed by an experienced operator is also of value in the preoperative assessment of multiple tumors, as it gives information regarding the size of the tumor and extent of liver involvement. US also may help distinguish cysts from solid tumors, and duplex US demonstrates tumor location with respect to important vascular structures, including the hepatic veins and vena cava (Gibson et al, 1986), and it is a valuable technique to further define blood vessels after initial CT scanning (Fig. 90B.9; Hann et al, 1998). US can be of particular importance in the preoperative evaluation of hilar cholangiocarcinoma by defining the extent of involvement of the portal vein and hepatic artery (Fig. 90B.10; Hann et al, 1997); however, as MRI and CT scan continue to produce higher quality images, the need for preoperative US evaluation has declined.

Hepatic angiography and inferior venacavography (see Chapter 19) usually are not necessary and should not be used except perhaps in the instance of large hemangiomata, for which precise information as to the arterial supply of the lesion

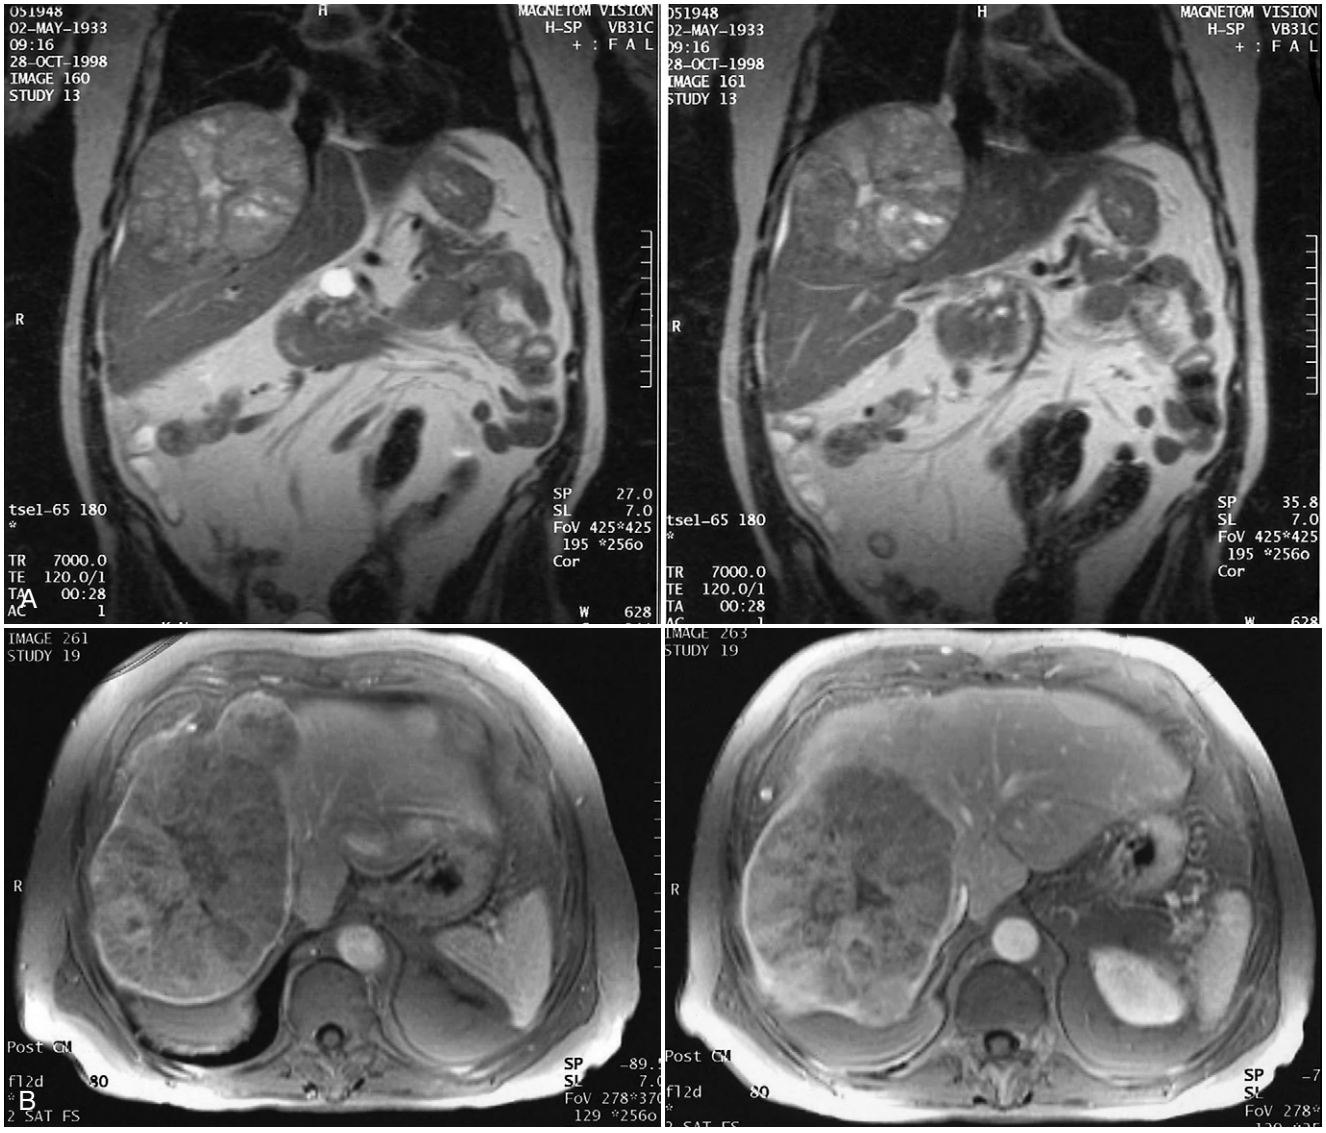

FIGURE 90B.8. Magnetic resonance imaging shows an extremely large but well-demarcated hepatocellular carcinoma occupying the right liver and extending into segment IV. **A,** Coronal views show that the tumor is seriously compromising and compressing the inferior vena cava (IVC); it extends upward and involves the right hepatic vein at its point of junction with the vena cava, distorting and compressing the suprahepatic IVC. At operation, the tumor—causing a pressure effect without direct invasion of the diaphragm—was found to lie just adjacent to the IVC–right atrium junction. **B,** Transverse scans illustrate the extent of the tumor and the severe compression of the IVC. Extended right hepatic lobectomy (right lobectomy) was done, and tumor clearance was obtained; hepatic vascular isolation was not used. The patient was alive and well 9 months after operation.

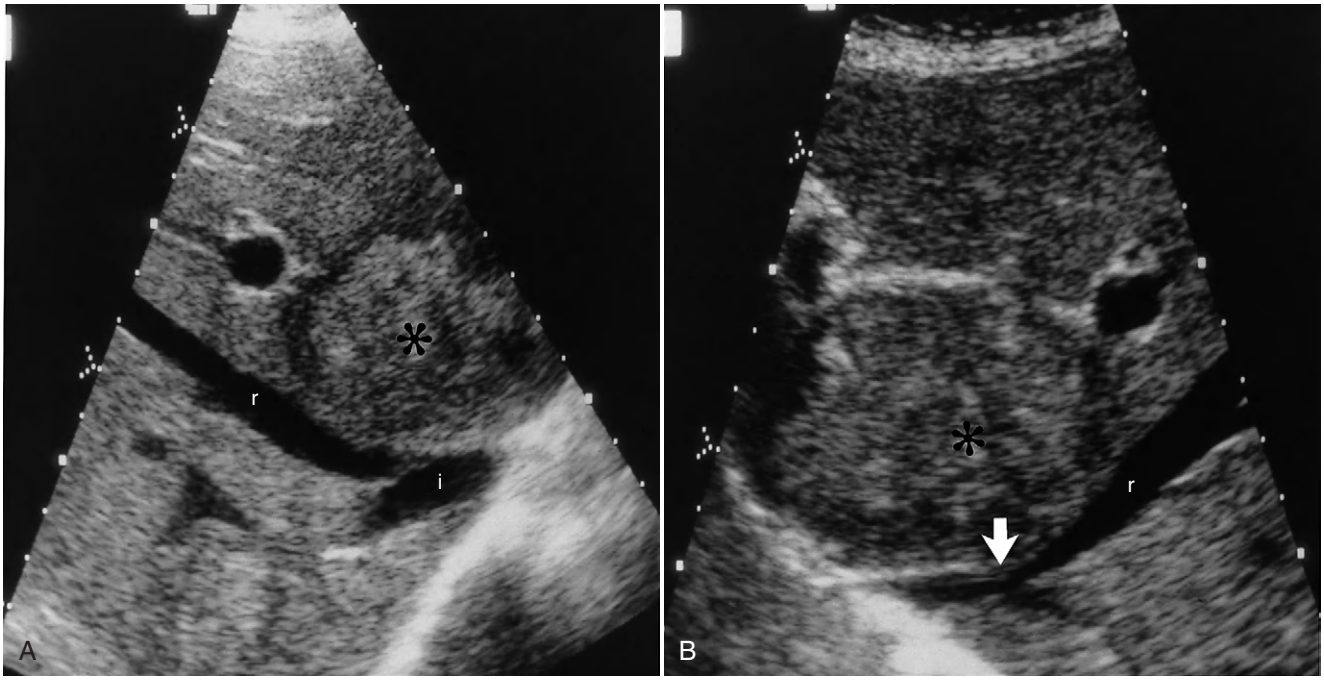

FIGURE 90B.9. Ultrasound defines the relationship between a colorectal metastasis and the veins at the hepatic vein confluence. **A,** Transverse ultrasound shows the metastasis (*asterisk*) making contact with the inferior vena cava (*i*) and right hepatic vein (*r*). **B,** Oblique intercostal projection confirms that the right hepatic vein is compressed (*arrow*) but not invaded by tumor (*asterisk*).

may assist at surgery, although modern advances in MRI and duplex US have all but rendered these studies obsolete. In the event that adequate US or MRI is unavailable, angiography still has a role in imaging (Blumgart, 1982; Voyles et al, 1983). Some figures of angiographic techniques are provided for illustrative purposes (Fig. 90B.11; see also Figs. 90B.1 and 90B.7), but it should be emphasized that they are unnecessary in most patients. In our practice, hepatic angiography is rarely obtained for the preoperative demonstration of extrahepatic arterial anatomy in patients being considered for placement of a hepatic arterial infusion (HAI) pump for postoperative adjunctive chemotherapy (see Chapter 86).

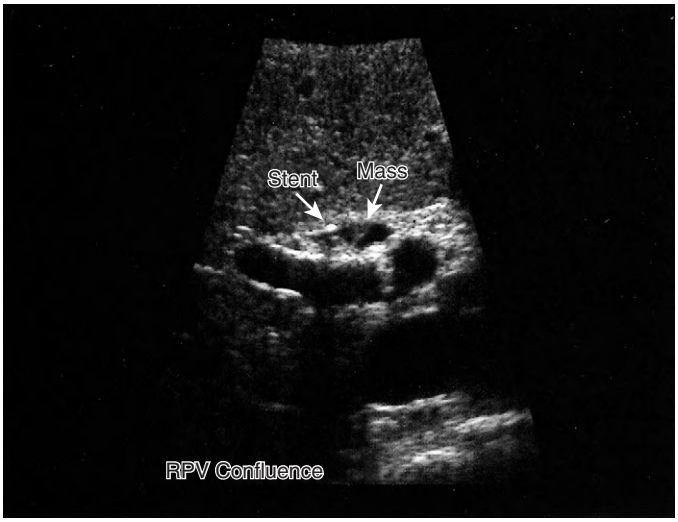

FIGURE 90B.10. Transverse ultrasound shows hilar cholangiocarcinoma at the confluence of the hepatic ducts. An endoscopically introduced stent is visible. The portal vein confluence immediately below the tumor is unaffected, and the portal vein is free. The tumor extended into the right hepatic duct, therefore an extended right hepatic lobectomy was necessary. The patient was alive, well, and tumor free 8 months after operation. RPV, right portal vein.

Other Investigations

To determine the oncologic appropriateness of hepatic resection, a thorough evaluation for the presence of extrahepatic disease should be performed by means of chest radiography, CT, or MRI before major hepatic resection is undertaken. When evaluating the chest, subcentimeter pulmonary nodules are frequently encountered that should not necessarily preclude hepatic resection, particularly for colorectal cancer liver metastases (Maithel et al, 2010). Positron-emission tomography (PET) scan may also be an important tool in the evaluation of the extent of spread of malignant disease (see Chapter 15; Beets et al, 1994; Fong et al, 1999a; Lai et al, 1996; Schüssler-Fiorenza et al, 2004).

If jaundice is present, and biliary involvement by the tumor is suspected, direct cholangiography may be carried out, either by endoscopic retrograde cholangiography (ERCP) or by percutaneous transhepatic cholangiography, to delineate the biliary anatomy (see Chapter 18); however, US and MRI cholangiography are noninvasive studies in many ways superior to direct cholangiography, and they have all but replaced preoperative invasive cholangiography for assessing tumor involvement of the bile ducts, such as in hilar cholangiocarcinoma (see Fig. 90B.10; see also Chapter 52). Of course, if preoperative biliary drainage is necessary, direct cholangiography, either endoscopic or percutaneous, will be required.

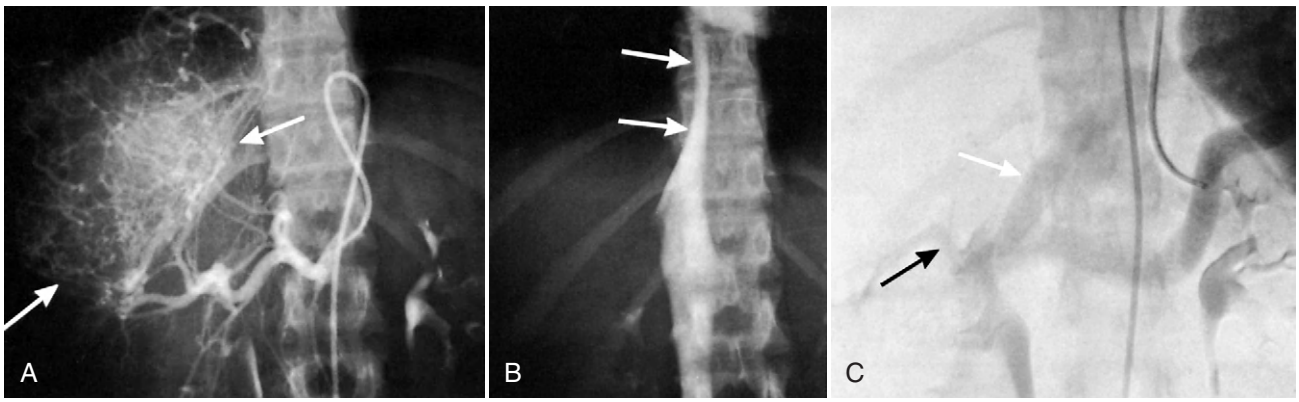

FIGURE 90B.11. A, Selective hepatic arteriogram shows a large primary hepatocellular carcinoma (*arrows*). **B,** Inferior venacavogram shows severe compression of the inferior vena cava (IVC) (*arrows*). Such severe compromise of the IVC demands vena caval control and precise dissection of the right hepatic vein. **C,** Selective splenic artery catheterization and late-phase splenoportogram show severe compromise of the right branch of the portal vein (*black arrow*). The left branch of the portal vein is intact (*white arrow*). Treatment was by right hepatic lobectomy. Angiographic techniques are now rarely performed.

Staging Laparoscopy

Staging laparoscopy and laparoscopic US are widely used to prevent unnecessary laparotomy in patients with hepatobiliary malignancy. Staging laparoscopy can significantly improve resectability rates at laparotomy, and laparoscopic evaluation has its greatest yield in detecting peritoneal metastases not detectable on cross-sectional imaging rather than identifying additional hepatic lesions. Furthermore, because of their location, laparoscopic evaluation often fails to identify lymph node metastases (Jarnagin et al, 2000; John et al, 1994; Lo et al, 1998). In one study at MSKCC (Jarnagin et al, 2000), 83% of patients subjected to laparotomy after laparoscopy underwent potentially curative resection, compared with only 66% of patients not staged laparoscopically (see Chapter 21).

Assessment of Resectability

Resectability is defined not only by what can be removed but, more importantly, by what can be left behind. Specifically, the liver remnant should be of sufficient quantity and quality with adequate inflow, outflow, and biliary drainage to sustain the patient's life in the postoperative period and for the duration of hepatic regeneration. In many instances, little difficulty is associated with assessing tumor resectability on preoperative imaging. This is particularly true for lesions situated in the periphery, at some distance from the major vascular structures, and with no radiologic evidence of additional tumors; however, at operation some patients may be found to have unexpected lymph node involvement or additional liver lesions visualized during laparoscopy or open exploration. This situation often relates to the oncologic appropriateness of resection, which should remain distinct from technical resectability. Given the advances and improved clarity of preoperative images, an unexpected finding at operation occurs in the minority of patients.

Major difficulties with accurate preoperative assessment of resectability can arise in two situations: First, tumors situated near the major hilar structures (see Fig. 90B.7) or those markedly compressing (see Fig. 90B.11) or involving the vena cava can be difficult to assess preoperatively. Involvement of major structures, such as invasion of bile ducts or portal venous branches, or apparent involvement of the IVC does not necessarily preclude resection (see Fig. 90B.1; Soreide et al, 1985). Second, very large tumors, which push structures aside and have been slowly growing over a long time, are difficult to define precisely, because pressure changes may mimic invasion on radiologic images. Thus, considerable caution must be exercised before declaring such cases unresectable. In patients with tumors of this nature, it is often difficult at initial exploration to be certain of resectability, and considerable dissection and mobilization is necessary before a clear-cut decision can be made. The morphologic configuration of tumors on imaging studies has been shown to have a clear relationship to subsequent resectability. Tumors that expand and compress surrounding tissues (*pushing tumors*) and tumors that are pedunculated and attached to the liver by a base of narrow width (*hanging tumors*) are nearly always resectable, and they can be distinguished from tumors that are irregular at the margins and clearly invasive (Baer et al, 1989).

In the early years of hepatic resection, the editor emeritus (Leslie H. Blumgart) adopted and promoted a deliberate policy of full investigation at laparotomy to assess resectability in all patients with solitary large liver tumors, provided no positive evidence of extrahepatic spread was apparent, patients were otherwise fit for major surgery, and the residual liver would be adequate. Of 22 patients with primary liver cancer evaluated in an early study, 13 patients were explored, and resection was carried out in all 13. Only three (23%) of the 13 underwent either a right or left hepatectomy or lesser procedure; the rest were submitted to extensive resections crossing the principal scissura (Cantlie's line) and necessitated extended resection (see Fig. 90B.11). Two of these 13 patients had tumor embolization before surgery to reduce vascularity and tumor size. Eight of these tumors were found to involve the right and left liver on CT scan; involvement of the main portal vein by tumor extension was found in two patients, one patient had involvement of the right branch of the portal vein, and six patients had severe compression or involvement of the IVC (see Fig. 90B.11). Although extrahepatic involvement was suspected in 3 patients, the resections carried out were potentially curative in 12 of the 13 patients with macroscopic clearance of all tumor; but in 1 patient with fibrolamellar hepatocellular carcinoma (HCC), a

deliberate extended resection was performed in the presence of regional lymph node metastases. No intraoperative or in-hospital (30-day) deaths were reported (Soreide et al, 1985). This early experience has been replicated in subsequent studies (Vauthey et al, 1993) and in studies by many other investigators.

The resectability rate within a specialized hepatobiliary surgery unit does not necessarily indicate the overall resectability rate for a particular tumor, because the patient population is highly selected; however, it does seem that an aggressive surgical policy is justified, even in patients with large solitary tumors. In particular, the size of the tumor alone is not a contraindication to resection, although for HCC, large tumor size is associated with earlier recurrence and reduced survival (Pawlik et al, 2005; Nathan et al, 2009). Other authors agree with this view and advocate an aggressive approach to resection (Adson & Weiland, 1981; Balasegaram & Joishy, 1981; Okamoto et al, 1984; Starzl et al, 1982; Steele et al, 1984).

As discussed earlier, radiologic demonstration of apparent involvement of major inflow and outflow vessels does not constitute an absolute contraindication to exploration for resection. Intraoperative techniques are now available to deal with portal vein and IVC involvement. This is particularly applicable to the fibrolamellar variant of HCC (Berman et al, 1980; Craig et al, 1980; Hemming et al, 1997; Nagorney et al, 1985; Soreide et al, 1986), as it tends to be less invasive to surrounding structures and is thus more readily removable. Furthermore, it may have a more favorable prognosis than standard HCC, and its presence should be suspected in patients who have a nonelevated α-fetoprotein with a large tumor in the background of a normal liver; other markers—particularly plasma neurotensin levels (Collier et al, 1984), vitamin B_{12} binding capacity (Paradinas et al, 1982), or both are increased with this tumor.

Some patients with primary HCC present with biliary tract obstruction secondary to tumor emboli within the bile ducts. These emboli may be shown by direct cholangiography, MRI cholangiography, or US. This presentation should not necessarily preclude an attempt at resection (Blumgart, 1978, 1980).

It has been stated that young patients with large, unresectable HCC are suitable candidates for transplantation, and many physicians and surgeons see liver transplantation as the only therapeutic alternative in such cases. This view seemed to be supported earlier by the National Institutes of Health (NIH) Consensus Development Conference Statement on Liver Transplantation (NIH, 1983); however, subsequent experience did not support this broad approach, and controversy emerged regarding the place of liver transplantation for the management of liver tumors. More recently, transplantation has emerged as an effective and viable treatment option in patients with cirrhosis and limited neoplastic disease, with the Milan criteria now firmly established for guiding patient selection (Mazzaferro et al, 1996). This issue is discussed further in Chapter 97D.

Finally, portal venous involvement in cholangiocarcinoma affecting the confluence of the bile ducts does not always preclude resection (Blumgart et al, 1984; Burke et al, 1998). This topic is fully discussed in this chapter and also in Chapter 50.

Preoperative Preparation

Preoperative preparation involves appropriate antibiotic prophylaxis and correction of anemia and coagulopathy. Patients with a significant history of active cardiopulmonary disease should undergo any indicated investigations and optimization prior to undergoing resection. All patients with chronic liver disease or cirrhosis are assessed carefully as to the possibility of present or past infection with hepatitis B or C virus, for a history of alcohol abuse, and for the magnitude of liver dysfunction as assessed by the CTP criteria and preoperative platelet count.

ANESTHETIC CONSIDERATIONS (SEE CHAPTER 22)

Intraoperative venous access should be appropriate to prepare for the possibility of major intraoperative bleeding. Adequate hemodynamic monitoring and facilities for rapid transfusion should be available, and the anesthesia team should be prepared for the possibility of a thoracoabdominal incision. Bleeding during hepatic resection usually occurs during parenchymal transection and arises from the hepatic veins or vena cava, thus we routinely perform a deliberate retrohepatic dissection of the minor and major hepatic veins before beginning parenchymal transection, unless the tumor location and size prohibit this approach and mandate an anterior approach.

To minimize bleeding during parenchymal transection, the anesthesiologist must maintain a low and controlled central venous pressure (CVP) below 5 mm Hg. For patients with relatively good health status, central venous access is not mandatory, as long as large-bore peripheral intravenous access is obtained, and the patient is not given much fluid until parenchymal transection is complete. To prevent air embolism, the dissection can be performed with the patient in a 15-degree Trendelenburg position. Low CVP is maintained at the desired level using a combination of minimal fluid resuscitation and agents that promote venodilation. A minimal intraoperative urine output (20 to 25 mL/h) is tolerated until parenchymal transection is complete (see Chapter 22; Cunningham et al, 1994; Melendez et al, 1998). Once the specimen is removed, hemostasis is achieved, and the patient is resuscitated.

Every effort should be made to avoid perioperative blood transfusion, as allogeneic red blood cell transfusion has been associated with worse perioperative outcome and possibly earlier cancer recurrence and shortened survival, although the latter remains controversial (Amato & Pescatori, 1994, 1998, 2006; Kooby et al, 2003b). The previous dictum of maintaining the hemoglobin at 10 gm/dL or hematocrit at 30% is no longer standard practice (Hebert et al, 1999). Allogeneic blood transfusion should be reserved for excessive blood loss and hemodynamic instability. A technique of acute normovolemic hemodilution, in which the patient's blood is removed intraoperatively and replaced with a combination of crystalloid and colloid fluids, can also reduce the need for allogeneic blood transfusion (Matot et al, 2002; Jarnagin et al, 2008; Maithel & Jarnagin, 2009); the blood that is lost is hemodiluted and contains less red blood cell mass. Once the dissection is complete, the blood removed from the patient earlier is reinfused, which minimizes the need for allogeneic transfusion. The body temperature should be carefully monitored, and normothermia is maintained with warmed fluids and external warming devices.

Should vascular isolation of the liver be necessary, the anesthetic management is slightly altered, because it requires the maintenance of cardiac output during cross clamping of the vena cava. We rarely use vascular isolation of the liver, even during the removal of large tumors close to or involving the hepatic veins and/or the IVC. Even tumors directly involving the vena cava may be removed without vascular isolation.

Nevertheless, some authors (Bismuth et al, 1989; Huguet & Gavelli, 1994; Huguet et al, 1978, 1992a, 1992b) have advocated vascular isolation techniques during hepatic resection, especially for large tumors. Other authors use this method for even limited resections (Kelly et al, 1996), but it is often unnecessary. Techniques for vascular isolation are discussed fully in Chapter 91A.

Postoperative analgesia can be delivered in the form of intravenous or epidural analgesia. The ability to metabolize narcotics after major liver resections may be reduced, thus patients must be monitored carefully for oversedation and respiratory depression. Our preference is to avoid using epidurals for major liver resections because of the potential for hemodynamic compromise, from the reduction in sympathetic tone and the rise in international normalized ratio (INR) that prevents epidural removal, and its association with increased risk of blood transfusion (Page et al, 2008).

OPERATIVE PROCEDURES

Patient Positioning

The patient should be positioned supine with the right arm extended at a right angle to the body. It is unnecessary to place the patient in a lateral decubitus position, as tilting the operating table allows for adequate exposure during operation. Electrocardiogram (ECG) leads should be kept clear of the right chest wall and the presternal area, and draping should expose the lower chest up to the nipple line and the entire upper abdomen to below the umbilicus (Fig. 90B.12). This exposure is adequate for most hepatic resections. If preliminary laparoscopy is to be performed, it is done at this stage.

For large, posteriorly lying tumors, a thoracoabdominal incision may be necessary, but this can usually be avoided with right lateral extension of the incision with good costal margin retraction. The abdomen should be widely exposed from midaxillary line to midaxillary line to allow adequate space for a transverse incision. A cross bar or similar device should be fitted to the table to hold a self-retaining retractor later to elevate the costal margin (see Fig. 90B.12). In patients in whom extracorporeal venovenous bypass is to be performed in conjunction with complete vascular isolation of the liver, or in those whose back-table resection is to be done in association with autotransplantation, or for cases of regional hepatic perfusion (see Chapter 89), the right and left groins, left axilla, and/or left neck should be prepared to allow access to the femoral vein, axillary vein, or internal jugular vein respectively.

FIGURE 90B.12. Position of the patient on the operating table. Note the wide exposure of the abdomen and chest. The cross bar later holds a large retractor, used to elevate the costal margin (see also Fig. 90B.14).

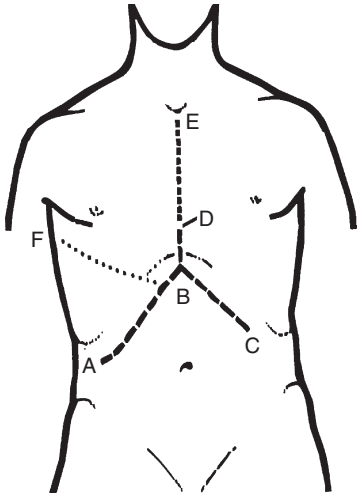

FIGURE 90B.13. Incisions used for partial hepatectomy. *ABC,* Rooftop incision with vertical extension. *DE,* Median sternotomy. *F,* Right thoracic extension. Most often an extended right subcostal incision (*ABD*) is adequate.

Incisions

The incision depends on circumstances (Fig. 90B.13), and the surgeon should not hesitate to extend or enlarge the wound to gain adequate access. For most hepatic resections, the initial incision should be an extended right subcostal incision (*ABD* in Fig. 90B.13) or a bilateral subcostal incision with a vertical extension. A slight variation of this incision that affords excellent exposure for most resections is an upper midline incision from the xiphoid process to approximately 2 to 3 cm above the umbilicus with right lateral extension toward a point midway between the inferior costal margin and anterior superior iliac spine. A limited upper midline incision may be made first to allow preliminary manual and visual exploration to exclude obviously unresectable disease or the presence of extrahepatic spread. In some situations, particularly for left-sided resections in thin patients, a midline incision is adequate. Large tumors of the right side of the liver, especially those lying posteriorly and involving the IVC, may require a right thoracoabdominal approach, but this is rarely necessary. Our experience in more than 2000 cases of liver resection necessitated a thoracoabdominal incision in only 3%. A median sternotomy gives good access, is rapid, and spares disruption of either pleural cavity, but it is also seldom required. If a median sternotomy is used, the diaphragm may be split through the central tendon to allow excellent exposure of the suprahepatic IVC and the major hepatic veins, and the open pericardium can be used to allow direct access to the intrapericardial IVC.

Exposure, Mobilization, and Assessment

When the abdomen is opened, the entire peritoneal cavity should be explored. In particular, the structures occupying the free edge of the lesser omentum, lymph nodes related to the hepatic artery and the celiac axis, and supraduodenal nodes should be assessed. Exploration of the lower abdomen through an upper abdominal incision may be difficult in patients who have had previous pelvic surgery, such as a sigmoid colectomy for primary colorectal cancer. When direct access is limited, palpation in conjunction with preoperative cross-sectional imaging (CT or MRI) and PET scans is sufficient.

Prior to exploration of the liver, the ligamentum teres is divided, and the falciform ligament is incised and separated from the anterior abdominal wall (Fig. 90B.14A). The falciform ligament is divided as far cephalad as the subdiaphragmatic IVC (see Fig. 90B.14, B and C). Vessels running within the falciform ligament are usually controlled with bovie electrocautery. A long suture should be left on the ligamentum teres to act as a retractor during subsequent exploration and dissection for manipulating the liver.

Visual and manual exploration of the liver should follow division of the ligamentum teres and falciform ligament. Elevation of the ligamentum teres helps expose the undersurface of the liver and the area of the hilus and umbilical fissure. Both hands should be utilized to enable bimanual palpation. Unless bimanual palpation is carried out, large lesions located deep within the parenchyma may be missed or underestimated with simple surface examination. The transparent tissue of the lesser omentum should be incised to facilitate manual palpation of the

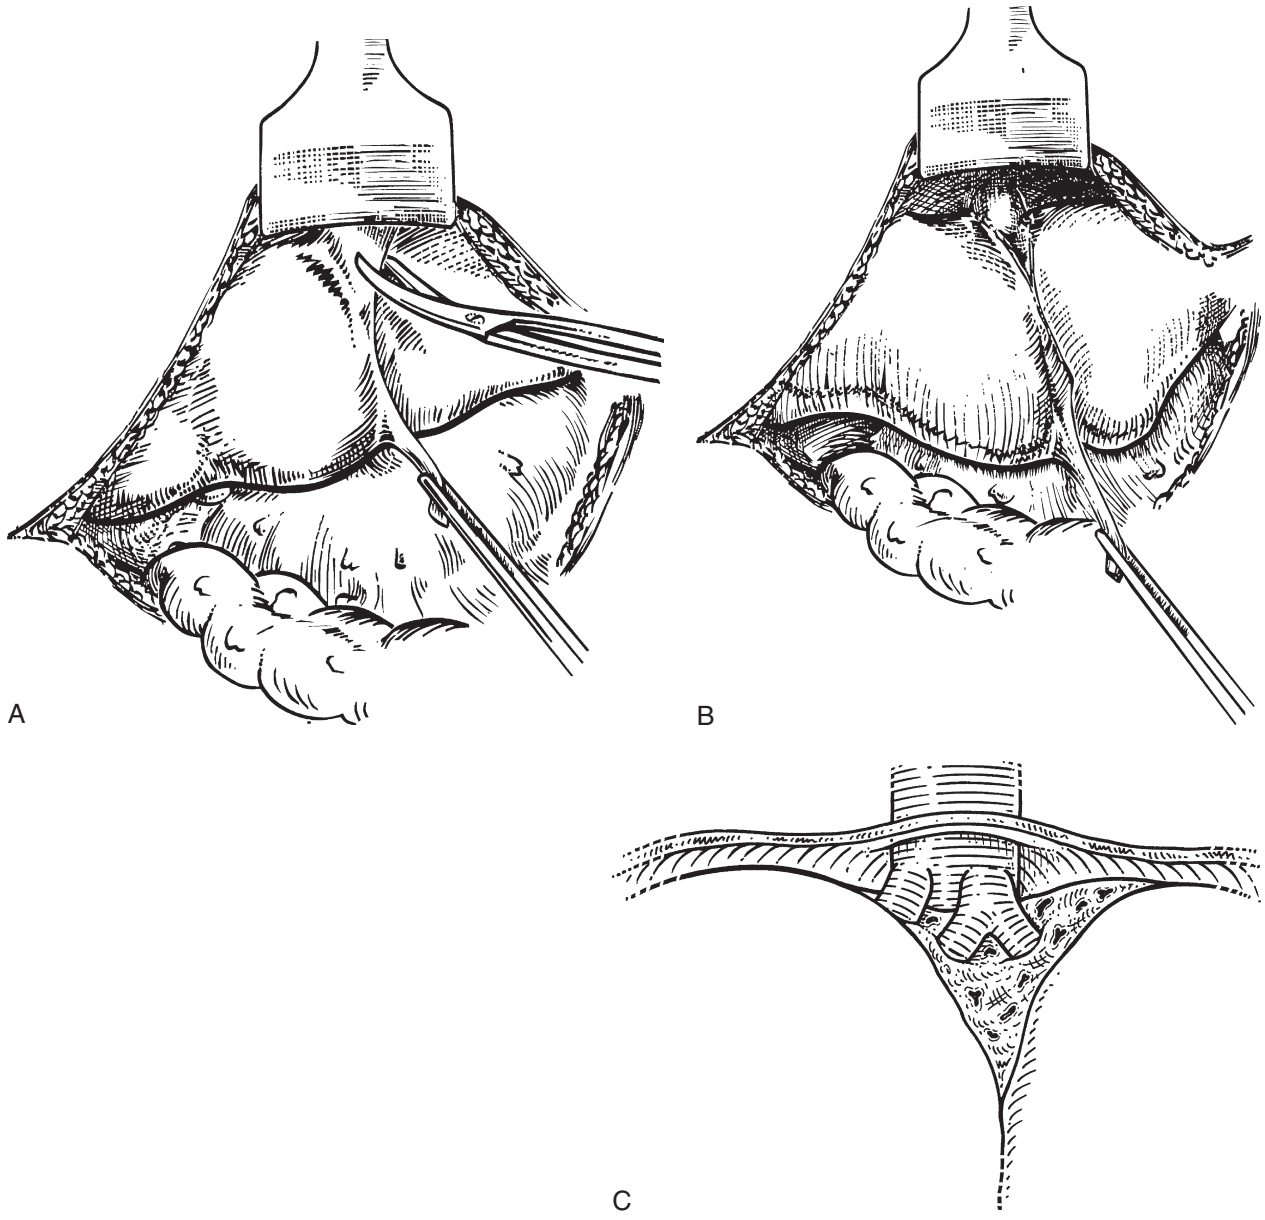

FIGURE 90B.14. **A,** The ligamentum teres is secured, and division of the falciform ligament is begun. **B,** The falciform ligament is divided backward to expose the suprahepatic inferior vena cava (IVC). **C,** Suprahepatic exposure of the major hepatic veins and IVC after division of the upper falciform ligament.

caudate lobe (segment I) and the celiac lymph node basin. If the lesser omentum needs to be further divided to facilitate an adequate evaluation, attention should be directed to the possible presence of an accessory or replaced left hepatic artery. Complete assessment and palpation of the right lobe requires mobilization of the right liver from the diaphragm and retroperitoneum. This maneuver may be delayed until US examination of the liver, in conjunction with initial palpation, indicates that the lesions are resectable.

Mobilization of the right liver begins with complete division of the falciform ligament and identification of the right hepatic vein. As the falciform ligament fibers begin to splay at the back, the surgeon must exercise caution, as the hepatic veins are in close proximity. Early identification of the right hepatic vein prevents subsequent injury during the lateral and posterior mobilization. Once the right vein is visualized, the peritoneal reflection at the edge of the right triangular ligament is incised laterally, and the incision is developed medially between the diaphragm and the liver, until the entire bare area of the liver on the right is exposed (Fig. 90B.15); this allows the liver to be turned to the left. During this dissection, the table is rotated a little to the left, so it is helpful for the surgeon to be standing to the patient's right.

Next, the short retrohepatic veins draining directly from the caudate lobe to the IVC are serially divided, progressing from the inferior aspect toward the hepatic veins. Complete exposure

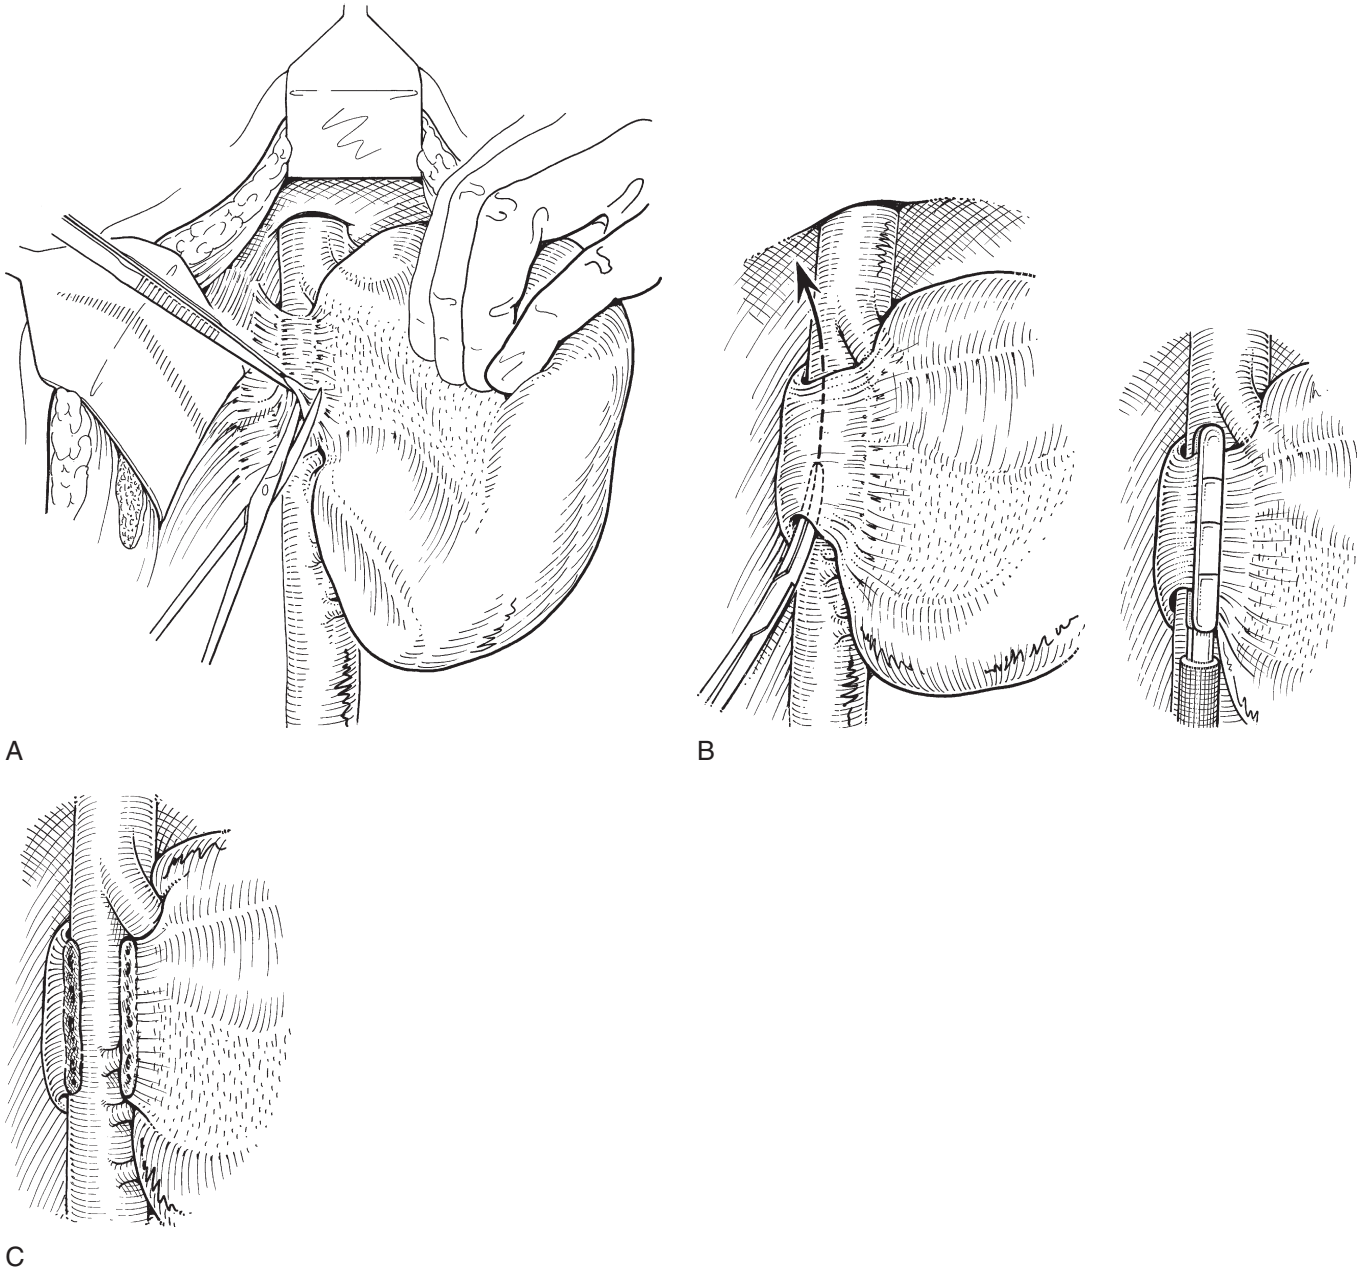

FIGURE 90B.15. A, Incision of the peritoneal reflection of the right triangular ligament allows mobilization of the right liver. The exposure is deepened to display the right lateral margin of the inferior vena cava (IVC). *Note:* If the right hepatic vein is to be exposed, the IVC ligament must be divided with scissors as illustrated. **B,** The ligament also may be mobilized, and a clamp is passed beneath it (*left*). It is divided with the Endo GIA (Covidien) vascular stapler (*right*). **C,** The retrohepatic IVC is fully exposed.

of the IVC and right hepatic vein requires division of the fibrous tissue, the vena caval ligament, which usually obscures the right side or the upper part of the retrohepatic vena cava (see Fig. 90B.15A). This division can be done with scissors (see Fig. 90B.15A), or an endoscopic gastrointestinal anastomosis vascular stapler (Endo GIA; US Surgical, Norwalk, CT) can be used (see Fig. 90B.15B) to expose the vena cava completely (see Fig. 90B.15C). The vena caval ligament also extends behind the vena cava posteriorly, embracing it and joining a similar fibrous extension from the caudate lobe on the left (see Chapter 1B). Rarely, this posterior part of the ligament is replaced by a thin rim of liver tissue, so that at this point, the vena cava runs through a tunnel of liver parenchyma. This can be a source of difficulty, but this thin plate of liver tissue can similarly be divided to expose the IVC completely. The vena caval dissection is particularly facilitated with low CVP anesthesia.

If the tumor is found attached to the diaphragm during mobilization of the right liver, this is usually only across a limited distance, and the affected area of diaphragm is separated, or a segment of the diaphragm is excised and subsequently repaired. An anterior approach with initial transection of the parenchyma without preliminary mobilization of the right liver is necessary and valuable in some cases (Lai et al, 1996b); this will be discussed later.

On the left side, the left lateral sector is mobilized by division of the apex of the left triangular ligament. The table is rotated a little to the right to allow good visualization. Care must be taken not to damage the stomach and spleen at the far left of the triangular ligament, and placing a laparotomy pad under the ligament helps to protect these structures while incising the ligament. The ligament is opened, and between its anterior and posterior leaves, the upper part of the IVC and the left hepatic vein become visible (Fig. 90B.16).

Intraoperative Ultrasound

We use IOUS to complete the assessment of the number and location of tumors along with their exact anatomic relationship with the major vascular and biliary structures within the liver parenchyma. US guidance is also utilized to perform a needle biopsy of small, deeply placed lesions and for ablative procedures, should such be necessary. Transhepatic cannulation of biliary or vascular elements to perform contrast studies (Hasegawa et al, 1991b) is rarely used; a detailed description of the use of IOUS in liver resection is provided in Chapter 21. Essentially, examination is carried out with a B-mode, real-time system. The probes utilized for IOUS are waterproof and sterile; a T-shaped probe or a finger probe is used that enables direct application of the probe to the liver surface, and the moisture of the liver allows good contact. Examination should be carried out in a systematic fashion, starting in the umbilical fissure, progressing to examination of the hilar structures, followed by a careful examination of the hepatic veins and finally of the hepatic parenchyma. In case of doubt, further examination may be done after mobilization of the right or left liver, particularly for posteriorly located tumors. The probe also may be used from the inferior surface of the liver.

The information obtained at IOUS is frequently valuable in assessing the liver and in planning resection. We have found that with modern high-quality preoperative imaging studies, more frequently than not, IOUS plays a confirmatory role in diagnosis rather than revealing features not suspected before laparotomy (Jarnagin et al, 2001b). This is particularly true in the noncirrhotic liver. High-quality laparoscopy and laparoscopic US are now available, and studies at MSKCC show that the findings at IOUS changed the operative plan in only a few patients; however, IOUS can help guide large segmental resections traversing narrow planes between the tumor edge and major vascular structures. Thus it is paramount that the surgeon have the ability to interpret IOUS in order to safely maneuver inside the liver.

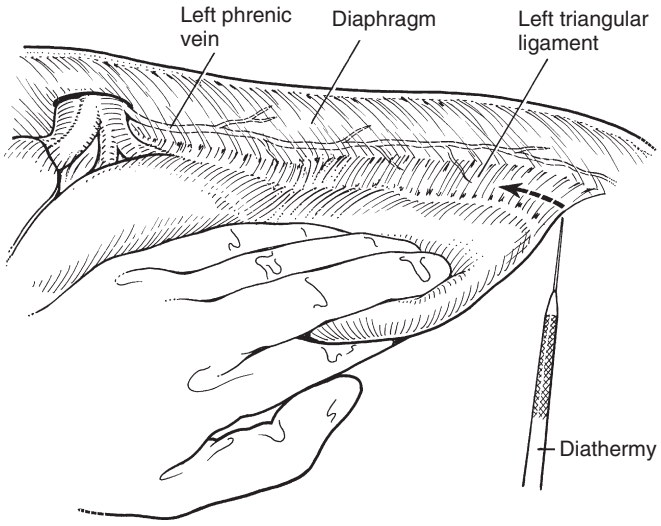

FIGURE 90B.16. The left triangular ligament is exposed and divided with cautery. Care should be taken not to injure the left phrenic vein.

MAJOR ANATOMIC HEPATIC RESECTIONS

All major hepatic resections mandate control of the inflow vasculature to the portion of liver to be resected, with preservation of adequate hepatic arterial and portal venous blood supply to the remnant. This may be done by dissection of the relevant portal pedicle at the hilus and outside the liver substance (Blumgart, 1982). Alternatively, the major branches may be secured within the liver by division of the liver tissue by finger fracture (Foster & Berman, 1977; Ton That Tung & Quang, 1963) or by crushing the liver substance with a Kelly clamp, as described by Ton That Tung (1979). More recently, Launois and Jamieson (1992a, 1992b) have advocated control of the intrahepatic pedicles if oncologically feasible; this is detailed in this chapter. In practice, most surgeons use a combination of techniques in hepatic resection (Fig. 90B.17). Biliary drainage from the remnant must be preserved without biliary leakage and without damage to the biliary tract. The hepatic venous outflow should be controlled after inflow division, and the liver parenchyma must be transected to provide tumor clearance in cases of malignancy.

Inflow Control and Preservation of the Integrity of the Biliary Tree

Control of the hepatic arterial and portal venous blood supply to the portion of liver to be removed can be obtained by extrahepatic dissection or alternatively by transecting the relevant

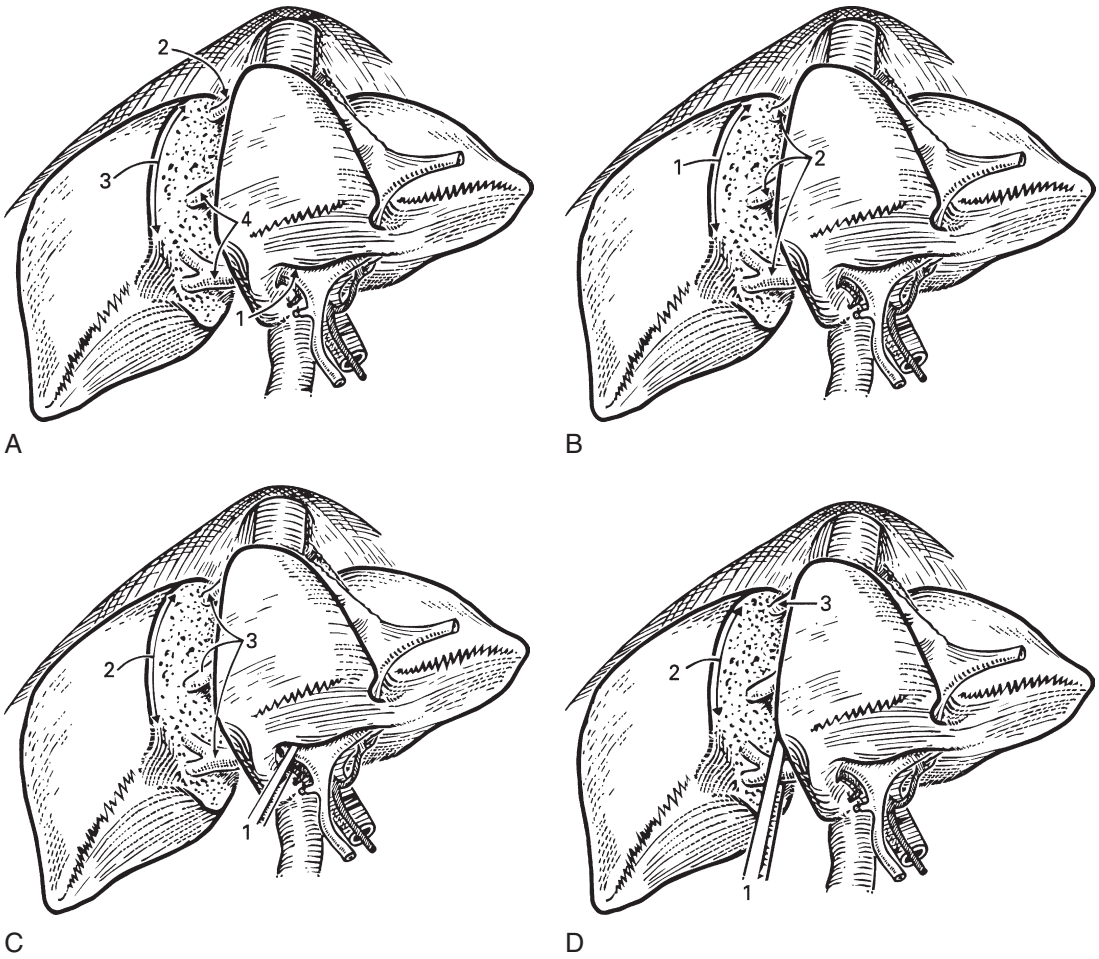

FIGURE 90B.17. Alternative steps in the performance of right hepatectomy. **A,** Initial division of the right portal triad (*1*) and of the right hepatic vein (*2*) and subsequent transection of the liver substance (*3*) with intrahepatic isolation of vessels (*4*). **B,** Initial parenchymal dissection (*1*) with intrahepatic control of the vessels (*2*). **C,** Initial dissection of the portal triad and clamp (*1*) followed by parenchymal transection (*2*) with intrahepatic control of the vessels (*3*). **D,** Intrahepatic control of the portal pedicles (*1*) followed by parenchymal transection (*2*) with subsequent intrahepatic control of the hepatic veins (*3*).

pedicles within the liver substance. Extrahepatic vascular dissection may be accompanied by extrahepatic dissection and control of the relevant biliary radicles, but this is associated with a higher risk of biliary injury, especially during dissection on the right side, where anatomic variations of the major right sectoral ducts at their junction with the main biliary channel are frequent (see Chapter 1). Thus, when performing extrahepatic dissection for vascular control of right-sided lesions, we typically divide the right hepatic artery and the right portal vein but leave the biliary structures for division within the pedicles at the time of parenchymal transection; however, extrahepatic biliary dissection must be performed for tumors that are close to the hilar structures, making an intrahepatic approach to the portal pedicles impossible without compromising tumor clearance. Extrahepatic dissection of the biliary system is, of course, mandatory in cases of hilar cholangiocarcinoma. For left-sided resections, although a pedicle approach is possible, we usually pursue dissection within or at the base of the umbilical fissure and well to the left of the hilar bifurcation. Since the work of Launois and Jamieson (1992b, 1993), we have used pedicular control.

Outflow Control

The major danger in controlling hepatic venous outflow is the risk of hemorrhage. Some authors prefer total vascular isolation techniques to overcome this problem, especially for large tumors abutting or involving the vena cava or major hepatic venous structures (Delva et al, 1989; Emond et al, 1995; Emre et al, 1993; Hannoun et al, 1993), but this is often unnecessary; for example, at MSKCC, total vascular isolation was not used in more than 1800 consecutive liver resections (Jarnagin et al, 2002).

Intrahepatic control of the hepatic veins, carried out during parenchymal transection, is feasible and acceptable for tumors that allow clearance superiorly with adequate tumor margins and with safe intrahepatic access to these vessels. Extrahepatic dissection and control of the major hepatic veins is possible in nearly all cases, and for the difficult tumor lying high and posteriorly, it enables adequate clearance together with reliable control of hemorrhage during right or left hepatectomy. Because the middle hepatic vein usually merges with the left hepatic vein prior to draining to the IVC, the middle and left hepatic veins

HVI, hepatic vascular isolation; LCVP, low central venous pressure

are often controlled as a single unit. If isolated left hepatic vein control is desired, a small hepatotomy is usually needed to dissect the plane between the two veins. Extrahepatic venous control necessitates two essential requisites that are applicable for all hepatic resections: 1) maintainence of CVP below 5 mm Hg (see earlier and in Chapter 22) and 2) precise extrahepatic dissection of the major hepatic veins. Dissection is performed with the patient in a 15-degree Trendelenburg position to minimize the risk of air embolism. Using this technique, no case of clinically significant air embolism has been encountered in 496 resected cases (Melendez et al, 1998). The techniques of vascular control described above are associated with an acceptable blood loss and a blood transfusion rate comparable with any series reported using total vascular isolation (Table 90B.2; Cunningham et al, 1994; Jones et al, 1998; Melendez et al, 1998). Furthermore, it avoids the need for fluid loading and for the use of pressor agents during periods of vascular isolation, and it prevents the adverse biochemical and hemodynamic effects that ensue when the clamps maintaining the vascular isolation are released.

Parenchymal Transection

Many surgeons place excessive importance on the technique of parenchymal transection, when in fact this aspect is not nearly as critical as proper exposure and vascular control, as outlined above. A number of methods may be used to transect the liver parenchyma. Our preference has been to use a simple crushing technique: the Glisson capsule is scored with diathermy along the line of proposed transection, and a Kelly clamp is used to crush the liver tissue and expose small vessels, biliary channels, and larger pedicles; once exposed, these structures can be secured and divided using a variety of techniques. The most simple and economic method is to use clips and suture ligation; however, a variety of devices can be used that include 1) computer-controlled bipolar cautery (LigaSure; Valleylab, Boulder, CO); 2) a saline-linked radiofrequency ablation monopolar device (TissueLink; TissueLink Medical, Dover, NH), or a bipolar variation (Aquamantys, TissueLink Medical); 3) a Harmonic Scalpel (SonoSurg; Olympus Key Med, New York, NY). All of these devices have been used with success by a variety of investigators (Clavien et al, 2004; Sakamoto et al, 2004; Strasberg et al, 2002). They also have been used successfully in the performance of laparoscopic partial hepatectomy, which will be discussed later. Larger structures can be controlled with sutures or vascular staplers (Fong & Blumgart, 1997).

The technique of using a Kelly clamp to crush the tissue is rapid and efficient, although the surgeon may choose to apply intermittent inflow occlusion (Pringle, 1908) to control blood flow to the remnant, usually maintaining inflow occlusion for periods of 15 minutes, interspersed by 5-minute periods of relief to allow perfusion of the remnant and decompression of the bowel. We rarely use prolonged periods of inflow occlusion, although this may done safely (Berney et al, 1998; Hannoun et al, 1993; Huguet et al, 1978, 1992a, 1992b), and we especially avoid prolonged occlusion during hepatic resection in patients with jaundice or cirrhosis. Prolonged portal inflow occlusion is unnecessary, and for major hepatic resections, complete parenchymal transection is usually accomplished in 20 to 30 minutes. During the short breaks between applications of the Pringle maneuver, the argon beam coagulator (Force GCU System; Valleylab) can be used to control small vessel oozing on the side of the remnant. Avitene (Davol, Warwick, RI), Surgicel (Ethicon, Somerville, NJ), or fibrin sealants also may be applied to the cut surface of the liver to achieve final hemostasis after transection is complete.

As a surrogate for the Kelly clamp to expose the intrahepatic vascular and biliary anatomy, an ultrasonic dissector may be used (Hodgson & DelGuercio, 1984) or a water-jet dissector (Baer et al, 1992b). The ultrasonic dissector (Hanna et al, 1996) has become popular and has some advantages in displaying vessels, particularly in the performance of segmental and subsegmental resections, and especially in the cirrhotic liver; but it is tedious and offers no apparent advantage in the performance of major resections. No published data are available to

indicate that the technique is associated with improved control of blood loss. The ultrasonic machine is expensive, and reliance on its use can leave the operator insecure when the instrument is not available. The new version of the water-jet dissector (Helix Hydro-Jet ERBE; USA Inc., Marietta, GA) is much more efficient than the original version, and it may be of considerable value in the exposure of major pedicles.

Some surgeons have described the use of coagulation devices, an example of which is the Habib 4X (AngioDynamics, Latham, NY). It uses radiofrequency energy to coagulate liver parenchyma indiscriminantly along the planned transection plane with or without with the use of vascular staplers; this is the primary mode of hepatic parenchymal transection, but it does not clearly expose the internal structures. We do not advocate such an approach and strongly believe that parenchymal transection should be a controlled dissection to avoid serious damage to the liver remnant.

Drainage of the Abdominal Cavity

Franco and colleagues (1989) suggested early on that hepatic resection should be performed without drainage. After performing a controlled clinical trial (Fong et al, 1996), the authors no longer use drainage routinely after major hepatic resection, unless there is ongoing biliary leakage from the cut liver surface that cannot be controlled with sutures. The placement of drains is associated with a prolonged hospital stay, an increased possibility of infection, and in our experience no decrease in the need for postoperative drainage catheters placed using interventional radiology; however, exceptions do exist, and sometimes a postoperative drain may need to be utilized. In our experience with simultaneous liver and colorectal resections, we have empirically noticed an increased incidence of infected fluid collections in the liver resection bed colonized with colonic flora. Thus for simultaneous resections, we now tend to leave a drain near the liver resection bed. In patients with cirrhosis who undergo resection, placement of a drain must be considered carefully, given the risk of significant ascites formation. Although a drain may protect the incision by preventing an ascitic leak and allowing the fascial closure to heal, the drain may become the source of protracted fluid loss with no clear end point of removal. Finally, we advocate drainage in patients undergoing resection, accompanied by biliary reconstruction. When drainage catheters are utilized, we maintain them on gravity-bag dependent drainage, as the amount of negative pressure generated by closed-suction drains is grossly underestimated (Fig. 90B.18; Grobmyer et al, 2002). For patients who undergo biliary reconstruction, the drain is removed usually within 4 to 5 days provided no bile leakage is evident.

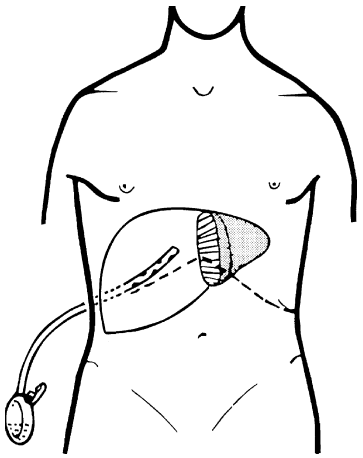

FIGURE 90B.18. Drainage of the right subdiaphragmatic space with simple large-bore drains connected to a closed system or to a suction apparatus. Our preference is abdominal closure without routine drainage.

Right Hepatectomy

Inflow and Biliary Control

The liver is elevated to display its inferior surface and the portal structures. We generally lower the hilar plate to expose the left hepatic duct and the confluence of the bile ducts (see Chapter 1B). Division of the peritoneal reflection along the free edge of the lesser omentum exposes the lateral side of the portal vein and the common bile duct. The peritoneum overlying the common bile duct is incised on the free edge of the lesser omentum and extending up into Calot's triangle, and the cystic duct and the cystic artery are exposed, ligated, and divided (Fig. 90B.19). The gallbladder can also be dissected in the anterograde fundus-down technique to expose the cystic duct and artery (see Chapter 33). The cystic duct is affixed with a suture ligature before being divided, and a tie is left on the cystic duct for later retraction.

Some surgeons now proceed to extrahepatic dissection of the right hepatic duct. We do not advocate this approach unless it is mandated for tumor clearance. Instead, we proceed to dissection of the right hepatic artery and portal vein and usually leave division of the right hepatic duct until later in the operation, during parenchymal transection.

The right hepatic artery is dissected, ligated, and divided (Fig. 90B.20). It originates from the main hepatic arterial trunk and passes posterior to the common bile duct in approximately 80% of patients (see Chapter 1B). It is usually ligated to the right of the common hepatic duct to protect the left hepatic artery from inadvertent ligation or injury and to facilitate access to the underlying portal vein. It is important to be certain that the left hepatic artery is preserved by palpation at the umbilical fissure after temporary occlusion of the right hepatic artery. Although the right hepatic artery can be ligated medial to the bile duct, we prefer to ligate it to the right of the common hepatic duct. We deliberately double-suture–ligate the proximal end and hold this after division for light traction to the left, which together with traction of the cystic duct stump is of considerable benefit in exposing the right portal vein.

The portal vein is approached laterally and posteriorly and is best exposed by dividing its peritoneal covering. The main portal trunk is exposed and dissected superiorly, until the left branch is revealed and preserved. Sometimes, the right anterior and posterior sectoral branches of the portal vein arise individually, and these origins may be separated by 2 cm (see Fig. 90B.20E). It is important not to misidentify these branches during dissection. The right branch of the portal vein may be delivered from the hilus by dividing the surrounding areolar tissue, and a good length amenable for division can usually be obtained. A renal pedicle clamp is passed gently around the right portal vein under direct vision, with special care taken not to damage the first posterior branch of the right portal vein,

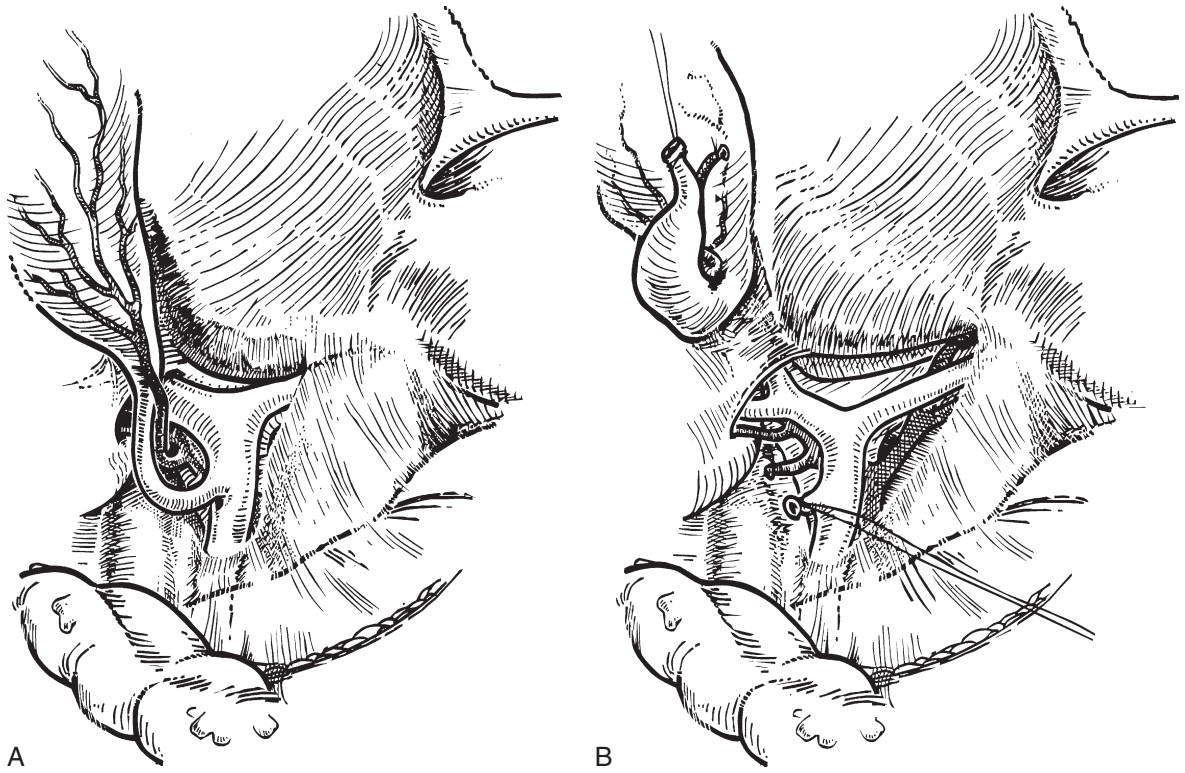

FIGURE 90B.19. A, The peritoneum overlying the common bile duct is incised on the free edge of the lesser omentum and extending up into Calot's triangle, and the common bile duct, common hepatic duct, and Calot's triangle are exposed. **B,** The cystic duct and cystic artery are secured, and a tie is left on the cystic duct for later retraction (see also Fig. 90B.20). The hilar plate is lowered to expose the left hepatic duct and the confluence of the bile ducts, and the right hepatic duct is dissected.

which comes off early and posteroinferiorly to supply the right portion of the caudate lobe. This branch should be deliberately identified to prevent inadvertent avulsion. If any difficulty is encountered in encircling the right portal vein, this branch should be individually ligated and divided before any instrument is passed around the right portal trunk.

Application of a straight-bladed vascular clamp is a safe method of transecting the right portal vein (see Fig. 90B.20). It is good practice to place two retaining prolene sutures to secure the vein before dividing it to prevent retraction. These sutures should be left with the needle in place and are used to oversew the stump after the vein has been divided (see Fig. 90B.20). If the vein is short, it is inadvisable to simply suture ligate the right portal vein and transect it, because the ligatures have a tendency to slip unless secured. The proximal stump should be doubly ligated. Another option to divide the portal vein, used with increasing frequency, is an Endo GIA (Covidien, Mansfield, MA) gastrointestinal anastamosis endovascular stapler (Fong & Blumgart, 1997). If the right anterior and posterior sectoral branches arise independently (see Fig. 90B.20E), they require individual control. If stapler transection of the right portal vein trunk or the anterior and posterior sectoral branches is contemplated, it is imperative to avoid compromise of the flow through the left vein.

If extrahepatic control of the right hepatic duct is necessary, the duct is now dissected. The confluence of the bile ducts and the origin of the extrahepatic course of the left hepatic duct should be seen clearly after lowering the hilar plate (see Fig. 90B.19B). Occasionally, and particularly if segment IV is large, it may help to divide the liver tissue that occupies the lower limits of the umbilical fissure and bridges the gap between the quadrate lobe (segment IV) and segment III of the left liver. This maneuver opens the umbilical fissure and allows better exposure of the subhepatic space.

When the right hepatic duct is dissected, it should be affixed, ligated, and divided (see Fig. 90B.20). Absorbable suture material should be used to prevent permanent suture acting as a nidus for future stone formation or infection. It may be that difficulty is encountered in passing a ligature around the right hepatic duct, in which case it may be divided under direct vision and subsequently oversewn with a 4-0 absorbable suture (e.g., polydioxanone suture [PDS]) on an atraumatic needle. Alternatively, an Endo GIA stapler can be used to divide and ligate the bile duct.

In many instances, the ducts draining the right anterior and posterior sectors are found entering the confluence separately, or the posterior sectoral duct may join the left hepatic duct (see Chapter 1B). In such cases, both of these major sectoral ducts should be individually identified and secured. It may be difficult to obtain a clear view of the right hepatic duct for dissection and ligation, in which case these structures are best left intact and divided intrahepatically. The duct or its major sectoral tributaries may be secured in the pedicles further laterally at the time of parenchymal dissection. We usually use this approach, because it is safe and obviates precise dissection of the ducts extrahepatically. Deliberate dissection of the hepatic duct must be carried out for tumors that approach the hilus of the liver and engulf the pedicles down to the point of entry of the portal triads into the liver substance.

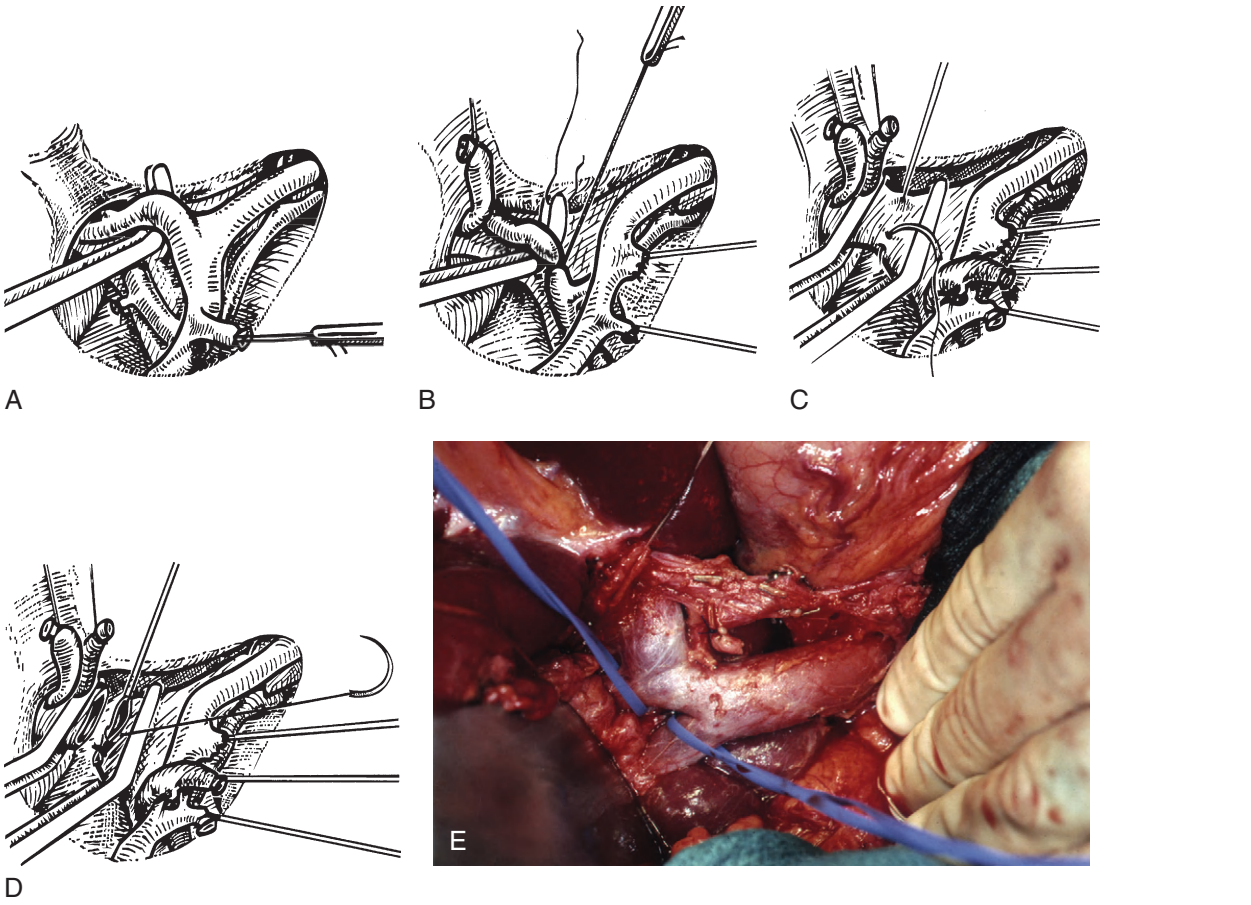

FIGURE 90B.20. **A,** The right hepatic duct is dissected (now, more often than not, we leave the right hepatic duct for intrahepatic control during parenchymal transection). The confluence of the hepatic ducts and the origin of the left hepatic duct are shown. **B,** The right hepatic duct has been affixed with absorbable suture material, divided, and ligated or oversewn. Alternatively, it may simply be divided under direct vision and then oversewn. In any event, the suture is held and retracted toward the left. Traction on the sutures attached to the cystic duct and the right hepatic duct stump allows retraction of the common hepatic duct and common bile duct to the left and assists display of the vessels beneath. The right hepatic artery is dissected, ligated, and divided, usually to the right (*as shown*) but sometimes to the left of the common hepatic duct. **C,** The right portal vein (PV) is dissected, and forceps are gently passed beneath it. Special care is taken not to damage the first branch of the right PV, which comes off early and posteroinferiorly. This branch is sought initially and ligated and divided or avoided. Straight-bladed vascular clamps are applied to the right PV. Note the retaining sutures that secure the vein before division. **D,** The vein is divided, and its proximal stump is oversewn using a vascular suture. The distal stump is affixed with 3-0 polyglactin 910 (Vicryl) suture and ligated. Light traction on the cystic duct, right hepatic duct stump, and right hepatic artery assists display. **E,** Photograph illustrates dissection of the PV and its branches, seen from the patient's right. The main PV gives rise to the anterior and posterior sectoral branches independently; both of these are surrounded by blue vessel loops. The left PV and the anterior right sectoral vein arise at the same point. It is important to recognize this variant anatomy and to identify all branches during dissection.

Pedicle Ligation

An important alternative to extrahepatic dissection of the hilar structures is the pedicle ligation technique that uses the intrahepatic approach first described in Japan by Takasaki and colleagues (1986a, 1986b) and then in the West by Launois (1994) and Launois and Jamieson (1992b, 1993). This approach is most useful for right-sided tumors located peripherally away from the hilus, which allows its use without compromising tumor clearance. This technique allows the surgeon to dissect and clamp the required sheaths early in the operation to better define the segment or segments to be removed.

Essentially, the method relies on intrahepatic definition and control of the portal triads to the segments to be removed. The structures of the portal triad carry the Glisson capsule with them, as they penetrate the liver and are contained in a well-formed sheath within the parenchyma (Fig. 90B.21). The

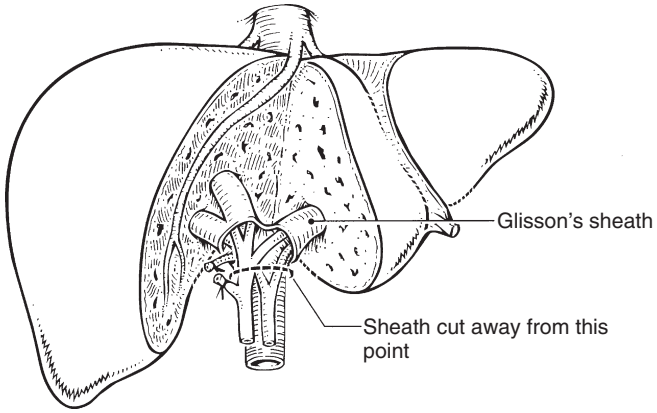

FIGURE 90B.21. Detailed view of the anatomy of the left and right portal pedicles at the hilus.

pedicular sheaths can be exposed after appropriate hepatotomies (Fig. 90B.22) and are tough enough to be encircled (Fig. 90B.23), dissected, and clamped. By eliminating the hilar dissection, pedicle ligation saves time and prevents potential injury to the contralateral vessels and bile ducts.

We have found it important first to ligate the most caudal retrohepatic veins draining from the caudate process and inferior part of the liver to the vena cava (see Fig. 90B.22A). Failure to do this has resulted in hemorrhage during passage of a finger or dissector (Fig. 90B.24) around the right portal pedicle, and this preliminary move is essential prior to using the right pedicle approach. Other than this cautionary note, the technique is almost identical to that described by Launois (described later). Care must be taken to respect the anatomy of the pedicles, in particular the pedicle to the right posterior sector (see Figs. 90B.23 and 90B.24). When the right pedicle has been exposed (see Fig. 90B.22B and E), and a trial of clamping reveals the demarcation line along the principal plane, the pedicle can be divided. A second confirmatory test prior to dividing the pedicle can be rapidly performed with real-time US to demonstrate flow with color Doppler in the left portal vein. We usually use a vascular stapling device to divide the pedicle (see Fig. 90B.22D and F; Fong & Blumgart, 1997). This method also can be used to control the left sheath, but we prefer to dissect the structures within the umbilical fissure, which will be discussed later.

Exposure and Control of the Right Hepatic Vein

The right hepatic vein may be controlled from within the liver during hepatic parenchymal transection, or it may alternatively be isolated and divided extrahepatically before proceeding with division of the liver tissue. Extrahepatic control of the right hepatic vein is important for large tumors lying posteriorly in segments VII and VIII adjacent to the vena cava, because it is difficult to obtain adequate tumor clearance during parenchymal dissection while avoiding potential major hemorrhage arising from accidental laceration to the vein.

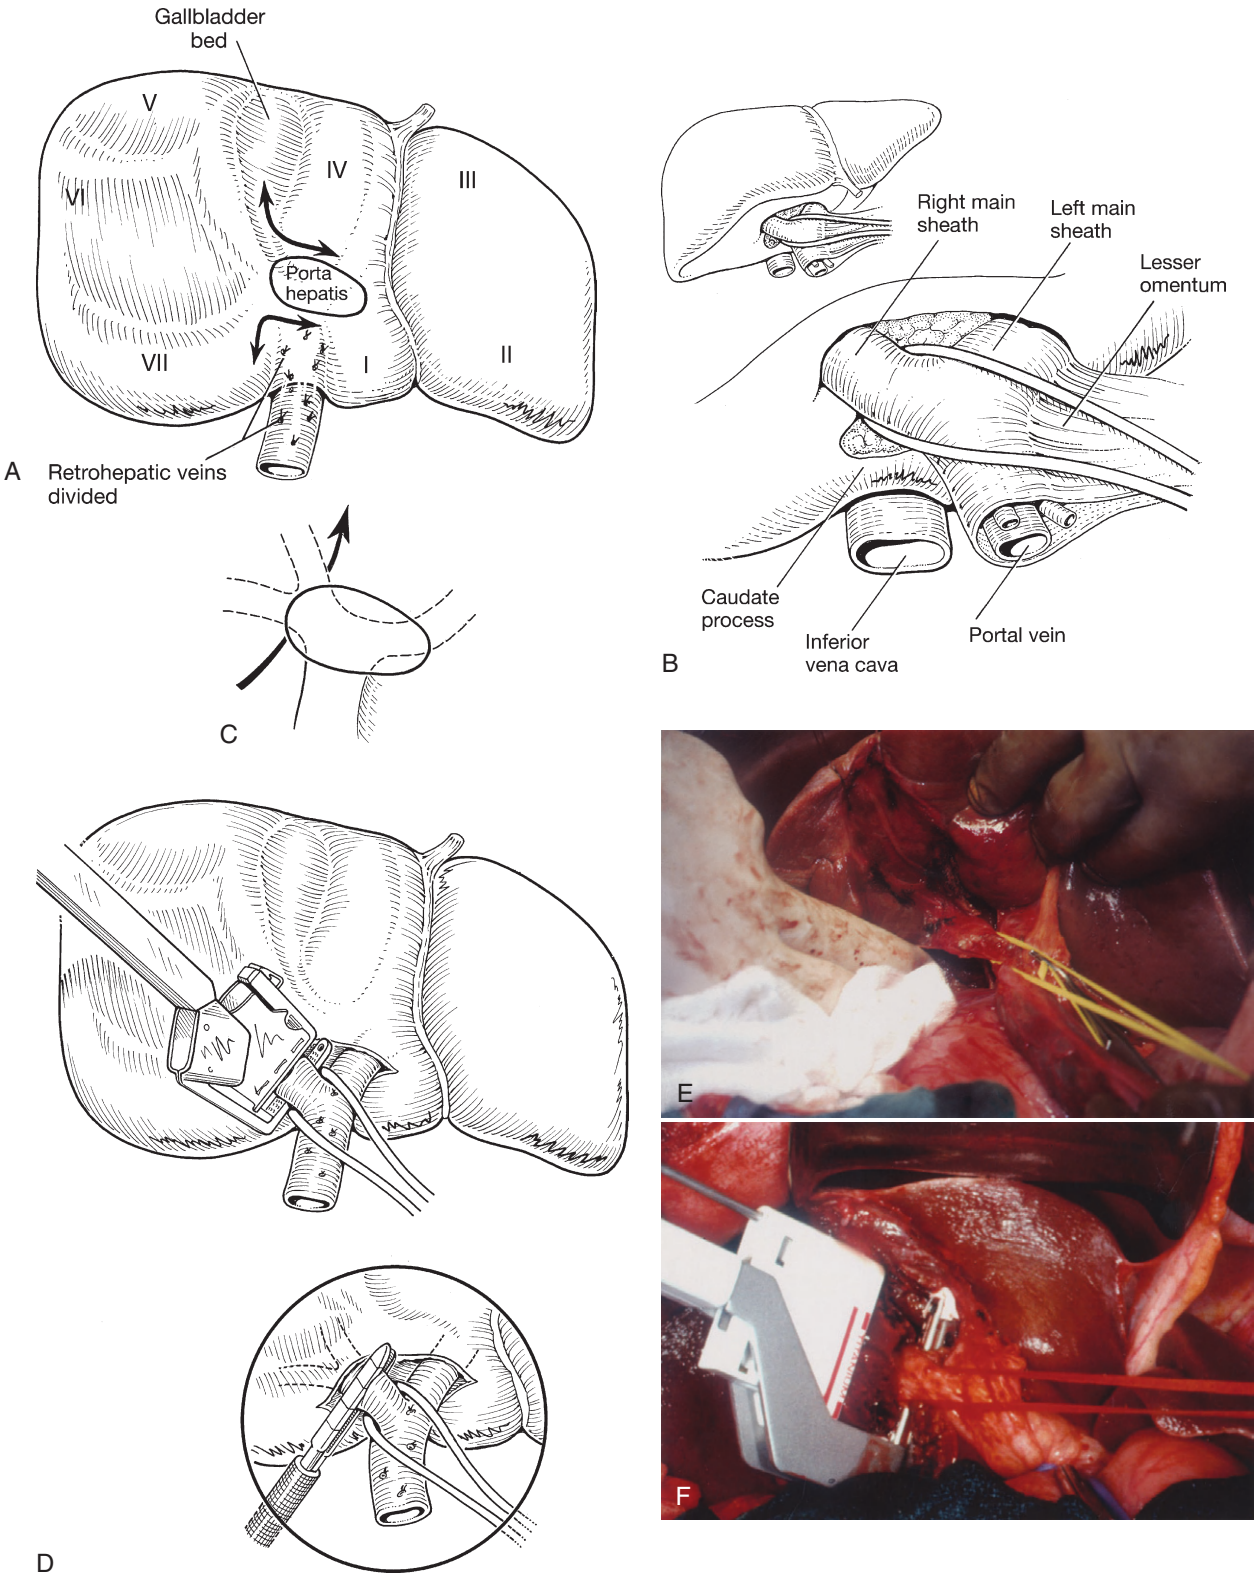
To control the right hepatic vein, the liver is turned to the left, and the retrohepatic veins draining directly into the IVC are ligated. Some surgeons pass umbilical tapes around the vena cava above and below the liver, but this is not mandatory, and we usually omit this step in routine cases. If the surgeon chooses to do so, an umbilical tape can be passed rather easily below the liver, between the inferior surface of the liver and the right renal vein. To control the suprahepatic cava, the left triangular and coronary ligaments must be divided, and subdiaphragmatic dissection of the IVC enables passage of an umbilical tape. If difficulty is encountered in gaining control of the suprahepatic IVC below the diaphragm, as is sometimes the case with large tumors, the surgeon should not hesitate to extend the incision to the right chest or vertically, as a sternotomy. The need for such a maneuver should be anticipated based on preoperative imaging. It is dangerous to persist through an abdominal incision in an attempt to mobilize a rigid right lobe of a liver containing a large tumor, because the right hepatic vein may tear posteriorly. When the chest is open, the vena cava may be approached more easily. Through a median sternotomy, the pericardium can be opened, and the IVC can be controlled within the pericardial sac; however, this incision is usually unnecessary, and in most cases, the IVC and the right hepatic vein can be dissected through an abdominal incision alone. Mobilization and control of the right hepatic vein is often performed prior to inflow occlusion. Then, once the right portal vein and artery are ligated, the right hepatic vein can be divided as well. It is ill advised to divide the right hepatic vein prior to inflow occlusion, as this may result in venous congestion.

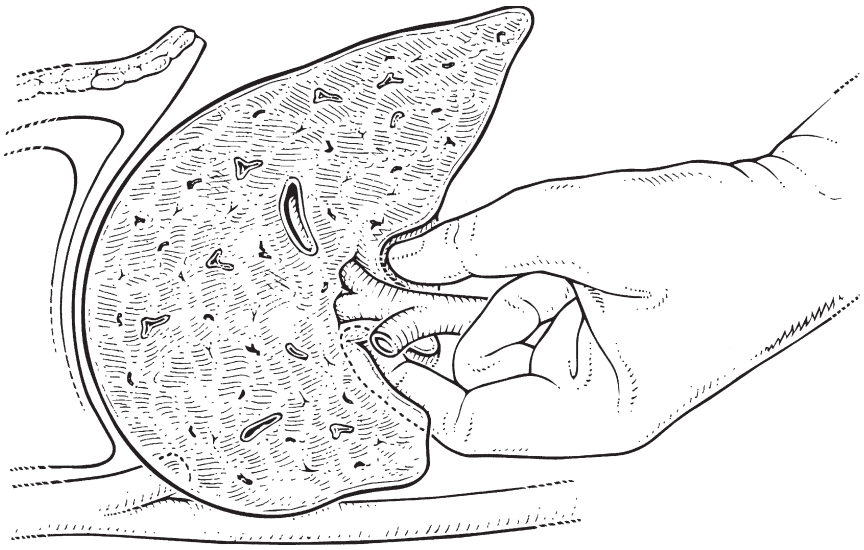
When dissecting the vena cava and the hepatic veins, it is important to maintain the CVP below 5 mm Hg to avoid inadvertent injury and substantial hemorrhage. To prevent air embolism, the patient can be placed in a 15-degree Trendelenburg position (Cunningham et al, 1994). The right hepatic vein is approached starting from the inferior aspect of the liver and working upward from the point where the caudate process crosses the IVC. The retrohepatic veins are sequentially dissected, controlled, and divided. This may be done with fine ligatures passed around the vessels with an aneurysm needle (Fig. 90B.25), but this can be tedious; for smaller vessels, we apply two clips on the vena cava side and one on the liver side of each vessel. These small veins can sometimes also be controlled with a coagulating device, such as a Harmonic Scalpel or the LigaSure device (Valleylab) when appropriate. Larger veins, and especially an inferior right hepatic vein, can be controlled by formal division between clamps or with an Endo GIA vascular stapler.

Complete posterolateral exposure of the right hepatic vein requires division of the IVC ligament, which obscures to a variable extent the right side of the upper part of the retrohepatic vena cava. This dissection may have been done at an earlier stage in the operation, but if not, it should be completed at this stage by the techniques described previously (see Fig. 90B.15). We often divide this caval ligament with an Endo GIA vascular stapler. It is important to perform an extensive retrohepatic dissection and to secure all the short hepatic veins draining from the posterior aspect of the liver; this dissection should be carried well over to the left of the IVC, because this is the only way sufficient access is obtained to visualize and dissect the main right hepatic vein safely.

Before any attempt is made to pass an instrument around the right hepatic vein, full exposure of the vein should be obtained superiorly. This exposure is achieved by dissecting the filamentous fibrous tissue above the liver and anterior to the suprahepatic IVC. This dissection may also have been done as a preliminary procedure during exposure and mobilization of the liver at an early stage (see Fig. 90B.14). In fact, it is advised to have the right hepatic vein in view prior to dividing the lateral attachments to the liver in order to prevent injury to the vein during lateral mobilization. The right phrenic vein emptying into the right hepatic vein provides a nice landmark for its location. This dissection must be performed right against the exposed liver substance, as it is ineffective and dangerous to wander away from the liver surface.

After the right hepatic vein is exposed and encircled, several methods may be used to safely divide it. Traditionally, a vascular clamp is applied on the caval side, usually with space for the application of a second clamp on the caval side and a third on the hepatic side, although this may not always be possible (Fig. 90B.26A). If it is not possible to place a clamp on the hepatic side, division of the vessel does not result in great hemorrhage, provided inflow control has been obtained previously. In any event, the vessel is now divided with a scalpel (see Fig. 90B.26B). One clamp is removed, and the exposed stump is closed with an over-and-over 3-0 polypropylene vascular suture (see Fig. 90B.26C). The proximal (hepatic) side of the right hepatic vein is now closed with a 3-0 polypropylene suture. Alternatively, in well over 1000 cases, we have used the Endo GIA vascular





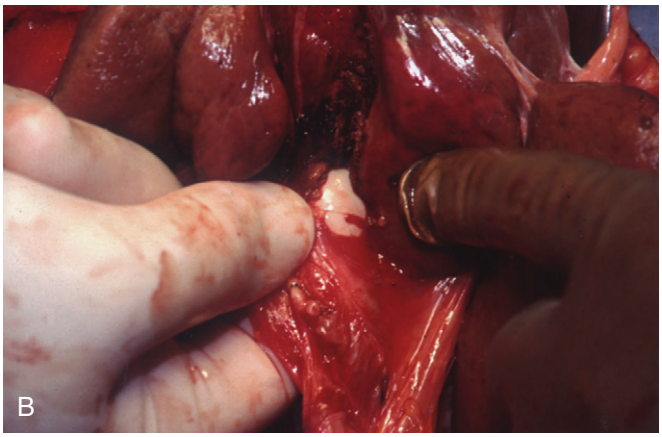


FIGURE 90B.22. **A,** Approach to the right portal pedicle. The liver has been mobilized from the inferior vena cava by division of the retrohepatic veins lying behind the caudate process. Hepatotomies have been made in the region of the gallbladder fossa and the caudate process. The curved double-headed arrows indicate the sites of the hepatotomies above and below the porta hepatis. The approach in the caudate process is essentially a posterior approach. **B,** A vessel loop is drawn about the right pedicle and pulled to the left to protect the left pedicular structures during control and transection of the right main sheath. **C,** The *curved arrow* indicates the path of the finger (see also Fig. 90B.23) or instrument during dissection of the right pedicle, allowing its isolation. **D,** The right portal pedicle is controlled and subsequently divided with a vascular stapler, such as the Endo GIA (*inset*). **E,** Intraoperative photograph shows the right portal pedicle exposed by finger dissection and surrounded by a yellow vessel loop, which is drawn to the patient's left (see also **B** above). The vessel loop is drawn firmly to the left, and the pedicle is divided using the stapler, as shown in **D. F,** Operative photograph shows division of the right portal vein pedicle, which is encircled by a red vessel loop pulled to the left. The vascular stapler is being used to divide the pedicle as illustrated in **D.**

A

B

FIGURE 90B.23. A, Illustration shows digital isolation of the right pedicle. **B,** Photograph illustrates insertion of the index finger through a hepatotomy in the caudate lobe, where it merges with the base of the gallbladder fossa to isolate the right portal pedicle. A vessel loop is drawn about the pedicle as shown in Figure 90B.22F.

stapler to divide the right hepatic vein and have rarely encountered any problems (Fig. 90B.27). The major concern is for misfiring of the stapler, which can result in a tear of the vein; however, this is an extremely uncommon event. The stapled approach is quick, effective, and safe (Fong & Blumgart, 1997), and we now use it routinely, except for large tumors located where the right hepatic vein drains into the IVC; by their size and rigidity, such tumors often limit the entry of the stapler into the tunnel to the left of the right hepatic vein and anterior to the IVC. Extrahepatic control of the middle hepatic vein is unnecessary during right hepatectomy. An important alternative approach to the right hepatic vein involves exposure by

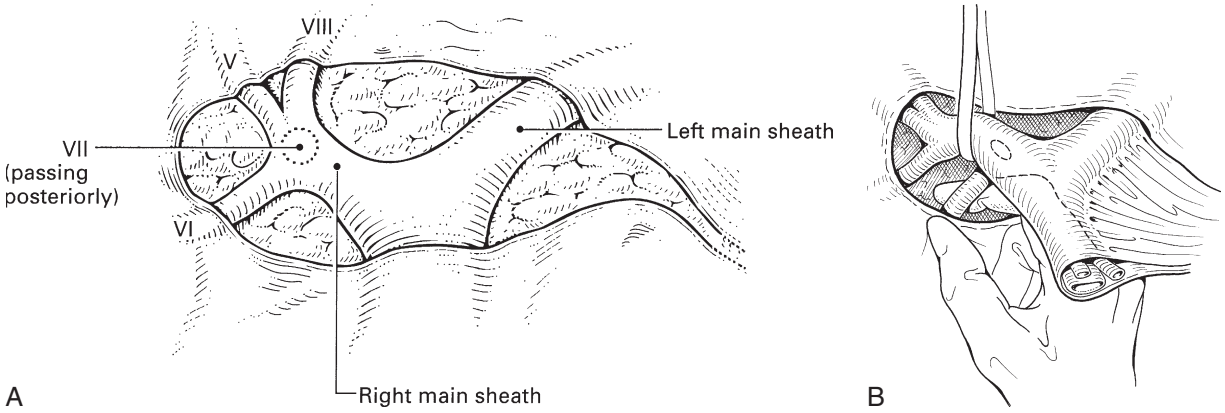

FIGURE 90B.24. A, Anatomy of the pedicles. The anterior sectoral pedicles to segments V and VIII pass upward. The posterior sectoral pedicles to segments VI and VII run posterolaterally. **B,** This illustration shows the approach to the right posterior pedicle (right lateral pedicle).

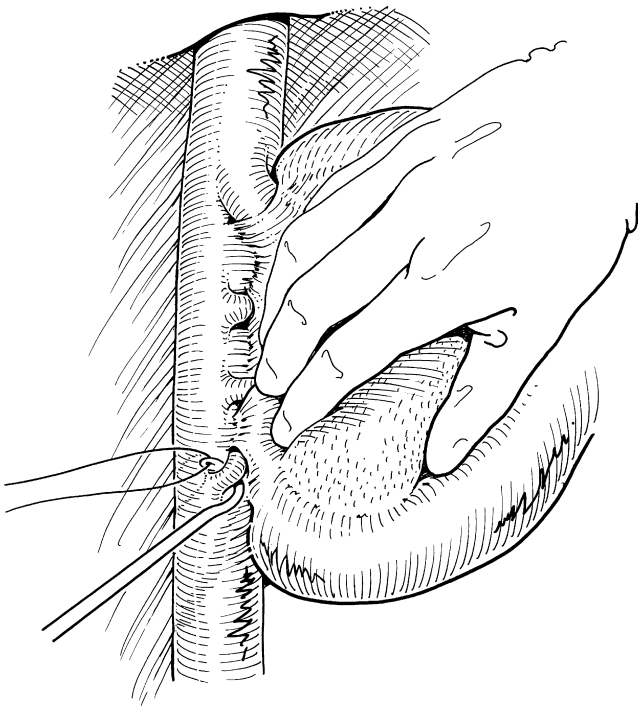

FIGURE 90B.25. Short hepatic veins issuing from the caudate lobe and the right liver are secured individually using aneurysm needles to pass fine sutures about the vessels, which are tied and cut. Alternatively, these vessels are clipped and divided. This procedure is carried upward beneath the liver until the right lobe is mobilized, and the vena cava is displayed up to the right hepatic vein. This is necessary for subsequent safe dissection of the right hepatic vein.

preliminary transection of the parenchyma down to the anterior surface of the IVC (Lai EC et al, 1996b). This so-called anterior approach is described later in this chapter.

Parenchymal Transection

Liver tissue is divided by a tissue-fracture technique, as described earlier. A Pringle maneuver is performed as needed, and the liver tissue is crushed in the line of transection, using a Kelly clamp or similar instrument (Fig. 90B.28) and leaving the vessels intact. During this process, inflow occlusion can be obtained by encircling and compressing the hilar structures in a vessel loop or umbilical tape. It may be helpful for the first assistant to compress the left liver with the hand and to pull it downward gently. Traction can also be applied by placing chromic sutures through the edge of the liver parenchyma on each side of the transection plane. Suction is applied at the blunt end of the sucker, which is used to tease the tissues away from the vessels (see Fig. 90B.28).

Large vessels may be isolated easily by crushing the tissue between the finger and thumb. When visualized, smaller vessels and bile ducts are ligated with metal clips, ties, or a coagulation energy device and divided. Large vessels may be suture ligated or controlled with an Endo GIA vascular stapler. As the tissue is divided, the fissure that is developed in the liver is opened by the operator, whose nondominant hand holds the right liver. With fingers located posteriorly in the region of the vena cava, that hand elevates the right lobe, opening the wound in the liver to expose its depth. As dissection proceeds, the middle hepatic vein is displaced to the left, and the dissection proceeds along its right margin. The branches from segments V and VIII are

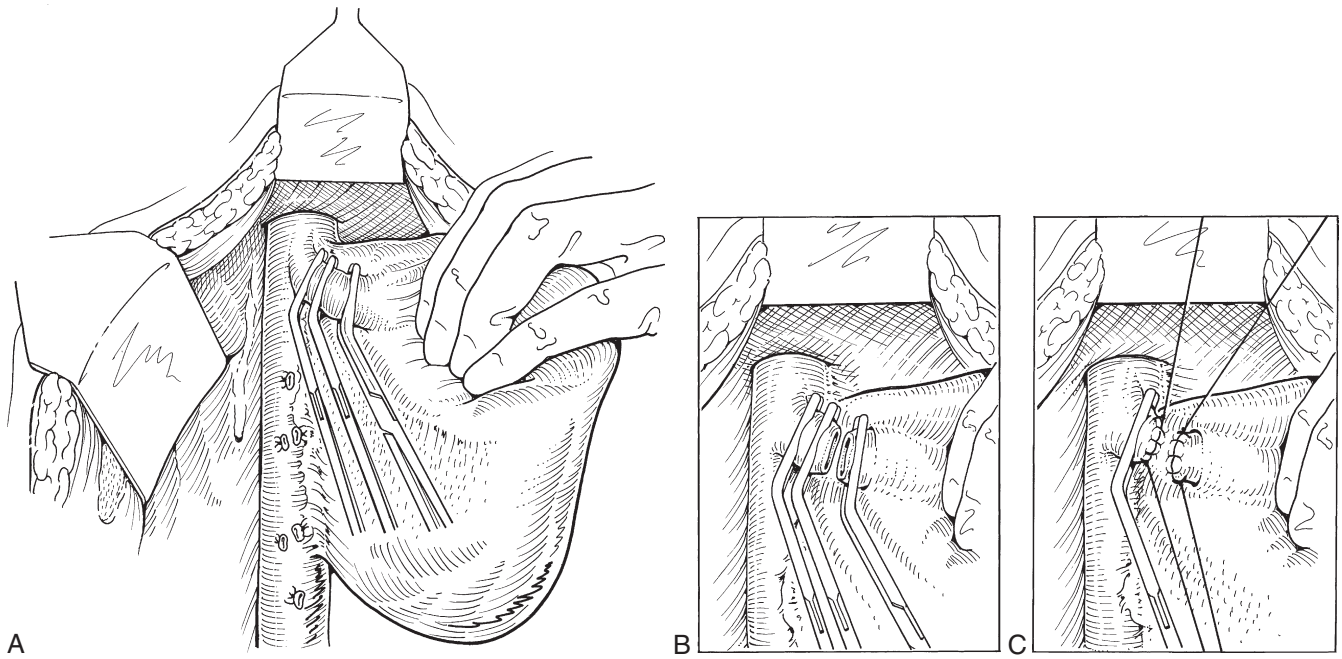

FIGURE 90B.26. A, Approach to the right hepatic vein. The right liver has been extensively mobilized, and the inferior vena cava is exposed up to the right hepatic vein. The right hepatic vein is dissected, and a vascular clamp is applied on the caval side. Another clamp is placed on the hepatic side, although this is not essential, because if the vein is divided after the portal triad at the hilus, bleeding from the exposed venous orifice can be readily controlled with a suture after division of the vein. A second clamp should be applied on the caval side before division of the vein, but if there is no space for this, a second clamp is applied immediately after the vein is divided. **B,** The right hepatic vein has been divided. **C,** The stump is closed with an over-and-over 3-0 vascular suture.

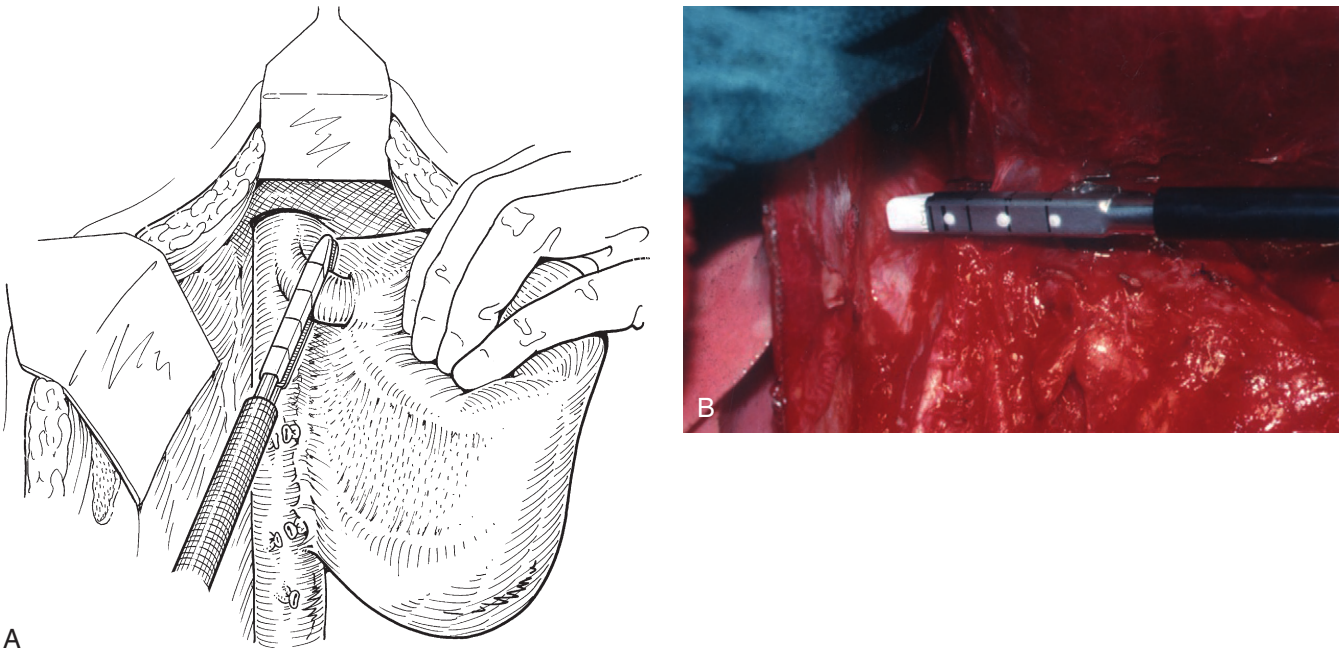

FIGURE 90B.27. A, The right hepatic vein also can be divided using the Endo GIA vascular stapler. This method is rapid and safe. **B,** Intraoperative image shows division of the right hepatic vein with the Endo GIA.

controlled. If the right sectoral bile ducts have not previously been divided extrahepatically, they are now controlled during division of the portal triads, whereupon the right portal triad is encountered and divided close to the hilus. If the right hepatic vein has not been secured behind the liver, it is now isolated and ligated or divided with the stapler within the liver (Fig. 90B.29).

Once the specimen is removed, final hemostasis is obtained by a variety of techniques. Suturing of large vessels is most appropriate; fibrinogen sealants (Guthy, 1986; Scheele, 1989) may be used for small vessels, but the argon beam coagulator is effective and is associated with very little tissue necrosis (Postema et al, 1993). In a few cases, if oozing should continue, and particularly if it seems to be coming from divided veins, the passage of large sutures (chromic catgut or vicryl) anteroposteriorly in a mattress fashion secures hemostasis. These sutures should not be so tight or so numerous as to cause tissue ischemia (Fig. 90B.30). It should be noted that the majority of bleeding at this stage of the operation is low-pressure venous oozing, which can often be controlled with manual pressure and time. Any bleeding from the exposed undersurface of the diaphragm must be carefully controlled; in this respect, the argon beam coagulator can be of great value.

Wound Closure and Drainage

If a diaphragmatic incision has been made, it is closed, and if any defects have been created in the diaphragm, these are similarly sutured. An attempt should be made to remove the pleural air via negative suction applied from the abdomen to obviate

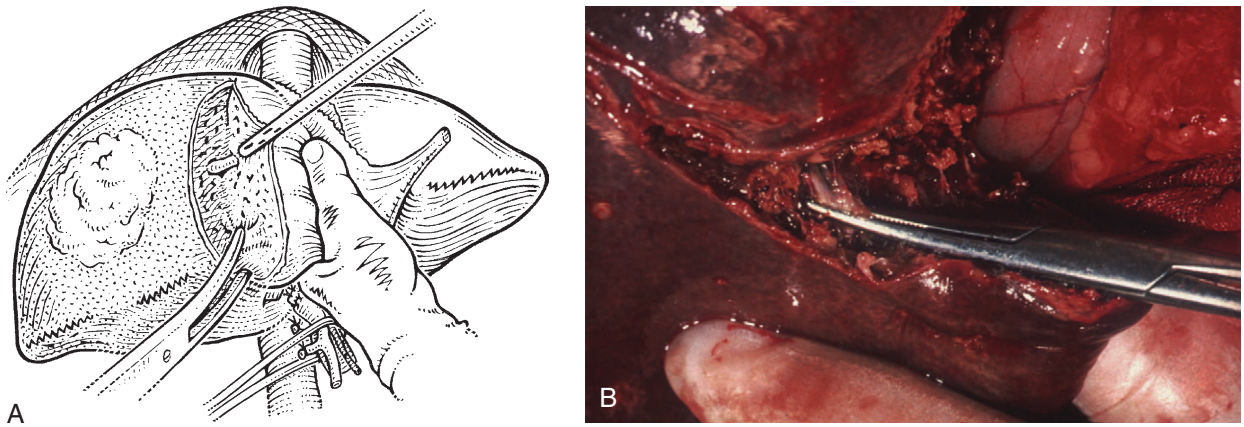

FIGURE 90B.28. A, Parenchymatous transection of liver tissue by a fracture or crushing technique using a clamp. The portal triad to the right liver has been divided, and a line of demarcation has developed. The liver tissue is opened in this line. The assistant's nondominant hand compresses the left liver close to the transection line. The operator opens the liver tissue, and a combination of crushing the liver between clamps, finger fracture, and strong suction exposes the vessels for ligation. The parenchymal transection is done with a vessel loop occluding the hilar vessels (Pringle maneuver). **B,** Intraoperative photograph shows the crushing of the parenchyma with exposure of vessels using a Kelly clamp.

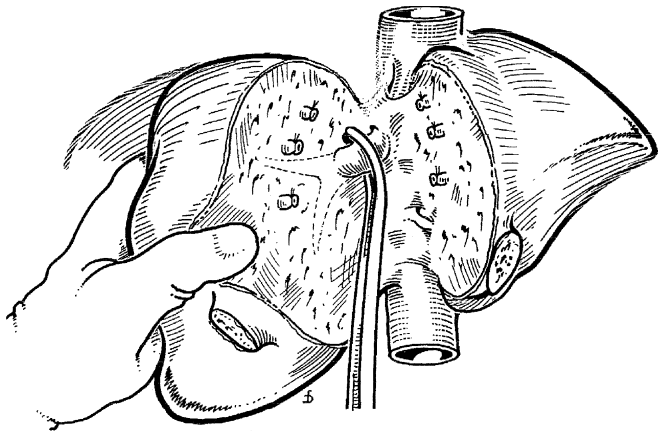

FIGURE 90B.29. Division of the liver tissue has progressed. The fingers of the operator's nondominant hand are located posteriorly, elevating the right lobe and opening the wound in the liver. At this stage, major hepatic veins are identified and secured within the liver substance. This is an alternative to extrahepatic isolation of the right hepatic vein.

the need for a chest tube. There is no need to attempt to close the exposed raw area of the liver with peritoneal flaps, because these could cause compression of liver tissue and distortion of hilar vessels. The ligamentum teres should not be used for this purpose, and similarly, omental grafts are usually unnecessary, although any convenient omentum may be laid against the raw surface. We do not drain the subdiaphragmatic space after routine liver resection, as discussed earlier; however, drainage of the subdiaphragmatic space is carried out with one or two drains if needed (see Fig. 90B.18). A chest drain may be needed in cases of diaphragm resection.

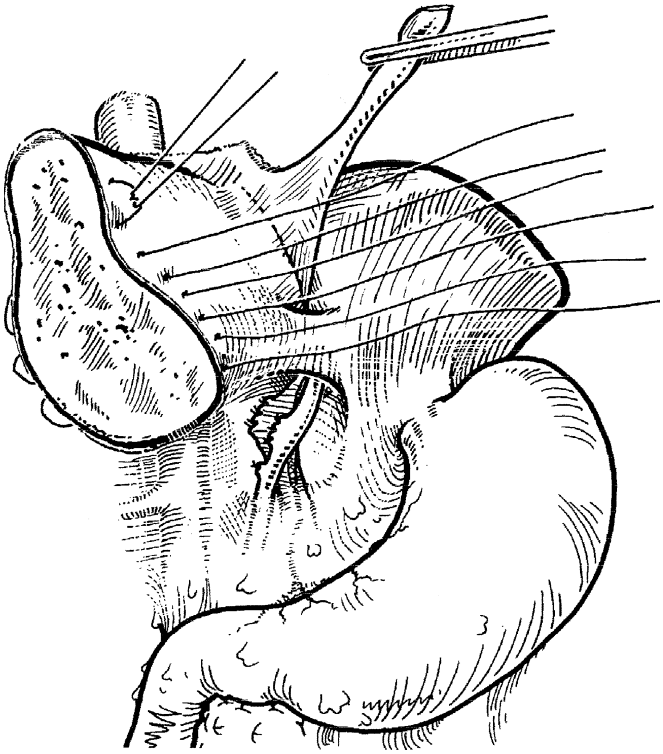

FIGURE 90B.30. Method of suture of the cut surface of the liver to achieve hemostasis. This technique is seldom necessary.

Anterior Approach to Right Hepatectomy

Hanging Maneuver

When performing a right hepatectomy, complete mobilization of the liver before parenchymal transection is considered a basic maneuver for conducting a safe procedure. When a large tumor invades the diaphragm or is attached to the lateral side of the vena cava at a higher level, mobilization may be difficult. In such cases, Lai and colleagues (1996b) reported an anterior approach with initial parenchymal transection from the anterior surface down to the IVC; this will be discussed later. Such an approach may also be useful for resecting large HCCs or adenomas that are soft and may fracture and bleed during the mobilization. Because it may be difficult to control bleeding in the deeper parenchymal plane, Belghiti and colleagues described a new technique of hanging the liver after lifting it with a tape passed between the anterior surface of the IVC and the liver parenchyma (Belghiti et al, 2001; Trotovsek et al, 2005).

The most important step in this maneuver is the definition of the anterior plane of the IVC. Initially, IOUS is performed to confirm the absence of tumor in contact with the anterior surface of the IVC. The upper surface of the liver is exposed up to the anterior surface of the suprahepatic IVC (see Fig. 90B.14). The space between the right and the middle hepatic veins is dissected approximately 2 cm downward; we find it convenient to do this using a right angle or a renal pedicle clamp. The anterior surface of the infraheptic IVC is exposed. The inferior-most veins draining between the caudate process and the vena cava are ligated and divided.

The most important step is the dissection of the plane anterior to the vena cava. A long Kelly clamp is passed gently upward, posterior to the caudate lobe. If a right inferior hepatic vein is present, it is dissected but not ligated, and the clamp is passed to its right side. With great care, the clamp is worked along the middle plane of the IVC, toward the space between the right and middle hepatic veins previously dissected. The tunnel beneath the liver measures about 4 to 6 cm of blind dissection, and the clamp appears between the right and middle hepatic veins. A tape is seized in the clamp and is pulled down behind the liver parenchyma; the tape then can be used to elevate the liver away from the anterior surface of the IVC.

Before parenchymal transection, the right pedicle is divided, devascularizing the right liver. The parenchymal transection is conducted from the anterior surface down to the posterior plane in front of the IVC. During the parenchymal transection, upward traction of the tape helps define the plane of transection and facilitates exposure of the deeper parenchymal plane in front of the IVC. After completing the exposure of the anterior surface of the IVC, the right side of the IVC is dissected with division and ligation of the inferior hepatic veins and IVC ligament. Finally, the trunk of the right hepatic vein is stapled with a vascular stapler or divided between clamps and oversewn. The coronary and right triangular ligaments are transected, and the specimen is removed. This technique can be applied routinely for right hepatectomy and does not necessarily need to be reserved only for large tumors abutting the right hepatic vein and IVC. One of the authors (J.B.) has considerable experience with this technique and has reported an experience of 200 cases performed safely (Ogata et al, 2007).

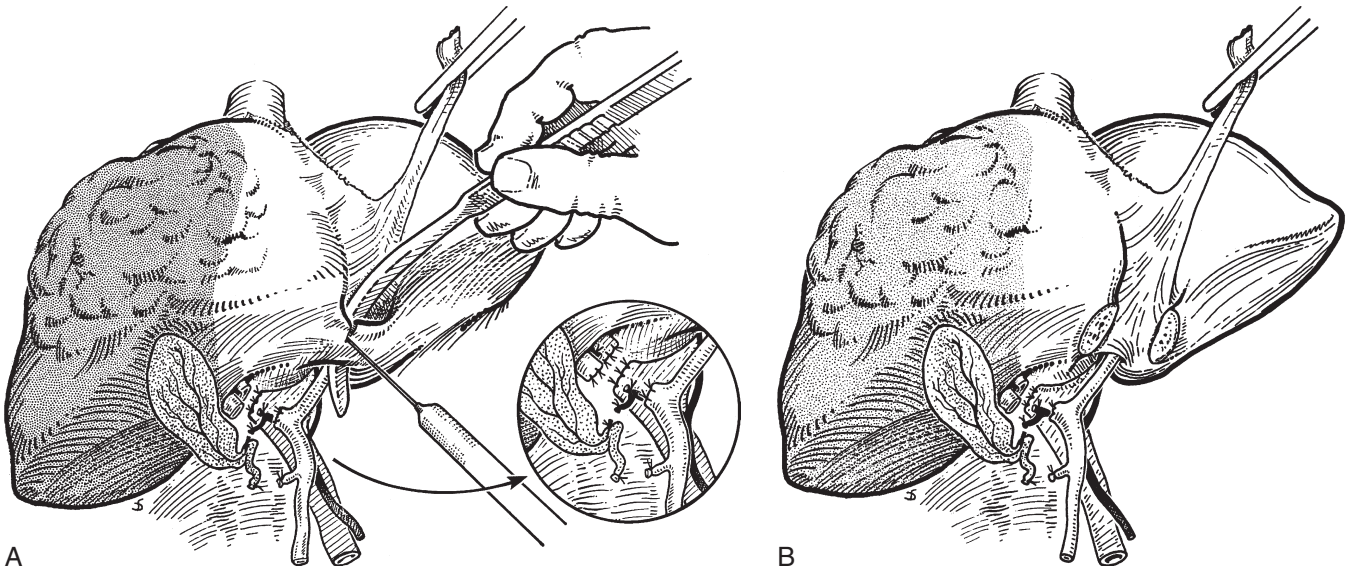

FIGURE 90B.31. A, Exposure of the umbilical fissure and division of the bridge of liver tissue at the base of the fissure. A director usually can be passed beneath the liver tissue, which is divided using diathermy. Note the vessels to the right liver already have been divided (*inset*). **B,** The bridge of liver tissue has been divided.

Anterior Approach

In some patients with very large right-sided hepatic tumors, an alternative is an anterior approach that involves initial parenchymal transection before the right hepatic lobe is mobilized. If this approach is adopted, the hilar inflow vessels are first controlled as described earlier, and the liver parenchyma is transected from the anterior surface of the liver working posteriorly. This parenchymal transection is pursued until the anterior surface of the right hepatic vein and IVC is encountered; the hanging maneuver described earlier can offer useful definition in this approach. Venous tributaries, including the right hepatic vein, are controlled from the front (Lai et al, 1996). The editor emeritus (Leslie H. Blumgart) has used this approach in selected patients and has found it possible even in the presence of diaphragmatic invasion.

Extended Right Hepatectomy

An extended right hepatectomy involves removal of segments IV, V, VI, VII, and VIII; this is in effect a right hepatectomy extended to segment IV. In the nomenclature of Goldsmith and Woodburne (1957), it is referred to as an *extended right hepatic lobectomy.* Starzl and coworkers (1975, 1980) referred to this procedure as a *right trisegmentectomy,* and this term is in common use in the United States.

The initial steps in the procedure are the same as described earlier for right hepatectomy, but the operation involves further dissection and mobilization before parenchymal transection. First, the quadrate lobe, segment IV of the liver, is devascularized; next, the middle hepatic vein must be divided. Occasionally, the caudate lobe (segment I) is removed together with segments IV through VIII as part of the procedure.

After inflow control to segments V, VI, VII, and VIII by extrahepatic dissection or pedicle control, as described for right hepatectomy, the next essential step is to display precisely the umbilical fissure of the liver (Starzl et al, 1975). A strong suture tied to the ligamentum teres is elevated. In many cases, the lower part of the umbilical fissure is concealed by a bridge of liver tissue fusing segment III of the left liver to the quadrate lobe (segment IV) (see Chapter 1B). This tissue is divided easily by passing a curved dissector beneath it (Fig. 90B.31). No large vessels traverse here, and hemostasis is readily secured by diathermy or with the argon beam coagulator.

After opening the umbilical fissure, the ligamentum teres can be visualized, running down to join the termination of the left portal vein within the umbilical fissure (see Fig. 90B.31B). The triad of the left portal vein, left hepatic artery, and left bile duct enters at the base of the umbilical fissure. Their anatomy is shown, with branching of the pedicles to supply segments II, III, and IV (Fig. 90B.32).

It is important for the safe performance of an extended right hepatectomy that the hilar plate be lowered (Fig. 90B.33; see Chapter 29), separating the main left bile duct from the undersurface of segment IV. Whether arising from the common hepatic artery or from the left gastric artery, the left hepatic artery always enters the base of the umbilical fissure and is not endangered during this operation. The middle hepatic artery supplying segment IV is sometimes identified separately, traveling to the right of the left hepatic artery and entering the umbilical fissure at its base and on its right (see Chapter 1B).

Close to the base of the umbilical fissure, a major branch—often two branches—of the left portal vein passes posterolaterally to the caudate lobe (see Fig. 90B.32). Division of these branches interrupts the portal flow to the caudate lobe, but this needs to be carried out only if the caudate lobe is to be removed together with the rest of the specimen. The vital step in the performance of an extended right hepatectomy is the division of inflow vessels that originate from the umbilical fissure of the liver from the left portal triads and feed back from the main left trunk to segments IVa and IVb, the medial sector of the left liver (see Fig. 90B.32). It is not important to attempt to divide these structures within the umbilical fissure, if no tumor is immediately adjacent to the fissure. It is easier and safer to secure them

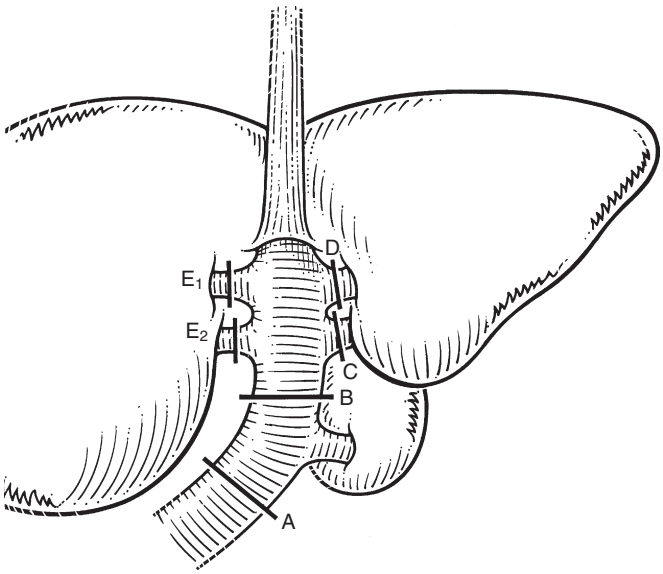

FIGURE 90B.32. Distribution and points of division of pedicles at the base of the left liver. **A,** Pedicle to left liver including segment I. **B,** Pedicle to left liver, sparing segment I. **C,** Pedicle to segment II. **D,** Pedicle to segment III. **E1,** Pedicle to segment IVb. **E2,** Pedicle to segment IVa.

within the liver substance during parenchymal dissection, just to the right of the umbilical fissure, because there is no chance of damage to the blood supply to or biliary drainage from the left lateral sector; however, when a tumor lies close to the umbilical fissure, it is necessary to control the feedback vessels at the right margin of the umbilical fissure. This control can be obtained by passing a suture around these vessels and ligating them in continuity (Fig. 90B.34). Alternatively, the vessels are dissected and individually ligated and divided.

The parenchymal dissection is begun anteriorly and proceeds down to the base of the umbilical fissure (Fig. 90B.35A). When the feedback vessels are divided, segment IV is devascularized. Division of the liver substance is developed toward the vena cava just to the right of the falciform ligament

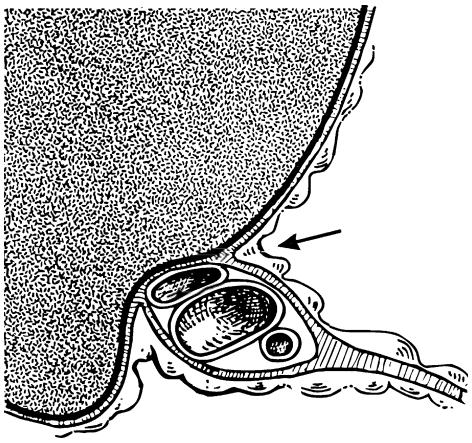

FIGURE 90B.33. Lowering of the hilar plate. The Glisson capsule is incised at the base of the quadrate lobe (segment IV), and the structures of the left portal triad are lowered from beneath the overhanging quadrate to expose the left hepatic duct. This step may be carried out before opening of the umbilical fissure.

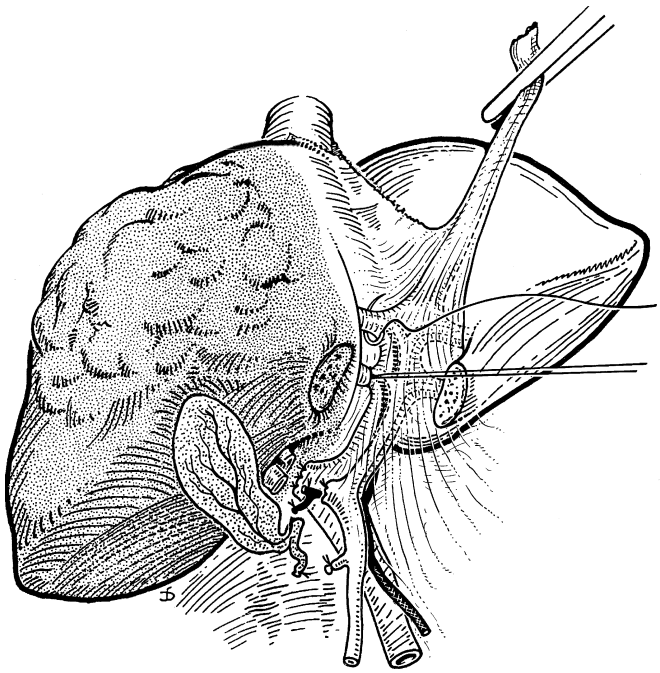

FIGURE 90B.34. Feedback vessels from the left portal triad may be secured in the parenchyma just a little to the right of the falciform ligament (see Fig. 90B.35). This dissection must be within the umbilical fissure in the event of adjacent tumor in segment IV, but this is more safely carried out within the liver tissue just to the right of the falciform ligament (see Fig. 90B.32). Preliminary suture ligation within the umbilical fissure may be performed as illustrated. This procedure deprives segment IV of its blood supply.

(Fig. 90B.35B). The middle hepatic vein is encountered as the dissection is deepened and projected toward the right. When it is identified, it is easily controlled by ligation or division with the Endo GIA stapler. If it is necessary to pursue the middle hepatic vein intrahepatically, toward the vena cava, to obtain tumor clearance, the index finger of the surgeon's nondominant hand can be slid gently along the upper surface of the vein (Fig. 90B.36). Any minor branches avulsed during this maneuver are controlled by finger pressure, and the vein is ligated distal to the finger (see Fig. 90B.36B). Alternatively, the tissue surrounding the vein can be crushed under direct vision, and the small tributaries that are exposed can be ligated. If the right hepatic vein has not previously been divided extrahepatically, it is now approached from within the liver substance, as described earlier, and appropriately controlled.

One particular difficulty may arise when a large tumor occupies segment IV and displaces the left bile duct at the base of that segment and as it traverses into the umbilical fissure (Fig. 90B.37). In such cases, mobilization of the left bile duct in the hilar area and at the base of the umbilical fissure is difficult, perhaps impossible, without deliberate excision of a portion of the left hepatic duct. In such cases, there should be no hesitation in sacrificing any necessary length of the left bile duct to obtain tumor clearance. After removal of the specimen, biliary repair may be carried out by anastomosing the stump of the left hepatic duct to the upper end of the common hepatic duct. Alternatively, biliary-enteric continuity may be restored by creation of a Roux-en-Y hepaticojejunostomy to the left bile duct, which is the preferred method (Fig. 90B.38).

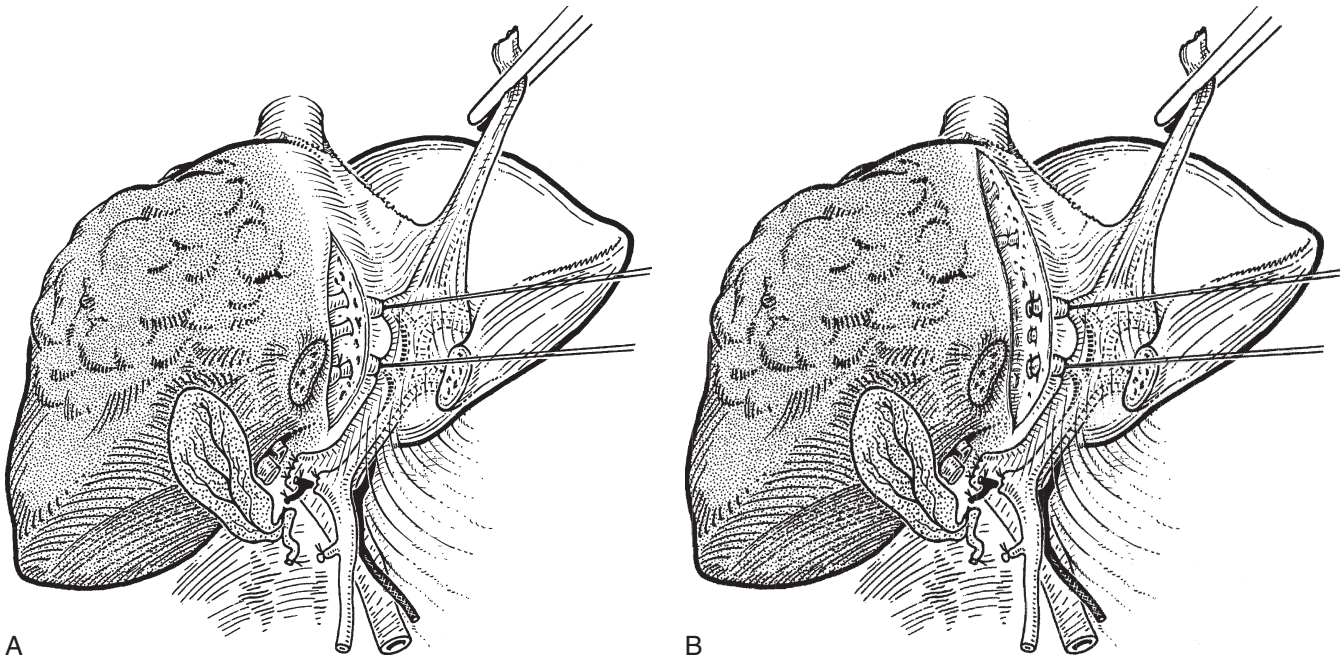

FIGURE 90B.35. A, Feedback vessels are secured within the parenchyma. **B,** Division of the liver substance is developed backward toward the vena cava just to the right of the falciform ligament.

Left Hepatectomy

Left hepatectomy can be a difficult procedure, particularly in the presence of a large, posteriorly situated tumor close to the junction of the middle and left hepatic veins with the vena cava.

Inflow Control

Inflow control to the left liver is obtained by dissection at the base of the umbilical fissure. The ligamentum teres is elevated, and the hilar plate is lowered as described earlier (see Fig. 90B.33). The left hepatic artery is easily identified by opening the peritoneum covering the left portion of the immediate subhilar area at the base of the umbilical fissure. It is double ligated and divided. The gastrohepatic ligament is inspected, and any accessory or replaced hepatic artery arising from the left gastric artery is similarly ligated.

Dissection at the base of the umbilical fissure exposes the left portal vein, as it traverses into the umbilical fissure; it should be controlled at this point and not at its origin from the main portal venous trunk. This dissection allows identification of the branches to the caudate lobe, which arise just before the left portal vein enters the umbilical fissure. If the caudate lobe is to

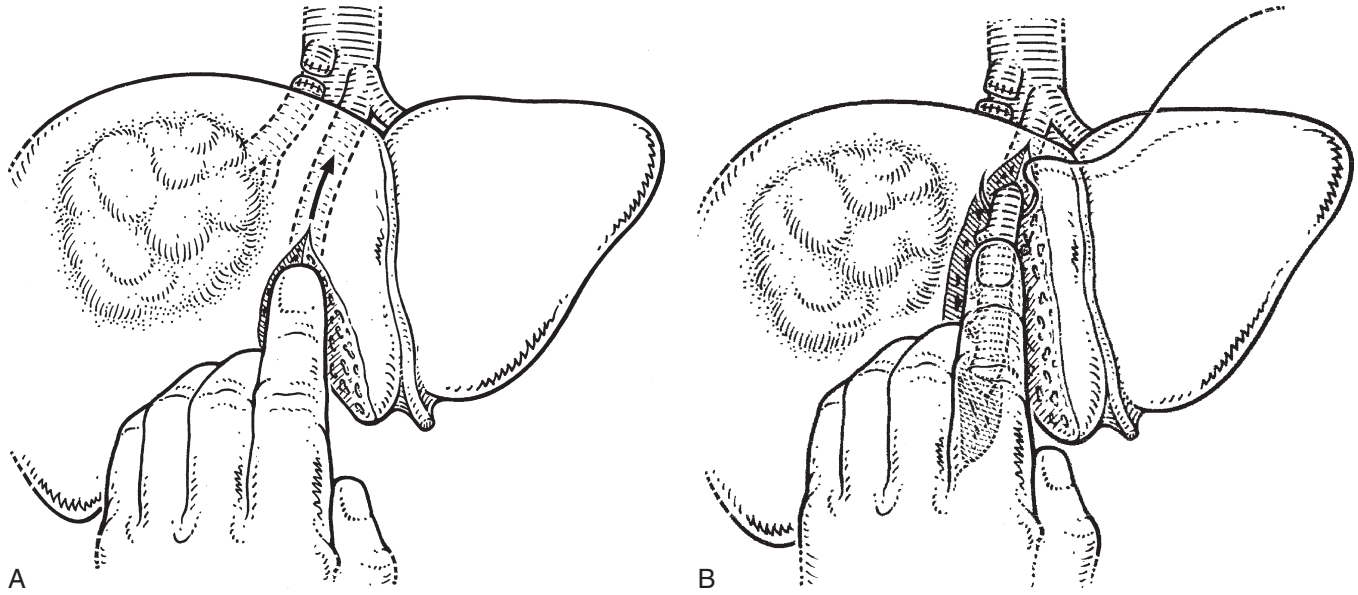

FIGURE 90B.36. A, The middle hepatic vein is exposed, and the index finger slid up its anterior surface shows its length. **B,** The middle hepatic vein is suture ligated.

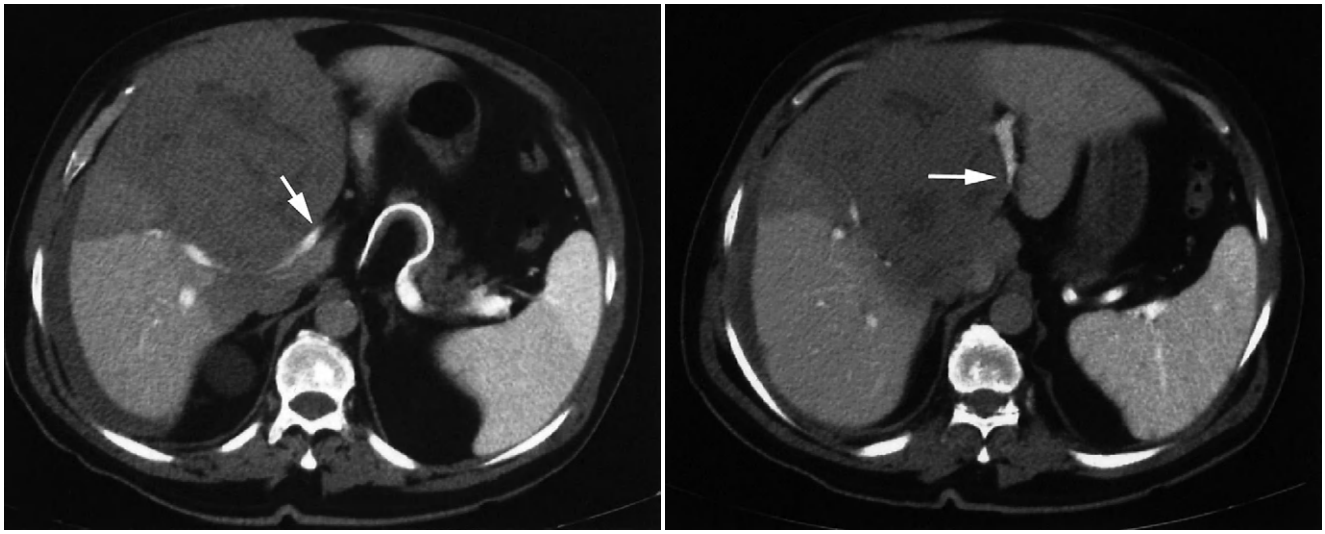

FIGURE 90B.37. Large metastatic carcinoma within segment IV threatens the integrity of the left hepatic duct (*arrows*). At operation, right lobectomy was performed, and a length of the left hepatic duct was excised and repaired as illustrated in Figure 90B.38.

be removed together with the left lobe, the vein is secured below the takeoff of the caudate branches (see Fig. 90B.32A). If the caudate lobe is to be preserved, which is usually the case, the vein is divided distal to the takeoff of the caudate branches (see Fig. 90B.32B). The left hepatic bile duct is easily identified just above the left portal vein, and it can be encircled with a suture and divided as it curves into the umbilical fissure; these steps are illustrated in Fig. 90B.39. A line of demarcation in the Glissonian plane, extending from the gallbladder fossa to the left of the vena cava, is now clearly visible on the liver surface (Fig. 90B.40) and is marked with a diathermy.

Outflow Control

The left lateral sector of the liver, segments II and III, is now mobilized from the diaphragm by division of the left triangular ligament from its tip up to the lateral margin of the suprahepatic IVC, taking care to avoid injury to the underlying spleen and stomach. As the dissection approaches medially, the surgeon must be careful not to injure the left hepatic vein. The upper surfaces of the left and middle hepatic veins and of the suprahepatic IVC are displayed (Fig. 90B.41; Czerniak et al, 1993). The main trunk of the middle hepatic vein usually joins the left

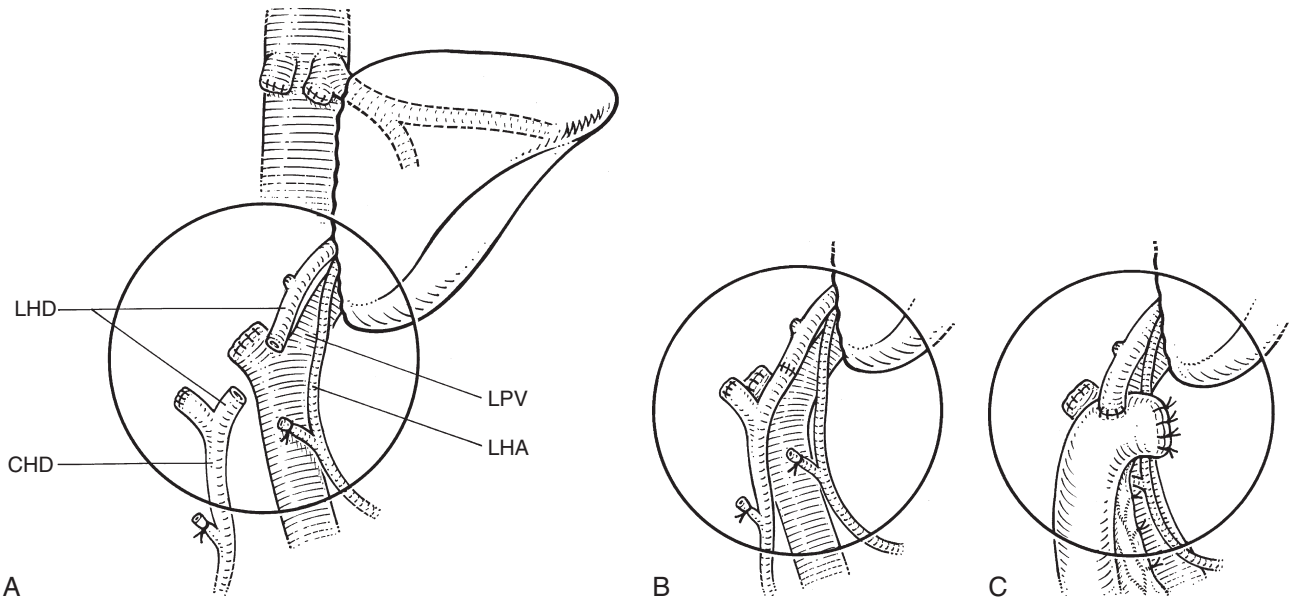

FIGURE 90B.38. The left hepatic duct may be compromised during right lobectomy for tumor extending into the base of segment IV and pushing into the umbilical fissure (see Fig. 90B.37). **A,** After resection with excision of a portion of the left hepatic duct (*LHD*). **B,** Repair of the duct by direct end-to-end anastomosis. **C,** Repair by hepaticojejunostomy Roux-en-Y. CHD, common hepatic duct; LHA, left hepatic artery; LPV, left portal vein.

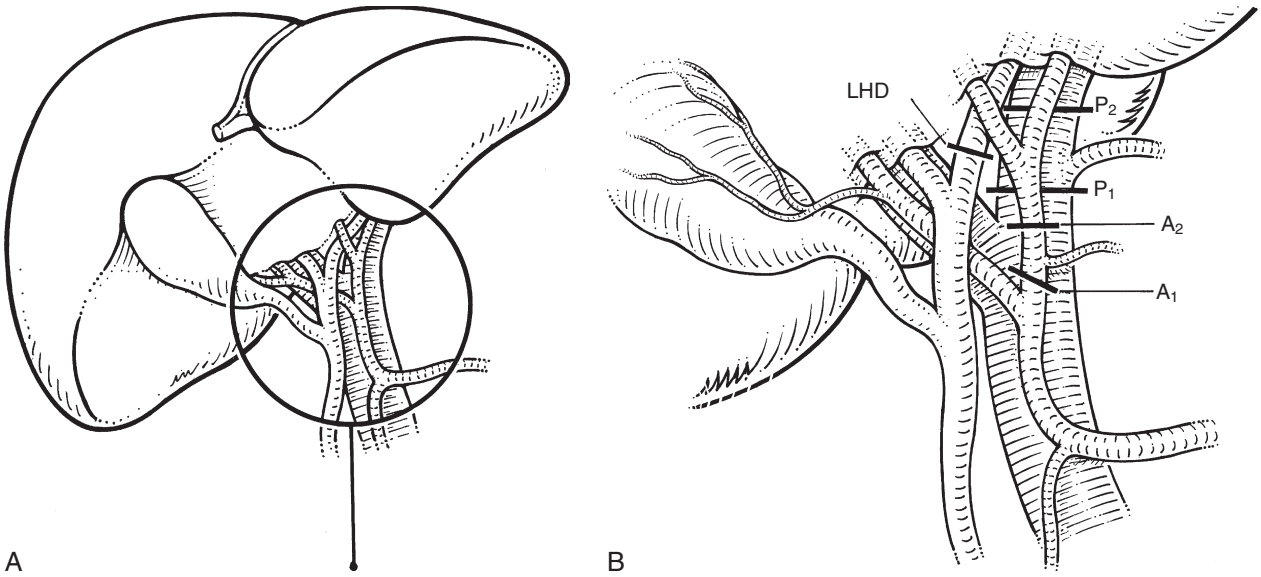

FIGURE 90B.39. A, Dissection for left hepatectomy at the base of the umbilical fissure. **B,** Left hepatic duct (*LHD*) is divided at the base of the umbilical fissure. A_1, point of division of left hepatic artery (LHA) for concomitant removal of caudate lobe; A_2, point of division of LHA for left hepatectomy; P_1, point of division of left portal vein (LPV) for left hepatectomy and caudate lobectomy; P_2, point of division of LPV for left hepatectomy alone.

hepatic vein but may enter the vena cava separately. In essence, the veins are cleared below the diaphragm, and their junction with the vena cava is displayed. The left lateral sector of the liver is turned to the right (see Fig. 90B.41), the gastrohepatic ligament is fully divided, and the ligamentum venosum is identified. We divide the ligamentum venosum close to its entry into the left hepatic vein. This division opens up a triangular tunnel, the sides of which are the left hepatic vein anteriorly, the anterior surface of the vena cava posteriorly, and the upper surface of segment II inferiorly. This tunnel is developed carefully, and an instrument is passed beneath the left and middle hepatic veins to emerge anterior to the vena cava, between the middle hepatic vein and the right hepatic vein (see Fig. 90B.41B), and the common trunk is controlled.

If the middle hepatic vein requires resection to obtain adequate tumor clearance, the common trunk can be divided at this time. It can be secured between vascular clamps, divided, and oversewn with a 3-0 polyproprylene suture. Alternatively, the Endo GIA vascular stapler may be used to divide the veins, which is our preferred method (Fig. 90B.42). If the middle hepatic vein can be preserved, the common trunk should not be divided. A small hepatotomy can be made in between the middle and left hepatic veins, which usually allows individual extrahepatic control of the left hepatic vein. Alternatively, the left hepatic vein can be divided intrahepatically during parenchymal dissection, if the tumor is located remotely. Controlling the major hepatic veins draining to the left liver is crucial in minimizing hemorrhage during the removal of large, left-sided tumors.

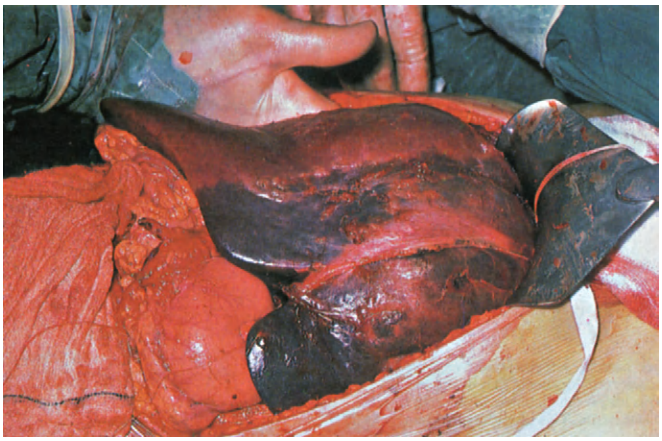

FIGURE 90B.40. The left liver has been devascularized before parenchymal transection for left hepatectomy.

Parenchymal Transection

A vessel loop or umbilical tape is now passed around the hilar structures to enable intermittent occlusion (Pringle maneuver) should it be necessary. The line of parenchymal transection follows the principal plane and can be either to the right or left of the middle hepatic vein, depending on what is necessary for tumor clearance. It is important that transection be carried out so that the parenchyma is divided posteriorly just anterior to the ligamentum venosum, separating the left liver from the anterior surface of the caudate lobe.

Extended Left Hepatectomy

In some instances, a large tumor occupying the left half of the liver encroaches across the principal scissura (Cantlie's line) into segments V and VIII, the anterior sector of the right liver (see Figs. 90B.1 and 90B.4). In other cases, multiple tumors occupy portions of the left liver and segments V and VIII. In such cases, left hepatectomy can be performed with extension of the procedure to also remove segments V and VIII.

The procedure is extensive, and although Couinaud (1957) described the anatomic basis for extension of a left hepatectomy to include removal of the anterior sector of the right liver, there

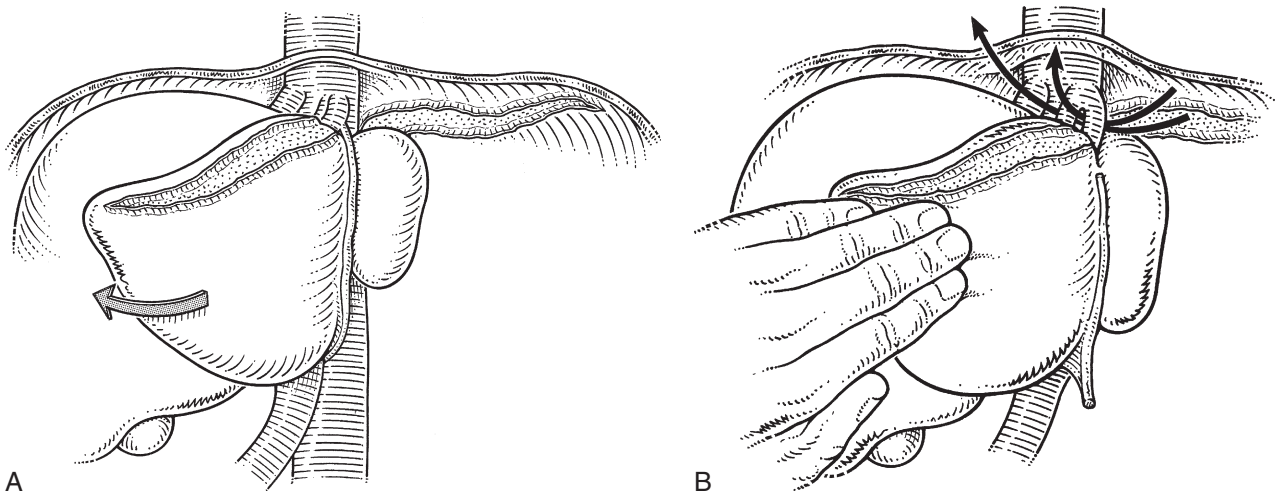

FIGURE 90B.41. Approach and dissection of the left and middle hepatic veins, applicable to left hepatectomy and extended left hepatectomy. **A,** The left lobe of the liver (segments II and III) is completely mobilized from the diaphragm and turned to the right. The gastrohepatic ligament is divided, and the line of the ligamentum venosum is exposed. **B,** The ligamentum venosum is divided. This maneuver allows the exposure of the window between the vena cava and the left hepatic vein. By dissection in this space, it is possible to dissect free the left and middle hepatic veins separately or together (*black curved arrows*). The left and middle hepatic veins are clamped, divided, and oversewn or divided with the Endo GIA vascular stapler.

were few reported series of successful operations. Joishy and Balasegaram (1980) reported extended left hepatectomy done in eight patients. The nature of these operations is described as indicating a line of transection to the right of the principal plane, but almost certainly not extending to the right scissura. An early description of this procedure was reported by Blumgart in 1978, but it was not until Starzl and colleagues (1982) reported four cases, which they referred to as *left hepatic trisegmentectomies,* that the necessary hilar dissection was described precisely. The difficulty in defining the plane of parenchymal transection on the right and in controlling hemorrhage and biliary complications was recognized. Subsequently, reports of small numbers of patients undergoing this procedure continued to populate the literature, but perioperative problems, and biliary complications in particular, were frequent (Al-Hadeedi et al, 1990; Hasegawa et al, 1989).

Preoperative Evaluation

Careful and detailed preoperative anatomic assessment is paramount, and patients should not be excluded from operation based on the size of the tumor alone. Even patients with very large tumors that displace blood vessels and compress bile ducts, so-called pushing tumors, may be selected for laparotomy (Baer et al, 1989). Quality cross-sectional imaging by either CT or MRI is important to delineate the expansile pushing form of a tumor (see Fig. 90B.6). US, including Doppler imaging of the portal and hepatic vessels, is also valuable in this regard. These studies also show impingement of large tumors on the vena cava. Arteriography and inferior venacavography are rarely if ever necessary.

Operative Technique

The operation involves removal of segments II, III, IV, V, and VIII (Blumgart et al, 1993). Segment I can be included in the resection if necessary for tumor clearance (Fig. 90B.43; see also Fig. 90B.32). An important aspect of the operative technique is the early and complete mobilization of the liver, not only by division of the left triangular ligament from its apex to the left of the IVC but also by complete division and mobilization of the ligament on the right. This mobilization not only allows palpation of segment VII for the presence of unsuspected additional tumor but also assists later in the identification of the correct plane of parenchymal dissection. IOUS is performed to confirm the previously defined anatomic configuration of the tumor and

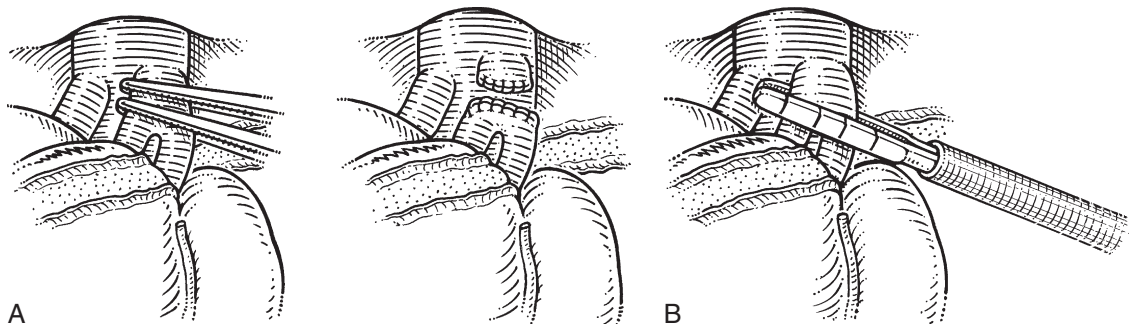

FIGURE 90B.42. A, The left and middle hepatic veins are clamped, divided, and oversewn. **B,** Alternatively, the veins may be divided with the Endo GIA stapler.

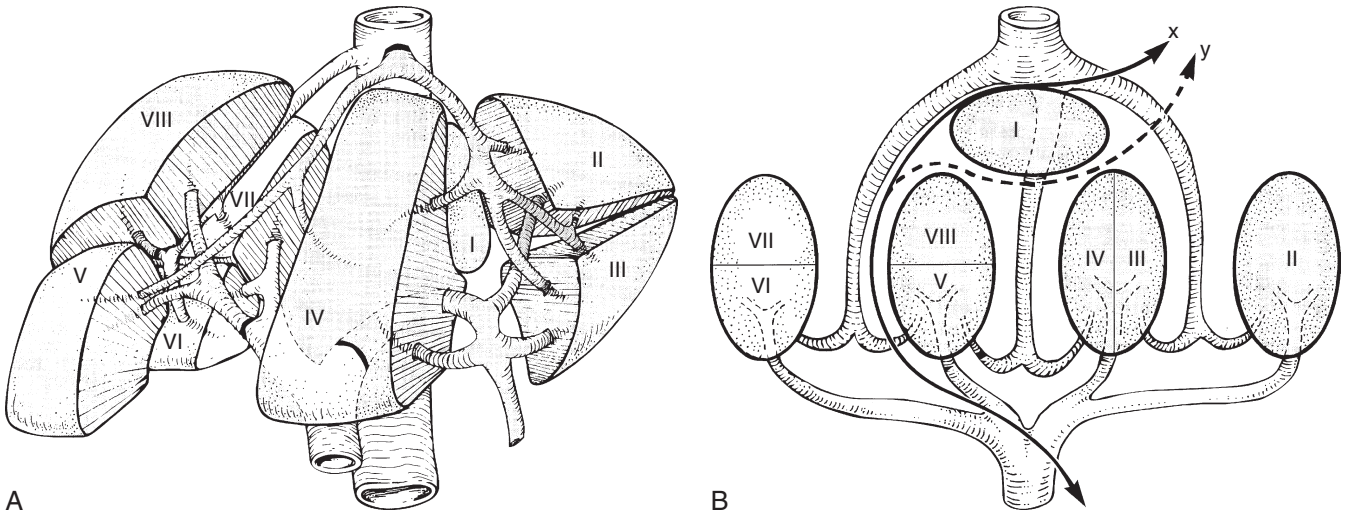

FIGURE 90B.43. A, Exploded view to show the sectors and segments of the liver. Extended left hepatectomy involves removal of segments II, III, IV, V, and VIII and sometimes segment I. The segments to be removed are shaded. The solid lines on the right anterior sectoral pedicle and the left portal triad illustrate the devascularization necessary. The solid line on the middle and left hepatic veins illustrates the point of hepatic venous transection. The right posterior sectoral triad supplying segments VI and VII is preserved, as is the right hepatic vein. **B,** Schematic representation of extended left hepatectomy. Note preservation of the posterior sectoral triad supplying segments VI and VII and of the right hepatic vein. The solid line *x* illustrates the line of transection for removal of the caudate lobe, and the dotted line *y* illustrates the line of transection if the caudate lobe is to be preserved.

major hepatic veins. In particular, an attempt is made to identify the presence of a large inferior right hepatic vein; its presence augments drainage of segments VI and VII and may allow the right main hepatic vein to be sacrificed during operation if required (Baer et al, 1991).

Initial dissection is identical to that for left hepatectomy. The suprahepatic bare area of the liver is fully exposed to display the suprahepatic IVC and the hepatic veins. The left liver is now turned to the right side, and the portal triad is approached from the left (Fig. 90B.44). The point of ligation of the portal vessels to the left liver is dictated by the involvement of the caudate lobe (segment I) by tumor. If segment I requires resection, the left hepatic artery, bile duct, and portal vein must be ligated close to the hilus to interrupt the blood supply to segment I and to the left liver (see Figs. 90B.32 and 90B.44). As described by Starzl and coworkers (1982) and Blumgart and colleagues (1993), however, when segment I is to be preserved, the structures of the left portal triad are secured at the base of the umbilical fissure to leave intact the biliary drainage and blood supply of segment I (see Fig. 90B.44).

After obtaining vascular control at the hilus, the middle and left hepatic veins and the left of the subdiaphragmatic IVC are dissected and exposed as described earlier for left hepatectomy (Czerniak et al, 1993). If the caudate lobe is to be removed en bloc, it is mobilized from the left side by dividing its direct venous tributaries to the IVC.

The difficult aspect of the operation is the definition of the line of transection of the parenchyma, which lies well to the right of the principal scissura. The plane is horizontal, lateral to the gallbladder fossa, and parallel and just anterior to the right scissura. In an attempt to define this plane, Starzl and coworkers (1982) described finger dissection, beginning from above and anterior to the main right hepatic venous entry into the vena cava. We have avoided this approach, which may be associated with considerable hemorrhage. It is important to define the plane of parenchymal dissection, however; it passes anterior to the right hepatic venous trunk and allows division of the anterior sectoral branch of the right portal triad, while preserving and avoiding damage to the posterior sectoral triad (Fig. 90B.45). Although there are no reliable surface markings, a plane passing from the anterior border of the right hepatic vein above and extending horizontally to emerge well to the right of the gallbladder fossa designates the approximate correct position within the parenchyma. This line can be accurately defined when it is possible to clamp the anterior sectoral pedicle to the right liver, and this is often possible using the pedicular glissonian approach. This approach should be possible in all cases in which the tumor does not extend so close to the right main pedicle as to make access impossible without compromising tumor clearance. The right anterior sectoral pedicle is isolated and clamped, and the right posterior pedicle is left intact; a line of demarcation extending along the right scissura develops rapidly (Fig. 90B.46).

The parenchymal transection phase is now carried out, opening the liver tissue from below, going upward, and keeping the plane of parenchymal dissection horizontal. Frequent use of IOUS facilitates continuing along the correct transection plane and spares injury to the right posterior pedicle and right hepatic vein. If significant bleeding occurs, it usually arises from branches of the right hepatic vein. Dissection carried out under low CVP (see Chapter 22) allows bleeding from the transected branches of the right vein to be visualized and controlled. When the right anterior sectoral pedicle has been identified, it should be test clamped prior to dividing it to ensure adequate perfusion to the posterior sector. The plane of transection is kept anterior to the right posterior pedicular structures. Unlike the hepatic veins, these structures are dense and white and should be readily appreciated.

Many large, expansile (pushing) tumors produce a narrow zone of compressed atrophic liver tissue just anterior to the

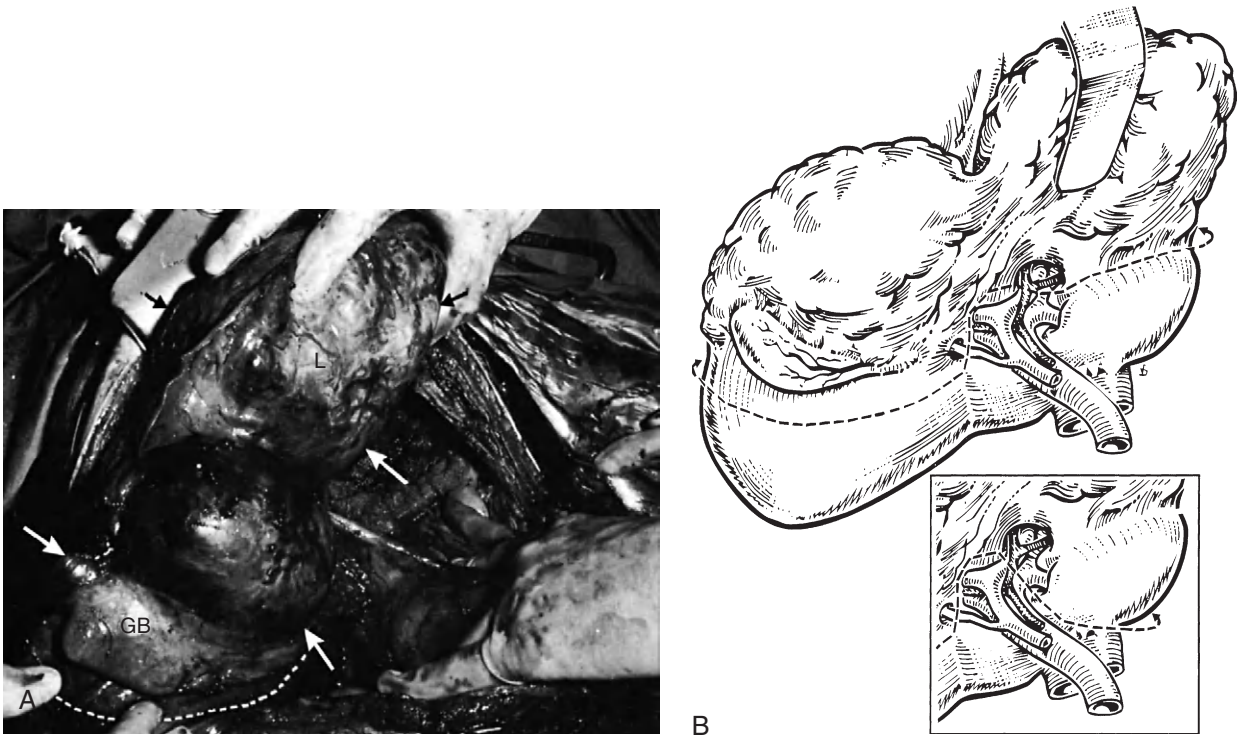

FIGURE 90B.44. A, Operative photograph of a large, left-sided primary hepatocellular carcinoma occupying the left lobe of the liver (segments II, III, and IV) and extending into segments V and VIII beneath the gallbladder (*GB*). The left lobe (*L*) has been mobilized and turned toward the right. The extent of the tumor is indicated by the *arrows*. The line of parenchymal incision in the right liver is indicated by the *dotted line*. **B,** Initial approach during extended left hepatectomy allows dissection of the portal triad structures from the left posterolateral aspect. The line of future transection is indicated. If the caudate lobe is to be preserved, the left portal vein is ligated beyond its caudate branch; but if the caudate is to be removed as well, the portal vein can be ligated more proximally (*inset*). The line of transection runs along the obliterated ligamentum venosum, then across the base of the quadrate lobe and hilus; it curves to the right, extending into the right scissura lateral to the gallbladder fossa. The dissection as illustrated in the main diagram would preserve the caudate lobe; in the inset, the caudate lobe also is removed (see also Fig. 90B.43).

FIGURE 90B.45. Extended left hepatic lobectomy. The liver tissue is entered for the parenchymatous transection just anterior to the estimated lower limit of the right scissura. This plane of dissection is followed, with the operator working toward the base of the gallbladder fossa and the point of entry of the right hepatic duct into the liver substance. The anterior sectoral vessel of supply and the bile ducts are identified in the liver substance (*arrow*) and can be ligated.

posterior pedicular triad. In such instances, although tumor clearance is narrow, it can be achieved by peeling the tumor away from the residual parenchyma in this atrophic plane. With large tumors, the plane of dissection is dictated by the tumor (see Fig. 90B.6). For smaller tumors, the plane of dissection can be anatomically defined.

If the middle and left hepatic veins have not been controlled and divided extrahepatically, they are ligated when encountered within the line of transection, and the parenchymal division is completed; however, it cannot be emphasized strongly enough that prior control of these veins is associated with substantially less venous bleeding during parenchymal transection.

After removal of the resected specimen, the remnant (segments VI and VII) presents an en face raw surface area (Fig. 90B.47). Any bleeding from small branches of the hepatic artery or portal vein is controlled, and any visible open bile ducts are closed with fine, resorbable sutures. Final hemostasis is achieved as described earlier, and the omentum may be laid over the cut surface. An increased risk for biliary complications attends this operation, and three of the four patients initially reported by Starzl and coworkers (1982) had biliary complications: two had fistulae, and one had bile duct stricture.

Experience: Extended Left Hepatectomy

Extended left hepatectomy has been described in some detail, because large tumors arising from the left liver and extending to the right, previously considered unresectable, can be removed successfully with complete tumor clearance and a chance of

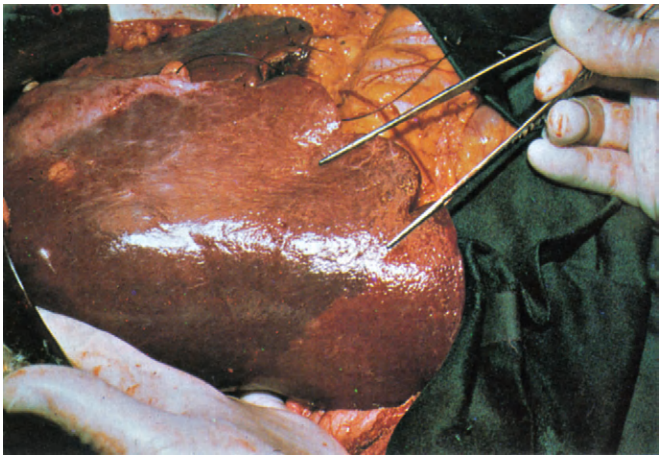

FIGURE 90B.46. Operative photograph taken during extended left hepatectomy for a large tumor occupying the left liver, which has already been devascularized; the anterior sector (segments V and VIII) is seen devascularized and demarcated from the posterior sector (segments VI and VII), which remains vascularized.

cure (Blumgart et al, 1993; Soreide et al, 1985). As stated earlier, prediction of resectability is sometimes difficult; but in large tumors with a clear-cut margin on cross-sectional imaging and evidence of displacement, rather than invasion, of right-sided posterior sectoral intrahepatic structures (see Fig. 90B.6), exploration for excision is worthwhile (Soreide et al, 1985). Although high perioperative morbidity and mortality and poor outcome have been reported with this operation (Hasegawa et al, 1989), many small series lend support to its utility (Al-Hadeedi et al, 1990; Bismuth et al, 1989, 1992; Blumgart et al, 1993; Elias et al, 1992; Houssin et al, 1993; Huguet et al, 1994; Iwatsuki & Starzl, 1988; Starzl et al, 1982; Tsuzuki et al, 1990).

In a series of 51 patients who underwent extended left hepatectomy at MSKCC from 1992 through 1998 (Povoski et al, 1999), no intraoperative deaths were reported, and postoperative morbidity was 53%; biliary leak and abdominal abscess were the most commonly encountered complications. Postoperative mortality rate was 8%. Compared with historic controls for hepatic resection at MSKCC from 1985 through 1994 (Fong et al, 1995), in which overall postoperative morbidity was 40% and postoperative mortality rate was 4%, morbidity and mortality rates were greater for extended left hepatectomy, although length of hospital stay was identical. In a more recent study, Cho and colleagues (2010) reported no operative deaths in 15 consecutive patients, emphasizing the importance of adequate venous drainage of the liver remnant. The morbidity in this study was high (40%), underscoring the point that extended left hepatectomy remains one of the most difficult procedures in hepatic resection surgery.

Factors that influence resectability and oncologic efficacy, especially with regard to such extensive anatomic dissections, have long been debated. In the series of patients from MSKCC, the finding of positive microscopic margins or of tumor within one high-power field (HPF) was associated with the largest hepatic lesions (Povoski et al, 1999).

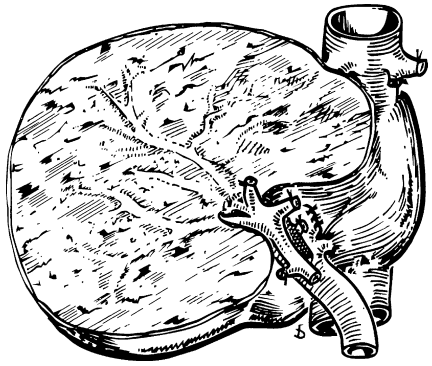

FIGURE 90B.47. The liver substance is removed anterior to the posterior sectoral ducts and vessels, and the upper part of this parenchymal dissection runs just anterior to the right hepatic vein and involves control of the middle and left hepatic vein. After resection, the right posterior sectoral portal triad can be seen branching on the surface of exposed liver tissue.

Left Lateral Sectorectomy (Left Lateral Segmentectomy)

The left lateral sector of the liver, which comprises segments II and III, is resected by approaching the portal triads to segments II and III in the umbilical fissure. Any bridge of tissue between segments III and IV is divided as described previously. The left lobe is mobilized, and dissection is carried out within the umbilical fissure to the left of the main triad; the pedicles to segments II and III usually can be dissected and controlled individually (see Fig. 90B.32). This approach is important in allowing tumor clearance for lesions close to the umbilical fissure. Alternatively, the liver may be split anteroposteriorly, just to the left of the ligamentum teres and the falciform ligament; as this is done, the vessels are encountered intrahepatically and divided serially. The latter approach is suitable only for more peripherally placed tumors.

As the liver tissue is divided, the left hepatic vein is encountered posteriorly and can be controlled within the liver substance. Division of the left hepatic vein usually completes the parenchymal transection. When a posteriorly situated tumor lies close to the junction of the left hepatic vein and the middle hepatic vein, it is best to approach the left hepatic vein extrahepatically, as described previously for left hepatectomy (see Figs. 90B.41 and 90B.42).

HEPATIC SEGMENTECTOMY

A detailed understanding of intrahepatic anatomy and advances in imaging technology have facilitated an approach to hepatic resection based on the removal of individual hepatic segments (Billingsley et al, 1998; DeMatteo et al, 2000; Franco et al, 1988; Gazelle & Haaga, 1992; Hemming et al, 1997; Takayama & Makuuchi, 1996). Hepatic segmentectomy is discussed in detail in Chapter 92 but is also briefly described here; however, resection of segment I, caudate lobectomy, is discussed in detail, because it is often done in combination with a major hepatectomy. The number of hepatic segments resected has been shown to be correlated with perioperative morbidity and mortality (Jarnagin et al, 2002).

Segmental resections offer a variety of advantages over classic major resections and nonanatomic wedge resections. Segmental resections conserve functional liver parenchyma and minimize the physiologic impact of liver resection. This is of

particular benefit in a patient with cirrhosis who has baseline impaired hepatocellular function. Nonanatomic wedge resection has been advocated as an alternative approach for parenchymal conservation (Brown et al, 1988); however, wedge resection can be hampered by excessive bleeding and unacceptable rates of margin positivity, as high as 35% in some series (Scheele et al, 1991, 1995). Uncontrolled intraoperative hemorrhage is usually avoidable with good parenchymal transection techniques and low CVP.

A segmentectomy may be regarded as a *unisegmentectomy,* when one segment is removed, or as a *plurisegmentectomy,* when two or more segments are excised (Castaing et al, 1985; Nagasue et al, 1985). More commonly performed segmental resections include resection of segment I, resection of segment IV, and segmentectomy to remove segments IV, V, and VI (Figs. 90B.48 and 90B.49). Central hepatectomy comprising resection of segments IV, V, and VIII is being increasingly performed, and this may be combined with resection of segment I, the latter operation being particularly indicated in some patients with hilar cholangiocarcinoma (Ogura et al, 1998). Resection of segments VI and VII is, in effect, a *right posterior sectorectomy,* and resection of segments V and VIII is a *right anterior sectorectomy.*

Although indicated for removal of some benign liver tumors and for biliary exposure in some cases of benign biliary stricture, isolated resection of segment IV is of value in the management of malignant lesions occupying only the quadrate lobe.

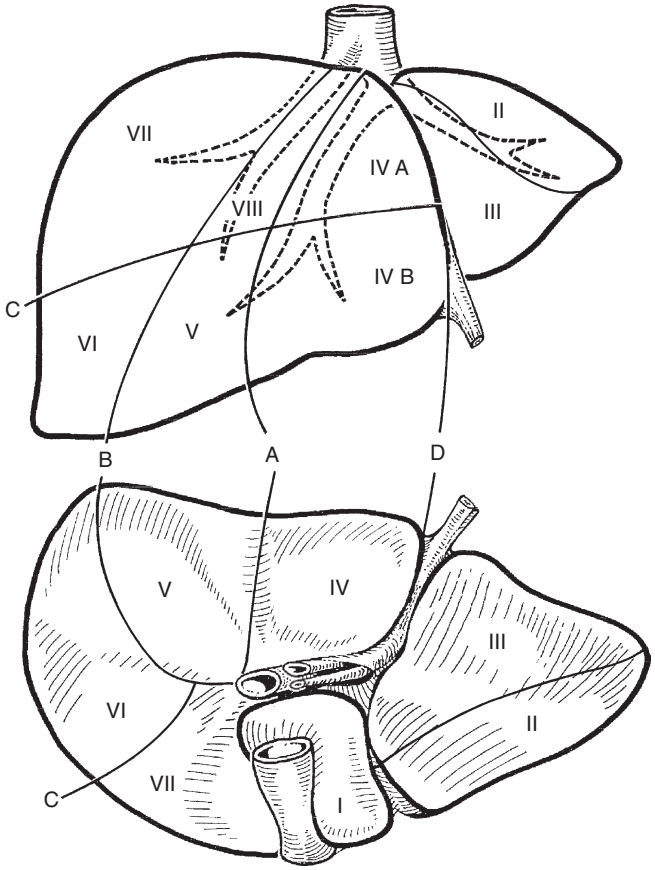

FIGURE 90B.48. Lines of resection for excision of various segments. Resection of segments VI and VII, right posterior sectorectomy. Resection of segments V and VIII, right anterior sectorectomy. Resection of segments IV, V, and VIII, central hepatectomy. Resection of segment IV follows *A-D*.

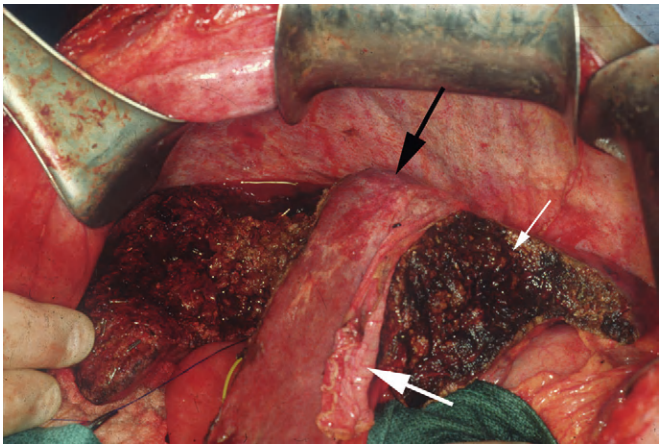

FIGURE 90B.49. Intraoperative photograph illustrates resection of segments III, V, and VIII. Segments II (*small white arrow*) and IV (*black arrow*) remain intact. The falciform ligament is evident (*large white arrow*).

Carcinoma of the gallbladder is a special case, because the organ lies between segments IV and V of the liver. Resection for gallbladder cancer should involve, at a minimum, removal of segments IVb and V (discussed later in this chapter and also in Chapter 49). A resection of segments II and III (Fig. 90B.50) may also be performed and is in effect a *left lateral sectorectomy.* Segment I may be removed on its own or in continuity with a right or left hepatectomy, central hepatectomy, or an extended right or left hepatectomy.

Segment I (Caudate Lobe) Resection

The caudate lobe of the liver is a frequent site of involvement in primary and secondary liver tumors. In addition, cholangiocarcinoma at the confluence of the hepatic ducts frequently involves caudate bile ducts and may extend to the caudate lobe. Resection of the caudate lobe of the liver is often necessary for complete tumor clearance. The procedure may be required as an isolated caudate resection, or it may be combined with a major hepatectomy. The anatomy of the caudate lobe and its

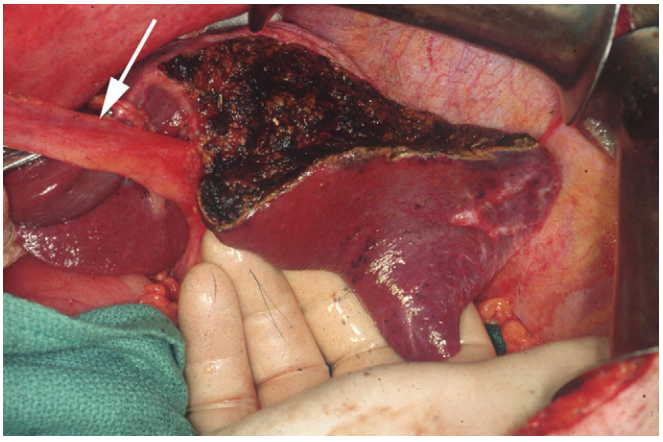

FIGURE 90B.50. Photograph illustrates resection of segment III. Segment II is turned forward by the operator's hand. The ligamentum teres is illustrated (*arrow*).

close proximity to major vascular structures make resection challenging.

Anatomy

The caudate lobe is the dorsal portion of the liver that embraces the retrohepatic IVC. The lobe lies between major vascular structures: at the inferior aspect of the liver, it is situated between the IVC posteriorly and the left portal triad anteriorly; at the superior aspect of the liver, it is bordered by the IVC posteriorly and the middle and left hepatic veins anteriorly (Figs. 90B.51 and 90B.52; see Chapter 1B). The main bulk of the lobe lies to the left of the vena cava, with the left and inferior margins being free in the lesser omental bursa. The gastrohepatic omentum separates the left portion of the caudate lobe from segments II and III of the left liver, as it passes between them and attaches to the ligamentum venosum. The left portion of the caudate lobe inferiorly traverses to the right side between the portal vein and IVC, where it is termed the *caudate process* as it fuses with the right lobe of the liver. Superiorly, the left portion of the caudate lobe is linked to the posterior margin of the hilum by a deep anterior portion, which passes embedded in the parenchyma immediately under the middle hepatic vein and fuses on the right side to segment VII, anterolateral to the IVC. The portion of the caudate lobe on the right varies but is usually quite small; it is often referred to as *segment IX*. The anterior surface of the caudate lobe within the parenchyma is covered by the posterior surface of segment IV, the limit being an oblique plane slanting from the left portal vein to the left hepatic vein. The caudate lobe has a constantly present left portion, and the right portion is of variable size (see Chapter 1B).

The inflow to the caudate lobe is supplied by branches from the right and left portal vein and the left hepatic artery close to the base of the umbilical fissure of the liver. The right portion of the caudate lobe, including the caudate process, receives predominantly portal venous blood from the right portal vein or the bifurcation of the main portal trunk; whereas on the left side, the major portal supply arises almost exclusively from the left branch of the portal vein. Similarly, the arterial supply and biliary drainage of the right portion is most commonly associated with the right posterior sectoral vessels or pedicle, and that of the left aspect is associated with the left main vessels (Mizumoto & Suzuki, 1988).

The hepatic venous drainage of the caudate lobe is unique in that it is the only hepatic segment that drains directly into the IVC. The number of hepatic veins varies (mean four, range one to nine; Heloury et al, 1988). In general, the veins are short and

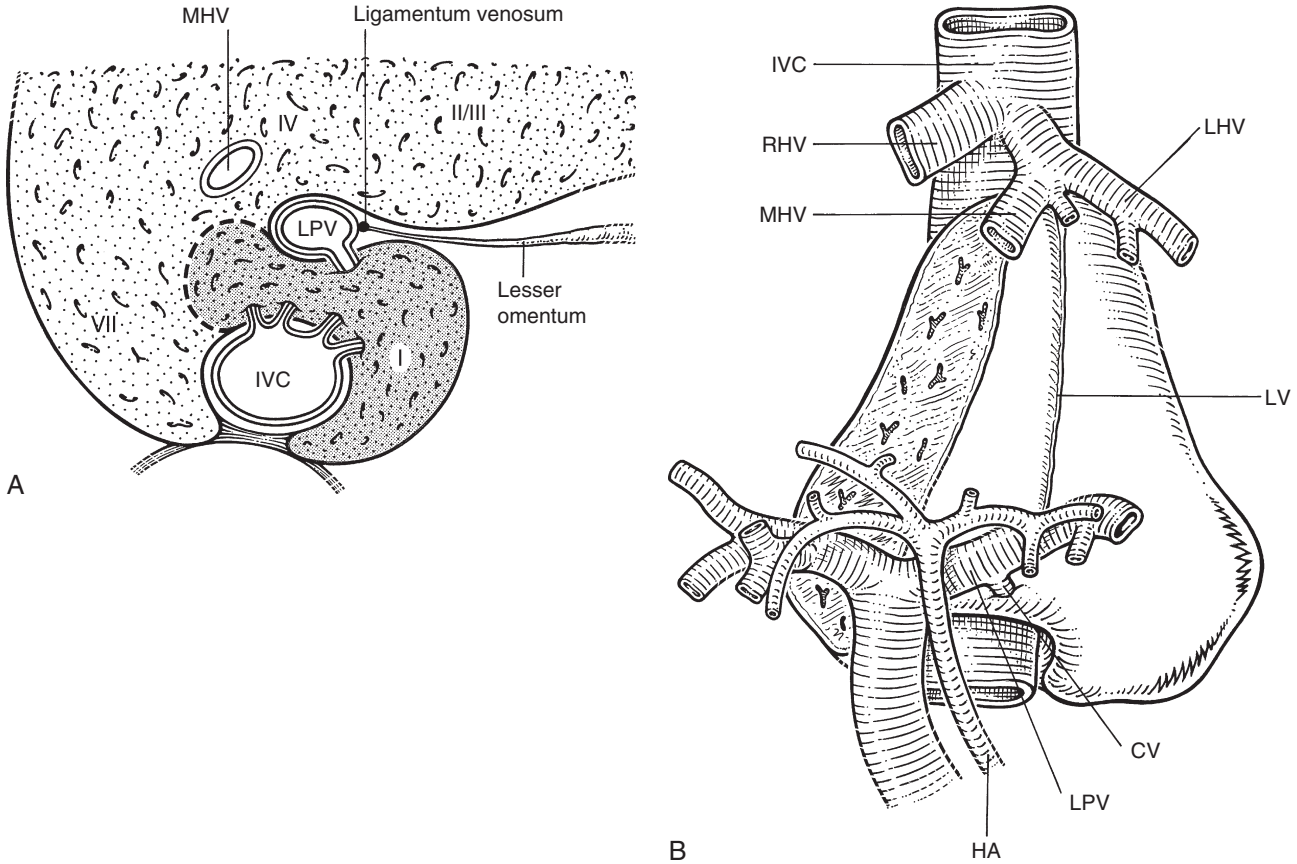

FIGURE 90B.51. A, Cross-sectional sketch shows caudate lobe anatomy at the level of the porta hepatis. Note the principal caudate branch of left portal vein (*LPV*). Note the position of 1) the lesser omentum and ligamentum venosum; 2) middle hepatic vein (*MHV*), which separates segments IV and V and is close to right portion of caudate lobe; and 3) the posterior ligamentous band joining segments I and VII. **B,** The relationships of the caudate lobe are illustrated. The caudate lies anterior to the inferior vena cava (*IVC*) but posterior to the portal venous structures; the caudate lobe has a right portion. Blood supply to the caudate lobe is mainly from the caudate branch (*CV*) of the LPV. This branch may arise from the main trunk of the portal vein in some cases. HA, hepatic artery; LHV, left hepatic vein; LV, ligamentum venosum; RHV, right hepatic vein.

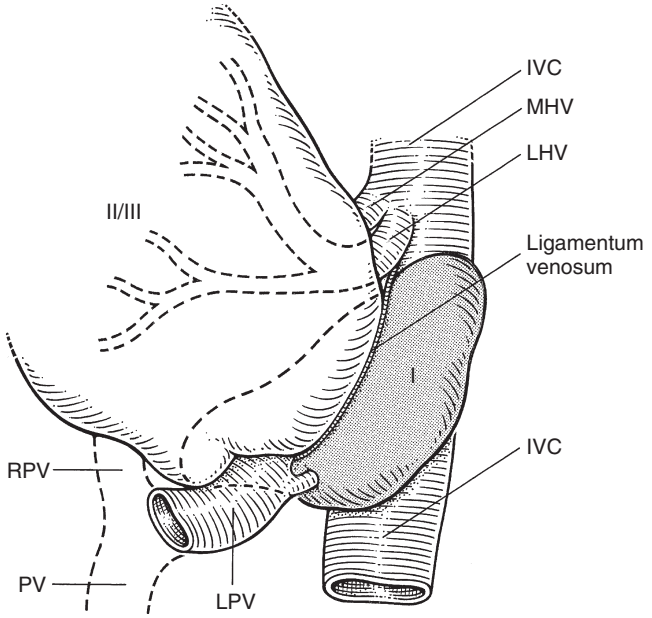

FIGURE 90B.52. Position of the caudate lobe relative to surrounding structures and particularly the vena cava. Segments II and III have been rotated to the right to expose the caudate lobe. The position of the ligamentum venosum is indicated. Note the extension of the caudate lobe between the vena cava and the portal vein (*PV*) anteriorly and between the vena cava and the middle and left hepatic veins (*LHVs*) superiorly. Caudate portal blood supply is via a branch of the left portal vein (*LPV*). IVC, inferior vena cava; MHV, middle hepatic vein; RPV, right portal vein (see also Fig. 90B.51).

drain from the caudate lobe directly into the anterior and left aspect of the vena cava (see Fig. 90B.51A and Chapter 1B); they may also drain into the posterior aspect of the vena cava, if a significant retrocaval caudate component is present, but this is rare.

The posterior edge of the caudate lobe, on the left, usually has a fibrous component that fans out to attach to the crus of the diaphragm; this extends posteriorly, behind the vena cava, and links with a similar component of fibrous tissue, protruding from the posterior surface of segment VII, and embraces the vena cava (see Fig. 90B.51A). In up to 50% of patients, this ligament is replaced, in whole or in part, by hepatic parenchymal tissue; thus the caudate may completely encircle the IVC and may contact segment VII on the right side. A significant retrocaval component may compromise a left-sided approach to controlling the caudate veins.

Resection

The major obstacles in caudate lobe resection are its mobilization, which mandates control of the retrohepatic caudate veins, and, in the presence of a large tumor, preventing and controlling bleeding from the posterior surface of the middle hepatic vein. Resection of the caudate lobe involves three major steps: 1) control of the inflow blood supply from the left portal vein and left hepatic artery, at the base of the umbilical fissure, and of other inflow vessels arising from the right portal vein; 2) dissection and ligation of the retrohepatic veins; and 3) division of the liver parenchyma between the right portion of the caudate process and the base of segments IV and the left side of segment VII to allow removal of the lobe (isolated caudate lobe resection).

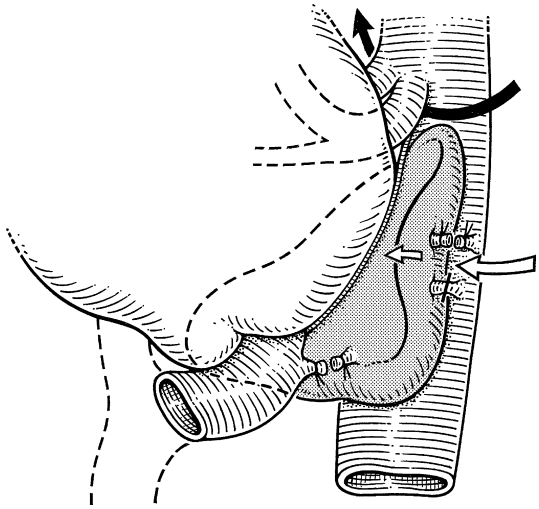

FIGURE 90B.53. Start of mobilization of the caudate lobe from the left. The caudate branch of the portal vein has been tied. The caudate lobe has been freed from the left side of the inferior vena cava (IVC) and turned medially (*small white arrow*). Dissection is proceeding between the vena cava and the caudate lobe (*large white arrow*). The retrocaudate hepatic veins are being tied. The *black arrow* indicates the tunnel between the middle and left hepatic veins and the IVC. Dissection of this tunnel allows placement of a clamp across the left and middle hepatic veins.

Dissection at the base of the umbilical fissure allows identification of the caudate vessels arising from the left side of the portal vein and the left hepatic artery, before these vascular structures enter the umbilical fissure (Figs. 90B.53 and 90B.54). The left lobe of the liver is mobilized and turned to the right. The left lateral margin of the caudate is freed by division of the fibrous extension of the tissue as it courses posteriorly to the IVC. This division allows access to the retrohepatic veins (see

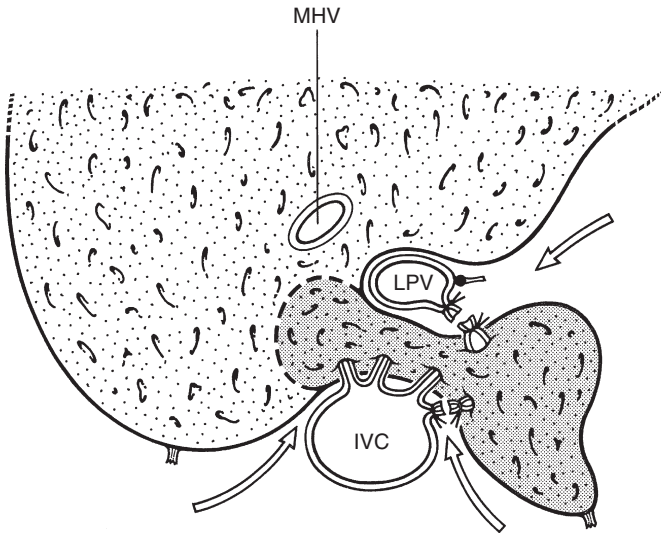

FIGURE 90B.54. Lines of approach (*arrows*) to free the caudate lobe. Compare with Figure 90B.51. The lesser omentum has been opened, and the caudate branch of the left portal vein has been tied. The ligamentous attachments of the caudate lobe posteriorly have been opened, and dissection of the retrohepatic caudate veins can be approached from the right or left side. IVC, inferior vena cava; MHV, middle hepatic vein; LPV, left portal vein.

Figs. 90B.51 and 90B.54). During this dissection, it becomes evident whether the caudate lobe is encircling the vena cava posteriorly, in which case no further attempt is made to free the lobe on the left side, but an approach should be made from the right (see Fig. 90B.54; Hasegawa et al, 1991a; Lerut et al, 1990).

After dividing the ligamentous attachments on the left side, the caudate can be elevated from the left, although providing adequate upward traction to expose the retrohepatic veins can be challenging, because there is often little parenchymal tissue to grasp. As the retrohepatic veins are encountered, they may be encircled and suture ligated or controlled with clips, working from the left side of the vena cava toward the right side; in this manner, complete mobilization can be performed (see Figs. 90B.51, 90B.53, and 90B.54). This technique is most suitable when the caudate lobe is not involved by a bulky tumor, such as in removal of the lobe in continuity to allow clearance in left hepatectomy for hilar cholangiocarcinoma. It is also valuable in extended left hepatectomy, during which it is our practice to attempt to use it as a matter of routine, because it allows less disturbance of the right liver.

A bulky tumor within the caudate lobe is often rigid, and upward mobilization of the caudate from the left is difficult and hazardous. In this case, the retrohepatic veins are best approached from the right side (see Fig. 90B.54; Lerut et al, 1990). Should right hepatectomy or extended right hepatectomy be necessary in continuity with caudate lobe resection, an approach from the right is easier and is a simple extension of the retrohepatic dissection. The right lobe is turned toward the left, and the retrohepatic veins are dissected serially, beginning from the inferior aspect of the caudate process and extending superiorly with division of all veins, until the major hepatic trunks are reached (Miyagawa et al, 1992). As this dissection is carried out, it is easy to extend it over the anterior surface of the IVC to the left side, until the caudate lobe is completely mobilized and freed from the vena cava (see Fig. 90B.54; Lerut et al, 1990).

For a right or left hepatic resection, which necessitates ligation of the middle hepatic vein, the caudate lobe is easily removed en bloc with the specimen without danger of tearing the posterior aspect of the middle hepatic vein, because it may be controlled extrahepatically for left-sided resections or intrahepatically for right-sided resections. In resection of the caudate lobe as an isolated procedure, and particularly if there is a bulky tumor within the caudate, it is important to recognize the risk of injuring the middle hepatic vein posteriorly during parenchymal dissection of the anterior aspect of the caudate lobe, which can result in substantial hemorrhage (Colonna et al, 1993). To prevent this, we have found it valuable to first isolate and control the left and middle hepatic veins extrahepatically, as described above (see Figs. 90B.41 and 90B.53). This maneuver provides temporary control during the parenchymal phase of dissection of the portion of the caudate lobe that lies anterior to the IVC, and it facilitates safe resection of large caudate tumors (Figs. 90B.55 and 90B.56). Some authors advocate splitting the liver anteriorly in the glissonian plane, thus separating the right and left liver and dividing the liver along the right margin of segment IV to approach the caudate lobe transhepatically (Yamamoto et al, 1992). A combination of these techniques allows preservation of middle hepatic venous flow and good control of bleeding. The resectional approach to performing a caudate lobectomy depends largely on the size and location of the lesion,

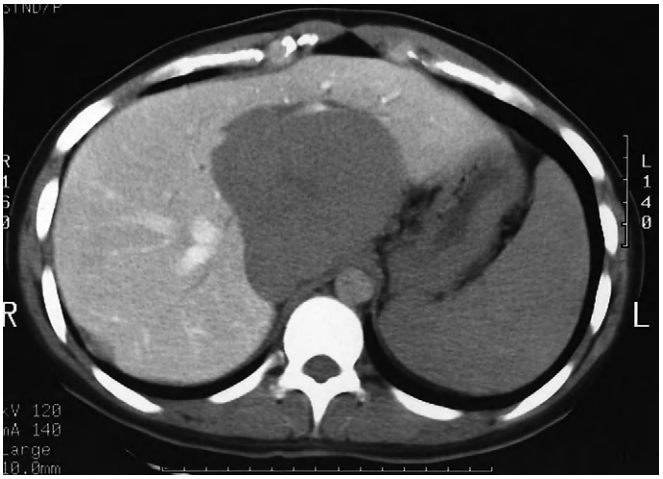

FIGURE 90B.55. Computed tomographic image of the liver of a 25-year-old woman with symptomatic focal nodular hyperplasia in the caudate lobe compressing the inferior vena cava and portal vein without invasion. Freeing of this tumor necessitated an approach to the retrohepatic veins from the right and left sides.

the type of associated resection, and the presence of scarring from any previous resection. In actuality, the liver frequently is rotated during the resection in order to approach it from both the left and right sides.

Preoperative imaging cannot accurately differentiate tumor invasion from compression of the IVC and of the portal vein, and thus most caudate lobe tumors warrant operative exploration to determine resectability. Many tumors that appear to invade the vena cava on preoperative imaging can be dissected

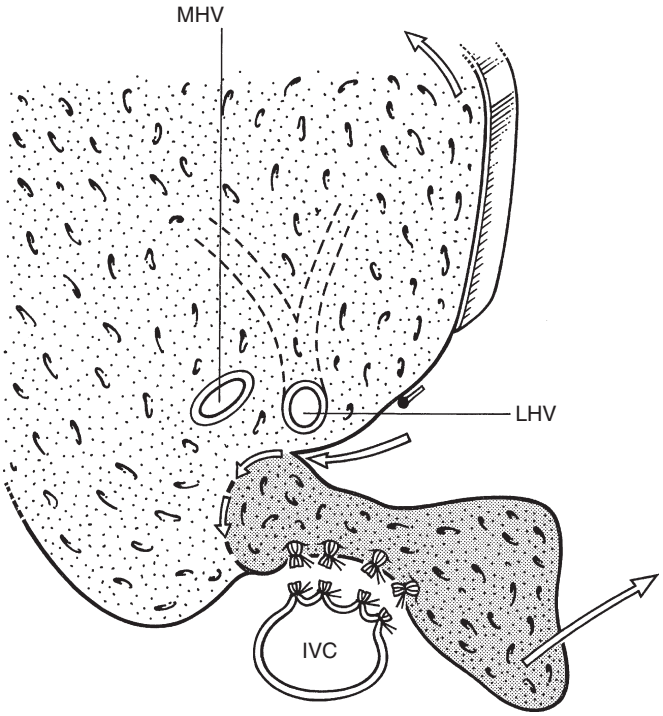

FIGURE 90B.56. Parenchymal phase of dissection (*arrows*). Note proximity of the left hepatic vein (*LHV*) and middle hepatic vein (*MHV*). The right portion of the caudate lobe lies just to the left of the MHV. IVC, inferior vena cava.

free of the cava in a tumor-free plane. In selected cases, the IVC can be resected in part or en bloc with the caudate lobe (Gardner et al, 1992; Takayama et al, 1991), but this is usually unnecessary. Short segments of the IVC can be repaired or reconstructed primarily or with autogenous grafts, whereas longer segments may require prosthetic grafts (Fig. 90B.57). A chronically occluded IVC can be resected without reconstruction, because abundant collateral vessels usually have developed (Takayama et al, 1991). Although techniques involving complete vascular isolation can be used for caudate lobe resection, this is usually not necessary.

Numerous series and case reports of caudate lobe resection are summarized in Tables 90B.3 and 90B.4. Nimura and associates (1990B) reported a large series of caudate resections for hilar cholangiocarcinoma. They described 45 complete caudate lobe resections for microscopic involvement of caudate bile ducts, including three isolated caudate lobectomies. The operative mortality rate was 7%. Elias and coworkers (1992) reported 20 resections involving the caudate lobe, only seven of which were complete caudate lobectomies. There were no operative deaths. Bartlett and colleagues (1996) reported a retrospective review of 21 consecutive complete caudate lobe resections over a 30-month period. Four of the 21 patients underwent complete isolated caudate lobectomy. The most common diagnosis was metastatic colorectal cancer in nine patients, and the most common procedure was an extended left hepatectomy with en

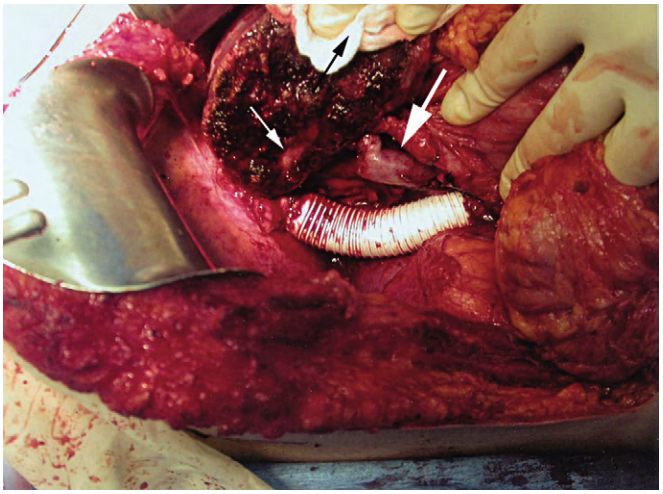

FIGURE 90B.57. Intraoperative photograph from the patient's right. Right lobectomy has been carried out together with excision of the caudate lobe and a portion of the inferior vena cava (IVC). Segments II and III are drawn upward and to the left by the operator's hand (*black arrow*). The middle hepatic vein coursing to join the upper IVC is seen (*large white arrow*); the IVC has been replaced by a Dacron graft. The main trunk of the portal vein and its left branch are illustrated (*small white arrow*). Tumor had occupied the dangerous portion of the caudate lobe, lying between the right branch of the portal vein, the middle hepatic vein, and the IVC.

bloc caudate lobectomy. In a more recent review from MSKCC (Hawkins et al, 2005), 150 patients underwent caudate lobectomy for cancer, including 21 isolated caudate resections (see Table 90B.3). The most common indications were metastatic colon cancer and hilar cholangiocarcinoma. Thirty patients required resection and reconstruction of the portal vein or vena cava (see Fig. 90B.57), nine patients (6%) died, and the death rate was significantly higher in patients who underwent major vascular reconstruction.

Resection of Segments II, III, IV, V, VI, VII, and VIII

Resection of isolated segments of the liver or combined resections of two or more segments necessitates control of the relevant pedicles (Fig. 90B.58). These resections are mentioned briefly here, but the technical details are described in Chapter 92.

Resection of Segment IV

Segment IV may be resected in its entirety (*quadrate lobe resection*), or a subsegmental resection of segment IVb can be done alone or in combination with an extended right hepatic resection. The procedure involves lowering the hilar plate to avoid injury to the left bile duct, exposure and control of vessels within the umbilical fissure, and parenchymal dissection to the right of the falciform ligament and along the principal scissura. Posteriorly, parenchymal transection separates segment IV from the upper surface of the right side of segment I. When combined with a right hepatectomy, a partial segment IV resection is feasible, because the inflow to segment IV comes from feedback vessels from the left, as they branch from the main left pedicle within the umbilical fissure. Thus, if a partial resection of segment IV is required to preserve parenchyma, the remnant of segment IV is well perfused.

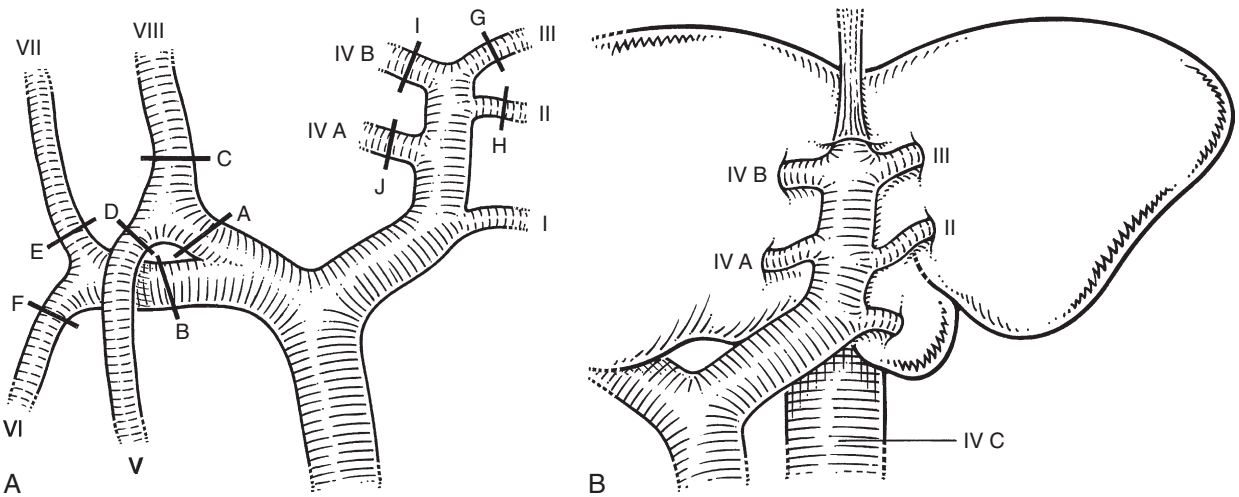

FIGURE 90B.58. A, Distribution of pedicles and points of control (*A* through *J*) for segmental resections. Note that control of the anterior (**A**) or posterior (**B**) sectoral pedicles allows anterior or posterior right sectorectomy. Control of pedicles at points *A, I,* and *J* allows central hepatectomy. **B,** Detailed diagram of the umbilical fissure of the liver (see also Fig. 90B.32). After the umbilical fissure is entirely exposed, the relevant portal triads to segments II, III, and IV are exposed. If the entire segment is to be removed, all portal pedicle branches from the umbilical portion to the right are divided. If segment IVb is to be resected only, its pedicle is divided. For left lobectomy, pedicles to both segments II and III are divided. For isolated segments II and III resection only, the relevant pedicle is controlled (see also Chapter 83 and Figs. 90B.49 and 90B.50).

Resection of Segments IV and V

The initial steps for removing segments IV and V are the same as those for an isolated segment IV resection. The liver parenchyma is split to the right of the falciform ligament, and the inflow vessels to segments IVa and IVb are divided. The liver tissue is then transected in an oblique line parallel to the right scissura to preserve segment VIII. This transection is then carried toward the right portal pedicle, and the middle hepatic vein is divided in the middle of the liver as the prinicipal plain is traversed. As the parenchyma is divided, the inflow pedicle to segment V is located, secured, and divided. This can be test clamped prior to division to ensure that the right anterior pedicle and inflow to segment VIII are preserved. The depth of parenchymal transection continues to include the gallbladder fossa and cystic plate, but to avoid injury, it must remain above the right and left hilar structures. The right and left parenchymal transection planes are then joined at this level to complete the resection (see Figs. 90B.48 and 90B.50). Resection of segments IVb and V, with preservation of segment IVa, is more commonly performed, often for gallbladder cancer, either en bloc with the gallbladder or after it has been removed in cases of incidental gallbladder carcinoma.

Resection of Segments V and VIII (Right Anterior Sectorectomy)

The primary indications for an isolated resection of segment VIII include small, solitary metastases and focal HCC in patients with cirrhosis. For resection of segments V and VIII (right anterior sector), the left plane of dissection is within the principal plane (Cantlie's line). The middle hepatic vein can be preserved or sacrificed, depending on the oncologic necessity. The lateral dissection is performed within the right portal scissura. The right hepatic vein must be preserved at its junction with the cava to allow adequate venous drainage of the right posterior sector, unless a large accessory right hepatic vein is present and can be preserved during right liver mobilization. The planes of parenchymal transection are as described by Makuuchi and colleagues (1993a). Inflow control is obtained by dividing the right anterior sectoral pedicle, and this should be test clamped prior to division to ensure that the posterior pedicle is intact.

Central Hepatic Resection

Central hepatic resection is a major procedure that involves en bloc resection of segments IV, V, and VIII. This procedure involves resection of liver parenchyma supplied by the right and left portal pedicles. This procedure is useful in preserving normal liver parenchyma for patients with central liver tumors and may include resection of segment I, particularly in selected patients with hilar cholangiocarcinoma (Ogura et al, 1998).

The approach involves a combination of the techniques described for resection of segment IV and resection of the right anterior sector. During the parenchymal transection phase, it is necessary to ligate the middle hepatic vein, because the dissection crosses the principal plane near the vena cava. Caution must be exercised to preserve the left hepatic vein, and the right hepatic vein must also be carefully identified and preserved (Kanematsu et al, 1984). For large centrally placed tumors that impinge on the area of the umbilical fissure, care must be taken not to damage the left hepatic duct at the base of the liver, within the hilar plate, or within the umbilical fissure. This is illustrated in Figure 90B.38.

Resections of Segments VI and VII (Right Posterior Sectorectomy)

For isolated resection of segments VI or VII, the major plane of dissection is usually just posterior to the right portal scissura. Inflow control is obtained by securing the segmental branches to segment VI or VII, the right posterior sectoral branches, within the liver (Reynaud et al, 1991). The right hepatic vein can be sacrificed for a segment VI resection. For an isolated segment VII resection, the right hepatic vein should be preserved to facilitate venous drainage of the remnant segment, VI unless an adequate accessory (inferior) right hepatic vein is present. Resection of segments VI and VII together (right posterior sector) can be done with or without sacrifice of the right hepatic vein, because venous drainage from segments V and VIII (right anterior sector) is carried by the middle hepatic vein.

Resection of Segment II or III

Isolated resection of segment II or III (see Fig. 90B.50) may be performed when it is necessary to preserve as much of the left lateral sector as possible. This is frequently the case when patients have undergone a prior liver resection or have underlying parenchymal disease. When isolated segmental resections in this area are performed, inflow control is achieved by isolation of the pedicles to segment II or III within the umbilical fissure, just left of the falciform ligament (Fig. 90B.59; see Fig. 90B.58). Ligation of the relevant pedicle provides demarcation of the parenchyma that guides resection. In these resections, the left hepatic vein must be identified and preserved to leave adequate venous drainage for the retained segment.

HEPATIC RESECTION FOR HILAR CHOLANGIOCARCINOMA

In the case of tumors close to the hilus of the liver or near the confluence of the hepatic ducts, a concurrent hepatic resection is usually necessary to obtain tumor clearance. Although the techniques described here are sometimes applicable for HCC involving hilar structures, the situation occurs more frequently when hilar cholangiocarcinoma extends into the adjacent liver or involves major vascular structures (Fig. 90B.60; see Chapter 50B). In this circumstance, the added complication of preoperative biliary tract obstruction is almost always present.

Some authors, particularly surgeons from Japan, routinely use preoperative biliary drainage and PVE for treating patients with hilar cholangiocarcinoma. We use these techniques selectively in deeply jaundiced patients or when the FLR is inadequate and PVE is required. In our experience, PVE is seldom needed (Kennedy et al, 2009; see Chapter 50B). In a series of 226 patients submitted to extended hepatic resection at MSKCC, the important preoperative variables associated with postoperative death were the presence of cholangitis, a preoperative creatinine value greater than 1.3 mg/dL, and a total bilirubin greater than 6 mg/dL. Five of 14 patients who died had biliary reconstruction procedures (Melendez et al, 2001). Most patients referred to MSKCC had already undergone biliary drainage procedures, sometimes inappropriately, via either percutaneous or endoscopic techniques. Many patients develop biliary infection secondary to drain placement, and we found that postoperative mortality is strongly related to presence of

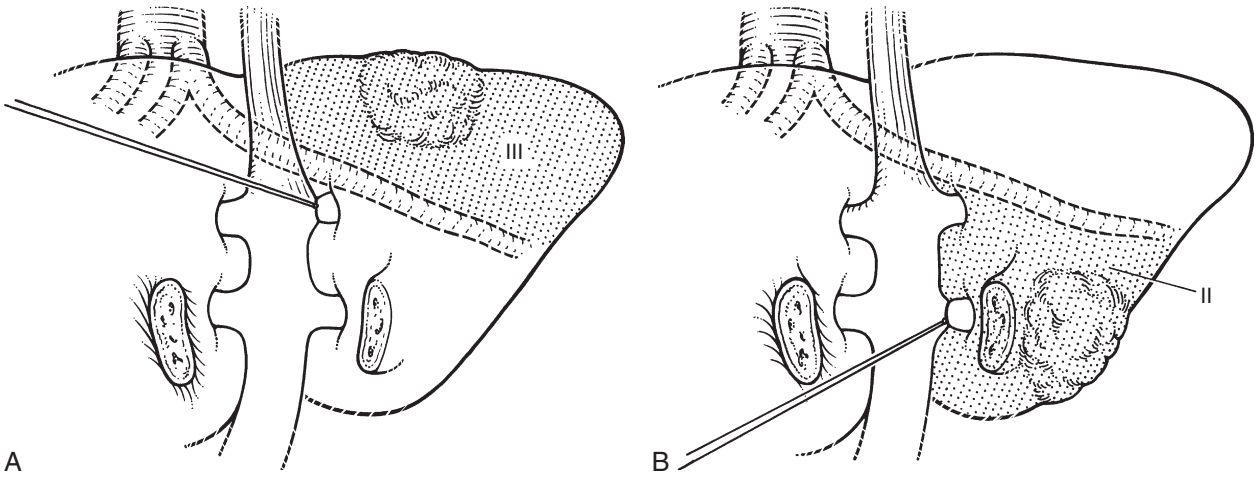

FIGURE 90B.59. **A** and **B,** Ligation of pedicles to segments II and III (see also Chapter 83 and Figs. 90B.48 and 90B.50).

infection. Similarly, in a study of 1803 consecutive liver resections performed from December 1991 through September 2001 at MSKCC, it was shown that patients with biliary malignancy had the highest morbidity and mortality of any patient group (Jarnagin et al, 2002). The indications for preoperative biliary drainage require further study, in particular, to define the criteria that necessitate such preoperative preparations. It should be noted that if preoperative PVE is needed, the FLR may require initial biliary decompression to facilitate an optimal hypertrophic response.

The major limiting factor for resection of hilar cholangiocarcinoma is related to involvement or compression of adjacent vessels and, in particular, main or branch portal vein involvement (Beazley et al, 1984; Blumgart et al, 1984; Voyles et al, 1983). The pattern of vascular involvement, taken in conjunction with ductal extension of tumor shown at cholangiography or on cross-sectional imaging (see Chapter 50B), gives valuable preoperative information to the surgeon with regard to the extent of operation and operative strategy (Burke et al, 1998; Jarnagin et al, 2002).

Local bile duct resection for small tumors not extending to the hilum or into the intrahepatic bile ducts or involving major vessels may be possible, but for more advanced lesions, liver resection is necessary to effect tumor clearance. Liver resection is mandatory when the lesion extends unilaterally into the right or left liver, and it is possible when the contralateral half of the liver is free of tumor and has an intact blood supply, making biliary reconstruction a viable option. More recent reports suggest that hepatic resection should be used in virtually all cases, because tumor clearance and long-term survival have been linked directly to hepatic resection (see Chapter 50B; Jarnagin et al, 2001a).

Hepatic resection in some instances may be limited to removal of the quadrate lobe (segment IV) or may include removal of segment I (caudate lobe); however, the procedures described subsequently relate to the more extensive resections,

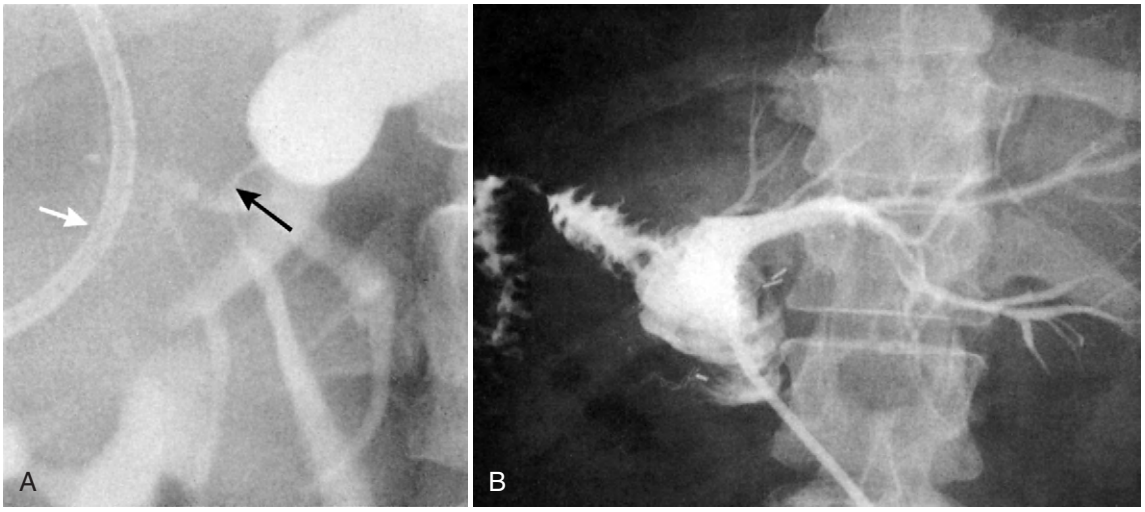

FIGURE 90B.60. **A,** Percutaneous transhepatic cholangiogram shows cholangiocarcinoma at the confluence of the bile ducts (*black arrow*). The left hepatic duct is involved only at its origin, but distally it is grossly dilated. A tube (*white arrow*) has been passed into the right hepatic ductal system using a percutaneous technique. There was involvement of the right branch of the portal vein by tumor, and the right hepatic artery was encased. Right hepatic lobectomy with tumor clearance was obtained. **B,** Tubogram in the postoperative period shows hepaticojejunostomy to the left hepatic duct at the level of the umbilical fissure. The patient was alive, well, and free of recurrence 3 years after operation.

right or left hepatectomy or extended right hepatectomy, which usually are necessary in these circumstances. The variations in technique compared with those described earlier relate to the dissection of the tumor at the hilus of the liver. A careful and detailed examination of the preoperative imaging is mandatory for these cases to assess for resectability and to plan the operation.

Preliminary laparoscopy before open exploration of the abdomen saves a proportion of patients with liver metastases or peritoneal seeding from a nontherapeutic laparotomy (Jarnagin et al, 2000). It is important to examine the liver for extension of the tumor and to obtain a biopsy any suspicious areas (Blumgart et al, 1984). Excisional biopsy with frozen section analysis of suspicious distant lymph nodes should be performed, as nodal involvement in distant lymph node basins—celiac, retropancreatic, and paraaortic—will negate any therapeutic benefit of resection. Should distant disease be present, a biliary bypass procedure can be performed if feasible, or, alternatively, patients are maintained postoperatively with either percutaneous or endoscopic stents.

To reach the confluence of the bile ducts and explore the related vessels, the operator must explore the area beneath the quadrate lobe. If no tumor invasion is evident at this point, the hilar plate is lowered according to the technique of Hepp and Couinaud (1957; Fig. 90B.61; see Chapter 29). If the left hepatic duct can be so lowered, the tumor is usually extending into the right hepatic duct, and a right hepatectomy is required. It is usually clear at this stage whether a sufficient length of the left bile duct can be preserved beyond the line of resection to allow tumor clearance and enable adequate reconstruction. In some cases, if the base of the quadrate lobe is involved over a limited area, the left duct may be identified further to the left, at the base of the umbilical fissure. Further exploration of the hilus can be facilitated by splitting the liver in the glissonian plane down to the hilus (Fig. 90B.62; Blumgart, 1980; Goff et al, 1967; Templeton & Dodd, 1963).

Before any form of resection is undertaken, involvement of the caudate lobe must be assessed. This is also assessed on preoperative imaging, specifically looking for bile duct dilatation in the caudate lobe, which is explored by exposing the IVC below the liver. The lowermost hepatic veins are divided to allow palpation of the caudate lobe from behind. Removal of the caudate lobe as an integral part of the operation is frequently necessary for left-sided tumors and is recommended as routine for all hilar tumors by some authors (Mizumoto et al, 1986; Nimura et al, 1990b). Central hepatic resection involving segments IV, V, and VIII together with the caudate is also possible (Ogura et al, 1998).

To allow for good exposure of the portal vessels and to facilitate a complete portal lymph node dissection, the common bile duct can be transected early in the operation, just above the duodenum (Figs. 90B.63 and 90B.64), and turned upward. Alternatively, if it is doubtful that resection is possible, the surgeon can attempt to do as much dissection as possible to expose the portal vein and hepatic artery without committing to bile duct transection. When the bile duct is to be transected, the duodenum is mobilized, and the bile duct is transected and ligated immediately above the duodenum. The duct is turned upward and forward, clearing the vessels of fascia and lymph nodes. As dissection proceeds, the gallbladder is also mobilized, so that the entire extrahepatic biliary apparatus is turned forward and upward (Fig. 90B.65). This allows a safe approach to the retroductal structures lying at the confluence behind the tumor.

The situation encountered next would be one of the following three scenarios: First, in patients whose tumor does not

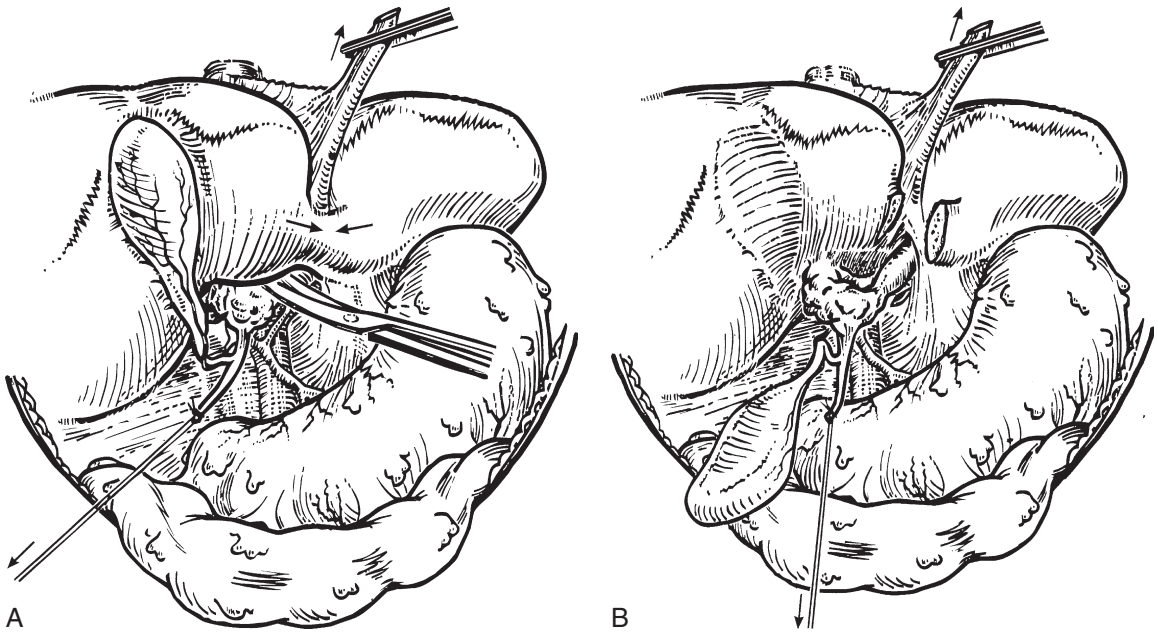

FIGURE 90B.61. A, Dissection to expose structures at the hilus of the liver. The ligamentum teres is strongly elevated, and the liver is turned upward. Dissection at the base of the quadrate lobe with scissors lowers the hilar plate. The bridge of liver tissue (*pair of arrows*) at the base of the umbilical fissure is still intact. The common bile duct is divided immediately above the duodenum, and its lower part is separated together with the associated connective tissue and lymph nodes. **B,** The biliary confluence has been delivered by lowering of the hilar plate, and the bridge of tissue at the base of the umbilical fissure has been divided.

FIGURE 90B.62. Hepatotomy in the glissonian plane. The left liver (*black arrow*) is separated from the right liver (*small white arrow*). The common bile duct has been transected and is elevated on a tie (*large white arrow*). A sling is passed about the left branch of the portal vein, which is involved by a cholangiocarcinoma just beyond this point, at the confluence of the bile ducts and extending into the left hepatic duct. The hepatic artery is dissected and shown to be free of tumor.

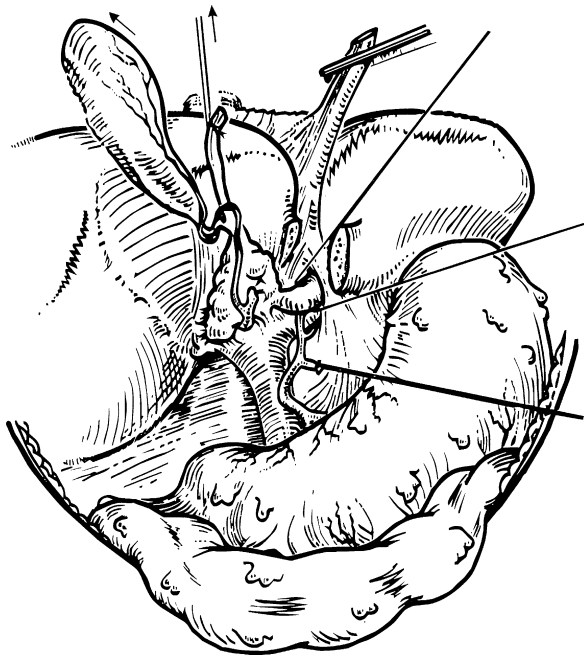

FIGURE 90B.63. The entire extrahepatic biliary apparatus has been elevated, together with the associated connective tissue and nodes, to allow dissection anterior to the bifurcation of the portal vein and elevation of the tumor, which is completely mobilized; the right hepatic artery has been tied and divided, and the portal vein has been skeletonized. The tumor extends into the right liver, and stay sutures are placed in the left hepatic duct.

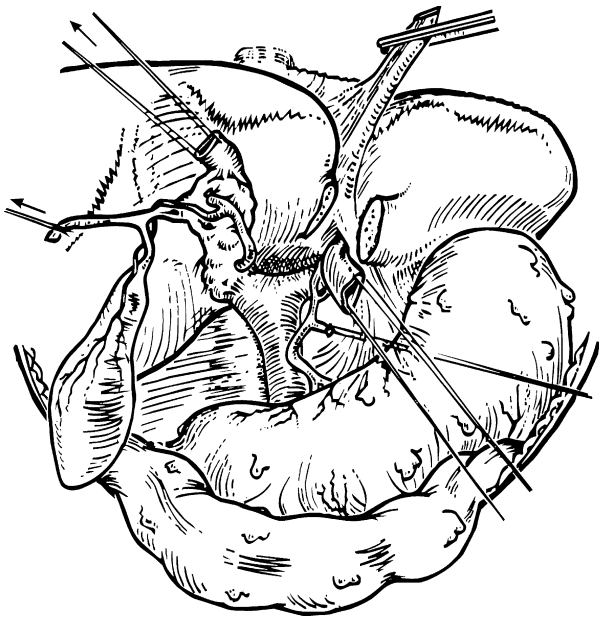

FIGURE 90B.64. The left hepatic duct has been divided, and the bifurcation of the portal vein has been cleared; however, the tumor is still attached to the right portal vein and extends into the right liver. An alternative method would leave the transection division of the bile duct until a later stage, during parenchymal transection.

involve the portal vein or hepatic artery, the lesion can be freed and turned forward. If the caudate lobe is involved, it should be mobilized as described earlier and freed for removal as an integral part of the resection. The left hepatic duct, having been previously mobilized, is now located, dissected, and secured with stay sutures. It is transected, and the specimen side is turned upward toward the right, which provides better exposure of the portal vein and hepatic artery (Fig. 90B.66). Alternatively, if the tumor extends into the left hepatic duct, it becomes necessary to transect the right duct initially and turn it to the left. It is also possible, and often practiced, to dissect the duct but delay transection until the time of parenchymal transection to maximize exposure and gain the most length for duct transection. In any event, when the ductal structures and the tumor are elevated, the relevant hepatic artery can be ligated, and the branch of the portal vein supplying the portion of the liver to be removed can be dealt with by clamping and oversewing in a standard fashion (see Fig. 90B.65A). An endovascular stapler can also be used to divide the portal vein. Hepatic resection proceeds as described previously for parenchymal transection, and the hepatic veins are controlled extrahepatically or within the liver substance (see Fig. 90B.65B).

The second situation is that the tumor may involve the right or left branch of the portal vein, with the area of bifurcation of the portal vein being entirely free. In this circumstance, the procedure is similar to that described earlier with the exception of the fact that transection of the affected portal branch may be difficult because of the proximity of the lesion. In this case, the portal vein transection can be postponed until after parenchymal division is complete to allow the best exposure for portal vein resection and, more importantly, for the reconstruction. If exposure is adequate, the portal vein can also be divided and reconstructed immediately, prior to parenchymal division.

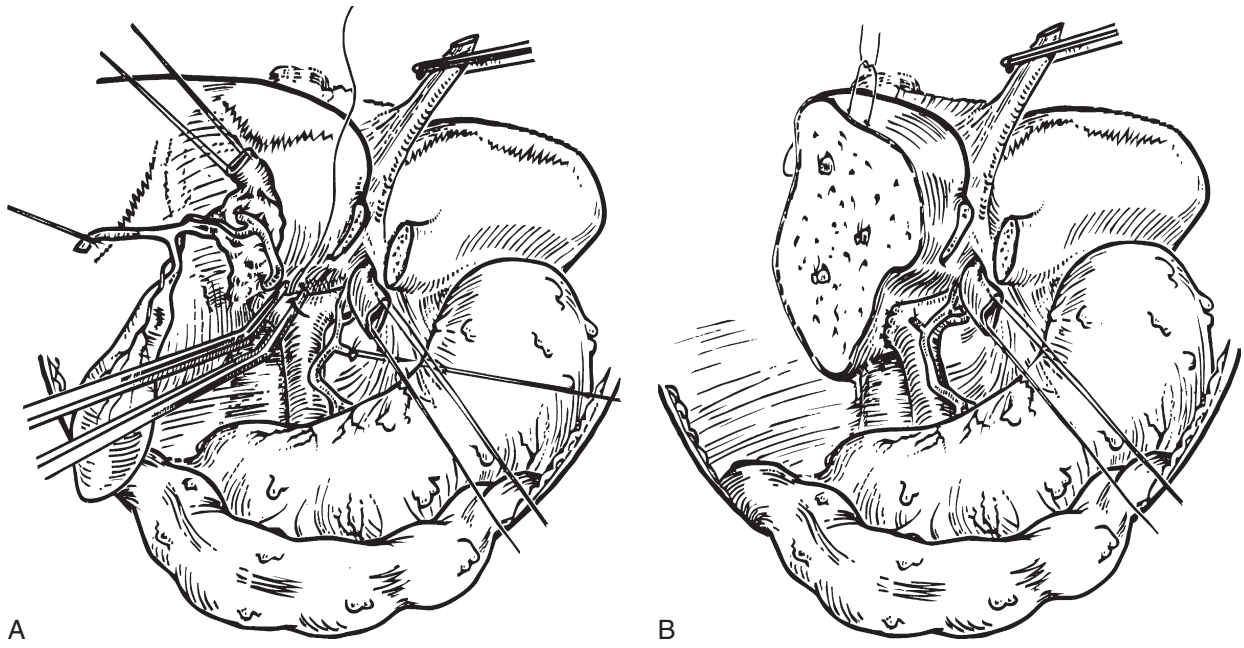

FIGURE 90B.65. **A,** Clamps are applied to the right branch of the portal vein, and a suture is passed through the vein between the clamps before the division of the vein and its subsequent suture. **B,** The right branch of the portal vein has been divided and oversewn using a 3-0 vascular suture. The right liver has been removed together with the attached biliary structures containing the tumor. The left hepatic duct is held on stay sutures, ready for subsequent anastomosis.

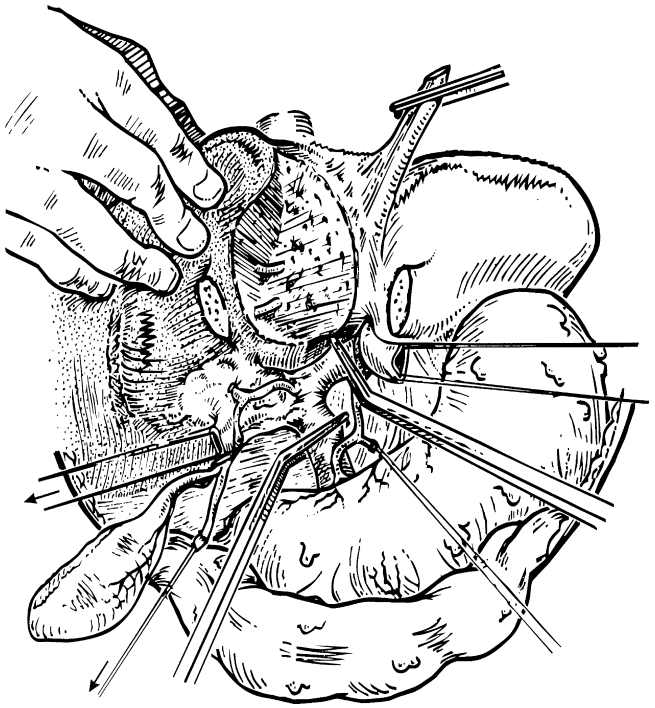

FIGURE 90B.66. Excision of hilar cholangiocarcinoma involving the bifurcation of the portal vein. The tumor is firmly attached to the portal vein. The initial steps are as described in Figures 90B.61, 90B.63, and 90B.64. The left hepatic duct has been identified and transected, and the right hepatic artery has been divided. The main trunk of the portal vein and its left branch have been dissected and are held in clamps; the tumor is firmly attached in the region of the bifurcation of the portal vein. Resection sometimes is facilitated by starting a split of the liver substance immediately to the right of the falciform ligament, dividing the feedback vessels that course to supply the quadrate lobe (segment IV).

In the third situation, the tumor may encroach on the portal vein bifurcation or involve the bifurcation directly. If this situation is encountered, a more extensive procedure is required. If the portal vein bifurcation is involved, and the tumor extends to involve the right ductal system, an extended right hepatectomy proceeds as follows: The common bile duct and gallbladder are mobilized and turned upward as described previously. Lowering of the hilar plate, as described earlier, is done if possible, and the left hepatic duct and the left portal vein are dissected. The right hepatic artery is ligated, but the left hepatic artery is preserved. Stay sutures are placed, and the left hepatic duct is transected. The left branch of the portal vein and its main trunk are cross-clamped (see Fig. 90B.66), and the affected segment of portal vein at the bifurcation is freed and turned to the right together with the medial part of the left hepatic duct (Fig. 90B.67). A direct anastomosis is performed between the main trunk of the portal vein and its own left branch (Fig. 90B.68). This anastomosis allows maintenance of an intact vascular supply to the left lobe.

The extended right hepatectomy proceeds along standard lines as described previously. As mentioned above, the portal vein resection can be postponed until the end of the procedure, after parenchymal transection is complete, to optimize exposure. If necessary, the caudate lobe is removed en bloc with the tumor. Biliary-enteric continuity is restored by fashioning a hepaticojejunostomy with a Roux-en-Y loop of jejunum to the left bile duct stump (see Fig. 90B.68).

Alternative methods for reconstruction of the portal vein using the splenic vein have been proposed (Longmire et al, 1973). An interposition of an autogenous venous graft may be necessary, if a long segment of portal vein is resected. If left hepatectomy is necessary, the principles of the procedure are as described earlier, but portal vein reconstruction may be more difficult.

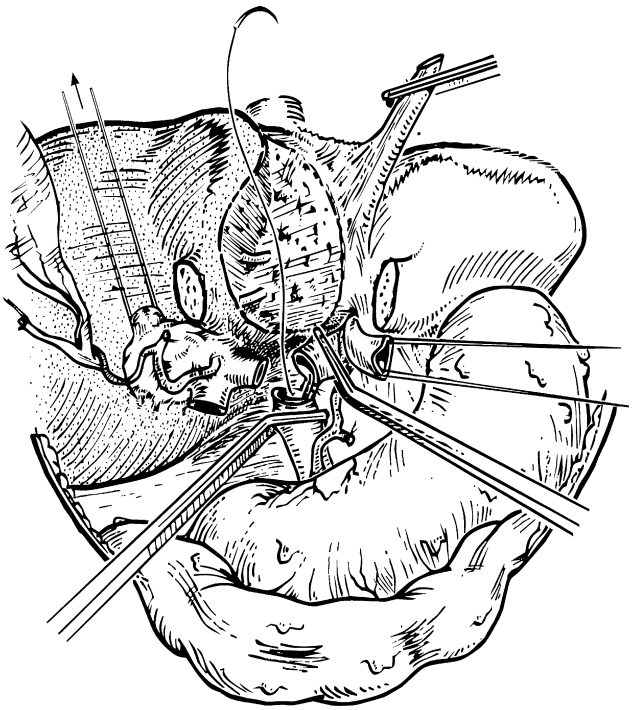

FIGURE 90B.67. The main trunk of the portal vein is divided, as is its left branch. The extrahepatic biliary apparatus, the confluence of the bile ducts, the tumor, and the bifurcation of the portal vein have been separated and are left attached to the right liver. The exposed ends of the main trunk of the portal vein and its left branch are approximated. End-to-end anastomosis is carried out using an over-and-over 4-0 vascular suture. When this anastomosis has been completed, the initial right hepatic lobectomy is completed, leaving a remnant of the liver comprising segments I, II, and III supplied by the left hepatic artery and the left branch of the portal vein and draining through the left hepatic duct. Individual caudate ducts exposed during the resection must be oversewn carefully or individually anastomosed. Alternatively, segment I, the caudate lobe, may be removed.

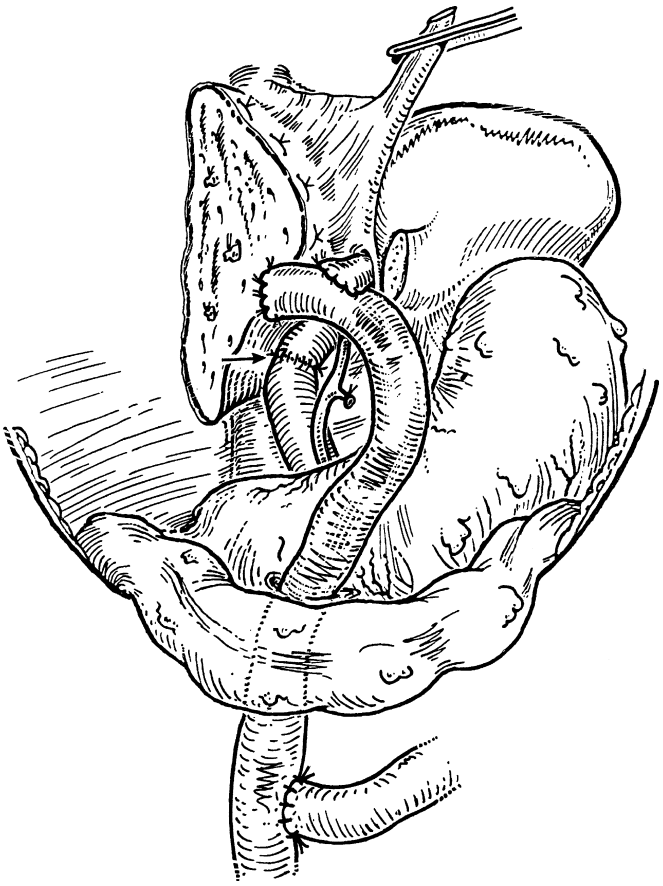

FIGURE 90B.68. The right hepatic lobectomy has been completed, with the line of resection running just to the right of the falciform ligament. The portal vein anastomosis is shown (*arrow*). A Roux-en-Y loop of jejunum is brought up in a retrocolic fashion and is anastomosed to the exposed left hepatic duct (see also Fig. 90B.60B).

In some cases, the division of the intrahepatic right or left hepatic ducts may be delayed until the final phase of parenchymal transection, and many surgeons prefer this approach. The selection of patients with hilar cholangiocarcinoma for liver resection and the results are discussed further in Chapter 50.

CRYOABLATION-ASSISTED HEPATIC RESECTION

Cryoablation, or the destruction of tissues by a freeze-and-thaw process, is a recognized approach to the treatment of malignant tumors (see Chapter 85B). The destruction of hepatic tumors using cryoablation is well described. Most studies (Atkinson et al, 1992; Charnley et al, 1989, 1991; Horton et al, 1991; Onik et al, 1991, 1993; Ravikumar & Steele, 1989; Ravikumar et al, 1987, 1991) report in situ freezing of hepatic tumors, and this is described in detail in Chapter 85B. The use of the cryoprobe as a device to assist during resection also has been suggested (Welling & Lamping, 1990) and developed (Polk et al, 1995).

Cryosurgery is used to assist resection in three particular situations. First, wedge resections, especially for lesions situated on the dome of the liver, are fraught with difficulty, not only regarding control of hemorrhage within the depths of the wedge but also in obtaining tumor-free margins. Wedge resections of the liver have been associated with an extremely high local recurrence rate. A major reason for the positive margin associated with wedge resections is the likelihood of fracturing the specimen along the interface of the hard tumor and soft liver. Freezing a rim of normal hepatic tissue around the tumor prevents fracture along this tumor-liver interface. Second, in many patients, major hepatic resection is required for removal of unilateral lesions, but accompanying minor lesions in the contralateral lobe could be resected if only a small amount of functional hepatic tissue were removed. Third, although cryosurgery has been used in the management of HCC (Zhou, 1992a, 1992b), it has been used in a cryoablative manner. The use of cryoablation-assisted resection in cases of HCC in the cirrhotic liver allows removal of tumors with adequate margins of clearance and maximum preservation of functional parenchyma.

Technique

The liver is examined by bimanual palpation and IOUS using a 7.5-mHz transducer, and lesions suitable for cryoablation-assisted resection are identified. The Glisson capsule is scored with diathermy at the point of insertion of the selected cryoprobe (Fig. 90B.69), which is gently inserted using direct vision

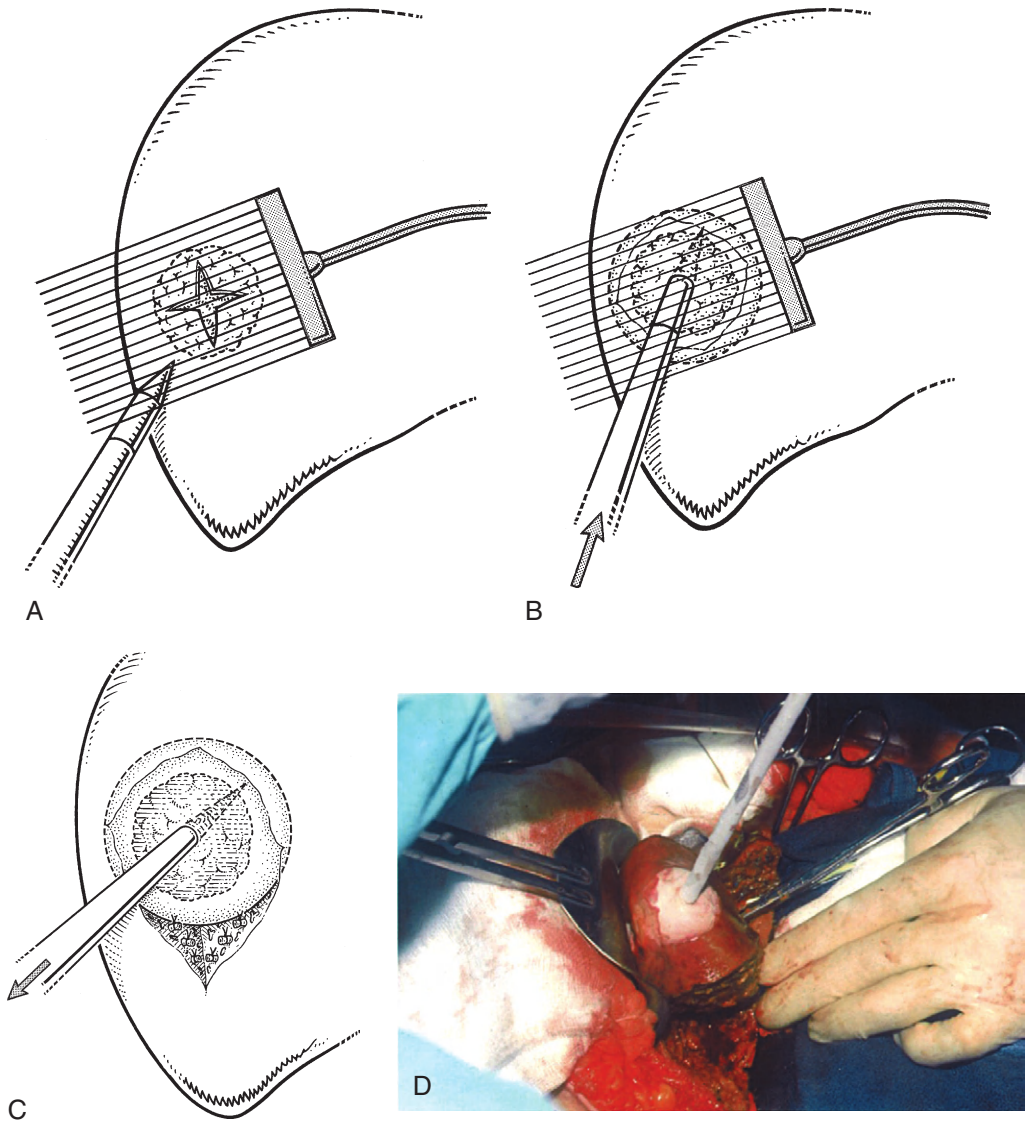

FIGURE 90B.69. **A,** Tumor is located using intraoperative ultrasound (US). The Glisson capsule is scored in cruciate fashion with the diathermy. **B,** The cryoprobe is introduced, and with its position controlled using US guidance, the tumor is frozen to approximately 1 cm of clearance. **C,** The cryoprobe is used as a handle to manipulate the tumor, which is excised at the ice ball's edge. **D,** Intraoperative photograph shows a cryoprobe inserted into a tumor in segment VI. The tumor is being removed using cryoablation-assisted technique.

and guided by US to the center of the lesion to be resected. Laparotomy pads are placed to protect adjacent structures. We occlude vascular inflow (Pringle maneuver) before starting the freeze cycle. Once the freeze cycle is initiated, US is used to monitor freezing. The freeze margin is easily seen as a hyperechoic rim with posterior acoustic shadowing that slowly develops from the center of the lesion. This margin is allowed to reach a distance of approximately 1 cm outside the periphery of the tumor (see Fig. 90B.69). At this point, hepatic vascular inflow occlusion is temporarily released. Two minutes are allowed for reperfusion of the liver after initial freezing, at which time the Pringle maneuver can be reinstituted for resection of the parenchyma. To maintain the ice ball at a constant size during resection, we allow freeze and thaw cycles of 1 minute each during the resection procedure; this cycling prevents extension of the ice ball or inadvertent removal of the probe, which can be used as a gentle handle to manipulate the lesion during resection. Dissection is performed directly on the ice ball or at a slight distance away from it (see Fig. 90B.69C). Traction on the cryoprobe and ice ball complex provides useful exposure to the line of parenchymal transection. Blood vessels are easily visualized, and they are individually controlled as they are encountered. In patients whose tumor approximates a major venous structure, such as the right hepatic vein, preliminary mobilization of the liver from the underlying vena cava and isolation of the right hepatic vein facilitate a safe resection.

The specimen is left attached to the cryoprobe (see Fig. 90B.69D) and is allowed to thaw, at which time it is removed and sectioned to ensure adequate resection margins. If there is doubt as to the adequacy of the margins, a flat cryoprobe may be inserted into the cavity, and further freezing of the relevant margin can be done.

ENUCLEATION OF GIANT HEMANGIOMATA AND OTHER BENIGN LIVER TUMORS (SEE CHAPTER 79A)

The surgical management of giant hemangioma was described in 1942 by Schumaker, and following the advent of noninvasive imaging techniques, interest in the subject has been renewed (Baer et al, 1987, 1992a; Iwatsuki & Starzl, 1988; Schwartz & Husser, 1987). Selective arteriography can give additional information by showing the characteristic patchy pooling of contrast material and by defining the intrahepatic and extrahepatic vascular anatomy, but it is rarely needed because of high-quality CT and MRI demonstrating a characteristic contrast-enhancement pattern.

A technique of enucleation (Alper et al, 1988; Baer et al, 1987, 1992a) is described below that can be applied to the elective management of a symptomatic giant cavernous hemangioma (Fig. 90B.70), ensuring minimal blood loss and the preservation of virtually all normal hepatic parenchyma. We also have used this technique to enucleate hepatic adenomas, fibronodular hyperplasia, and metastatic neuroendocrine tumors. Others (Lerner et al, 2004) have confirmed that this approach offers preservation of normal parenchyma and fewer complications than formal hepatectomy.

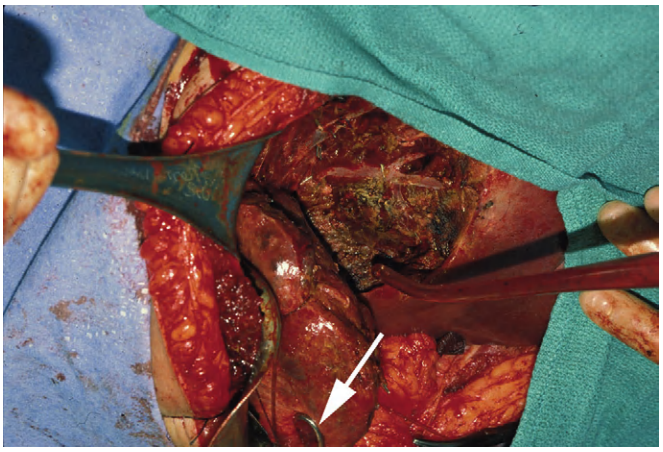

FIGURE 90B.70. Intraoperative photograph shows enucleation of a large hemangioma of the right lobe of the liver. The hemangioma has been compressed and can be manipulated with forceps (*arrow*). It is enucleated from the liver substance, and a major branch of the middle hepatic vein is seen exposed in the depths of the wound. Normal liver tissue is not sacrificed (see Fig. 90B.71).

Technique

The common hepatic artery is identified, and depending on the side of the lesion, the right or left hepatic artery is identified and controlled. Bleeding from the enucleation site is minimized by prior complete extrahepatic vascular control. Ligation of the right or left hepatic artery for a major lesion of the right or left liver is usually adequate; however, for lesions involving segment IV, a more selective dissection to control the relevant vessels within the umbilical fissure may be necessary. Once the arterial inflow is controlled, the lesion usually can be compressed and drained of its blood. As tension in the mass is relieved, it can be clamped to provide traction as the dissection proceeds, which is described later. Inclusion of only a few millimeters of liver tissue at the periphery of the hemangioma is usually the extent of parenchymal dissection required. At this point, a sheath of compressed liver tissue is encountered that defines the border between the cavernous tissue and the normal liver parenchyma. Dissection is now possible by gliding a finger along this plane, following the margin of the lesion and avoiding entry into the liver parenchyma or into the tumor itself; as blood vessels or bile ducts are encountered, they are controlled and divided. They can be controlled with suture ligatures, clips, or a coagulation device. Proceeding in this way, it is possible to shell out the hemangioma from the parenchyma without damage to major vessels or bile ducts (see Fig. 90B.70). The resulting hepatic defect after enucleation can be treated in a variety of ways. Generally, the bleeding from the bed of the hemangioma is minimal and can be controlled using compression and argon beam coagulation. The omentum also may be mobilized and placed over the raw surface as an omentoplasty.

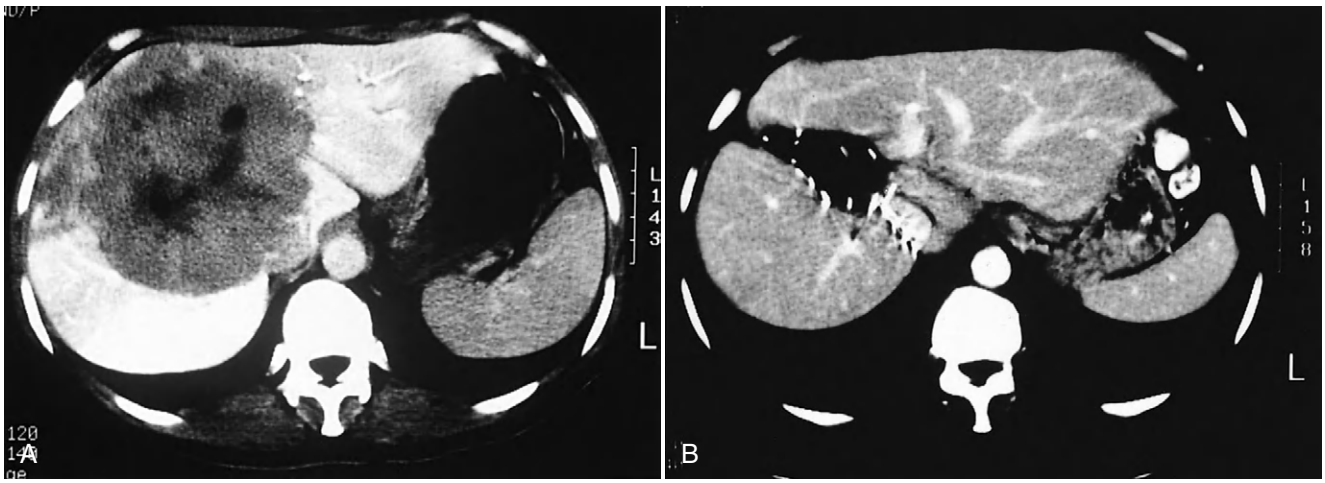

FIGURE 90B.71. A, Computed tomographic (CT) scan shows a large, symptomatic hemangioma within segments IV, V, VI, and VIII of the right liver. This hemangioma was enucleated without loss of any functional liver tissue. The large cavity was filled with an omentoplasty. **B,** CT scan after operation shows no loss of parenchyma.

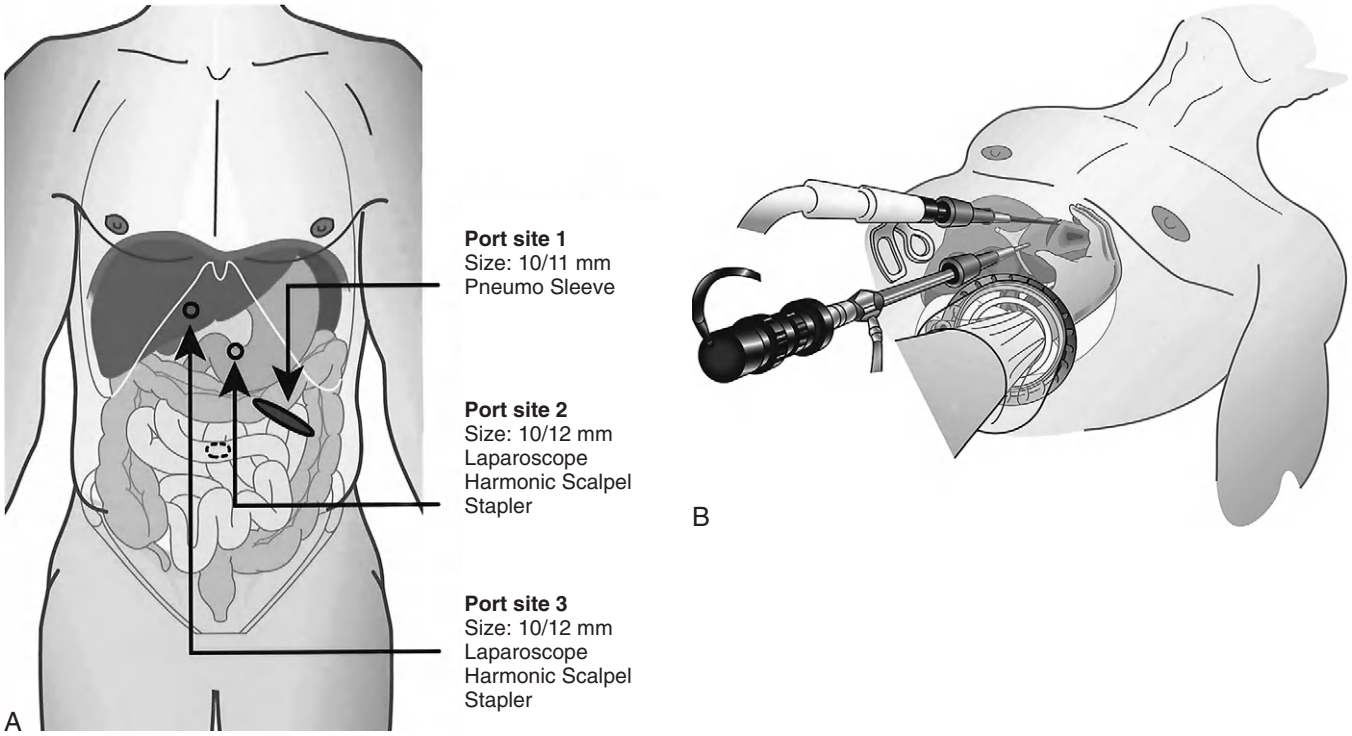

FIGURE 90B.72. **A,** Port placement for laparoscopic left lateral segmentectomy. These are the main ports; additional ports are placed as necessary. **B,** Laparoscopic left lateral segmentectomy. After complete mobilization of the left lateral segment by dividing the left triangular ligament, the liver parenchymal transection is performed using the Harmonic Scalpel (Olympus Key Med) and the vascular endoscopic stapler. The hand is used for retraction and to assess for tumor clearance. A bulldog clamp can be placed across the porta hepatis to provide for the Pringle maneuver.

The technique described allows large hemangiomata to be resected with a limited disruption of the surrounding liver tissue (Fig. 90B.71). The reason this technique of enucleation is possible is that these lesions are usually surrounded by a relatively avascular plane, which can be demonstrated on histology (Baer et al, 1992a). The few blood vessels that do transverse the capsule are controlled during the dissection, and the amount of normal functioning parenchyma removed is minimal. Even when the size of the tumor necessitates removal of most of the right or left liver, the disturbance in liver function is clinically insignificant. This enucleation technique also can be applied to pericystectomy in the operative management of echinococcal cysts, but great care must be taken not to disrupt the cyst contents (see Chapter 68; Fig. 90B.72).

CHAPTER 90C

Extended hepatic resections for biliary tumors: an alternative approach

Tsuyoshi Sano and Yuji Nimura

OVERVIEW

Our recent approach to perihilar cholangiocarcinoma has gradually changed, from the very detailed preoperative percutaneous transhepatic biliary drainage (PTBD), cholangioscopy, and vascular imaging to multidetector-row computed tomography (MDCT) and three-dimensional CT angiography that facilitates sufficient assessment of tumor extension and staging to selective endoscopic nasobiliary drainage (ENBD), only for the future remnant liver. When cholangiography provides insufficient information of the tumor extent, or segmental cholangitis develops, additional PTBD should be applied to the undrained bile ducts. In this chapter we introduce a recently developed "Japanese" extended resection for difficult perihilar cholangiocarcinoma that might differ from the Western approach.

PREOPERATIVE DIAGNOSIS AND MANAGEMENT OF HILAR CHOLANGIOCARCINOMA

Accurate preoperative staging using extensive investigation is indispensable prior to radical resection for hilar cholangiocarcinoma (Nagino et al, 1998; Nimura, 1994, 1997; Nimura et al, 1990a, 1995b, 2000). Most cases of hilar cholangiocarcinoma are associated with jaundice as a result of obstruction of the proximal bile ducts, either within or outside of the liver. Obstruction usually involves multiple ducts as a result of proximal spread of carcinoma along the intrahepatic segmental bile ducts. Multiple applications of PTBD (Nagino et al 1992; Nimura et al 1995a; Takada et al 1976) to relieve the cholestasis and restore the functional reserve of the future remnant liver, we believe, is essential prior to operation involving extensive hepatic resection.

In the third edition of this text, we explained that the first step in the preoperative management of hilar cholangiocarcinoma was PTBD; however, MDCT is taken before biliary drainage to define which side of the liver should be resected, and PTBD applied by the direct anterior approach under fluoroscopic guidance (Takada et al, 1976) or ENBD for the future liver remnant (FLR) are selected to relieve cholestasis of the FLR. This offers both diagnostic and therapeutic advantage (Nagino et al, 1995a), and it minimizes PTBD sessions and the number of PTBD catheters. On the other hand, magnetic resonance cholangiopancreatography (MRCP) is occasionally insufficient to diagnose the difficult local anatomy of the separated intrahepatic segmental and/or sectoral ducts and to design an appropriate operative procedure, especially in patients with Bismuth type III or IV tumors (Bismuth & Corlette, 1975). In such cases, high-quality cholangiograms through the PTBD catheters, taken in various positions—supine, right and left anterior oblique, right and left lateral, and cephalad-anterior-oblique positions (Kamiya et al, 1994)—often clearly demonstrate the tumor location and provide the most reliable information on the proximal extension of hilar cholangiocarcinoma along the intrahepatic segmental bile ducts (Ebata et al, 2002; Sakamoto et al, 1998; Fig. 90C.1).

When cholangiography provides insufficient information on the tumor extent, additional PTBD is performed to the undrained bile ducts. After dilating the sinus tract of PTBD, percutaneous transhepatic cholangioscopy (PTCS) can also provide reliable information on anatomic variations of the biliary tree and mucosal extension of the cancer (Kamiya et al, 1994; Nimura, 1993; Nimura et al, 1989). Superficial mucosal extension of the carcinoma is often associated with polypoid and/or nodular tumors of a macroscopic type (Igami et al, 2009). Thus PTCS or per oral cholangioscopy with biopsy may be valuable in diagnosis of the extent of cancer (Itoi et al, 2000, 2007; Nimura et al, 1988; Sakamoto et al, 1997). On the other hand, coexistence of biliary tract infection negatively affects the functional reserve of the liver. When intrahepatic segmental cholangitis develops, even in patients with PTBD catheters during preoperative period, urgent additional selective PTBD to the affected segmental duct should be performed (Kanai et al, 1996; Fig. 90C.2).

Concomitant vascular resection and reconstruction is indicated in some advanced cases of hilar cholangiocarcinoma (Nimura et al, 1991). We previously performed visceral angiography, percutaneous transhepatic portography, and selective retrograde hepatic venography to assess the vascular invasion of the tumor (Nishio et al, 1999, 2003). Recently, three-dimensional images of MDCT using techniques of volume rendering, multiplanar reformation, and maximum intensity projection have taken over because of the high-quality images and reduced invasiveness (see Fig. 90C.13). We usually estimate the relationship between a tumor and the vascular system in the liver and hepatoduodenal ligament and diagnose the vascular involvement of the tumor on the multiplanar reformatted images; we plan the methods of resection and reconstruction—wedge or segmental resection, direct end-to-end anastomosis, or segmental auto vein grafting—by volume-rendered images and maximum-intensity projection images (Senda et al, 2009; Sugiura et al, 2008).

Postoperative morbidity and mortality rates remain considerable, particularly if extensive resection is necessary (Nagino et al, 2001). Postoperative liver failure sometimes occurs and

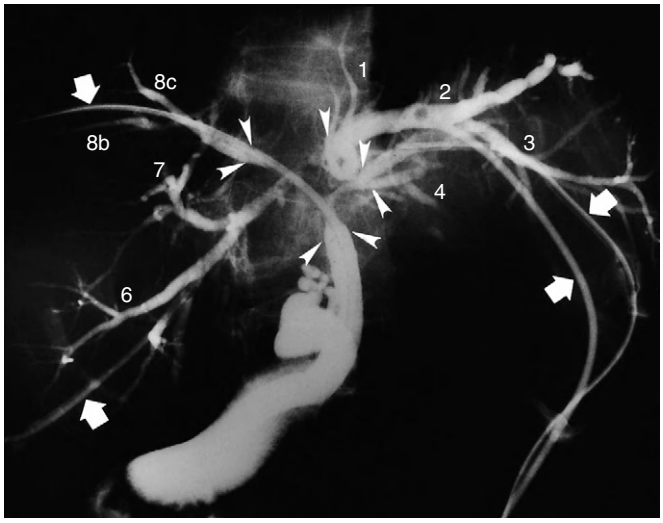

FIGURE 90C.1. A cholangiogram through four percutaneous transhepatic biliary drainage catheters (*arrows*) shows stricture at the hepatic hilum and suggests cancer extension along the intrahepatic segmental bile ducts (*arrowheads*). Numerals refer to the Couinaud's segments of the liver: *8b* is a lateral branch of the right anterior superior segmental bile duct, and *8c* is a dorsal branch of the right anterior superior segmental bile duct.

results in death. For this reason, liver resection is usually scheduled only after the liver has been decompressed and the serum total bilirubin concentration falls below 2 mg/dL. In addition, since 1989, we have routinely performed percutaneous transhepatic portal vein embolization (PVE) (Nagino et al, 1993, 1996, 2000, 2006a) as preoperative preparation for extensive liver resection. This is done to minimize the incidence of postoperative liver failure. After estimation of the resultant compensatory hypertrophy by volumetric CT scan (Nagino et al, 1995b, 1995c) and of the functional reserve of the liver as assessed by the indocyanine green clearance rate (Uesaka et al, 1996), hepatectomy is performed, usually 2 to 3 weeks after PVE. A Japanese series implemented a management strategy for patients with hilar cholangiocarcinoma that consisted of preoperative biliary drainage, PVE, and major hepatobiliary resection; it reported a 0% mortality rate in more than 100 consecutive cases (Sano et al, 2006).

Impaired intestinal barrier function does not recover with PTBD without bile replacement, which can restore the intestinal barrier function during external biliary drainage in patients with biliary obstruction, primarily as a result of repair of physical damage to the intestinal mucosa. Thus, in patients with hilar cholangiocarcinoma and external biliary drainage, we routinely replace bile prior to operation (Kamiya et al, 2004; Kanazawa et al, 2005). Also, perioperative administration of synbiotics can enhance immune responses, attenuate systemic postoperative inflammatory responses, and improve the intestinal microbial environment (Sugawara et al, 2006). These procedures may reduce postoperative infectious complications after major hepatobiliary resection in difficult patients with hilar cholangiocarcinoma.

RIGHT HEPATIC RESECTION WITH TOTAL CAUDATE LOBECTOMY, EXTRAHEPATIC BILE DUCT RESECTION, AND PORTAL VEIN RESECTION AND RECONSTRUCTION

Right hepatectomy with total caudate lobectomy is carried out for tumors involving the right anterior and posterior sectoral bile ducts, with sparing of the left medial segmental bile duct to segment IV, or when the right hepatic artery is also involved (see Chapters 50B and 90B). If the cancer involves the right hepatic duct and the left medial segmental duct, anatomic right hepatic trisectionectomy with caudate lobectomy is indicated (Nagino et al, 2006b).

At operation and after exploration of the peritoneal cavity, PTBD catheters are fixed at the liver surface to maintain intraoperative biliary drainage. The right lobe is often atrophic to some extent, and a faint demarcation between the right and left lobe is observed as a result of the preoperative PVE.

After retropancreatic lymph node dissection, the distal bile duct is divided above the pancreas with a histologic free margin; the hepatoduodenal ligament is dissected, and the vessels are skeletonized and removed (Bhuiya et al, 1992). The middle hepatic artery usually runs ventral to the left portal vein and enters the liver below the left medial segment branch of the portal vein; this artery is carefully preserved. The left hepatic artery enters the liver to the left of the umbilical portion of the portal vein (Figs. 90C.3 to 90C.5).

Following skeletonization of the hepatoduodenal ligament, preparation of the caudate lobe is carried out by isolation, ligation, and division of the arterial branches and portal branches of the caudate lobe. The details of the technique are described above (Figs. 90C.3 to 90C.7; see also Fig. 90C.12). Although the arterial branches directly arise from the left and right hepatic arteries, they cannot be accurately identified in some cases. Two to six branches of the portal vein arise from the left portal vein, two to three branches arise from the right portal vein, and one

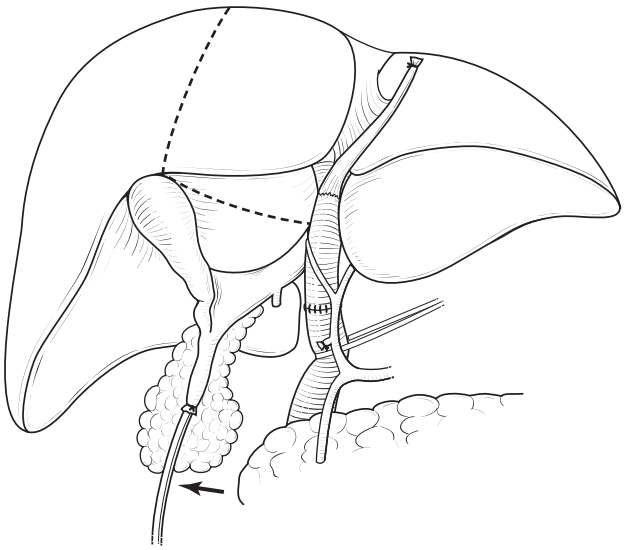

FIGURE 90C.3. A schematic illustration after skeletonization of the hepatoduodenal ligament is shown. A catheter is inserted from the distal stump of the common bile duct for intraoperative biliary drainage (*arrow*).

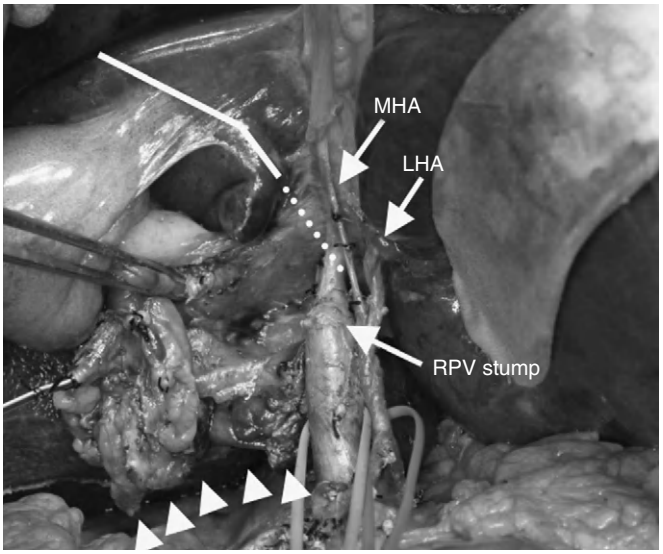

FIGURE 90C.5. Intraoperative image during a right hemihepatectomy with caudate lobe resection showing complete skeletonization of the hepatoduodenal ligament. Regional lymph nodes and connective tissues (*arrowheads*) are dissected en bloc. The transection line of the liver parenchyma (*solid line*) and the resection point of the left intrahepatic ducts (*dotted line*) are shown. The right portal vein (*RPV*) is transected at its origin with transverse suture closure. MHA, middle hepatic artery; LHA, left hepatic artery.

to two branches arise from the main trunk or the bifurcation of the portal vein.

The significance of total caudate lobectomy in cases of hilar cholangiocarcinoma is, of course, not resection of the parenchyma of the caudate lobe but clearance of the connective tissue of the hilar plate around the caudate bile duct branches, which are often involved by cancer (Nimura et al, 1990). After complete division of the caudate arteries and portal vein branches, the right hepatic lobe is mobilized, and short retrohepatic veins are ligated and divided. The caudate lobe is completely detached from the inferior vena cava (IVC) as described above, and the confluence of the right hepatic vein (RHV) with the IVC is carefully encircled, clamped, divided, and closed with a running suture or a vascular stapler.

In case of direct cancer invasion of the portal bifurcation, portal vein resection and reconstruction is performed prior to liver resection (Figs. 90C.8 to 90C.12). Direct end-to-end anastomosis of the main trunk of the portal vein and the left branch is carried out (Ebata et al, 2003; Nimura et al, 1991;

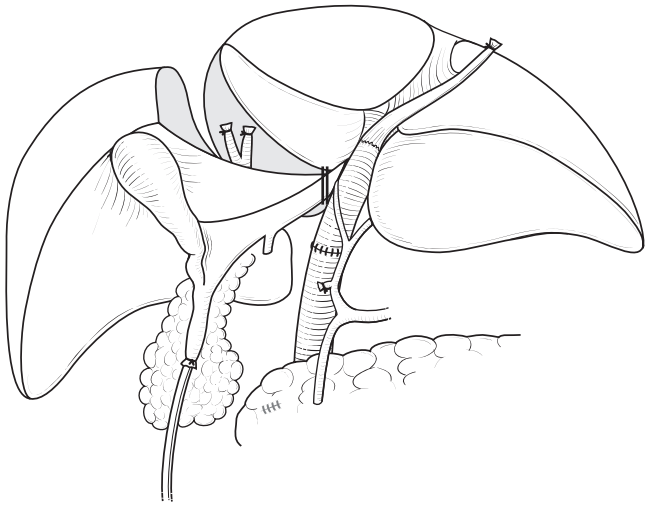

FIGURE 90C.4. A schematic illustration just prior to resection of the left intrahepatic sectoral ducts. The right liver and caudate lobe are extracted to the right side. The resection line is indicated by *double lines.*

FIGURE 90C.6. An intraoperative view of a right hemihepatectomy with caudate lobe resection depicts a view just prior to bile duct resection. The *dotted line* shows resection point of the left intrahepatic sectoral ducts.

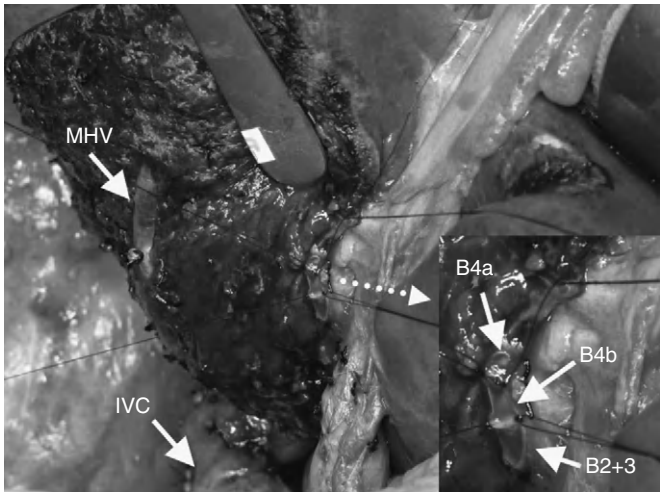

FIGURE 90C.7. Intraoperative view after right hepatectomy with total caudate lobectomy; extrahepatic bile duct resection is demonstrated. Hepaticoplasty is done for left hepatic segmental and/or subsegmental ducts. B4a, transected inferior branch of the left medial segmental bile duct; B4b, transected superior branch of the left medial segmental bile duct; B2+3, the left lateral sectoral bile duct; IVC, inferior vena cava; MHV, middle hepatic vein.

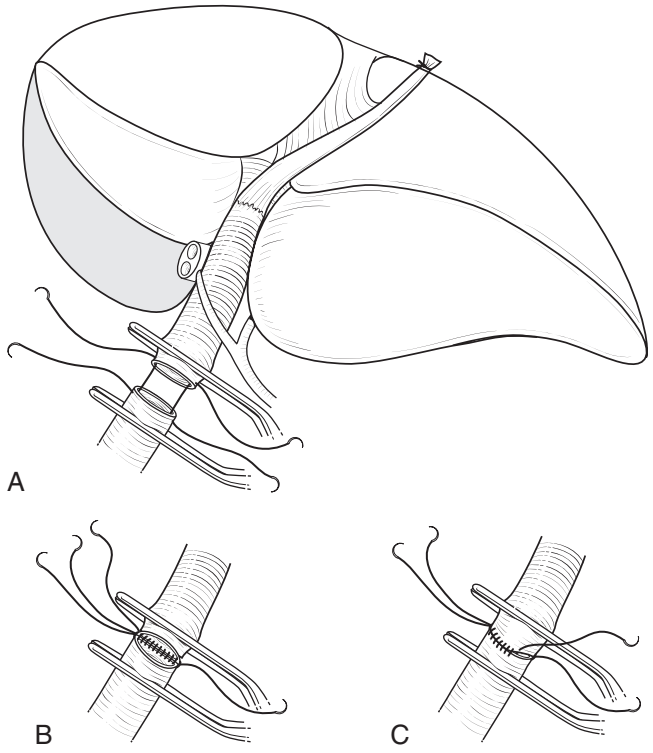

FIGURE 90C.8. Schematic illustration of portal vein resection and reconstruction by end-to-end anastomosis during right hepatectomy. After stay sutures are placed at both edges (**A**), the intraluminal technique is used for the posterior wall suture (**B**), and over-and-over sutures are placed for the anterior wall (**C**).

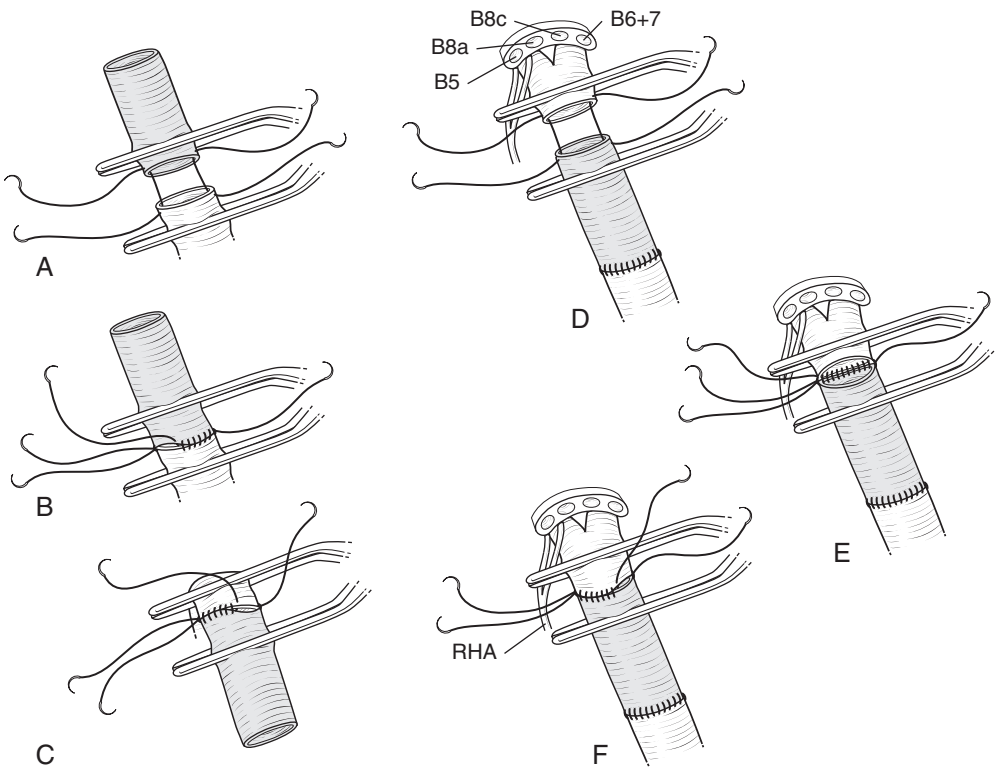

FIGURE 90C.9. Schematic illustration of portal vein resection and reconstruction using a right external iliac vein graft during left hepatic resection. First, the distal anastomosis between the right portal vein and the graft is performed using an over-and-over technique for both sides with 6-0 prolene. Next, stay sutures at both edges are placed, and the proximal side anastomosis between the vein graft and the main portal vein is performed with intraluminal technique for the posterior wall suture; an over-and-over technique is used for the anterior wall with 6-0 or 5-0 prolene. RHA, right hepatic artery.

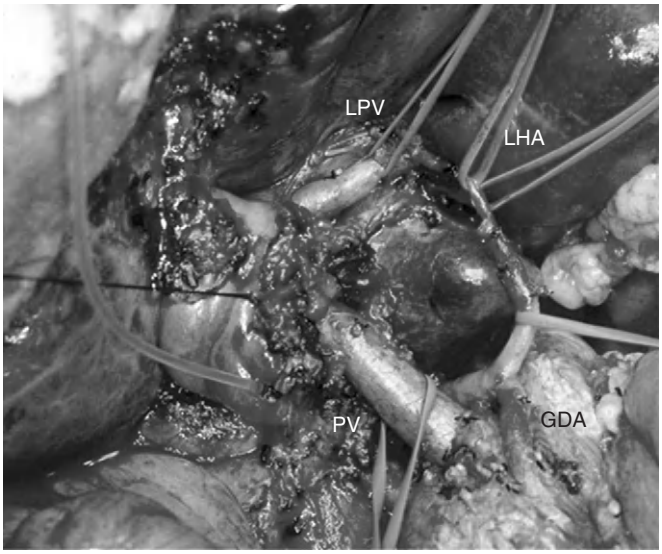

FIGURE 90C.10. An intraoperative image during a right hemihepatectomy shows tumor involvement of the portal vein. LPV, left portal vein; LHA, left hepatic artery; PV, main portal vein; GDA, gastroduodenal artery.

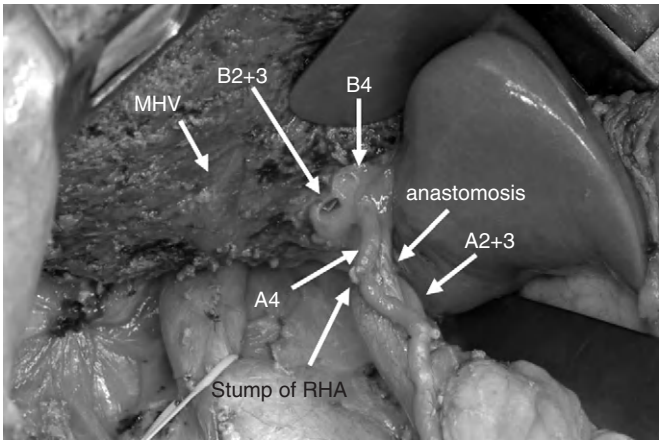

FIGURE 90C.12. Intraoperative image after a right hepatectomy with total caudate lobectomy, extrahepatic bile duct resection, and portal vein (PV) resection and reconstruction. The PV reconstruction is done by end-to-end anastomosis. The left medial hepatic artery (*A4*) originates from the right hepatic artery, which has been divided. B2+3, transected left lateral segmental bile duct; B4, transected left medial segmental bile duct; A2+3, left lateral sectoral hepatic artery; MHV, middle hepatic vein; RHA, right hepatic artery.

see Chapter 91B). Portal vein resection and reconstruction is carried out during the hilar dissection prior to hepatic parenchymal transection, because the portal flow to the FLR is easily impeded as a result of kinking during operative manipulations. Direct end-to-end anastomosis between the main portal trunk and the left portal vein is usually possible during right-sided resections (Kondo et al, 2003). On the other hand, interposition of an autogenous vein graft is often required during portal vein reconstruction, between the right portal vein and the main trunk during left-sided resections (Figs. 90C.9 to 90C.15). We usually harvest an external iliac vein for an autogenous vein graft by an extraperitoneal approach. The key to portal vein resection and reconstruction during right-sided hepatectomy is the feasibility of cross clamping the root of the umbilical portion of the left portal vein. In the case of left hepatectomy, isolation and clamping of the right posterior sectoral and/or the right anterior sectoral portal vein are key maneuvers.

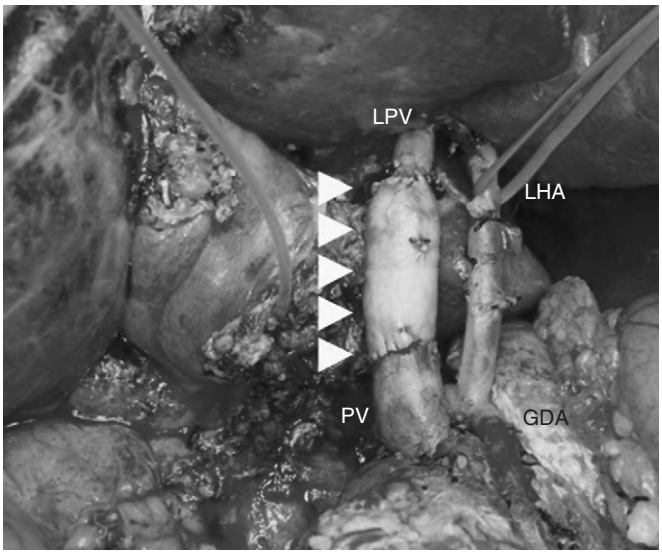

FIGURE 90C.11. Intraoperative view during a right hemihepatectomy shows portal vein resection and reconstruction with an external iliac vein (*arrowheads*). In many cases of right hepatobiliary resection, portal vein (*PV*) resection and reconstruction with or without an interposition graft is performed prior to liver parenchymal transaction. LPV, left portal vein; LHA, left hepatic artery; GDA, gastroduodenal artery.

After confirmation of the course of the middle hepatic vein (MHV) using intraoperative ultrasonography, liver transection is performed along the demarcation line that appears after ligation of the right hepatic artery. On the caudal aspect of segment IV, the liver transection line is horizontally advanced approximately 1 cm ventral to the hilar plate to achieve a free surgical margin. When the MHV is exposed, liver transection is reduced toward the left, lateral to the distal portion of the ligamentum venosum. When the caudodorsal aspect of the MHV is completely exposed, the confluence of the MHV and IVC is seen. At this point, the caudate lobe can be turned and pulled ventrally from behind the left lateral segment. Finally, the bile duct is transected after placing a stay suture, and the right hepatic lobe is resected en bloc with the entire caudate lobe, portal bifurcation, and extrahepatic bile duct. The transected bile duct stumps, left medial sectional branch (segment IV), left lateral anterior sectional branch (segment III), and left lateral posterior sectional branch (segment II) are noted just to the right of the umbilical portion of the left portal vein (see Fig. 90C.7).

Bilioenteric continuity is reestablished using a Roux-en-Y jejunal loop. In our fashion, the jejunal limb is brought to the transected hepatic ducts via the retrocolic-antegastric or the retrocolic-retrogastric route (Nagino et al, 2002). We perform hepaticojejunostomy in one layer using a 5-0 absorbable monofilament suture; a biliary drainage tube is placed across all anastomoses either through the jejunal loop and/or transhepatically (Nagino et al, 2007).

FIGURE 90C.13. FIGURE 90C.15. Intraoperative view after an extended left hepatic resection with total caudate lobectomy, extrahepatic bile duct resection, and portal vein resection and reconstruction. The vessel loop is around the right posterior sectoral artery. An autologous graft using the right external iliac vein is demonstrated. The right posterior superior (*B7*) and the right posterior inferior (*B6*) segmental bile ducts are divided separately above the reconstructed portal vein. RHV, right hepatic vein; RAHA, right anterior hepatic artery; A6, right posterior inferior segmental hepatic artery.

EXTENDED LEFT HEPATIC RESECTION, CAUDATE LOBECTOMY, EXTRAHEPATIC BILE DUCT RESECTION, AND PORTAL VEIN RESECTION AND RECONSTRUCTION

Extended left hepatic resection with caudate lobectomy is used for hilar cholangiocarcinoma, which predominantly involves the left intrahepatic bile ducts in continuity with the duct to the right anterior section (see Chapters 50B and 90B). During the subhepatic dissection of the hepatoduodenal ligament, the left hepatic artery and middle hepatic artery, if present, are ligated and divided at their origins, and the right hepatic artery is carefully isolated up to its bifurcation into the anterior and posterior sectoral branches. Then the anterior sectoral branch and caudate lobe branches of the right hepatic artery are ligated and divided. Mobilization of the gallbladder provides a good operative view of the right posterior pedicle. The left portal vein is ligated and divided, followed by division of the right anterior branch of the right portal vein and caudate lobe branches arising from the main portal trunk and right portal vein. If cancer invasion of the portal bifurcation or the right portal vein is observed, combined portal vein resection and reconstruction is usually performed after liver transection for left hepatectomy or before liver transection in some cases of right hepatectomy. The caudate lobe and segment II and III are mobilized to the right, and the short retrohepatic caudate veins are ligated and divided, beginning on the left caudally and progressing cranially. When the confluence of the ligamentum venosum and the left hepatic vein (LHV) or IVC is displayed, the ligament is ligated and divided. The LHV and MHV are divided and closed with a running suture or a vascular stapler. The caudate lobe and the left lobe are then completely detached from the IVC.

Subsequently, the liver is transected along a demarcation line in the right portal scissura between the right anterior and right posterior sections. The course of the RHV is confirmed ultrasonographically. After parenchymal transection, the RHV should be exposed on the raw surface of the liver. The plane of the liver transection courses between the right posterior superior section (segment VII) and the right portion of the caudate lobe and begins from the sulcus on the right side of the caudate process and advances cranially along the right margin of the IVC. Finally, the right wall of the IVC is clearly exposed (Fig. 90C.16; see also Fig. 90C.15).

The right posterior sectoral bile duct is exposed cranially to the right portal vein and is divided so as to obtain histologically free margins. Finally, vascular clamps are placed distally and proximally to the involved portal bifurcation: the distal clamp is placed obliquely to adjust the caliber of the distal portal vein to the transversely transected main portal trunk, and the specimen is resected en bloc, including the entire caudate lobe, the involved segment of the portal vein, and the extrahepatic bile duct. The portal vein reconstruction between the main portal trunk and the right posterior sectoral portal branch is then performed (see Fig. 90C.16), and an interposition graft of autogenous vein is often necessary (see Fig. 90C.15).

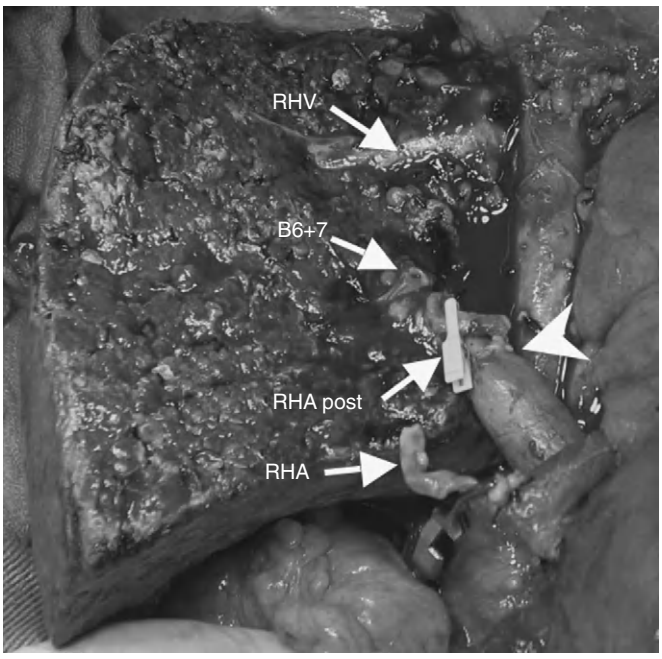

FIGURE 90C.16. Intraoperative image after extended left hepatic resection, caudate lobectomy, extrahepatic bile duct resection, and combined simultaneous resection of the right hepatic artery (*RHA*) and portal vein (PV). End-to-end anastomosis between the main PV and the right posterior sectional branch is accomplished (*arrowhead*). A posterior branch of the right hepatic artery (*RHA post*) and the proximal part of the RHA are cross-clamped with vascular clips. B6+7, stump of the right posterior sectoral bile duct; RHV, right hepatic vein.

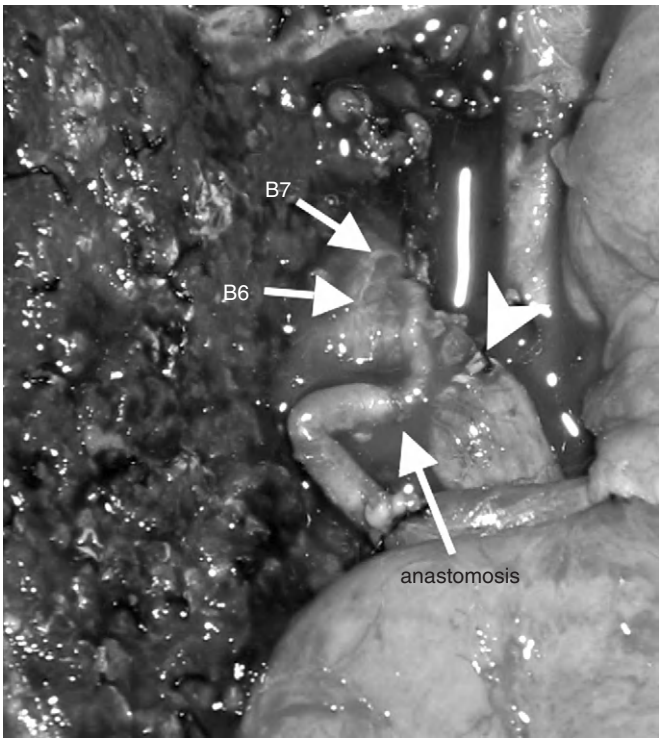

FIGURE 90C.17. Hepatic arterial reconstruction is through an end-to-end anastomosis between the proximal right hepatic artery and the posterior branch of the right hepatic artery with microscopic vascular techniques. The *arrowhead* shows the end-to-end anastomosis of the portal vein reconstruction. B6, stump of the right posterior inferior segmental bile duct; B7, stump of the right posterior superior segmental bile duct.

In some locally advanced cases, combined resection and reconstruction of the right hepatic artery with an end-to-end anastomosis is a requisite to achieve a negative margin (Fig. 90C.17; see also Fig. 90C.16). Microsurgical techniques are used for arterial reconstruction with or without using right gastroepiploic artery or radial artery as an interposition graft (Sakamoto et al, 2006). When arterial reconstruction is impossible, one potential countermeasure is creation of an arterioportal shunt to prevent possible leakage of the hepaticojejunostomy, liver abscess, and fatal liver failure (Kondo et al, 2004). Oblique-to-side anastomosis is performed between the common hepatic artery and the main portal vein. Three weeks after surgery, transcatheter arterial embolization of the common hepatic artery is carried out to prevent further portal hypertension. It must be remembered, however, that the development of liver failure or an abscess in the remnant liver are not eliminated by arterioportal shunting.

CHAPTER 90D

Hepatic resection for living donor transplantation

See Ching Chan and Sheung Tat Fan

OVERVIEW

Donor hepatectomy is a major surgical operation performed on a healthy subject only for the benefit of a recipient, who requires liver transplantation (see Chapter 97A). In 1989, Strong (1999) performed donor left hepatectomy and removed segment IV of the liver on the back table prior to implantation of segments II and III into a pediatric recipient. In 1990, Tanaka and coworkers (Yamaoka et al, 1994) used a right liver graft to transplant a pediatric recipient. Living donor left liver transplantation (LDLT) for adults was first performed by Makuuchi in 1993 (Hashikura et al, 1994). The first case of right liver adult LDLT was performed by Fan in 1996 (Lo et al, 1997a). A priori, the right liver graft included the middle hepatic vein (MHV) to address the problems of small-for-size syndrome by providing good venous outflow of the right anterior sector. The first seven recipients who underwent right LDLT all had acute liver failure before the transplantation; one died from candidiasis and the other six survived (Lo et al, 1997b). Subsequently, semiurgent and elective cases were accepted.

DONOR WORKUP

Donor workup is started after indication for LDLT for the potential recipient is ascertained. The workup is to evaluate whether the donor will be psychologically and physically healthy in the long-term after recovery from the organ donation. In a stepwise fashion, expedience is achieved without omission (Chan et al, 2007a). Only healthy individuals who have reached the age of consent are accepted (Abecassis et al, 2000).

Step 1

A detailed medical history is taken to identify any comorbidities. A body mass index of 30 kg/m^2 or more (27 kg/m^2 for Asians; World Health Organization, 2004) raises the concern for fatty liver– and obesity-related comorbidites. Blood group compatibility is verified. Hepatitis B and C virus and HIV carrier status preclude liver donation, although hepatitis B core antibody positivity by itself does not preclude liver donation, it mandates lifelong prophylaxis with lamivudine in the recipient (Lo et al, 2003).

Step 2a

A psychologic assessment is performed to verify the potential donor's knowledge of the operation to be performed and coping skills. The donor should have adequate knowledge of donor and recipient morbidity, mortality, and survival and should be apprised of the urgency of the transplant.

Step 2b

Chest radiographs are taken, and an electrocardiogram is performed. Computed tomography (CT) of the liver under sodium bicarbonate cover (Merten et al, 2004) is also performed, and maximum-intensity projections of the portal veins and hepatic veins are produced. Volumetry of the donor liver by the Heymsfield method (Heymsfield et al, 1979) measures the volumes of the right liver and left liver (for pediatric recipients, segments II and III), using the MHV as a demarcation line on the plane between the right and left livers (Fig. 90D.1). Attenuation of the liver parenchyma in comparison with the spleen on the plain film is appraised for detection of fatty change. Hepatic vein anatomy is determined by the axial cuts in the venous phase and by maximum-intensity projections for easier appreciation. The presence of any inferior hepatic veins allows anticipation at the operation of either preservation or division. Attention to the presence of the segment IVb hepatic vein or segment III hepatic vein draining into the MHV calls for a more caudal division of the MHV to preserve adequate drainage of segment IV of the remnant left liver (Chan et al, 2004a). The right, left, and segment IV hepatic arteries are also illustrated by the three-dimensional (3D) reconstructions for the images obtained during the arterial phase.

Step 3

Liver biopsy is performed in selective donors and after genuineness and suitability of the potential donor is ascertained. Steatosis of up to 15% for right liver donors and 20% for left liver donors are acceptable.

Step 4

Informed consent is obtained from the donor and the donor's relative. Donor and recipient morbidity and mortality are stated explicitly.

SIDE AND SIZE OF GRAFT

The graft to standard liver volume ratio (Urata et al, 1995) is crucial in LDLT. A ratio of more than 35% is required for a predictable recipient success (Fan et al, 2003a). However, a 20% overestimation of the right liver graft size based on CT volumetry is commonly given a conversion factor of 1.19 g/mL

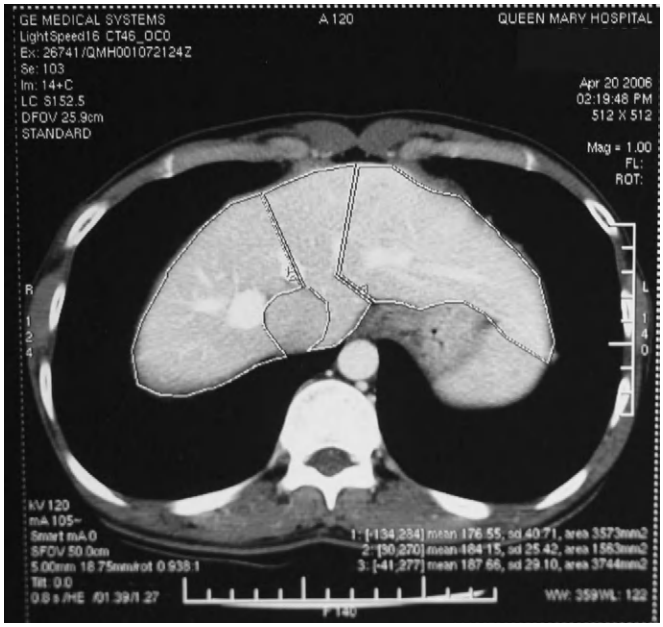

FIGURE 90D.1. Volumetric analysis of the donor liver on computed tomography.

(Chan et al, 2006a). Because the left liver is usually one third the size of the total liver, for a donor with a body size no larger than the recipient, the left liver is usually less than 35% of the recipient standard liver volume. For an individual with a larger left liver/right liver ratio, the left liver may be large enough. It is worth noting that in left LDLT, a gram-to-gram equivalence of graft is not applicable, and a left liver graft of the same size as the right is less efficacious (Chan et al, 2007b).

For right liver donation, the liver donor should have a remnant left liver of at least 30% of the total liver volume. For a pediatric recipient, a liver graft of 3% of the body weight is optimal; however, the graft size is lowered to 2% of the body weight for older children and teenagers because a graft of more than 5% of the body weight predisposes to hypoperfusion. In such cases, graft reduction to even a monosegment may be necessary.

DONOR RIGHT HEPATECTOMY (SEE CHAPTER 98B)

Exposure

The donor is placed supine on the operating table with care to avoid pressure sores over the occiput, heels, and sacrum. The position of the donor must be optimal for the surgeon and his first assistant to face the operative field directly, unhindered by the metal bars of the upper hand retractor or those used to set up a fence between the surgeon and anesthetist (Fan, 2007). Access is gained through a right subcostal incision with upper midline extension. The ligamentum teres is ligated and divided, and the falciform ligament is taken down. The two curved blades of the Bookwalter retractor (Codman and Shurtleff, Raynham, MA) pull the rib cage laterally and anteriorly to open up the aperture made by the costal margins. Excising the xiphoid process may improve access to the suprahepatic inferior vena cava (IVC) and the roots of the hepatic veins. Following careful laparotomy, intraoperative ultrasonography (IOUS) is performed to study the junction of the middle and left hepatic veins with the IVC. The relation of the segment IVb hepatic vein to the MHV, already known from CT, is ascertained by IOUS. This also registers the flow characteristics of the hepatic arteries, portal veins, and hepatic veins for reference throughout the operation.

Isolation of Major Vessels and Parenchymal Transection

The triangle of Calot is dissected, and the cystic artery is divided between ligatures. The gallbladder is dissected from its fossa, and the cystic duct is cannulated with a 3.5-Fr Argyle catheter (Tyco Healthcare, Mansfield, MA). The cystic duct is then severed at the site of insertion of the catheter for delivery of the gallbladder. Next, the peritoneum overlying the right hepatic duct (RHD) is divided for identification. A large metal LigaClip (Ethicon Endo-Surgery, Cincinnati, OH) is put on the liver capsule at the planned line of division of the RHD, 3 to 4 mm away from the duct confluence. The biliary anatomy is then demonstrated by operative cholangiogram with undiluted contrast under fluoroscopy with a C-arm. The image quality of the cholangiogram can be improved by temporary and gentle occlusion of the distal common bile duct with an atraumatic vascular clamp (Featherlight Bulldog Clamp; Geister, Tuttlingen, Germany) (Fig. 90D.2). To avoid devascularization of the donor distal common bile duct, care must be taken not to dissect more tissue than necessary for application of the clamp; the clamp must be removed once the cholangiogram is finished. The supine donor will have the right posterior sectoral duct demonstrated first, followed by the right anterior sectoral duct and then the left ducts (Fan et al, 2002). The parallax technique executed by rotation of the C-arm to the right clarifies the

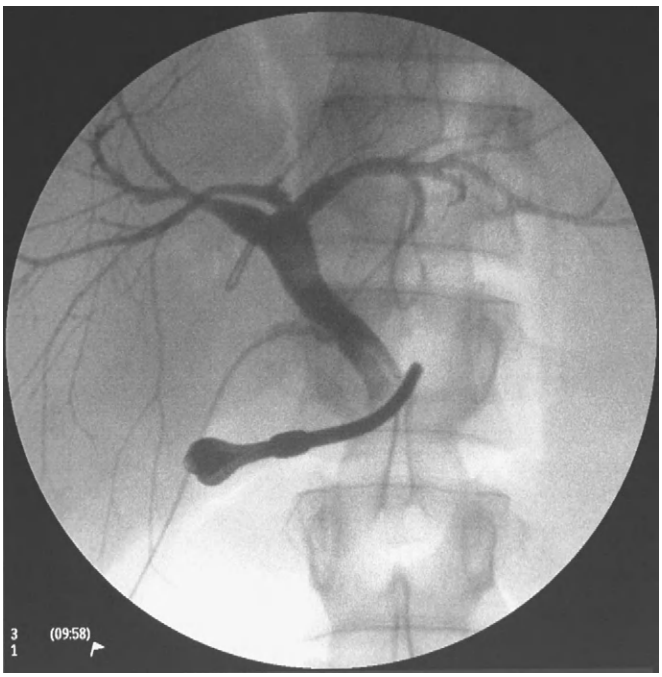

FIGURE 90D.2. Operative cholangiogram with metal clip marking the planned line of division of the right hepatic ducts.

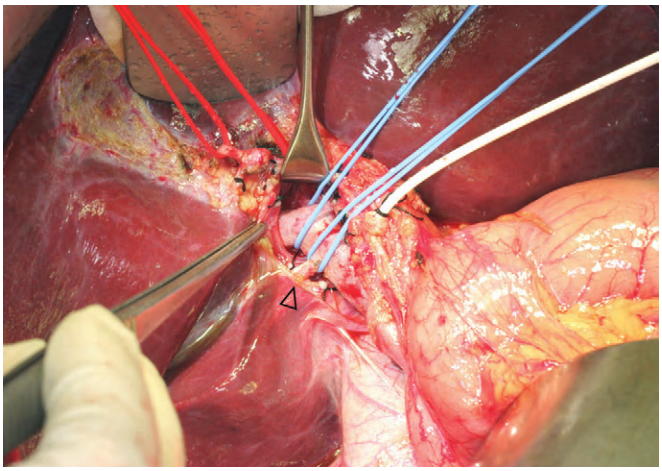

FIGURE 90D.3. Hilar dissection with isolation of the right hepatic artery and right portal vein. The branch of portal vein supplying segment VI was preserved (*arrowhead*).

anteroposterior position of the right anterior and posterior sectoral ducts. This also provides the true anteroposterior view of the biliary system. A marking is made with reference to the LigaClip on the liver capsule with diathermy for the line of division of the RHD.

Hilar dissection is continued to isolate the right hepatic artery and right portal vein. The space between the right hepatic artery and right hepatic duct should not be disrupted in order to preserve the blood supply to the latter. To gain an entire length of the right portal vein, branches to the caudate lobe are ligated and then divided. It is important to note that a sizeable branch from the right portal vein may represent vessels supplying segment VI, which should be preserved (Fig. 90D.3). Temporary right liver inflow control is performed (Fig. 90D.4A) to mark the line of transection along Cantlie's line (Fig. 90D.4B) with electrocautery. The line on the inferior surface is just to the left of the gallbladder fossa, joining the planned line of division of the right hepatic duct marked earlier.

The right triangular ligament is then taken down, leaving the Gerota fascia intact. In a normal donor liver, the right adrenal gland can often be freed from the liver with careful dissection using electrocautery. Minor bleeding from the right adrenal gland is controlled by the argon beam coagulator, and more severe bleeding is addressed by plication with sutures. Short hepatic veins on the right side of the midline of the IVC are divided between ligatures and plicated as required. Inferior right hepatic veins (RHVs) larger than 5 mm are preserved for anastomosis with the IVC in the recipient (Fig. 90D.5).

In contrast to hepatectomy for neoplasm (see Chapter 90), continuous inflow control during liver transection is not practiced. Although the Pringle maneuver with intermittent reperfusion of the liver, which is adopted by some centers, has been shown to result in less blood loss in the donors, the difference did not reach statistical significance (Imamura et al, 2002). Possible explanations to this are that bleeding from the hepatic vein tributaries is not controlled by inflow control, and there is bleeding during the 5-minute reperfusion interval. Another potential advantage of the Pringle maneuver is downregulation of the apoptosis pathway by ischemic preconditioning for grafts with a long cold ischemic time (Clavien et al, 2000); however,

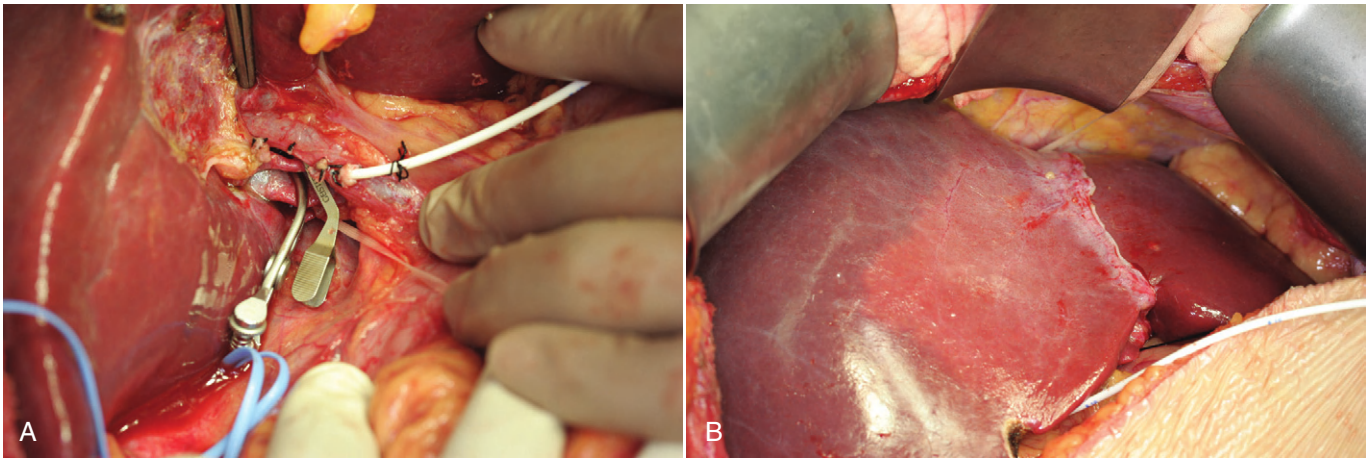

FIGURE 90D.4. **A,** Temporary hemiinflow control with vascular clamps applied to the right hepatic artery and right portal vein. **B,** Cantlie's line is revealed after temporary hemiinflow control.

this has been associated with poorer initial graft function by a prospective trial in deceased donor liver procurement (Azoulay et al, 2005). For adult LDLT, prolonged cold ischemia should not be an issue, because graft delivery matches the explantation of the native liver. In addition, a low central venous pressure (CVP) can be attained through good rapport with the anesthetist, and this lowered pressure has been proven effective in reducing blood loss (Jones et al, 1998). Elevating the head and the trunk by 10 to 15 degrees and complete muscle relaxation of the donor are also helpful.

After mobilization of the right liver from its posterior attachments, a full-thickness suture at the liver edge on both sides of this line helps open up the transection plane by the weight of hemostats. The placement of the laparotomy pad behind the right liver renders the transection plane more vertical, but not excessively so, to compromise retraction of the liver during transection. Liver parenchymal transection is started with electrocautery for the first 1 to 2 cm of parenchyma between segments V and IVb. The rest of the liver transection is done using the Cavitron Ultrasonic Surgical Aspirator (CUSA; Valleylab, Boulder, CO); it exposes the left side of the MHV, which lies two thirds of the depth from the superior surface of the liver (Fan et al, 2000). At a frequency of 23 kHz, the CUSA is set at an amplitude of 60% for the normal donor liver, and irrigation with normal saline continues at around 4 to 6 mL/min. The liver parenchyma is disrupted by cavitation of the aerosol. When the dissector is set at lower amplitudes, there is a tendency for the operator to bring the instrument into direct contact with the liver parenchyma, which will damage small and friable vessels. Suction is set to a moderately high level, just enough to provide a clear operative field. Electrocautery incorporated into the CUSA allows diathermy of vessels less than 1 mm in diameter. Should the segment IVb hepatic vein insert into the MHV, transection is stopped to preserve this vein for adequate drainage (Chan et al, 2004a).

At the liver hilum, the right portal pedicle containing the right hepatic duct is also dissected with minimal use of the CUSA. To denude the right hepatic duct from its blood supply, the dissection should not be overdone. The line of division already marked and verified by operative cholangiogram is followed, and any right hepatic ducts are severed with scissors tangential to the transection plane, which is often quite horizontal. The right hepatic duct stump is repaired by 6-0 polydioxanone continuous suture, and an operative cholangiogram is performed to confirm the patency of the left and main bile ducts (Fig. 90D.6). Liver parenchyma dorsal to the MHV and the caudate lobe are transected, until the IVC is exposed. Lifting up of the caudate lobe with a cotton-tape or a right-angled forceps facilitates the transection, and care must be taken to dissect in a definable plane between the liver capsule and the IVC.

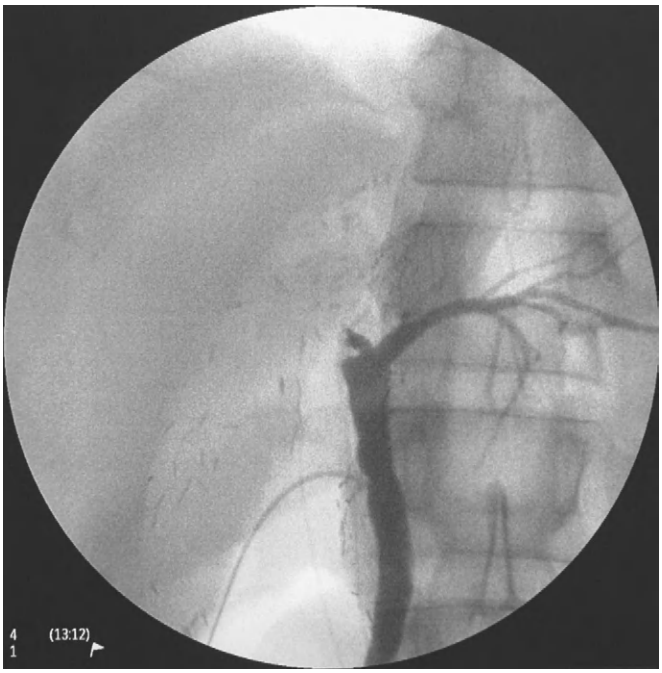

FIGURE 90D.6. Operative cholangiogram confirms patent left and main ducts.

Graft Delivery

To have short cold ischemic time, the graft is not delivered until the recipient is ready for explanting of the native liver. Graft delivery starts with application of a clamp onto the proximal right hepatic artery, distal to the segment IV hepatic artery. The right hepatic artery is then divided with scissors, and the right portal vein is divided between the vascular clamps, applied at a right angle to the course of the main portal vein. The MHV, RHV, and, if present, the inferior RHV are controlled with the vascular stapler (TA 30; Tyco Healthcare) prior to its division by scissors. To avoid stricture of the portal vein, the right portal vein stump is sutured in a transverse manner with 6-0 Prolene continuous back-and-forth sutures. Biliary leakage and patency of the remnant left hepatic duct are checked with intraoperative cholangiogram and dilute methylene blue instillation; the methylene blue in the bile ducts must be flushed away by normal saline. The cystic duct is ligated with 2-0 Vicryl, and the remnant left liver is maintained in the anatomic position by reconstitution of the falciform ligament with nonabsorbable sutures (Fig. 90D.7). Patency of the vessels is verified with IOUS. The hepatic flexure of the colon and the corresponding portion of the greater omentum are allowed to ascend into the right subphrenic space for prevention of adherence of the small bowel

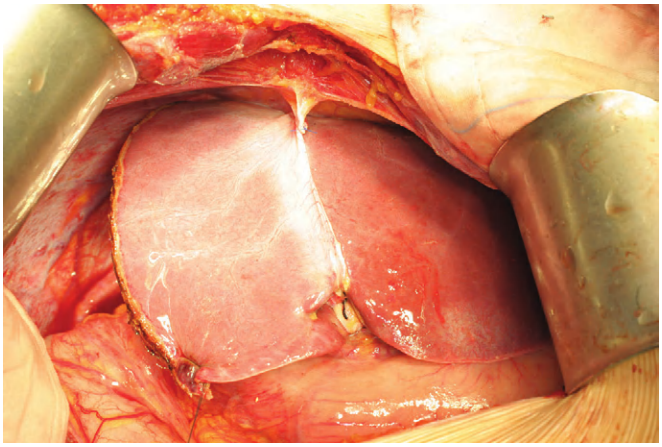

FIGURE 90D.7. Remnant left liver is prevented from dropping into the right subphrenic space by suturing the falciform ligament.

to the transection surface of the remnant left liver, and the abdomen is closed without drainage (Liu et al, 2005).

The outcomes of donor right hepatectomy including the MHV have improved with accumulation of experience. In our consecutive series of 200 donor right hepatectomies, all including the MHV, the operation time was shortened, and blood loss decreased with maturity of these techniques (Chan et al, 2007c).

INCLUDING THE MIDDLE HEPATIC VEIN

An area of ongoing controversy in right LDLT is whether or not to include the MHV. Deleterious effects of no drainage to segments V and VIII include severe venous congestion and necrosis of these segments (Lee et al, 2001). The decision to exclude the MHV requires demonstration of collaterals between segment V and VIII tributaries and the RHV (Cescon et al, 2002).

Researchers at Kyoto University devised an algorithm that includes the MHV when the graft is MHV dominant, or the graft to recipient weight is less than 1%, and in all cases, the remnant left liver is larger than 35% (Tanaka & Yamada, 2005). Chang Gung Memorial Hospital includes the MHV when the graft to estimated standard liver volume is 50% or less, or when the segment V and VIII hepatic veins are large, and the RHV is small (de Villa et al, 2003). Researchers at Tokyo University observed congestion of segments V and VIII of the graft after temporary clamping of the right hepatic artery before determining venous interpositional grafting (Sano et al, 2002).

We include the MHV in all right liver grafts for the simplicity and familiarity of the technique (Fan et al, 2003b). Irrespective of the venous drainage pattern of segment IV of the remnant left liver, the segment IVb hepatic vein is preserved. Utmost care is needed for its preservation, when it drains into the MHV (Chan et al, 2004a). On the back table, the outflow capacity is guaranteed by venoplasty of the MHV and RHV into a single cuff (Liu et al, 2003). The venoplasty is further marked by a more expedient hepatic vein to the IVC anastomosis and higher outflow capacity of the right liver graft (Liu et al, 2003).

In summary, adequate graft size and quality, excellent venous outflow, and moderate portal inflow are the keys to the success of LDLT.

DONOR LEFT HEPATECTOMY

For a donor with a low body mass index, an upper midline incision can provide adequate access for the procedure. The left coronary ligament is taken down, and adequate mobilization of the left liver requires division of the ligamentum venosum or Arantius ligament between ligatures. The left hepatic duct, which may have a short extrahepatic course, is marked by a large metal clip, and the planned line of division is verified by cholangiogram under fluoroscopic guidance. Special attention is given to identify an insertion of the right posterior sector duct into the left hepatic duct (Fig. 90D.8). In this situation, the left hepatic duct can only be divided to the left of the right posterior sectoral duct. The middle hepatic artery should be preserved, when it arises from the left hepatic artery. A middle hepatic artery that is not large and arises from the right hepatic artery can usually be sacrificed, and segment IV will be supplied adequately by collaterals from the left hepatic artery. A replaced left hepatic artery arising from the left gastric artery allows a good length of isolated artery (Fig. 90D.9). Temporary inflow control of the left hepatic artery and portal vein by the vascular clamp reveals the Cantlie line. Liver transection is to the right of the MHV by CUSA. A low insertion of the segment VIII hepatic vein into the MHV calls for caution in the final part of the liver transection; this segment VIII vein should be preserved for venous outflow of the right anterior sector of the remnant right liver, and inadvertent damage of the vein results in torrential bleeding. When compared with donor right hepatectomy also including the MHV, blood loss is more significant, and the operation time is longer; these are likely the results of a larger liver transection surface (Chan et al, 2007b).

FIGURE 90D.8. Operative cholangiogram with a large metal clip marking the planned line of division of the left hepatic duct.

SEGMENT II AND III DONOR HEPATECTOMY

By and large, exposure and hilar dissection are similar to donor left hepatectomy. Following isolation of the left hepatic artery and the left portal vein, an operative cholangiogram is performed with a large metal clip to mark the planned line of division of the left hepatic duct. Special attention still must be paid to the location of the right posterior sectoral duct, which may insert into the left hepatic duct. If the middle hepatic artery that supplies segment IV arises from the left hepatic artery, and enough length is distal to it, it can be preserved; otherwise, it is sacrificed, and the entire left hepatic artery is included in the graft. A middle hepatic artery that arises from the right hepatic artery is most favorable and need not be isolated. The liver transection line is about 1 cm to the right of the falciform ligament. The pedicles supplying segment IV are isolated, ligated, and plicated before division, whereas the caudate lobe is often not included into the graft, because the upper abdomen of the recipient often has limited space. The caudate vessels and bile ducts are ligated and divided and plicated if necessary.

ANATOMIC ANOMALIES OF THE DONOR (SEE CHAPTER 1B)

Besides inadequacy of size and proportion of the donor liver, occasional anatomic anomalies of the donor liver may preclude liver donation. When a major segmental branch of the right portal vein arises from the left portal vein intrahepatically, both right and left hepatectomy become too hazardous for the donor, so such a finding contraindicates donation. On the other hand, in the case of trifurcation of portal vein branches, if these are extrahepatic, donor operation is still feasible (Fig. 90D.10A); however, the right anterior and posterior branches of the portal veins require venoplasty to conform into a single cuff prior to graft implantation (Fig. 90D.10B). If the two branches are too short to merge into one, the portion of the recipient's portal vein at the bifurcation can be used as an interpositional graft, using the recipient portal vein (Fig. 90D.10C). These are done on the back table. The segment III or IVb hepatic vein could at times drain into the MHV (Fig. 90D.11A and B); however, MHV to RHV venoplasty is still feasible (Fig. 90D.11C).

Biliary tract anomalies occasionally render a liver graft unsuitable, as in the case of multiple small branches in the graft (Liu et al, 2004).

LIVER GRAFT BACK-TABLE PROCEDURE: PERFUSION AND TRIMMING

To shorten the cold ischemic time, the right liver graft is not delivered until the recipient is almost ready for graft implantation. Once delivered, the graft is flushed with three times the graft volume of a cold solution of histidine-tryptophan-ketoglutarate (HTK; Dr. Franz Köhler, Chemie GmbH, Alsbach-Hähnlein, Germany), while being immersed in an ice-sludge basin on the back table. The right portal vein is cannulated and adapted to the vein wall with fingers and not ligature (Fig. 90D.12A; Chan et al, 2004b). The right liver graft with separate right anterior and posterior portal veins requires simultaneous flushing with two cannulae (Fig. 90D.12B). The right hepatic artery is flushed with 100 drops of HTK solution through a 21-Fr angiocatheter by gravity (Fig. 90D.12C). Inadvertent damage to the artery intima can result in unrecoverable graft loss. The right anterior and posterior sectoral ducts are also flushed with cold HTK solution to minimize duct damage during preservation. The graft is weighed and transferred to another basin with cold HTK solution. Venoplasty of the MHV with the RHV of the graft is then performed (Liu et al, 2003). Even though the MHV and the RHV are often at a distance of

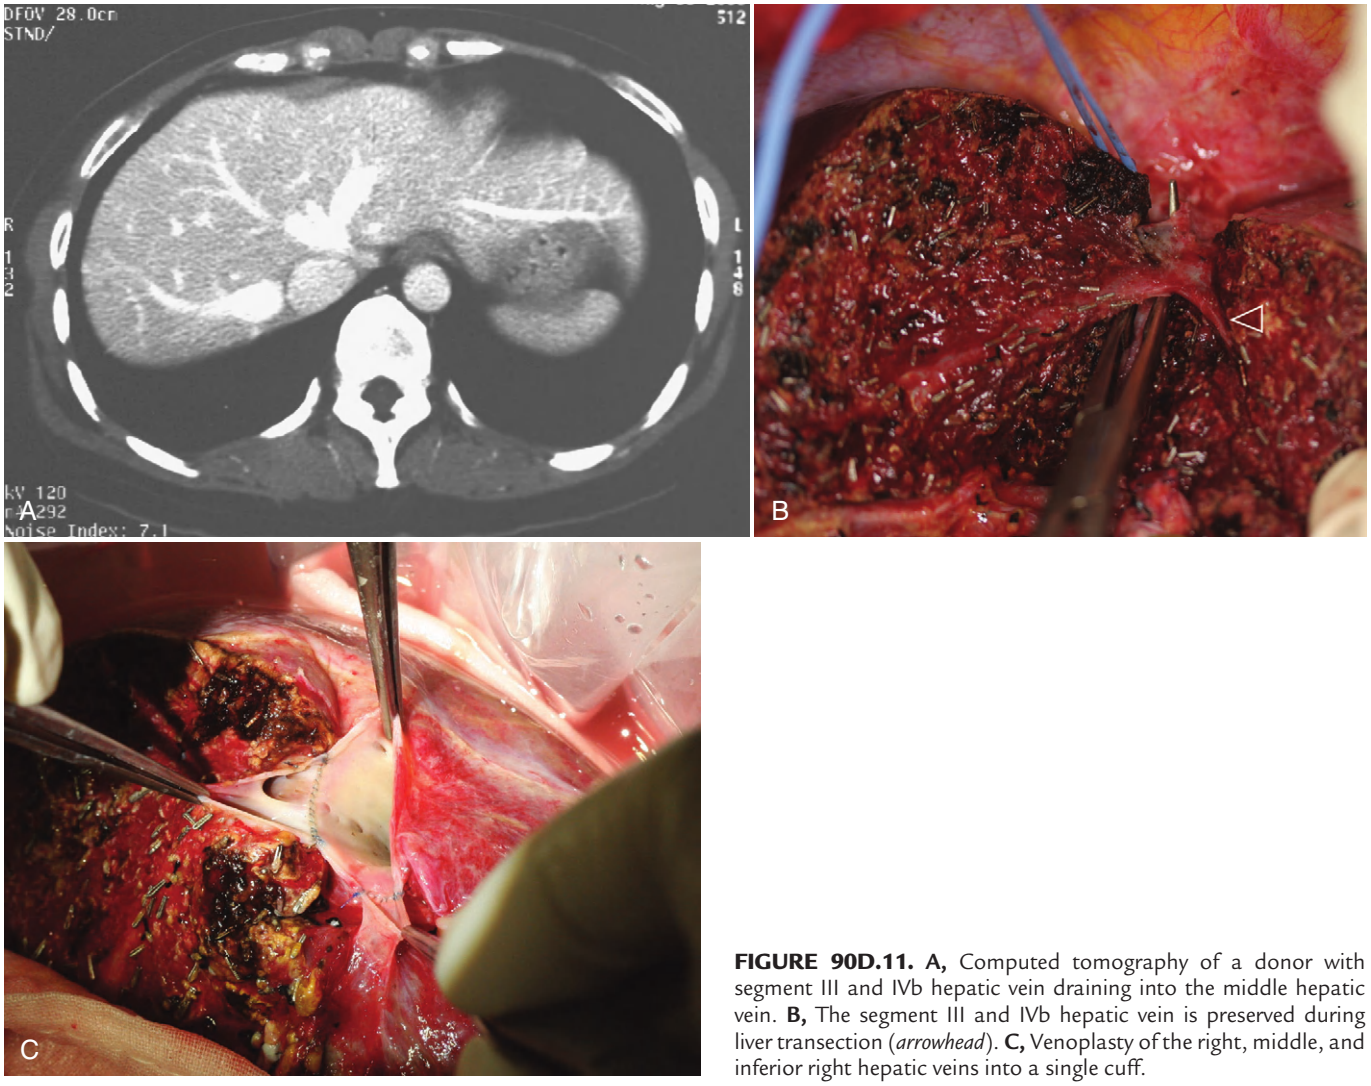

FIGURE 90D.11. A, Computed tomography of a donor with segment III and IVb hepatic vein draining into the middle hepatic vein. **B,** The segment III and IVb hepatic vein is preserved during liver transection (*arrowhead*). **C,** Venoplasty of the right, middle, and inferior right hepatic veins into a single cuff.

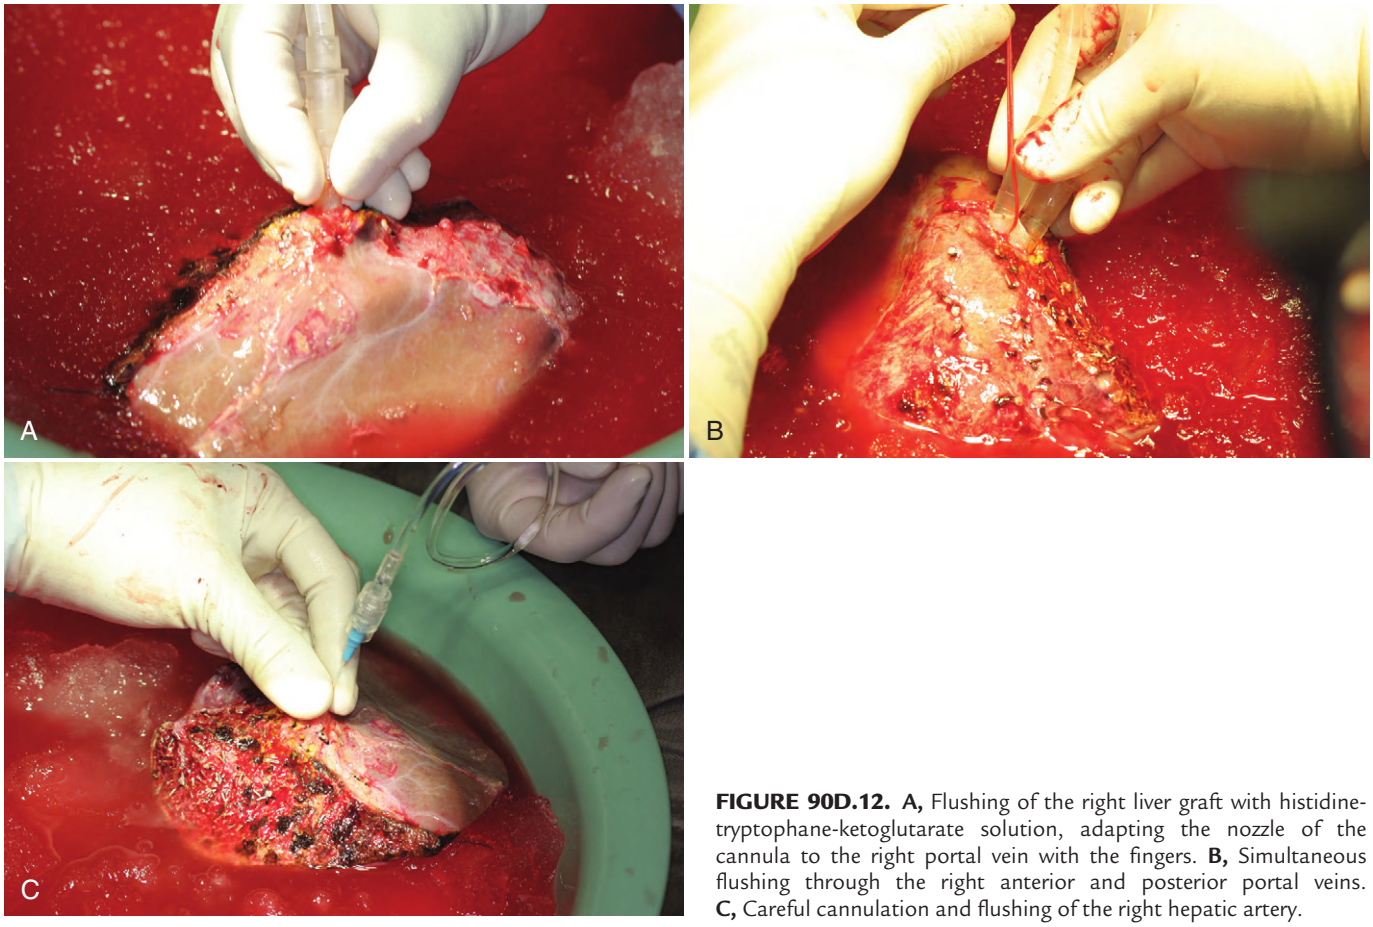

FIGURE 90D.12. A, Flushing of the right liver graft with histidine-tryptophane-ketoglutarate solution, adapting the nozzle of the cannula to the right portal vein with the fingers. **B,** Simultaneous flushing through the right anterior and posterior portal veins. **C,** Careful cannulation and flushing of the right hepatic artery.

up to 2 cm (Fig. 90D.13A), they can be drawn together for fashioning of a single venous cuff (Fig. 90D.13B; Chan et al, 2005). Often misled by planar schematic drawings, some have a false perception of the inadequate length of the MHV wall portion of the venoplasty for anastomosis to the IVC. In practice, the IVC—which is tubular, with a venotomy made over the RHV stump—faces the venoplasty of the MHV and RHV. The portion of the recipient IVC, in between the RHV and MHV, also makes up for the deficit in length on the MHV not included in the graft to preserve the segment IVb hepatic vein for venous drainage of the remnant left liver of the donor.

For the left liver graft and the segment II and III graft, if the MHV and the segment II and III vein are separate, they are merged into an equilateral triangle with a single cuff with an

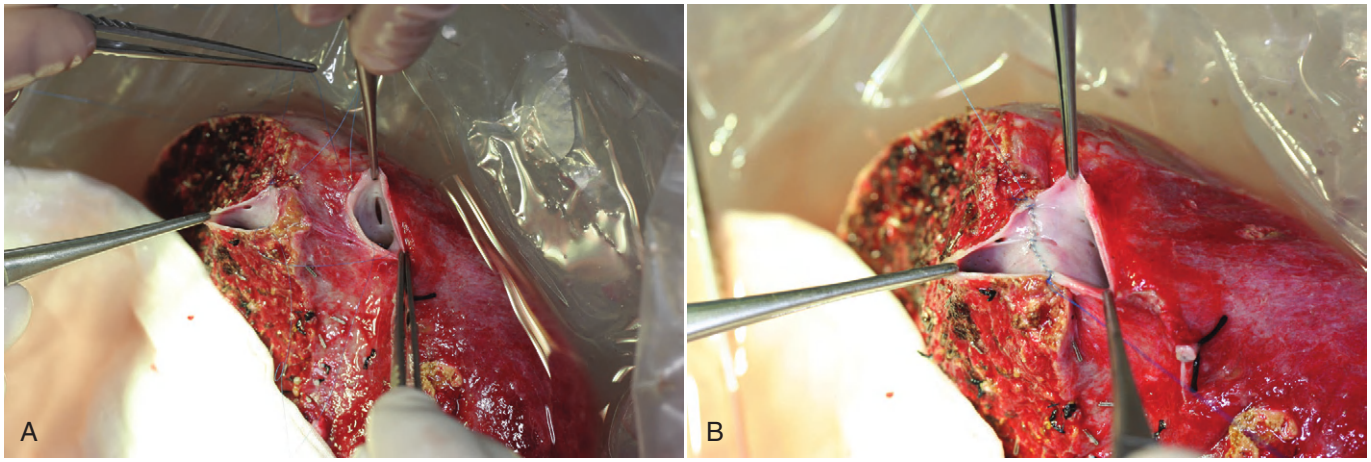

FIGURE 90D.13. A, Right and middle hepatic veins with a significant distance. **B,** Merging of the right and middle hepatic veins into a single triangular cuff with little tension.

apex point to the left by venoplasty. This facilitates hepatic vein to IVC anastomosis in the recipient.

The graft is weighed, and the weight is recorded. The percent of graft to standard liver volume is calculated, and the graft is then immersed in ice sludge.

DONOR POSTOPERATIVE CARE

Donor hepatectomy, both right and left, is a major surgical procedure undertaken on a healthy volunteer. Meticulous postoperative care is the least that can be offered by the health care profession. Postoperatively, the donor is transferred to the intensive care unit for close monitoring of hemodynamics and respiratory function. Early mobilization and institution of chest physiotherapy lower the risks of deep vein thrombosis and chest infection. The donor will also receive a 6-week course of proton pump inhibitor for peptic ulcer prophylaxis (Chan et al, 2007c). Females on hormone replacement therapy and those taking oral contraceptives require aggressive prophylaxis against deep vein thrombosis.

DONOR MORTALITY AND MORBIDITY

Donor safety is fundamental to LDLT (see Chapter 98B). As the application of LDLT has been extended from the child to the adult, and from using the left liver to using the right, the dilemma between recipient success and donor risk has come to the spotlight. The reported overall complication rate of donors is around 20% but has been reported as high as 67% in one series (Beavers et al, 2002). A unified system of complication reporting (Dindo et al, 2004) may narrow this range. Although even one donor mortality is too many, there are at least 19 known donor deaths (Trotter et al, 2006). The estimated mortality for donor right and left hepatectomy is 0.1% and 0.5% respectively (Barr et al, 2006), although mortality is lower in a multicenter series in Japan (Hashikura et al, 2009). In achieving a 5-year recipient survival rate of 80%, it takes one donor life to save 160 recipients. Less tangible are the quality of life changes of the donor in comparison to the predonation state (Chan et al, 2006b). The long-term biologic consequences of donor hepatectomy are not fully known. Nevertheless, decreases in white cell count, platelet counts, and elevation of liver transaminases are demonstrable even 2 years after right liver donation (Chan et al, 2006c).

CONCLUSION

Donor mortality after LDLT remains a reality; however, by lowering the donor mortality and morbidity and improving recipient survival, the justification of LDLT becomes stronger. Donor hepatectomy is a major surgical operation on a healthy person who does not require operation, and it is thus an ethical challenge, and this procedure was once viewed by the medical community and society with caution and skepticism (Cronin et al, 2001; Strong, 1999; Surman, 2002). Donor procedures can only be partially justified by the benefit to a recipient who has no other treatment options. Our common ground is the commitment to provide care of the highest standard to the living liver donor and to perform donor operations in experienced centers (Malago et al, 2001). This is the only way to maintain the highest quality and to decrease donor mortality and morbidity.

CHAPTER 90E

Minimally invasive techniques in hepatic resection

Michael D. Kluger and Daniel Cherqui

OVERVIEW

Over the latter portion of the twentieth century, liver surgery has rapidly progressed from a risky procedure to a safe therapy for benign and malignant liver disease. As with many surgery disciplines, minimally invasive approaches were pursued in the 1990s. Gagner is credited for the first laparoscopic partial hepatectomy in 1992 (Gagner et al, 1992), and in a prospective series of 30 patients published in 2000, we demonstrated the safety and reproducibility of laparoscopic partial hepatectomy (Cherqui et al, 2000), which was followed by the safe application of these techniques to living donor left lateral sectionectomy in 2002 (Cherqui et al, 2002). Despite close to 20 years of development and nearly 3000 reported cases internationally, minimally invasive liver surgery remains an emerging field that should be approached with caution by surgeons experienced in the perioperative care and planning of both liver and laparoscopic surgery (Nguyen et al, 2009). Six centers have reported series of more than 100 patients, and most perform fewer than half of their total cases laparoscopically (Bryant et al, 2009; Buell et al, 2008; Chen et al, 2008; Cho et al, 2008; Koffron et al, 2006, 2007; Topal et al, 2008;). We have performed more than 200 laparoscopic partial hepatectomies since 1996, which represents 23% of our hepatectomy volume.

Whereas the percentage of resections for benign lesions has remained relatively stable over our experience, the percentage of resections for malignant lesions continues to increase year after year. The objective of this chapter is twofold: to present a balanced view of the current understanding of these techniques and to elucidate the technical details of the most commonly performed resections.

TERMINOLOGY

In 2008, leaders in the field met to discuss the current status of laparoscopic liver surgery (Buell et al, 2009). In the so-called Louisville Statement that resulted, those in attendance agreed on three procedural definitions: 1) pure, 2) hand-assisted, and 3) hybrid laparoscopy. *Pure laparoscopy* involves complete mobilization and resection via laparoscopic ports, with an incision for specimen extraction only. *Hand-assisted laparoscopy* involves the elective placement of a hand port for mobilization or resection, which is then used for specimen extraction. *Hybrid laparoscopy* refers to a procedure in which the resection and extraction are performed through a minilaparotomy, but laparoscopy, with or without hand assistance, is utilized for mobilization.

According to a comprehensive international review performed by Nguyen and colleagues (2009), 75% of reported laparoscopic resections were pure laparoscopy, 17% were hand-assisted procedures, and 2% used the hybrid technique. In addition, 4.8% were conversions to laparotomy or hand-assisted procedures, with the remaining 2% using less common techniques, such as a thoracoscopic approach.

Laparoscopic resections should be categorized no differently than open resections, based on the Brisbane 2000 terminology of liver anatomy and resections (Pang, 2002). Anterior and lateral segments II, III, IVb, V, and VI are most amenable to laparoscopic resection. Isolated resections of segments I, IVa, VII, and VIII have been reported, as surgeons extend the limits after safe mastery of anterior resections. Of the nearly 3000 internationally reported laparoscopic liver resections, the majority (44.9%) were wedge resections or segmentectomies, followed by left lateral sectionectomies (20.3%). Major resections, consisting of three or more Couinaud segments, included right hemihepatectomy (9%) and left hemihepatectomy (6.8%). Extended right hepatectomy, caudate lobectomy, central hepatectomy, and extended left hepatectomy each made up less than 1% of the total reported cases (Nguyen et al 2009).

We performed 96% of our resections using pure laparoscopy, with hand assistance (4%) selectively used for right hepatectomies or posterior segmentectomies. Major resections comprise 19% of our experience, and limited resections comprise 81% (Bryant et al 2009).

INDICATIONS

Liver pathology under consideration for open partial hepatectomy should be evaluated for the feasibility of a laparoscopic resection (see Chapter 90A); however, the potential benefits of a minimally invasive resection do not confer a prescription to resect all hepatic lesions for the purpose of providing a definitive diagnosis. Specifically, the laparoscopic approach should not be used to resect incidental, asymptomatic lesions convincingly recognized by imaging and markers to be benign and without harmful potential (cysts, hemangiomas, focal nodular hyperplasia), nor should laparoscopic resection be performed for the purpose of diagnosis, when lesions are safely amenable to percutaneous biopsy.

The indications for laparoscopic resection do not vary from those for open resection (Box 90E.1); however, lesion size and location are the most important determinants of when laparoscopic resection is appropriate. Resection of benign and malignant solid lesions and cystic and parasitic lesions are possible laparoscopically. The most favorable lesions for laparoscopic resection are solitary, 5 cm or less, and located in peripheral liver segments II to VI (Fig. 90E.1; Buell et al, 2009). Pedunculated tumors greater than 5 cm are often easily resectable laparoscopically. In experienced hands, laparoscopic left lateral

Box 90E.1

Indications and Contraindications for Laparoscopic Partial Hepatectomy

Indications

Location

Segments II through VI

Pathology

Benign and malignant neoplasms
Cystic lesions
Parasitic lesions

Size

Lesions <5 cm
Left lateral section lesions of any size not in proximity to major vascular structures
Pedunculated neoplasms of any size not in proximity to major vascular structures

Relative Contraindications

Location

Lesions near the inferior vena cava, hilum, or distal hepatic veins
Multiple or bilateral lesions
Segments I, IVa, VII, or VIII

Pathology

Coagulopathy or thrombocytopenia
Moderate to severe portal hypertension
Previous operation, especially upper abdominal

Size

Laparoscopic approach requiring a larger parenchymal resection than would be necessary via an open approach
Nonpedunculated benign and malignant neoplasms >5 cm

Absolute Contraindications

Gallbladder cancer and hilar cholangiocarcinoma
Inability to obtain a surgical margin that would otherwise be possible in an open resection
Patient unable to tolerate an open operation or pneumoperitoneum
Insufficient surgeon training

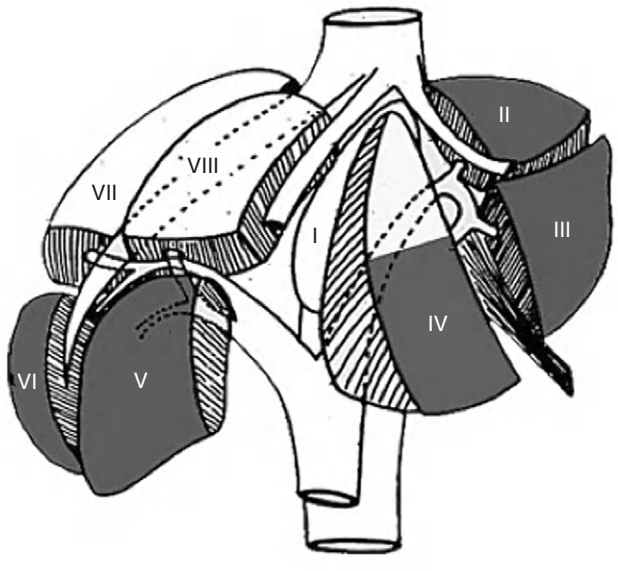

FIGURE 90E.1. The anterolateral liver—composed of segments II, III, IVb, V, and VI—is most amenable to the laparoscopic approach.

sectionectomy should be the standard approach for pathology in segments II and III (Buell et al, 2009; Chang et al, 2007).

Relative contraindications include lesions isolated to segments VII and VIII, multiple or bilateral lesions, and lesions located in proximity to the major hepatic veins, the inferior vena cava, or the hepatic hilum. These contraindications are considered relative, because in experienced centers, these lesions are increasingly managed laparoscopically (Buell et al, 2008; Koffron et al, 2007; Vigano et al, 2009a). A more extensive laparoscopic resection than would otherwise be necessary through an open approach may be contraindicated. An example would be a laparoscopic right hemihepatectomy for a posterior lesion that could be resected by a more limited open posterior segmentectomy. For each patient, the surgeon must weigh the risks and benefits of the laparoscopic and open techniques with the benefits of parenchymal preservation.

Surgical margins for benign lesions do not vary between open and laparoscopic resections. If there is concern that an adequate margin cannot be obtained laparoscopically, but it is technically feasible by an open approach, the former is contraindicated. Other contraindications include gallbladder cancer and hilar cholangiocarcinoma, because of the risk of peritoneal and port-site seeding and the necessary complex hilar dissection and extensive resection, respectively (see Chapters 49, 50B, 90B, and 90C).

SAFETY AND BENEFITS

Laparoscopic partial hepatectomy provides the benefits that laparoscopy has offered to patients undergoing many other abdominal operations. Case-control studies have demonstrated shorter operative times (Bryant et al, 2009; Buell et al, 2008; Koffron et al, 2007), shorter lengths of hospitalization (Buell et al, 2009; Cai et al, 2008; Koffron et al, 2007; Topal et al, 2008), less operative blood loss (Bryant et al, 2009; Buell et al, 2008; Koffron et al, 2007; Lesurtel et al, 2003), reduced transfusion requirements (Buell et al, 2008; Koffron et al, 2007; Topal et al, 2008), a reduced need for analgesia (Cai et al, 2008), quicker return to oral consumption (Cai et al, 2008), lower morbidity (Buell et al, 2008; Koffron et al, 2007; Topal et al, 2008), and fewer postoperative adhesions (Belli et al, 2009; Laurent et al, 2009). Studies have demonstrated decreased costs when accounting for shorter operative times and hospitalizations (Buell et al, 2008; Koffron et al, 2007; Polignano et al, 2008).

The mortality and morbidity rates in these studies are at least equivalent to, if not better than, those of large case series of open liver resections. In their review of 127 published articles on laparoscopic hepatic resection, Nguyen and colleagues (2009) found a cumulative mortality rate of 0.3%. This compares favorably to the 0% to 5.4% reported in the open-resection literature from high-volume centers. All deaths were postoperative, and most often caused by liver and multiorgan system failure. Of 2804 patients, 295 morbid complications were reported (10.5%), with a range of 0% to 50% across the 127 studies (Nguyen et al 2009). Liver-specific complications included bile leaks (1.5%), transient liver failure and ascites (1%), and abscess (2%). The remaining 6% were complications common to all operations, including but not limited to hemorrhage, wound infection, hernia, bowel injury, arrhythmia, and urinary or respiratory tract infections.

Laparoscopy has been utilized with success in cirrhotic patients (see Chapter 90F), with multiple small case-control

studies and series demonstrating lower morbidity and improved recovery. The laparoscopic approach also decreases the rate of postoperative ascites in this subgroup. Possible explanations include the preservation of venous and lymphatic collateral pathways in the abdominal wall, less intraoperative mobilization of the liver, and reduced intraoperative volume loading (Belli et al, 2007; Buell et al, 2009; Cherqui, 2006; Gigot et al, 2002; Kaneko et al, 2009; Laurent et al, 2003; Santambrogio et al, 2009; Vigano et al, 2009a). Nearly 40% of our laparoscopic experience has been with those patients who have chronic liver disease. These patients typically require longer operations and more pedicle clamping but globally have a better recovery than their open counterparts (Bryant et al, 2009).

As a consequence of decreased adhesions formed after an initial laparoscopic resection, reoperations, such as repeat hepatectomy and liver transplantation can often be performed more easily, with less blood loss, reduced transfusion requirements, and reduced operative time than following an initial, open partial hepatectomy (Belli et al, 2009; Bryant et al, 2009; Laurent et al, 2003). In our study comparing patients who had undergone a previous open or laparoscopic liver resection, the absence of adhesions at the time of liver transplantation in the laparoscopic group allowed for hepatectomy in a mean of 150 ± 52 minutes versus 247 ± 71 minutes in the open group. Additionally, a median of 2 U blood was transfused during hepatectomy in the open group versus zero in the laparoscopic group (Laurent et al, 2009). These are significant benefits, given that patients who require repeat operations often have diseased parenchyma because of cirrhosis or chemotherapy effects and the negative immune and oncologic impact of blood transfusion.

Barriers to the wide acceptance of laparoscopic surgery—such as threat of gas embolism, violation of oncologic principles, and significant risk of bleeding—have not been apparent in the literature (Vigano et al, 2009a). In addition, studies have consistently demonstrated that operative safety and postoperative morbidity improve with experience (Nguyen et al, 2009). When comparing our early and late groups, we found statistically significant reductions in operative time (210 to 150 minutes), blood loss (300 to 200 mL), conversion (16.9% to 2.4%), and morbidity (17.2% to 3.4%) (Vigano et al, 2009b).

Additional benefits include better cosmesis, improved maintenance of the sensorimotor integrity of the abdominal wall, and earlier access to adjuvant therapy because of quicker recovery. Despite these favorable results, it is important to acknowledge that these findings are from nonrandomized studies, and that laparoscopic cases remain highly selected for their potential for success. It can be inferred from the colorectal and bariatric literature that these benefits are real, especially for indicated cases (see Box 90E.1); however, the benefits may not be as robust for cases with relative contraindications (Castaing et al, 2009; Cho et al, 2008).

ONCOLOGIC OUTCOMES

Perhaps more important than demonstrating perioperative benefit is confirmation that oncologic principles are not dismissed. With regard to margins, recurrence, and survival, comparable results between open and laparoscopic resections have been well demonstrated in the literature (Nguyen et al, 2009; Vigano et al, 2009). In a meta-analysis of 165 laparoscopic liver resections and 244 open liver resections, Simillis and colleagues (2007) found no difference in tumor-free margin status, overall survival, and disease-free survival between laparoscopic and open liver resection for cancer. This has been demonstrated for both hepatocellular carcinoma (HCC) and colorectal metastatic disease (Castaing et al, 2009; Cherqui et al, 2009; Nguyen et al, 2009; Sarpel et al, 2009). Laparoscopic resection of other metastatic tumors has been reported in small numbers, mainly breast cancers and melanomas. Further, port-site metastases and peritoneal dissemination have not occurred with the use of closed-bag methods for specimen extraction.

As chemotherapeutic, biologic, and radiation options expand, patients with primary and metastatic liver cancer may anticipate longer survival despite the high possibility of recurrence. Resection of HCC as a bridge to future transplantation should also be a consideration (Cherqui et al, 2009; Laurent et al, 2009). As such, parenchyma-sparing procedures should be promoted in anticipation of repeat operative needs. Rather than performing a laparoscopic right or left hepatectomy because of relative ease technically, segmental resections along anatomic lines must be performed when possible.

GENERAL PRINCIPLES

Imaging

High-quality imaging with vascular reconstruction is necessary to understand a patient's intrahepatic arterial and portal anomalies. Review of recent magnetic resonance (MR) or computed tomography (CT) imaging should be performed before proceeding to the operating room.

Equipment

All laparoscopic equipment must be state of the art and in good working order, and nursing staff should be familiar with the proper setup and functioning of equipment so as not to occupy the surgeon's attention during the operation at critical moments. The center should have an adequate backup supply of cameras, monitors, insufflators, electrical surgery generators, cables, tubing, and laparoscopic instruments and devices. A set of conventional instruments and retractors for open surgery should be readily available in case of vascular emergency.

We prefer a 10-mm, 30-degree laparoscope for its versatile imaging. A CO_2 insufflator to maintain a pneumoperitoneum of 12 mm Hg is used, although some centers prefer a pneumoperitoneum as low as 8 mm Hg for the prevention of hepatic vein gas embolism. To our knowledge, no major centers are currently using gasless laparoscopy. Hand-assisted laparoscopy can be used for right-sided and posterior lesions or as needed for failure of case progression or to aid in obtaining hemostasis, but this is more often used in the United States than in Europe. A gas-tight port is placed, and the incision is later used for extraction of the specimen. In our experience, hand assistance was used in selected cases and/or to prevent conversion to laparotomy when mobilization and parenchymal transection were difficult.

Positioning

For all except resection of segments VI and VII, the patient is placed in the supine position with the lower limbs apart on a split-leg table. Both arms are padded and tucked at the sides,

and the patient is prepared and draped from the pubis to the nipple line. The surgeon stands between the patient's legs with an assistant at each side. The assistant opposite the side of resection can be replaced by an adjustable instrument holder. Freestanding monitor towers are placed lateral to each shoulder, with a hanging monitor above the patient's head, if such a monitor is available. The scrub nurse and instruments are positioned lateral to the patient's right leg or behind the surgeon.

For segment VI and VII segmentectomies, the patient is placed in the left lateral decubitus position. The surgeon and one assistant stand on the patient's ventral side, with the scrub nurse opposite at the patient's legs. The monitor towers are positioned across from the surgeon, and a reverse Trendelenburg position allows the bowels to drop into the lower abdomen; the table is tilted laterally as necessary.

Incisions, Exploration, and Exposure

The open technique is used to gain access to the abdomen supraumbilically. The remaining four ports are placed under direct vision, with incisions sized to accommodate the necessary cannulas as pictured in Figure 90E.2. The median trocar is the camera port, the paramedian ones are the working ports, and the most lateral right and left ports are for retraction. For segment VI and VII resections, four ports are used: a 10-mm port in the left upper quadrant, a supraumbilical 12-mm port, a 12-mm paraumbilical port in the midclavicular line, and a 10-mm trocar in the anterior-axillary line (Fig. 90E.3).

After a thorough inspection of the peritoneal cavity for ascites, carcinomatosis, and signs of portal hypertension, attention is turned to the liver for signs of superficial lesions, steatosis, cholestasis, cirrhosis, or other gross pathology. Next, laparoscopic ultrasound is performed. A thorough knowledge of both B-mode and Doppler laparoscopic ultrasonography is mandatory for safe and accurate laparoscopic resections. A high-frequency laparoscopic probe is used to look for lesions less than 1 cm, which may be difficult to assess by extracorporeal imaging, and to confirm adequate margins (Foroutani et al, 2000; Milsom et al, 2000; Montorsi et al, 2001).

The round ligament is divided close to the abdominal wall. This prevents a dangling remnant that might obstruct the view or soil the tip of the scope. Then the falciform ligament is divided along its length to the insertion of the hepatic veins into the vena cava. The round ligament along with the gallbladder or remnant cystic duct can be used as "handles" for manipulation of the liver.

If pedicle occlusion is anticipated, the pars flaccida is opened, and an instrument is passed behind the portal triad to encircle it with a tape. The tape is then extracorporeally inserted through a 16-Fr rubber tube to serve as a tourniquet, and it is returned to the abdomen. If pedicle clamping is to be used, we favor 15 minutes of clamping interrupted by 5 minutes of pedicle flow. If parenchymal bleeding occurs during the 5 minute period, the transected parenchyma can be opposed or packed with some gentle lateral pressure. Although we do not routinely clamp the pedicle, this should be another safety tool in the arsenal of the new laparoscopic liver surgeon, or it may be used as an emergent maneuver, if parenchymal bleeding obscures visualization. Liberal use of on-demand, intermittent inflow occlusion, meticulous technique, and low central venous pressure (CVP) anesthesia are very effective at limiting blood loss during these

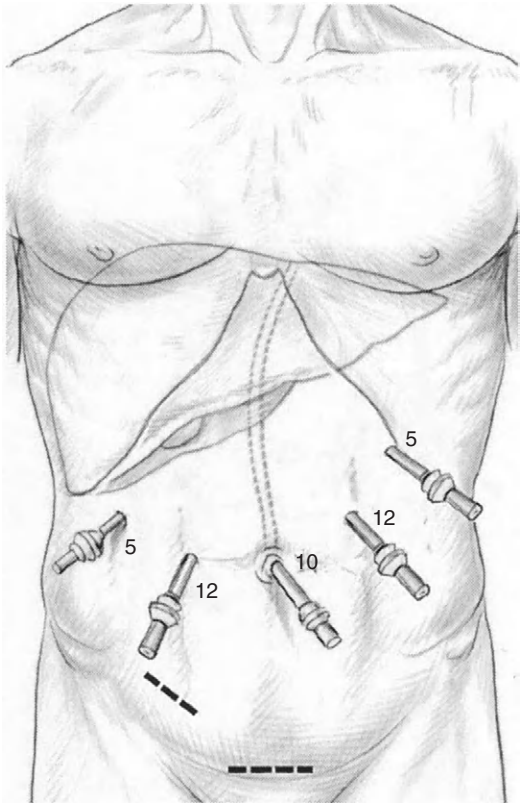

FIGURE 90E.2. Common port sites, trocar sizes (in millimeters), and positioning for laparoscopic partial hepatectomy. The patient is supine, and the surgeon is positioned between the patient's legs. Specimen extraction may be through a suprapubic or right lower quadrant incision (*dotted lines*). *(From Cherqui D, et al, 2000: Laparoscopic liver resections: a feasibility study in 30 patients. Ann Surg 232:753-762.)*

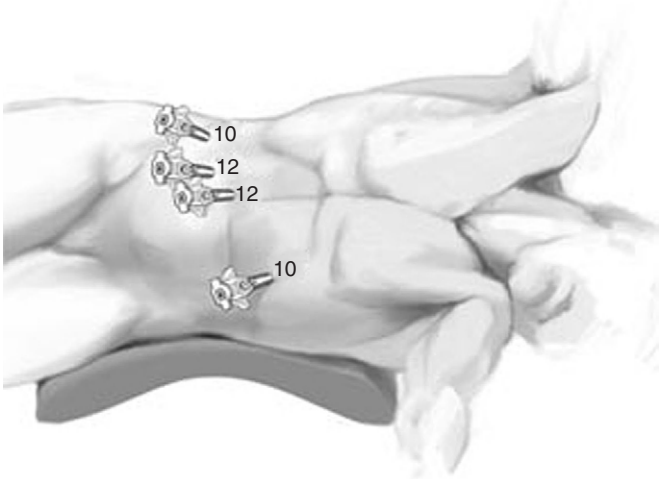

FIGURE 90E.3. Port sites and trocar sizes (in millimeters) for laparoscopic resection of segments VI and VII. The patient is in the left lateral decubitus position with the surgeon and assistant ventral to the patient. *(From Cherqui D, et al, 2000: Laparoscopic liver resections: a feasibility study in 30 patients. Ann Surg 232:753-762.)*

cases. Complete vascular occlusion is difficult laparoscopically, and any resection requiring this should be performed as an open procedure.

Transection Techniques

The transection line is outlined along the liver capsule with monopolar diathermy based on preoperative imaging, knowledge of hepatic anatomy, laparoscopic ultrasonography, or demarcation lines, when hepatic artery and portal vein flow are interrupted. Whereas in open surgery, the clamp-and-crush method is a standard and inexpensive transection technique, newer technology is required for laparoscopic operations. The Harmonic Scalpel (Ethicon Endo-Surgery, Cincinnati, OH) and the LigaSure vessel-sealing device (Valleylab, Boulder, CO) are effective for transecting the superficial 2 to 3 cm of parenchyma. For deeper parenchyma, an ultrasonic dissector is used (e.g., CUSA Dissectron, Integra, Plainsboro, NJ; SonoSurg, Olympus, Tokyo). Subsequently, vascular and biliary structures less than 3 mm are ligated and transected using the Harmonic Scalpel, LigaSure, bipolar diathermy, or titanium clips. Larger arteries, such as the hepatic artery, and bile ducts are ligated with plastic locking clips (Hem-o-lok; Teleflex Medical, Research Triangle Park, NC) and then divided. Laparoscopic linear staplers (Endo GIA, Covidien, Mansfield, MA; Echelon Endopath Stapler, Ethicon Endo-Surgery) are used for the portal and hepatic veins. A staple depth of 2.5 mm secures hemostasis in the large-diameter, thin-walled vessels encountered in liver surgery. Load lengths include 30, 45, and 60 mm, but the 45 mm is the most commonly used. The stapler can be applied to segmental portal pedicles or to isolated large veins; however, the stapler should never be forced closed over a thick tissue mass, nor should excessive tissue length be squeezed into the jaws; such maneuvers risk misfiring, which can lead to bleeding that is difficult to control. Rather, further dissection should be performed, or the length of the jaws increased, until the tissue fits effortlessly within the stapler. Prior to stapling the right or left portal branch near the bifurcation, flow to the opposite pedicle should be confirmed.

Parenchymal transection by repeated application of a linear stapler is practiced by some centers, with the cost of the devices said to be offset by reduced operating time and length of hospitalization (Buell et al, 2008). We prefer a method of complete visualization, believing that blind application of the linear stapler is a rougher and less precise technique.

Extraction, Drainage, and Closure

Small lesions can be removed through extensions of trocar incisions after placement in an endoscopic bag. Larger lesions can be removed through preexisting McBurney or midline incisions or through hand-port incisions. In the virgin abdomen, specimens are removed through a 5- to 8-cm Pfannenstiel incision. Regardless of the chosen incision, the abdominal wall is incised to the fascia, and a 15-mm trocar is inserted at the center of the incision under direct laparoscopic vision. A large capacity endoscopic bag is introduced, and the specimen is retained. The specimen is then retracted against the fascia, and the fascia and peritoneum are opened only as much as necessary for retrieval. The fascial layers are reapproximated, the pneumoperitoneum is reintroduced, and the operative site is lavaged and examined for hemostasis and biliary tract integrity.

Intraoperative cholangiography is not routinely performed, but it can be used if there is concern for a bile leak or aberrant biliary anatomy. Because of the large dead space created, right hepatectomies are usually the only resections we drain. The skin and port-site incisions are closed with absorbable subcuticular sutures.

Conversion to Laparotomy

Conversion rates in the literature range from 0% to 55%. The most cited reasons for conversion are hemorrhage, adhesions, and anatomic difficulties (Nguyen et al, 2009a). Many of these can be prospectively prevented by proper patient selection based on quality imaging and an understanding of laparoscopic principles. Conversion should not be considered failure and should be performed without hesitation when a patient's well-being is at risk.

Hemorrhage may be brisk, or it may be of a continuous, slow nature. Brisk hemorrhage may result from either arterial or venous bleeding. Arterial bleeding is controlled with instruments used to compress or grasp the vessel while clips or sutures are applied. The hepatic vein is the most common source of hemorrhage, and bleeding from the hepatic and portal veins and vena cava may be more difficult to manage because of vessel fragility and retraction (Vigano et al, 2009). Significant bleeding should ideally be managed laparoscopically, at least temporarily, because shock may ensue by the time the laparotomy is performed. This is a matter of urgent decision making by the surgeon, perfect collaboration with the anesthesiologist, and above all, mastering the advanced laparoscopic techniques required to embark on these procedures, such as intracorporeal suturing. Continuous, slow bleeding occurs during transection and may be due to elevated CVP, fragile liver parenchyma, or inappropriate technique. This slows the procedure and often interferes with visualization. In all situations, intermittent portal triad clamping may be utilized, and if rapid introduction of a hand port and conservative measures are ineffective to manage the bleeding, conversion to laparotomy should be performed without delay.

Insufficient exposure, proximity to major vessels, and inability to obtain appropriate margins are a few of the reported anatomic difficulties that may cause failure to progress, although this may also be the result of a more difficult or dangerous dissection or transection than was anticipated. In any case, this should be recognized as early as possible to avoid conversion after a lengthy and inefficient procedure.

SPECIFIC PARTIAL HEPATECTOMY PROCEDURES

Left Lateral Sectionectomy

The left lateral sectionectomy is the most straightforward laparoscopic liver procedure, and it represents the standard of care for our division. The left lateral section is mobilized by dividing the round, falciform, left triangular, and coronary ligaments with the Harmonic or LigaSure. The entire length of the lesser omentum is opened close to the liver, and a replaced left hepatic artery is divided if present. If a parenchymal bridge covers the inferior surface of the round ligament, it is divided with the harmonic shears.

The parenchymal transection is performed to the left of the patient's falciform ligament with the Harmonic or LigaSure.

The plane of transection is better visualized by retracting the round ligament superiorly and to the right and the left lateral segment superiorly and to the left. The ultrasonic dissector can then be used to open the deeper parenchyma, progressing cranially from anterior to posterior, with small vessels and ducts controlled as previously discussed; however, transection can be completed with the Harmonic Scalpel or LigaSure device, because there are few bridging structures in this procedure. Transection is continued until the portal pedicles of segments II and III are visualized. These pedicles can then be divided with two to three firings of the linear stapler (Fig. 90E.4). Parenchymal transection continues cranially, until the left hepatic vein is visualized, at which point it is divided with the linear stapler (Fig. 90E.5).

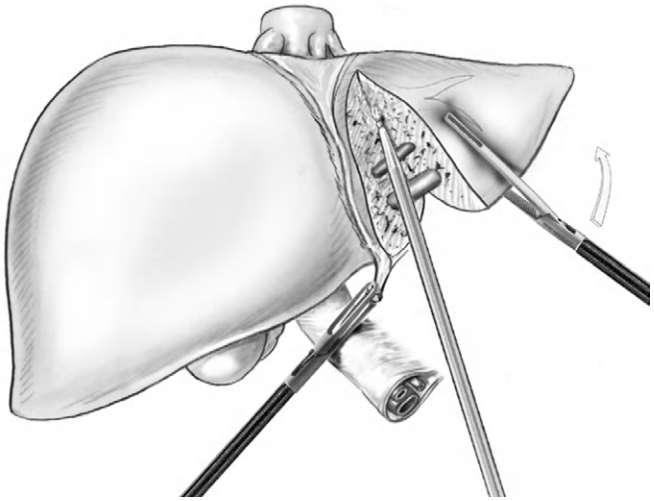

FIGURE 90E.4. Left lateral sectionectomy. Atraumatic graspers retract the round ligament to the right and the specimen to the left. The ultrasonic dissector is used to dissect the parenchyma, exposing the segment II and III pedicles for subsequent ligation and division.

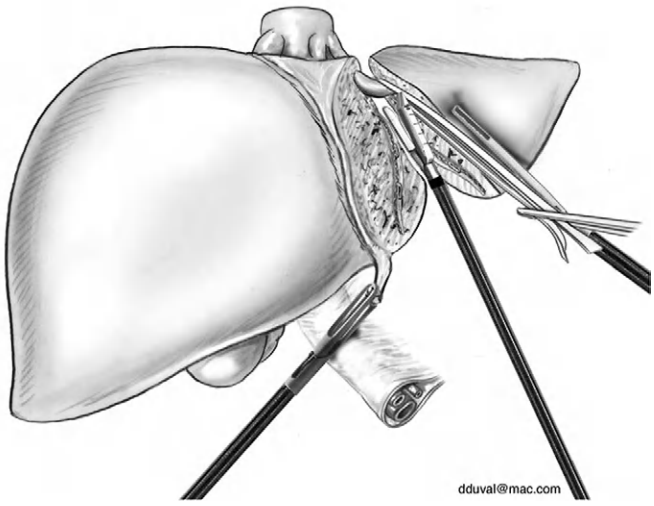

FIGURE 90E.5. After the left hepatic vein is dissected free of parenchyma, a tape is passed around it for better control and exposure. A linear stapler is passed around the hepatic vein and fired, thereby ligating and dividing the vessel. The left and right hepatic veins are divided in a similar manner for the left and right hemihepatectomy, respectively.

Left Hemihepatectomy

The left liver is mobilized as for the left lateral sectionectomy, and a tourniquet can be assembled around the main portal triad. A cholecystectomy is performed if the gallbladder is present, but the gallbladder is left partially attached so that it may be grasped and retracted superiorly and to the left. The extrahepatic left glissonian pedicle is now exposed and dissected using endoscopic scissors, right-angled forceps, and bipolar diathermy. The left hepatic artery and left portal vein are then individually divided or clamped with bulldog clamps passed through a 12-mm trocar. The extrahepatic clamping delimits the plane that intersects the gallbladder and inferior vena cava fossae, known as the *midplane* of the liver.

Parenchymal transection is performed along this line using the Harmonic Scalpel or LigaSure device superficially and the ultrasonic dissector more deeply. Once dissection enters the hilar plate, the left intraparenchymal glissonian pedicle is divided with a linear stapler. Parenchymal transection continues cranially, until it reaches the insertion of the left hepatic vein into the vena cava, at which point it is divided with the linear stapler.

Right Hemihepatectomy

Right hemihepatectomy is the most difficult of the common laparoscopic liver resections, and previous mastery of more limited laparoscopic resections is a prerequisite. As previously detailed, the falciform and round ligaments are dissected, and a tourniquet around the main portal triad is assembled. The cystic duct and artery are ligated and divided, and the gallbladder remains in situ as a retraction point for elevating the liver to the right. The remnant cystic duct is retracted to the left, exposing the short course of the extrahepatic right glissonian pedicle. A replaced right hepatic artery is ligated and divided if present, and the right branches of the hepatic artery and portal vein are gently dissected and individually encircled with tapes to retract them for easier division. The right branch of the artery is divided between plastic locking clips, and the right branch of the portal vein is divided with a linear stapler or between locking clips. Identification of the origin of the left branch of the portal vein should be assured before occluding the right portal branch. When possible, intraparenchymal dissection to the branches of the hepatic artery and portal vein limits risk to the portal triad bifurcation. The line of demarcation along the midplane of the liver is identified and marked. The procedure can be done without or with initial mobilization of the right lobe; the former is referred to as the *anterior approach,* which is our preferred method.

For the anterior approach, the right hepatic vein is not controlled prior to parenchymal transection. After ligation of the right hepatic artery and portal vein, parenchymal transection is started at the inferior edge of the liver in the anterior-posterior direction along the line of demarcation. The previously described techniques are utilized. As progress is made cranially, the proximal hepatic veins draining segments V and VIII toward the middle hepatic vein are exposed, clipped, and divided (Fig. 90E.6). At the level of the hilar plate, the right bile duct's anterior and posterior branches are divided between clips or staples. Division of the intraparenchymal bile ducts and hilar plate allows the plane to be opened widely for easier parenchymal transection, and the junction between the right lobe and segment I is divided to allow exposure of the retrohepatic vena cava. The posterior Glisson capsule is now divided along the anterior surface of the vena cava, while systematically clipping

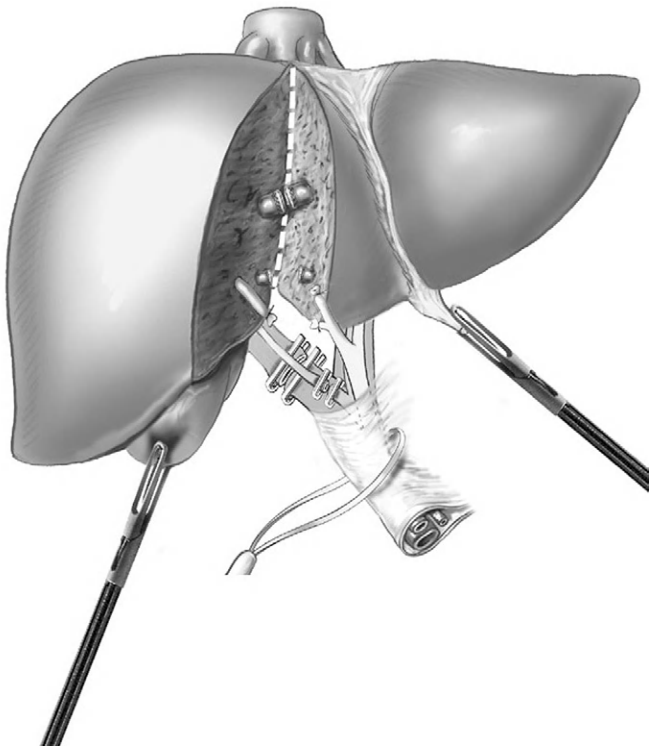

FIGURE 90E.6. Right hemihepatectomy. Atraumatic graspers retract the gallbladder to the right and the round ligament to the left, opening the dissection plane (*white dashed line*). The right hepatic artery and right portal vein are ligated extraparenchymally, and the right bile duct is ligated intraparenchymally. The hepatic veins draining segments V and VIII into the middle hepatic vein are encountered intraparenchymally, ligated, and divided. A laparoscopically assembled tourniquet around the portal pedicle is pictured and can be used for the Pringle maneuver if necessary. *(From Cherqui D, et al, 2010: Hepatectomies par abord laparoscopique, Encyclopedie Medico Chirurgicale. Masson, France, Elsevier.)*

FIGURE 90E.7. The use of a hand port in the right iliac fossa allows for manual manipulation and palpation of the liver; it is only used for difficult right-sided resections. Fewer laparoscopic ports are necessary, and the specimen is removed through the hand-port incision. Hand ports can be used from the outset of the operation or as an adjunct during a difficult resection. *(From Cherqui D, Chouillard E, 2007: Laparoscopic liver resections. In Clavien PA, et al [eds]: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery, Berlin, Springer.)*

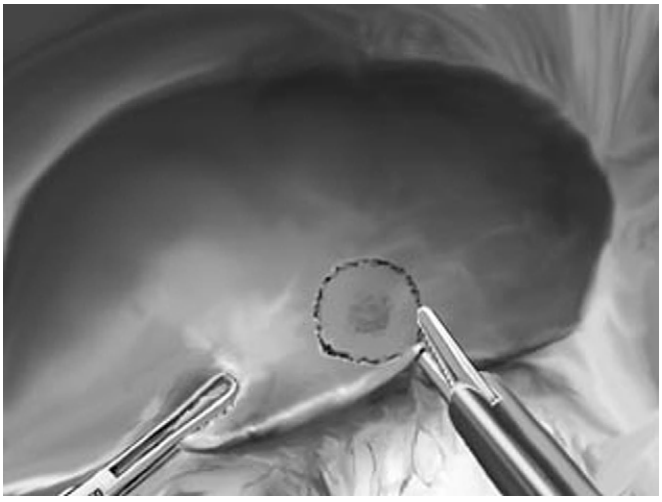

FIGURE 90E.8. Metastasectomy. The lesion is circumscribed with a 1- to 2-cm margin, and either a Harmonic Scalpel or LigaSure device can be used to resect the lesion. *(From Cherqui D, Chouillard E, 2007: Laparoscopic liver resections. In Clavien PA, et al [eds], 2007: Atlas of Upper Gastrointestinal and Hepato-Pancreato-Biliary Surgery. Berlin, Springer.)*

and dividing the small bridging veins. The right hepatic vein is identified at its insertion into the vena cava and is transected with a linear stapler. The specimen is now retracted to the right, as the hepatocaval ligament and the attachments of the right hemiliver are freed from the diaphragm.

When parenchymal transection is to be performed after mobilization of the right hemiliver, the right glissonian pedicle is dissected and divided as discussed for the anterior approach. This mobilization approach may require the use of a hand port (Fig. 90E.7). Next, the right triangular and coronary ligaments are divided. The liver is retracted to the left and anteriorly, and the accessory veins between the right hemiliver and vena cava are clipped and divided. As progress is made cranially, the hepatocaval ligament is divided between clips, and the right hepatic vein is subsequently divided with a linear stapler. The liver is now both completely mobilized and devascularized, and parenchymal transection is performed along the line of demarcation according to previously discussed principles.

Peripheral Partial Hepatectomies: Segmentectomy, Metastasectomy, or Tumorectomy

Peripheral partial hepatectomies are performed for lesions in the anterior or lateral segments. They can be anatomic, such as segmentectomies along theoretic segmental borders, or they can be nonanatomic, as with metastasectomy or tumorectomy (Fig. 90E.8). They usually do not require liver mobilization, especially for anterior lesions. For malignant lesions, 10- to 20-mm margins are determined using ultrasonography and are marked using diathermy. For benign lesions, a wide margin is unnecessary. Parenchymal transection can be performed with the Harmonic Scalpel or LigaSure, and it follows the margins marked on the liver surface. Hemostasis is achieved with bipolar diathermy and clips. If significant veins or pedicles are within

the resection margins, these are clipped and divided; the use of a linear stapler is rarely necessary.

CONCLUSION

Laparoscopic partial hepatectomy is a safe procedure for selected patients, when performed by appropriately trained surgeons, and it offers considerable perioperative benefits compared with laparotomy. In addition, oncologic outcomes and survival for HCC and colorectal metastases have been demonstrated to be equivalent in nonrandomized trials. Although the indications for laparoscopic surgery are somewhat rigid when it comes to lesion size and location, greater experience and newer technology are continually expanding the possibilities of this procedure. Surgical resection of benign, asymptomatic lesions remains contraindicated despite the safety and benefits of laparoscopic surgery. The most common laparoscopic procedures are detailed above, based on safe practices developed over our 14 years of experience. Left lateral sectionectomies and limited resections of the anterior and lateral segments of the liver are safe and well-accepted procedures. Major hepatectomies and limited segmentectomies involving segments I, IVa, VII, and VIII are increasingly reported, but by no means are they approaching the standard of care. This remains an expanding and exciting field in liver surgery, especially considering its role in the multidisciplinary approach to primary and secondary liver cancers and transplantation.

CHAPTER 90F

Liver resection in cirrhosis

Jacques Belghiti and Safi Dokmak

OVERVIEW

Hepatocellular carcinoma (HCC) is the main indication for hepatectomy in the cirrhotic liver. The vast majority of HCC in patients with chronic liver disease (CLD) is related to hepatitis B or C viral infection, chronic alcoholic consumption, and metabolic syndrome (see Chapters 70 and 80). Other malignant tumors developed in CLD include intrahepatic cholangiocarcinoma (see Chapter 50A) and liver metastases (see Chapter 81; Iascone et al, 2005; Uchiyama et al, 2011; Welzel et al, 2007;). Some benign tumors—including regenerative nodules, hemangiomata, and focal nodular hyperplasia (FNH)—can be discovered in cirrhotic liver (Brancatelli et al, 2001a, 2001b; Libbrecht et al, 2006; Luciani et al, 2007; see Chapter 79).

Although liver transplantation (LT) offers the best chance of cure in patients with early stage HCC (Mazzaferro et al, 2009; see Chapter 97A), the persistence of graft shortage in many countries had led some authors, including those in our group, to advocate hepatic resection as the first-line treatment for HCC in cirrhotic patients with preserved liver function (Belghiti et al, 2008; Cherqui et al, 2009; Del Gaudio et al, 2008; Poon et al, 2002a). Liver resection is an effective treatment for HCC under appropriate conditions, but impaired liver regeneration, altered texture of liver parenchyma, portal hypertension, and collateral circulation make liver resection in cirrhotic patients challenging.

In the 1990s, operative mortality in patients with normal livers was 1%, compared with 8% among patients with diseased parenchyma (Belghiti et al, 2000; see Chapter 90). The higher risk associated with liver resection in patients with diseased parenchyma results from increased operative bleeding and postoperative complications, with liver failure mainly as a result of impaired liver regeneration in cirrhosis (see Chapter 5); however, with appropriate attention to preoperative patient selection, improved liver function assessment, better understanding of the segmental liver anatomy with more accurate imaging studies, advanced operative techniques, and better perioperative management, hepatectomy now can be performed in the cirrhotic liver with acceptable operative morbidity and mortality in major centers (Dahiya et al, 2010; Ferrero et al, 2005; Imamura et al, 2003; Wei et al, 2003). This chapter describes general surgical aspects and risks of liver surgery in patients with liver cirrhosis.

PREOPERATIVE ASSESSMENT

The improvement in the outcomes of liver resection in cirrhotic patients is mainly the result of good preoperative evaluation and appropriate patient selection (Ikai et al, 2007). A systematic and careful assessment of the patient's general medical fitness, the tumor extent and stage, the underlying liver function, and the volume of the anticipated future liver remnant (FLR) are critical in ensuring proper patient selection (see Chapters 2 and 70).

General Status of Patients

Attention to the general medical fitness of patients is paramount in selecting patients with HCC for hepatic resection, especially in cirrhotic patients, who are at higher risk of postoperative complications. Comorbid illness is a major predictor of the mortality of patients undergoing hepatectomy (Wei et al, 2003). Severe comorbid illnesses, such as congestive heart failure and chronic renal failure, are definite contraindications for hepatectomy, although patients with less severe comorbid illnesses may still benefit from hepatic resection, if accompanied by meticulous perioperative care. The impact of diabetes mellitus, which is a common comorbid illness in cirrhotic patients, is debated (Gedaly et al, 2009). It has been shown that postoperative morbidity and mortality after hepatectomy in patients with diabetes mellitus were similar to those of patients without diabetes mellitus, as long as optimal perioperative control of blood glucose levels and appropriate postoperative care were provided (Poon et al, 2002b).

Tumor Status

The assessment of the tumor extent included a triple-phase (early vascular or arterial phase, portal phase, and delayed phase) helical computed tomography (CT) of the thorax and the abdomen (see Chapter 16). The liver is studied using thin slices acquired during the unenhanced phase and during the arterial, portal, and late or equilibrium phase after contrast administration. HCC is hypervascular during the early arterial phase and hypovascular in late phase ("washout"). Magnetic resonance imaging (MRI) is the modality of choice for imaging when contrast agents are contraindicated, better lesion characterization is needed, or the anatomic relationship between tumor and major vascular or biliary structures requires further delineation (see Chapter 17).

The usual criteria for hepatic resection with regard to the tumor status include absence of extrahepatic metastasis and tumor thrombus in a main portal vein or in the inferior vena cava (see Chapter 80). Large tumor size alone should not be considered a contraindication for hepatic resection. Despite the technical problems encountered with large tumors, liver resection for large HCCs has been shown to be safe (Kosuge et al, 1993; Pawlik et al, 2005a, 2005b; Ramacciato et al, 2010;

Yang et al, 2009). In a series of 300 patients who underwent partial hepatectomy for HCCs larger than 10 cm, the 30-day mortality rate was 5% (Pawlik et al, 2005b). Because cadaveric orthotopic liver transplantation (OLT) and radiofrequency ablation (RFA) are contraindicated in these patients, surgical resection remains the treatment of choice for large HCCs.

HCC associated with biliary invasion should not be considered a contraindication to surgical resection, if curative resection can be achieved (Hanaoka et al, 2008; Lee et al, 2006; Peng et al, 2005). Multifocal disease generally is a contraindication to surgical resection, but in some patients with good liver function, resection can be reconsidered after clearance or stabilization of contralateral liver nodules by chemoembolization or RFA (Ishizawa et al, 2008; Liu et al, 2003; Ng et al, 2005; Ramacciato et al, 2010).

HCCs with major portal or hepatic vein involvement represent a technical and oncologic challenge. Patients with HCC that involves hepatic veins or vena cava have a high rate of pulmonary metastases (Ikai et al, 2003), although it has been shown that in a selected group of patients with normal liver function and excellent general status, extensive liver resection with removal of the vascular thrombus can achieve favorable survival results (Le Treut et al, 2006; Minagawa et al, 2001; Poon et al, 2003; Shi et al, 2010). Extension to surrounding structures, such as the diaphragm, does not represent a contraindication, provided that negative resection margins can be attained.

Tumor recurrence represents the major drawback after curative liver resection and is the most common cause of treatment failure. Within 5 years of resection, recurrence in the liver remnant occurs in about 50% to 70% of cases (Huang et al, 2010; Poon et al, 2000; Shi et al, 2007). The rate of repeated resection, ranging from 10% to 30%, depends on the underlying liver status, pattern of recurrence, and extent of first resection; lower rates are seen in series with a high proportion of major resection during the first hepatectomy, and repeat hepatectomy has been proven to be a safe and worthwhile procedure with a low mortality rate and an acceptable 5-year survival (20% to 57%) (Minagawa et al, 2003; Poon et al, 1999; Tsujita et al, 2010; Wu et al, 2009).

Spontaneous rupture of HCC occurs in 5% to 15% of patients, particularly with large, superficial, or protruding tumors. In patients with good liver function and a solitary tumor that is otherwise amenable to resection, rupture should not be regarded as a contraindication to subsequent elective surgical treatment; however, initial treatment should be aimed at stabilizing the patient and arresting the hemorrhage through nonsurgical means, typically through arteriography and embolization.

Assessment of Liver Function Reserve (See Chapters 2 and 70B)

Careful assessment of the liver function reserve is critical in patient selection for hepatectomy in patients with cirrhotic liver to avoid postoperative liver failure and mortality. Several systems may be used to evaluate the liver prior to operation.

Child-Turcotte-Pugh Classification

In most of Western centers, preoperative liver function is assessed using the Child-Turcotte-Pugh (CTP) classification, which incorporates variables related to conventional liver function and portal hypertension. This classification is easy and remains very accurate in its assessment of the surgical risk (Table 90F.1). According to this system of classification, major resection is performed only in CTP class A patients, limited resection of small superficial tumors is sometimes performed in class B patients, and no resection, regardless of the extent, is considered in class C patients; however, this classification is not enough to predict surgical risk in some patients, because two parameters are subjective—ascites and encephalopathy—and even within the class A group with apparently good liver function, some degree of portal hypertension and/or hepatic dysfunction may be present, and the risk of liver surgery may be underestimated. Therefore more sophisticated quantitative liver function tests or volumetric assessments are needed to predict the operative risk (Durand & Valla, 2005).

Table 90F.1

Pugh's Modification of Child's Grading of Cirrhosis

Measurements	1 Point	2 Points	3 Points
Bilirubin (μmol/L)	17 to 34	35-50	>50
Prothrombin time	1 to 3	4-6	>6 prolongations
Albumin (g/L)	>35	28-34	<28
Ascites		None	Mild
Moderate to severe encephalopathy	None	Grade 1 or 2	Grade 3 or 4

Child's class A = 5 to 6 points; class B = 7 to 9 points; class C = 10 to 15 points

Indocyanine Green Test

Most Eastern centers use more sophisticated quantitative liver function tests that include indocyanine green (ICG) clearance (Imamura et al, 2003), galactose elimination capacity (Redaelli et al, 2002), and a lidocaine test (Ravaioli et al, 2003) to predict the risk of postoperative liver failure in patients with cirrhosis. The Hong Kong group showed in a multivariate analysis that of the many liver function tests, ICG retention at 15 minutes to 20% was the best test for predicting hospital mortality after major hepatectomy for HCC (Lau et al, 1998; Lee & Hwang, 2005). Imamura and Makuuchi proposed a decision tree based on combined parameters from the CTP classification (ascites and bilirubin) and ICG retention test (Imamura et al, 2005; Fig. 90F.1). Based on this strategy, liver resection is contraindicated in patients who have elevated bilirubin (>2 mg/dL) or ascites. The extent of liver resection is then based on the ICG retention test at 15 minutes (see Table 90F.1), and major liver resection is proposed only in patients with normal bilirubin and ICG levels below 10%. Adopting this decision strategy, the authors reported only one mortality among the 685 patients who underwent liver resection for HCC (Imamura et al, 2005).

Model for End-Stage Liver Disease Score

The Model for End-Stage Liver Disease (MELD) score uses only objective variables calculated from the international normalized ration (INR), serum total bilirubin (mg/dL), and serum creatinine (mg/dL). This system was initially created to predict survival in patients with complications of portal hypertension undergoing elective placement of transjugular intrahepatic portosystemic shunts (TIPS) (Malinchoc et al, 2000). The MELD score was validated subsequently as an accurate predictor of survival among different populations of patients with advanced

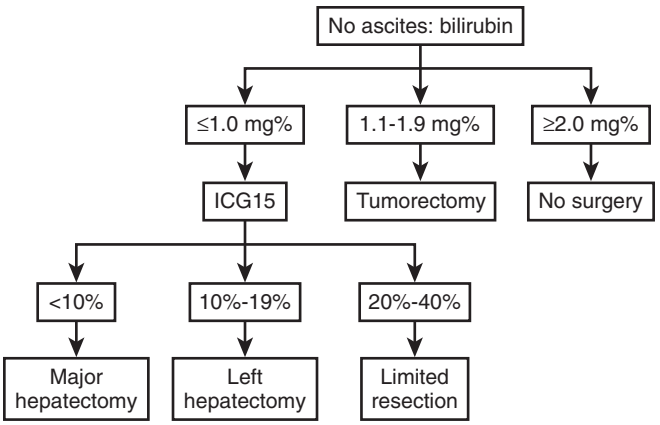

FIGURE 90F.1. Japanese algorithm for resection in cirrhosis. ICG, indocyanine green. *(Modified from Makuuchi M, 1993: Surgery for small liver cancers. Semin Surg Oncol 9:298-304.)*

liver disease (Kamath et al, 2001). The most frequent use of the MELD score has been in the allocation of organs for patients awaiting liver transplantation (Freeman et al, 2005; Wiesner et al, 2001). Regarding liver resection in cirrhotic patients, the MELD score was only retrospectively studied. Cirrhotic patients who underwent liver resection for HCC with a MELD score greater than 8 had a higher risk of death, morbidity, and impaired long-term survival (Cucchetti et al, 2006; Delis et al, 2009).

Transaminase Levels

Postoperative mortality has been shown to be higher in a cohort of 285 patients who underwent hepatectomy for HCC when histologic evidence of cirrhosis and active hepatitis versus cirrhosis alone was found (Eguchi et al, 2000). Although the presence of high serum transaminase levels does not always correlate with hepatitis and could be associated with intratumoral necrosis in a huge tumor, increased complication and death rates have been reported in those patients with levels of elevated transaminases (Haber et al, 1995; Noun et al, 1997). Patients with an aspartate aminotransferase level greater than 100 IU/L or alanine aminotransferase at least twice the normal level are considered poor candidates for major hepatic resection. In this setting, preoperative biopsy of the nontumorous liver should be performed to exclude active underlying liver parenchymal disease.

Portal Hypertension (See Chapter 70)

The presence of portal venous pressure greater than 10 mm Hg is often associated with esophageal varices, splenomegaly, and thrombocytopenia (<100,000). Undiagnosed and latent portal hypertension in a cirrhotic patient undergoing liver resection puts the patient at risk of major complications in the postoperative period; such complications include variceal bleeding, endotoxemia, and hepatic decompensation. In a prospective study in class A cirrhotic patients, it was shown that the hepatic venous pressure (HVP) gradient, a surrogate measurement of portal venous pressure, was the only predictor of hepatic decompensation following hepatic resection (Bruix et al, 1996). Thus liver resection in cirrhotic patients with esophageal varices is contraindicated; however, several authors have shown that portal hypertension is not an absolute contraindication to surgical resection in selected patients with preserved liver function (Capussotti et al, 2006; Ishizawa et al, 2008). These authors advocate an aggressive preoperative prophylactic treatment for portal hypertension, such as ligation of esophageal varices.

The negative effect of thrombocytopenia on liver regeneration can be related to the presence of portal hypertension or its direct impact on liver regeneration (Lesurtel & Belghiti, 2008). The development of venous collaterals in patients with elevated portal pressure can reduce the hepatic portal flow and thereby impair the regenerative capacity of the remnant parenchyma after liver resection, therefore we contraindicate major liver resection in cirrhotic patients with venous collaterals.

Liver Atrophy and Underlying Disease

Liver atrophy is a major prognostic factor that should be considered before any liver resection, even those in patients with preserved liver function (see Chapters 5 and 50B). In our practice, we do not consider major liver resection in HCC patients with liver atrophy. Similarly, the underlying etiology of liver cirrhosis should be considered before liver resection, and it should be noted that the extent of fibrosis is more severe in patients with hepatitis C than in patients with hepatitis B (Roayaie et al, 2000). Our tendency is to consider a major liver resection more favorably in patients with hepatitis B than in patients with some other etiology of CLD, even if the remnant liver volume is similar.

Among patients with CLD, the postoperative risk is higher in those with cirrhosis (F4) than in those with extensive fibrosis (F3) (Farges et al, 1999). This suggests that preoperative liver biopsy should be considered in all candidates for major liver resection for histologic fibrosis grading. In patients with F3 or F4 fibrosis requiring major hepatectomy, preoperative portal vein embolization should be performed in an effort to decrease morbidity.

Volume of the Future Liver Remnant

Measurement of the volume of the remnant liver after planned resection using CT volumetry has been shown to be helpful in selecting patients for major hepatic resection (see Chapters 2 and 93). A small liver remnant volume is associated with worse postoperative liver function and a higher complication rate after extended hepatectomy (Ribero et al, 2007). The safety limit for the remnant liver volume in patients with normal liver is approximately 30% of the total nontumorous or functional liver volume, but this is much higher in patients with CLD. The safety limit in terms of remnant liver volume in patients with CLD has not been clearly documented, and it varies depending on the severity of cirrhosis, which influences the regeneration capacity of the diseased parenchyma. But in general a remnant liver volume of 40% to 50% of the total liver volume should be left before considering major liver resection (Azoulay et al, 2000; Lee & Hwang, 2005; Ribero et al, 2007).

ROLE OF PREOPERATIVE PORTAL VEIN EMBOLIZATION

For patients who require major or extended hepatectomy but have inadequate remnant liver volume, preoperative portal vein embolization (PVE) can be used to induce hypertrophy of the

remnant liver (Makuuchi et al, 1990; see Chapter 93). A general concern is that preoperative PVE may be less effective in the cirrhotic liver, compared with normal liver, because of its impaired regenerative capacity (Abdalla et al, 2002); however, recent studies have demonstrated that preoperative PVE is effective in inducing hypertrophy of remnant liver and decreasing postoperative complications in patients with cirrhotic livers undergoing hepatic resection for HCC. Our center also used PVE in selected F3 and F4 cirrhotic patients undergoing major hepatectomy. The procedure was well tolerated, but the degree of hypertrophy varied according to the degree of fibrosis and the severity of cirrhosis (Farges et al, 1999).

Absence of hypertrophy of the FLR should be considered an absolute contraindication for hepatic resection (Belghiti & Ogata, 2005; Sato et al, 2000); however, we showed that preoperative sequential transarterial chemoembolization (TACE) and PVE increased the hypertrophy of the FLR. In addition, we found a clear relationship between the rate of hypertrophy and postoperative risk after major hepatectomy in cirrhotic patients. These results were recently confirmed by a similar study, which showed that sequential TACE and PVE increase the hypertrophy rate of the remnant liver and are associated with improved overall and recurrence-free survival in patients with HCC, compared with those who have PVE alone (Yoo et al, 2010). After right hepatectomy for HCC, all postoperative deaths and most severe complications were experienced in F4 patients with less than a 10% increase of FLR. Based on these observations, we propose that a minimum increase of 10% of the FLR in F3 or F4 patients is essential to safely perform a right hepatectomy.

OPERATIVE TECHNIQUES

The general techniques of liver resection are described in Chapters 90A and 90B. This chapter focuses mainly on operative techniques specifically related to the cirrhotic liver.

Skin Incision

A bilateral subcostal incision is the standard incision for hepatic resection and is adequate for most cases of hepatectomy; an extended right subcostal incision is an acceptable alternative. The approach to large tumors located in the upper segment of the right liver or in its posterior surface (segment VII) can be facilitated by an upward midline extension or by a J-incision (Sato et al, 2000). Although the diaphragm incision increases the rate of pleural effusion, it facilitates parenchymal transection by making the transection plane perpendicular to the wound. A study by the Hong Kong group (Xia et al, 2003) showed that a thoracoabdominal approach for right-sided hepatectomy does not increase operative morbidity, compared with an abdominal approach alone, and may help reduce blood loss and transfusion requirements. For cirrhotic patients with HCC in the superior segments of the liver located beneath the right diaphragm, an exclusive transthoracic approach has been described, but this approach allows only limited resection with a high risk of positive margin (Pocard et al, 2002).

Intraoperative Ultrasound

Intraoperative ultrasound (IOUS) with color Doppler is an invaluable tool in hepatic resection, allowing localization of intrahepatic vessels, assessment of their relationship with tumors, and detection of other nodules and tumor thrombus. IOUS also enables accurate marking of the transection line to ensure an adequate tumor-free margin (see Chapter 21). The use of IOUS optimizes the balance between oncologic radicality and sparing of the largest amount of functioning liver parenchyma in the cirrhotic liver. Recently, systematic segmentectomy and subsegmentectomy by IOUS-guided finger compression was described (Torzilli et al, 2010). This technique can be potentially applied in each segment of the liver, as long as the thickness of the parenchyma and the anatomy of the liver are suitable. The IOUS-guided finger compression of the vascular pedicle feeding the tumor at the level closest to the tumor results in a demarcation area that allows oncologic resection.

Contrast-enhanced ultrasound examination using microbubble contrast agents (SonoVue; Bracco Imaging, Milan, Italy) provides information about tumor hypervascularity, which is useful for nodule differentiation. This improves the accuracy of assessing focal liver lesions in cirrhotic livers, particularly those lesions less than 1 cm. Contrast agents such as Sonazoid (Daiichi Sankyo, Japan) show two different patterns of enhancement: early hypervascular phase, a result of tumor vascularity, and late hypoechoic phase, a result of Kupffer cell uptake. This increases the specificity of diagnosing HCC of less than 1 cm in cirrhotic livers.

Anterior Approach

When liver tumors are large, the use of conventional techniques may require forceful retraction and mobilization of the liver, with possible consequences that include compression of both right and left lobes and possible tumor disruption or dissemination of tumor cells. Mobilization of the cirrhotic liver is technically more demanding, because of the firm texture of the fibrotic liver. The collateral vessels formed secondary to portal hypertension may increase the risk of bleeding during liver mobilization. Prolonged forceful rotation of the liver increases the risk of avulsion injury to the hepatic veins and may twist the inflow and outflow vascular pedicles, resulting in ischemic damage to the remnant liver. Care should be taken to avoid prolonged rotation of the liver. The anterior approach attempts to diminish manipulation of the tumor-bearing liver by initial vascular inflow control, parenchymal transection until the anterior surface of the inferior vena cava is exposed, venous outflow control, and finally mobilization of the right liver (Agrawal & Belghiti, 2011).

Once the devascularized tumorous liver is disconnected from the vena cava, it makes sense that its mobilization is less hemorrhagic, and that this "no touch" liver resection could reduce possible systemic dissemination of cancer cells. In a prospective randomized controlled study of the anterior versus conventional approach in patients with HCC greater than 5 cm, a group from the University of Hong Kong demonstrated significantly less frequent major operative blood loss greater than 2 L (28.3% vs. 8.3%) and also demonstrated superior overall survival—median 68.1 months versus 22.6 months—with the anterior approach (Agrawal & Belghiti, 2011).

The liver-hanging maneuver, originally described by our group, involves the passage of a tape in the avascular retrohepatic precaval space to suspend the liver during parenchymal transection, thereby facilitating the anterior approach by minimizing bleeding in the deeper parenchymal plane and guiding the direction of the parenchymal transection (Agrawal & Belghiti, 2011). The traction of this tape allows delineation of the

planned parenchymal transection, which follows a hepatic vein. The transection plane along a hepatic vein represents an oncologic plane and preserves the outflow of the remnant liver, increasing both its function and its potential for regeneration. Application of the hanging maneuver has been further extended to the three Glisson pedicles and hepatic veins, facilitating the performance of right and left anatomic liver resections (Agrawal & Belghiti, 2011). Although more data based on long-term survival are expected, several arguments are leading to recommend the anterior approach in combination with the hanging maneuver as the preferred operative approach for liver malignancy.

Technique of Liver Transection

The main difficulty of hepatic resection in the cirrhotic liver lies in control of bleeding during transection of the fibrotic parenchyma. Clamp crushing, the conventional method of liver transection, is still used in some centers (Imamura et al, 2003; Jarnagin et al, 2002); however, the Cavitron Ultrasonic Surgical Aspirator (CUSA, Valleylab, Boulder, CO) is probably a better alternative and appears to reduce blood loss compared with the clamp-crushing technique (Fan et al, 1996). The CUSA has become the standard technique of liver transection for cirrhotic liver in many centers (Takayama et al, 2001).

Other techniques of liver transection use the Harmonic Scalpel (Ethicon Endo-Surgery, Cincinnati, OH) and multiprobe bipolar radiofrequency device (Habib 4X; AngioDynamics, Latham, NY). The latter allows surgeons to perform minor and major hepatectomies with minimal blood loss, a low blood transfusion requirement, and reduced mortality and morbidity rates (Ayav et al, 2008); however, this device is seldom used in tertiary reference centers for treatment of HCC because of concerns about the preservation of venous drainage of the remnant liver and the risk of postoperative bile leak and necrosis (Kim et al, 2003; Lupo et al, 2007). The role of this technology probably is limited to segmental or wedge excision because of the potential risk of vascular and bile duct injury when using multiprobe bipolar radiofrequency near the liver hilum and its inability to control bleeding from large venous branches. Saline-linked cautery (TissueLink Medical, Dover, NH) uses a metal probe to deliver radiofrequency energy conducted through a slow infusion of saline. This procedure enlarges the transection margin (Kianmanesh et al, 2008) and can be associated with ultrasonic dissection in a standardized fashion (Aloia et al, 2005).

Anatomic and Nonanatomic Resection

Intrahepatic metastasis of HCC along the portal vein is the basis of anatomic liver resection. In cirrhotic patients, oncologic safety must be balanced with future liver volume. Analysis of a nationwide Japanese database that included 72,144 patients showed improved disease-free survival with anatomic resection compared with nonanatomic resection, but no difference in overall survival was found (Eguchi et al, 2008). When survival was stratified by tumor size, disease-free survival was significantly improved with an anatomic resection for HCC with a diameter of 2 to 5 cm. The low incidence of vascular invasion in HCC of less than 2 cm may explain the absence of a beneficial effect with anatomic resection and the equivalent efficacy of local ablative therapy. For HCC greater than 5 cm, the tumor is often associated with vascular invasion, satellite nodules, and other adverse pathologic features, which probably offsets the effect of the type and extent of hepatectomy (Agrawal & Belghiti, 2011).

Vascular Staplers

Staplers can be used in liver surgery for control of inflow and outflow vessels. The use of a vascular stapler may help reduce blood loss, especially in situations in which a large tumor in the right or left lobe hinders exposure of the right or left hepatic vein, or during control of the middle hepatic vein deep in the transection plane. The vascular stapler also can be used to divide the hepatic pedicle in right or left hepatectomy (Figueras et al, 2003) with results similar to those of hilar dissection. The use of vascular staplers to divide the hepatic pedicle saves suturing time, but care must be exercised not to narrow the hepatic duct confluence, especially during a right or left extended hepatectomy (Wang & Fan, 2003).

Vascular Occlusion

During liver resection, reducing blood loss and thereby reducing the need for transfusion is essential, especially in cirrhotic patients, who have a poor tolerance to hemodynamic instability and to massive transfusion. A review of the literature concerning the relationship between blood loss and blood transfusion during liver surgery for malignant tumors and postoperative outcome showed a significant and clinically relevant association between blood transfusion and postoperative mortality and morbidity, especially postoperative infectious complications (De Boer et al, 2007). In particular, blood transfusion may have an impact on tumor recurrence in patients with early stages of HCC. Vascular clamping in an effort to reduce intraoperative blood loss is counterbalanced by a poor tolerance of cirrhotic parenchyma to warm ischemia. Total vascular occlusion, even when associated with in situ cold perfusion of the liver, is contraindicated in patients with diseased liver (Azoulay et al, 2006). Intermittent inflow occlusion, with 15 minutes of clamping and 5 minutes of unclamping, is well tolerated for up to 90 minutes in selected cirrhotic patients with good liver function (Ishizaki et al, 2006). In our center, we do not hesitate to use intermittent inflow clamping when resection is difficult or when there is a need to define adjacent vascular or biliary structures in the margin of resection.

Overall, a tendency to perform hepatic resection without clamping has resulted from several factors, including 1) increased experience of surgeons in liver resection; 2) the use of isolated inferior vena cava occlusion without any risk of ischemia on the liver parenchyma, and 3) the practice of low central venous pressure (CVP) anesthesia. One of the most important factors related to intraoperative blood loss is pressure within the inferior vena cava (Johnson et al, 1998). As hepatic venous pressure directly reflects the caval pressure, the maintenance of a low CVP is an effective technique to reduce back bleeding from the hepatic veins.

Abdominal Drainage

The risk of hemorrhage and bile leakage and the high rate of ascites after hepatectomy in the cirrhotic liver leads many surgeons to consider abdominal drainage. In a retrospective study that included 1269 consecutive patients who underwent

elective hepatectomy with drain insertion for malignant tumors, seven patients had postoperative bleeding (0.6%), and bile leakage was found in 111 patients (8.7%; Kyoden et al, 2010). The authors concluded that placement of drains was effective in a considerable proportion of patients undergoing hepatectomy, with regard to reducing the frequency of subphrenic fluid collections and biliary fistula.

In a prior review, Burt and colleagues (2002) showed that placement of drains after routine hepatic resection was unnecessary, but the use of drainage after routine liver resection remains a point of controversy. A randomized controlled trial (RCT) performed in the Hospital Clinic of Barcelona (Fuster et al, 2004) showed that intraabdominal closed drainage is advisable in cirrhotic patients undergoing liver resection for HCC, mainly for patients with preoperative portal hypertension. By contrast, another RCT showed that the placement of abdominal drains after hepatic resection in the cirrhotic liver was associated with increased wound and septic complications and prolonged hospital stay (Liu et al, 2003), because the drain provides a route for ascending infection and results in loss of protein and electrolytes.

LAPAROSCOPIC RESECTION

Laparoscopic liver resections represent about 10% to 20% of all liver resections performed at most centers (see Chapter 90E). Limited to a few centers worldwide (Dagher et al, 2007, 2008; Vigano et al, 2009), laparoscopic resections are associated with a long learning curve, difficulty achieving wide resection margins and in performing anatomic resections, and technical difficulties in mobilization and parenchymal transection with risk of massive bleeding; all of these remain obstacles for the emergence of laparoscopic liver resection as a routine procedure. Anticipated advantages from laparoscopic liver resections include that it is a less aggressive approach with less painful incisions, fewer pulmonary complications, and earlier recovery, and it requires less extensive peritoneal dissection; this means the avoidance of collateral ligation, less bleeding, minimal ascites, and decreased postoperative liver failure (Cherqui et al, 2000).

These potential benefits could expand indications of liver resection in some patients with class B cirrhosis (Agrawal & Belghiti, 2011). Moreover, fewer postoperative adhesions after laparoscopic liver resection, compared with open liver resection, might facilitate subsequent salvage liver transplantation with decreased morbidity (Laurent et al, 2009). The laparoscopic approach is also a potentially useful tool for treating tumors with RFA (Santambrogio et al, 2005).

Lesions located in posterior segments (VII, VIII, IVa, or I) have typically been difficult for a purely laparoscopic approach and are more often described with hand-assisted resections (Huang et al, 2009; Koffron et al, 2007) or assisted laparoscopic resections (Nitta et al, 2010). Laparoscopy also has limited role in lymph node or porta hepatis dissections.

Morbidity and Mortality

Improvements in patient selection and surgical technique have resulted in a remarkable decrease in perioperative mortality rates. In the 1980s, the mortality rate after liver resection in cirrhotic patients was typically 15% to 30%, and liver resections in cirrhotic patients were largely restricted to segmental or subsegmental resections (Bismuth et al, 1986; Matsumata et al, 1990); however, over the past several years, significant improvements in operative and perioperative care were realized, such that the current mortality rate is approximately 5%, with some centers approaching zero mortality (Jaeck et al, 2004; Torzilli et al, 1999). The Hong Kong group showed that even extended right or left hepatectomy could be performed in cirrhotic patients with acceptable morbidity and mortality, which were not significantly different from rates of patients with less extensive resections (Poon et al, 2002c).

Because the operative morbidity after hepatic resection in the cirrhotic liver remains high (30% to 40%), further efforts are required to reduce the operative morbidity. Cirrhotic patients who undergo hepatic resection require close postoperative monitoring and careful management in the postoperative period. Management aims at adequate oxygenation and perfusion to ensure optimal function and regeneration of the remnant liver.

Intravenous Fluid

Although fluid restriction has been found to reduce the incidence of postoperative morbidity in some surgical patients (Nisanevich et al, 2005), optimal fluid substitution strategies remain controversial, because fluid optimization increases tissue oxygen tension and microcirculatory perfusion (Futier et al, 2010). It has been shown that excessive fluid restriction leads to hypovolemia and reduced central venous oxygen saturation, thereby increasing postoperative complications (Futier et al, 2010). Excessive fluid restriction should be applied cautiously in cirrhotic patients. Crystalloid solution (dextrose and saline) is used for maintenance of intravenous fluid. In some centers, fresh frozen plasma is used routinely for fluid replacement during and after the operation (Imamura et al, 2003), although there is no evidence to support such a practice. In our center, albumin is used instead, because fresh frozen plasma is associated with potentially significant transfusion-related complications.

Antibiotics

There is a tendency to administer prophylactic antibiotics to cirrhotic patients beyond the accepted single preoperative dose because of their immunocompromised state. Intraoperative antibiotic prophylaxis is aimed at preventing translocation of intestinal enterobacteria to the systemic circulation in patients with both healthy and diseased livers. The risk of infection is aggravated further by the prolonged operation and the high frequency of ascites. Septic complications, especially wound infection, are the most common complications after hepatectomy for HCC (Fan et al, 1999); however, no randomized trials suggest the optimal regimen of antibiotics in patients with cirrhosis.

Pain Control

Adequate pain control is an important factor in reducing the incidence of pulmonary complications after hepatic resection for HCC (see Chapter 22).

Nutrition Support

Because of the prevalence of malnutrition in cirrhotic patients, nutrition support is important to enhance postoperative recovery and liver regeneration (see Chapter 24). Oral feeding is started early, on postoperative day 1, if the patient does not manifest signs of liver failure. Since a randomized, controlled trial published in 1994 (Fan et al, 1994) showed the benefit of

parenteral nutrition in reducing postoperative morbidity, postoperative parenteral nutrition has become a routine practice in many centers for patients with cirrhosis undergoing major hepatic resection.

In addition to complications associated with all major surgery, specific risks of liver resection in cirrhotic patients include ascites, right pleural effusion, subphrenic abscess, bleeding, biliary leak and fistula, and hepatic insufficiency.

Postoperative Ascites

Postoperative ascites is a classic complication following liver resection in cirrhotic patients, and it affects more than one third of patients. Significant ascites is poorly defined, but the presence of ascitic fluid drainage from thoracic and abdominal drains exceeding 10 mL/kg of preoperative body weight (Ishizawa et al, 2009) or a daily output greater than 500 mL after postoperative day 3 require a specific aggressive intervention. Factors that increase the rate and amount of ascites include preexisting ascites before resection, the presence of portal hypertension, low platelet count, major resection, pedicular clamping, lymph node dissection, and perioperative fluid infusion, including blood transfusion. Ascites after liver resection in cirrhotic patients has several potential deleterious consequences, including abdominal pain, impairment of ventilation, development of pleural effusion, infection, impairment of renal function, and abdominal leak. Ascites leakage through the abdominal incision can result in loss of electrolytes and protein, and the risk of intraabdominal infection is also increased.

The management of ascites requires replacement of fluid lost and, in some cases, aggressive diuretic therapy. Fresh frozen plasma transfusion during and after liver resection is advocated by some surgeons (Ishizawa et al, 2009) but is not supported by other studies, which show an increased risk of transmitting diseases and more adverse consequences, such as transfusion-related acute lung injury, acute allergic and anaphylactic reactions, and high cost (Caldwell et al, 2006). In several centers such as ours, fresh frozen plasma is replaced by albumin or other plasma expanders.

Postoperative Bleeding

The risk of postoperative bleeding is very low, around 1% (Belghiti et al, 2000; Imamura et al, 2003; Jarnagin et al, 2002). The presence of bleeding during the first postoperative day is a life-threatening complication that requires reoperation, and it comes with a 30% risk of death in cirrhotic patients. This high risk makes ensuring a perfect hemostasis at the end of liver resection imperative for all liver operations, but especially those in cirrhotic patients.

Biliary Fistula (See Chapter 42)

Bile leakage after hepatic resection can cause septic complications, which lead to a high risk of mortality in cirrhotic patients. The rate of biliary leakage was found to be approximately 6% in a single-center series of 605 liver resections for HCC, and it was increased by preoperative chemoembolization and with tumors with a central location (Lee et al, 2005). Although drainage fails to prevent postoperative biliary collection in approximately one third of patients, and percutaneous drainage is therefore required (Kyoden et al, 2010), this risk of bile collection has led some authors to adopt the use of long-term drains (Torzilli et al, 2005). In a prospective cohort study that enrolled 58 patients, who underwent liver resection for tumors with abdominal drains maintained for at least 7 days postoperatively, Torzilli and colleagues (2005) showed that the bilirubin level in the drain was higher on the fifth postoperative day than on the third and seventh postoperative days, leading them to advocate the use of long-term drains.

Portal Thrombosis

This life-threatening complication in cirrhotic patients is poorly described and can be induced by several factors, including portal hypertension, previous preoperative PVE, and portal vein injury. Patients should therefore undergo regular ultrasound evaluation during the first postoperative week if hepatic function shows no signs of improvement, especially if significant clinical deterioration is apparent. The presence of portal thrombosis early after resection might require urgent reoperation and/or anticoagulation treatment, particularly when associated with deteriorating liver function.

Liver Failure

Patients with cirrhosis have decreased liver functional reserve and a limited capacity for liver regeneration. As a result, major hepatectomy in cirrhotic patients is associated with a significant risk of liver failure that could occur primarily as a result of inadequate liver remnant, but more often it is precipitated by massive bleeding or septic complications. Despite improvements in the safety of hepatectomy in recent years, postoperative liver failure still occurs in 3% to 10% of patients after resection for HCC (Kubo et al, 2004; Osada & Saji, 2004).

Liver failure is associated with a high mortality rate and is the most common cause of hospital mortality following hepatic resection in the cirrhotic liver (Belghiti et al, 2000; Wu & Zhang, 2002). Cirrhotic patients are also prone to gradual hepatic decompensation in long-term follow-up, especially after major hepatic resection for large HCCs (Huo et al, 2004). Although several clinical and biologic factors are markers of impaired liver function—such as ascites, encephalopathy, jaundice, prolonged prothrombin time, hyperbilirubinemia, and hypoalbuminemia—no standardized definition of postoperative liver failure (PLF) has been agreed upon, nor have any precise data on its correlation with postoperative mortality been reported.

The need for standardization of PLF is important. Prothrombin time (PT) and serum total bilirubin level (SB)—two biologic indicators of liver dysfunction in the Child-Turcotte-Pugh scoring system (and also two of the three components of the MELD score)—are less reliable postoperatively because of the natural impairment of liver function tests during the first postresection days. We found that on postoperative day 5, the association of PT less than 50% and SB greater than 50 ml/L, the so-called 50-50 criteria, was a simple, early, and accurate predictor of a higher than 50% mortality rate after hepatectomy (Balzan et al, 2005). Moreover, these clinical criteria may be useful to identify high-risk patients before clinical evidence of complications appear, allowing the institution of specific interventions that may help improve outcome. Postoperative complications that include portal vein thrombosis, ascites, and pulmonary infection are difficult to diagnosis early after operation, but they result in late mortality in a high proportion of patients. Early recognition of postoperative liver failure is an important factor that may allow early intervention and improved outcome.

CHAPTER 93B

Preoperative portal vein embolization: technique

David C. Madoff

OVERVIEW

Portal vein embolization (PVE) is performed preoperatively to reduce the risk of extensive surgery in patients with small anticipated remnant livers (Makuuchi et al, 1990; de Baere et al, 1993; Abdalla et al, 2002; Madoff et al, 2005a; see Chapter 30a). PVE redirects portal blood flow to the intended future liver remnant (FLR) in an attempt to initiate hypertrophy of the nonembolized segments, and it has been shown to improve the functional reserve of the FLR before surgery. In appropriately selected patients, PVE has also been shown to reduce perioperative morbidity, and it allows for safe, potentially curative hepatectomy for patients previously considered ineligible for resection based on anticipated small remnant livers (Azoulay et al, 2000; Madoff et al, 2005a; Abulkhir et al, 2008). For this reason, PVE is now performed at many comprehensive hepatobiliary centers worldwide prior to major hepatectomy. This section details the techniques currently used to perform PVE, discusses their advantages and disadvantages, and reviews the potential complications that can occur from this procedure.

TECHNICAL ASPECTS OF PORTAL VEIN EMBOLIZATION

Access Routes to the Portal Venous System

PVE can be performed by any of three standard approaches: 1) the intraoperative transileocolic venous approach, 2) the transhepatic contralateral approach (i.e., percutaneous portal vein is accessed via the FLR), and 3) the transhepatic ipsilateral approach (i.e., percutaneous portal access is via the liver to be resected; Madoff et al, 2005a). It is important to note that the approach to the portal vein is chosen at the discretion of the operator, and the decision may be based on multiple factors, including the extent of the embolization and surgery, the operator's preference for a specific embolic agent, tumor burden within the liver, and the operator's level of experience with one technique over another (Avritscher et al, 2008). An alternative approach, portal vein ligation, is typically performed intraoperatively during the first stage of a two-stage resection for hepatic colorectal metastases, and it has been reported to be as effective as percutaneous embolization methods (Aussilhou et al, 2008). Regardless of the technique used, the operator must be aware of variations in portal venous anatomy that may impact the conduct of the procedure (see Chapter 1B).

Transileocolic Venous Approach

The transileocolic venous approach was the first approach described for performing preoperative PVE, and it is still used in many Asian centers. This technique is performed at laparotomy by direct cannulation of the ileocolic vein and introduction of a catheter into the portal system for embolization (Abdalla et al, 2002). Conventional teaching has been that this approach is performed when additional treatment is needed during the same surgical exploration, when a percutaneous approach is not considered feasible, or when an interventional radiology suite is not available (Azoulay et al, 1995; Denys et al, 2002).

The disadvantages of this method are the need for general anesthesia and laparotomy, with their inherent risks, and the inferior imaging equipment often available in the operating room, compared with the state-of-the-art imaging equipment available in most modern interventional radiology suites; however, as more minimally invasive techniques have become favored, and as the equipment used—imaging equipment, catheter systems, embolic agents, and so on—has become more sophisticated, the reasons for using this technique apply in very limited situations, such that the transileocolic venous approach is being used less often than the techniques described below.

Percutaneous Transhepatic Ipsilateral Approach

The percutaneous transhepatic ipsilateral approach was first described by Nagino and coworkers (1996), and it is now advocated by many other investigators (Madoff et al, 2003, 2005b; Gibo et al, 2007; Tsuda et al, 2006). With this approach, access is obtained through the portal branches within the tumor-bearing liver (Fig. 93B.1). A distinct advantage of the ipsilateral approach is that the FLR is not instrumented. It also allows for straightforward catheterization of segment IV branches, should embolization of segment IV be required. When planning the puncture, the anterior segment of the right portal vein is preferred, because its use is associated with a lower complication rate (Kodama et al, 2002); however, catheterizing the right portal branches can be challenging, owing to the sharp angulation of the right portal veins, which often necessitates using reverse-curve catheters or balloon occlusion catheters with multiple lumina (Nagino et al, 1996, 2000a).

In Nagino's approach (see Fig. 93B.1), the right anterior portal vein is punctured using sonographic guidance, and a 6-Fr sheath is introduced into the right portal vein system (Nagino et al, 2000a). To make this procedure feasible, the authors designed two types of 5.5-Fr triple-lumen balloon catheters. The first catheter, "type 1," was designed with one lumen connected to the balloon and two lumina connected to the tip. The second catheter, "type 2," had two separate lumina opening proximal to the balloon, and the balloons were used to prevent any backflow of embolic material. Both catheters had two separate lumina so that fibrin glue and iodized oil could be injected simultaneously. To facilitate resection, the authors advocated that a proximal

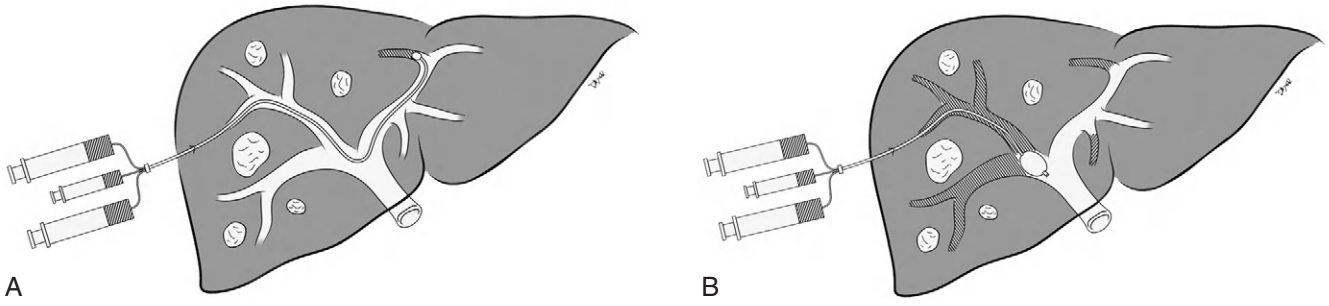

FIGURE 93B.1. Schematic representation of the ipsilateral approach for right portal vein embolization (PVE) and segment IV as described by Nagino and coworkers. Different balloon catheters are used for antegrade embolization of segment IV veins (**A**) and for retrograde delivery of the embolic agent into the right portal system (**B**).

right portal vein segment at least 1 cm in length remain patent. Depending on the portal vein anatomy, and the need to spare the proximal right portal vein, type 1 or type 2 catheters were used for embolization. The type 1 catheter was used for embolization of branches distal to the catheter tip, whereas the type 2 catheter was used for embolization of branches proximal to the catheter tip, as mandated by each patient's portal vein anatomy.

In a recent study, Gibo and coworkers (2007) reported on a modified technique utilizing a four-lumen balloon catheter in eight patients. The authors recommended using this modified catheter because of its larger occlusion balloon and lumina, which allow for safer and easier embolization using fibrin glue. Unfortunately, neither the original nor the modified catheters are available in the United States.

In the early 2000s, Madoff and coworkers (2003, 2005b) described a technique using angiographic catheters commercially available worldwide (Figs. 93B.2 and 93B.3). Under sonographic guidance, a 22-gauge Chiba needle (Neff Percutaneous Access Set; Cook Medical, Bloomington, IN) is used to puncture a distal branch of the right portal system. Subsequently, a 5- or 6-Fr vascular sheath is advanced over a guidewire into the right portal vein branch to aid with subsequent catheter

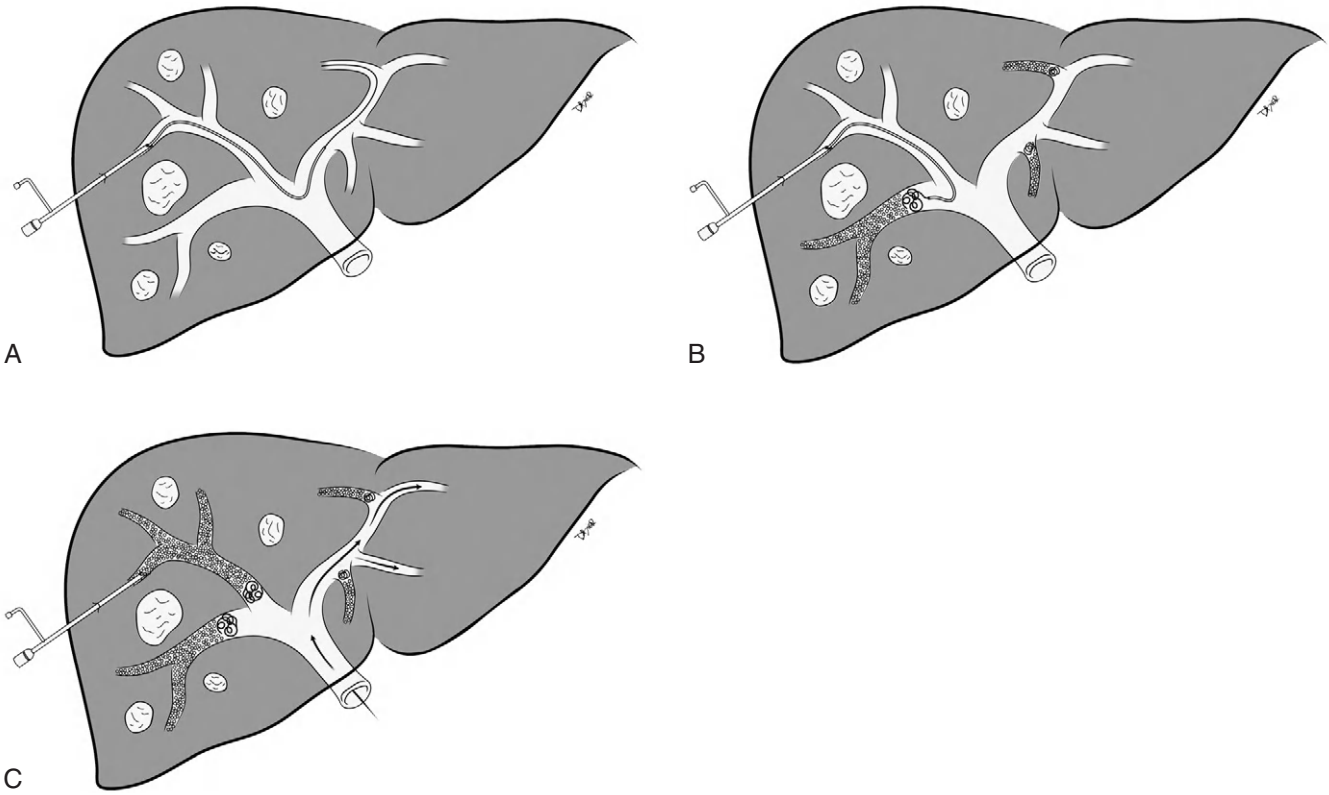

FIGURE 93B.2. Schematic representation shows modification of the ipsilateral technique for right portal vein embolization (RPVE) extended to segment IV. **A,** Placement of a 6-Fr vascular sheath into the right portal branch. An angled 5-Fr catheter is placed into the left portal system with coaxial placement of a microcatheter into a segment IV branch. Particulate embolization is performed followed by placement of coils, until all the branches are occluded. **B,** After segment IV embolization is completely occluded, a 5-Fr reverse-curve catheter is used for RPVE. **C,** After embolization of the right and segment IV portal veins are complete, the access tract is embolized with coils to prevent subcapsular hemorrhage.

FIGURE 93B.3. A 67-year-old man with pancreatic insulinoma metastatic to the liver who had transhepatic ipsilateral right portal vein embolization (RPVE) with particles and coils prior to right hepatectomy. **A,** Contrast-enhanced computed tomographic (CT) scan of the liver shows a hypervascular mass in the right liver consistent with metastatic disease (*arrow*). **B,** Contrast-enhanced CT scan of the liver shows a small left liver within the shaded area (functional liver remnant/total estimated liver volume ratio [FLR/TELV] of 16%). **C,** Anteroposterior flush digital subtraction portogram shows a 6-Fr vascular sheath (*arrowheads*) in a right portal vein branch and a 5-Fr flush catheter (*arrow*) in the main portal vein. **D,** Postprocedure anteroposterior flush portogram shows occlusion of the portal vein branches to segments V through VIII (*white arrows*) with continued patency of the vein supplying the left liver (*black arrow*). An *arrowhead* shows subtracted contrast within a right portal vein branch overlying the left liver. **E,** A later phase of portogram confirms persistent flow to the left liver (*arrows*). **F,** Contrast-enhanced CT scan of the liver performed 1 month after RPVE shows hypertrophy of the left liver within the shaded area (FLR/TELV of 34%). The patient soon after underwent an uneventful right hepatectomy.

exchanges. Flush portography is performed with a 5-Fr angiographic flush catheter placed within the main portal vein. Anteroposterior and craniocaudal projections are obtained as needed to delineate the portal anatomy.

When embolization of the right portal vein is extended to segment IV (Fig. 93B.4), segment IV embolization should be performed first (Madoff et al, 2005b). This sequence is advocated because of the potential difficulty of exchanging catheters through a previously embolized right portal system and the possible dislodgement of embolic material from the right liver during the subsequent treatment of segment IV, which is usually embolized with a 3-Fr microcatheter placed coaxially through a selective 5-Fr angiographic catheter.

Early on, polyvinyl alcohol (PVA) particles (Contour SE Microspheres; Boston Scientific, Natick, MA) were the embolic agents of choice (Madoff et al, 2003). PVA was administered in a stepwise fashion: smaller particles (355 to 500 μm) were used first to occlude the distal branches, and larger particles (up to 1000 μm) were used subsequently to occlude branches more proximally. Larger particles were not used until the forward portal blood flow was considerably reduced. Additional embolization with the larger particles was then performed, until near complete stasis was achieved. Later, with the advent of spherical embolic agents, tris-acryl gelatin microspheres (EmboGold Microspheres; Biosphere Medical, Rockland, MA) became the embolic agent of choice (Madoff et al, 2005b). EmboGold microspheres ranging from 100 to 700 μm in diameter are administered in a stepwise fashion, similar to the method used for the PVA particles. After particulate embolization is complete, platinum microcoils (Boston Scientific) are placed within the proximal segment IV branches to further reduce portal blood inflow that could lead to recanalization.

For right PVE (RPVE), the working catheter is exchanged for a 5-Fr reverse-curve catheter (Sos-2, AngioDynamics, Latham, NY) to enable delivery of the particulate embolic agent. These catheters are chosen for their ease of manipulation into the right portal branches, given the severe angulation of the right portal tree with the ipsilateral approach. As with segment IV embolization, smaller particles are used first to occlude the distal, smaller portal branches, and the larger particles are used later to occlude the more proximal, larger branches. After near complete stasis is achieved, 0.035- or 0.038-inch embolization coils (Gianturco, Cook Medical) are placed within the secondary portal branches to further reduce portal inflow that could lead to recanalization. A final portogram is obtained with the flush catheter positioned within the main portal vein to assess completeness of the embolization. At the completion of the procedure, the access tract is embolized with coils and/or Gelfoam to minimize the risk of bleeding at the liver puncture site.

Overall, the ipsilateral approach is safe and effective for achieving FLR hypertrophy preoperatively. Although disadvantages of the ipsilateral approach do exist, they are minor. As mentioned above, catheterization and embolization of the right portal vein branches may be challenging because of the severe angulations between right portal branches; however, this is rarely a problem when reverse-curve catheters are used. Operators also need to be aware that the ipsilateral approach carries the risk of puncture through tumor tissue when multiple or large tumors are present, which could theoretically lead to bleeding or tumor seeding.

Percutaneous Transhepatic Contralateral Approach

The percutaneous transhepatic contralateral approach was first described by Kinoshita and coworkers (1986) to slow the progression of tumor thrombus within the portal system. Modifications of this technique were later developed for the purpose of causing FLR hypertrophy (de Baere et al, 1993, 1996; Figs. 93B.5 and 93B.6). Similar to the ipsilateral approach, this approach also requires ultrasound-guided percutaneous puncture, using an 18- or 22-gauge needle, of a peripheral portal branch, preferably segment III accessed via the subxiphoid route. Because access is gained through the FLR, great care is taken to limit the number of punctures, and as with the ipsilateral approach, the most peripheral branch possible is targeted to avoid damage to the central structures.

Depending on the embolic agent used, an introducer sheath may or may not be required; a standard 5-Fr polyethylene catheter is inserted over a guidewire and placed with its distal tip within the main portal trunk to allow for flush portography. Depending on the specific targeted portal veins, embolization is carried out using either standard angiographic or balloon occlusion catheters. A short catheter between 25 and 30 cm in length is commonly used, as it is easier to handle and provides a smaller "dead space," which is especially important when using liquid embolics, such as n-butyl cyanoacrylate (NBCA) for embolization.

In terms of accessing the portal vein, the contralateral approach can be challenging when segment IV embolization is also needed. To ensure an adequate distance between the portal entry point and the segment IV branches, the operator must perform the puncture in a branch of the left lateral liver, usually from the Rex recess. Unlike the ipsilateral approach, segment IV embolization is performed after RPVE has rendered the segment IV branches more easily visible and dilated; however, a puncture in the Rex recess will make catheterization difficult, owing to the sharp angle of the vein and the risk of losing access. Segment III is often easier to access than segment II, and sonographic guidance in the axial plane makes it easy to differentiate segment II from segment III and the Rex recess. Because segment III branches arise in front of segment II branches within the Rex recess, catheterization of segment IV branches may be easier after puncture of segment III branches. After achieving complete occlusion of the targeted portal branches, the 5-Fr catheter is removed. Because the catheter entry site traverses the FLR, embolic material is not used to seal the puncture tract.

The major advantage of the contralateral approach over the ipsilateral approach is that catheterization of the right portal branches is technically easier and does not have to contend with awkward angles. In addition, embolization is performed with the catheter pointed toward the direction of flow. Some authors report that the contralateral approach allows better visualization of the embolized portal branches during the final portogram (Di Stefano et al, 2005); however, different operators have found that in using the modified ipsilateral approach, the image quality of the final postembolization portography is similar. In addition, with the use of reverse-curve catheters, ipsilateral PVE in the right liver can also be performed safely in the direction of portal venous flow (Madoff et al, 2002).

The main drawback of the contralateral approach is that it requires instrumentation of the left hepatic parenchyma during catheterization of the portal venous branches supplying the

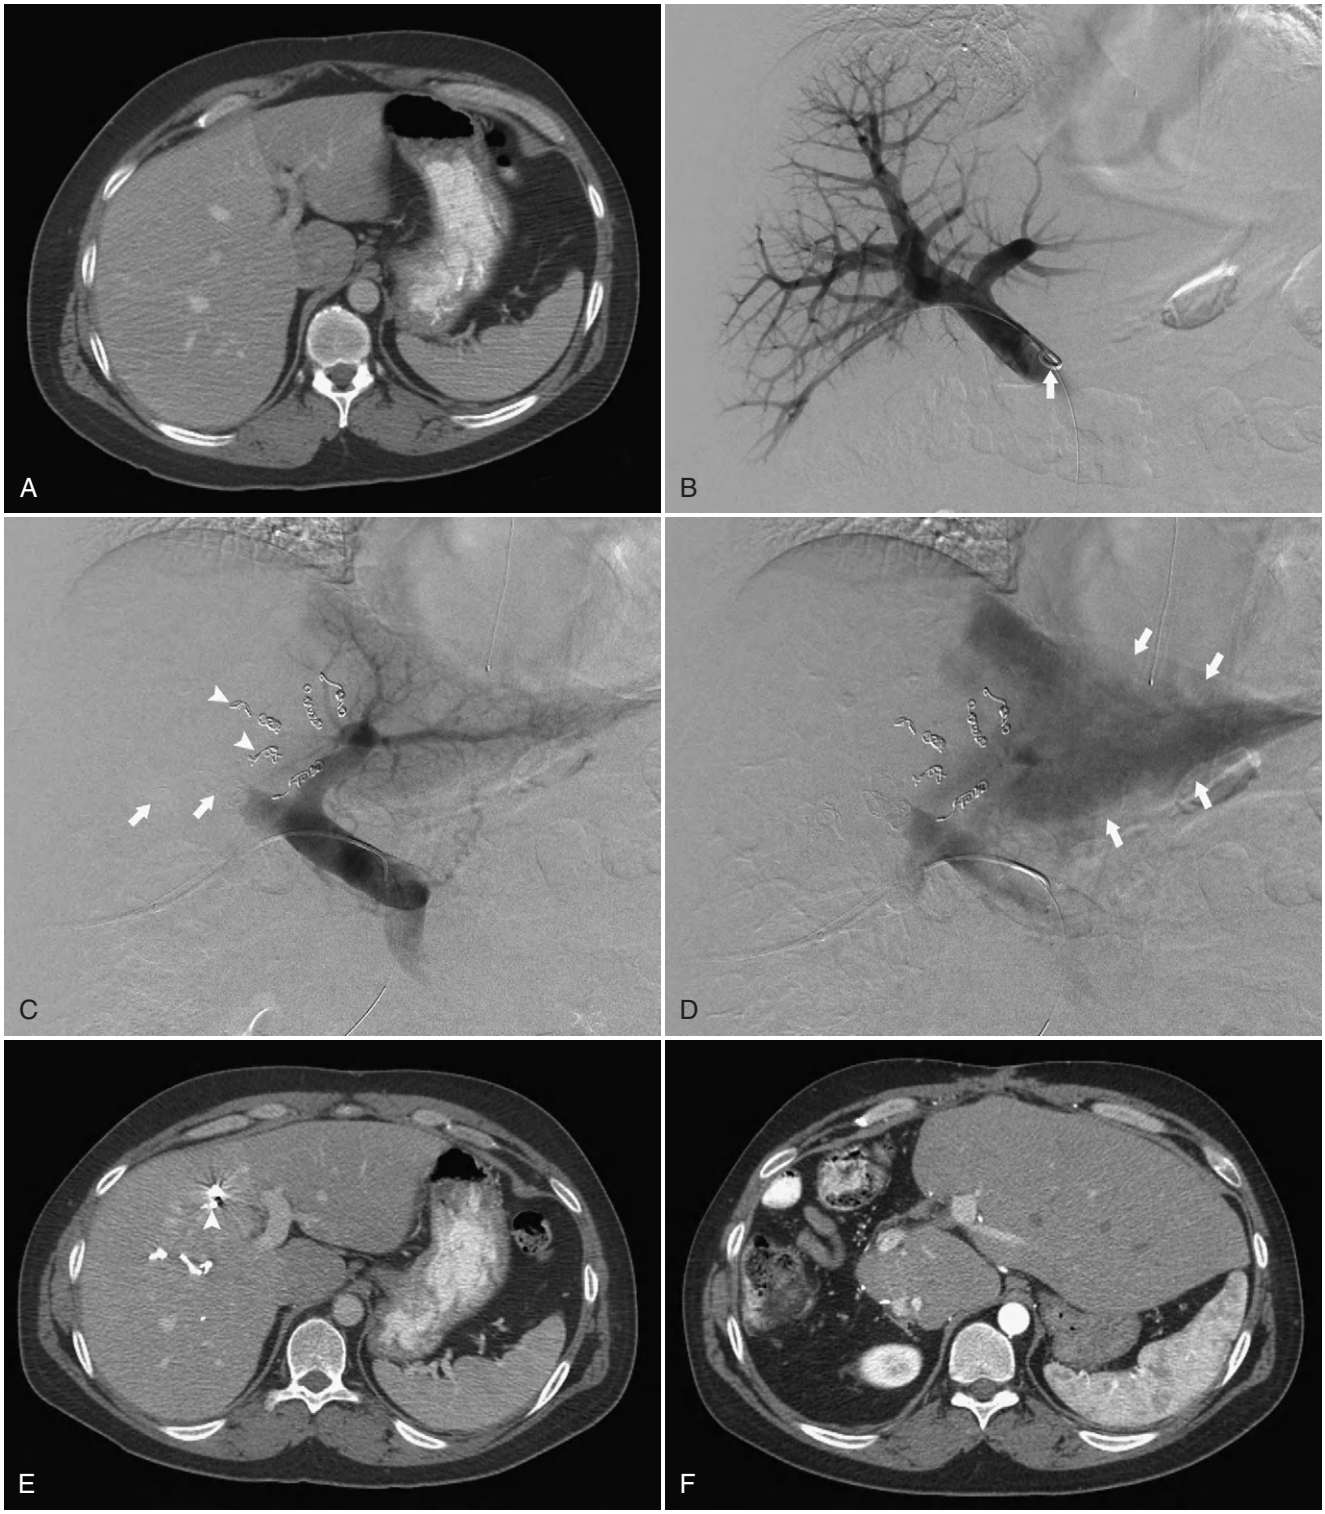

FIGURE 93B.4. A 38-year-old man with metastatic colorectal cancer to the liver who had transhepatic ipsilateral right portal vein embolization with particles and coils extended to segment IV prior to extended right hepatectomy. **A,** Contrast-enhanced computed tomography (CT) scan of the liver shows a small left lateral liver (functional liver remnant/total estimated liver volume ratio [FLR/TELV] of 16.9%; *shaded area*). **B,** Anterior–posterior flush portogram from the ipsilateral approach shows a 6-Fr vascular sheath in a right portal vein branch and a 5-Fr flush catheter (*arrow*) in the main portal vein. **C,** Postprocedure portogram shows complete occlusion, with particles and coils, of the portal vein branches to segment IV (*arrowheads*) and the right liver (*arrows*) with continued patency of the veins supplying the left lateral liver. **D,** A later phase of portogram confirms persistent flow to the left liver (*arrows*). **E,** Contrast-enhanced CT scan performed 4 weeks after portal vein embolization shows hypertrophy of the left lateral liver (FLR/TELV is now 27.2%, a degree of hypertrophy of 10.3%) with rounded margins (*shaded area*). A coil within segment IV (*arrowhead*) and coils within the right liver are seen. **F,** Contrast-enhanced CT scan of the liver performed after successful extended right hepatectomy shows hypertrophy of the liver remnant.

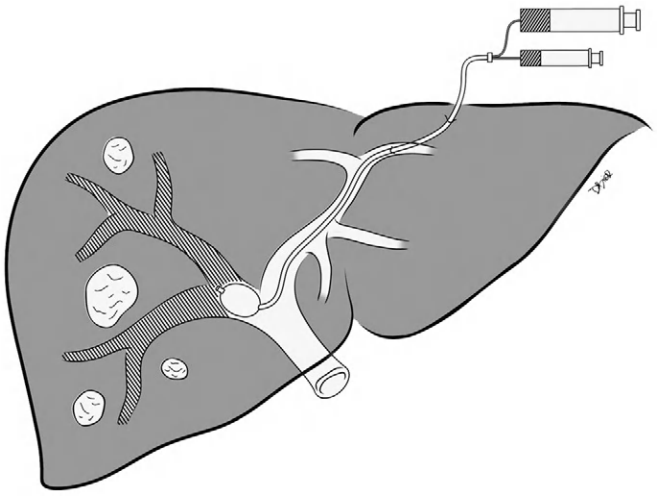

FIGURE 93B.5. Schematic representation of the contralateral approach. An occlusion balloon catheter is placed from the left lobe into the right portal branch, with delivery of the embolic agent in the antegrade direction.

FLR, potentially causing injury to the FLR parenchyma and/or to the left portal vein (Madoff et al, 2005a). If there are complications after PVE, these may involve the FLR and make the planned surgical resection more difficult or, at times, impossible.

Additional Approaches

Portal Vein Embolization with Transjugular Access

RPVE by means of the transjugular route has also been described (Perarnau et al, 2003). This technique was tried because of the familiarity gained during the preceding decade with transjugular intrahepatic portosystemic shunts (TIPS). Under sonographic guidance, the right internal jugular vein was accessed, and then with fluoroscopy, a right or left portal branch was punctured from a right, middle, or left hepatic vein. A catheter was placed near the portal bifurcation and used to perform RPVE with a mixture of NBCA and iodized oil. All 15 procedures were technically successful without any serious complications. FLR hypertrophy was deemed sufficient, and right hepatectomy was performed in 12 patients (80%). Although this approach appears safe and effective, the series was small, and further studies are needed before this approach becomes widespread. RPVE in patients with cirrhosis may be an attractive alternative; however, the technical feasibility of RPVE extended to segment IV has yet to be explored.

Portal Vein Embolization Followed by Bland Transarterial Embolization

Other approaches have been used for PVE. The combination of PVE and transarterial embolization (TAE) for complete portal venous and hepatic arterial occlusion has been reported in patients with biliary tract cancer and colorectal metastases who had inadequate hypertrophy after PVE alone (Nagino et al, 2000b; Gruttadauria et al, 2006). Nagino and coworkers (2000b) described a patient who required an extended left hepatectomy, but the FLR volume (i.e., the right posterior liver) did not increase 51 days after PVE. After arterial embolization, the FLR volume increased from 485 cm^3 before PVE to 685 cm^3 after PVE, an addition of 215 cm^3. Another patient required a right hepatectomy, but no significant volume change was seen after PVE (pre-PVE, 643 cm^3; post-PVE, 649 cm^3). After arterial embolization, the left liver volume enlarged to 789 cm^3, an increase of 140 cm^3. Both patients underwent uneventful resection after the staged procedures.

It must be noted that this procedure does have potential drawbacks. As both arterial and portal systems are deprived of blood, the potential for hepatic infarction exists such that only half the target segments were treated with arterial embolization superselectively. Although this approach was effective, the disadvantage is that two separate procedures are required, performed at different times, leading to considerably longer waiting periods. During these waiting periods, tumor progression could occur to the degree that the tumors become unresectable.

Sequential Arterial Embolization and Portal Vein Embolization

In 2004, Aoki and colleagues described their experience with the use of sequential transcatheter arterial chemoembolization followed within two weeks by PVE in 17 patients with hepatocellular carcinoma (HCC). Their justification for this approach was that, first of all, the livers of most patients with HCC are compromised by underlying liver disease such that the liver's regenerative capability after hepatic resection is weakened, making it hard to predict whether adequate FLR hypertrophy can be achieved after PVE. Second, arterioportal shunts often found in cirrhotic livers and HCC may limit the effects of PVE. Third, since most HCCs are hypervascular, supplied largely by arterial blood flow, termination of portal flow induces compensatory augmentation in arterial blood flow (i.e., "arterialization of the liver") in the embolized segments that may lead to rapid tumor progression after PVE.

To this end, sequential chemoembolization and PVE were used to prevent tumor progression during the interval between PVE and planned hepatectomy and to strengthen the effect of PVE by embolizing arterioportal shunts with chemoembolization. As a result, the combined procedures were deemed safe and were found to have induced sufficient FLR hypertrophy within 2 weeks, and they caused no worsening of the basal hepatic functional reserve and no increase in tumor progression. Importantly, when the explanted livers were assessed, tumor necrosis was profound but without substantial injury to the noncancerous liver, and the authors therefore encourage the aggressive use of this strategy in patients with large HCC and chronically injured livers.

More recently, a French group reported on the use of sequential chemoembolization and PVE in 36 patients with HCC and chronic liver disease prior to right hepatectomy (Ogata et al, 2006; Fig. 93B.7). In their study, 18 patients underwent chemoembolization, followed 3 to 4 weeks later by PVE, and the remaining 18 patients underwent PVE alone. Although PVE was well tolerated in all patients, the mean increase in percentage of FLR volume was significantly higher for patients in the combined chemoembolization and PVE group than in those who underwent PVE alone ($P = .022$). The incidence of complete tumor necrosis (83% [15/18] vs. 6% [1/18]; $P < .001$) and 5-year disease-free survival rate (37% vs. 19%; $P = .041$) were also significantly higher in patients who underwent chemoembolization and PVE. Given the risks of hepatic infarction, the authors recommended that the two

FIGURE 93B.6. Technique of transhepatic contralateral right portal vein embolization using n-butyl cyanoacrylate mixed with ethiodized oil. **A,** Ultrasound view of needle puncture of a segment III portal branch (*arrowheads*). **B,** Anteroposterior flush portogram shows a 5-Fr flush catheter within the main portal vein (*arrow*). **C,** Single image obtained during fluoroscopy shows cast of embolic material within right portal vein branches (*arrowheads*). **D,** Final portogram shows occlusion of the portal vein branches (*arrows*) to segments V through VIII with continued patency of the veins supplying the left liver. *(From Avritscher R, et al, 2008: Percutaneous transhepatic portal vein embolization: rationale, technique and outcomes. Semin Interv Radiol 25:132-145.)*

procedures should be separated by at least 3 weeks to reduce procedure-related morbidity; however, similar to Nagino's approach of performing PVE followed by TAE, the downside of the combined approach is that two separate procedures and increased waiting times are required.

Extent of Embolization

The optimal extent of PVE is presently a subject of considerable debate (van Gulik et al, 2008). Currently, most who prepare patients for extended right hepatectomy with PVE occlude only branches of the right portal vein and leave the segment IV portal veins patent (de Baere et al, 1993; Capussotti et al, 2005). Although FLR hypertrophy does occur, full diversion of portal flow to segments II and III ensures the maximal stimulus for FLR hypertrophy (Nagino et al; 1995, 2000; Kishi et al, 2008; Mueller et al, 2008). Further, incomplete embolization of the liver to be resected will also lead to hypertrophy of segment IV, which is undesirable for an extended right hepatectomy because of increased morbidity associated with a larger area of intraoperative parenchymal transection across this hypertrophic segment (Nagino et al, 1995).

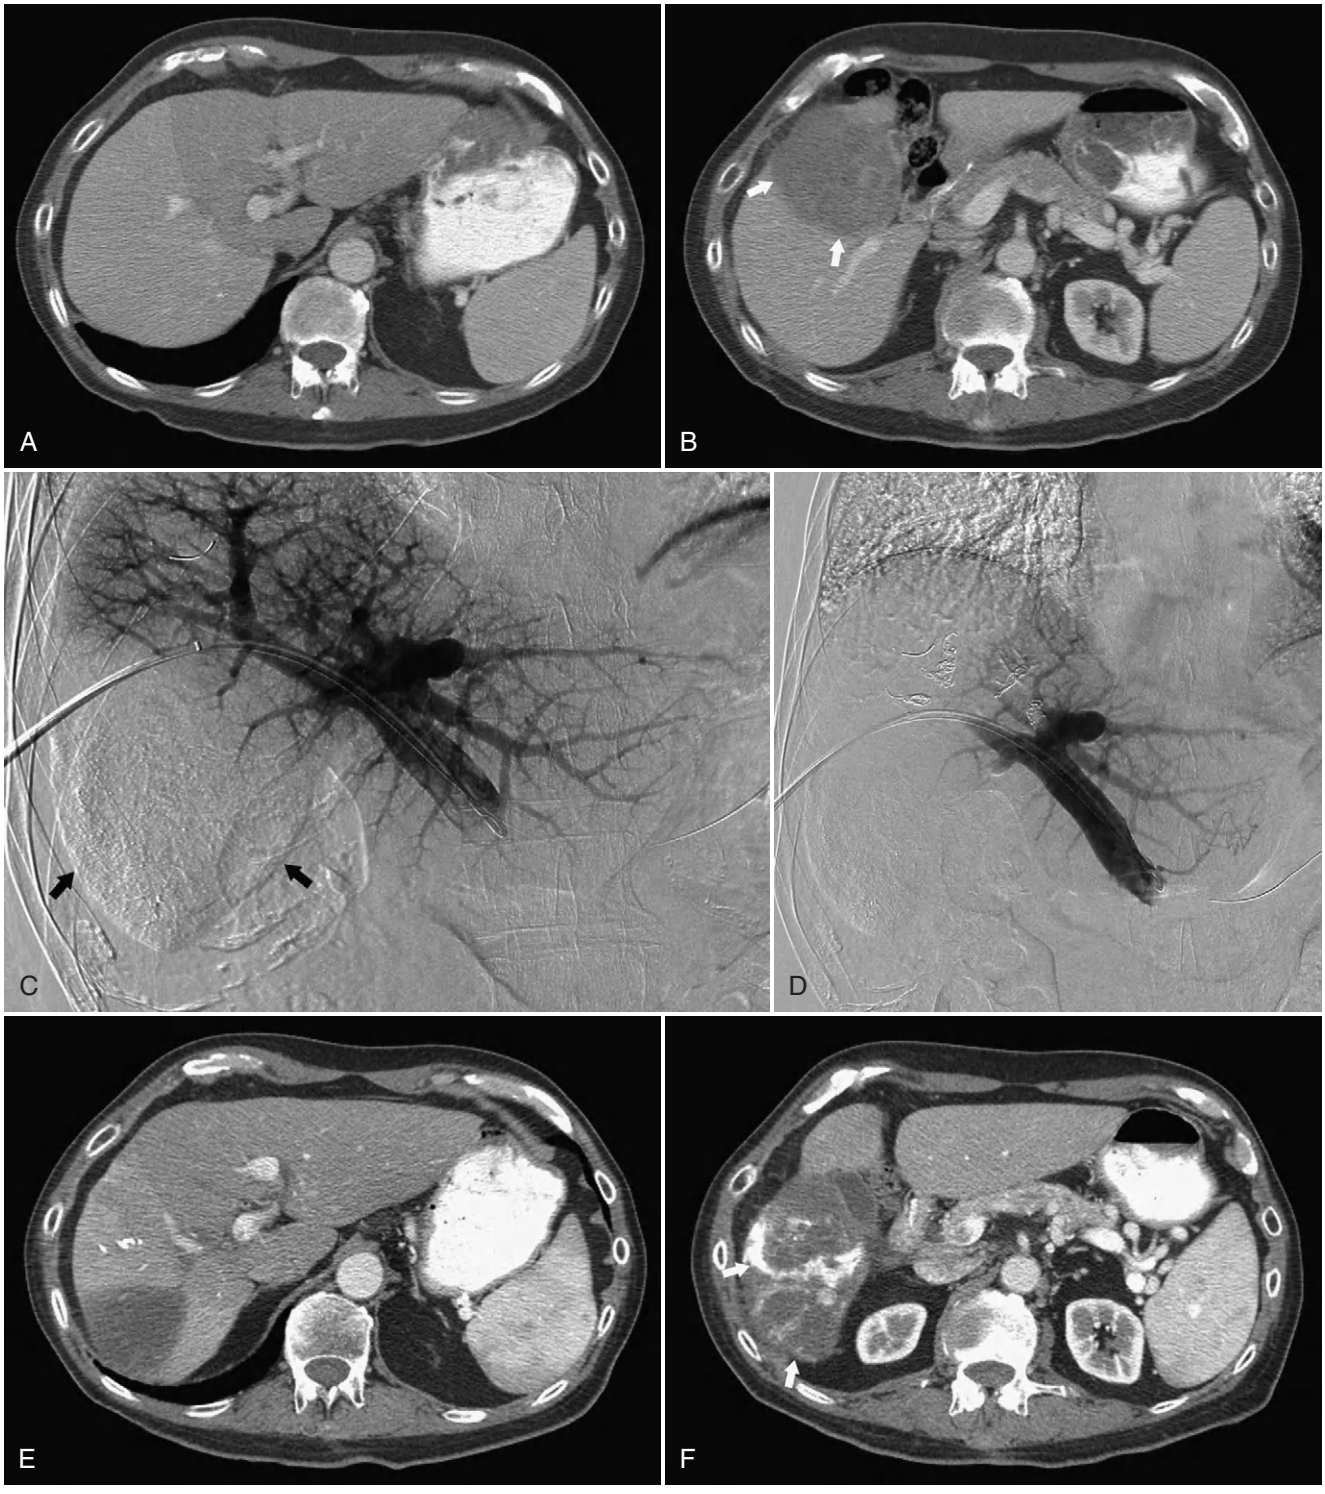

FIGURE 93B.7. A 74-year-old man with an 8-cm solitary hepatocellular tumor and hepatitis C cirrhosis who underwent sequential transcatheter arterial chemoembolization followed 1 month later by right pulmonary vein embolization (PVE) prior to a right hepatectomy. Prior to treatment, the patient's α-fetoprotein level (AFP) was 61,507 ng/mL. **A,** Single image from pre-PVE contrast-enhanced computed tomographic (CT) scan shows a small left liver and a functional liver remnant/total estimated liver volume ratio (FLR/TELV) of 27% (*shaded area*). **B,** Single image caudal to **A** shows the solitary 8-cm tumor (*arrows*). **C,** Preembolization portogram after chemoembolization shows persistent iodized oil uptake within the right lobe (*arrows*). The right posterior sector portal vein was occluded as a result of the prior chemoembolization. **D,** Postembolization portogram shows complete occlusion of all branches to right portal vein. The left portal vein remains patent. **E,** Single image from post-PVE contrast-enhanced CT scan shows hypertrophy of the left liver. The FLR/TELV increased to 47% (*shaded area*). **F,** Single image from post-PVE contrast-enhanced CT scan more caudal to **E** shows massive atrophy of the right lobe with necrosis of the tumor. After the combined treatment, the patient's AFP level decreased to 2.9 ng/mL. The patient subsequently underwent uncomplicated right hepatectomy. No viable tumor cells were found in the resected specimen, and the patient was disease free 4 years after surgery.

Nagino and coworkers (2000) first showed that a greater left lateral bisegment hypertrophy occurs after right PVE extended to segment IV (50% increase in FLR volume) than after only right PVE (31% increase, $P < .0005$). Recent studies have supported Nagino's conclusions, and without any increase in PVE-associated complications (Kishi et al, 2008; Mueller et al, 2008). Because segment IV embolization has been shown to be advantageous, the ipsilateral approach for right PVE extended to segment IV has been further refined, which has led to improved FLR hypertrophy and better operative outcomes. Lastly, left PVE is rarely needed because of consistently large volumes of the right posterior liver (segments VI and VII; Nagino et al, 1995; Abdalla et al, 2004; Leelaudomlipi et al, 2002).

Another potential benefit of extending right PVE to include segment IV, from an oncologic perspective, is that the entire tumor-bearing liver is systematically embolized (i.e., right PVE for right hepatectomy, right PVE extended to segment IV for extended right hepatectomy) to reduce the risk of tumor growth that may result from increased portal blood flow and hepatotrophic factors (Madoff et al, 2005a; Ribero et al, 2007; de Graaf et al, 2009). A recent study from a large academic cancer center evaluated 112 patients in whom the entire tumor-bearing liver was systematically embolized and found no increase in the median tumor size during the waiting period (Ribero et al, 2007); however, tumor growth within the nonembolized liver has been discussed upon analysis of a very limited number of patients with primary and secondary liver tumors after right PVE alone, although; comparison to pre-PVE tumor growth rate was made; the true effect of PVE on tumor growth could therefore not be proven (Elias et al, 1999; Kokudo et al, 2001). Furthermore, liver hypertrophy occurs quickly in patients with normal liver, and thus resection can be undertaken in most patients with multiple colorectal metastases within 3 to 4 weeks of PVE.

Embolic Agents

Many embolic materials have been used for PVE, with no remarkable differences reported in the rate or degree of hypertrophy. These agents include, but are not limited to, fibrin glue, NBCA mixed with ethiodized oil, gelatin sponge, thrombin, metallic coils, spherical and nonspherical microparticles (e.g., PVA particles, tris-acryl gelatin microspheres, others), and absolute ethanol. Importantly, a true comparison of the embolic agents used for PVE is difficult given that the available literature reports dissimilar patient populations, variable CT volumetric methodology, inconsistent imaging follow-up times, and varied PVE technique. Therefore, choosing a particular embolic agent is at the operator's discretion, and the decision is based on the extent of the embolization and surgery, preference for a particular catheter and approach, and their experience with a specific agent. Some of the more common embolic agents used for PVE are detailed below.

Early in the experience with PVE, gelatin sponge was widely used as an embolic agent; however, recanalization of the embolized portal veins was frequently observed within 2 weeks of the procedure (Makuuchi et al, 1990; Kinoshita et al, 1986; de Baere et al, 1996), and when compared with other embolic agents, it seemed less effective at 4 weeks in terms of causing hypertrophy. Also, fibrin glue combined with ethiodized oil is a commonly used mixture for PVE. This mixture also leads to early recanalization, as it results in less than 75% portal occlusion at 2 weeks and less than 25% portal occlusion at 4 weeks (Makuuchi et al, 1990; de Baere et al, 1996).

Some investigators advocate NBCA mixed with ethiodized oil, because the mixture leads to fast, reliable hypertrophy and lessens the delay between PVE and resection. NBCA ensures portal occlusion that endures beyond 4 weeks. Because polymerization time can be adjusted by varying the volume of Lipiodol added to the NBCA, distal and proximal branches can be aggressively embolized. Usually, NBCA is mixed with Lipiodol at a ratio of 1:1 to 1:3. As it is a liquid, NBCA can be rapidly delivered throughout the entire right portal system, which greatly reduces procedure time.

In terms of effectiveness, de Baere and coworkers (1996) reported that PVE with NBCA led to a 90% increase in FLR volume after 30 days, and Denys and coworkers (2005) found it useful in inducing hypertrophy in patients with underlying hepatic fibrosis or cirrhosis; however, there are some drawbacks of using NBCA for PVE. For example, the NBCA injections have to be precise because of the increased risk of nontarget embolization; thus it requires a highly experienced operator. Furthermore, NBCA can be difficult to use in patients with reduced hepatopetal flow, as is commonly seen in patients with chronic hepatic disease. These altered flow dynamics have been associated with increased risk of procedural complications (Di Stefano et al, 2005). NBCA also induces an inflammatory process that may make hepatectomy more difficult (de Baere et al, 1996; Avritscher et al, 2008). Lastly, although this agent may be straightforward when the anatomy is favorable (e.g., the anterior and posterior sector portal veins originate from a right portal vein), it may not be the best alternative in situations where variant anatomy is present, or when multiple segment IV veins are to be embolized (i.e., multiple microcatheters are needed, leading to considerable expense and increased risk of nontarget embolization to the FLR).

Absolute ethanol is another efficient embolic agent for PVE. Ogasawara and coworkers (1996) showed near doubling of the FLR volume within 4 weeks for patients with chronic hepatic disease and HCC who underwent PVE with this agent. Unfortunately, of all the embolic agents used for PVE, the most marked changes in liver function tests and the poorest patient tolerance is seen with absolute ethanol.

Recently, the use of particulate agents for PVE was also proposed. In the first clinical report in a single patient, no recanalization of the right portal vein was observed 5 weeks after PVE with PVA particles alone (Brown et al, 2001). Later, Madoff and coworkers (2002, 2003, 2005b) showed that a combination of particles (e.g., polyvinyl alcohol particles [PVA], tris-acryl gelatin microspheres) and coils is safe and effective for PVE. Particles are safe, they cause little periportal reaction, and they generate durable portal vein occlusion, especially when used in combination with coils (Madoff et al, 2002, 2003). In 2003, results from their first 26 patients who had PVE with nonspherical PVA particles, ranging in size from 300 to 1000 μm, and coils were reported; the mean FLR/total estimated liver volume (TELV) increased 7.8% (pre-PVE FLR/TELV, 17.6%; post-PVE FLR/TELV, 25.4%), and the mean absolute FLR increase was 47% (Madoff et al, 2003).

The subsequent advance of spherical particulate embolics has led to even further refinements in technique for PVE by using a stepwise infusion of very small (100 to 300 μm)

tris-acryl gelatin microspheres followed by larger spheres (up to 700 μm; Madoff et al, 2005b). This type of distal embolization is thought to limit development of collateral circulation that may potentially reduce hypertrophy because of the improved targeting of distal portal vein branches (nonspherical particles tend to clump and therefore do not always reach the targeted size vessel). Metallic coils are then used proximally to block venous inflow and further reduce the possibility of recanalization. This newer approach was used for right PVE extended to segment IV and led to an absolute increase in FLR volume of 69.0%, an FLR/TELV increase of 9.7%, and a subsequent resection rate of 86% that was a significant improvement over their previously reported method.

COMPLICATIONS OF PORTAL VEIN EMBOLIZATION

As with all transhepatic procedures, complications include subcapsular hematoma, hemoperitoneum, hemobilia, arterioportal shunts, arteriovenous fistula, pseudoaneurysm, portal vein thrombosis, transient liver failure, pneumothorax, and sepsis (Kodama et al, 2002; Di Stefano et al, 2005). Kodama and colleagues (2002) compared complication rates between the contralateral and ipsilateral approaches in 47 patients who underwent PVE and found that in 11 patients who underwent contralateral PVE, 2 (18.1%) experienced complications, and in 36 patients who underwent ipsilateral PVE, 5 (13.9%) experienced complications. This difference was not statistically significant, and the rate of technical complications associated with percutaneous PVE using either approach was 14.9%. The following complications were those found in this patient cohort: two subcapsular hematomas, two pneumothoraces, one inadvertent arterial puncture, one pseudoaneurysm (in a patient who also had a subcapsular hematoma), one hemobilia, and one portal vein thrombosis. Complications more specific to percutaneous PVE included portal vein thrombosis and portal hypertension resulting in esophageal variceal hemorrhage. The authors stressed that given the potential for injury to the FLR when using the contralateral approach, the ipsilateral approach should be tried first.

Di Stefano and coworkers (2005) later reported on 188 patients who underwent PVE using the contralateral approach. They reported that only one patient experienced a major complication (complete portal vein thrombosis) directly related to the contralateral approach that precluded the planned surgical resection. Two other patients experienced inadvertent migration of embolic material into the FLR that required intervention; one needed a portoportal graft during hepatic resection because of portal vein thrombosis. On CT imaging, another 10 patients were found to have embolic material in nontargeted portal venous branches.

In 2007, Ribero and coworkers (2007) reported on 112 patients who underwent PVE with the ipsilateral approach. In this study, only one patient had nontarget embolization to the FLR; however, the overall complication rate was 8.9%, which was not substantially different than the rate reported by Di Stefano and coworkers (2005). If it is taken into account that they considered clinically occult incidental CT findings in their complication rate, the studies reported remarkably similar numbers. Further, the study by Ribero and others (2007) found no difference in the complication rate, whether right PVE was extended to segment IV or not.

CONCLUSION

Preoperative PVE is a safe and effective method of inducing FLR hypertrophy before major hepatic resection. Currently, the percutaneous transhepatic ipsilateral and contralateral PVE approaches are the most commonly used worldwide. Surgeons must pay particular attention to the technical aspects, aberrant portal venous anatomy, and treatment strategies when PVE is used to ensure the best outcomes for patients.

CHAPTER 97B

Liver transplantation: anesthesia, perioperative management, and postoperative care

Andrea Vannucci and Ivan Kangrga

OVERVIEW

Approximately 20,000 liver transplantations are performed annually worldwide (Matesanz et al, 2009), but the number of patients on the waiting list continues to exceed the donor organ availability. Because of the continuous donor shortage, dramatic changes in recipient and donor selection have emerged in the past decade, leading to an amplification of clinical challenges for perioperative liver transplant physicians. In fact, United Network for Organ Sharing (UNOS) data from 2009 (UNOS/OTPN, 2010) show that older patients are now accepted to the waiting list and transplanted; combined kidney and liver transplants are performed more often than in prior years; and extended-criteria donors, including donors after cardiac death, are increasingly utilized (see Chapter 97A).

Despite the increasing medical complexity, overall graft and patient outcomes have continued to improve. According to the UNOS database, survival rates for patients transplanted with a cadaveric graft are around 87% at 1 year, 80% at 3 years, and 74% at 5 years. These encouraging figures, achieved by experienced transplant teams, have resulted in part from the progressive advancement and standardization of surgical and anesthetic techniques (Mandell et al, 2008). If the current trends continue, with transplantation of increasingly older and sicker recipients (Costa et al, 2009; Xia et al, 2008) and use of marginal donor organs, the outcomes will greatly depend on accurate preoperative assessment and on appropriate and timely intraoperative medical management of comorbidities.

PREOPERATIVE ANESTHETIC ASSESSMENT

Liver transplantation is the current gold standard treatment for acute and chronic irreversible liver failure (see Chapters 70A, 72, and 97A); for selected clinical syndromes not manifesting with end-stage liver disease (ESLD), including polycystic liver disease (see Chapter 69B) and other metabolic diseases; for some malignancies confined to the liver (see Chapters 97D and 97E); and for cholestatic liver diseases in children, such as biliary atresia (see Chapters 40 and 71). Four contraindications to liver transplantation are widely accepted: 1) unstable cardiopulmonary conditions, such as symptomatic coronary artery disease (CAD), severe systolic dysfunction, advanced cardiomyopathy, severe valvular heart disease, and severe pulmonary hypertension; 2) substance abuse; 3) morbid obesity (body mass index [BMI] >40); and 4) uncontrolled sepsis (Gallegos-Orozco & Vargas, 2009; Murray & Carithers, 2005).

As part of a multidisciplinary transplant team, anesthesiologists should participate in the evaluation of candidate recipients. Ideally, an anesthetic evaluation should precede the acceptance of patients to the waiting list. The goals of this assessment are to appraise suitable candidates based on functional status and comorbidities and to design a patient-specific preoperative and perioperative treatment plan. For patients in whom the burden of comorbidities presents a prohibitive operative risk, alternative treatments should be sought (Merion, 2004).

Cardiovascular System

Hyperdynamic circulation, cardiomyopathy, and CAD are common clinical problems that impact postoperative outcomes in orthotopic liver transplantation (OLT) candidates (Fouad et al, 2009).

Hyperdynamic Circulation

Patients with ESLD develop high cardiac output hemodynamics secondary to reduced systemic vascular resistance (SVR) and abnormal distribution of central, splanchnic, and peripheral circulation. This condition is due to humoral and autonomic dysregulation (Møller & Henriksen, 2008). When this situation is associated with cardiac valve dysfunction, especially mitral or tricuspid valve insufficiency, more hemodynamic support is needed in the perioperative period (Alper et al, 2009).

Coronary Artery Disease

Perioperative complications and mortality rates are high in patients with CAD: up to 50% of patients with significant CAD may die perioperatively from cardiac complications (Plotkin et al, 1996). Safadi and colleagues (2009) recently reported that history of stroke, CAD, postoperative sepsis, and increased interventricular septal thickness were markers of adverse perioperative cardiac outcomes, whereas use of perioperative β-blockers was significantly protective. Occult CAD is also common: 5% to 26% of OLT candidates have at least one critical coronary stenosis. Computed tomography (CT) scan detection of coronary calcification is a sign of possible ischemic heart disease in asymptomatic patients, but the sensitivity and specificity are low (Mandell & Tsou, 2008; Tiukinhoy-Laing et al, 2006).

Dobutamine stress echocardiography and dobutamine myocardial perfusion imaging are considered the most sensitive noninvasive tests to assess occult CAD in liver

transplant candidates. Both tests have a higher negative than positive predictive value (Donovan et al, 1996; Mandell & Tsou, 2008; Murray & Carithers, 2005; Plotkin et al, 1998; Williams et al, 2000). Cardiac catheterization is indicated in patients with a positive noninvasive test to assess coronary lesions and plan further treatment. Left-heart catheterization is associated with higher risk of minor complications but can be performed safely in candidates for OLT (Sharma et al, 2009).

CIRRHOTIC CARDIOMYOPATHY. Cirrhotic cardiomyopathy is characterized by systolic dysfunction more evident under conditions of hemodynamic stress, impaired diastolic relaxation, and electrophysiologic alterations often manifesting with a prolonged QT interval. Diagnosis is based on electrocardiograph (ECG), cardiac echo, and elevated levels of brain natriuretic factor. Physiopathologic hallmarks of this disease are altered β-adrenergic activity, myocardial fibrosis, myocyte hypertrophy, and ion-channel defects. Medical treatment is based on sodium restriction and administration of β-blockers and aldosterone antagonists; however, liver transplantation can reverse this condition (Fukazawa et al, 2009; Mandell & Tsou, 2008; Wong, 2009).

NONISCHEMIC CARDIOMYOPATHY. Nonischemic cardiomyopathy can complicate alcoholic cirrhosis, amyloidosis, hemochromatosis, and Wilson disease, and it must be considered in the anesthetic preoperative assessment and intraoperative management. Dilated and hypertrophic cardiomyopathy can also be present in OLT candidates, and these rarely revert to normal even after OLT (Mandell & Tsou, 2008).

Pulmonary System

As many as 70% of patients with chronic liver disease (CLD) suffer from respiratory problems, that manifest as impaired respiratory mechanics and gas exchange (Kim et al, 2009). Most pulmonary diseases are independent from the liver disease but are in some instances related to liver disease (e.g., α_1-antitrypsin deficiency and cystic fibrosis) (Yeshua et al, 2009). Pulmonary evaluation includes history and physical examination, radiologic studies, arterial blood gas, and pulmonary function tests. Right-heart catheterization is indicated when clinical or ECG evidence suggests pulmonary hypertension.

Chronic Obstructive Pulmonary Disease and Smoking

Chronic obstructive pulmonary disease (COPD) is common and is often undiagnosed in candidates for liver transplantation. In a recent prospective study involving several academic centers in the United States, 18% of OLT candidates had COPD, and 80% of those patients had not been previously diagnosed. Older age and smoking were significant risk factors for this condition, although the impact of COPD on perioperative outcome in liver transplantation has not been well defined (Ryback et al, 2008).

HEPATIC HYDROTHORAX. *Hepatic hydrothorax* is defined as a pleural effusion greater than 500 mL not caused by cardiac or pulmonary diseases in a patient with cirrhosis (Singh & Sager, 2009). A diaphragmatic defect allowing passage of ascites from the peritoneal to the pleural cavity is considered the main mechanism leading to this complication. Pleural effusions are symptomatic in 6% to 10% of patients with ESLD (Kiafar & Gilani, 2008), and the main respiratory impairment is hypoxemia secondary to atelectasis and shunting; chest radiograph confirms the diagnosis. Treatment is based on medical management of ascites with paracentesis and possible placement of a transjugular intrahepatic portosystemic shunt (TIPS). In cases of refractory hydrothorax, pleurodesis and diaphragmatic repair can be considered; thoracentesis is performed only in emergency situations, because avoidance of tube thoracostomy is preferred.

PORTOPULMONARY HYPERTENSION. *Portopulmonary hypertension* (PPHTN) is a specific type of pulmonary artery hypertension. It comprises increased pulmonary vascular resistance (PVR) and portal hypertension with or without advanced liver disease. From 2% to 10% of patients with cirrhosis are affected by PPHTN (Yeshua et al, 2009). The physiologic mechanism is multifactorial and incompletely understood, but hyperdynamic circulation, imbalance between pulmonary vasodilators (nitric oxide and prostacyclin) and vasoconstrictors (endothelin-1 and thromboxane), and proliferative pulmonary arteriopathy all play a role in the genesis of this syndrome (Singh & Sager, 2009).

Diagnosis requires presence of portal hypertension, mean pulmonary arterial pressure (mPAP) greater than 25 mm Hg, PVR greater than 240 dynes/sec/cm^{-5}, and pulmonary artery occlusion pressure of less than 15 mm Hg (Rodriguez-Roisin et al, 2004); right-heart catheterization is indicated if pulmonary artery systolic pressure is higher than 50 mm Hg on ECG screening. The severity of PPHTN is then evaluated based on hemodynamic data obtained by right-heart catheterization at rest and is classified as *mild* (mPAP of 24 to 34 mm Hg), *moderate* (mPAP of 35 to 44 mm Hg), or *severe* (mPAP ≥45 mm Hg) (Singh & Sager, 2009).

Medical optimization is indicated before transplantation, and treatment is based on vasodilators. Prostaglandins (intravenous epoprostenol or inhaled iloprost), phospodiesterase inhibitors (sildenafil), and endothelin-1 antagonists (bosentan) are often used in combination therapy. Most liver transplant centers do not transplant patients with an mPAP greater than 50 mm Hg or a PVR greater than 240 dyne/sec/cm^{-5}; however, 5-year survival is 14% without treatment, 45% with medical management, and 65% for those who had an OLT following pretreatment with prostacyclin (Swanson et al, 2008).

HEPATOPULMONARY SYNDROME. Hepatopulmonary syndrome (HPS) is a vascular disorder characterized by hypoxemia secondary to pulmonary capillary vasodilation in patients with liver disease. The estimated incidence in patients with cirrhosis is between 5% and 32% (Singh & Sager, 2009). The natural course of HPS is characterized by poor survival, especially in patients with a Pao_2 level of less than 50 mm Hg: median survival without liver transplantation is approximately 24 months (Schenk et al, 2002; Umeda & Kamath, 2009).

The pathologic feature of HPS is gross dilation of the pulmonary precapillary and capillary vessels (Rodriguez-Roisin & Krowka, 2008) leading to a ventilation-perfusion mismatch. The clinical symptoms are dyspnea with or without orthodeoxia (arterial oxygen desaturation while standing). The diagnosis is confirmed with arterial blood gas measurement and contrast-enhanced ECG or macroaggregated albumin lung perfusion scan. The ECG diagnostic sign is the visualization of saline bubbles in the left heart, three to six beats after the appearance of bubbles in the right heart, following the injection of agitated saline in a peripheral vein.

No effective medical therapy for HPS has been found, and liver transplantation is the only treatment. UNOS criteria consider a Pao_2 level below 60 mm Hg an indication of high priority for OLT, even if the allocation of "exception points" to patients with HPS has now become controversial (Sulieman et al, 2008). About 85% of patients who underwent OLT for HPS showed resolution or improvement of hypoxemia. Still, the mortality after liver transplantation is significantly increased in patients with HPS (Fallon et al, 2008).

Hemostasis in End-Stage Liver Disease

The liver synthesizes most of the factors involved in clot formation and, equally importantly, factors opposing clot formation or mediating its lysis. The traditional concept that patients with advanced liver disease are hypocoagulable has been challenged. The current view emphasizes complex disturbances of platelet function, procoagulant, anticoagulant, and fibrinolytic pathways that result in rebalancing of the hemostatic system (Senzolo et al, 2006). The net effect may be a hypocoagulable or hypercoagulable state with a tendency for bleeding or thromboembolism (Warnaar et al, 2008b). Understanding the hemostatic system in ESLD is essential to perioperative coagulation management and optimization of blood product transfusion practices, which are directly related to morbidity and mortality in liver transplantation (de Boer et al, 2008; Massicotte et al, 2005).

Deficiency in primary hemostasis is due to quantitative and qualitative platelet changes (Pereboom et al, 2008). Mild to moderate thrombocytopenia is common. Causes are splenomegalic platelet sequestration in portal hypertension, impaired megakaryocytopoiesis as a result of reduced production of thrombopoietin by the cirrhotic liver, folic acid deficiency in alcoholic cirrhosis or acute hepatitis C infection, and reduced platelet half-life related to autoantibodies (Lisman & Leebeek, 2007; Senzolo et al, 2006). Evidence for impaired platelet aggregation and adhesion in cirrhosis is controversial. The proposed mechanisms are complex and multifactorial, including the important role of two potent endothelium-derived platelet inhibitors, nitric oxide and prostacyclin. Contrary to this, more recent work suggests that the functional capacity of platelets in cirrhotic patients may be normal when platelet number and hematocrit are normalized (Lisman & Leebeek, 2007; Tripodi et al, 2007), suggesting that the main defect in primary hemostasis is thrombocytopenia. An important compensatory mechanism for the overall deficient platelet function in cirrhosis is an increase in endothelium-synthesized von Willebrand factor (vWf). The markedly upregulated vWf promotes adhesion of platelets to injured vasculature and seems to be more effective than plasma from healthy volunteers (Lisman & Leebeek, 2007).

Hepatocytes synthesize all procoagulant factors except vWF, which is synthesized by the endothelium. Factor VIII is synthesized by hepatocytes but also by nonhepatic sinusoidal endothelial cells. Reduced levels of coagulation factors are observed in acute and chronic liver disease. Several factors—II, VII, IX, and X—require vitamin K as an essential cofactor and exist in plasma as inactive precursors when vitamin K is deficient as a result of decreased absorption (cholestasis) or antagonism (warfarin). In acute liver failure (ALF), plasma concentrations of coagulation factors with the shortest half-life (factor VII, 4 to 6 hours; factor V, 12 hours) decrease first, followed by those with a longer half-life. An exception are factors VIII and vWf, which may be elevated in chronic and acute liver disease because of inflammatory cytokine-mediated upregulated extrahepatic production and because of relative sparing as a result of inhibition of thrombin by antithrombin III. Fibrinogen is usually well preserved, and decreased fibrinogen is a mark of advanced cirrhosis or ALF; however, even when levels are normal, fibrinogen is often functionally aberrant because of impaired fibrin polymerization and results in an abnormal thrombin time (TT) despite normal international normalized ratio (INR) and partial thromboplastin time (PTT).

The deficiency in procoagulant factors is, at least in part, offset by decreased production of anticoagulants, including proteins C and S, antithrombin III, and heparin cofactor II. Proteins C and S are vitamin K dependent and may be deficient in cholestatic disease, and although genetic deficiency of these two proteins is rare, such deficiency is found in both Budd-Chiari syndrome and portal vein thrombosis. Antithrombin III is synthesized by hepatocytes and endothelium, deficiencies are usually mild, and thromboembolic complications rare.

All proteins involved in fibrinolysis are synthesized by the liver except tissue plasminogen activator (tPA) and plasminogen activator inhibitor type 1 (PAI-1). Consequently, reduced levels of liver-synthesized factors—plasminogen, plasmin inhibitor, thrombin activatable fibrinolysis inhibitor (TAFI), and factor XIII—are found in both acute and chronic liver failure. Cirrhosis is classically associated with hyperfibrinolysis, whereas patients in ALF may have hypofibrinolysis as a result of increased production of PAI-1. The recent expert viewpoint is contrary to the traditionally held view and emphasizes that the existing in vitro evidence of hyperfibrinolysis in cirrhosis is weak (Lisman & Leebeek, 2007). Increased levels of fibrinogen degradation indicators—D-dimers, plasmin-antiplasmin and thrombin-antithrombin complexes, thrombin fragment F1+2—could be explained by their delayed clearance by the diseased liver.

Coagulation tests, such as the prothrombin time (PT) and activated partial thromboplastin time (aPTT), are used to assess the severity of synthetic dysfunction, and PT-INR is a part of the Child-Turcotte-Pugh (CTP) and Model for End-Stage Liver Disease (MELD) prognostic indexes (Ng, 2009). As tests of in vivo coagulation function, PT-INR and PTT are conceptually deficient because they measure only the procoagulant pathway and ignore the anticoagulant function. This inadequacy is best illustrated by the observation that when the (prolonged) PT is modified by including thrombomodulin to allow full activation of protein C, the thrombin generation in cirrhotic patients is close to normal (Tripodi et al, 2005). This may in part explain why PT-INR and PTT are poor predictors of bleeding in cirrhosis and in liver transplantation (Massicotte et al, 2008). Thromboelastogram (TEG; Haemoscope Corp., Niles, IL) and rotation thromboelastometry (ROTEM; Pentapharm, Munich, Germany) have the advantage of assaying whole-blood clot formation and lysis, including the platelet contribution, but these assays do not incorporate the endothelial component (see Intraoperative Monitoring, below). Importantly, these assays allow easy recognition of hypercoagulable states (Fig. 97B.1A).

Renal System

Renal failure confers increased risk of death to cirrhotic patients, both while on the transplant waiting list and after liver transplantation. Implementation of the MELD score in 2002

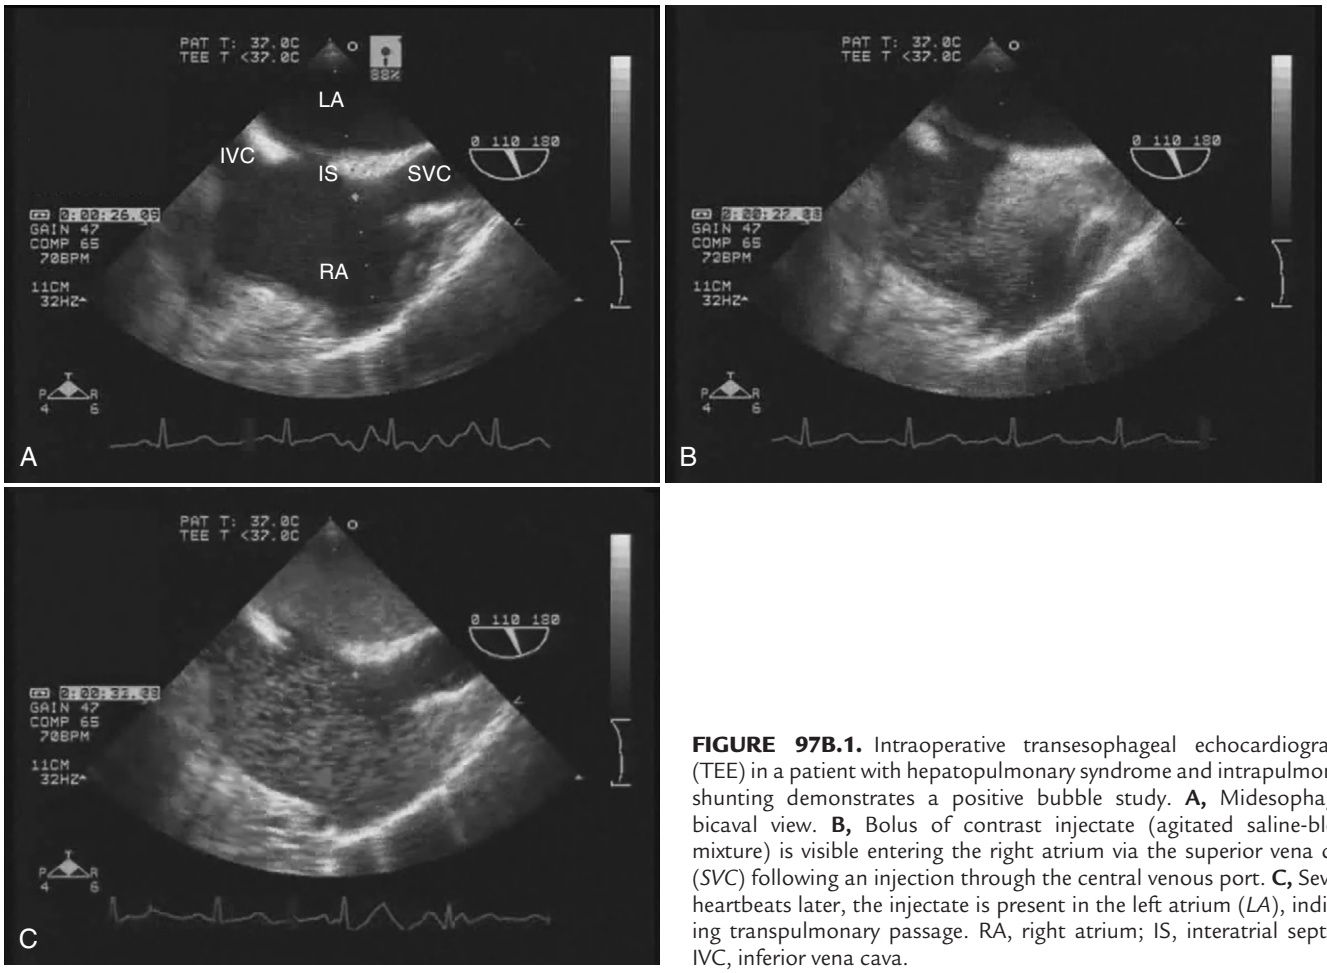

FIGURE 97B.1. Intraoperative transesophageal echocardiography (TEE) in a patient with hepatopulmonary syndrome and intrapulmonary shunting demonstrates a positive bubble study. **A,** Midesophageal bicaval view. **B,** Bolus of contrast injectate (agitated saline-blood mixture) is visible entering the right atrium via the superior vena cava (*SVC*) following an injection through the central venous port. **C,** Several heartbeats later, the injectate is present in the left atrium (*LA*), indicating transpulmonary passage. RA, right atrium; IS, interatrial septum; IVC, inferior vena cava.

(Moreau et al, 2003) has prioritized patients with renal failure waiting for a liver transplant, resulting in reduced overall mortality on the transplant list (Ojo, 2009).

Hepatorenal syndrome (HRS) is a specific type of renal failure in patients with cirrhosis, ALF, or alcoholic hepatitis. It is marked by functional renal vasoconstriction and a severe reduction in glomerular filtration rate (GFR <30 mL/min) but only minimal renal histologic abnormalities (Gines & Schrier, 2008). The primary pathophysiologic process in HRS is a circulatory disturbance: portal hypertension facilitates translocation of bacteria from the intestinal lumen into the mesenteric lymph nodes and induces production of inflammatory cytokines and local vasodilators, such as nitric oxide, carbon monoxide, and endogenous cannabinoids. Resulting splanchnic vasodilatation decreases the overall systemic vascular resistance and activates a number of compensatory mechanisms. The initial response is hyperdynamic and comprises tachycardia, increased cardiac output, low SVR, and relative hypotension.

With progression of cirrhosis, sympathetic and renin-angiotensin vasoconstrictor systems are activated that temporarily maintain arterial blood pressure, but they also cause renal vasoconstriction and hypoperfusion. Activation of nonosmotic hypersecretion of arginine vasopressin, aimed at preserving circulatory volume, results in retention of solute-free water with attendant hyponatremia, edema, and ascites. HRS is almost invariably associated with ascites and rarely develops in its absence (see Chapter 74). HRS is classified into one of two types: *HRS 1* is characterized by a rapid decline in renal function reflected in doubling of serum creatinine (SCr) to above 2.5 mg/dL over a 2-week period; this type of HRS has a particularly ominous clinical course, leading to multiorgan dysfunction that affects the heart, brain, and other organs. *HRS 2* has a more benign, slowly progressive course. It is manifested by a milder elevation of SCr (1.5 to 2.5 mg/dL) and refractory ascites. Onset of HRS is often triggered by a discrete event, such as spontaneous bacterial peritonitis, use of nonsteroidal antiinflammatory drugs (NSAIDs), or hypovolemia as a result of diuretic use, gastrointestinal (GI) bleeding, or fluid losses.

It is important to recognize that HRS may be superimposed on a chronic disease, such as glomerulonephritis as a result of hepatitis B virus (HBV) or hepatitis C virus (HCV) infection, interstitial nephritis as a side effect of certain drugs, or nephropathy resulting from diabetes or CLD. Diagnosis of HRS is of great prognostic significance: median survival for HRS 1 is 1 month; for HRS 2, it is 6 months.

Measurement of SCr remains the primary test of renal function despite its well-known limitations. By consensus, SCr above 1.5 mg/dL (133 μmol/L) defines renal insufficiency in cirrhosis (Gines & Schrier, 2008; Salerno et al, 2007). GFR and creatinine clearance are more accurate but less practical tests when repeated assessments are needed. Other tests measure serum and urinary electrolytes, fractional sodium excretion (FENa), albumin, osmolarity, sediment, and biologic markers.

Specific diagnostic tests for HRS do not exist, rather diagnosis is based on the presence of liver disease, a precipitating factor, and FENa less than 1%, signifying preserved tubular reabsorption; however, the latter test is invalidated by the use of diuretics.

General treatment measures are aimed at 1) preventing infection, in particular subacute bacterial peritonitis; 2) maintaining adequate intravascular volume; and 3) avoiding nephrotoxic agents. Circulatory volume losses, often the result of large-volume paracentesis or a GI bleed, are best treated with albumin or, if indicated, by blood products and not with crystalloids, to avoid retention of solute-free water.

The main pharmacologic approach utilizes vasoconstrictors, including a selective vasopressin V1 receptor agonist, such as terlipressin, or α-adrenergic agonists, such as norepinephrine and midodrine. Vasoconstrictors in conjunction with albumin are only modestly beneficial but are the best medical therapy currently available. Two recent studies showed a marked improvement in renal function in 40% of patients treated with terlipressin and albumin compared with controls treated with albumin alone (Martin-Liahi et al, 2008; Sanyal et al, 2008). Although the overall survival in the treatment group was not better than in the control group, the probability of 3-month survival in patients who responded with improved renal function was significantly higher (58% vs. 15%) than in nonresponders (Martin-Liahi et al, 2008); however, organ ischemia is a concerning side effect of vasoconstrictor administration.

Placement of a TIPS improves renal function and GFR and reduces sympathetic and renin-angiotensin-aldosterone axis activation in about 60% of patients (Cardenas & Gines, 2009; see Chapter 76E). TIPS is less applicable in HRS 1 as a result of severe liver disease, but it may delay progression of HRS 2 to HRS 1. No advantage in survival has been demonstrated in patients with refractory ascites treated by TIPS compared with repeated paracentesis and intravascular volume replacement with albumin.

Renal replacement therapy (RRT) offers a bridge to transplant, but the optimal RRT method in HRS and the benefit to patient outcomes are not known (Gines & Schrier, 2009). Continuous venovenous hemodialysis (CVVHD) seems to be hemodynamically the most favorable form of RRT (Davenport, 2009). CVVHD can be used to effectively control intravascular volume, pH levels, and solutes (Na, K, SCr, urea, ammonia); in addition, it corrects sodium in a time-controlled fashion, which is particularly relevant to minimize the risk of pontine demyelination in patients with hyponatremia.

Liver transplantation is the treatment of choice for patients with cirrhosis and HRS (Cardenas & Gines, 2009; see Chapter 97A). About 90% of patients with HRS recover kidney function after successful liver transplantation. The remaining 10% do not recover their kidney function and require prolonged RRT and eventual kidney transplantation. When the cause of renal failure in cirrhosis is HRS, the best predictor of need for a combined liver-kidney transplant is pretransplantation RRT for longer than 8 weeks.

Central Nervous System

Hepatic encephalopathy (HE) is a progressive but potentially reversible metabolic disorder of the central nervous system (CNS), and it is associated with variable degrees of brain edema. HE is an overt manifestation of cirrhosis in up to 45% of patients, and it is a defining sign and main cause of death in ALF (Eroglu et al, 2009). The World Congress of Gastroenterology recognizes three classifications of HE based on the etiology (Ferenci et al, 2002): *type A* is associated with ALF, *type B* with TIPS, and *type C* with cirrhosis. Based on the severity of neurologic impairment, HE ranges from normal (grade 0) to mildly impaired cognitive and neuromuscular function (grade 1), progressive lethargy (grade 2), confusion with muscle rigidity or clonus (grade 3), to coma and brain death (grade 4). Although presence and severity of HE has prognostic and therapeutic significance in cirrhosis and ALF, it is not a part of the MELD score.

The pathophysiology of HE is complex and incompletely understood. Multiple putative mediators have been implicated that include ammonia, endogenous benzodiazepine-like or γ-aminobutyric acidlike agonists, reactive oxygen species, inflammatory cytokines, hyponatremia, and manganese. The exact pathogenesis of cerebral edema remains controversial, but good evidence supports the role of ammonia, which promotes astrocyte and neuron swelling by increasing intracellular glutamine content. Transported to the mitochondria, glutamine contributes to production of reactive oxygen species and activation of mitochondrial transition permeability pore and various kinases, resulting in cellular swelling. Increased ammonia levels have been shown to alter cerebral blood flow and brain glucose utilization (Bjerring et al, 2009; Sundaram et al, 2009). High arterial and brain levels of ammonia in ALF correlate well with cerebral edema and increased ICP, with consequent high risk of mortality from brain herniation and hypoxia (Wendon et al, 2008).

HE in cirrhosis features slow onset, a progressive course, and only partial responsiveness to therapy. Significant cerebral edema typically does not develop, and a precipitating event—such as infection, excessive dietary protein, dehydration, or GI bleeding—can be often identified. TIPS is a known risk factor and is associated with 30% of new or worsening encephalopathy (see Chapter 76E). In addition to correction of any precipitating factors, treatment includes nonabsorbable disaccharides, which reduce the intestinal production and absorption of ammonia; antibiotics that target urease-producing bacteria; ornithine and acarbose; benzodiazepine receptor antagonists; and probiotics.

The hallmarks of HE in ALF are cerebral edema and increased intracranial pressure (ICP). Both are life-threatening complications of grade 3 and 4 encephalopathy. Treatment includes a number of general and specific interventions (Table 97B.1) aimed at promoting cerebral perfusion pressure (CPP) above 60 mm Hg; this is achieved by maintaining mean arterial pressure (MAP) and reducing ICP to below 20 to 25 mm Hg by reducing brain edema. Grade 3 or 4 HE requires endotracheal intubation for airway protection. Mild hyperventilation temporarily relieves brain hyperemia, but prolonged hyperventilation is not beneficial and may cause CNS ischemia. Mannitol is effective in reducing ICP in the short term, but its prophylactic use is not recommended. Recent evidence demonstrates that N-acetylcysteine treatment may also prolong transplant-free survival in ALF unrelated to paracetamol/acetaminophen toxicity (Lee et al, 2007).

The role of ICP monitoring is controversial, as ICP monitor placement is associated with high risk of bleeding in this patient population, and no data exist to support its role in improving patient outcomes. The Acute Liver Failure Study Group recommends this intervention only for liver transplant candidates but

Table 97B.1

Management of Encephalopathy and Elevated Intracranial Pressure in Acute Liver Failure

General Measures	Specific Interventions
Head elevation to 30 degrees	Endotracheal intubation for grades 3 and 4 hepatic encephalopathy
Judicious (restrictive) fluid management	Hyperventilation: limited, temporary benefit
Judicious if any sedation	N-acetylcysteine: benefits all causes of acute liver failure
Cerebral perfusion pressure >60 mm Hg	Renal replacement therapy: CVVHD
Osmotic diuresis, hypertonic saline	ICP monitoring (>10% bleed); transcranial Doppler
Empiric: antibiotics, disaccharides	Hypothermia: mild, bridge to transplantation

CVVHD, continuous venovenous hemodialysis; ICP, intracranial pressure

recognizes regional practice differences (Stravitz et al, 2007). An attractive, noninvasive alternative to ICP monitors is transcranial Doppler (TCD) sonography. By measuring blood flow velocities in middle and anterior cerebral arteries and calculating resistance and pulsatility indexes, TCD allows serial estimates of cerebral blood flow in the setting of impaired autoregulation and developing brain edema (Bhatia & Gupta, 2007). In a small series of ALF patients, confirmation of adequate cerebral blood flow by TCD was successfully used as a basis to proceed with OLT (Bindi et al, 2008). Intraoperative use of TCD in OLT has not been reported.

Mild to moderate hypothermia (32° C to 35° C) is an emerging therapeutic modality. Hypothermia reduces brain ammonia and cytokine levels and in part restores cerebrovascular autoregulation and brain glucose metabolism. Although experimental evidence provides a strong rationale, only limited clinical data on efficacy and safety of hypothermia in humans in ALF are available, and future studies are warranted (Stravitz et al, 2009).

INTRAOPERATIVE MONITORING

Hemodynamic Management

Hemodynamic management is a cornerstone in the perioperative care of liver transplant patients, but no consensus has been reached on the standards of hemodynamic monitoring (Claus-Georg & De Wolf, 2008). Continuous invasive arterial pressure monitoring may be the only ubiquitously used hemodynamic monitor in liver transplantation. When measured at the most common site, the radial artery, peripheral arterial pressure may underestimate the true aortic pressure, particularly during periods of hypotension. A femoral arterial line reflects central aortic pressure with higher fidelity and consistently records higher systolic pressures than the radial artery. The difference between the femoral and the arterial pressure waveform is particularly pronounced after graft reperfusion or when high doses of vasopressors are used (De Wolf, 2006; Shin et al, 2007). Because of this discrepancy, and because of the need for frequent arterial blood sampling, some centers routinely use both femoral and radial arterial lines.

The pulmonary artery catheter (PAC, see Chapter 22) has long been the mainstay of hemodynamic monitoring in liver transplantation (De Wolf et al, 1993); however, the clinical utility of PACs has recently been questioned because of criticisms that its invasiveness is not justified by improved outcomes (Sandham et al, 2003; Wheeler et al, 2006) and that measured pressures are not good estimates of ventricular preload (Kumar et al, 2004). Although a number of less invasive technologies have emerged, resulting in a decrease in their use, PACs are still advocated by many for OLT (Della Rocca et al, 2008; De Wolf, 2008; Pinsky, 2006), and the ability of PACs to continuously display pulmonary artery pressures is particularly advantageous when managing patients with portopulmonary hypertension. Transesophageal echocardiography (TEE) provides different but complementary information to that provided by PACs (see below), and concurrent use of both devices is considered superior (De Wolf & Aggarwal, 2008). A notable shortcoming of PACs in OLT is the inaccuracy of thermodilution cardiac output in the period following liver reperfusion because of postreperfusion hypothermia and subsequent instability of central temperature.

Newer, less invasive hemodynamic monitors for OLT have been introduced. The PiCCO system (Pulsion Medical Systems, Munich, Germany) combines transpulmonary thermodilution and arterial pressure contour analysis, and it provides continuous cardiac output in alignment with PAC thermodilution and a number of indices of preload that include global end-diastolic volume (GEDV) and intrathoracic blood volume (ITBV), which agree better with cardiac index than filling pressures (Della Rocca et al, 2002a, 2002b). PiCCO requires central venous and femoral or brachial arterial access, which arguably is not much less invasive than the PAC. The LiDCO device (LiDCO Group, London, UK) estimates cardiac output based on the peripheral arterial pressure waveform pulse power analysis after a lithium dilution calibration, and it has been used successfully in patients recovering from liver transplantation in the ICU (Costa et al, 2008). A device that estimates cardiac output based on the arterial pressure waveform without need for calibration, Flo-Trac/Vigileo (Edwards Lifesciences, Irvine, CA), did not perform well intraoperatively during OLT (Biais et al, 2008; Biancofiore et al, 2009).

The accuracy of all arterial pressure–based cardiac output monitors depends critically on accurate determination of arterial compliance, which changes rapidly in liver transplantation, particularly at reperfusion or clamping of major vessels; and because it cannot be readily measured, the assumed value of vascular compliance used in the algorithms of the devices to calculate cardiac output may lead to inaccurate calculations. The inaccuracy may be mitigated by repeated calibrations with the LiDCO or PiCCO.

Cardiac output determined by a novel suprasternal ultrasound cardiac output monitor (USCOM Pty, Coffs Harbour, Australia) correlates well with the PAC cardiac output (Wong et al, 2008; Su et al, 2008). Other USCOM measurements, such as Doppler estimation of peripheral artery pressures and left ventricular contractility, remain to be validated.

TEE has been gaining more popularity in liver transplantation (Burtenshaw & Isaac, 2006). Data from 2002 estimated use of TEE in only 21% of high-volume centers in the United States (Schuman, 2003), but a more recent survey showed that 86% of anesthesiologists in 40 large-volume U.S. centers use TEE in some or all liver transplantations (Wax et al, 2008).

The main advantages of TEE are that it provides continuous, real-time visualization of cardiac structures and dynamic function. TEE is a superior modality for estimating ventricular volume status, global LV contractility and ejection fraction, right ventricular function, segmental wall motion abnormalities, and septal motion. Doppler modalities allow for interrogation of transvalvular flows, dynamic left ventricular outflow obstruction, intracardiac shunts, and diastolic function. In addition, TEE is the only intraoperative monitor that allows an instantaneous diagnosis of pulmonary or intracardiac thrombus (Ellenberger et al, 2006; Planinsic et al, 2004) and pericardial or pleural effusion. TEE detection of a transpulmonary shunt as a positive bubble test in a patient with HPS is presented in Figure 97B.1.

Dynamic monitoring of the right ventricular function and detection of right ventricular failure are critically important in managing patients with portopulmonary hypertension, particularly during reperfusion. Assessment of right ventricular volume and contractility, severity of tricuspid regurgitation, and measurement of lows in the inferior vena cava (IVC) may help guide volume, inotrope, and pulmonary vasodilator therapy.

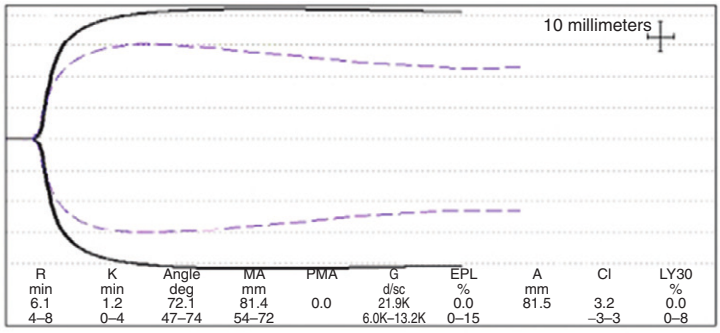
In addition to requiring significant training and resources, TEE has several important disadvantages. An obvious concern in the liver transplant patient population is the risk of rupture of gastroesophageal varices. Although this complication is very rare, it does emphasize the need for careful risk/benefit assessment of this monitoring modality in each individual recipient. It is prudent to withdraw the TEE probe from the stomach during surgical gastric retraction, making transgastric views inaccessible during most of the procedure. Another disadvantage is that TEE is not adept at providing and trending traditional numerical data (e.g., cardiac output), which are readily provided by the PAC. Visual assessments used in TEE are also highly operator dependent. Finally, unlike the PAC, the TEE probe is typically removed at the end of surgery; therefore the continuity of monitoring is interrupted, and the transfer of specific parameters of hemodynamic management to the postoperative ICU is difficult. This problem may be mitigated by the introduction of less expensive, disposable TEE probes.

Monitoring of Hemostasis

Conventional tests of hemostasis, PT and aPTT, have several important limitations (Dalmau et al, 2009; Ng et al, 2009). First, these assays utilize plasma samples devoid of platelets. The activated platelet surface, the naturally occurring medium of the in vivo coagulation, is replaced by addition of phospholipids. The contribution of platelets is thus not considered by these tests. Second, PT and PTT measure only the activity of procoagulant factors and do not take into account the anticoagulant factors. When PT is modified to include anticoagulant factors, thrombin generation in cirrhotic patients is not different from normal controls (Tripodi et al, 2005). The reported higher intralaboratory variability of INR than of PT may be of more relevance for MELD score determination than for acute intraoperative management (Lisman & Leebeek, 2007).

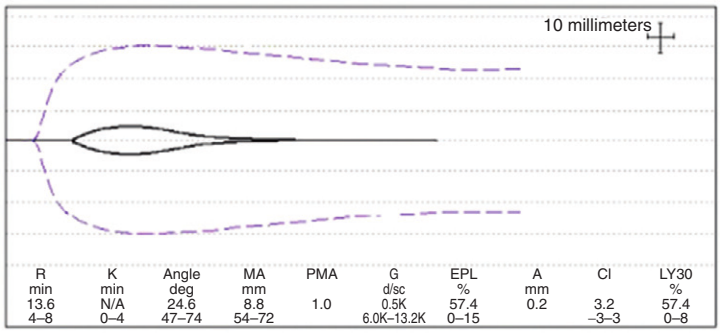
An important shortcoming of the conventional PT and PTT is a long turnaround time, typically about 45 minutes—suboptimal for an ongoing transplant surgery. Point-of-care (POC) assays require only a minimal delay between blood sampling and attaining the results of the test. POC assays of PT and PPT are quick (5 to 15 minutes), cartridge-type, whole-blood tests offered by several manufacturers. An acceptable agreement of such assays with corresponding plasma-based tests has been reported in OLT (Herbstreit et al, 2010), suggesting that the POC tests can effectively replace the slower, conventional testing.

Activated clotting time (ACT) was developed for POC monitoring of high-dose unfractionated heparin therapy, and it should be a part of the POC battery; with reperfusion of the graft, a massive dose of unfractionated heparin is flushed into the circulation. In conjunction with other POC tests, ACT may help guide the use and dosing of protamine.



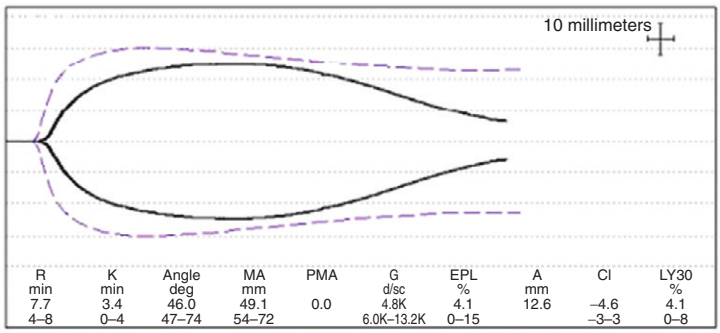
TEG and ROTEM are POC assays that measure viscoelastic properties of whole-blood clot formation and lysis. Both technologies have been used to drive transfusion algorithms (Kang et al, 1985; Coakley et al, 2006). TEG measures time to onset of clot, rate of clot formation, clot tensile strength, and rate of clot lysis (Fig. 97B.2). Treatment of samples with an intrinsic pathway activator, kaolin, shortens clot formation, whereas addition of heparinase dissects the effects of exogenous heparin from intrinsic heparinoids. TEG results are available more rapidly than the conventional laboratory tests. In our institution, progress of TEG clot formation and lysis is displayed on a dedicated operating room monitor and is available to the anesthesiologist in real time.

ROTEM generates a similar trace to that of TEG, although a ROTEM assay may be modified by a heparinase reagent (hep-TEM), an intrinsic pathway activator (in-TEM), and a tissue-factor activator (ex-TEM). In addition, ROTEM includes a qualitative test of fibrinogen activation and fibrin polymerization (fib-TEM), which is based on adding a blocker of platelet function. ROTEM is very useful in determination of poor tensile clot strength as a result of combined platelet and fibrinogen deficiency, and it is the most reliable method for detecting hypofibrinogenemia or dysfibrinogenemia, both common in liver disease (Kalina et al, 2008).



Both TEG and ROTEM are quick and superior monitors of hypercoagulability, fibrinolysis, and therapeutic effects of antifibrinolytics. The main conceptual deficiency of the two monitors is the inability to evaluate endothelial function. It is worth emphasizing that although both instruments plot clot formation in a similar fashion, TEG and ROTEM do not generate the same results when analyzing blood without exogenous activation, therefore they are not interchangeable (Coakley et al, 2006; Nielsen, 2007).

Monitoring and management of hemostasis remain great challenges of OLT, and it has been well established that blood loss and blood product transfusion are an important cause of morbidity and mortality (de Boer et al, 2008; Massicotte et al, 2005; Ramos et al, 2003). Adherence to an algorithm-driven transfusion practice may reduce unnecessary perioperative blood and blood-component transfusion (Avidan et al, 2004; Kang, 1997; Kang et al, 1985), but no consensus has been reached on what constitutes standard intraoperative monitoring of hemostasis or a standard hemostatic intervention.



Difficulties stem from the incomplete understanding of complex coagulation abnormalities in liver disease and OLT and from the limitations of currently available tests to emulate the in vivo conditions. For example, preoperative coagulation tests do not predict intraoperative bleeding (Massicotte et al, 2004; Steib et al, 2001), and transfusion requirements are

A

B

C

FIGURE 97B.2. Intraoperative thromboelastogram (TEG) recordings from three orthotopic liver transplantation patients with different hemostatic derangements. In each panel, a "normal" TEG trace, generated by the instrument, is presented with an interrupted line. **A,** Hypercoagulable state in a patient with primary biliary cirrhosis. **B,** Postreperfusion TEG shows profoundly suppressed clot formation and marked fibrinolysis. **C,** Mild hypocoagulability and fibrinolysis in a patient with hepatitis C.

actually lower when abnormal coagulation test results do not lead to routine correction by infusion of fresh frozen plasma (FFP) and other blood products (de Boer et al, 2005). Finally, bleeding in OLT is often related to factors other than coagulopathy. These findings emphasize the need for careful interpretation of coagulation tests within the clinical context rather than relying on interventions formulated solely on the basis of test results.

Metabolic Monitoring

Glucose Control

ESLD is associated with impaired glucose control, and hypoglycemia is common in ALF, whereas peripheral insulin resistance and metabolic syndrome are common in CLD. Factors that contribute to acute intraoperative hyperglycemia are routine administration of steroids and postoperative immunosuppressants and response to surgical stress. Two retrospective studies have shown association of a higher incidence of infections and 1-year mortality with poor perioperative glucose control (Ammori et al, 2007; Park et al, 2009). These studies, in general agreement with other perioperative outcome studies, emphasize the need for close POC perioperative monitoring and management of blood glucose levels, but the exact target range is unknown.

Electrolytes

Electrolyte monitoring is done as POC testing, usually on an hourly basis and when indicated, such as to optimize electrolyte balance immediately before graft reperfusion. Hyperkalemia is ominous and may cause fatal arrhythmias, particularly after reperfusion. Independent predictors of hyperkalemia are the number of red blood cells (RBCs) transfused and higher initial values, especially in acidemic patients with renal insufficiency (Naksuji & Bookallil, 2000). Ionized calcium levels predictably decrease with blood product and albumin administration. Low serum sodium is a hallmark of advanced cirrhosis and an independent predictor of mortality on the transplant waiting list (Kim et al, 2008; Yun et al, 2009), and intraoperative sodium levels are elevated by administration of normal saline-based

FIGURE 97B.3. A two-lead intraoperative electrocardiogram (*ECG*) recorded on the operating room monitor shortly after reperfusion, shows profound bradycardia and tall T waves. Such changes are not uncommon in the period immediately following graft reperfusion.

fluids and particularly by sodium bicarbonate; in addition, rapid correction of serum sodium levels may cause pontine demyelination (Zhang et al, 2009).

Temperature Monitoring

Monitoring of temperature is usually achieved via a PAC or an esophageal probe. Surprisingly little has been reported on temperature management in OLT, considering the fact that hypothermia is a key sign of liver failure and a significant problem during surgery. Well-known detrimental effects of hypothermia include impaired wound healing and impaired coagulation. An acute decrease in central temperature results from the cold perfusate returning to the heart following graft reperfusion. This precipitous hypothermia contributes to postreperfusion hemodynamic instability and bradyarrhythmias that may progress to cardiac arrest (Fig. 97B.3). The hypothermic insult can be partially mitigated by achieving upper-limit normothermia in the prereperfusion period, thus the value of continuous temperature monitoring and measures to assure normothermia cannot be overemphasized. A special circumstance is deliberate mild hypothermia, which acts by decreasing brain metabolism and mediators of oxidative stress; thus mild hypothermia is an accepted treatment of increased intracranial pressure in ALF (Stravitz & Larsen, 2009).

INTRAOPERATIVE MANAGEMENT

Ventilatory Management

Mechanical ventilation should optimize respiratory gas exchange and maintain lung volumes and capacities to facilitate early postoperative extubation. Preexisting respiratory comorbidities, such as hydrothorax, have to be considered in setting the ventilatory parameters. Although not much is reported about the ventilator setting in OLT, it seems reasonable to adopt a protective ventilatory strategy and to avoid high airway peak pressures (below 30 to 35 cm H_2O). Tidal volume of 6 to 8 mL/kg are a reasonable initial setting (Slinger, 2008; Shultz, 2008), but tidal volumes of least 8 mL/kg are necessary for reliable pulse pressure variation (PPV) or stroke volume variation (SVV) monitoring (Michard, 2005).

Multiple factors can cause increased pulmonary capillary permeability and predispose the lungs to interstitial edema. Positive end-expiratory pressure (PEEP) is a rational tool to prevent lung edema, and a PEEP of up to 10 mm Hg has been proven safe in maintaining hemodynamics and graft perfusion after cadaveric and living-donor liver transplant (LDLT) (Saner et al, 2006a, 2006b; 2008). Fio_2 can be increased to modulate pulmonary resistance in case of pulmonary hypertension. It is not known whether high intraoperative values of inspiratory fraction of oxygen may have a role in modulating ischemia-reperfusion injury after reperfusion (Kabon & Kurz, 2006).

Intraoperative Hemodynamic, Fluid, and Transfusion Management

Hemodynamic management of fluids and blood-product transfusions are critically interconnected and should be considered together. Excessive fluid administration may result in increased pressure in the IVC, portal vein, and collateral veins, possibly contributing to blood loss during liver dissection, hemodilution of coagulation factors and platelets, and tissue edema (see Chapter 22; Westercamp et al, 2009). Conversely, inadequate intravascular volume repletion may result in hemodynamic instability and organ hypoperfusion.

Better understanding of pathophysiology in ESLD, improvement in surgical and anesthetic techniques, and availability of POC laboratories have resulted in marked reductions in blood-product administration, including those for transplantations without transfusion. This is of great significance, as reduced blood-product transfusion is associated with better long-term outcomes (Bennett-Guerrero et al, 2001; Massicotte et al, 2007; Pereboom et al, 2009).

A strategy of maintaining low central venous pressure (CVP ≤5 mm Hg) through restrictive fluid administration and phlebotomy has been advocated by Massicotte and colleagues (2006) as an effective and safe strategy for transfusion-free OLT (see Chapter 22). In contrast, Schroeder and colleagues (2004) reported increased mortality and renal failure associated with low-CVP management. Whereas the low-CVP strategy may be possible in select patients with normal kidney function and good cardiovascular reserve, targeting one specific low CVP (i.e., 5 mm Hg) may not be physiologically advantageous in patients with poor ventricular compliance and preexisting renal dysfunction.

A low-CVP regimen usually requires vasopressor administration to maintain arterial blood pressures (Ponnudurai et al, 2005; Schroeder et al, 2004) but with the possible side effect of end-organ hypoperfusion. As CVP is not a reliable index of preload, volumetric assessment with TEE or fluid-responsiveness indexes (dPP or SVV) may be a more physiologic approach to guide fluid management (Biais et al, 2008; Della Rocca, 2009). Fluid management strategy and interpretation of CVP values may vary based on the surgical technique; for example, during a complete IVC clamp, blood is sequestered below the clamp, and low CVP does not accurately reflect volume status. After unclamping of the IVC and portal vein, the CVP increases rapidly and may abolish the pressure gradient between the portal vein and the right atrium and thereby compromise liver perfusion. Hemodynamic changes during a piggyback technique rarely reach such magnitude.

Hypotension is common during all phases of OLT, but little is reported on the impact of intraoperative hypotension on long-term patient outcomes. Reich and colleagues (2003) reported the worst surgical outcomes early after liver transplantation in patients who had at least one episode of arterial hypotension with an MAP below 40 mm Hg.

Little evidence is available to provide guidance regarding the choice of intraoperative vasopressors. Agents are chosen based on their pharmacologic properties and side effects (Zhang et al, 2005). Commonly used agents are neosynephrine, norepinephrine, vasopressin, and dopamine. Of note, vasopressin 1 receptors and α_1-adrenergic agonists are useful in preserving renal function in HRS (Gines & Schrier, 2009); vasopressin reduces splanchnic blood flow, which may reduce bleeding from portal

collaterals during the dissection phase but may also impede portal vein flow during the neohepatic phase (Wagener et al, 2008).

Most centers use a combination of crystalloids and colloids for fluid replacement. A recent study showed that use of new-generation hetastarch (HES 130/0.4) may be a safe alternative to conventionally used 5% albumin (Mukhtar et al, 2009), but more studies are needed.

Severe pulmonary hypertension (PVR >240 dynes/sec/cm^{-5}) is associated with high perioperative mortality and is a contraindication for proceeding with liver transplant. In moderate PPHTN with preserved right ventricular function, the goal of intraoperative management is to lower pulmonary vascular resistance and promote myocardial contractility. General measures include increasing Fio_2, avoidance of hypercapnia and acidosis, and administration of nitrous oxide. Selective pulmonary vasodilators, inhaled nitric oxide, and prostacyclin are superior to intravenous vasodilators, which may cause systemic hypotension and compromise right-heart perfusion and preload. Milrinone and dobutamine are used as inotropes and pulmonary vasodilators but with caution, as they also cause systemic hypotension. Pulmonary pressure management is particularly challenging in the postreperfusion period, and pulmonary vasodilators are weaned gradually to avoid rebound pulmonary hypertension. Extubation should be delayed if inhalational vasodilators agents are needed (Mandell, 2004; Teo & Greenhalg, 2010).

With implementation of the MELD scoring system, more patients with renal insufficiency are being treated with OLT. Renal failure is associated with increased short- and long-term mortality after OLT, and perioperative renal failure often requires postoperative RRT. Intraoperative renal protection strategy is based on the maintenance of adequate intravascular volume and renal perfusion. No specific intraoperative renoprotective agents have been proven effective, but it is reasonable to maintain perfusion pressure with vasopressin and adrenergic agonists, which are effective in management of HRS. Surgical techniques that preserve vena caval flow, such as a piggyback technique, favor better renal outcomes. Intraoperative RRT is feasible and has been proven safe and successful in maintaining electrolyte and fluid balance (Ramsay & Garcia-Valdecasas, 2009; Townsend et al, 2009), although many transplant units try to avoid the need for it during the course of an OLT if at all possible. New markers of renal injury, such as neutrophil gelatinase–associated lipocalin, may be more useful than SCr in assessing acute kidney injury (AKI) (Niemann et al, 2009). The prognostic value of this rapid assay may prove useful in future studies to confirm the validity of intraoperative renoprotective strategies.

The administration of RBCs, FFP, and platelets has been associated with increased mortality (Bennett-Guerrero et al, 2001; de Boer et al, 2008; Massicotte et al, 2005; Pereboom et al, 2008; Ramos et al, 2003). Average blood-product requirements have decreased dramatically over the past decade, and now OLT can often be performed without transfusion (De Boer et al, 2005; Ozier & Tsou, 2008). Although it would be useful to prospectively identify patients at high risk of major bleeding, factors predictive of higher transfusion requirements are still debatable. Low pretransplant hemoglobin and a MELD score higher than 30 are better established predictors than previous abdominal surgery, prolonged INR, and low platelet counts (Massicotte et al, 2009; Ozier & Tsou, 2008; Xia et al, 2006).

No thresholds have been universally accepted for transfusing RBCs, FFP, and platelets, and practice differs among various centers and clinicians. POC testing, including TEG and ROTEM, have been used to define transfusion algorithms (see Monitoring of Hemostasis above).

The selective use of antifibrinolytic agents in the presence of persistent fibrinolysis is indicated, but routine prophylactic use of these agents is controversial. Aprotinin and tranexamic acid have been shown to reduce transfusion requirements in high-risk patients (Dalmau et al, 2000; Molenaar et al, 2007). Based on several case reports focused on the association of antifibrinolytics with vascular thrombosis (Dalmau et al, 2000; O'Connor et al, 2000) of either the arterial or venous circulation, and considering the current low transfusion rate, we question the validity of an indiscriminate prophylactic treatment in the absence of clinical and laboratory signs of hyperfibrinolysis. A recent meta-analysis (Molenaar et al, 2007) and a retrospective study of aprotinin by the same group (Warnaar et al, 2009) did not provide evidence for an increased risk of thromboembolic events associated with antifibrinolytic drugs in liver transplantation. It should be emphasized that in both of these studies, trends were observed that suggested a possible association between antifibrinolytics and thrombosis that did not reach statistical significance, perhaps because of the limited number of subjected enrolled and other confounding factors.

No consensus exists regarding the choice of any specific antifibrinolytic agent, dose, or time of administration; therefore monitoring of fibrinolysis and early detection of hypercoagulability are of critical importance. The prevailing view is that TEG/ROTEM may best provide such information, and TEE may be useful for detection of intracardiac clots adhering to the central lines. Use of activated factor VII as a prophylactic treatment has not been proven advantageous in a liver transplant setting, but it has been used successfully as a rescue treatment in a few individual cases (da Silva Viana, 2006). Cryoprecipitate, a source of factors I and VIIIc and of vWF, and prothrombin complex concentrates that contain vitamin K–dependent factors II, VII, IX, and X are increasingly used as an alternative to FFP. The advantage of these products over FFP is that a smaller volume is required, and risk of infectious complications is reduced (Ofosu et al, 2008; Samama et al, 2008).

CRITICAL INTRAOPERATIVE EVENTS

Postreperfusion Syndrome and Refractory Hypotension

Postreperfusion syndrome (PRS), first described by Aggarwal and colleagues in 1987, was originally defined as a decrease in systemic arterial pressure to less than 70% of the prereperfusion value or a mean blood pressure (BP) below 60 mm Hg within 5 minutes of liver reperfusion and lasting at least 1 minute. The low systemic BP was associated with an increase in PVR and central pressures and occasionally with bradycardia, which could progress to asystole (Aggarawal et al, 1993). Other authors proposed similar definitions based on hemodynamics (Ayanoglu et al, 2003; Chui et al, 2000; Nanashima et al, 2001; Paugam-Burtz et al, 2009), and one proposed an expanded concept that, in addition to unstable hemodynamics, included postreperfusion fibrinolysis that required administration of antifibrinlolytics (Hilmi et al, 2008). Depending upon the reporting center, significant PRS is evident in 25% to 55% of patients, an acknowledgment that the incidence depends on the definition. In a significant percentage of patients undergoing liver transplant, reperfusion can be complicated by

bradycardia that is resistant to chronotropic agents and asystole that requires cardiopulmonary resuscitation.

The mechanisms behind bradycardia and reperfusion syndrome are not yet fully understood. Several possible factors have been indicated, such as the release of vasoactive substances from the liver graft or the recipient gut—potassium, acids, prostanoids, bradykinin, interleukins—along with hypovolemia, hypothermia, or small air or thrombotic emboli (Chui et al, 2000; Ricciardi et al, 2002). In a multivariable logistic regression analysis, Paugam-Burtz and colleagues (2009) found that absence of portocaval shunt and duration of cold-ischemia time were independent predictors of PRS.

PRS is associated with adverse outcomes, including an increase in blood loss with an attendant increase in blood-product requirements, higher incidence of postoperative allograft loss, kidney failure, and early mortality (Paugam-Burtz et al, 2009; Ramsay, 2008). No universally accepted preventative strategies have been developed, but common interventions include pretreatment with chronotropic and vasoconstrictor agents and optimization of temperature, pH, and electrolytes. The occurrence of ischemia-reperfusion injury is well recognized, but its exact relevance to PRS is not fully understood. Therapeutic approaches that use nitric oxide, prostaglandin E_1 and various antioxidants aimed at mitigating the inflammatory response and cellular cascade triggered by the ischemia-reperfusion are undergoing clinical evaluation (Ramsay, 2008). Methylene blue has been reported in treatment of refractory hypotension after reperfusion, but its effectiveness has not been confirmed in larger studies (Cao et al, 2009; Fischer et al, 2010).

Pulmonary Embolism

Pulmonary air and thromboembolism are rare but potentially fatal complications of OLT. With air embolism, a simultaneous laceration of a large vein, such as the IVC or hepatic veins, and a low CVP allow active entrainment of air into the central circulation; in addition, partial disconnection of the venovenous bypass circuit can also lead to air entrapment in the central circulation.

Intravascular clotting may manifest with pulmonary embolism, and intracardiac thrombi may occur with or without venous thrombosis and are frequently adherent to central venous lines. The mechanism of intravascular clotting in OLT patients is not fully understood. Some ESLD diagnoses, such as primary biliary cirrhosis or primary sclerosing cholangitis, are associated with hypercoagulability. In other cases, intravascular clotting has been related to administration of antifibrinolytics or transfusion of blood products (Warnaar et al, 2008a). Use of aprotinin in patients undergoing OLT may be associated with an increased incidence of venous thrombosis (Warnaar et al, 2009). Still, in a single-center case series, four episodes of PE were reported in the absence of antifibrinolytic use (Lerner et al, 2005).

Paradoxical embolus is a possible complication when an anatomic or functional atrial septum defect is present. Such complication is more likely to happen in pediatric recipients and in the early postreperfusion period, when right artery pressure is often higher than left artery pressure. During the pretransplant evaluation of pediatric patients, it is worthwhile to rule out such a defect or to plan for an atrial septal defect percutaneous closure when the defect size is significant and unlikely to heal before the transplant date.

In a recent single-center series, reported incidence of pulmonary embolism was 3.3% (El-Baghdadi & Sakai, 2010); however, very high overall and intraoperative mortality were reported in a recent review focused on pulmonary embolism in an OLT setting (Warnaar et al, 2008a): hospital mortality was 68%, and intraoperative mortality rate 82%.

The most common initial indication of intraoperative pulmonary embolism is usually systemic hypotension with a simultaneous increase in pulmonary pressure (Ellenberger et al, 2006; Warnaar et al, 2008a). End-tidal CO_2 may also decrease. A reasonable preventive strategy is based on prompt identification of hypercoagulable conditions with TEG/ROTEM and avoidance of unnecessary prophylactic administration of antifibrinolytics (Planinsic et al, 2006). TEE can be a diagnostic tool, but its role as a preventive tool is less clear. Treatment is based on hemodynamic support, and successful intraoperative administration of recombinant tissue plasminogen activator has been reported (Jackson et al, 2006).

SPECIAL SITUATIONS

Acute Liver Failure

Acute liver failure is defined as a severe liver dysfunction causing encephalopathy and coagulopathy (INR >1.5) within 24 weeks of the onset of symptoms in patients without previous liver disease (see Chapters 72 and 97C); it is considered *fulminant ALF* if it develops in less than 2 weeks. Overall transplant-free survival in ALF is dependent on etiology and is just above 40%; it is highest for acetaminophen/paracetamol overdose, which requires transplantation in less than 10% of patients (Trotter, 2009). Liver transplantation is the only proven therapeutic intervention in advanced ALF, accounting for just over 5% of all liver transplantations, and carries a 1-year survival of 60% to 80% (De Gasperi et al, 2008; Trotter, 2009; see Chapter 97C).

Increased ICP and severe coagulopathy are the hallmarks of ALF and are also the main perioperative challenges. As cerebral edema is the most common cause of death in ALF, control of intracranial hypertension and maintenance of adequate cerebral perfusion pressure (CPP) are critical intraoperative tasks. Widely accepted minimal goals are ICP of less than 25 mm Hg and CPP of 50 to 60 mm Hg or higher. Continuous invasive monitoring of ICP is ideal for guiding management, but it is associated with a high risk of bleeding.

ICP typically arises during the dissection phase and peaks after reperfusion. A simultaneous and precipitous drop in MAP makes postreperfusion the most critical and challenging period for management of CPP. A protocol that included intraparenchymal ICP monitoring, maintenance of CPP greater than 60 mm Hg by administration of vasopressors, hyperventilation (P_{CO_2} at 30 to 35 mm Hg), mannitol and 3% saline, mild hypothermia (33° to 34° C), and a high dose of pentobarbital titrated to ICP effect resulted in favorable neurologic outcomes in a small series of ICU and liver transplant patients (Raschke et al, 2008).

No randomized trials or consensus statements are available that stipulate the safety and efficacy of different types of ICP monitors or specific management protocols during liver transplantation, but it is increasingly recognized that clinically meaningful inferences may require multimodal approaches, including brain tissue oxygen monitoring and microdialysis (Stevens & Merritt, 2008). Interventions aimed at management of CPP are outlined in Table 97B.1.

Despite profound coagulation abnormalities in ALF (Box 97B.1), serious bleeding is rare during liver transplantation,

Box 97B.1

Hemostatic Abnormalities in Liver Disease

Anticoagulant
Thrombocytopenia
Impaired platelet function (?)
Reduced hematocrit
Upregulated NO* and prostacyclin* inhibit platelets
Low levels of coagulation factors II, V, VII, IX, X, and XI
Vitamin K deficiency
Hypofibrinogenemia, dysfibrinogenemia
Decreased factor XIII, TAFI
Elevated levels of tPA,* decreased PAI-1*
Procoagulant
Elevated factor VIII† and von Willebrand factor*
Decreased proteins S and C and antithrombin III†
Decreased plasminogen and α_2-antiplasmin

*Extrahepatic synthesis
†Extrahepatic and intrahepatic synthesis
NO, nitric oxide; PAI-1, plasminogen activator inhibitor type 1; TAFI, thrombin activatable fibrinolysis inhibitor; tPA, tissue plasminogen activator

Lisman T, Leebeek WG, 2007: Hemostatic alterations in liver disease: a review on pathophysiology, clinical consequences, and treatment. Dig Surg 24:250-258.

because ALF patients have minimal or no portal hypertension (Muñoz et al, 2009). No evidence-based protocols have been outlined for correcting coagulopathy in ALF, but it is recognized that prophylactic administration of FFP and other products simply to correct the prothrombin time is not justified. Correction of coagulopathy is important before placement of an ICP transducer. Whole-blood assays (TEG, ROTEM) and clinical assessment are more useful guides for intraoperative treatment of coagulopathy. A major limitation of FFP is the potential for volume overload and transfusion-related acute lung injury (TRALI). Cryoprecipitate is typically indicated when the fibrinogen level falls below 100 mg/dL; activated recombinant factor VII (rFVIIa) and thrombin concentrates are beneficial, but optimal use of these last two remain to be determined. Antifibrinolytics should be considered if clinically significant fibrinolysis is proven.

Both high-dose steroids given during the anhepatic period and a functioning graft may cause hyperglycemia in the neohepatic phase. As hyperglycemia has an adverse effect on ischemia-reperfusion brain injury, plasma glucose should be kept in the normal range, and continuous infusion of insulin is often required. Restoration of liver function by the functioning graft gradually eliminates encephalotoxins and improves metabolic homeostasis, which eventually leads to reduction of brain edema and normalization of intracranial and cerebral perfusion pressures.

Combined Liver-Kidney Transplantation

With the introduction of the MELD scoring system, the percentage of simultaneous liver-kidney transplantation doubled, to about 4.4% of all liver transplantations performed in the United States (Gines & Schrier, 2009). Although it is obvious that combined transplantation should be reserved only for patients with irreversible renal failure, reliable predictive factors for reversibility are sometimes difficult to fully define. Current criteria recommended by the International Liver Transplant Society expert panel (Gonwa & Davis, 2009) include patients who, in addition to having liver disease, are on dialysis because of end-stage renal disease; patients with AKI that requires dialysis for at least 6 weeks; and those not on dialysis but who have a low glomerular filtration rate (<30 mL/min) and proteinuria (3 g/day, 24-hour urine protein/creatinine ratio >3).

A matched case-control analysis of patients dialyzed for more than 3 months demonstrated a favorable impact of combined liver-kidney transplantation compared with liver transplantation alone. Patient survival was improved (87.2% vs. 74.5%), as was liver-graft survival (84.5% vs. 70.8%), 1 year after transplantation (Locke et al, 2008). In contrast, 1-year survival of the kidney graft was lower than after kidney transplantation alone (77.2% vs. 89.3%). The inferior renal results and the priority given to the kidney on the long waiting list point to a need for a standardized approach to combined liver-kidney allocation and for a better understanding of reversibility of renal dysfunction (Davis, 2008).

Patients presenting for a combined liver-kidney transplantation present a particular anesthetic challenge. Electrolyte abnormalities and metabolic acidosis may mandate preoperative hemodialysis, whereas hyperkalemia greater than 5.5 mmol/L and hyponatremia of less than 120 mmol/L are typically considered prohibitive to transplantation. Intraoperative monitoring of preload and strategies for judicious volume administration and correction of electrolyte abnormalities are essential. Hyperkalemia is common and should be managed aggressively by maintaining a normal pH and administering insulin or glucose, inhaled β-adrenergic agonists, and furosemide, if urine output is preserved. Banked blood is a major source of potassium; ideally, it should be washed, and units with the longest remaining shelf life should be preferentially used.

Intraoperative continuous RRT is possible, and its use is routine in some centers. In a series of 41 OLTs, this modality was well tolerated hemodynamically, and it allowed achievement of neutral fluid balance without a need for systemic anticoagulation (Townsend et al, 2009). Fluid strategies for the two parts of the combined procedure may seem conflicting; although the kidney transplantation part may prompt a somewhat more liberal fluid regimen, in our opinion, goals for both OLT and kidney transplantation should be maintenance of a normal range preload to allow optimal organ perfusion.

Retransplantation

Most common reasons for retransplantation are primary nonfunction, recurrence of viral hepatitis, acute or chronic rejection, and thrombosis of the hepatic artery (Ma et al, 2008; Pfitzmann et al, 2007). The time interval between the primary transplantation and retransplantation—that is, early versus delayed retransplantation—depends on the etiology of the graft failure.

Almost 11,000 retransplantations have been performed since the inception of the UNOS registry—about 11% of all the OLTs ever performed. A declining trend toward the need for retransplantation is apparent; for example, in 1988, the retransplantation rate was 24.5%, whereas in 2009, the rate was only 7.3%.

The survival rate for retransplanted patients is lower than for primary transplant recipients: at 1 year, the survival is 67.2% versus 83.4%; at 5 years, it drops to 46% versus 67.4% (UNOS, 2010). With appropriate recipient selection, better outcomes are possible, and 1- and 5-year survival rates have been reported as high as 78% and 67%, respectively, with retransplantation (Ma et al, 2008; Pfitzmann et al, 2007). General agreement has

been reached on two points: 1) that whole graft should be used in adults (Pfitzmann et al, 2007) and 2) that retransplantation should not be undertaken with extended-criteria donors (Zimmerman & Ghobrial, 2005).

The current modest results emphasize the need for strategies to improve retransplantation survival. In particular, a strong interest has been shown in the development of valid predictive criteria; for example, according to Zimmerman and Ghobrial (2005), patients who require mechanical ventilation, those who have advanced renal failure, and patients of advanced age have worse outcomes and should not be considered for retransplantation. MELD score has prognostic value in retransplantation: patients with of a score below 20 have better outcomes than those with higher scores (Ma et al, 2008); in another study, worse results were reported when MELD was more than 25 (Zimmerman & Ghobrial, 2005).

A few studies have also looked at survival as a function of the time interval between the primary transplantation and retransplantation; survival was better when retransplantation occurred less than 8 or more than 30 days after the initial transplantation (Ma et al, 2008).

Intraoperative anesthetic challenges depend on the overall patient condition on the day of surgery; factors that may impact transplantation include difficult vascular access, a need to support liver and coagulation function, increased blood losses, and a higher requirement for blood-product transfusions. The main causes of death were bacterial infection, multisystem organ failure, bleeding, and recurrence of disease (Pfitzmann et al, 2007).

Pediatric Transplantation

Indications for liver transplantation in the pediatric population include 1) primary liver disease, such as extrahepatic biliary atresia, and intrahepatic cholestasis, which includes sclerosing cholangitis, Alagille syndrome, and other similar syndromes; 2) metabolic diseases, such as Wilson disease, α_1-antitrypsin deficiency, Crigler-Najjar syndrome, disorders of the urea cycle, oxaluria type 1, and disorders of carbohydrate metabolism; 3) ALF; and 4) liver disease brought about through other causes, including primary liver tumor and cystic fibrosis (Spada et al, 2009; Yudkowitz & Chietero, 2005; see Chapter 71).

According to UNOS data, more than 12,000 OLTs have been performed since 1988 in patients younger than 18 years, with the majority carried out in patients younger than 5 years.

Age at Transplantation

Age at transplantation mainly depends on the specific etiology of the liver disease. Historically, age at transplantation was one of the main factors that determined survival, and infants used to have poorer outcomes than older children; however, with recent improvement of surgical techniques and better overall perioperative care, infant survival is close to that of older children following OLT (Bennett & Bromley, 2006).

Survival

One-year survival for chronic liver disease is greater than 90%, and survival at 5 years is over 80% in most centers in the United States and Europe (Bennett & Bromley, 2006). Nephrotoxicity secondary to calcineurin inhibitors (CNIs) remains a frequent cause of posttransplant renal dysfunction (Bucuvalas & Alonso, 2008).

Recipient Selection

Organ allocation to pediatric recipients in the United States is based on the Pediatric End-Stage Liver Disease (PELD) score, developed based on data derived from a database of children with ESLD to predict mortality on the waiting list; it considers bilirubin, INR, serum albumin, age, and growth factors. Additional PELD points are awarded for specific risk factors not taken into account in the original PELD equation, such as presence of HPS, metabolic diseases, and liver tumors (Bennett & Bromley, 2006; Spada et al, 2009).

Type of Surgical Graft

Whole, reduced, and split grafts from both cadaveric and living donors have been used to maximize the number of pediatric liver transplants performed and to minimize the risk of patients dying while on the waiting list.

Intraoperative Anesthesia Challenges

Multifactorial hypoxemia is sometimes present, possibly related to HPS, whereas PPHTN is usually present only in children affected by Alagille syndrome. Cuffed endotracheal tubes should be used to guarantee effective mechanical ventilation in the presence of high airway pressure peaks. Most children undergoing liver transplantation have preserved kidney function, but they are at high risk of developing hypoglycemia.

VASCULAR ACCESS. Two large bore intravenous needles are usually sufficient for fluid and blood administration. Arterial catheters are usually placed in the upper limbs, as a femoral line may produce unreliable values once the surgeon clamps the aorta to build an arterial conduit. The length of the central venous line catheter must be appropriate for the body size of the patient, and PACs are rarely used because of size issues.

It is important to note that children are at increased risk of intraoperative hypothermia, and active maintenance of temperature is critical to prevent occurrence of dysrrhythmias, clotting abnormalities, and possible wound infections.

Thrombosis of the hepatic artery is a frequent complication that may lead to a graft loss and need for retransplantation. Keeping the hematocrit between 25% and 30% to prevent excessive blood viscosity and avoidance of overcorrecting the coagulation function are common protective strategies. Aspirin can be given (in adults) in the immediate postoperative period to blunt platelet activity (Bennett & Bromley, 2006; Yudkowitz & Chietero, 2005).

Living-Related Donor Liver Transplantation

Since 2006, fewer than 300 OLTs with a graft from a living relative donor have been performed annually in the United States—about 3% of adult and 10% of pediatric OLTs (see Chapter 98B). This is a marked decline with respect to the year 2001, when a record 524 OLTs came from living donors—about 9% of adult and 18% of pediatric OLTs. Although survival of the recipients of a living graft is superior to that of cadaveric graft recipients (UNOS, 2010), a justified concern for donor morbidity and mortality drives this trend. Challenges for the anesthesiologist depend more on the recipient's characteristic and comorbidities than on the donor category (Table 97B.2).

Table 97B.2

Early Complications After Liver Transplantation

Type	Complication
Pulmonary	TRALI/ARDS, pneumonia, pleural effusions, persistent shunting
Cardiovascular	CHF, hypotension, myocardial ischemia, arrhythmias
Renal	ATN, hepatorenal syndrome, CNI nephrotoxicity
Metabolic	Hyperglycemia/diabetes mellitus, electrolyte abnormalities
Neurologic	Persistent encephalopathy, seizures, posterior leukoencephalopathy, central pontine myelinolysis
Infectious	Wound infections, seromas, intraabdominal abscess, sepsis
Abdominal	Surgical bleeding or bleeding as a result of coagulopathy
Vascular	Hepatic artery or portal vein stenosis/thrombosis, IVC obstruction
Biliary	Biliary stricture or leaks
Rejection	Cellular rejection
Immunosuppressant toxicity	Seizures, kidney failure

ARDS, acute respiratory distress syndrome; ATN, acute tubular necrosis; CHF, congestive heart failure; CNI, calcineurin inhibitor; IVC, inferior vena cava; TRALI, transfusion-related acute lung injury

POSTOPERATIVE INTENSIVE CARE

Transfer to the ICU should be smooth, and it should maintain the same level of monitoring and care as in the operating room. The main goals of the early postoperative period are maintenance of homeostatic equilibrium, timely recognition and treatment of complications, and diagnosis and treatment of infections and acute rejection. The risk of developing early postoperative complications is dependent upon the patient's preoperative condition, the quality of the graft, and the quality of the surgical, anesthetic, and intensive care management.

Early Extubation

Safe early or even immediate postoperative extubation of a majority of liver transplant patients has been reported by some centers; however, the exact criteria, the benefits of early extubation to liver recipients, and any cost benefits remain a matter of debate. A multicenter cohort study by a proponent group (Mandell et al, 2007) reported a lower rate (7.7%) of postoperative adverse events in the immediate extubation group than that commonly reported for ventilated liver transplant patients. This study showed great variability in rates of extubation (5% to 67%) and rates of complications between centers, suggesting a significant impact of the regional patterns of practice, intraoperative events, and physician experience. Multiple studies agree that encephalopathy, whether the result of acute or chronic liver failure, is a strong predictor of the need for prolonged ventilation. Other factors, such as volume of blood transfused and RRT, are less consistent predictors among studies and may be only indirect markers of poor graft function, severity of illness, and a lack of standardized intraoperative protocols (Mandell et al, 2009).

No randomized studies are currently available that demonstrate that early extubation improves patient outcomes or reduces cost (Ozier & Klinck, 2008). Although experienced clinicians can select appropriate patients for early extubation, no evidence-based criteria exist in support of this practice; more studies are needed to establish whether this intervention is beneficial and whether it should be a therapeutic goal in liver transplant recipients.

Medical Complications

Pulmonary complications that include acute respiratory distress syndrome (ARDS), TRALI, pneumonia, and pleural effusions are common in the immediate postoperative period. These complications are reported to occur in over 50% of patients after liver transplantation and lead to hypoxemia that often requires prolonged mechanical ventilation (Biais et al, 2009; Bozbas et al, 2008; Li et al, 2010). ARDS and TRALI may be related to blood-product transfusion and fluid overload. Pneumonia is the most frequent postoperative infection in patients following OLT, and it carries a high mortality. Pleural effusion is another common pulmonary complication; it promotes atelectasis and contributes to impaired respiratory exchange. The addition of PEEP monitoring may be effective in improving oxygenation in postoperative patients. PEEP of up to 10 cm of H_2O was found not to affect the perfusion of the grafted liver, as assessed by Doppler (Saner et al, 2006b).

Cirrhotic patients continue to exhibit hyperdynamic circulation during the first hours or days after OLT. Arterial hypotension and the need for vasopressors are common. With the graft functioning and no evidence of surgical complications, the hemodynamics tend to normalize, which allows downgrading of invasive monitoring and of hemodynamic support. Maintenance of kidney perfusion pressure is paramount because AKI is common (17% to 95%) (Pham et al, 2009) and is associated with increased ICU length of stay and mortality (Smith et al, 2009). The causes of post-OLT acute renal failure are multifactorial and include preexisting renal dysfunction, HRS, perioperative acute tubular necrosis, and CNI nephrotoxicity. RRT is necessary in 5% to 35% among patients who develop postoperative AKI.

Endocrine and metabolic complications are common in the early posttransplant period. Surgical stress, corticosteroid administration, and CNIs contribute to early posttransplant hyperglycemia, which frequently evolves to diabetes mellitus, and hypertension. Diabetes occurs in up to 30% of posttransplant patients, and hypertension is seen in over 50%. Hyperglycemia requires an intravenous insulin regimen and improves as steroids are tapered; hypertension should be treated aggressively to prevent cardiovascular complications (Kallwitz & Cotler, 2008).

Neurologic complications may occur in up to 50% of liver transplant recipients (Saner et al, 2009). Such complications contribute to longer ICU and hospital stays and may result in long-term poor quality of life. The most common neurologic complications are encephalopathy and seizures, followed by psychotic disorders, stroke, and poorly understood posterior leukoencephalopathy. The etiology is multifactorial and includes poor graft function, use of steroids and possibly CNIs, infection and systemic inflammatory response, electrolyte imbalance, and embolic events.

Meticulous perioperative neurologic assessment and quick recognition of neurologic impairment are essential. Specific therapeutic modalities are limited (i.e., tapering steroids, exchanging CNIs), but if applied in a timely manner, they may improve outcome. In addition, a key factor of neurologic improvement is the recovery of graft function.

Infections are the primary cause of death after liver transplantation. Many infections that occur in the first days after transplantation are related to the surgery itself, such as wound infections, seromas, and perigraft fluid collections. Postoperative and opportunistic infections are common in the immunocompromised and debilitated transplant patient. Such infections may lead to sepsis and multiorgan failure; therefore they require a high level of suspicion and routine postoperative prophylactic protocols that include broad-spectrum antibacterial, antiviral, and antifungal therapy.

Posttransplant rejection ranges from 10% to 30% (Mueller et al, 2004). Cellular rejection is suspected with increasing transaminases and normal hepatic vascular Doppler studies, and diagnosis is confirmed with liver biopsy; however, early episodes respond well to boluses of corticosteroids and rarely lead to graft failure.

Surgical Complications

Postoperative hemorrhage is primarily a clinical diagnosis that can be confirmed by abdominal imaging techniques, and it occurs in 10% to 15% of OLT patients. A priority is to distinguish whether hemorrhage is due to persisting coagulopathy or to surgical causes. Hemodynamic instability and transfusion of more than 4 to 6 U packed blood cells over a 24-hour period are usual indications for surgical reexploration (Mueller et al, 2004).

Early vascular complications include hepatic artery and portal vein stenosis or thrombosis and venocaval obstruction or kinking. Poor graft function and protracted elevation of liver enzymes point to a vascular complication; however, the diagnosis is made based on a bedside vascular Doppler and can be confirmed with conventional or MRI angiography. Hepatic artery thrombosis occurs in 2.5% to 10% of adult patients and in 5% to 20% of children; portal vein thrombosis is much less common (0.3% to 2.2%), and flow obstruction at the level of the infrahepatic and suprahepatic vena cava occurs in 1% to 2%.

All vascular complications require urgent surgical intervention. If vascular repair is delayed, the ensuing graft failure may necessitate retransplantation. Many vascular complications have been successfully treated using various endovascular approaches, including percutaneous angioplasty, stent placement, or thrombolysis (Amesur & Zajko, 2006).

Biliary complications occur in about 10% to 15% of patients following liver transplantation. Stricture of the bilary tree accounts for most of the complications, but biliary leak is a more common early complication. The most severe manifestations of biliary leak are peritonitis and sepsis, but asymptomatic bilomas are also a common presentation. The diagnosis of the leak is based on percutaneous transhepatic cholangiography (PTC) or endoscopic retrograde cholangiography (ERCP). Ultrasound and CT scan are useful in diagnosis of biliary dilations due to obstruction, bile collections, or abscesses. Treatment of biliary obstruction includes percutaneous balloon dilation and drainage or surgical revision. Treatment of biliary leaks involves percutaneous transhepatic drainage (PTD), a technically difficult alternative to surgical repair. Nonanastomotic leaks and leaks secondary to hepatic artery thrombosis are particularly ominous, because they are less amenable to percutaneous repair and often require retransplantation (Amesur & Zajko, 2006; Mueller et al, 2004).

Recipients of grafts from donors after cardiac death (DCD) have worse graft and patient survival, a higher rate of postoperative complications, and higher resource utilization than the recipients of dead-brain donation (DBD) grafts (Reich et al, 2009). Primary graft nonfunction, nonanastomotic biliary strictures, and hepatic artery stenosis are the most significant postoperative complications of DCD liver transplantation. Higher immediate perioperative mortality in DCD transplants has been reported (Pine et al, 2009), but most complications lead to increased mortality or to the need for retransplantation in the weeks or months following the transplantation (Grewal et al, 2009). Strategies to improve DCD outcomes currently under development include a super-rapid recovery technique by experienced procurement teams, premortem cannulation techniques, ex vivo organ perfusion, and minimization of cold- and warm-ischemia time (Reich et al, 2009). Although DCD grafts are associated with inferior outcomes, DCD donation remains a valuable resource, and with selective and judicious use, these can be used to achieve acceptable results (Pine et al, 2009).

CHAPTER 97C

Liver transplantation in patients with fulminant hepatitis

Alejandra Villamil, Francisco Juan Mattera, and Eduardo De Santibañes

OVERVIEW

Fulminant hepatic failure (FHF) is a rare, cataclysmic clinical entity resulting from acute massive necrosis of liver cells and is characterized by the rapid onset of a potentially mortal condition in a previously healthy individual. Occurrence is estimated to range between 1% and 1.2% of all jaundice cases in acute hepatitis (Bernuau et al, 1999). Depending on the etiology and severity of liver injury, some patients may undergo rapid hepatic regeneration and spontaneously recover with *ad integrum* restitution of the liver; however, the majority will die without orthotopic liver transplantation (OLT).

Before the advent of liver transplantation (see Chapter 97A) and advances in the intensive care management of these patients (see Chapters 72, 73, and 97B), prognosis was very poor, with mortality rates exceeding 80% (Bernuau et al, 1986; Riordan et al, 2008). At the present time, mortality rates are approximately 30% to 40%; whereas 20% to 25% of patients require liver transplantation, only 40% to 45% of patients are able to survive spontaneously (Lee et al, 2008; Ostapowicz et al, 2002; Polson, 2008). Prompt recognition and early management decisions are critical and can affect outcome. Because of their medical complexity, patients with FHF should be managed in an intensive care unit (ICU) in centers with active liver transplant programs. Referral should be done as early as possible, as it is hazardous to transfer patients later in the disease course because of increased intracranial pressure (ICP) and clinical instability. It has been suggested that transfer to a specialized ICU should be arranged when the patient's international normalized ratio (INR) exceeds 2.0 or grade 2 hepatic encephalopathy develops (Stravitz & Kramer, 2009). High-risk patients, including those at the extreme ends of the age range (>45 years or <10 years) or with etiologies of acute liver failure (ALF) that carry a poor prognosis should be considered for transfer to a liver transplant center whenever any degree of encephalopathy develops.

DEFINITION

Originally defined by Trey and Davidson in 1970 as an acute hepatitis complicated by ALF with hepatic encephalopathy (HE) occurring less than 8 weeks after the onset of jaundice, it is nowadays accepted that FHF is a complex clinical syndrome characterized by the development of a severe acute liver injury with impaired synthetic function and encephalopathy in a patient without previous liver disease within 26 weeks from the onset of jaundice to the development of encephalopathy. The chronologic evolution of the clinical course of ALF, estimated by the interval between onset of jaundice and encephalopathy, is predictive of clinical features and outcome (O'Grady et al, 1993). According to the length of this presentation interval, Bernuau et al (1986) has described two distinct types of FHF: *fulminant* (interval <2 weeks) and *subfulminant* (interval between 2 weeks and 3 months).

The group at King's College Hospital (KCH) in London has defined three groups of patients: those with *hyperacute liver failure* (development of encephalopathy within 7 days after jaundice), *acute liver failure* (within 7 to 28 days), and *subacute liver failure* (from 28 days to 3 months) (O'Grady et al, 1993). Hyperacute presentation is more frequently associated with hepatitis A virus (HAV) or paracetamol (acetaminophen) overdose, whereas idiosyncratic drug reactions usually present a delayed-onset clinical course. Cerebral edema, a major complication of ALF, is more frequent in hyperacute liver failure, but it is rare in subfulminant disease. In contrast, manifestations of portal hypertension with ascites and renal failure are far more common in patients with subfulminant liver failure.

The cessation of liver cell destruction, rather than the occurrence of liver regeneration, appears to be the most critical variable governing outcome (Bernuau et al, 1999). A protracted course in patients with a subfulminant presentation are associated with persistence of elevated transaminases, suggesting persistence of liver cell destruction. Not surprisingly, hyperacute disease has a relatively good likelihood of spontaneous recovery compared with subacute disease, which has a very poor prognosis without liver transplantation (O'Grady et al, 1993).

To what extent these differences in survival are related to the rapidity of onset or to etiology itself is difficult to say. Likelihood of spontaneous recovery is not uniform and depends on the etiology of the insult. Previously, mortality was thought to be lower in patients with HAV and acetaminophen overdose (50% to 60%), compared with 80% to 95% mortality rate in patients with non–acetaminophen-induced ALF, halothane anesthesia, fulminant disease of indeterminate cause, and non-A, non-E fulminant hepatitis (O'Grady, 1988); however, more recent data used to evaluate prognosis of indeterminate liver failure showed no significant difference compared with other etiologies (Wei, et al, 2008).

Age younger than 10 years or older than 40 years is considered an adverse marker of outcome. Outcome in older patients was recently reevaluated by Schiodt and colleagues (2009), who observed superior overall survival in younger compared with older patients (67.9% vs. 48.2%; $P < .001$), yet no significant differences were demonstrated in reference to spontaneous survival among both groups, suggesting that hepatic regeneration is preserved in the elderly, a fact that is in accordance with

the rise in α-fetoprotein (AFP) levels that is similar in both populations.

Other factors that have been associated with lower survival are a high body mass index (BMI), although data are still controversial (Kanda et al, 2005), and the presence of systemic inflammatory response syndrome (SIRS) (Miyake et al, 2000, 2007). The magnitude of SIRS in patients with ALF and infection correlate with mortality: 16.7%, 28.4%, 41.2%, and 64% in patients with 0, 1, 2, and 3 maximum concurrent SIRS components, respectively (Rolando et al, 2000).

ALF adversely affects most organ systems, and the majority of deaths result either from sepsis and subsequent multiorgan failure or from cerebral edema that evolves to intracranial hypertension and brainstem herniation. Patients with ALF are susceptible to a wide variety of additional complications, including renal failure, hypoglycemia, metabolic acidosis, coagulopathy, and cardiopulmonary distress. Advances in the intensive care management of patients with ALF and the early recognition of these complications has greatly contributed to a marked improvement in overall survival (see Chapters 72, 73, and 97B).

ETIOLOGY

ALF is an infrequent entity that can affect patients of all ages, and it shows a predominance in females that remains unexplained. Etiologies and prognoses vary in adults compared with infants and children (Polson et al, 2005; Squires et al, 2006). ALF results from a wide variety of causes (Box 97C.1), yet relative frequency of etiologies shows geographic (Lee et al, 2008) and temporal variations. These variations depend mainly on epidemiologic, socioeconomic, and cultural factors. Worldwide, acute viral hepatitis is the predominant cause of ALF, particularly in developing countries and especially in pediatric series. Data from Sudan (Mudawi, 2007), Bangladesh (Alam et al, 2009), Mexico (Fernandez Hernandez et al, 2003), and India (Acharya et al, 1996; Dhiman et al, 1998; Jaiwal et al, 1996) report a prevalence of viral hepatitis among patients with ALF that varies from 27% to 94% and includes hepatitis A, B, D, and E and a combination of hepatitis A with hepatitis E.

In the United States and Western Europe, viral hepatitis prevalence in patients with ALF is decreasing (Taylor et al, 2006), and acetaminophen overdose has become the most common cause of fulminant hepatitis (Larson et al, 2005), resembling the experience in the United Kingdom, where it is responsible for more than 70% of ALF cases (Williams, 1996). Comparing two time periods, after 1993 in France, 28% of patients with ALF were affected with acute viral hepatitis (Feray et al, 1993) compared with 48% before 1993 (Wright et al, 1991). The United States Acute Liver Failure Study Group (USALFSG), a multicenter network established in 1997 to gather data prospectively on all forms of ALF, observed in a recent analysis of 1033 patients enrolled through 2007 that acetaminophen toxicity accounts for approximately 46% of ALF cases in the United States, followed by ALF of indeterminate origin (15%) and idiosyncratic drug reactions (12%).

The clinical pattern of presentation of acetaminophen toxicity is still different in the United States (Zimmerman et al, 1995) compared with the United Kingdom, because only half of the time does it stem from ingestion of large doses taken in an intent to commit suicide; in the remainder, ingestion results from unintentional overuse of acetaminophen-containing compounds for pain or fever relief at therapeutic doses, mainly by patients with ongoing alcohol abuse, starvation, or in those concurrently taking medications known to induce the cytochrome P450 system, such as anticonvulsants, a situation known as *therapeutic misadventure* (Licht et al, 1980; Seeff et al, 1986; Wootton & Lee, 1990). Although the mortality rates associated with this syndrome are lower than that observed with suicidal ingestion, they are still at least 20% in most reviews (Kumar et al, 1991; Wootton & Lee, 1990).

Idiosyncratic drug reactions are the cause of about 15% of ALF cases in the United States and other countries. Antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), and anticonvulsants constitute some of the most commonly involved classes of prescription medications involved (Chalasani et al, 2008; Ostapowicz et al, 2002; Russo et al, 2004). It is expected that enhanced awareness of potential risks and drug mechanisms of liver injury may minimize in the future the frequency of serious hepatotoxicity (Murray et al, 2008).

Despite extensive evaluation of the etiology of ALF, in approximately 15% to 40% of cases, the cause remains elusive, even though the incidence of cryptogenic disease is declining (Larson et al, 2005). Available data suggest that in 20% of these patients, ALF may be attributable to undiagnosed acetaminophen overdose (Davern et al, 2006).

Box 97C.1

Etiology of Acute Liver Failure

Viral

Hepatitis A, B, D, and E
Herpes simplex, herpes 6, and varicella zoster
Epstein-Barr
Cytomegalovirus
Parvovirus B19
Adenovirus
Dengue fever

Drug Related

Paracetamol/acetaminophen
Tetracyclines
Isoniazid-pyrazinamide
Halothane
Monoamine oxidase inhibitors
Nonsteroidal antiinflammatory drugs
Antithyroid medications

Other

Microvesicular steatosis
Fatty liver of pregnancy
Reye syndrome

Vascular

Ischemic hepatitis (shock liver)
Acute Budd-Chiari syndrome
Venoocclusive disease

Toxins

Amanita mushrooms
Chemical solvents
White phosphorus
Toxins of plant origin
Illicit drugs, such as cocaine and ecstasy

Miscellaneous

Wilson disease
Massive tumor invasion
Autoimmune hepatitis

In Argentina, ALF represents 9% to 21% of all annual liver transplantations, even though its frequency has been decreasing in recent years. Data from the INCUCAI, the national organ procurement institution in Argentina, reflects a completely different etiologic profile. Indeterminate disease represents 29%; this is followed by 1) fulminant autoimmune hepatitis, which is rare in the United States and Western Europe and represents 19% of our total population with ALF; 2) hepatitis B virus (HBV), which is responsible for ALF in 15%; 3) drug-induced causes, which represent 12%; and 4) ALF secondary to HAV, which accouns for 11% in Argentina. Not a single transplantation was done for acetaminophen hepatotoxicity. The high prevalence of autoimmune hepatitis remains unexplained, even though it correlates with the high percentage of patients transplanted for autoimmune disease among those with cirrhosis, suggesting a more severe course of the disease. Similar data have been reported in other Latin American countries (Uruguay [Gerona, Cohen]; Chile [*Clinica Alemana*]; personal communication).

CLINICAL PRESENTATION

The rapid identification of ALF in a patient with liver dysfunction and an altered mental status in the setting of an acute hepatic disease is of paramount importance, as a delay in diagnosis has relevant prognostic implications. French investigators have highlighted the importance of recognizing the syndrome even at earlier stages, as soon as prothrombin ratio falls below 50% during the course of an acute liver disease and before the development of encephalopathy, as it has been recognized that prompt referral to a specialized liver unit and rapid medical intervention with specific therapies in certain etiologies can prevent progression in the clinical picture (Bernuau et al, 1993).

HE is a major defining criterion of FHF in the adult population. Children, particularly the very young, do not demonstrate classic features of encephalopathy, resulting in a revision of the definition of ALF for this specific population of patients to include pediatric patients with advanced coagulopathy, regardless of mental status (Squires, 2008). Severity of encephalopathy can be classified into four stages according to the definition of Trey and Davidson (1970): *stage 1,* slow consciousness; *stage 2,* accentuation of stage 1 and presence of asterixis; *stage 3,* presence of deep confusion or reactivity only to vocal stimuli; and *stage 4,* presence of deep coma with minimal (4a) or no response (4b) to noxious stimulus.

The development of cerebral edema is a life-threatening complication. Although precise pathogenic mechanisms remain unclear, most widely accepted theories relate to the development of astrocyte swelling and cerebral hemodynamic derangements characterized by high cerebral blood flow and failure of cerebral autoregulation in response to changes in mean arterial pressure (Larsen, 1996; Larsen et al, 2000), resulting in cerebral edema (see Chapters 72 and 97B). Loss of cerebral autoregulation of blood flow has been related to the rapidity of occurrence of electrolyte disorders in ALF, in contrast to what happens in cirrhosis or even in subacute liver failure, in which the mechanisms of osmotic regulation are still active. Cerebral edema develops in 75% to 80% of patients with grade 4 encephalopathy (Williams, 1991), and incidence is variably reported, although it appears to be progressively less frequent.

Several risk factors for the development of cerebral edema have been identified. It is more prevalent among patients with hyperacute liver failure compared with subacute disease, probably as a result of the rapid accumulation of glutamine in hyperacute presentation that overwhelms the mechanisms of compensatory expulsion of organic osmolytes from the astrocytes. High serum ammonia concentrations (>150 to 200 μmol/L) also increase the risk of cerebral edema, although the relationship between ammonia and ICP is not linear (Bernal et al, 2007; Bhatia et al, 2006; Clemmesen et al, 1999a).

Recent work suggests a central role of proinflammatory cytokines—such as tumor necrosis factor (TNF)-α and interleukin (IL)-6 and IL-1β—in patients with uncontrolled ICP, indicating activation of the inflammatory cascade in the brain (Wright, 2007). Other variables predictive of progression of intracranial hypertension and HE are the Model for End-Stage Liver Disease (MELD) score alone and in combination with ammonia levels, young age, requirement for vasopressors and renal replacement therapy, and the presence of infection and/or SIRS (Bernal et al, 2007; Vaquero et al, 2003). Evidence also emphasizes the importance of free-radical formation occurring at a mitochondrial level as the potential mediator of cellular dysfunction induced by ammonia neurotoxocity (Norenberg et al, 2009).

In severe cases, consequences of cerebral edema within the confinement of the cranial vault are the development of intracranial hypertension with potential risk of brainstem herniation and a decrease in intracerebral perfusion (Blei, 1991; see Chapter 97B). Severity of encephalopathy has prognostic implications, and overall prognosis for patients with only grade 1 or 2 encephalopathy is good, whereas for patients with grade 3 or 4 encephalopathy, prognosis is much poorer. Full recovery of cerebral function is the rule in patients whose liver function recovers, but permanent brain damage has been observed in patients making an otherwise complete recovery of liver function (O'Brien et al, 1987).

Coagulopathy

Along with neurologic involvement, coagulopathy is also a major criterion of ALF, resulting from the inadequate hepatic synthetic capacity of clotting factors. This is associated with increased consumption, particularly of factors II, V, VII, and X; reduced clearance of both activated factors and/or factor inhibitor complexes; and quantitative and qualitative platelet dysfunction (see Chapters 72 and 97B). Patients are seen with low fibrinogen and low levels of factors II, V, VII, IX, and X that result in the prolongation of prothrombin time (PT) and partial thromboplastin time (PTT) (Gazzard et al, 1975). Platelet counts are less than 100,000/mm^3 in more than two thirds of patients, and platelet function is altered (O'Grady et al, 1986); however, serum concentrations of thrombopoietin do not correlate with platelet counts (Schiodt et al, 2003), and the pathogenesis of thrombocytopenia remains unclear.

Although low-grade fibrinolysis and intravascular coagulation may occur, these syndromes are hard to distinguish from the changes that result from the failure of hepatic synthesis alone (Preston, 1991). Among patients with ALF, it has been observed that coagulopathy was moderate in 81% (INR 1.5 to 5), severe in 14% (INR 5 to 10), and very severe (INR >10) in 5%. Certain etiologies are associated with greater severity of coagulopathy, and ALF in fatty liver of pregnancy represents the least severe coagulopathy (Muñoz et al, 2008).

In spite of the evidence of a bleeding diathesis in patients with ALF, spontaneous bleeding is unusual, being most common in the gastrointestinal (GI) tract (8%) or brain (<1%); yet spontaneous intracranial bleeding is exceedingly rare in the absence of an ICP monitor. The incidence of upper GI bleeding in ALF patients has been decreased by gastric acid suppression with intravenous H_2 receptor antagonists (McDougall et al, 1978), therefore intravenous H_2 blockers or proton pump inhibitors are recommended.

Prophylactic administration of fresh frozen plasma (FFP) is usually not recommended, because it has not been proven to influence mortality rate, it can interfere with assessment of liver function, and it may worsen cerebral edema (Caraceni et al, 1995); therefore it is only indicated in the setting of active hemorrhage or prior to invasive procedures. The goal for correction of the INR to a value of no higher than 1.5 to minimize bleeding risk arises from common practice, although it has not been adequately tested. Use of recombinant human factor VIIa has been evaluated in small pilot studies (Chuansumrit et al, 2000; Negrier et al, 2000; Shami et al, 2003), and it was associated with improvement or normalization of PT and bleeding control. It has also been suggested that the combination of recombinant human factor VIIa with FFP is superior to FFP alone in correcting coagulopathy, with a beneficial effect on morbidity and mortality (Shami et al, 2001). Larger controlled studies are still required, but it has become acceptable to administer recombinant factor VIIa (rFVIIa) when FFP has failed to correct PT-INR to an acceptable level, or when the patient has become volume overloaded, before performing invasive procedures with a high risk of bleeding, such as transjugular liver biopsy or placement of an ICP monitor. Serial determinations of INR and factor V provide useful prognostic information in the follow-up of patients with ALF.

Infections

Infections are common in patients with ALF and constitute a leading cause of mortality. Patients with ALF are at increased risk of infection and sepsis as a result of deficient opsonization resulting from reduction of factors such as fibronectin, opsonins, and chemoattractants, including components of the complement system. Additionally, infections in ALF patients present an increase in bacterial translocation, white blood cell dysfunction, Kupffer cell dysfunction, and a high requirement for invasive maneuvers. Bacteriologically proven infection was recorded in up to 80% of patients, and fungal infection was found in 32%, with a predominance of *Candida*. Most common sites of infection are respiratory tract (47%) and urinary tract (22%), but bacteremia with (12%) or without (15%) a defined source was present, as was bacteremia of indwelling catheters (4%).

In one prospective study of 50 patients, 80% had culture-proven infection, and in half of the remaining patients, infection was suspected, but cultures were negative (Rolando et al, 1990). gram-positive organisms, mainly streptococci and *Staphylococcus aureus,* predominate in ALF, suggesting that entry through the skin is more important than intestinal entry, the pathway of gram-negative organisms (Wyke et al, 1982). Leukocytosis and fever are frequently absent (<50%), but a high index of suspicion of active infection should be raised at the worsening of encephalopathy, renal function, or clinical status. Daily bacterial surveillance cultures (blood and urine) and chest radiographs are recommended, as early diagnosis of infection may improve outcome.

Aggressive treatment of presumed infection is essential, because prophylactic antibiotic regimens have shown little benefit (Rolando et al, 1993); however, a low threshold for starting appropriate antibiotics and antifungals should be maintained. Administration of antibiotics is recommended when infection or the likelihood of impending sepsis is high, surveillance cultures reveal significant isolates, clinical progression of HE or renal failure is apparent, hypotension is refractory, or SIRS is evident, individual components of which include temperature above 38° C or below 36° C, white blood count above 12,000/mm^3 or below 4,000/mm^3, and pulse greater than 90 beats/min (Stravitz et al, 2007).

Broad-spectrum coverage for gram-positive and gram-negative bacteria, such as with a third-generation cephalosporin, should be chosen with consideration of patient-specific isolates from surveillance cultures and historic hospital-specific isolates (Stravitz et al, 2007). Vancomycin is specifically recommended for all patients with possible intravenous catheter–related sepsis and/or risk factors for infection with methicillin-resistant *Staphylococcus aureus* (MRSA). An antifungal agent also is recommended in any patient who does not display prompt improvement in signs of infection after institution of antibacterial agents (Stravitz et al, 2007).

The occurrence of infection may aggravate all instances of the inflammatory mechanisms that are activated by ALF and may precipitate the occurrence of multiorgan failure and death. A finding of disseminated fungemia is predictive of a poor prognosis (Walsh et al, 1983).

Renal Disorders

Renal compromise is frequent in patients with fulminant and subfulminant hepatic failure, and oliguria is a common finding (Caraceni et al, 1995). Acute renal failure complicates 30% to 50% of cases, taking an increase in creatinine concentrations as a diagnostic criterion; yet normal creatinine concentrations do not exclude the presence of acute renal failure. Therefore the true incidence of renal compromise is probably underestimated.

Acute renal failure in ALF can result from two different situations: First, direct nephrotoxic effects result from some causes of ALF, as has been observed with toxic quantities of acetaminophen (Mazer et al, 2008) and NSAIDs and with *Amanita* mushroom intoxication (Escudié et al, 2007; Joshi et al, 2007), usually resulting in acute tubular necrosis. Second, patients may present with a certain degree of dehydration or may develop functional renal failure that resembles the hepatorenal syndrome of cirrhosis. Pathogenesis remains unclear, even though marked reduction in renal blood flow and glomerular filtration rate is similar to renal perfusion changes in cirrhosis, with marked renal arteriolar vasoconstriction as a result of loss of systemic vascular resistance, activation of compensatory vasoconstrictor systems, and reduced renal prostaglandin excretion; however, ALF has distinctive hemodynamic features, and only rarely is the degree of portal hypertension in ALF comparable to that of hepatorenal syndrome in cirrhotics (Navasa et al, 1992). The mean reported hepatic venous pressure gradients for patients with ALF and renal dysfunction is significantly lower compared with those in cirrhotic patients

with hepatorenal syndrome (14 vs. 21 mm Hg) (Navasa et al, 1992; Ruiz-del-Arbol et al, 2005).

Recently, Leithead and colleagues (2009) demonstrated that ALF is associated with SIRS, and this association is independent of the presence of infection and severity of liver injury. Recognition of renal failure also has important clinical implications, and once established, it is usually progressive and associated with increased mortality (Jain et al, 2000; O'Grady et al, 1989; Ring-Larsen et al, 1981). Treatment options without transplantation are limited, and preventive measures are restricted to maintain adequate hemodynamics, early identification and adequate treatment of infection, and avoidance of nephrotoxic agents such as NSAIDs and aminoglycosides.

Renal replacement therapy (RRT) is usually recommended early to correct intravascular fluid overload, electrolyte disorders, or acidosis. Potential triggers for initiation of RRT might be low urine output, a rise in creatinine levels over 0.3 mg/dL over baseline, or a rise in serum ammonia above 150 µmol/L (Stravitz & Kramer, 2009).

Continuous rather than intermittent modes of renal replacement, such as continuous venovenous hemofiltration, are usually preferred to avoid abrupt shifts in solute concentrations that can result in increased ICP (Davenport et al, 1993).

Hemodynamic Complications

ALF is characterized by a hyperdynamic circulation with low systemic vascular resistance (SVR), high cardiac output, and low mean arterial pressure (MAP). Features of systemic inflammation, hemodynamic patterns, and progression of organ dysfunction resemble sepsis. Generalized systemic vasodilation is not limited to the splanchnic circulation, as it occurs in cirrhotics (Maroto et al, 1993; Ytrebø et al, 2006). Volume status in patients with ALF is difficult to assess, so placement of a pulmonary artery catheter may be of help, as management of hemodynamic balance can be complicated by the occurrence of elevated ICP and renal dysfunction. In most hypotensive patients, initial volume resuscitation is required, and it has been recommended that fluid replacement with colloids (albumin) should be preferred, rather than crystalloids (saline), and all solutions should include dextrose to maintain euglycemia (Polson et al, 2005).

Even after adequate volume repletion, vasopressors may be required to maintain a MAP of at least 50 to 60 mm Hg and a cerebral perfusion pressure (CPP) of 60 to 80 mm Hg (Polson et al, 2005). Vasopressor support with epinephrine, norepinephrine, or dopamine is usually instituted to maintain adequate perfusion of vital organs.

Hepatectomy has been advocated based on anecdotal references as a terminal salvage therapy in patients with severe refractory circulatory dysfunction. It has also been suggested that adrenal dysfunction might be an additional contributing factor to circulatory collapse; however, the benefits of supplemental corticosteroids in these patients are still unknown (Harry et al, 2002).

Pulmonary Complications

Pulmonary compromise is usually present in 30% of patients with ALF. Impaired gas exchange leading to hypoxemia and mixed acidosis may favor progression of HE (Kramer et al, 1991; Larsen et al, 2000), and mechanical ventilation may be required to ensure oxygenation and to secure the airway in patients who progress to grade 3 encephalopathy. Caution should be maintained, as it has been observed that positive end-expiratory pressure (PEEP) can worsen cerebral edema. In patients with acetaminophen intoxication, acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) can occur in one third of patients with ALF and can cause intractable hypoxemia that may contribute to death (Baudouin et al, 1995).

Metabolic Disturbances

Common metabolic abnormalities in FHF include acid-base and electrolyte disorders, hypophosphatemia, and hypoglycemia. Among acid-base disorders, hypocapnia with mixed alkylosis is frequent in the early stages of FHF in more than 50% of patients (O'Grady et al, 1993), yet as ALF progresses, patients typically evolve to metabolic acidosis with respiratory alkalosis. At the same time, ALF is a catabolic state characterized by negative nitrogen balance and increased resting energy expenditure. It is recommended that metabolic homeostasis be carefully maintained, and overall nutritional status—as well as phosphate, glucose, potassium, and magnesium levels—must be frequently monitored (Polson et al, 2005). Enteral nutrition should be administered early whenever possible, avoiding excessive free-water provision that can result in hypoosmolality, which aggravates cerebral edema. No firm evidence proves that branched-chain amino acids are superior to other enteral preparations (O'Grady et al, 1989; Naylor et al, 1989). If enteral feeding is contraindicated, parenteral nutrition remains an option, but severe protein restrictions should be avoided.

MANAGEMENT

As a result of its high mortality, heterogeneity, and low frequency, FHF is extremely difficult to study, randomized controlled trials are limited (Kaidu, 2008), and optimal management remains poorly defined and center specific. Management should be centered in three main areas: 1) definition of etiology so that specific treatment can be provided in selected cases; 2) prevention, recognition, and early treatment of complications that could potentially lead to multiorgan failure and death; and 3) assessment of prognosis for distinguishing patients who have the potential to improve spontaneously versus those who will require liver transplantation and who should be urgently included on the waiting list (see Chapters 72, 73, and 97B).

Specific treatments are limited and are reserved exclusively for a few etiologies, and any available treatment should be delivered as early as possible (Box 97C.2). Some treatments have been systematically studied only for acetaminophen overdose. The role of N-acetylcysteine (NAC) in limiting liver injury through repletion of hepatic glutathione (Mitchell et al, 1974), improving prognosis, has been shown to be effective and safe in large case series (Harrison et al, 1990; Smilkstein et al, 1988, 1991) and in a small, controlled trial (Keays et al, 1991); firm evidence supports the utility of NAC administration, even when there is doubt concerning timing, dose ingested, or plasma concentration of acetaminophen, and NAC should not be withheld, even if ingestion was 48 to 72 hours before the patient sought medical attention. In acetaminophen overdose, oral NAC is recommended as first-line therapy in patients with mild or no encephalopathy, whereas intravenous NAC should be reserved

Box 97C.2

Indications for Transplantation

King's College Criteria

Acetaminophen-induced FHF

Arterial pH <7.3 or the following three factors:
- PT >100 sec
- Grade 3 or 4 encephalopathy
- Serum creatinine >300 µmol/mL

Non–acetaminophen-induced FHF

Prothrombin time >100 sec or three of the following:
- Age <10 years or >40 years
- Non-A, non-B hepatitis or drug- or halothane-induced FHF
- Bilirubin >300 µmol/L
- Jaundice to encephalopathy time >7 days
- Prothrombin time >50 sec

Clichy Criteria

Grade 3 or 4 encephalopathy *and*
- Factor V <20% (age <30 years) *or*
- Factor V <30% (age >30 years)

FHF, fulminant hepatic failure; PT, prothrombin time

for patients with advanced encephalopathy, hypotension, or some other reason to suggest that oral dosing might not be tolerated, such as vomiting or ileus. The length of NAC administration should be determined by clinical improvement—resolution of HE, improving coagulopathy, and declining transaminases—or outcome (death or liver transplantation) rather than by time or serum acetaminophen levels.

In addition to its role in limiting liver injury, NAC also has beneficial effects on systemic hemodynamic parameters and oxygen delivery to peripheral tissues (Harrison et al, 1991, 1996). Consequently, it has also been evaluated as a treatment for other forms of ALF unrelated to acetaminophen overdose. A recent study evaluated 173 patients with non-acetaminophen ALF, who were randomly allocated to receive either intravenous NAC or placebo; no benefit was demonstrated on 21-day survival, although transplant-free survival and 1-year posttransplant survival were improved. Furthermore, in the subgroup of patients with grade 1 or 2 HE, survival at 1 year was significantly better in those who received NAC than in all other individuals (Lee et al, 2009).

Even though there is still insufficient data to recommend specific therapies for ALF resulting from other etiologies, with the exception of prompt delivery in women with acute fatty liver of pregnancy or HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, several etiology-specific measures are recommended based upon experience, relative innocuousness of the measures, and the high mortality of the clinical syndrome. Specific measures have been suggested in ALF secondary to autoimmune hepatitis, HBV, and herpesvirus infection; ingestion of *Amanita* species; ischemia; and fatty liver of pregnancy.

Management of Complications of Acute Liver Failure

Cerebral Edema and Intracranial Hypertension

The most accepted pathogenetic theory of HE is the increased production of nitrogenous substances in the gut lumen, and effective medical management of cerebral edema in patients with ALF has been directed to the reduction of the generation and absorption of these products through orally administered lactulose and/or nonabsorbable antibiotics such as rifaximin. But the ability of these modalities to lower the risk of cerebral edema in patients with ALF has not yet been tested, and the utility of oral lactulose in this setting is controversial (Alba et al, 2003) and may even have detrimental effects, as it may increase gaseous distension of the bowel, predispose to aspiration, and foster intravascular depletion.

The monitoring of ICP by using an intracranial sensor is controversial (Blei, 1991; Schafer & Shaw, 1989; see Chapter 97B), but it is used by over half the transplantation programs in the United States (Hoofnagle et al, 1995) and around the world. Major complications are bleeding and infection, although complication rates vary among the different types of catheters used. It has been estimated to be 4% with epidural catheters, compared to significantly higher rates for subdural (22%) and parenchymal catheters (22%), with 1% to 5% of deaths as a direct result of catheter placement (Blei et al, 1993). Some centers report that ICP monitoring is useful to control CPP and to guide the decision to proceed with transplantation (Lidofsky et al, 1992). Before ICP monitor placement, a CT scan of the head is recommended in patients upon progression of encephalopathy or in those who experience an abrupt change in mental status; this is necessary to rule out any other rare intracranial pathology, especially bleeding.

The goal of therapy is to maintain ICP below 20 mm Hg and CPP above 50 mm Hg (Hoofnagle et al, 1995). Patients should be kept in an environment with minimal sensory and physical stimulation, and even endotracheal suctioning should be minimized. Fever increases ICP and should be vigorously treated with cooling measures. Hypo-osmolality, specifically hyponatremia, should be avoided and corrected immediately. The head of the patient's bed should be elevated to 30 degrees, except if CPP falls below 30 mm Hg, in which case the patient should be put in the supine position. Spontaneous hyperventilation should not be inhibited; this occurs regularly in patients with ALF and results in mild hypocapnia that promotes cerebrovascular constriction (Baudouin et al, 1995; Strauss et al, 1998).

The development of intracranial hypertension despite these prophylactic measures should prompt urgent treatment. First-line therapy includes increasing blood osmolality, with mannitol and/or hypertonic saline boluses to draw water from swollen astrocytes back into the intravascular space. Early reports demonstrated the efficacy of mannitol (1 g/kg body weight) to decrease ICP (Canalese et al, 1982; Nath & Gailbraith, 1986), yet it was not effective in returning ICP to an acceptably low level (<25 mm Hg) in patients with severe intracranial hypertension (>40 to 60 mm Hg) (Hanid et al, 1980). In addition, improvements usually were temporary and required multiple doses, with the attendant risk of hyperosmolality. When renal failure with oliguria is present, mannitol can be deleterious, so continuous venovenous hemofiltration or hemodialysis with polyacrylonitrile membranes is performed to decrease hyperkalemia, fluid overload, and ICP.

If no response is seen, or relapse of ICP is observed after mannitol administration, alternative measures may include the use of hypertonic saline boluses, the induction of therapeutic hypothermia, or sedation with propofol (Wijdicks & Nyberg, 2002), barbiturates (Lidofsky et al, 1992), or intravenous boluses of indomethacin (Tofteng et al, 2004). Indomethacin perfusion (25 mg IV by every peak of ICP) has been shown to normalize ICP and CPP, probably through a direct arteriolar

constriction of cerebral vessels (Clemmesen et al, 1997). Induction of moderate hypothermia (32° C to 33° C) is useful in treating uncontrolled elevations in ICP (Ginsberg et al, 1992; Jalan et al, 1999; Kurt et al, 1996; Roberts & Manas, 1999), probably by preventing hyperemia, altering brain ammonia or glucose metabolism, or by a combined effect. Concern remains over potential deleterious effects of hypothermia on risk of infections, coagulation disorders, cardiac arrythmias, and liver regeneration rates (Schubert, 1995). As a final desperate measure in patients with intracranial hypertension that is refractory to all medical therapy, total hepatectomy has been advocated to remove the major source of proinflammatory cytokines that contribute to cerebral hemodynamic derangements.

The observation that patients with ALF may have subclinical, nonconvulsive seizure activity that could result in increased cerebral blood flow that favors cerebral edema provided the rationale for the evaluation of seizure prophylaxis with IV infusion of phenytoin in these patients. Two randomized controlled trials in patients with ALF and advanced HE came to different conclusions with regard to the efficacy of phenytoin in preventing seizures and cerebral edema and in influencing survival (Bahtia et al, 2004; Ellis et al, 2000).

Prognostic Factors and Criteria for Liver Transplantation in Patients with Acute Liver Failure

In spite of great advances in the intensive care management of patients with ALF, patients managed exclusively with medical supportive therapy have poor survival. The only therapy proven to significantly improve outcome is OLT, which is associated with 1-year survival rates greater than 80% (Lee et al, 2008). Unfortunately, the window of time is very narrow for the application of liver transplantation, as the procedure must be performed at the optimal time, not too early but never too late, to avoid unnecessary transplantations in patients who would survive otherwise and to prevent transplantation in those who would not survive, even with a new liver (Lo, 2008).

Accurate prognosis, especially early predictors of death, are exceedingly difficult to obtain; however, several prognostic indicators have been suggested that allow early identification and listing of those patients who would not survive without a transplantation. Prognosis is dependent on factors such as age, etiology of hepatic failure, clinical and biologic status on admission, interval between onset of jaundice and clinical encephalopathy, degree of encephalopathy, severity of coagulopathy, AFP levels, arterial ketone body ratio, arterial pH, bilirubinemia, renal function, phosphatemia, and extent of parenchymal necrosis on biopsies, even though liver histology has not proven accurate to predict outcome and is not recommended for routine use.

Coagulation factor activities are significant indicators of prognosis. Factor V activity was found to be the most effective independent predictor of survival among 115 patients with fulminant HBV in a French study. Plasma protein actin-free Gc globulin, a member of the extracellular scavenger system, is synthesized by the liver and was shown to be decreased in ALF; it correlates with poor survival.

An ideal model to predict outcome would ensure that all patients who need transplantation may get one (*positive predictive value*), and all patients who may survive would not (*negative predictive value*), but presently none exists that completely fulfills these goals (O'Grady, 2007). The ability to predict the likelihood of spontaneous recovery or death without OLT remains of paramount importance in patients with ALF (see Chapters 72 and 97B). Many criteria have been proposed to anticipate the probability of death without OLT (Box 97C.3), but data are insufficient to recommend a particular scheme, given that none have been found to be adequately sensitive and specific.

Box 97C.3

Prognostic Factors in Fulminant Hepatitis

Age
Etiology of acute liver failure
Encephalopathy
King's College criteria
Clichy-Villejuif criteria
Arterial blood lactate

Serum creatinine levels
Extent of necrosis in biopsies
Computed tomographic liver volume/standard liver volume

Outcome in children is more favorable (Dhawan et al, 2004). In the series of Dhiman and colleagues (2007), the survival rate in patients older than 50 years was lower than in younger patients. In an American study by Ostapowicz and colleagues (2002), age does not seem to correlate with outcome, although spontaneous survival was higher in patients aged 26 to 35 years. The lowest survival rate (33%) corresponds to patients older than 65 years, who often have more comorbidities but less acetaminophen intoxication.

In a study by Brandsaeter and colleagues in 2002, of 315 patients listed for transplantation, spontaneous survival was higher in patients with HAV infection (43%), followed by acetaminophen overdose (31%), HBV infection (8%), liver disease of indeterminate origin (7%), and other drug-induced ALF (0%). In other series the same favorable prognosis corresponds to acetaminophen overdose, HAV infection, and pregnancy-related ALF but not to patients with disease of an indeterminate cause, non–acetaminophen-related ALF, HBV infection, autoimmune hepatitis, Wilson disease, or Budd-Chiari syndrome (Lee et al, 2008; Ostapowicz et al, 2002). A higher degree of encephalopathy (grades 3 and 4) on admission also seems to be a significant independent variable of poor outcome (O'Grady et al, 1989).

Two statistical models have been developed for predicting outcome: one by the KCH group (O'Grady et al, 1989) in London, based on a retrospective cohort of 588 medically managed ALF patients and later validated in an additional prospective study of 175 ALF patients; the other by the Paris group (Bernuau et al, 1986, 1991). At the present time, they are the most widely used prognostic criteria.

At KCH, prognostic criteria discrimination was etiology based, as predictors were stratified according to whether ALF was secondary to acetaminophen ingestion, a condition in which recovery is more probable even in the presence of severe synthetic dysfunction. In patients with acetaminophen-induced fulminant hepatitis (FH), a pH less than 7.3 at 24 hours or more after overdose is an indication per se for liver transplantation, after appropriate volume replacement and correction of

hypothermia. Otherwise, liver transplantation should be considered in the presence of all three of the following factors: 1) PT greater than 100 seconds, 2) grade 3 or 4 encephalopathy, and 3) serum creatinine (SCr) greater than 300 μmol/L. In non–acetaminophen-related FH, the decision whether to transplant is based on the presence of three of the following: 1) non-A, non-B hepatitis; 2) drug-induced hepatitis; 3) halothane exposure; 4) serum bilirubin greater than 300 μmol/L; 5) PT greater than 50 seconds; 6) age younger than 10 years or older than 40; or 7) time from jaundice to encephalopathy of more than 7 days. PT greater than 100 seconds in isolation is considered an indication for liver transplantation (O'Grady et al 1989, 1991).

In France, selection was made on the basis of factor V level. According to this group, patients younger than 30 years with FH and encephalopathy with a level of factor V less than 20%, or less than 30% in patients older than 30 years, should be included on the transplant list (Bernuau et al, 1986; Bismuth et al, 1987, 1995).

The KCH criteria have good clinical applicability with few differences in sensitivity and specificity as reported by Shakil and others (2000). Generally, KCH criteria are useful in predicting death, although the absence of these criteria is not predictive of survival.

Increases in arterial blood lactate (Bernal et al, 2002) and serum phosphate concentrations (Schmidt & Dalhoff, 2002) are factors predictive of poor prognosis in patients with acetaminophen-induced ALF, and these have been proposed as additional criteria to those initially reported by the KCH group. Similarly, serum AFP levels increase in patients undergoing rapid liver regeneration, and increasing levels indicate a better prognosis (Schmidt et al, 2005). Upon admission, serum levels of Cc-globulin, a plasma protein synthesized in the liver (Schiodt et al, 1996), could be used to make decisions about liver transplantation. More recently, a high level of soluble CD163 from activated macrophages has been proposed to predict mortality in patients with ALF (Moller et al, 2007). Interestingly, Volkmann and colleagues (2008) found that caspase activation, which increases cytokines IL-6 and TNF-α, is associated with spontaneous recovery.

In patients with non–acetaminophen-induced ALF, the MELD score has been proposed to identify patients with the worst prognosis; other patients have shown a high rate of spontaneous recovery independent of MELD score (Kremers et al, 2004). Yantorno and colleagues (2007) suggest that MELD scores obtained upon admission may be helpful to establish the optimal timing for pre-OLT evaluation and listing. Nevertheless, they do not propose a cutoff value for MELD.

Dhiman and colleagues (2007) describe another prognostic model and compare its performance with the KCH criteria and to the MELD score. They identify six parameters: age over 50 years, time from jaundice to encephalopathy of more than 7 days, grade 3 to 4 encephalopathy, cerebral edema, PT greater than 35 seconds, and SCr above 1.5 mg/dL. The presence of any three of these factors indicates a poor prognosis. A comparative evaluation suggests that this model was better than both the MELD and the KCH criteria at predicting prognosis; however, according to O'Grady (2007), this is not a valid comparison, because it takes into account only the initial set of data, whereas the KCH model is a dynamic process; the same applies to the study by Yantorno and colleagues.

Barshes and colleagues (2006) made a distinction between low-risk patients (5-year survival, 81%) and high-risk patients (5-year survival, 42%), depending on the four risk factors present at the time of listing for liver transplantation. These factors include 1) recipient age older than 50 years, 2) a BMI of 30 or more, 3) a history of life support, and 4) SCr level above 2 mg/dL. Risk of mortality after transplantation increases by approximately 150% for each additional point.

Detectable liver atrophy has classically been associated with a poor prognosis (Rueff, 1971). Yamagishi and colleagues (2009) reported that the ratio of the estimated liver volume (ELV) to the standard liver volume (SLV) reflects the prognosis of patients with ALF very well. They investigated the usefulness of the ratio of the computed tomography–derived liver volume (CTLV) to the calculated SLV to establish a new prognostic formula to predict the course of ALF. The CTLV/SLV ratio was calculated both at the time of ALF diagnosis and 5 days later. In patients who recovered, liver atrophy was not found at day 0 or at day 5, and liver atrophy progressed in those who died or underwent liver transplantation. Sensitivity was 94.1%, and specificity was 76.9%, but the findings of this small study need to be confirmed in a larger series. In spite of the criteria described above, the controversy about the best prognostic model for ALF will continue.

Whether or not patients are listed for liver transplantation, they should be monitored for the many complications of ALF, as they progress to the point of recovery, death, or transplantation. Likewise, patients listed for transplantation may develop complications that preclude this intervention or may occasionally show unexpected signs of recovery before a donor organ becomes available. In this dynamic process, the final decision on transplantation is made when an organ is available. Neurologic limits to transplantation are controversial. Brain death, uncontrolled systemic sepsis, and hemodynamic instability as a result of multiple organ failure are considered absolute contraindication for liver transplantation.

Survival rates at 1 year of patients undergoing liver transplantation for ALF range between 61% and 76% and are 7% to 15% less than in patients transplanted for chronic end-stage liver disease (European Transplant Registry; Freeman et al, 2008). This is due to the fact that even when liver transplantation is finally achieved, patients eventually die because of poor health status at the moment of transplantation—brain damage, sepsis, or multiorgan failure—or because of the use of marginal or ABO-incompatible donor organs (Farges et al, 1995; Gugenheim et al, 1990). The higher retransplantation rate in patients with ALF is due to the use of these organs, giving way to increasing rates of acute rejection, primary graft nonfunction, and intrahepatic biliary strictures.

PREOPERATIVE MANAGEMENT (SEE CHAPTER 97B)

Once the need for liver transplantation is established, the patient is included on an emergency list (UNOS status I) and is prepared for the procedure (Wiesner et al, 2004). Coagulation defects should be corrected with plasma, a balance between fluid restriction and a satisfactory CPP should be achieved, and the increase of brain edema should be avoided. A catheter to monitor ICP is useful in patients with grade 4 encephalopathy. We usually perform plasmapheresis immediately before the surgical procedure for toxin removal and FFP supply.

In 1993, Ringe and colleagues described a two-stage total hepatectomy with temporary portacaval shunt, a procedure

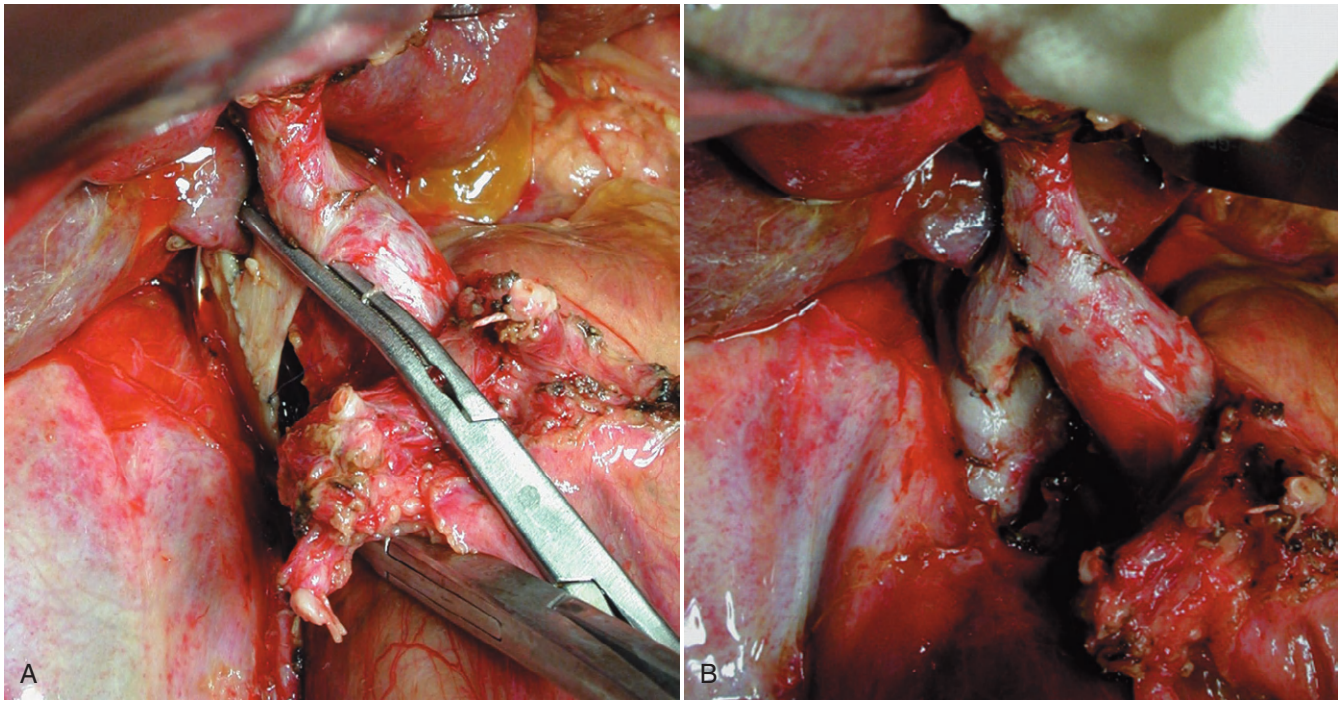

FIGURE 97C.1. Shunt portocava with only right branch. **A,** The right portal vein is cross-clamped, and the anastomosis done. **B,** After removing the clamp, the shunt is functioning.

carried out in patients who have *toxic liver syndrome* with cerebral edema or multiorgan failure; the patient is left anhepatic and subsequently undergoes liver transplantation. It has been reported that the longest period of time a patient was left anhepatic was 21 hours. Although this extreme procedure can be lifesaving, it is exceptional (Ferraz-Neto et al, 2008) and is only justified by the fact that hepatectomy decreases the serum concentration of circulating proinflammatory cytokines—IL-1, IL-6, and TNF-α—which may be important in the pathogenesis of intracranial hypertension in patients with FHF (Jalan et al, 2002a).

The surgical procedure is basically the same (OLT, see Chapter 98), but other details must be taken into account. For one, patients run a serious risk of bleeding during surgery as a result of severe coagulopathy. The absence of portal hypertension and the presence of an atrophic liver facilitate hepatectomy; however, to avoid brain damage, the surgical approach varies according to the hemodynamic state of the patient and the level of the ICP.

Because of the absence of portal hypertension, the total clamping of the inferior vena cava (IVC) and the portal vein (PV) is poorly tolerated. Hence it is necessary to perform a venovenous bypass with pump-assisted venous return from the IVC and PV to the superior vena cava (SVC) or to preserve the IVC using the *piggyback technique* (Tzakis et al, 1989). Belghiti and colleagues (1995) reported that the maintenance of portal and caval flow during hepatectomy and graft implantation avoids drops in venous return and cardiac index and prevents other hemodynamic changes that result from venous clamping, release of metabolites, and secondary effects of fluid management seen in patients undergoing liver transplantation (LT) for fulminant and subacute liver failure in the absence of portosystemic venous collaterals. Clamping of the PV in this situation may lead to hemodynamic instability and cerebral edema, thus worsening the previous condition; it also leads to splanchnic venous congestion with associated hemorrhage and intestinal edema.

Performing a temporary portacaval anastomosis (end-to-side portocaval shunt) facilitates liver mobilization without changes in the hemodynamic state that could increase the ICP and cause brain damage. A review by Davila and colleagues (2008) supports its use. In adult patients with a very unstable hemodynamic condition, the portocaval shunt using only the right portal branch is recommended, leaving the left branch unclamped (Fig. 97C.1) to avoid interruption of the portal flow. After the shunt has been opened, total hepatectomy is completed by dividing arterial branches, left PV, and major hepatic veins without occlusion of the IVC (Kawasaki et al, 1996). On the other hand, children weighing less than 20 kg tolerate IVC and PV clamping quite well. Also, a rapid clamping and liver removal improve their hemodynamic condition.

Careful anesthetic management of the patient is necessary: the operating table should be positioned at 30 degrees, and fluctuations in ICP should be carefully controlled, and steps to avoid an increase in ICP should be taken to protect the brain; in addition, ICP monitoring should be maintained for 24 hours after liver transplantation, because pressure may increase after surgery (O'Grady et al, 2008). Longer monitoring may be required in cases of poor graft function.

Given the urgency of liver transplantation, marginal donors are often accepted, thus increasing the risk of poor function or primary nonfunction. Initially, ABO-incompatible livers were widely used, but discouraging results have limited their use nowadays (Gugenheim et al, 1990); few reports show good results (Ascher et al, 1993; Toso et al, 2007), although the final decision lies with the surgical team.

Living-Donor Liver Transplantation (See Chapter 98C)

Living donors (LDs) are the only source of organs in countries where the availability of deceased donors is severely restricted, such as in Asia, or scarce, as in Latin America. The use of living-donor liver transplantation (LDLT) for children suffering from ALF has gradually gained acceptance, because the procedure's lifesaving potential by far outweighs any ethical aspects (Emond et al, 1993; Uemoto et al, 2000). Expansion of LDLT to adult patients with ALF has recently been reported (Lo et al, 1997; Marcos et al, 2000); however, both the donor risk and the ethical dilemma are involved in this issue, because potential donors are likely to be brothers, sisters, children, or spouses, in other words, those who are influenced by the imminent death of the patient.

On the other hand, compared with deceased-donor liver grafts, living donor grafts offer three distinct advantages: 1) early transplantation of ALF patients, 2) better graft function, and 3) shorter cold-ischemia time; however, a satisfactory survival rate of patients with ALF undergoing adult LDLT is a prerequisite to justify the risk of emergency liver transplantation. Ikegami and colleagues (2008) use smaller grafts, wherein graft volume (GV) in proportion to standard liver volume is 30% to 35% for ALF. The reason for this is that ALF is an acute event, and most patients are usually healthy beforehand and do not have portal hypertension that allows use of the left lobe in most cases. In other countries with limited availability of cadaveric donors, LDLT in patients with ALF is performed with similar results (Uribe et al, 2008), especially in children, although it is still controversial among adults.

In a report by Campsen and colleagues (2008), only 14 of 1201 potential LDLT recipients (1%) in the A2ALL study, which evaluated LDLT in the United States, were diagnosed with ALF. Among these, 10 received a living-donor graft, and their survival rate was similar to that of patients who received cadaveric grafts, and no recipients died on the waiting list. The authors concluded that LDLT is rarely performed for ALF in the United States but could be performed with acceptable recipient and donor outcomes.

The increased use of full-liver grafts from donors after cardiac death (DCD) has had a beneficial impact on elective liver transplantation in adults; however, these grafts are more susceptible to poor initial function, and most centers are reluctant to consider their use as segmental grafts, let alone in the setting of ALF, in which good initial function is imperative. Nevertheless, Perera and colleagues (2009) describe the use of a segmental graft from a living or heart-beating deceased donor and report the successful outcome in two children with ALF, aged 6 weeks and 6 years.

Auxiliary Liver Transplantation

Auxiliary partial orthotopic liver transplantation (APOLT) has been used in ALF as a bridge to survival without the need for lifelong immunosuppression. The precise indications have not yet been determined but are molded by two important considerations: the ability of the native liver to regenerate to normal morphology with time and the absence of a clinical need for the immediate benefits of total removal of the diseased liver. Proponents of auxiliary transplantation for ALF claim that in most cases, had the patient survived, the native liver would have recovered. If true, then removal of the entire native liver during transplantation for ALF eliminates any such recovery and unnecessarily commits the patient to the lifelong risks of immunologic rejection and immunosuppression (Bismuth et al, 1996; (Kasahara et al, 2005).

The surgical procedure for APOLT is more complex than the procedure for OLT. The liver is placed in orthotopic position, and both the graft and the recipient's liver are reduced; this is done on opposite sides, removing left segments of the recipient's liver and right segments of the graft, or vice versa). The absence of fibrosis in the native liver must be confirmed by a frozen section biopsy.

The key issue regarding APOLT is determining when native liver regeneration is likely to occur, which is sometimes difficult. Monitoring includes hepatobiliary iminodiacetic acid (HIDA) scintigraphy, computed tomography (CT), and biopsy when necessary. When sufficient regeneration of the native liver is evident, immunosupression can be discontinued according to two different options: *abrupt discontinuation* often requires surgical removal of the graft because of severe and symptomatic rejection; *progressive tapering* of immunosuppression with the aim of inducing a slowly progressing chronic rejection with subsequent atrophy of the graft is the approach preferred by most groups (Belghiti et al, 2004a).

In 2002, Jaeck and colleagues reported a series of 15 patients receiving APOLT, of which 10 are alive, and 6 of those are free of immunosuppression with a regenerated native liver. Recently, Azoulay and colleagues (2001) compared the results of APOLT with those of total orthotopic liver transplantation (TOLT) in the treatment of ALF. They showed similar survival rates after both procedures, but the postoperative complication rates—particularly those of biliary complications, neurologic sequelae, and retransplantation rate—were significantly higher after APOLT. In the Paul Brousse experience, both full native liver regeneration and discontinuation of immunosuppression were observed only in 25% of the cases.

Acetaminophen-induced liver failure and hyperacute syndromes are more likely to regenerate to normal morphology when regeneration does occur. In seronegative hepatitis and the subacute syndromes, regeneration may occur, but it does so at the risk of significant fibrosis. Quaglia and colleagues (2008) described the evolution of histologic changes in native livers after APOLT for ALF. In up to 62.5% of patients, the native liver regenerates to full recovery. In all such patients, immunosuppression can be reduced, and in the vast majority (80%), it can be ultimately suspended. Acetaminophen toxicity in particular is an excellent indication for APOLT, with full native liver recovery occurring in 100% of surviving patients with an auxiliary graft.

Peter Lodge and colleagues (2008) proposed a new approach for patients with ALF resulting from acetaminophen overdose, fulfilling KCH criteria for super-urgent liver transplantation. This new approach consists of a subtotal hepatectomy—that is, resection of segments IVb, VI, VII, and VIII—to remove 75% of liver volume and reduce the toxic liver, followed by auxiliary transplantation with a whole liver (AWOLT; maximal liver volume to aid recovery) and gradual withdrawal of immunosuppression after recovery over a 2- to 3-month period. The results in 13 patients treated with this approach were compared with those in 13 patients who had undergone OLT in the same period: they were similar in morbidity and mortality rates but better in terms of quality of life, because they did not need long-term immunosuppression.

For the authors (Lodge et al, 2008), temporary support by AWOLT with a subsequent liver regeneration may offer a better quality of life in all domains when compared with OLT. This could be due to the fact that patients can lead a more normal life without the effects of immunosuppression. Bernal and colleagues (1998) reported that only 19 of 33 survivors of OLT for acetaminophen-related ALF were back to a normal lifestyle. In contrast, all 8 of our successful AWOLT patients (Lodge et al, 2008) have returned to a normal lifestyle, including full-time education or employment, and all seem to be in normal relationships. Except for these latter results, and results presented in a paper by Girlanda and colleagues (2005), outcome after APOLT is poor; this is reflected in registry data, with 1-year survival just barely over 50%.

Finally, in case of fulminant hepatitis (FH), APOLT should only be proposed to select patients with good chances of liver regeneration; those aged less than 40 years with fulminant, rather than subfulminant, hepatitis resulting from HAV or HVB or acetaminophen toxicity (Jaeck, 2007). When the native liver has regenerated, it is recommended that immunosuppression be reduced gradually to induce a progressive atrophy of the graft, which is left with the patient. Removal of the auxiliary graft should not be attempted.

LIVER-SUPPORT SYSTEMS

Liver supports are designed to improve the life-threatening symptoms often caused by ALF. Their goal is to maintain patients with FH until their own livers regenerate or to maintain patients in a stable condition until liver transplantation can be performed, and it might decrease the mortality rate in patients with ALF. To accomplish these goals, a liver-support device should be able to remove toxic substances from the patient's blood and to provide temporary liver function, until either transplantation or functional recovery occurs. Because of the scarcity of donor organs, liver-support technologies have been developed in the last 2 decades and have been clinically tested with the intent of supporting a patient in ALF.

Developing an effective liver-support system has proven difficult, because of the complexity of liver functions that must be replaced and because of heterogeneity of the patient population. Nonbiologic systems may have a role in the treatment of specific forms of liver failure, when the primary goal is to provide blood detoxification and purification. Biologic systems appear to be useful in treating liver failure when the primary objective is to provide whole-liver function that has been impaired or lost.

Two major categories of devices are currently being tested (Phua & Lee, 2008): *artificial liver support* is cell free, purely mechanical, and includes albumin dialysis; *bioartificial systems* contain cellular material from human or animal livers or hepatocytes. A truly effective device will perform three functions: 1) detoxification, 2) biosynthesis, and 3) regulation; however, only bioartificial systems can perform all three functions; artificial liver support only detoxifies. Support of the failing liver is reviewed in further detail in Chapter 73.

Artificial Liver Support

Artificial liver support (ALS) is used to control serious symptoms of FH, such as brain edema, which may induce postoperative neurologic deficit. The key role of ALS is to remove toxins, both known and unknown, that are responsible for HE and multiorgan failure secondary to liver failure. Hemodialysis, hemofiltration, hemodiafiltration, and hemadsorption are methods that have failed to show any major outcome in early randomized trials (Davenport et al, 1993; Kramer et al, 2001). These systems remove toxins that result from hepatic failure but are limited by their inability to provide missing liver-specific functions.

One problem with these techniques lies in the difficulty of removing toxins bound to large protein molecules, such as albumin. To address this, Inoue and colleagues (2009) recommended the use of plasma exchange combined with hemodiafiltration. Using large buffer volumes is a promising and effective bridging method to liver transplantation that enables patient recovery from coma, prevents brain edema, and identifies those patients in need of urgent liver transplantation. Several nonrandomized studies show that the use of plasmapheresis increases hepatic blood flow, decreases blood ammonia levels, and could reduce mortality rates (Clemmesen & Clemmesen 2001; Du et al, 2005; Li et al, 2004).

Molecular Absorbent Recycling System

Proposed by Stange and colleagues (1993), the molecular absorbent recycling system (MARS) blood detoxification system has been tested in thousands of patients, but additional well-conducted controlled studies are warranted to better define the role of MARS in the treatment of patients with acute hepatic failure and acute exacerbation of chronic liver disease. MARS is a two-circuit system composed of a blood circuit and a secondary circuit. The blood circuit passes the patient's blood through a high-flux dialyzer, making the membrane impermeable to albumin. This membrane is permeable to water-soluble, low- and medium-molecular-weight substances. The opposing side of this membrane consists of 600 mL of 20% human albumin dialysate, which makes up the secondary circuit; this circuit provides conventional low-flux dialysis, as well as detoxification, over absorbent columns that include an anion exchange resin and an activated charcoal column, allowing transport of ions of low molecular weight (LMW).

The key feature to the function of albumin dialysis is the concentration gradient of LMW substrate between the patient's blood and the 20% albumin in the secondary circuit. This concentration gradient allows diffusible LMW substrates to flow down their gradient over the membrane, where they are transiently bound by albumin in the secondary circuit (Steiner et al, 2004). The LMW substrate is then removed from the system by conventional dialysis and hemodiafiltration within the secondary circuit, and the 20% albumin dialysate is then recirculated. The coagulation profile present in liver failure obviates the need for anticoagulation in most patients being treated with MARS.

A meta-analysis of four randomized controlled trials concluded that treatment with MARS provided no survival benefit (Khuroo et al, 2004). Aside from one study suggesting that 4 out of 14 patients (29%) with relatively mild liver failure avoided transplantation after MARS (Camus et al, 2006), most recent descriptive reports show that short-term mortality rates for patients treated with MARS but without transplantation ranged from 78% to 100% (Chiu et al, 2006; Wai et al, 2007).

As a proposed bridge to transplantation, the study of Novelli and colleagues (2007) evaluated the change in MELD score in patients with acute-on-chronic liver failure awaiting

transplantation after treatment with MARS. Inclusion criteria were a MELD score above 20, bilirubin greater than 15, encephalopathy higher than grade 2, and INR above 2.1. Patients were treated with MARS for a minimum of five treatments and a maximum of 20 over 3 months. MELD was evaluated after treatment with MARS and at a 3-month follow-up, and significant improvement was reported at both time points. Hetz and colleagues (2006) also proposed using MARS for allograft dysfunction after transplantation.

Mortality rate aside, MARS improves other parameters, including bilirubin levels, especially conjugated bilirubin; encephalopathy; renal function; and hemodynamics (Heemann et al, 2002); it also decreases serum copper levels in Wilson disease (Sen et al, 2002). Although these effects may be mediated by cytokine clearance, it is unclear whether MARS decreases serum cytokine levels significantly (Guo et al, 2003; Stadlbauer et al, 2006). Importantly, MARS may worsen coagulopathy and bleeding (Bachli et al, 2007), hence minimization of anticoagulation should be considered; in addition, it can cause hypoglycemia in the absence of glucose-containing dialysate.

Fractionated Plasma Separation and Absorption (Prometheus)

The Prometheus system (Fresenius Medical Care, Bad Homburg, Germany) uses fractionated plasma separation. Whereas MARS is a two-circuit system separated by an albumin impermeable membrane, Prometheus utilizes a membrane with a 250-kDa cutoff between circuits, thereby making the membrane permeable to albumin and hence to albumin-bound toxins. Although a large portion of the toxins that accumulate during liver failure are water soluble, many are still bound by albumin; therefore fractionated plasma separation may be advantageous with regard to toxin removal. The patient's endogenous albumin loads the secondary circuit that distinguishes Prometheus from MARS. Since albumin-bound toxins can enter the secondary circuit by convection, as well as by diffusion, in theory, Prometheus should offer more effective detoxification than MARS does (Rifai et al, 2003).

In a retrospective analysis by Evenepoel and colleagues (2006) of prospectively collected data on patients with acute-on-chronic liver failure treated with either Prometheus or MARS for 2 to 5 consecutive days, blood clearance of toxins was superior when patients were treated with Prometheus as compared with MARS at all time points; in addition, certain substances that are tightly bound to albumin, such as unconjugated bilirubin, were exclusively cleared by Prometheus. The limited data available suggest that Prometheus maybe used as a bridge to transplantation, rather than to recovery, as mortality rates with Prometheus treatment alone without transplantation exceed 80% (Skwarek et al, 2006).

Bioartificial Support Devices

Bioartificial supports are cell-based systems that provide both metabolic support and detoxification. A bioartificial liver (BAL), which incorporates hepatocytes from various sources, has the theoretic advantage of not only providing blood purification through dialysis but also of providing the hepatocyte-specific functions lost in ALF (Rozga et al, 1993). Although primary human hepatocytes appear to be the most appropriate cells for use in a bioartificial liver, some factors have prevented their use, such as lack of availability and loss of function when cultured. For this reason, immortalized cell lines, such as C3A human hepatoblastoma, have been studied in vitro and have been utilized; however, many problems will likely preclude their use in a therapeutically successful bioartificial liver. Currently, porcine hepatocytes are the most reasonable choice, and several systems have been clinically assessed.

HepatAssist (Arbios Systems, Allendale, NJ) is a device that uses a hollow-fiber extracorporeal bioreactor loaded with 7 billion cryopreserved porcine hepatocytes. The system also utilizes a charcoal column, combined oxygenator/blood warmer, and perfusion pump, all driven by a plasmapheresis machine. The separation between hepatocytes and patient circulation is by a semipermeable membrane that avoids the need for immunosuppression. A randomized, controlled, multicenter Phase II and III clinical trial was conducted on patients with fulminant/subfulminant liver failure, and those with primary graft nonfunction were included (Demetriou et al, 2004). The study demonstrated favorable safety, but it failed to demonstrate statistical significance in improving 30-day survival in the overall study population.

Other cell-based systems include the ELAD system (Vital Therapies, San Diego, CA), which utilizes the C3A human hepatoblastoma cell line; the MELS system (Charité Medical Center, Berlin, Germany); BLSS (Excorp Medical, St. Paul, MN); and AMC BAL (Amsterdan Medical Center, The Netherlands). The last three use primary porcine hepatocytes but differ in cell source and mass (100- vs. 500-g cartridge), use of plasma or whole blood, the rate of perfusion (20 to 200 mL/min), and duration of treatment (continuous vs. intermittent). All of these systems have been used in clinical trials, been proven safe, and have shown at least some biologic effect, but none has received FDA approval for use in the United States.

The next generation of BAL systems is a hybrid that uses cellular and noncellular components in an albumin-based extracorporeal perfusate circuit that combines albumin dialysis, charcoal therapy, and dialysis with hepatocyte cell based therapy. In preliminary studies, one system using 200-g porcine hepatocyte spheroids provided cerebral protection not seen in the control group (Nyberg et al, 2005).

A Cochrane review of support systems concluded that results have not yet demonstrated that these systems affect survival in ALF (Liu et al, 2004). No single system has reproducibly demonstrated improvement in patient mortality; however, with the advent of new technology and improved cell acquisition techniques, further randomized controlled trials will be necessary to determine the role of artificial and BAL support devices in the treatment of patients with ALF. (McKenzie et al, 2008). Ex vivo liver perfusion was attempted in the past, before the era of liver transplantation, with disappointing results; but in one modern study, pig and human livers unsuitable for transplantation were successfully used as a bridge to transplantation in a small number of patients (Chari et al, 1994).

Hepatocyte Transplantation

After success in animal models, human hepatocyte transplantation for ALF was attempted. Strom and colleagues (2006a, 2006b) infused cryopreserved human hepatocytes into a small number of children with limited success. Further progress in many areas will be needed, however, before this approach is clinically viable.

CONCLUSION

Acute liver failure is a dramatic clinical condition that puts a healthy patient in a deadly situation. Improvements in intensive care management have optimized survival, yet the only definite treatment in a number of patients is emergency liver transplantation. Any effort to maintain a patient in good clinical condition as a bridge to transplantation through plasmapheresis, artificial support, total hepatectomy, or other measures is worthwhile and should be further evaluated. Carrying out randomized studies may be difficult within this context, but such studies may be useful whenever they prove effective in individual cases.

CHAPTER 97D

Liver transplantation for hepatocellular carcinoma

Garrett R. Roll and John Roberts

OVERVIEW

Cancer of a solid organ is an uncommon indication for organ transplantation, but hepatocellular carcinoma (HCC) is an important exception to that general rule (see Chapter 97A). HCC is the most common tumor treated with whole-organ transplantation, and it is listed as the primary indication in approximately 15% to 20% of liver transplantations. The existing treatment options for HCC include hepatic resection, local ablation, or liver transplantation, and in the last decade, transplantation has become the therapy of choice for early-stage disease. The literature lacks randomized controlled trials regarding the treatment of HCC; most centers therefore base their practice guidelines on local experience, retrospective data, theoretic decision analyses, and the availability of treatment options.

Ever since the first liver transplantation was performed in a patient with HCC in the 1960s, recurrence has been a concern. Prior to the late 1990s, liver transplantation for HCC carried high recurrence rates, and the 2-year survival was only about 30%. The poor outcomes were due to the consensus at that time to treat smaller tumors with liver resection and more advanced disease with liver transplantation. Discouraging results plagued liver transplantation for HCC, until it was noted that subgroups of patients with smaller tumors who underwent transplantation achieved better outcomes (Pichlmayer, 1993).

A group from Milan, Italy, conducted a prospective trial, published in 1996, in which patients with smaller tumors achieved 4-year survival rate of 75%, equivalent to the survival for non-HCC patients who underwent transplantation (Mazzaferro et al, 1996), and similar results were seen in the United States (Venook, 1993). Resultant changes in patient selection, dictated by these *Milan criteria,* allowed similar results to be reproduced at other centers (Jonas et al, 2001; Llovet et al, 1998), and the United Network of Organ Sharing (UNOS) adopted these criteria in 1998 and gave priority for transplantation to HCC patients. This priority, coupled with the rise in patients with hepatitis C virus (HCV), who frequently develop HCC, fueled the rapid expansion of this indication for transplantation. This chapter will discuss liver transplantation for HCC, concentrating on its unique pathophysiology and how it relates to diagnosis and dictates therapy.

HEPATOCELLULAR CARCINOMA

HCC is the fifth most common cancer and the most common primary liver tumor (see Chapter 80). This disease develops in the setting of cirrhosis in more than 90% of cases (Fattovich et al, 2004). The risk of HCC development in patients with cirrhosis from any cause is about 2.0% to 6.6% per year versus 0.4% for patients with viral hepatitis without cirrhosis (Benvegnu et al, 2004; Degos et al, 2000; Ikeda et al, 1993a; Llovet et al, 2003; Sangiovanni et al, 2004; see Chapters 64 and 70).

The incidence of HCC has been rising since the late 1990s (Bosch et al, 2004; Deuffic et al, 1998; El-Serag & Mason, 1999; Parkin et al, 2001; Stroffolini et al, 1998; Taylor-Robinson, et al, 1997), a trend that is expected to continue for at least the next 2 decades because patients who were infected with HCV 20 to 30 years ago are currently living with cirrhosis and are aging (El-Serag, 2004). In addition, the epidemic of obesity and resultant nonalcoholic fatty liver disease (NAFLD) can be expected to generate cirrhotic patients at risk for the foreseeable future (see Chapter 65). Currently, only the incidence of thyroid cancer is rising faster than the incidence of HCC in the United States (Fattovich et al, 2004). It is hoped that the introduction of vaccination for HBV will decrease the incidence of HCC, an effect that has been seen already in Taiwan (Chang et al, 2009).

Biology of Hepatocellular Carcinoma

An understanding of the biology of HCC is critical to assist in clinical decision making about surveillance and treatment. Although the molecular biology of HCC remains to be fully elucidated, the close association between cirrhosis and the development of HCC is clear (Miyazawa et al, 2003; see Chapter 8C). Viral hepatitis, chronic alcohol use, and NAFLD are the most common causes of cirrhosis in the Western world (see Chapters 64, 65, and 70A). NAFLD, an unfamiliar diagnosis as recently as the early 1980s, is now present in 17% to 30% of Americans (Farrell & Larter, 2006); that progresses to steatohepatitis in 32% to 37% (Fassio et al, 2004; Harrison et al, 2003; Hui et al, 2003) and then to cirrhosis in 5% to 24% (El-Zayadi, 2008; Hui et al, 2003). The development of cirrhosis in patients with NAFLD is driven by repetitive liver injury from lipid peroxidation, fatty acid toxicity, mitochondrial impairment, and oxidative stress.

Viral infection with HBV and HCV lead to cirrhosis by different mechanisms. HBV induces transgene activation, oncogene transcription, and loss of tumor suppressor genes as a result of viral DNA integration into the host genome (Brechot et al, 1980; Bressac et al, 1990; Di Bisceglie, 2000; Kim et al, 1991). As many as 30% of patients with chronic HBV without cirrhosis will develop HCC (Zhou et al, 2001). HCV does not integrate into the host genome but rather leads to chronic inflammation through continued viral replication (Sherlock, 1994). This rapid hepatocyte turnover in the presence of oxidative stress drives the development of multiple dysplastic nodules.

Unlike what has been found in some other cancers, no sequential progression of genetic defects has been identified that leads to the development of HCC. Instead, a variety of genetic alterations are commonly seen, and they have been broadly grouped into events that occur either early or late in the development of a tumor. Genetic alterations that lead to inhibition of the insulin-like growth factor II receptors are considered early mutations (Yamada et al, 1997). Loss of heterozygosity of a variety of genes, often of tumor suppressor genes such as *TP53*, is a late event in the development of neoplasia (Buetow et al, 1989; Fang et al, 2000).

Clinically Relevant Aspects of Hepatocellular Carcinoma Pathogenesis

The clinician must understand three aspects of HCC pathogenesis: 1) the influence of cirrhosis on HCC development, 2) arterial recruitment of the tumor, and 3) the tendency for HCC to invade portal vein branches.

First, HCC most commonly develops in the context of cirrhosis, and the biology of HCC is related directly to the environment found in the cirrhotic liver. Repeated insult causes chronic inflammation driven by tumor necrosis factor (TNF)-α; transforming growth factor (TGF)-β and interleukin (IL)-1 from Kupffer cells; endothelial cells; and hepatocytes. This inflammation stimulates nodular regeneration with bridging fibrosis. Rapid cellular turnover in this regenerative environment leads to low-grade dysplastic nodules that do not contain atypia and high-grade dysplastic nodules that do. Eventually, a small percentage of these high-grade dysplastic nodules will go on to develop microscopic foci of HCC before becoming frank carcinoma (Rocken & Carl-McGrath, 2001). Recent evidence suggests that tumor cells may even secrete IL-6 and TNF-α, directly contributing to the inflammatory microenvironment by activating Toll-like receptors (Kim et al, 2009).

Because of the diffuse nature of the injury, multiple tumors can develop at the same time. If a focus of HCC is removed, recurrence most often happens at a distant site (Koike et al, 2000; Fig. 97D.1). This second tumor at the distant site is most likely a second primary tumor. As most of the second lesions are found within a few years of treatment of the primary lesion, the tumor was most likely present when the first tumor was treated but was too small to be detected. The occurrence of synchronous and metachronous lesions in the same organ suggests the entire cirrhotic organ has the potential for neoplastic conversion, much like the genetic defect in the colon in familial adenomatous polyposis, which leads to multiple cancers; this situation is referred to as a *field defect*.

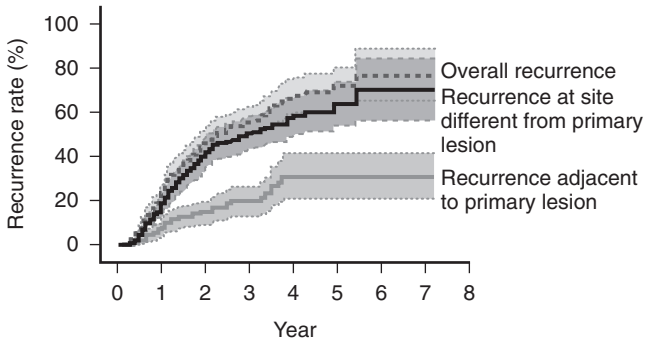

FIGURE 97D.1. Recurrence of hepatocellular carcinoma after ablation most often occurs at a site distant from the primary tumor, suggesting a second tumor was present at the time of treatment that was too small to be detected. *(From Koike Y, et al, 2000: Risk factors for recurring hepatocellular carcinoma differ according to infected hepatitis virus: an analysis of 236 consecutive patients with a single lesion. Hepatology 32(6):1216-1223. Copyright John Wiley & Sons, 2000. Reprinted with permission of John Wiley & Sons.)*

Secondly, there is a clinically relevant difference in blood supply between foci of HCC and low-grade dysplastic nodules, which derive most of their blood supply from the portal vein. Histopathologic evaluation of high-grade dysplasia and HCC demonstrates the tumor being fed by branches of the hepatic artery that are not paired with the other structures of the portal tract, a process called *arterial recruitment,* or *neoangiogenesis.* The resulting hepatic artery dominance in blood supply produces the characteristically hyperdense appearance of HCC that is used to identify tumors during the arterial phase of contrast imaging (Matsui, 2004; Willatt et al, 2008), and it allows for treatment via selective hepatic artery embolization.

Lastly, HCC is known to invade vascular structures, most commonly the portal vein but also hepatic veins and, less commonly, the biliary tree. The development of vascular invasion appears to be a key step in the metastatic potential of the tumor, and the risk of portal venous invasion seems to be directly related to size and differentiation status of the tumor (Esnaola et al, 2002). Venous invasion is such a strong predictor of metastatic disease that tumor size and tumor number can be thought of as surrogate markers for vascular invasion.

The likelihood of microvascular and macrovascular portal venous invasion has implications for treatment decisions; for example, evidence of portal venous invasion on imaging or biopsy rules out transplantation, because the probability of recurrence is unacceptably high. It is this risk of recurrence with large or multiple tumors that resulted in the poor outcomes with early attempts at liver transplantation for HCC, and it is the reason why patients with small tumors are selected for transplantation.

Hepatocellular Carcinoma Screening

HCC presenting as symptomatic disease has a 0% to 10% 5-year survival rate (Llovet et al, 2003), so a screening program that identifies early disease can have a major impact on treatment outcomes. HCC meets the World Health Organization criteria for performing screening (Meissner et al, 2004), and a randomized, controlled clinical trial showed that screening for HCC reduces mortality (Zhang et al, 2004). An effective screening program evaluates patients at risk of developing disease, using a highly standardized and relatively inexpensive test with a high sensitivity. A screening program is used if the cost of screening a large population is less than the benefit of early detection of the disease in a small number of individuals in that population. Several decision-analysis and cost-efficiency models for HCC screening suggest the ability of a screening program to decrease mortality while remaining cost-effective depends on the inclusion of patients with an incidence of HCC of at least 1.4% to 1.5% (Arguedas et al, 2003; Lin OS, et al, 2004; Sarasin et al, 1996). Patients who should be included in a screening program can be found in Box 97D.1. Further information about the incidence of HCC in cirrhosis from

Box 97D.1

Populations with Hepatocellular Carcinoma Incidence Sufficiently High for Inclusion in Surveillance Programs

Causes of Cirrhosis Other than Hepatitis B

Hepatitis C
Chronic alcohol abuse
Hemochromatosis
Primary biliary cirrhosis

Hepatitis B Carriers

Asian males ≥40 years
Asian females ≥50 years
Hepatitis B carriers with cirrhosis
Family history of hepatocellular carcinoma
Africans ≥20 years
Noncirrhotic hepatitis B carriers with ongoing hepatic inflammatory activity

Other Predisposing Conditions*

Nonalcoholic steatohepatitis
α_1-Antitrypsin deficiency
Autoimmune hepatitis

*These patients with increased but unknown HCC risk should be screened, but no defined surveillance recommendations currently exist.

Modified from Bruix J, Sherman M, 2005: Management of hepatocellular carcinoma. Hepatology 42(5):1208-1236. Copyright John Wiley & Sons, 2005. Reprinted with permission of John Wiley & Sons.

nonalcoholic steatohepatitis (NASH), α_1-antitrypsin deficiency, and autoimmune hepatitis is required, but most centers include these patients in their screening population.

Traditionally, the most commonly used serum tumor marker to detect HCC was α-fetoprotein (AFP), a protein produced by normal fetal hepatocytes, and by tumor cells, but not by healthy, mature hepatocytes. AFP has traditionally been used for diagnosing HCC, predicting outcome after resection, and screening for recurrence postoperatively (Tan et al, 2003). The normal range of AFP in the serum is 10 to 20 ng/mL; an absolute value of 20 ng/mL was used commonly as the screening cutoff; however, using this cutoff yields a sensitivity of only about 64%, making it a poor screening test (Sherman et al, 1995). Moreover, normal AFP levels vary widely across ethnic backgrounds (Soresi et al, 2003), and the test has a lower positive predictive value in patients with acute viral hepatitis or cirrhosis from a viral cause (Nguyen et al, 2002; Soresi et al, 2003).

In patients with a liver mass, a concomitant serum AFP greater than 200 ng/mL carries a very high positive predictive value (Sherman et al, 1995), but because of its unacceptably low sensitivity and specificity, the American Association for the Study of Liver Disease (AASLD) recommended that serum AFP no longer be used as a screening tool, although it still plays a diagnostic role (Bruix & Sherman, 2005). Using an absolute value greater than 400 ng/mL is considered diagnostic regardless of the patient's ethnic background or the cause of their liver disease. Research is ongoing to identify better serum markers for screening, diagnosis, and prognostication, and possible candidate compounds include AFP-L3 and des-γ-carboxy prothrombin (Bruix & Sherman, 2005; Grazi et al, 1995; Izuno et al, 1995; Koike et al, 2001; Marrero et al, 2003; Tsai et al, 1990).

Ultrasound (US) is the most widely used radiologic screening tool. It has a sensitivity of 65% to 85% and specificity over 90% when used as a screening test (Bolondi et al, 2001). Although the performance of US in cirrhotic patients is not as well defined (Bruix et al, 2001; Chen et al, 2002; Larcos et al, 1998; Sherman, 1999), and the test is operator dependent, US remains superior to any widely available serologic screening test. A large, prospective, randomized controlled study done in China suggests that surveillance of high-risk individuals with US and serum AFP testing every 6 months reduces HCC-related mortality by close to 40%, even though patients in that trial were offered only resection but not transplantation. One of the limitations of this study is that screening compliance was only approximately 60%, which may have dampened the reduction in mortality (McMahon, 2009; Zhang et al, 2004). Combined AFP and US surveillance increases sensitivity, but it raises the cost, and using both tests increases the rate of false-positive results from 5% for AFP alone to 7.5% for combined screening (Zhang & Yang, 1999). It is clear that further randomized controlled trials are needed, but based on the available information, the AASLD recommends screening patients at risk for HCC with US alone every 6 to 12 months (Bruix & Sherman, 2005). Evaluation of serum AFP can be added to US in the event of concerns regarding operator influence, but the use of AFP as the lone surveillance tool is discouraged.

Most centers use a 6-month screening interval, but this remains controversial. No evidence suggests that a 6-month interval improves outcome compared with a 12-month interval (Santagostino et al, 2003). The surveillance interval was derived from tumor growth rates, so the interval does not need to be shortened for patients who have a very high risk of developing HCC.

Early HCC can be difficult, if not impossible, to distinguish from cirrhotic nodules by US, but any suspicious nodule less than 1 cm should be evaluated for stability by repeat US at 3- to 6-month intervals for up to 2 years. All 1- to 2-cm nodules should be investigated with a dynamic contrast-enhanced imaging modality—computed tomography (CT), magnetic resonance imaging (MRI), or US—although contrast-enhanced US has not yet been adopted in the United States.

A nodule that is 2 cm or larger and hypervascular with portal venous washout on a single dynamic imaging study, or a 1- to 2-cm nodule on two such confirmatory studies, is treated as HCC. If the results are contradictory, a biopsy of the lesion should be obtained (Bruix & Sherman, 2005). If the lesion is larger than 2 cm and has a typical appearance on a single dynamic imaging study, or if it is found in concert with a serum AFP level above 200 ng/mL, biopsy is not required. Biopsy should be performed on any 1- to 2-cm lesion in any noncirrhotic patient has who has risk factors for the development of HCC. Biopsies should be read by expert pathologists, and patients with negative biopsy results should undergo US or CT scanning every 3 to 6 months and should be rebiopsied if the characteristics of the lesion change (Bruix & Sherman, 2005). Biopsy results that suggest a high risk for progression to HCC include *dysplastic nodules,* both low and high grade (Hytiroglou et al, 2007); *small and large cell change,* formerly called *small cell dysplasia* and *large cell dysplasia* (International Working Party, 1995; International Consensus Group for Hepatocellular Neoplasia [ICGHN], 2009); and *dysplastic foci,* defined as atypia outside of a dysplastic nodule (ICGHN, 2009).

Another commonly used radiologic surveillance tool is CT scanning (Kobayashi et al, 1985; Miller et al, 1994; Takayasu et al, 1990). Although the use of CT scanning is becoming commonplace, the radiation exposure to a patient from

screening every 6 to 12 months is considerable. The use of CT for diagnosis and staging has been defined, but the performance of CT as a screening test has not been described. Finally, CT scan is the diagnostic test used to confirm HCC, and the screening test should be different from the confirmatory test.

MRI with gadolinium-based or iron oxide–based contrast has not been widely studied as a screening test, but there are reports that this modality is 81% sensitive and 85% specific for HCC compared with 68% and 93% for contrast-enhanced helical CT scanning (Colli et al, 2006). Moderate signal strength on T2-weighted images is specific for HCC, because dysplastic and regenerating nodules are not hyperintense on T2—unless they have infarcted, which can occur. Delayed venous phase hypointensity with concomitant delayed enhancement of the rim of the lesion are also features specific for HCC (Freeny et al, 2003). Similar to CT scanning, characterization of small nodules remains difficult, as MRI is only 50% to 80% sensitive for lesions 2 cm or smaller and only 4% to 33% sensitive for lesions 1 cm or smaller (Willatt et al, 2008); this is due in part to the fact that lesions 1 cm or smaller are frequently isointense on T2 (Krinsky, 2004). It remains to be seen whether contrast-enhanced MRI is cost-effective as a screening tool for HCC, but it may prove to be marginally superior to CT scanning for characterization of known hypervascular lesions.

TREATMENT OPTIONS

HCC is not responsive to traditional cytotoxic chemotherapeutic agents. Recently, a Phase III clinical trial showed that sorafenib, an oral multikinase inhibitor of the vascular endothelial growth factor receptor, the platelet-derived growth factor receptor, and Raf kinase prolonged the median survival (10.7 vs. 7.9 months) and the time to radiologic progression (5.9 vs 2.8 months) in patients with advanced HCC versus placebo (Llovet et al, 2008). Given this modest improvement, local ablation/embolization, hepatic resection, and liver transplantation are still the best options available for patients with early stage disease to achieve a cure.

Treatment decisions should be based on three factors: 1) extent of local disease, 2) underlying liver disease, and 3) local organ availability. Patients whose liver disease is Child-Turcotte-Pugh (CTP) class A who have early-stage HCC are candidates for treatment with the goal of long-term survival free of HCC. Unfortunately, because of the advanced biologic activity of the cancer, 80% to 90% of patients will present at a stage too advanced for surgical resection or transplantation (Llovet et al, 2004). Those patients with advanced disease or patients with poor functional status should be offered sorafenib, locoregional therapies, or palliative care.

In the rare patient without cirrhosis, no evidence of venous invasion or metastatic disease, and tumor burden limited to one lobe, resection should be considered. Conversely, resection of part of a cirrhotic liver invariably leaves scattered dysplastic nodules behind. The tumorigenic cytokine milieu that bathes the remaining dysplastic nodules puts the patient at risk for the development of a second primary tumor. In addition to these de novo tumors, some researchers have suggested recurrence is more frequently the result of microscopic dissemination of the primary tumor at the time of treatment (Chen et al, 2000; Morimoto et al, 2003). Astoundingly, the risk of developing recurrence after resection for HCC in cirrhotic patients is about 35% at 1 year (Lu et al, 2009), 40% to 50% over 3 years (Koike et al, 2000; Jaeck et al, 2004; Sakon et al, 2000), and as high as 70% at 5 years (Bismuth et al, 1999; Llovet et al, 1999; Mazzaferro et al, 1996; Minagawa et al, 2003), making the history of a previous HCC the greatest risk factor in the development of a new primary HCC.

It is this high risk of recurrence that has driven liver transplantation as a method to remove the precancerous liver to prevent the development of subsequent lesions. The results of liver transplantation have improved dramatically in the last 20 years, in large part because of better patient selection, and currently the recurrence rate ranges from 11% to 18%. The mortality rate after liver resection for HCC is 1% to 7%, and the major cause is decompensated liver failure (Fong et al, 1999; Grazi et al, 2001; Hanazaki et al, 2000; Hsia et al, 2000; Makuuchi et al, 1998; Poon et al, 2001; Takenaka et al, 1996; see Chapter 90F). Given the risks of HCC recurrence and postoperative liver failure following resection, some controversy exists regarding the best treatment strategy in patients with limited disease and adequate hepatic function. Although sufficient hepatic reserve can usually be determined, no method is currently available to determine whether a patient will be among the 60% to 70% to recur within 5 years, or if they will remain recurrence free.

The long waiting time experienced in some regions must also be taken into consideration in the decision of resection versus transplantation. The risk of tumor progression while awaiting liver transplantation must be balanced against the risk of recurrence. If waiting times are relatively long in a given region, this may favor liver resection, because a prolonged waiting time risks tumor progression that may exclude the patient as a candidate for any surgical treatment.

A decision analysis from 2000 compared primary resection and salvage transplantation for recurrence versus primary liver transplantation in patients with small tumors (Majno et al, 2000). Theoretic decision models use multiple variables, so the weight of any single variable is difficult to determine, but the authors concluded that wait times shorter than 6 months favored liver transplantation, and those longer than 12 months favored primary liver resection.

Another decision analysis compared the projected survival benefit from liver transplantation when compared to resection in patients with small HCCs (Sarasin et al, 1998). The authors noted that the magnitude of the survival benefit relied heavily on the amount of time spent on the waiting list. They concluded that if the waiting period exceeded 6 to 10 months, the survival benefit gained from removal of the field effect is overwhelmed by the risk of progression while waiting, and resection becomes the preferred therapy (Fig. 97D.2). Although this analysis did not include the costs or clinical effects of locoregional therapy, it offers insight into how extended waiting times increase the relative benefit of resection, transarterial chemoembolization (TACE), and radiofrequency thermal ablation (RFA; see Chapters 83 and 85A).

The possibility of mitigating the risk of progression with a locoregional therapy while awaiting a transplantation has been suggested. Whether locoregional therapy offers a measure of disease control while awaiting a liver transplantation is not clear. Maddala and colleagues (2004) examined 54 patients with HCC treated with an average of three TACE sessions prior to transplantation at a median of 211 days. Eight patients dropped off the waiting list, two for non-HCC reasons and six from HCC progression. Of the six with progression, two developed extrahepatic metastases, two developed portal vein

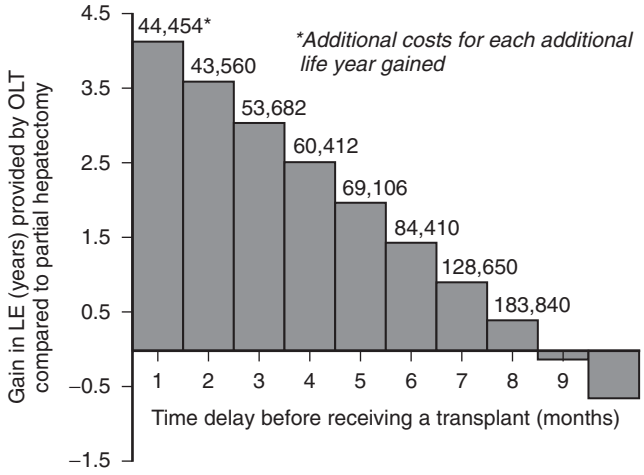

FIGURE 97D.2. Mean gain in life expectancy (*LE*) and marginal cost-effectiveness ratios provided by orthotopic liver transplantation (*OLT*) compared with partial hepatectomy (*vertical axis*) as a function of different time delays before receiving a transplant (*horizontal axis*). *(From Sarasin FP, et al, 1998: Partial hepatectomy or orthotopic liver transplantation for the treatment of resectable hepatocellular carcinoma? A cost-effectiveness perspective. Hepatology 28(2):436-442. Copyright John Wiley & Sons, 1998. Reprinted with permission of John Wiley & Sons.)*

invasion, and two had intrahepatic progression. Interestingly, these events all occurred within 4 months of listing. The short period of time between initiation of therapy and discovery of disease progression would suggest the disease had spread much earlier, and neither resection nor transplantation would have been helpful.

In a small study of 20 patients (median of two treatments, mean time to transplantation of 343 days), Hayashi and colleagues (2004a) found that seven patients whose tumors were within Milan guidelines dropped off the waiting list: two for causes unrelated to HCC, one for decompensation, and the other five for increased intrahepatic disease. The time to exclusion for HCC was less than 6 months in four of five patients, and no patients developed HCC after transplantation at a mean follow-up of 2.9 years.

RFA has also been reported to provide good results in patients who undergo subsequent transplantation. Mazzaferro and colleagues (2004) reported 50 patients who underwent a single ablation session and then waited an average of 9.5 months before transplantation. Apparently, there were no waiting list dropouts, and at a median follow-up of 22 months, only two patients had cancer recurrence. Lu and colleagues (2005) reported 52 patients who underwent RFA, most frequently in isolation (mean sessions 1.46). After 12 months, three patients had dropped out at a mean of 11 months, and two patients had extrahepatic disease; in all, 41 patients underwent transplantation, and none had HCC recurrence at a mean follow-up of 15 months. For small tumors, it has been suggested that RFA may be equivalent to resection for long-term disease control, with a lower risk of postoperative liver decompensation (Shiina, 2009), but further trials with long-term outcome data are required.

In summary, resection and ablation are viable options for patients with small tumors without cirrhosis and for patients with cirrhosis and preserved liver function (normal bilirubin and wedged hepatic vein pressure gradient <10 mm Hg) in regions with waiting times longer than 6 months. Liver transplantation is appropriate for patients with tumors that fall within the selection criteria and in those with small tumors but poor liver function.

Indications for Transplantation (See Chapter 97A)

An unlimited supply of organs and money would allow for a liberal policy of transplantation for patients with HCC confined to the liver; but resources are limited, so efforts must be made to allocate organs to those recipients with a high likelihood of long-term survival. Recurrence risk is clearly higher in patients with more advanced disease, and the size and number of nodules in the patient's explanted liver is directly correlated with the risk of HCC recurrence (Jonas et al, 2001; Mazzaferro et al, 1996).

Based on these observations, selection criteria have been developed. The primary set of selection criteria are the Milan criteria, created to allocate organs to patients with HCC who would have a similar chance for long-term survival as patients without HCC (Mazzaferro et al, 1996; Fig. 97D.3). To allocate scarce organs in such a way that all recipients have an acceptable chance for long-term survival, patients with HCC are currently evaluated for suitability based on three factors: 1) tumor size in centimeters, 2) number of radiologically evident tumors, and 3) evidence of portal venous invasion or extrahepatic disease. These factors are a crude but somewhat effective method for predicting overall tumor biology and subsequent risk of recurrence.

Preoperative staging, as outlined by UNOS, includes a triple-phase CT scan (Otto et al, 2006) of the abdomen to quantify intrahepatic disease burden, and a scan should be done of the chest to look for extrahepatic disease. This can also be accomplished with an MRI of the abdomen and a noncontrast CT of the chest (Bruix et al, 2003; Maddala et al, 2004). Unfortunately, these imaging modalities—the gold standard for HCC imaging—understage about 20% of patients (Yao et al, 2005) and can sometimes also overestimate actual tumor burden. A review of the HCC imaging literature that included only studies with explant pathologic correlation reported that triple-phase CT scan is only 37% to 75% sensitive at detecting HCC in a cirrhotic liver (Krinsky, 2004), although it remains the gold standard for diagnosis and preoperative staging. Bone scintigraphy was used in the past to locate extrahepatic disease but is no longer used because of low sensitivity and specificity.

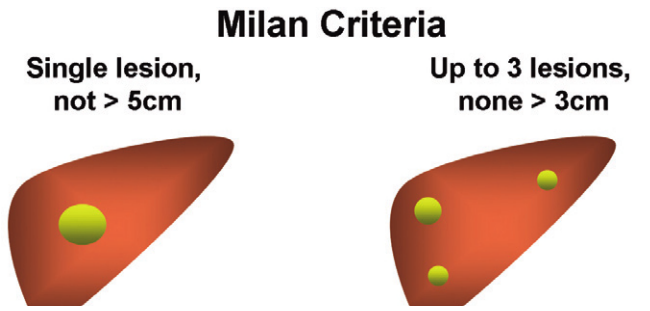

FIGURE 97D.3. Milan selection criteria for transplantation call for either a single lesion 5 cm or smaller or two to three lesions all ≤3 cm, equivalent to T1 and T2, respectively, of the American Liver Study Group modified tumor-node-metastasis classification system.

Table 97D.1

American Liver Tumor Study Group Modified TNM Staging and the University of California–San Francisco Staging Criteria

MODIFIED TNM		UCSF CRITERIA	
Traditional Stage	**Tumor Burden**	**Stage**	**Tumor Burden**
T1	One nodule ≤1.9 cm		
T2	One nodule 2 to 5 cm or two to three nodules all ≤3 cm		
T3	One nodule >5 cm or two to three nodules, at least one >3 cm	IIIa	One nodule 5.1 to 6.5 cm, two to three nodules, all ≤4.5 cm, or total diameter ≤8 cm
		IIIb	One nodule >6.5 cm, two to three nodules, of which one is ≥4.5 cm, or they have a total diameter >8 cm
T4a	Four or more nodules, any size		
T4b	T2, T3, or T4a plus gross intrahepatic portal or hepatic vein involvement as indicated by CT, MRI, or ultrasound		

TNM, tumor-node-metastasis; CT, computed tomography; MRI, magnetic resonance imaging

Modified from Yao FY, et al, 2001: Liver transplantation for hepatocellular carcinoma: expansion of the tumor size limits does not adversely impact survival. Hepatology 33(6):1394-1403. Copyright John Wiley & Sons. Reprinted with permission.

In the United States, the modified tumor-node-metastasis (TNM) staging system of the American Liver Tumor Study Group (ALTSG) is used to allocate livers from deceased donors to patients with HCC awaiting transplantation (UNOS, 2004; Table 97D.1) to ensure that all patients who receive an organ have a reasonable chance at long-term survival. The original transplantation criteria from the mid-1990s, the Milan criteria, are equivalent to stage I or II of this TNM classification system. Using these criteria, recurrence is between 4% and 16%, and 5-year survival is 71% to 75% (Hayashi et al, 2004b; Jonas et al, 2001; Llovet et al, 1998, 1999). Patients whose disease falls outside the ALTSG criteria for stage II disease, and thus outside the Milan criteria, may be at higher risk for recurrence.

In February 2002, the Model for End-Stage Liver Disease (MELD) scoring system was implemented. As part of this system, priority was given to patients with TMN stage T1 and T2 HCC in an effort to combat the risk of tumor progression in patients awaiting a transplant. The prioritization was revised in 2004 to no longer include T1 tumors, so that only patients with T2 tumors get priority listing (Wiesner et al, 2004) to prevent overallocation of organs to patients with HCC, and because approximately 30% of patients with presumed HCC (a single lesion ≤2 cm with arterial enhancement) were found to have no tumor in their explant (Wiesner et al, 2004). Currently, the MELD points added to a patient with a T2 lesion are equivalent to a 15% 3-month probability of candidate mortality.

It has been suggested that the Milan criteria are too restrictive and that the size criteria are somewhat arbitrary. Several centers have extended their criteria to include highly selected stage III patients who are expected to have a tolerable rate of recurrence (Duffy et al, 2007; Herrero et al, 2001; Kneteman et al, 2004; Onaca et al, 2007; Roayaie et al, 2002; Yao et al, 2001, 2007). A recent retrospective analysis of 1556 patients undergoing transplantation at 36 centers included 1112 patients with tumor burden exceeding the Milan criteria on posttransplant pathologic review. Of these, 283 patients had no evidence of microvascular invasion with tumor burden up to 7 cm in largest diameter or up to seven nodules, and this subset of patients achieved a 5-year survival of 71%.

The Univerity of California–San Francisco (UCSF) criteria—single tumor smaller than 6.5 cm, maximum of three total tumors with none larger than 4.5 cm, and cumulative tumor size smaller than 8 cm (see Table 97D.1)—represent a modest expansion of the Milan criteria and have been validated at other centers. One such evaluation, a retrospective review of preoperative imaging and explant pathology, looked at 467 transplantations performed over a 20-year period and found similar 5-year survival in patients meeting the Milan criteria and the UCSF criteria by explant pathology (86% vs. 71%) and preoperative imaging (79% vs. 64%). Survival for patients with tumors beyond UCSF criteria was less than 50% at 5 years (Duffy et al, 2007).

This discussion highlights the point that tumor burden is only a surrogate for vascular invasion and microscopic metastatic disease, which along with extrahepatic disease limits the effectiveness of liver transplantation. Formal guidelines for transplantation of patients with disease outside the Milan criteria have not been established, but with many centers reporting equivalent survival of highly selected patients outside the Milan criteria, and with the advent of downstaging, this topic has taken on widespread debate.

Another consideration is the impact of MELD exception points for cancer patients or the selection of patients with liver failure as a result of benign disease. In regions with long waiting times, if patients with tumor burden beyond the Milan criteria are transplanted, organs are taken away from patients with liver failure from other causes. Volk and colleagues (2008) examined the issue of what is the acceptable outcome risk for transplantation of patients with HCC as compared to using the organ in a patient without HCC. On a national basis, the authors found that expansion of the Milan criteria would significantly increase waiting list mortality, unless 5-year posttransplant survival for the expanded criteria recipients exceeded 61%.

The authors also showed a dramatic difference in the effect of a policy change based on transplant region. This regional variability appeared to result from dramatic differences in the risk of death for patients without HCC, because the MELD score at transplantation of non-HCC patients was quite low in some regions. In regions where the risk of death of the non-HCC patients without transplantation is low (low MELD score at transplantation), the HCC criteria could be expanded to allow transplantation in the HCC patients with a posttransplant survival in the HCC patients of 25%, which would mean that patients could have very large tumors or those that number greater than four or five. This is compared with the need for criteria for transplantation in HCC patients that resulted in a posttransplant survival of 70% in regions where there was a

greater need for transplantation (higher MELD scores) in the non-HCC population. This wide variation in outcome suggests that changes in national policies would have a variable effect, depending on the region.

Waiting List Screening for Hepatocellular Carcinoma

Patients awaiting transplantation are cirrhotic and are therefore at risk for HCC, so longer wait times can affect survival. The average waiting time for liver transplantation is extremely variable and is based on ABO blood group, progression of liver failure, and geographic location. The mean waiting time in the United States is approximately 4 months, but this varies among regions, ranging from 2 to 7 months; about 50% of patients are transplanted within 3 months. For patients with prolonged waiting times, it is important to screen patients with a CT or MRI scan of the abdomen every 3 to 6 months while they await transplantation.

Pretransplant Management of Patients with Hepatocellular Carcinoma

Unfortunately, controlled trials to evaluate different treatment options for patients awaiting transplantation have not been completed. The sole published series followed patients undergoing surveillance without local therapy and showed a high rate of dropouts from the waiting list because of tumor progression or progression of liver failure over the period of the study (Llovet et al, 1999). This report, combined with the understandable anxiety felt by patients and caregivers observing unhindered tumor progression, compelled most centers to offer cancer-directed treatment for patients awaiting transplantation. Retrospective data would suggest that cancer-directed therapy should be used if the expected waiting time exceeds 6 months (Bruix & Sherman, 2005).

Options for pretransplant locoregional control include TACE, RFA, percutaneous ethanol injection (Hoshida et al, 2008), or some combination of these modalities (see Chapters 83 and 85A). TACE is used by many centers because it offers locally effective treatment with a low risk of complications. Three studies support the argument that TACE may help reduce attrition from the pretransplant waiting list (Maddala et al, 2004; Majno et al, 2007; Millonig et al, 2007). These data include patients with variable waiting times and follow-up periods, but they suggest that pretransplant TACE is associated with a dropout rate of only 2% to 14%, with the possible added benefit of a lower posttransplant recurrence rate (8% to 10%).

A recent decision analysis evaluated the waiting-list time interval associated with the greatest impact of neoadjuvant TACE (i.e., greatest reduction in the dropout rate) and showed the greatest benefit in patients transplanted within 4 to 9 months (Aloia et al, 2007). The authors reported that when waiting time was less than 4 months, waiting-list attrition was similar in treated and untreated patients (20% vs. 34%; P = .08), and when waiting times exceed 9 months, dropout rates reequilibrated (33% vs. 46%; P = .06).

No studies have described percutaneous ethanol injection (PEI) as a sole treatment in patients awaiting a transplantation, although several studies suggest it is a safe and reliable component of multimodal therapy for tumors smaller than 3 cm (Troisi et al, 1998; Veltri et al, 1998; Vilana et al, 1992). PEI uses a small needle that reduces the risk of tract seeding to 0.6%. Some authors have suggested that pretreatment with arterial embolization to disrupt intratumoral septae facilitate the ethanol diffusion and may therefore improve the efficacy of subsequent ethanol injection (Lencioni et al, 1994). PEI requires several sessions when used as primary treatment for unresectable HCC, and prospective evidence supporting it as a neoadjuvant therapy is lacking; as a result, the trend has been toward other treatment methods.

RFTA induces tissue necrosis by delivering heat at the tip of one or several electrodes. Major complications occur in less than 10% of patients, and mortality is less than 1% (Orlando et al, 2009). This strategy is at least as efficacious as PEI for tumors smaller than 2 cm but requires fewer treatments (Livraghi et al, 1999; Lencioni et al, 2003), and randomized controlled trials suggest it improves survival (Lencioni, et al, 2003; Lin SM, et al, 2004; Livraghi et al, 1999).

A recent meta-analysis reported that RFA is superior to PEI in the treatment of small HCC with respect to survival and cancer-free survival at 1, 2, and 3 years; tumor response; and risk of local recurrence (Orlando et al, 2009). Recurrence is more common in patients with tumors larger than 4 cm, and in 95%, it occurs within 6 months and at a site distant from the primary tumor (Curley et al, 2000). This again suggests that tumor size is only a surrogate marker for microscopic metastatic spread and neoplastic potential of the remaining dysplastic nodules.

Given these data, RFA has evolved into the preoperative treatment of choice for tumors larger than 2 cm (Bruix & Sherman, 2005). With the advent of sorafenib, a chemotherapeutic agent that has shown greater activity against HCC than older cytotoxic agents (see Chapter 88), the paradigm may shift to a combination of locoregional therapy and chemotherapy. Trials examining these combinations are underway.

Another strategy is to prioritize, or fast-track, patients to have them receive a transplant as soon as possible without pretransplant treatment. Although this may be the most reassuring strategy for patients, it takes away the ability to observe the tumor biology over time. A subset of patients with newly diagnosed HCC will have very unfavorable tumor biology, and even if transplanted shortly after diagnosis, they are likely to experience rapid recurrence. A reasonable amount of time on the waiting list may in fact be beneficial, allowing tumor biology to unfold such that very aggressive disease will become obvious in short-term follow-up, thereby avoiding a futile procedure.

Patients with small tumors that fall within the Milan criteria have about a 10% risk of recurrence, which corresponds reasonably well to the percentage of patients with tumors that have aggressive histologic characteristics (Jonas et al, 2001). Fast-tracking such patients likely would significantly increase recurrence rates. One series examining this issue showed that recurrence rates were significantly higher in patients who were fast-tracked and in patients who underwent living-donor liver transplantation (LDLT) compared with patients who had longer waiting times (Kulik & Abecassis, 2004).

Patients with small but aggressive tumors are infrequent, but fast-tracking yields unacceptably high recurrence rates in the more common patient, with tumor burden close to the limits of or beyond the Milan criteria (Bismuth et al, 1993; Jonas et al, 2001; Llovet et al, 1999; Mazzaferro et al, 1996). It has also been suggested that fast-track prioritization is not cost-effective (Sarasin et al, 2001). Unfortunately, no stated guidelines have

been established, but it appears that even for LDLT, a waiting time of approximately 6 months is appropriate (Bruix & Llovet, 2002).

Downstaging

Two observations have fueled the current debate about the proper selection criteria for transplantation in patients with HCC. First, it is clear that not all tumors of the same size carry the same risk of recurrence. Secondly, it is well documented that some patients outside the Milan criteria will benefit from liver transplantation (Yao, 2008). This has led to efforts to select patients with more advanced disease, but with favorable tumor biology, who might benefit from transplantation (Otto et al, 2006). The process of downstaging disease to within Milan criteria may be a mechanism for identifying such patients. This approach allows treatment of the tumor, and concomitant selection of patients with favorable tumor biology, by excluding patients who do not respond to locoregional ablative therapy, and it allows time for unfavorable biology to manifest.

A prospective intention-to-treat analysis evaluated 61 highly selected patients with tumor stage exceeding T2 who underwent tumor-directed therapy prior to transplantation. The study included patients with one lesion larger than 5 cm but smaller than 8 cm; those with two to three lesions, with one lesion larger than 3 cm but smaller than 5 cm, with a total diameter less than 8 cm; and those with four to five lesions, all smaller than 3 cm with a total diameter less than 8 cm (Yao et al, 2008). An interval of at least 3 months was required between treatment and transplantation. Downstaging was successful in 70% of patients, with the remaining patients dropping out, usually from disease progression. The 1- and 4-year posttransplant survival rates were 96% and 92%, respectively, suggesting that carefully selected patients with disease exceeding the Milan criteria can be downstaged with excellent posttransplant outcome.

It is important to note that the median time between the first treatment and transplantation was 8.2 months, with a range of 3 to 25 months. It is this waiting time that appears to allow tumor biology to manifest; patients with more biologically aggressive tumors dropped out during the waiting period, allowing selection of lower risk patients for transplantation. There are no formal guidelines for downstaging, but the UCSF protocol for downstaging of patients initially exceeding the Milan criteria is included for reference (Box 97D.2).

Box 97D.2

University of California–San Francisco Downstaging Protocol for Patients Initially Outside the Milan Criteria

Inclusion Criteria for Downstaging

One tumor >5 cm and ≤8 cm
Two or three lesions, at least one >3 cm but ≤5 cm and total tumor diameter ≤8 cm
Four or five lesions, all ≤3 cm, and total diameter ≤8 cm
No evidence of vascular invasion by imaging

Criteria Defining Success of Downstaging by Imaging

Tumor size and number meeting UNOS T2 criteria *or*
Complete tumor necrosis by imaging without suggestion of residual tumor

Criteria Defining Treatment Failure

Death from any cause before liver transplantation
Exclusion from liver transplantation
Recurrence of hepatocellular carcinoma after liver transplantation

Additional Guidelines

A minimum follow-up period of 3 months is required before liver transplantation, with concomitant imaging studies that meet the "success" criteria.
Approval must be obtained by the regional United Network of Organ Sharing review board for priority listing for deceased-donor liver transplantation after successful downstaging.
Patients can undergo living-donor liver transplantation if a donor is available and imaging studies meet the selection criteria.
Patients with liver decompensation after downstaging are not eligible for liver transplantation unless the above criteria are met.
In patients treated with resection as a downstaging procedure, the presence of microvascular invasion in the resection specimen is a contraindication to liver transplantation.

Modified from Yao FY, et al, 2008: Excellent outcome following down-staging of hepatocellular carcinoma prior to liver transplantation: an intention-to-treat analysis. Hepatology 48(3):819-827. Copyright John Wiley & Sons, 2008. Reprinted with permission.

Technical Aspects of Liver Transplantation in Hepatocellular Carcinoma (See Chapter 98A)

Liver transplantation for HCC presents some technical challenges that need special consideration. The most important consideration is to perform the operation based on well-established oncologic principles, involving clear surgical margins and avoiding tumor seeding during the procedure to ensure the lowest recurrence rate. The tumor should be handled as little as possible, using the so-called no-touch technique, until the lymphovascular pedicle has been ligated. Hepatic artery ligation at the beginning of the hepatectomy can theoretically limit tumor dissemination during the dissection; however, no proof is available to suggest that such an approach lowers the posttransplant recurrence risk.

The transplant surgeon should be aware of prior therapy, because during RFA or biopsy, the needle tract and the diaphragm may be seeded with tumor. If a limited amount of diaphragmatic seeding is identified during the native hepatectomy, it is reasonable to perform a diaphragmatic resection with primary repair at the time of hepatectomy. Primary repair of the diaphragmatic defect is usually sufficient, and tube thoracostomy is not required. Diffuse seeding should preclude transplantation.

Predicting and Screening for Recurrence

The propensity of HCC to recur after surgical therapy has spurred investigations of potential biomarkers that might help improve patient selection. Recently, formalin-fixed tissue was used for genome-wide expression profiling of the normal tissue surrounding a focus of HCC, and a reproducible expression signature was seen that correlated well with survival (Hoshida et al, 2008). Even with the diversity of genetic events that lead to HCC, specific regions of loss of heterozygosity have been identified that could be used to quantify a patient's risk of HCC recurrence.

Efforts have been made to identify markers of extrahepatic tumor spread to avoid transplantation in the face of unrecognized extrahepatic disease. One attempt has been to find evidence of malignant cells in the bone marrow of patients with

HCC as a method to predict recurrence or survival (Sutcliffe et al, 2005), although this practice is not routinely performed.

A recent multivariate analysis of 136 patients undergoing hepatectomy for HCC reported that low AFP mRNA levels identified by real-time quantitative polymerase chain reaction (PCR) correlated with patient survival and disease-free survival (Kamiyama et al, 2006; Lindemann et al, 1992; Pantel et al, 1996). Patients with negative AFP mRNA had 97% survival at 1 year and 91% survival at 3 years versus 86% and 56%, respectively, in patients with positive AFP mRNA ($P < .0001$). Similarly, 1- and 3-year disease-free survival were 73% and 45% in patients with negative AFP mRNA versus 55% and 26%. Although not widely used, these tests may help quantify risk of recurrence and could have implications for organ allocation and the effectiveness of transplantation for cure.

Unfortunately, evidence-based data regarding posttransplant screening protocols are lacking, and screening all patients with imaging and serum AFP for recurrence does not appear to be cost effective (Roberts, 2005). Alternatively, screening high-risk patients, as defined by adverse histopathologic characteristics in the explanted liver, is a more promising and potentially cost-effective strategy (Roberts, 2005; Ladabaum et al, 2011). Moreover, because 70% to 75% of recurrence occurs within the first 2 years after transplantation, screening during this time period is the most critical and is most likely to have the greatest yield (Regalia et al, 1998; Roayaie et al, 2004).

Once patients experience recurrence after transplantation, therapeutic options are somewhat limited. In approximately 40% of patients, HCC recurs at extrahepatic sites, and chemotherapy is generally ineffective, leading to a median survival of only 8.7 months (Mazzaferro et al, 1996). A subset of roughly 10% of patients with recurrence can be expected to achieve long-term survival after resection (Roberts, 2005). The use of sorafenib in this situation is currently being studied.

Salvage Transplantation

As a way to better maintain the pool of donor organs, some have argued that primary liver resection should be first-line therapy for patients with preserved liver function and solitary HCCs smaller than 5 cm, and salvage transplantation can be offered to patients who experience recurrence that falls within the Milan criteria. In 2003, Poon and Wong evaluated survival and recurrence after resection of potentially transplantable small HCCs. They concluded that in patients with preserved liver function (CTP class A) with small solitary HCCs, primary resection achieved 5-year survival of 70%, comparable to reported survival after primary transplantation for similar size tumors. In order to apply salvage transplantation, screening must be diligent to find those who recur. Screening after resection with US every 3 months would be an important aspect of any treatment strategy using salvage transplantation for treatment of recurrence. The hope is that if patients recur, they will do so with transplantable disease within the Milan criteria.

Two studies have addressed the issue of outcome after salvage transplantation but reached opposing conclusions. The first was a retrospective analysis of 358 patients with cirrhosis and HCC who underwent either transplantation (n = 195) or resection (n = 163, of whom 98 were transplant candidates at the time of therapy); those patients with recurrence after resection underwent salvage transplantation (n = 17). The authors reported lower operative mortality rate (2% vs. 28%), lower recurrence rate (18% vs. 54%), and higher 5-year posttransplant survival (61% vs. 41%) and disease-free survival rates (58% vs. 29%) for patients who underwent transplantation compared with patients who underwent resection and then had salvage transplantation for recurrence (Adam et al, 2003).

The results of this study suggest that resection and salvage transplantation produced worse outcomes, but this was not supported by the second study of 88 patients with disease meeting the Milan criteria who underwent liver transplantation versus 18 who underwent resection followed by salvage transplantation for recurrence (Belghiti et al, 2003). The authors reported no difference in morbidity (51% vs. 56%), 30-day mortality (5.7% vs. 5.6%), 3-year survival (82% vs. 82%), 5-year survival (59% vs. 61%), or recurrence after primary liver transplantation versus salvage transplantation (n = 3 vs. 1).

Reasons for the discordant results could be the differences in time to salvage transplantation, patient selection, or operative technique of liver resection between the studies (27% underwent a transthoracic resection in the latter study). Another issue limiting the comparability of these two studies is that 7 of the 18 patients who underwent "salvage transplantation" in the latter study did not have recurrence but were transplanted for deterioration of liver function or because of pathologic findings in the resection specimen. Also of note, as Adam and Azoulay pointed out in a letter to the editors of the *Annals of Surgery*, the theoretical transplantability of patients with recurrence after resection seems to be different than the actual transplantability documented by many centers (Adam & Azoulay, 2005). Although Poon and colleagues describe an optimistic rate of patients with recurrence who would theoretically be transplantable after resection (79%), the percentage of patients who have undergone salvage transplantation, documented in the literature, is 1% to 30% (Belghiti et al, 2002; Llovet et al, 1999; Poon et al, 2002).

Reports of recurrence after salvage vary widely, from 5% to 54% (Adam et al, 2003; Belghiti et al, 2003; Lo & Fan, 2004). Currently, the efficacy of resection followed by salvage transplantation for recurrence is limited by the difficulties that attend screening for recurrence, prolonged waiting times, and a shortage of donor organs, but it may be a viable option for patients with hepatitis B without cirrhosis who have a single lesion.

Future Perspectives

Liver transplantation for HCC has proven to offer long-term survival and recurrence-free survival for patients with cirrhosis, but the shortage of donor organs is likely to perpetuate interest in resection and salvage transplantation. Currently, no consensus exists about an optimal method to select patients for transplantation after resection, which may be offered to patients with documented recurrence, but a more proactive strategy might improve outcomes.

One strategy would be to use the well-established histopathologic findings of microvascular invasion or multiple nodules unseen on preoperative imaging (Castells et al, 1993; Ikeda et al, 1993b; Izumi et al, 1994; Llovet et al, 1999; Nagasue et al, 1993; Okada et al, 1994) to select patients who are high risk for recurrence after resection. Identification of these findings in the resection specimen could initiate listing for liver transplantation (Sala et al, 2004). This strategy may select for patients who are at risk for early recurrence to undergo

transplantation (Colella et al, 1997; Klintmalm, 1998), thus selecting a population that is likely to recur, even if they do undergo transplantation. The concern with this strategy is that patients whose explant specimens after transplantation demonstrate vascular invasion are at increased risk for development of extrahepatic disease.

Another possible strategy takes advantage of recent advances in gene-expression profiling of fixed liver tissue, from the liver parenchyma away from the tumor, to reliably predict risk of late (de novo) recurrence by quantifying the field defect (Hoshida et al, 2008). Using this technology, gene-expression profiling could theoretically select the population with a field defect that places them at high risk for late recurrence; this group would perhaps be targeted for transplantation, while allowing those with low risk for late recurrence to have resection and be followed (Sherman, 2008). Although this strategy offers some promise, it remains investigational.

Even with the improvements in overall and cancer-free survival in the last 20 years, many areas in the treatment of HCC are in need of randomized controlled trials, such as the areas of preoperative screening, postoperative surveillance, and downstaging protocols. Nontransplant therapies—such as re-resection, RFA, TACE, and PEI—need to be evaluated against salvage transplantation for patients with recurrence. Lastly, therapeutic options for patients with advanced HCC need to be expanded to improve survival.

CHAPTER 97E

Liver transplantation for cholangiocarcinoma and other neoplastic diseases

Justin M. Burns, Charles B. Rosen, Julie K. Heimbach, and Gregory J. Gores

OVERVIEW

Liver transplantation for malignancies other than hepatocellular carcinoma (HCC) remains highly controversial. Nonhepatocellular carcinomas most commonly treated with liver transplantation include cholangiocarcinoma (CCA), metastatic neuroendocrine cancer (NEC), and hepatic epithelioid hemangioendothelioma (HEHE). Single-center and multicenter results have been equivocal with discrepancies in survival and efficacy. Herein we review the results of liver transplantation for these malignancies—specifically CCA, metastatic NEC, and HEHE—with an aim to suggest guidelines for the application of liver transplantation in the treatment of these diseases.

HILAR CHOLANGIOCARCINOMA (SEE CHAPTER 50B)

CCA, the second most common primary malignant tumor of the liver, arises from the cholangiocytes of the intrahepatic and extrahepatic bile ducts. The incidence of this tumor has been estimated at 3000 to 5000 cases per year (de Groen et al, 1999; Olnes & Erlich, 2004), and the prevalence of intrahepatic disease appears to be on the rise (Shaib et al, 2004). CCA can arise within the liver, in the perihilar location, or along the extrahepatic bile duct (see Chapters 50A and 50B). CCA has three growth patterns: 1) *mass-forming tumors* are usually intrahepatic, 2) *sclerosing tumors* arise in the perihilar and extrahepatic bile ducts, and 3) *polypoid tumors* grow within the major intrahepatic and extrahepatic ducts. Surgical extirpation has been the standard treatment for all three tumor types.

The treatment of hilar CCA has been most troublesome because it is impossible to achieve a tumor-free (R0) margin of resection. Radical resection with partial hepatectomy was shown to improve survival (Launois et al, 1979) for patients with hilar CCA, but few patients come to medical attention with disease amenable to complete resection. Indeed, fewer than 30% of patients are candidates for resection at diagnosis because of either bilateral liver involvement, encasement of hilar vascular structures, involvement of sectoral bile ducts, and/or underlying liver disease, such as primary sclerosing cholangitis (PSC; see Chapter 41). Liver transplantation appears promising for the treatment of intrahepatic and hilar CCA, because the procedure affords a radical resection, is not limited by bilateral ductal or vascular involvement, and treats underlying liver disease.

EARLY EXPERIENCE WITH LIVER TRANSPLANTATION

Unfortunately, early experiences with liver transplantation for the treatment of CCA were uniformly poor. Liver transplantation for both intrahepatic and hilar CCA was fraught with high recurrence rates and poor patient survival. The Cincinnati Tumor Registry reported a large multicenter analysis for patients transplanted from 1968 to 1997, wherein 1-, 3-, and 5-year patient survival rates were only 72%, 48%, and 23%, respectively (Meyer et al, 2000). The recurrence rate was 51% with a median time to recurrence of only 9.7 months. Local recurrence within the allograft was the most common initial site of recurrence (47%) followed by distant metastases to the lung (30%). Recurrence of tumor portended an extremely poor prognosis, with a median survival of only 2 months. Adjuvant therapy was not found to be beneficial, and no difference was reported in the survival rate of known tumors versus incidental tumors found at the time of orthotopic liver transplantation (OLT); results were poor for both intrahepatic and hilar tumors.

A multitude of retrospective studies have confirmed these findings. A Spanish multicenter study reported similar results for 59 patients who underwent OLT for CCA from 1988 to 2001 (Robles et al, 2004) and found 5-year survival was 30% with a 53% recurrence rate for 39 patients with hilar CCA. Results were equally poor for 23 patients with intrahepatic CCA, for which 5-year survival was 42%, and the recurrence rate was 35%. Similarly, a Scandinavian study reported a 5-year survival of 30% following OLT in a primary sclerosing cholangitis (PSC) population with early-stage CCA (Brandsaeter et al, 2004).

Several centers have reported their outcomes with incidental tumors discovered in patients undergoing transplantation for chronic liver disease. Ghali and colleagues (2005) reviewed the Canadian experience from 1996 through June 2003 and identified 10 cases, 8 arising in patients with PSC. Most of these tumors had favorable characteristics that included small size (<1 cm) and absence of perihepatic lymph node involvement; 90% were well differentiated, and 60% arose in the extrahepatic or hilar ducts. Despite the favorable characteristics, 3-year survival was only 30%. Only the University of California–Los

Angeles has reported reasonable survival outcomes in incidental CCA detected in the explant after OLT (Goss et al, 1997). Ten patients with incidental CCA had a 5-year survival of 87%, which was comparable to PSC patients without CCA, although pathologic characteristics were not included in the paper. As with all other experiences, the 4 patients transplanted with known CCA had poor outcomes, and none were alive at 5 years.

A more radical approach with cluster abdominal transplantation reported by the University of Pittsburgh had equally poor results: a 3-year survival of 20% and a 57% recurrence rate (Alessiani et al, 1995). A similar experience was recently reported by Neuhaus' team in Berlin (Seehofer et al, 2009). Sixteen patients with CCA were treated by combined liver transplantation and pancreatoduodenectomy (PD) between 1992 and 1998, and results were compared to those achieved for 8 patients who did not undergo PD, which at the time of liver transplantation was associated with significantly higher morbidity than transplantation alone. Long-term survival (>4 years) was achieved in only 3 lymph node–negative patients of 20 patients who survived the perioperative period. Neuhaus and colleagues concluded that "there is no good evidence that more radical resections alone are able to markedly improve long-term results."

With uniformly poor results of liver transplantation for these tumors, intrahepatic and hilar CCA became widely recognized as absolute contraindications for liver transplantation. Both intrahepatic and hilar CCA are best treated by resection; unresectable disease has a prohibitively high recurrence rate after transplantation and warrants additional or palliative therapy.

NEOADJUVANT THERAPY AND LIVER TRANSPLANTATION

Despite the poor results with liver transplantation alone, some patients with favorable hilar CCA—that is, those with negative margins and no regional lymph node metastases—did benefit from transplantation (Shimoda et al, 2001). In addition, a small group of patients at the Mayo Clinic treated with primary radiotherapy and chemosensitization alone, without resection, had a 5-year survival of 22% (Foo et al, 1997). Based on the known palliative efficacy of radiotherapy for CCA—and knowledge that CCA resection failures are usually due to locoregional recurrence, rather than distant metastases (Jarnagin et al, 2003)—the transplant team at the University of Nebraska pioneered a strategy of high-dose neoadjuvant brachytherapy and chemotherapy followed by liver transplantation (Sudan et al, 2002) for patients with unresectable hilar CCA.

The initial Nebraska protocol utilized high-dose intrabiliary brachytherapy, 6000 cGy, followed by daily intravenous 5-fluorouracil (5-FU) until OLT. Patients underwent operative staging when a donor liver became available for transplantation. At operation, the patients were assessed for extrahepatic metastases or regional lymph node involvement. Either finding precluded transplantation, and the donor liver was reallocated to another patient. Seventeen patients received neoadjuvant brachytherapy: 2 patients died from disease progression, and 4 were found to have extrahepatic disease at exploration; 11 patients underwent transplantation. Median survival after transplantation was 25 months; 5 (45%) were alive and disease-free at a median of 7.5 years (range, 2.8 to 14.5 years) after transplantation, 2 patients died from recurrent disease, and 4 patients died from perioperative complications. Overall survival was 30% for the 17 patients 5 years after the start of neoadjuvant therapy.

MAYO CLINIC EXPERIENCE

The transplant team at the Mayo Clinic embraced the concept pioneered by the team at the University of Nebraska and implemented a protocol in 1993 through a collaborative effort of oncologists, hepatologists, and surgeons. The general theory is that neoadjuvant therapy and liver transplantation should provide the best possible control of local disease. The rationale for the protocol was based on several factors: 1) the known CCA tumor response to high-dose radiotherapy; 2) hepatotoxicity of radiotherapy is obviated by liver transplantation; 3) liver transplantation achieves radical resection, including removal of residual disease following neoadjuvant therapy; 4) liver transplantation is not limited by underlying liver disease (PSC), vascular involvement, or concern about intrahepatic extension of disease; 5) neoadjuvant therapy prior to operative staging and transplantation might avoid tumor dissemination during operation; and 6) careful patient selection with operative staging prior to liver transplantation could exclude patients with advanced disease and regional lymph node metastases that are destined to develop distant metastatic disease.

Inclusion and Exclusion Criteria

Criteria for protocol enrollment are designed to select those patients least likely to develop metastatic disease, most likely to respond to neoadjuvant therapy, and who have a high probability for survival after transplantation. Appropriate patients include those with early-stage hilar CCA determined to be unresectable or those who have underlying PSC, because CCA arising in the setting of PSC has a very poor natural history following standard resection (Rosen et al, 1991).

Criteria for anatomic unresectability include bilateral segmental ductal extension, encasement of the main portal vein, unilateral segmental ductal extension with contralateral vascular encasement, and unilateral atrophy with either contralateral segmental ductal or vascular involvement. Due to the difficulty of assessing extent of disease along the bile duct, especially in the setting of PSC, no longitudinal limits exist for bile duct involvement.

Original criteria required that hilar CCA not extend lower than the cystic duct, but it was subsequently found that early CCA arising in PSC with unsuspected common bile duct involvement found at transplantation was amenable to transplantation with PD; however, patients with CCA extending below the cystic duct on cholangiography are excluded, because they have larger tumors that are more likely to abut the portal vein and be less amenable to complete extirpation during transplantation.

Vascular encasement of the hilar vessels is not a contraindication to transplantation. The upper limit of tumor size is 3 cm when a mass is visible on cross-sectional imaging studies, and there must be no evidence of intrahepatic or extrahepatic metastases by chest computed tomography (CT), abdominal CT or magnetic resonance imaging (MRI), ultrasonography, or bone scan. Endoscopic ultrasound (EUS) is performed prior to neoadjuvant therapy to exclude patients with regional lymph node metastases.

The Mayo Clinic protocol specifically excludes patients with evidence of intrahepatic or extrahepatic metastases or gallbladder involvement. Surgical intervention and any type of transperitoneal biopsy or fine needle aspiration have emerged as absolute contraindications to enrollment. These procedures result in an unacceptable rate of peritoneal seeding, which has been discovered during operative staging (unpublished data). Candidates must have no active infections or medical conditions that preclude either neoadjuvant therapy or OLT.

Tumor Diagnosis

Diagnostic criteria for neoadjuvant therapy and liver transplantation require a malignant-appearing stricture on cholangiography and either visualization of a mass on cross-sectional imaging, cytologic or histologic confirmation of CCA by transluminal brushing or biopsy, elevation of carboydrate antigen (CA)19-9 greater than 100 U/mL, or polysomy by fluorescence in situ hybridization (FISH). Patients with indeterminate diagnostic criteria—such as FISH trisomy (7 or 3), dysplasia from brushings, FISH polysomy in the absence of a malignant-appearing stricture, or a malignant-appearing stricture in the absence of a mass lesion are followed closely with repeat endoscopic retrograde cholangiography (ERCP) with brushings, cross-sectional imaging, and laboratory testing.

Neoadjuvant Therapy

Neoadjuvant therapy is administered by external beam radiation (40 to 45 Gy), followed by transcatheter radiation (20 to 30 Gy) with iridium wires. Wires are placed preferentially by ERCP and percutaneous transhepatic cholangiography (PTC) when ERCP is technically not possible. Intravenous 5-fluorouracil (5-FU) is administered for chemosensitization during radiation therapy, and capecitabine is administered afterward, while patients await transplantation.

Staging Operation

All patients undergo operative staging prior to OLT. Operative staging includes a thorough abdominal exploration with careful palpation of the liver to identify small, previously undetected intrahepatic metastases, biopsy of any suspicious nodules, and excision of a proximal proper hepatic artery lymph node (at the take-off of the gastroduodenal artery) and a pericholedochal lymph node posterior to the common bile duct just superior to the pancreas. The caudate process and retrohepatic vena cava are assessed for suitability of a caval-sparing hepatectomy, which is necessary for recipients of living-donor liver grafts. Extrahepatic or intrahepatic metastases, lymph node involvement, or locally extensive disease preclude transplantation. Survival for patients with these findings is low, and survival beyond a year is very rare. The staging operation was initially performed through a right subcostal incision with extension along the future liver transplant incision as necessary; however, during the past few years, most procedures have been accomplished by hand-assisted laparoscopy utilizing a smaller, right subcostal incision.

Timing of the staging operation depends on the possibility of a living-donor liver transplantation (LDLT) or the anticipated waiting time for a deceased-donor liver transplantation (DDLT). The staging procedure is performed 1 to 2 days prior to LDLT or as the patient nears the time for DDLT. Patients with underlying cirrhosis as a result of PSC or liver dysfunction as a result of cholestasis are somewhat prone to decompensation following the staging procedure, which may lead to an increase in a patient's MELD score and advance their position on the deceased-donor waiting list, but it also leads to an increase in perioperative morbidity and mortality. Unfortunately, only supportive care is possible for those patients who decompensate after a positive staging operation, and few survive the perioperative period.

Prior to 2003, 30% to 40% of patients had findings during the staging operation that precluded transplantation. EUS-guided aspiration of regional nodes (not the primary tumor) was implemented to exclude patients with lymph node metastases prior to initiation of neoadjuvant therapy. Initial findings from 47 patients identified eight (17%) with metastases (Gleeson et al, 2008). No morphologic features of the lymph nodes were found at EUS that predicted microscopic disease. Since routine use of EUS was implemented in 2003, the percentage of patients with a positive staging exploration has been reduced to 15%. EUS avoids the morbidity and mortality of high-dose neoadjuvant therapy and prevents an unnecessary operation for patients destined to fall out at operative staging.

Liver Transplantation

The technical difficulty and nuances of transplantation outweigh those of standard OLT. The operation is performed via a standard bilateral subcostal incision with vertical extension in the midline. Hilar dissection is avoided to prevent tumor manipulation and to reduce the possibility of intraoperative dissemination. There is typically extensive scar tissue in the hepatoduodenal ligament because of the neoadjuvant therapy and the previous staging procedure, which can make the dissection very difficult. The irradiated native hepatic artery is avoided during transplantation with a deceased donor, and arterial inflow is established with a segment of deceased donor iliac artery sewn to the infrarenal aorta. This approach was initially applied to LDLT but unfortunately resulted in an unacceptable rate of hepatic artery thrombosis. Better results have been achieved using the native artery, which is sewn directly to the living donor artery despite prior radiation therapy.

Next, the bile duct is transected as close to the pancreas as possible, and it may be possible to enucleate a short segment of additional common bile duct from the head of the pancreas. The margin is submitted for frozen section examination. Microscopic tumor involvement at this margin occurs in 10% to 15% of patients with PSC, and the possibility of PD is discussed with all patients prior to initiation of neoadjuvant therapy. Bilioenteric continuity is restored with a standard Roux-en-Y hepaticojejunostomy (living-donor graft) or choledochojejunostomy (deceased-donor graft).

The portal vein may be somewhat brittle as a result of the neoadjuvant therapy, and an injury may be difficult to control. The portal vein is divided as low as possible and is not dissected free up into the hilus of the liver. Despite low division, the deceased-donor portal vein is almost always long enough for an end-to-end anastomosis. A segment of a deceased-donor iliac vein is used as an interposition graft between a living-donor right or left portal vein and the native vein during LDLT. A caval-sparing hepatectomy is performed in most cases, and the donor suprahepatic vena cava is sewn to the left/middle hepatic

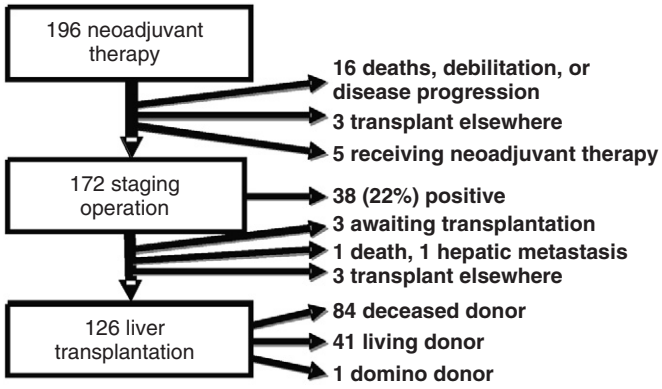

FIGURE 97E.1. Mayo Clinic neoadjuvant therapy and liver transplantation for hilar cholangiocarcinoma, 1993 through 2010.

vein trunk during DDLT; the hepatic vein is reconstructed in an end-to-end fashion during LDLT. If there is concern for tumor extension into the caudate, which is usually detectable during the staging operation, the retrohepatic cava is excised, and the donor retrohepatic vena cava is sewn to the suprahepatic and infrahepatic cavae as an interposition graft, usually via portovenous and venovenous bypass.

Results

One hundred ninety-six patients were enrolled in the Mayo Clinic protocol from 1993 until April 10, 2010 (Fig. 97E.1). Sixteen patients died, became too debilitated for transplantation, or had disease progression prior to operative staging. Three patients underwent transplantation at other centers, and five were receiving neoadjuvant therapy and/or awaiting operative staging. One hundred seventy-two patients underwent operative staging, and 38 patients (22%) had findings precluding transplantation. After staging, 1 patient died from hepatic decompensation, 1 developed intrahepatic metastases, and 3 patients underwent transplantation at other centers. The remaining 126 patients underwent transplantation, 84 with deceased-donor grafts, 41 with living-donor grafts, and one with a domino familial amyloid donor graft.

Overall patient survival from enrollment in the protocol (intention-to-treat analysis) was 56% ± 4% at 5 years after the start of neoadjuvant therapy (Fig. 97E.2), 63% ± 5% for patients with underlying PSC, and 44% ± 7% for patients with de novo CCA. Five-year survival after transplantation was 74% ± 5%; 80% ± 5% for patients with underlying PSC and 64% ± 8% for patients with de novo CCA (Fig. 97E.3). No difference in survival was reported among patients undergoing LDLT versus DDLT.

Thirty-eight patients (22%) had findings at the staging operation that precluded transplantation. The majority of these findings were regional lymph node (n = 17) and peritoneal (n = 14) metastases; 8 patients had invasion of adjacent organs/tissues, and 5 had intrahepatic metastases that had not been detected by preoperative imaging studies. Findings were missed in 4 patients found to have gallbladder involvement (n = 1) and invasion of neuroconnective tissue (n = 3) during transplantation within several weeks of their staging operations. Remarkably, the patient with gallbladder involvement also had microscopic disease at the common bile duct margin. She did not undergo PD, as it was not technically possible, and she is alive and disease-free 6.5 years after transplantation. The three patients with neuroconnective tissue involvement underwent reexcision

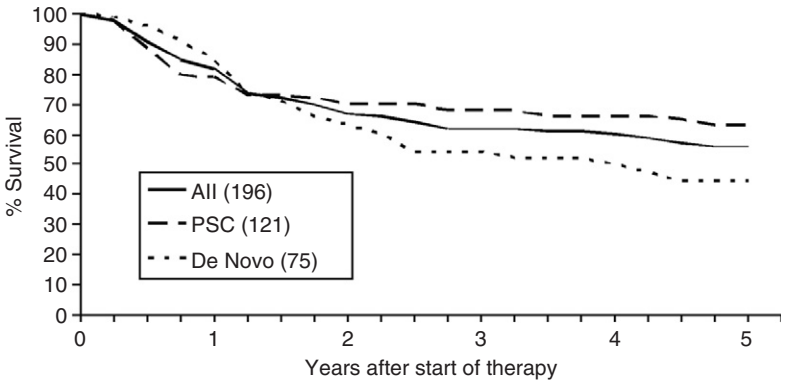

FIGURE 97E.2. Patient survival after start of neoadjuvant therapy. PSC, primary sclerosing cholangitis.

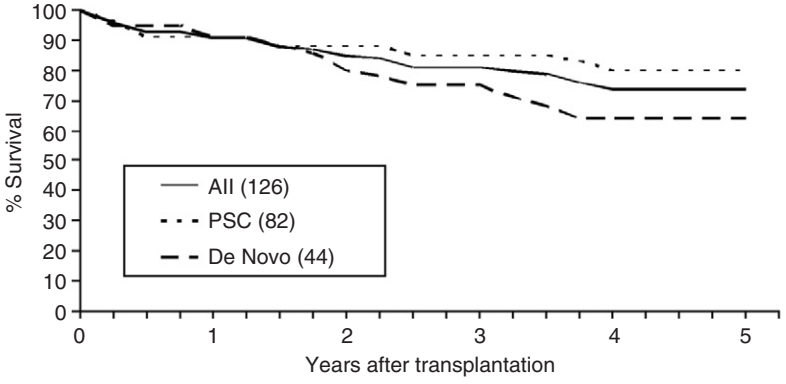

FIGURE 97E.3. Patient survival after transplantation. PSC, primary sclerosing cholangitis.

during the transplant operation and are alive at 13, 32, and 66 months after transplantation. The patient at 13 months has a very high CA19-9 level and presumably will develop detectable recurrent disease. The other 2 patients show no evidence of recurrent disease.

Twenty-nine patients (23%) died after transplantation: 7 from surgical complications (1 to 5 months) and 17 from recurrent CCA. Other causes of death were graft-versus-host disease (n = 2 at 1 and 4 months), posttransplant lymphoproliferative disease (23 months), an indeterminate hematologic disorder (31 months), and uterine cancer (45 months).

Recurrence and Prognostic Factors

Twenty-one of the 125 patients (17%) who underwent OLT developed recurrent disease at a mean of 25 months (range, 7 to 64 months) after transplantation, and 10 (48%) of the 21 recurrences were distant metastases. The initial sites for recurrent CCA are shown in Table 97E.1.

The Mayo group reviewed their experience in 2006 with an aim to identify clinical and pathologic predictors of recurrence (Heimbach et al, 2006). At that time, 65 patients had undergone transplantation; the mean follow-up was 32 months, and 11 patients (17%) had documented recurrences after transplantation. Clinical factors identified as predictors of recurrence included older patient age, prior cholecystectomy, CA19-9 greater than 100 at the time of transplantation, a visible mass on cross-sectional imaging, and an extended waiting time between conclusion of neoadjuvant therapy and OLT. Pathologic findings identified as predictors of recurrence included residual CCA larger than 2 cm, high-grade histology, and perineural invasion.

Pancreatoduodenectomy and Transplantation

The addition of a PD greatly increases the technical complexity of transplantation and has a significant impact on postoperative morbidity and mortality. A 5-year survival rate of 56% (±17%, compared with 75% ± 5% overall) was reported in 11 patients who underwent OLT with concomitant PD, and 9 of 67 PSC patients (13%) were found to have microscopic involvement of the common bile duct margin at the time of transplantation, and 8 of these patients (5 deceased donor, 2 living donor, and one amyloid donor) underwent PD. Currently, 5 are alive and disease free at 9 months to 11 years after transplantation; however, 2 patients died within 3 months from hepatic artery thrombosis (deceased-donor graft) and hepatic artery thrombosis with pseudoaneurysm (living-donor graft), and adhesions precluded PD in the remaining patient, who was also found to have gallbladder involvement; remarkably, this patient is alive and without evidence of disease 6.5 years after transplantation.

Two patients with previous biliary operations underwent OLT with en bloc PD. One patient is alive and disease-free 7 years after transplantation; the other patient died 45 months after transplantation from uterine cancer. Additionally, one PSC patient known to have positive brushings in the common bile duct in addition to a hilar CCA underwent planned OLT with en bloc PD and is alive and disease-free at 13 months. No patient with de novo hilar CCA has had a positive common bile duct margin at the time of transplantation.

Table 97E.1

Cholangiocarcinoma Recurrence After Transplantation

Site	Time (mo)	Status (mo)
Regional	7, 10, 14	Dead at 10, 17, 18
	14, 15, 17, 65	Alive at 21, 16, 24, 67
Peritoneal	15	Alive at 23
	22, 25, 27	Dead at 29, 41, 43
Chest	18, 24	Alive at 36, 48
	22, 30, 40	Dead at 24, 30, 64
Bone	7, 8, 55	Dead at 37, 10, 84
	47	Dead at 48
Miscellaneous	34	Alive at 37
	47	Dead at 48

Mean time to recurrence was 25 months.

Vascular Complications

Late vascular complications are much more common after transplantation for CCA than after other indications because of the neoadjuvant therapy (Mantel et al, 2007). Use of the irradiated native common hepatic artery is avoided during DDLT in lieu of a deceased-donor iliac artery graft from the infrarenal aorta. This strategy was initially implemented in LDLT but resulted in an unacceptable rate of acute hepatic artery thrombosis. Subsequently, the native hepatic artery has been used for arterial inflow in LDLT; this strategy reduced early hepatic artery thrombosis but it is associated with a 20% late stenosis/thrombosis rate. Likewise, there is also a 20% rate of late portal vein stenosis (with or without thrombosis) seen with both living- and deceased-donor transplantation. A deceased donor iliac vein is used as an interposition graft during LDLT, and the stenosis has always involved the native portal vein and its anastomosis with the interposition graft.

All patients undergo Doppler US and contrast CT examination 4 months after transplantation. These imaging studies enable detection of an asymptomatic stenosis that is usually amenable to angioplasty with or without stent insertion. Arterial complications are treated by a transarterial approach, and portal complications are treated transhepatically. Fortunately, the Mayo group has not lost a graft from a portal stenosis or an arterial stenosis detected prior to thrombosis.

Medical and Neoadjuvant Complications

The effect of neoadjuvant radiotherapy on the liver is profound (Fig. 97E.4). Widespread necrosis is found in the hilus with necrotic debris in the major ducts (Fig. 97E.5); thus pretransplant infectious complications related to neoadjuvant therapy are very common and require continuous care and frequent hospitalization for patients awaiting transplantation. Nearly all patients have one or more episodes of cholangitis with occasional development of intrahepatic abscesses. Cholecystitis is treated nonoperatively with antibiotics, although severe cases may require endoscopic placement of a cystic duct stent or percutaneous cholecystostomy. Several patients have developed gallbladder necrosis with rupture that required emergency operations. Gastritis, duodenitis, and poor gastric emptying are also common and can persist after transplantation, which can lead to difficulties with nutrition. Several patients have

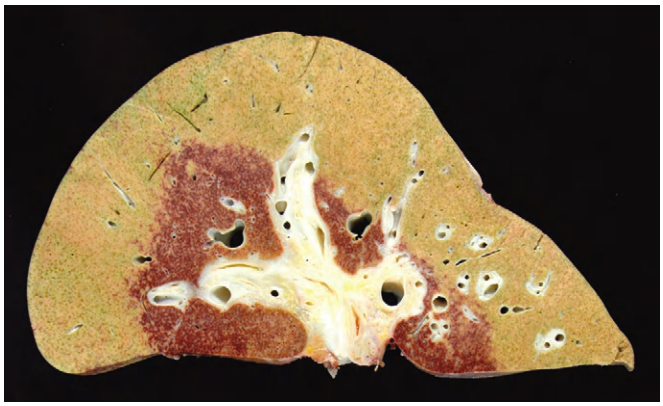

FIGURE 97E.4. Explanted liver after neoadjuvant therapy showing radiation effect.

required operative intervention for duodenal perforation or life-threatening hemorrhage from duodenitis and peptic ulceration.

CCA patients are hypercoaguable and at risk for deep venous thrombosis (DVT) and pulmonary embolism, as observed with other types of malignancies. Thus, they receive DVT prophylaxis whenever hospitalized for nonbleeding complications and especially during the perioperative period following operative staging.

Key Questions

Despite the success reported by the Mayo Clinic, the results remain controversial. Key questions fueling the controversy pertain to 1) accuracy of diagnosis prior to neoadjuvant therapy, 2) efficacy of the protocol, 3) whether transplantation for CCA is an appropriate use of donor organs, 4) whether these patients warrant prioritization for deceased-donor liver allocation, and 5) whether transplantation after neoadjuvant therapy should be used for patients with potentially resectable CCA in lieu of standard resection.

Diagnostic Accuracy

The protocol diagnostic criteria allow enrollment of patients without pathologic confirmation of CCA. It is indeed probable that some patients who did not have CCA were treated with neoadjuvant therapy and liver transplantation; although these patients would favorably affect the results, their impact is not significant. Furthermore, it would be difficult to require pathologic confirmation of disease prior to treatment. Pathologic confirmation is notoriously difficult for hilar CCA, and a large proportion of patients treated without it are subsequently confirmed by findings at the staging operation or transplantation. Pathologic confirmation of CCA is associated with a significantly higher rate of fallout at operative staging: 32% versus 10%; however, there are no significant differences in residual CCA in the explanted liver (42% vs. 54%) or recurrence rates after transplantation (15% vs. 20%) between those who did and did not have pathologic confirmation. It would thus be difficult to deny treatment to patients who fulfill the diagnostic criteria but do not have pathologic confirmation of CCA; 28 of 65 patients were eventually confirmed by pathologic findings, 27 with residual disease in the explant and 1 with a recurrence.

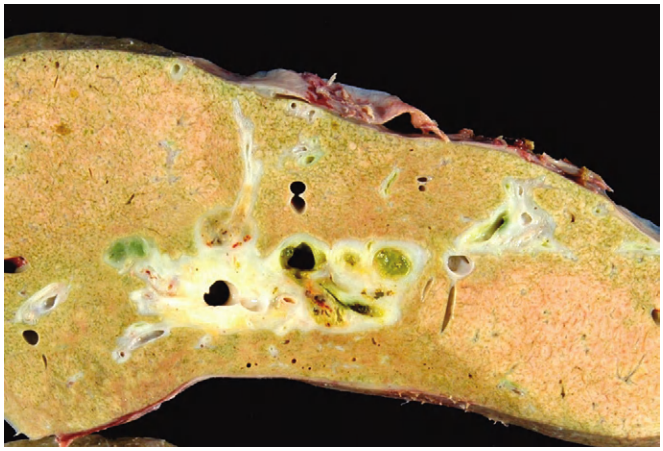

FIGURE 97E.5. Explanted liver after neoadjuvant therapy showing duct necrosis and intraductal debris.

Efficacy

The Mayo protocol's efficacy is self-evident: all of the patients had either CCA arising in the setting of PSC or unresectable CCA arising de novo. Resection was not possible, and the results with the Mayo protocol are clearly better than the natural history of untreated CCA, which has a 50% to 70% mortality rate at 1 year (Burak et al, 2004; Farley et al, 1995). The standard surgical treatment for hilar CCA is resection with partial hepatectomy, en bloc excision of the extrahepatic duct, and radical lymphadenectomy. After complete extirpation of tumor, 5-year survival following an R0 resection ranges from 30% to 45%.

The Mayo protocol has also achieved comparable results with patients having unresectable de novo CCA, with 5-year survival of 44% for 75 patients after the start of neoadjuvant therapy and 5-year survival of 64% for 44 patients after transplantation. Furthermore, the results clearly demonstrate efficacy of neoadjuvant therapy, because 35 (57%) of 61 patients with pathologic confirmation prior to neoadjuvant therapy had neither residual disease in the explant nor a recurrence after transplantation.

Appropriate Use of Donor Organs

The results achieved with liver transplantation for CCA after neoadjuvant therapy and operative staging are comparable to results achieved with liver transplantation for other malignant, chronic, and acute liver diseases such as PSC, hepatitis C, and HCC (Heimbach et al, 2004). Because patients with CCA arising in the setting of PSC and those with unresectable CCA arising de novo have no other potentially curative treatment options, liver transplantation is an appropriate use of both deceased-donor and living-donor livers.

Deceased-Donor Allocation and Prioritization

As CCA emerged as a valid indication for liver transplantation, allocation of deceased-donor livers became highly controversial. Mayo Clinic-Rochester is within United Network of Organ Sharing (UNOS) Region 7, and that region's review board members agreed to Model for End-Stage Liver Disease (MELD) score exception guidelines shortly after the implementation of MELD for liver allocation in 2002. MELD score exceptions were given to patients who successfully completed neoadjuvant therapy and had no evidence of metastases at

operative staging. The initial adjustment was a score of 20, matching that of HCC at the time, and was increased in parallel to the score schedule for HCC, but at 6-month rather than 3-month intervals, as was done for HCC.

Additional aims of the guidelines were to determine the risk of disease progression in patients awaiting transplantation and to retain incentives for use of living liver donors and utilization of extended criteria donors. The Mayo Clinic transplanted 42 patients between September 2002 and January 2006, with a median staging-to-transplant interval of 114 days. After transplantation, one of 21 patients with an interval less than 114 days developed recurrent disease, whereas four of 21 patients with an interval greater than 114 days developed recurrent disease (92% ± 7% vs. 56% ± 19% disease-free 2.5-year survival). Although the difference was not statistically significant because of the small number of patients, the results suggested that prolongation of waiting time leads to an increase in recurrent disease after transplantation (unpublished data).

A group of transplant surgeons and physicians met as an ad hoc MELD Exception Study Group in March 2006 to review the available data for the treatment of hilar CCA with neoadjuvant therapy followed by OLT (Gores et al, 2006). The group concluded that sufficient data existed to justify priority for patients enrolled in clinical trials that used neoadjuvant therapy provided that 1) transplant centers submit formal patient care protocols to the UNOS Liver and Intestinal Committee; 2) candidates satisfy accepted diagnostic criteria for CCA and are considered to be unresectable on the basis of technical considerations or underlying liver disease, such as PSC; 3) tumor mass, when visible on cross-sectional imaging studies, is less than 3 cm in radial diameter; 4) imaging studies to assess patients for intrahepatic and extrahepatic metastases are repeated prior to interval score increases; 5) regional hepatic lymph node involvement and the peritoneal cavity is assessed by operative staging after completion of neoadjuvant therapy and prior to transplantation; and 6) transperitoneal aspiration or biopsy of the primary tumor is avoided because of the high risk of tumor seeding associated with these procedures. The group also concluded that prioritization of patients with biliary dysplasia to avoid progression to CCA was unjustified. In 2009, UNOS adopted these MELD exception criteria, and the score adjustment is identical to that for HCC, with score increases at 3-month intervals.

Resection Versus Transplantation

Because results with the Mayo protocol equal or exceed the results achieved with resection, it would seem reasonable to consider neoadjuvant therapy and liver transplantation in lieu of resection for patients with potentially resectable disease. Rea and colleagues (2005) retrospectively compared results for patients treated by potentially curative resection and neoadjuvant therapy and liver transplantation at the Mayo Clinic between 1993 and 2004. Although no statistically significant difference in survival was found between the two groups, a strong trend was seen toward better survival in the group treated with neoadjuvant therapy and liver transplantation.

Since that time, the Mayo group has accrued a larger experience with liver transplantation for patients with unresectable de novo CCA, and the results with the protocol show an overall survival of 44% at 5 years after the start of neoadjuvant therapy, a result not too dissimilar from those achieved with resection. A prospective trial of resection versus transplantation is impractical because of the large number of patients that would be necessary to show a significant difference in survival. Furthermore, a crossover would not be possible. Patients treated with neoadjuvant therapy would not be amenable to resection. The effect of high-dose neoadjuvant therapy on the underlying liver and bile duct is profound (see Figs. 97E.4 and 97E.5) and precludes biliary reconstruction because of widespread intrahepatic duct necrosis. Patients found to be unresectable at operation would not be appropriate for subsequent neoadjuvant therapy and transplantation. Results with resection are also improving with increasing experience and technical innovation; Neuhaus and colleagues (1999, 2003) demonstrated excellent 5-year survival using vascular reconstruction with extended hepatectomy (Jonas et al, 2008).

In summary, neoadjuvant therapy followed by OLT for the treatment of hilar CCA achieves excellent results for highly selected patients with early stage disease. The results compare favorably to survival after OLT for chronic liver disease and for HCC. Neoadjuvant therapy with subsequent liver transplantation has emerged as the treatment of choice for patients with unresectable hilar CCA or hilar CCA arising in the setting of PSC. Success requires careful patient selection with adherence to protocol and operative staging prior to OLT, and LDLT enables transplantation to be performed in a timely fashion, without prolongation of waiting time, and achieves results similar to those seen with DDLT. Neoadjuvant therapy introduces considerable morbidity and unique complications not usually encountered with transplantation alone, and these challenges highlight the need for a multidisciplinary team that includes hepatologists, interventional radiologists, gastroenterologists, radiation and medical oncologists, and transplant surgeons in order to achieve success.

NEUROENDOCRINE CANCER (SEE CHAPTER 81B)

Gastroenteropancreatic neuroendocrine cancers (NECs) are a rare, diverse group of tumors with an incidence of one to two cases per 100,000 per year with a slight female predominance (Taal & Visser, 2004). These tumors are characteristically indolent in nature and are frequently found to be metastatic at the time of diagnosis. The liver is the most common site for metastases, and widespread hepatic dissemination is the leading cause of death in these patients (Frilling et al, 2009). Fortunately, these cancers are often confined to the liver for protracted periods of time with 5-year survival of 13% to 54% even without treatment (Godwin, 1975; Thompson et al, 1988; Que et al, 1995).

Various therapeutic options have been utilized for NEC with hepatic metastases; such treatments include transarterial chemoembolization (TACE), radiofrequency and cryoablation, systemic chemotherapy, peptide receptor radionuclide therapy (see Chapters 84A, 84B, 85A and 85B), cytoreductive resection, surgical resection (see Chapter 81B), and liver transplantation. Surgical extirpation with an R0 resection is the most effective therapy for metastatic NEC confined to the liver; however, only 10% to 57% of these tumors are amenable to compete resection (Chen et al, 1998; Elias et al, 2003; Frilling et al, 2009; Grazi et al, 2000; Mazzaferro et al, 2007; Musunuru et al, 2006; Yao et al, 2001).

Liver transplantation is an option for treatment of patients with a low probability of achieving an R0 resection. The goals of

liver transplantation are to 1) achieve palliation by alleviating symptoms for patients with functioning NEC; 2) achieve palliation by delaying death as a result of tumor replacement of the liver, taking advantage of the slow progression and the time it will take to replace the new liver with tumor, "resetting the clock"; and 3) achieve a cure. Liver transplantation is highly effective at relieving symptoms for patients with functioning NEC. There are several single-center (Florman et al, 2004; Frilling et al, 2006; Mazzaferro et al, 2007; Rosenau et al, 2002) and multicenter (Le Treut et al, 2008) studies reporting 36% to 90% patient survival at 5 years. The possibility of achieving a cure, however, is very low. Disease-free survival is only 20% to 77% at 5 years, and tumor recurrence after 5 years is common.

Widespread acceptance of OLT as a reasonable option for the treatment of this disease remains limited and controversial for multiple reasons that include the scarcity of deceased-donor organs available for OLT and the availability of other treatment modalities that can also provide palliation. Furthermore, reliable selection criteria have not been identified, and long-term data are limited because of the low incidence of the disease. Most importantly, it remains difficult to determine the actual benefit derived from OLT as a result of the protracted course of metastatic disease and unknown natural history of disease for those patients selected as candidates for transplantation.

The Mayo Clinic developed a protocol in 2002 designed to assess efficacy of liver transplantation for patients with metastatic NEC confined to the liver and regional hepatic lymph nodes (van Vilsteren et al, 2006). The clinical inclusion/exclusion criteria are summarized in Box 97E.1. Each patient was screened for locally recurrent and extrahepatic disease with chest, abdomen, and pelvic CT scans, bone scan, and somatostatin receptor scintigraphy within 60 days of preliminary registration for transplantation. Prior treatment modalities did not exclude patients, as long as they did not technically prohibit OLT. Patients were observed for 6 months following resection of the primary NEC to exclude extrahepatic disease progression. Reevaluation for metastatic disease prior to liver transplantation was performed every 4 months via laboratory tests, tumor marker assays, and abdominal imaging studies. Extrahepatic metastases were excluded via operative staging with laparoscopy prior to OLT.

The results were published with short follow-up. Since that time, 23 patients with metastatic NEC have undergone transplantation at the Mayo Clinic, with 76% patient survival and 37% disease-free survival at 5 years (unpublished data). Consistent with information in the literature, patients with carcinoid tumors fared slightly better than those with islet cell tumors originating in the pancreas. Patient and disease-free survival at 5 years was 86% and 45% for 10 patients with carcinoid tumors, 78% and 44% for 9 patients with islet cell tumors, and 50% and 0% for 3 patients with gastrinoma and one patient with glucagonoma. Thirteen patients developed recurrent disease, and survival after recurrence was less than 30% at 4 years, 50% for those with carcinoid or islet cell tumors, and 0% for those with gastrinoma or glucagonoma. As a result, patients with metastatic glucagonoma and gastrinoma are no longer considered for transplantation.

In summary, liver transplantation effectively alleviates symptoms for patients with diffuse, functioning NEC liver metastases. Liver transplantation may improve patient survival for those destined to succumb to liver replacement by tumor, but no studies actually demonstrate efficacy. Recurrence is common following transplantation, and results with metastatic gastrinoma and glucagonoma are poor, so transplantation should not be done for these types of tumors. Indications for transplantation and optimal timing in the course of disease remain ill defined, and the absence of prioritization (MELD score adjustment) in the United States precludes widespread application.

Box 97E.1

Mayo Clinic Transplantation Selection Criteria for Patients with Metastatic Neuroendocrine Carcinoma

Inclusion Criteria

1. Histologic confirmation of NEC (liver primary vs. metastatic disease confined to the liver)
2. Unresectable hepatic disease involving both lobes
3. Complete resection of the primary NEC or single dominant liver NEC believed to be a primary lesion
4. Absence of extrahepatic disease with the exception of regional lymph nodes resectable as part of standard liver transplantation
5. At least a 6-month interval from resection of primary NEC and transplantation without extrahepatic disease progression
6. Patient deemed suitable for liver transplantation, meeting all United Network for Organ Sharing listing criteria

Exclusion Criteria

1. Prior nonselective hepatic artery embolization unless approved by the transplant surgeon (only for living-donor transplantation)
2. Rectal NEC
3. Anaplastic or poorly differentiated (grade 3 or 4) tumor
4. Right atrial pressure >15 mm Hg
5. Known pregnancy
6. Other factors that preclude transplantation, including severe comorbidities, infection, or other malignancies

Other

1. Patients are staged with computed tomographic scan of the chest, abdomen, and pelvis; bone scan; and somatostatin receptor scintigraphy scan
2. All patients undergo open or laparoscopic staging celiotomy
3. Patients are reevaluated every 4 months with abdominal imaging to evaluate for extrahepatic disease progression

NEC, neuroendocrine cancer

HEPATIC EPITHELIOID HEMANGIOENDOTHELIOMA (SEE CHAPTER 78B)

HEHE, first described in 1982, is a rare neoplasm that originates from vascular endothelium, and it has unpredictable malignant potential (Weiss & Enzinger, 1982). Ishak and colleagues (1984) first reported liver involvement in a series of 32 patients with HEHE, which arises between the second and ninth decades with a 3:2 female/male predominance (Mehrabi et al, 2006). The etiology of HEHE remains elusive, although a multitude of conditions have been proposed to contribute to its development; these include viral hepatitis, liver trauma, oral contraceptives, primary biliary cirrhosis, alcohol consumption, and exposure to vinyl chloride, asbestos, and Thorotrast (Darras et al, 1988; Dean et al, 1985; Lauffer et al, 1996; Makhlouf et al, 1999; Mehrabi et al, 2006; Soslow et al, 1997).

The most common clinical manifestations of HEHE are right upper quadrant pain, hepatomegaly, and weight loss. Weakness, anorexia, epigastric mass, ascites, nausea, jaundice,

and fatigue are additional symptoms. Up to 25% of these lesions are detected as incidental findings (Lauffer et al, 1996; Mehrabi et al, 2006).

Two variants of HEHE have been described, *nodular* and *diffuse*. In actuality, the variants represent early- and late-stage disease. The *nodular type* is seen early with a highly variable number of 1- to 12-cm lesions arising throughout the liver. The lesions are typically hypodense on CT scan with high-density contrast uptake in the periphery. Individual nodules increase in size by spreading along the hepatic or portal veins, and they eventually coalesce to form diffuse peripheral lesions. The CT appearance of the later *diffuse type* is typically a large, slow-growing lesion resulting from coalescence of smaller lesions. Flattening of the capsule may occur because of fibrosis, peripheral enhancement of contrast may be seen with many hypervascular central lesions, and hypertrophy of the unaffected segments of the liver may be apparent (Fulcher & Sterling, 2002; Lyburn et al, 2003; Miller et al, 1992).

Definitive radiographic diagnosis of the HEHE is usually not possible, especially in the nodular form, because of the similarity of this tumor with primary epithelial liver tumors and hepatic metastases. In a review of 434 cases of HEHE, the majority of patients (87%) had multifocal disease involving both lobes of the liver at the time of presentation. Extrahepatic disease at diagnosis was common (36.6%) with involvement of the lung (8.5%), regional lymph nodes (7.7%), peritoneum (6.1%), spleen (3.2%), and diaphragm (1.6%) (Mehrabi et al, 2006).

Histologically, HEHE may resemble other conditions such as venoocclusive disease, CCA, hemangioma, angiosarcoma, and metastatic signet ring cell carcinoma (Corrin et al, 1979). Furthermore, immunohistochemical staining may suggest a tumor of neuroendocrine origin. Histologic findings are consistent with epithelioid or histiocytoid morphology and intracytoplasmic lumina containing red blood cells. Immunohistochemical staining is positive for factor VIII–related antigen and endothelial cell markers (CD31, CD34) and negative for mucin, bile, carcinoembryonic antigen, and α-fetoprotein. Ultrastructural findings are characterized by a well-developed basal lamina, pinocytotic vesicles, and Weibel-Palade bodies (Ishak et al, 1984; Lauffer et al, 1996; Mehrabi et al, 2006).

Treatment of HEHE is difficult. Resection is often not possible because of the presence of multifocal bilobar disease at the time of diagnosis. In the review by Mehrabi and colleagues (2006), only 9.4% of patients were amenable to resection. Patient survival was 100% at 1 year and 75% at 5 years. For many patients, observation alone is reasonable, because progression may be extremely slow, if it occurs at all. Others have reported poorer results (Ben-Haim et al, 1999) and have suggested that resection should be limited to patients presenting with unilobar, liver-confined disease (Mosoia et al, 2008).

Liver transplantation is an option for patients with extensive intrahepatic disease. Several series have reported outcomes equivalent to those for liver transplantation for other diagnoses. In a report from the European Liver Transplant Registry (ELTR), patient survival rates at 1, 5, and 10 years were 93%, 82%, and 72% with 90%, 82%, and 64% disease-free survival, respectively. Neither disease-free survival nor patient survival was influenced by neoadjuvant therapy, lymph node status, or the presence of extrahepatic disease; however, vascular invasion had a negative impact on patient survival (Lerut et al, 2007). A multicenter Canadian experience with 11 patients reported 5-year survival of 82% with a 36.4% recurrence rate (Nudo et al, 2008). A recent query of the UNOS database identified 110 patients who underwent OLT for HEHE in the United States between 1987 and 2005 (Rodriguez et al, 2008). Patient survival was 80% and 64% at 1 and 5 years. In their survey of the available literature, Mehrabi and colleagues (2006) reported 1- and 5-year patient survival of 96% and 54.5%, respectively, after OLT.

The Mayo Clinic recently reviewed its experience with 30 patients treated for HEHE between 1984 and 2007 (Grotz et al, 2010) and found a 2:1 female predominance with a mean age at diagnosis of 46 years (range, 21 to 79 years). The diagnosis of HEHE was confirmed in all cases by immunohistochemical staining for factor VIII–related antigen, CD31, and CD34. Patients were divided into groups based on the number and size of nodules present within the liver: half had 10 or fewer nodules, and half had more than 10 nodules; the largest lesion was smaller than 5 cm in 43%, it was 5 to 10 cm in 30%, and it was larger than 10 cm in 27% of cases. Extrahepatic disease was present at diagnosis in 37% of patients (n = 11). Sites of metastases included lung (n = 8), peritoneum (n = 2), bone (n = 2), brain (n = 1), and skin (n = 1), and one third of the patients had multiple sites of extrahepatic involvement.

Therapeutic management included OLT (n = 11), primary resection (n = 11), systemic chemotherapy (n = 5), and no medical treatment (n = 3). Median follow-up was 41.6 months (range, 0 to 243), and in this time, 12 deaths (40%) were reported, one patient died within 2 years of primary resection, six patients died after OLT (1 month to 11 years), and five patients treated nonsurgically died 1 month to 4 years after diagnosis. Patient survival following primary resection at 1, 3, and 5 years was 100%, 86%, and 86%, respectively, compared with 91%, 73%, and 73%, respectively, for patients treated with OLT. Patient survival following nonoperative management was 57%, 43%, and 29% at 1, 3, and 5 years, respectively. Disease-free survival following primary resection was 78%, 62%, and 62% at 1, 3, and 5 years, respectively, compared with 64%, 46%, and 46% after OLT. Although no significant differences were seen in patient survival ($P = .128$) or disease-free survival ($P = .405$), patients who underwent primary resection had significantly fewer tumor nodules and less diffuse liver involvement compared with those who underwent OLT ($P = .004$).

Morphologic features associated with prolonged disease-free survival were nodular disease pattern ($P = .01$) and largest hepatic lesion 10 cm or smaller ($P = .003$). Patients with 10 or fewer tumor nodules showed a trend toward better survival ($P = .052$). Factors associated with decreased overall patient survival were tumor size larger than 10 cm ($P = .0007$, hazard ratio [HR], 10.97; 95% confidence interval [CI], 2.76 to 43.68), more than 10 nodules ($P = .023$; HR, 5.83; CI, 1.27 to 26.8), diffuse disease pattern ($P = .0076$; HR, 8.14; CI, 1.75 to 37.91), and involvement of more than four liver segments ($P = .041$; HR, 4.92; CI, 1.06 to 22.77). The presence of extrahepatic disease did not have an impact on patient survival ($P = .5$).

The Mayo Clinic findings demonstrate that primary resection and liver transplantation achieve comparable survival for patients with HEHE. Resection is favored for patients with 10 or fewer lesions, involvement of four or fewer liver segments, and disease amenable to complete extirpation of tumor. Transplantation is recommended for those with more than 10 lesions, involvement of more than four liver segments, and unresectable disease.

SUMMARY

Liver transplantation is appropriate therapy for selected patients with malignancies other than HCC. Excellent results have been achieved for patients with unresectable hilar CCA and hilar CCA arising in the setting of PSC. Success requires rigorous adherence to protocol with careful selection of patients with early stage disease confined to the hilus along with neoadjuvant chemoradiotherapy and operative staging to exclude patients with regional lymph node metastases. Liver transplantation without prior neoadjuvant therapy is rarely successful and should not knowingly be performed for patients with CCA.

The role of liver transplantation in the treatment of metastatic NEC remains unclear. Experience to date shows that most patients develop recurrent disease; however, transplantation may prolong survival by delaying death from tumor replacement of the liver. Because of the indolent nature of the disease, survival beyond 5 years is achievable, but the actual benefit—that is, the difference in survival with and without transplantation—remains unknown.

Liver transplantation achieves results comparable to resection for patients with HEHE, and transplantation should be considered for patients with more than 10 nodules, involvement of more than four liver segments, or tumors not amenable to resection. Additional experience is necessary to confirm reports that transplantation is beneficial for patients with limited extrahepatic disease.

CHAPTER 98B

Living donor liver transplantation: open and laparoscopic

Alan J. Koffron and Julie A. Stein

OVERVIEW

Organ availability continues to be a major issue in contemporary transplantation. Living-donor renal transplantation is accepted globally as an important alternative to cadaveric renal transplantation for patients with end-stage renal failure. In 2008, living donors were the source of 36% of the total kidney transplants in the United States (United Network of Organ Sharing [UNOS], 2008). This is largely because the kidneys are paired organs, laparoscopic donor nephrectomy is widespread, and donor morbidity and mortality is low (Kocak et al, 2006).

Despite advances in hepatobiliary surgery, hepatic resection remains a technically demanding surgical endeavor, with higher complication rates than kidney transplantation (Miller et al, 2004a; Pomfret, 2003). Liver transplantation, now standard treatment for many hepatic diseases (see Chapter 97A), has gone through the same evolution as renal transplantation with respect to live donation. Transplantologists embarked on living-donor liver transplantation (LDLT) in the late 1980s, principally as a means to combat pediatric waiting-list mortality (Broelsch et al, 1991; Raia et al, 1989). The inception and refinement of LDLT and split-liver transplantation (see Chapter 98C) have significantly reduced pediatric waiting-list mortality (Testa et al, 2001), thus paving the way for the development of LDLT in adults.

As the indications for liver transplantation have broadened, and cadaveric organ supply has remained largely static, the waiting-list mortality for adults has increased. Thus, in the mid-1990s, as in pediatric transplantation, adult LDLT was initiated in response. In Japan, where death defined by neurologic criteria is not accepted, LDLT began with left-lobe adult LDLT (Hashikura et al, 1994), leading to right-lobe LDLT (Yamaoka et al, 1994) with substantial acceptance and growth of this practice in Asia (Chen et al, 2003), followed by initiation and refinement in the United States in the late 1990s (Boillot et al, 1999; Marcos et al, 1999; Miller et al, 2001; Wachs et al, 1998). Despite the inherent donor risks—and rare, but high-impact, donor deaths (Miller et al, 2004a; Fan et al, 2003)—right-lobe LDLT has remained a strong option in the treatment of liver disease. To that end, as of 2008, LDLT has made up 4% to 9% of all adult liver transplantations performed in the United States (UNOS, 2008). Currently, donor safety remains the primary focus of LDLT, superceding the omnipresent clinical incentive: the static cadaveric donor pool and transplant waiting-list mortality (Salame et al, 2002; Surman, 2002).

In 2002, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) established a multicenter clinical study, the Adult-to-Adult Living Donor Liver Transplantation (A2ALL) cohort study, which consists of nine transplant centers experienced in performing LDLT and a data coordinating center responsible for directing and maintaining a clinical database for the retrospective (1998 through 2003) and prospective (2004 through 2010) arms of the study. This study, in collaboration with the American Society of Transplant Surgeons (ASTS) and the Health Resources and Services Administration (HRSA) has two principal objectives: 1) to determine whether it is more beneficial for a liver transplant recipient candidate to pursue LDLT or wait for a deceased-donor liver transplant (DDLT), and 2) to study the impact of liver donation on the donor's health and quality of life. Secondary objectives will address selected biologic and clinical issues in transplantation structured around the comparison between DDLT and LDLT, including immunosuppression, malignancy, and hepatitis. Although the prospective arm of this valuable study is ongoing at the time of this publication, thus far, the resulting contributions have given considerable insight into LDLT, and these insights will be referenced in following sections of this chapter.

Congruent with the tenet of donor safety, reducing donor morbidity is of equal importance. The great advances that have been made in minimally invasive liver resection have now been applied to liver donation in hopes of reducing surgical morbidity and enhancing donor recovery. Similar to the evolution of recipient procedures, minimally invasive liver donation began in the pediatric setting, with laparoscopic harvest of the left lateral section (Cherqui et al, 2002). As centers gained experience in minimally invasive hemihepatectomy (Koffron et al, 2007a; O'Rourke & Fielding, 2004), these methods were carefully applied to right-lobe donation (Koffron et al, 2006) in the hope of reducing donor morbidity, enhancing recovery, and secondarily increasing the willingness to consider donation (Baker et al, 2009). These efforts show promise in their initial results, but greater experience and analysis of clinical outcomes is necessary to define the role of laparoscopy in liver donation and transplantation as a whole.

LIVING DONOR LIVER TRANSPLANTATION: INDICATIONS AND RESULTS

Many of the indications for LDLT are the same as those for liver transplantation in general (see Chapters 97A, 97C, 97D, and 97E). Given this, the reasons to consider LDLT as opposed to DDLT center largely on chronology with regard to hepatitis C virus (HCV), hepatocellular carcinoma (HCC), and the likelihood that a cadaveric donor organ would become available in a timely fashion. These reasons are always weighed against the tenet that it is unjustified to subject even a volunteer to the risks

inherent in donor hepatectomy if the recipient has a reasonable chance of receiving a cadaveric liver graft prior to medical decompensation or progression.

Pediatric Living Donor Liver Transplantation

In pediatric LDLT (see Chapter 98C), although the results in all indications are equivalent with whole-liver grafts, cadaveric graft allocation remains the major concern in the setting of acute hepatic failure. The combination of outcome and availability has made acute liver failure (ALF) a well-accepted indication for pediatric LDLT. For other indications for liver transplantation, split-liver transplantation—in which a cadaveric donor organ is divided to transplant two recipients—is an attractive and increasingly popular alternative to LDLT, and it avoids placing a healthy donor in harm's way.

Adult Living Donor Liver Transplantation

Experience has shown that although retransplantation is higher after LDLT, patient survival is similar to DDLT (Abt et al, 2004; Freise et al, 2008). There are many reasons for this phenomenon, many of which are related to implantation of a smaller allograft. It seems intuitive that the more advanced the liver disease (liver decompensation, severe portal hypertension), the more ill the patient, and consequently the need for greater hepatocellular mass. In this light, many centers would not perform LDLT on patients with Child-Turcotte-Pugh (CTP) class C cirrhosis, unless the donor can provide a graft of substantial size. Fortunately, in most circumstances, the current U.S. organ allocation system can accommodate such gravely ill patients with DDLT.

Adult LDLT in the treatment of fulminant hepatic failure (FHF) has a unique geographic paradigm. This phenomenon is largely a result of differences in organ donation. In Western countries, LDLT for acute hepatic failure has acceptable results (Sugawara et al, 2002a, 2003), but the organ allocation scheme in the United States places patients with ALF at highest allocation priority, and so it is favorable that DDLT would be available. Therefore, in the United States the concern is raised that LDLT for ALF may place live donors at unnecessary risk in a clinical situation in which a potentially clinically superior DDLT may be possible. The A2ALL retrospective study resulted in a similar conclusion (Campsen et al, 2008). In the nine U.S. transplant centers, LDLT was rarely performed for ALF but was associated with acceptable recipient mortality and donor morbidity; however, the authors raised the concern that a partial graft might result in reduced survival of critically ill recipients and that the rapid course of ALF would lead to selection of inappropriate donors.

This contrasts sharply with the role of LDLT for ALF in Asia, where cadaveric donation is scarce. Here, LDLT accounts for more than 90% of the liver transplantations (de Villa & Lo, 2007; Kobayashi et al, 2003; Lubezky et al, 2004). FHF was the indication for transplantation in 5.7% of the adult LDLT series reported by the Asian group (Lee et al, 2007), in 12% of the series reported by the Hong Kong group (Lo et al, 2004), and in 14.6% of the series reported by the Kyoto group (Morioka et al, 2007); therefore in the East, the consensus is reflected in the findings of a large study on this subject (Ikegami et al, 2008). Over 10 years, 42 LDLTs performed for ALF were reviewed, concluding that outcomes were acceptable even in severely ill recipients, and that LDLT is the accepted treatment of choice for ALF.

Investigation of LDLT has provided clarity in other aspects of this form of liver therapy. Interestingly, results of the A2ALL retrospective cohort study did not show an immunologic advantage for LDLT versus DDLT (Shaked et al, 2009). Longer cold ischemia time was associated with a higher rate of acute cellular rejection in both groups despite much shorter median cold ischemia time in LDLT.

In terms of general recipient complications, the A2ALL study has provided additional data regarding LDLT. Complication rates were higher after LDLT (median, 3%) versus DDLT (median, 2%) and included biliary leak (32% vs. 10%), unplanned reexploration (26% vs. 17%), hepatic artery thrombosis (6.5% vs. 2.3%), portal vein thrombosis (2.9% vs. 0.0%), and complications leading to retransplantation or death (15.9% vs. 9.3%; $P < .05$) (Freise et al, 2008). Most notably, this analysis demonstrated that although the complication rates were initially higher with LDLT, with increasing center experience, complication rates declined to levels comparable to DDLT.

Hepatitis C Virus

Considerable reservations surround LDLT for patients with HCV (see Chapters 64 and 97A). If a patient has detectable HCV RNA before transplantation, the concern is that recurrence after LDLT may rapidly progress to cirrhosis and graft loss. In the first half of the decade, many centers reported that the course of recurrent HCV after LDLT was worse than in patients who received DDLT (Bozorgzadeh et al, 2004; Gaglio et al, 2003; Garcia-Retortillo et al, 2004; Shiffman et al, 2004; Zimmerman & Trotter, 2003), causing some centers to avoid performing LDLT for this indication (Garcia-Retortillo et al, 2004).

In addition, it has been shown that the degree of transplant center experience may influence the outcome after LDLT for HCV. The A2ALL retrospective study found that graft and patient survival was significantly lower for LDLT in centers of limited experience (<20 cases), but 3-year graft and patient survival were not significantly different (Terrault et al, 2007). This may be a significant factor, as there are more recent reports that are encouraging for LDLT in the treatment of HCV.

Although the hepatocellular mechanisms remain unknown, Schmeding and colleagues (2007) studied 289 patients and found that the intensity of HCV recurrence was not increased in living-donor graft recipients compared with recipients of full-size grafts. These findings have been reported by other groups (Takada et al, 2006). Furthermore, there is encouraging evidence that when HCV recurrence occurs, combination therapy with ribavirin and interferon appears to improve the outcome of recurrent HCV-infected patients after LDLT (Park et al, 2007).

One specific advantage of LDLT in the treatment of HCV is the ability to optimize transplantation timing. It has been reported that patients who clear HCV RNA with interferon/ribavirin have a high likelihood of remaining HCV RNA-negative after transplantation (Berenguer & Wright, 2003). The availability of a living donor allows for treatment of HCV to proceed to transplantation shortly after HCV RNA clearance has been achieved. Unfortunately, pretransplantation treatment used to prevent progression of disease or to minimize recurrence posttransplantation has highly variable effectiveness, tolerability, and outcome.

In attempts to allow greater patient tolerance and thereby achieve HCV RNA clearance prior to transplantation, the so-called low accelerating dose regimen (LADR) has been studied. Using LADR, Everson and colleagues (2005) studied 124 patients, and although 63% experienced treatment-related complications, 46% patients were HCV RNA negative at the end of treatment, 24% in follow-up; more significantly, 12 (80%) of 15 who were RNA negative before transplantation remained negative for 6 months after transplantation. One of the secondary aims of the A2ALL cohort prospective study is to evaluate LADR in combination with LDLT for reducing post-transplantation HCV recurrence.

Primary Hepatic Malignancy

Liver transplantation is now considered a treatment option for unresectable primary hepatic malignancy. The guidelines for LDLT in the treatment of malignancy largely parallel DDLT for both HCC and cholangiocarcinoma as discussed in Chapters 97D and 97E, respectively. But because of constraints in organ supply and allocation, as well as in the timing of transplantation, LDLT offers several strategic options not available in DDLT.

The growth of LDLT has been fostered in part by the inherent ability to treat hepatic malignancy with the chronologic advantage that scheduled LDLT provides. This is particularly evident in the treatment of HCC. In cirrhotic patients with early stage, unresectable HCC, transplantation is the favored treatment. Under the constraints of the Milan criteria (see Chapter 97D), posttransplantation survival rates equal those in patients without HCC. Patients with HCC within the Milan criteria are given added priority in the organ-allocation system. The combination of this systematic design, combined with therapies to delay tumor progression, such as ablation and arterial-based therapy, results in generally accepted outcomes. In spite of this validated process, some patients may incur prolonged waiting times. This time may allow for progression in some of these patients (Yao et al, 2003), excluding them as transplant candidates under the established guidelines.

In this circumstance, LDLT allows patients with HCC to proceed more rapidly to transplantation, potentially reducing the chance of tumor progression and/or posttransplantation recurrence. This has logically led many centers to offer LDLT for HCC; and similar to DDLT, the efficiency and efficacy of LDLT for HCC is widely reported (Gondolesi et al, 2004c; Kaihara et al, 2003; Todo & Furukawa, 2004). However, as LDLT is increasingly utilized to treat patients with locally advanced HCC not prioritized under the organ-allocation system, patients with large tumors logically experience a higher rate of recurrence (Axelrod et al, 2005).

In the era of limited organ availability, it is necessary to impose guidelines such as the Milan criteria to reduce post-transplantation cancer recurrence and to use resources wisely. This is the setting in which LDLT can provide a therapeutic alternative. In carefully selected patients, those who have been studied to determine that estimated risk of HCC recurrence is low enough to justify placing a healthy donor at risk, LDLT may provide benefit without taxing the organ pool. The acceptable success rates and controversial expanded HCC criteria designed to select such patients have been proposed by numerous centers (Bruix & Llovet, 2002; Gondolesi et al, 2004c; Lang et al, 2002).

Despite the sincere desire, and obvious ability, to treat patients with HCC, caution and practicality should supercede. LDLT may limit the waiting time and, as a result, may decrease the progression of disease so that the recurrence rate, intuitively, should be lower than for recipients awaiting DDLT; however, the reverse may also occur, and rapid transplantation may preclude waiting-list drop out, leading to higher recurrence post-transplantation. One example of this phenomenon was reported by the Northwestern group (Kulik & Abecassis, 2004), who reviewed the institutional experience in LDLT for HCC and found a higher recurrence rate, stage for stage, in recipients whose transplantations were accelerated ("fast tracked") by performing LDLT, especially in the prior era, in which patients with HCC were disadvantaged by the allocation algorithm. Clearly, the role of LDLT in management of patients with HCC requires prospective direct analysis of both recurrence and drop-out rates in comparable patient cohorts with HCC undergoing either deceased- or living-donor liver transplantation.

DONOR EVALUATION

The appropriate liver donor for LDLT is a legal adult who is healthy, without liver disease, not significantly overweight, has a blood type compatible with the recipient, and is able to provide a graft of adequate size. Donor evaluation is carried out by a physician who serves as the donor's advocate physician (New York State Committee on Quality Improvement in Living Liver Donation, 2002). The comprehensive medical evaluation includes 1) a complete history and physical examination; 2) blood analysis to exclude viral and autoimmune liver disease, diabetes, hyperlipidemia, and hypercoagulable states; 3) cardiology clearance; and 4) extensive psychosocial evaluation, with psychiatry consultations in cases of even minor concern.

As in resection for other indications, patient (potential donor) obesity increases perioperative risk and degree of hepatic steatosis. It is known that magnetic resonance imaging (MRI) can predict the presence of significant steatosis (>15%) and simplify donor evaluation in overweight candidates (Rinella, et al, 2003). Routine preoperative biopsy is not widely practiced (Ryan et al, 2002), but in many centers, potential donors who are significantly overweight (Schiano et al, 2001) or who have MRI findings suggestive of steatosis undergo liver biopsy to fully assess both donor and recipient short- and long-term risk (Hwang et al, 2004).

Our understanding of steatosis and its effect in liver transplantation has improved (Soejima et al, 2003b), and guidelines for DDLT have been established (Fishbein et al, 1997; Uchino et al, 2004). In LDLT, where liver mass is limited, hepatic steatosis must be considered in the calculation of true hepatocellular mass to ensure adequate engraftment (Limanond et al, 2004).

Estimation of graft volume (GV) is critical in LDLT to optimize donor safety and recipient outcome. Liver volume can be estimated by calculation or imaging, but no consensus exists on the most clinically effective method. To provide clarity in this dilemma, one study examined the accuracy of formula-derived GV estimates and compared them to both radiogically derived estimates and actual measurements (Salvalaggio, et al, 2005). This study found a marginal concordance between the formula-derived calculation and GV for right-lobe donors, but the error ratio was lower than for radiologic estimates; in contrast, MRI measurements for left lateral section grafts demonstrated a

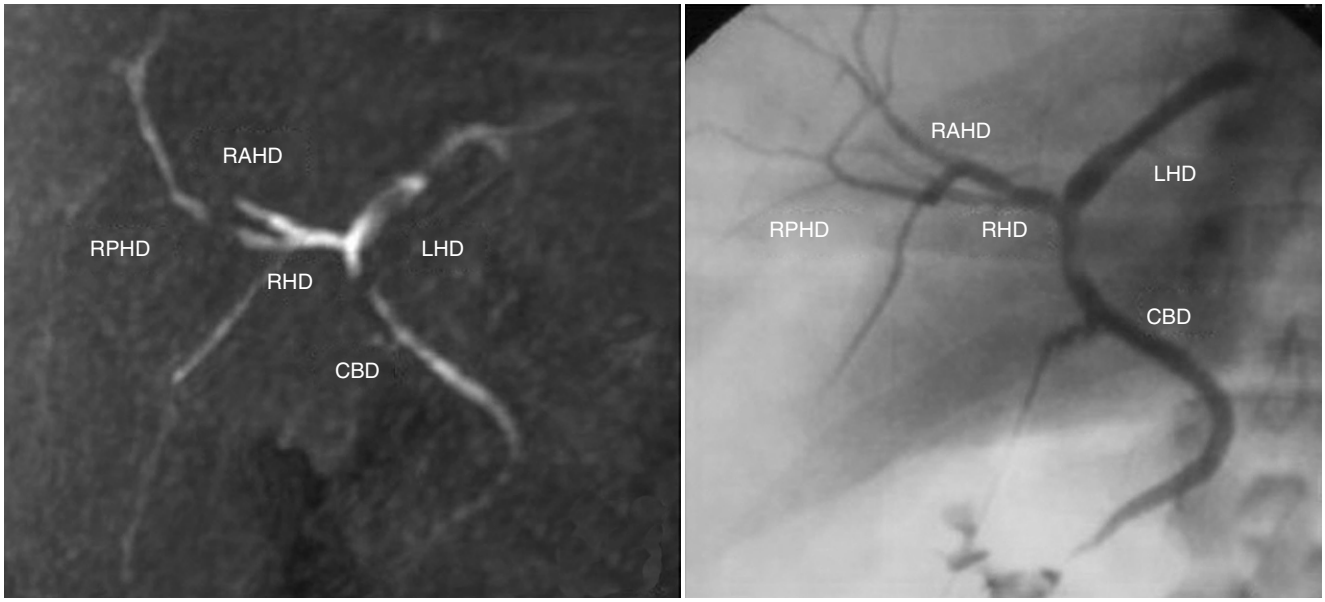

FIGURE 98B.1. Example of preoperative mangafodipir-enhanced magnetic resonance cholangiogram and operative cholangiogram. CBD, common bile duct; LHD, left hepatic duct; RAHD, right anterior hepatic duct; RHD, right hepatic duct; RPHD, right posterior hepatic duct.

lower error ratio than formula-derived estimation. The authors therefore concluded that formula-derived estimates of GV should be routinely used in the initial screening of potential living donors.

Following successful medical clearance, liver vasculobiliary anatomy and graft-remnant liver volumes are assessed radiologically. MRI that includes arteriography (MRA), venography (MRV), and cholangiography (MRC) is frequently chosen, as it simultaneously defines graft-remnant liver volume, vascular and biliary anatomy, and overall hepatic integrity. MRC with mangafodipir trisodium may be used to enhance visualization of small-order biliary structures (Fig. 98B.1; Cheng et al, 2001; Goldman et al, 2003; Yeh et al, 2004).

Advances in both imaging hardware and software allow greater resolution and computer-assisted surgical simulation, aiming to improve accuracy and both donor and recipient outcome. It is logical that accurate assessment of liver graft anatomy is also pivotal in the recipient procedure, allowing management of the multitude of possible anatomic variations.

ANATOMIC VARIATIONS (SEE CHAPTER 1B)

The general segmental anatomy of the liver provides reliable external landmarks for living donation. Using the main hepatic scissura, anatomic resection of the left lateral section and hemilivers is commonplace for a wide variety of indications (see Chapters 90A and 92); however, LDLT relies not only on successful resection but also on the need to maintain intrahepatic and extrahepatic vasculobiliary structures, first, for donor remnant liver viability, and second, to facilitate reconstruction and implantation in the recipient. Therefore, to be successful, identification and management of the hepatic anatomy is crucial throughout the donor and recipient procedures. The following sections focus on the anatomic variations influential in LDLT.

Hepatic Artery

A great understanding and comfort managing arterial variations has resulted from liver transplantation. It is imperative to delineate precisely the arterial anatomy, because "normal" anatomy is present in just over half of the population (Gruttadauria et al, 2001; Hardy & Jones, 1994; Hiatt et al, 1994; Kawarada et al, 2000). The described arterial anatomic variations and their frequency are depicted in Figure 98B.2 (Varotti et al, 2004).

It is intuitive that arterial anatomy would have considerable impact on both donor candidacy and recipient surgical management. Experience has shown that a totally replaced right or left hepatic artery simplifies, rather than complicates, donor hepatectomy; in such situations, greater vessel length may be obtained. Rarely, imaging identifies two arteries supplying the graft. Although back-table reconstruction is possible (Marcos et al, 2001a, 2003), it may be prudent to evaluate other potential donors, if the surgical team has concerns about the recipient procedure.

Portal Vein

Clinically significant portal variations are less common than arterial variations (Nakamura et al, 2002) but have equal technical implications in both the donor and recipient procedures. These variations involve the configuration of the right portal vein bifurcation into sectorial branches. Instead of a portal bifurcation and a left and right common portal trunk, the right anterior and posterior sectorial branches may arise separately, effectively forming a portal trifurcation (Fig. 98B.3). When these sectorial branches arise immediately adjacent to each other, it is sometimes possible to leave a common wall between them to allow for single anastomosis in the recipient; however, sectorial branches that are significantly separated must be taken

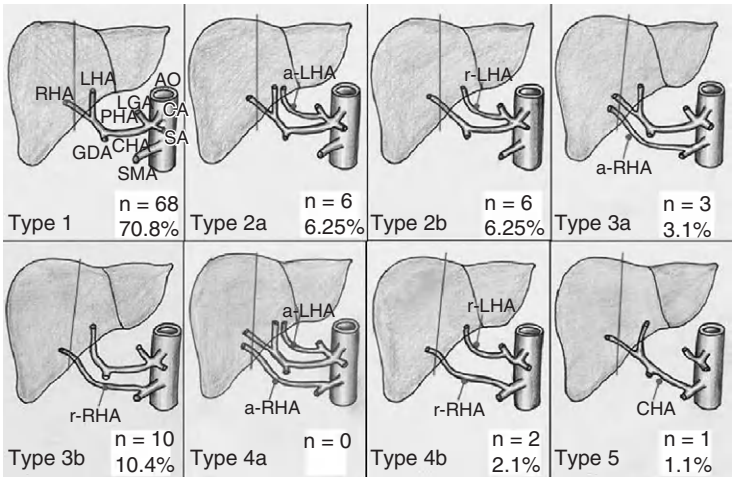

FIGURE 98B.2. Classification and incidence of the common anatomic variations of the hepatic artery. AO, aorta; a-LHA, accessory left hepatic artery; a-RHA, accessory right hepatic artery; CHA, common hepatic artery; GDA, gastroduodenal artery; LGA, left gastric artery; LHA, left hepatic artery; PHA, proper hepatic artery; RHA, right hepatic artery; r-LHA, replaced left hepatic artery; r-RHA, replaced right hepatic artery; SA, splenic artery; SMA, superior mesenteric artery. *(From Varotti G, et al, 2004: Anatomic variations in right liver living donors. J Am Coll Surg 198:577-582.)*

individually to avoid altering the portal flow to the remnant left lobe. Logically, to use such a lobe for LDLT, an extensive reconstruction using a bifucated interposition graft, such as a recipient portal vein bifurcation, is required (see Fig. 98B.3; Varotti et al, 2004). For this reason, many centers may choose to find a donor with less complex anatomy.

Biliary Anatomy

Biliary anatomic variations (Fig. 98B.4) tend to mimic those of the associated vascular structures, especially the portal vein (Lee, et al, 2004), but they may have greater surgical impact, particulary in right-lobe LDLT.

The standard anatomy consists of a confluence of left and right hepatic ducts to form the common hepatic duct. Usually, the segment II and III ducts join in the umbilical fissure, and dividing the hilar plate in this area provides a single duct for anastomosis (Renz et al, 2000). During left-lobe donation, care must be taken to avoid injury to a right posterior sectorial duct that is found to cross the Cantlie line, joining the left hepatic duct at the base of segment IV (see see Fig. 98B.4).

Right-lobe biliary anatomy may be quite complex. Only half of the donors have a single right hepatic duct (Kawarada et al, 2000) or a short duct, which is divided proximally in the interest of donor safety. Logically, the incidence of biliary complications increases with more complex anatomy and anastomoses (Gondolesi et al, 2004a). The most difficult variation is perhaps a right posterior sectorial duct draining into the left hepatic duct, which may be inadvertently transected, as it lies cephalad and posterior to the right portal vein. Because of its location, this bile duct branch is particularly difficult to reconstruct once the portal vein is anastomosed in the recipient.

Hepatic Veins

The variations in hepatic venous anatomy typically do not pose significant difficulty for left lobe or left lateral section donation. A common venous trunk of the middle and left hepatic veins is the usual configuration, facilitating a single venous outflow anastomosis in a left-lobe graft. Left lateral section grafts may be more complex. The confluence of the segment II and III veins may be at or near the junction with the middle hepatic

J Am Coll Surg 198:577-582.)*

vein. Safe donation may render two veins with a common septum, or it may necessitate performance of a side-to-side venoplasty to simplify implantation.

The venous drainage of the right lobe is much more complex. Typically, the right hepatic vein represents the main venous outflow of the right hemiliver, although variations occur that may drain individual liver segments (Fig. 98B.5). For this reason, in many centers, surgical decision making has evolved from considering the right liver as a whole to considering segmental venous drainage.

Although still somewhat controversial, it is generally agreed that venous structures 5 to 10 mm in diameter constitute significant drainage of the graft; therefore identifying and characterizing these structures has significance in LDLT. As illustrated in Figure 98B.5, imaging frequently identifies significant veins draining the anterior and posterior sectors. Those veins draining the posterior sector directly into the cava (e.g., segment VI inferior vein) may be preserved and reimplanted (Hwang et al, 2004). Anterior sector (segment V and VIII) veins drain into the middle hepatic vein. These may require preservation and later reconstruction in cases of marginal graft-recipient weight ratio (GRWR) and/or significant recipient portal hypertension (Sugawara & Makuuchi, 2001).

GRAFT SIZE AND SMALL-FOR-SIZE SYNDROME

We are only beginning to understand the unique ability of the liver to regenerate after injury or resection (see Chapter 5). Since the genesis of LDLT, however, one persistent problem has been posttransplantation hepatic insufficiency as a result of small graft mass (Lo et al, 1999). This underscores the importance of accurate estimation in the donor, especially as there is significant variation in total liver volume relative to body size and in the configuration of the liver (Gondolesi et al, 2004b).

Predonation imaging can accurately estimate the total donor liver volume and the volume of the proposed graft. Formulas to estimate expected liver volume have also been developed (Yoshizumi et al, 2003) and are slightly superior to imaging in donor screening (Salvalaggio, et al, 2005). Many centers use a combination of techniques to screen and then confirm the graft weight, which is then compared with the weight of the potential recipient. The ratio of the estimated weight of the donor liver graft to the weight of the recipient, expressed as a percent, is the GRWR.

It is well established that when the GRWR is less than 0.8%, there is significant risk of the recipient developing *small-for-size syndrome* (SFSS) (Sugawara et al, 2001). SFSS is posttransplantation hepatic insufficiency presenting as prolonged cholestasis, coagulopathy, and ascites formation in the absence of hepatic vascular insufficiency (see Chapter 100). Because this results in death or the need for retransplantation in half of the patients, over time the use of the right lobe has become the preferred graft in adult LDLT. The exception is when a very large person donates to a smaller recipient, where a left-lobe graft may be of adequate mass.

Additional factors contribute to recipient SFSS, including advanced cirrhosis, portal hypertension, and associated hyperdynamic splanchnic circulation. It is known that recipients of this type require a GRWR greater than 0.8% (Ben-Haim et al, 2001). The splanchnic hemodynamic mechanisms responsible for SFSS are poorly understood (Asakura et al, 1998; Gondolesi et al, 2002b; Huang et al, 2000; Niemann et al, 2002; Piscaglia et al, 1999). In attempts to reduce the hyperdynamic portal circulation and abrogate graft injury, some centers have studied adjunctive splenectomy, portosystemic shunt, or octreotide infusion with mixed results (Masetti et al, 2004; Troisi & de Hemptinne, 2003).

Although certainly an important factor for liver graft function in general, optimizing liver graft outflow, is a possible way to reduce hyperdynamic liver injury. In right-lobe grafts, the outflow of the anterior sector to the middle hepatic vein, via segment V and VIII veins, is variable. In patients in whom the GRWR is low, surgical reconstruction of these middle hepatic vein tributaries may reduce hepatic congestion and potentially prevent the development of SFSS (Sugawara et al, 2004). Venous reconstruction may be in the form of including the main trunk of the middle hepatic vein with the graft, or interposition grafting can be used to recreate the intrahepatic middle hepatic vein.

Another proposed method of avoiding SDSS is increasing liver mass by using dual liver grafts. One center reported their preliminary experience using dual grafts from one right lobe without the middle hepatic vein and one left lateral segment in adult-adult LDLT (Chen et al, 2009). They concluded that dual grafts prevent SFSS in adult-adult LDLT and secure the safety of the donors. Although this strategy reduces the individual donor risk by avoiding extended resection, it places two individuals at risk in efforts to perform a safer transplantation in one recipient; further study will clarify the utility of this approach in LDLT.

DONOR AND RECIPIENT SURGICAL PROCEDURES (SEE CHAPTER 90D)

General Principles

It is paramount to make donor safety the primary concern when contemplating liver donation leading to LDLT. Despite the enormous advances in surgical conduct and patient care in hepatobiliary surgery, live donation places a person who lacks medical indications for surgery in a potentially life-threatening situation for the medical improvement of another. In addition, contrary to pathology-based liver resection, in LDLT there is equal concern for the portion of the liver to remain in the donor (remnant liver) as for the portion being donated; therefore identifying and managing the hepatic vasculobiliary anatomy has particular significance to ensure 1) the remant liver is fully viable and able to regenerate and continue normal function in the donor, and 2) the donated portion is anatomically amenable to successful transplantation in the recipient. Furthermore, in efforts to avoid ischemic injury to the liver graft, hepatic inflow occlusion is generally avoided during parenchymal transection, but some centers find it of no clinical consequence (Imamura et al, 2004; Miller et al, 2004b).

One clinical advantage of LDLT is the ability to choreograph both the donor and recipient procedures, not only the timing of transplantation in the medical course of the recipient, reducing hepatic graft cold ischemic time during the event. The procedures are performed by two separate surgical teams, in adjacent rooms, such that donor safety is optimized, and liver graft is transferred efficiently. Typically, the donor operation takes longer than the recipient hepatectomy, and therefore the donor procedure is begun first; however, when there is concern that the recipient operation could be aborted, such as upon finding hepatic malignancy, the procedures are reversed. When the recipient is being transplanted for hepatic malignancy, the recipient is surgically explored to exclude disease undetected on preoperative studies, and the donor procedure is initiated, if no recipient contraindications are found (Gondolesi et al, 2002a).

The combination of ever-increasing experience in living donor hepatectomy and minimally invasive liver surgery and the ubiquitous desire to minimize donor morbidity has led to the application of minimally invasive techniques in transplantation. Thus far, these advances have been applied to liver donation surgery. Although initial experience in minimally invasive and robotic-assisted renal transplantation is expanding (Hoznek et al, 2002; Rosales, 2010), the ability to perform laparoscopic liver recipient procedures seems doubtful because of graft size and operative domain requirements.

In the following sections, both the open and minimally invasive liver-donation procedures will be described. These sections will focus on laparoscopic variations, as the open procedures are reviewed in detail in Chapter 90D.

Left Lateral Section Transplantation

Open Donor Procedure

The abdomen is entered by a variety of candidate incisions—upper midline, left subcostal, or bilateral subcostal incision with an upper midline extension to the xiphoid—depending on donor habitus and the surgical exposure needed. The left lobe is mobilized by dividing the teres, falciform, coronary, and left triangular ligaments, and these are inspected. Ultrasound (US) may be used to confirm intrahepatic vascular anatomy. In addition, cystic duct cholangiogram may be performed to localize the left hepatic duct in cases where early division of segement II and III ducts is suspected.

Once anatomic variations identified preoperatively are confirmed, the gastrohepatic omentum is divided. During this time, dissection proceeds carefully to preserve a replaced left hepatic artery arising from the left gastric artery to facilitate reconstruction during the recipient procedure (Kostelic et al, 1996). If present, the parenchymal bridge overlying the umbilical fissure between segments III and IV is divided, exposing the left portal structures within the umbilical fissure. Vascular dissection is approached at the origin of the left hepatic artery and proceeds distally. If there is more than one artery supplying segments II and III, all are carefully preserved in the donor for later reconstruction (Soin et al, 1996; Suzuki et al, 1971). The artery supplying segment IV is sacrificed, unless it originates proximal enough to be preserved and yet provide adequate arterial length to the graft, or if it arises from the right hepatic artery (Fig. 98B.6). The resultant ischemia of segment IV is tolerated well in the donor with expected radiographic postsurgical changes (Shoji et al, 2003).

The full length of the left portal vein is isolated by sacrificing the portal branches to segment IV medially and the caudate lobe dorsally (see Fig. 98B.6; Broelsch et al, 1991). The left hepatic vein is isolated, including division of the ligamentum venosum, but carefully preserving the middle hepatic vein, as the left and middle veins unite in, or just cranially to, their exit from the hepatic parenchyma. The segment II and III bile duct is divided sharply at the hilar plate at the base of the umbilical fissure, and the distal end is oversewn. The parenchyma between segment IV and segments II and III is divided using the dissecting device of the surgeon's choice without hepatic inflow occlusion.

Now that the liver graft is separate from the remnant right trisegment, the left hepatic artery is ligated proximally and divided, the left portal vein and left hepatic vein are divided (cut

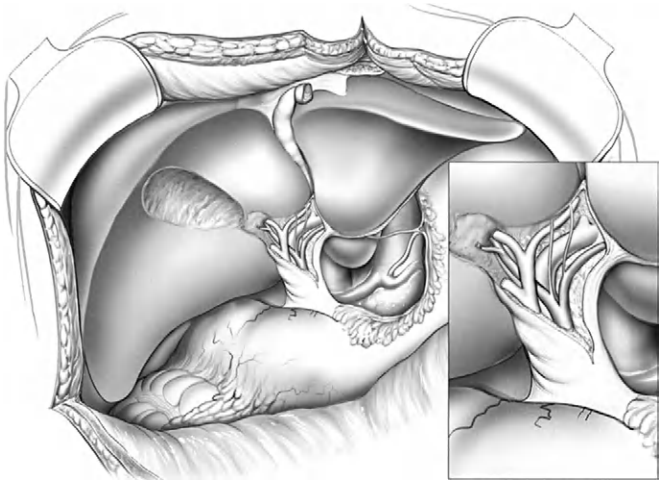

FIGURE 98B.6. Hilar structures for the left lateral segment are exposed. When the segment IV artery arises separately from the segment II and III arteries (*inset*), it is preserved in the donor. Portal vein branches to segment IV are ligated before parenchymal transection.

ends are oversewn in the donor), and the liver graft is removed. The graft is taken promptly to the back-table and is flushed with preservative and prepared for implantation (Tanaka et al, 1993; Yamaoka et al, 1995).

Laparoscopic Donor Procedure

Cherqui and colleagues (2002) first described the laparoscopic donor procedure, which consists of removing segments II and III, left arterial and portal inflow, left bile duct, and left hepatic vein without hepatic inflow occlusion (see Chapter 90E). Logically, the operative strategy and extent of vascular dissection parallels that of the open procedure.

With the donor under general anesthesia, in supine position with legs abducted, laparoscopy is achieved using a five-trocar approach. The left lobe is mobilized by dividing the teres, falciform, and left triangular ligaments. Using a laparoscopic dissector, the left branches of the hepatic artery and the portal vein are dissected and encircled, and the arterial and portal branches to the caudate lobe are clipped and divided. The liver parenchyma is divided on the right side of the teres and falciform ligaments, including the pedicles to segment IV, with a coaptive sealing device to achieve hemostasis during transection with a linear stapler. The left bile duct is then transected sharply, and the proximal end of the duct is sutured. Hepatic parenchymal transection progresses up to the level of the left hepatic vein, which is isolated, leaving the graft attached to the remnant liver by its vascular connections only. As in the open procedure, extreme caution is taken to avoid injuring the middle hepatic vein at the cranial margin of the liver.

For graft extraction, a 10-cm suprapubic cutaneous incision is made, allowing insertion of a large specimen retrieval bag. The graft is finally retrieved by clipping and dividing the arterial branch and using the linear stapler to secure the left portal and hepatic veins, completing the suprapubic incision by section of the fascia, muscle, and peritoneum, venting the pneumoperitoneum and removing the specimen bag through this incision. The graft is prepared for transplantation, while the incisions are closed, thereby completing the donation procedure.

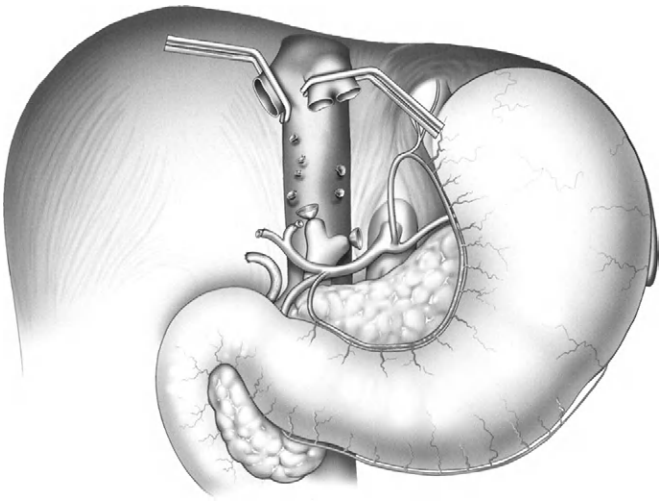

FIGURE 98B.7. Recipient hepatectomy is performed with preservation of the vena cava. The right hepatic vein and the middle hepatic vein–left hepatic vein confluence are clamped separately. Dissection is performed high in the hilum to preserve the bifurcation points of the portal structures.

Recipient Procedure

As in all varieties of LDLT, recipient hepatectomy is performed with both preservation of the recipient vena cava and meticulous dissection of the hepatic hilum to preserve maximum length of the hepatic artery and portal vein (Fig. 98B.7).

Once the diseased liver is removed, the recipient vena cava is occluded; this allows the orifices of the hepatic veins to be joined sharply to create a common orifice that matches the donor left hepatic vein. This maneuver is pivotal in creating the maximum achievable graft outflow tract. The venous anastomosis is created in a wide, triangular fashion (Fig. 98B.8).

The venous anastomosis is completed in a manner that allows later graft flushing prior to reperfusion. The graft left portal vein is anastomosed to the recipient portal bifurcation or, if indicated, to the level of the mesenteric-splenic confluence,

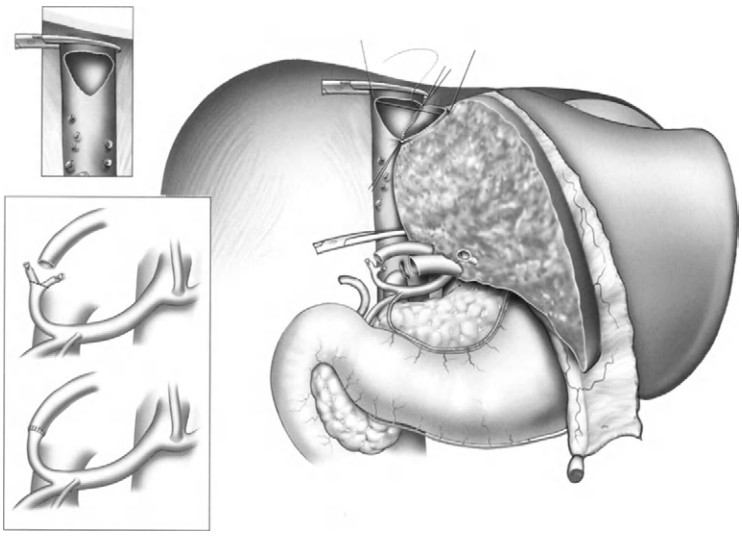

FIGURE 98B.8. The ostia of the hepatic veins are joined, and the cava is incised caudally to create a wide triangular opening (*top inset*) to match up to the donor left hepatic vein. The proper hepatic artery usually is transected at its bifurcation to match up to the donor left hepatic artery (*bottom inset*).

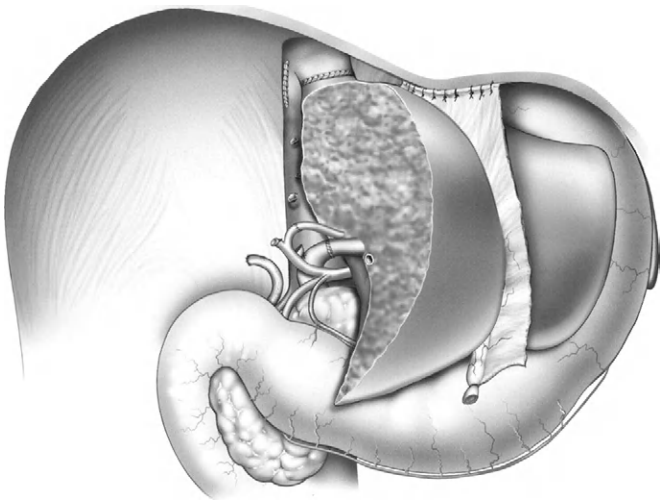

FIGURE 98B.9. The left-lobe graft with completed vascular anastomoses and reattachment of the falciform ligament.

utilizing an autologous venous interposition graft. To prevent anastomotic coarctation, the portal anastomosis is performed with interrupted sutures (Emre, 2001) or with a running suture tied for a large growth factor. The hepatic arterial reconstruction is performed under high magnification, using a surgical loupe or an operating microscope, typically by creating a hepatic artery bifurcation branch patch to match the size of the hepatic artery of the graft (see Fig. 98B.8; Stevens et al, 1992; Wei et al, 2004). Biliary-enteric continuity is achieved with a Roux-en-Y hepaticojejunostomy (Fig. 98B.9).

Left Hepatic Transplantation

Open Donor Procedure

The approach for the donor procedure is similar to that for the left lateral section, although the left medial section is not devascularized. Following exposure and mobilization of the left hemiliver, cholecystectomy is performed, and the left hepatic artery and left portal vein are isolated at their origin. Aberrant arterial anatomy is identified and preserved for possible later reconstruction, including a large segment IV artery originating from the right hepatic artery. The hilar plate is lowered at the biliary confluence, and a cholangiogram via the cystic duct confirms both the biliary anatomy and the site of safe left hepatic duct transection. The left hepatic duct is isolated and divided, and the remnant side is secured. The posterior right hepatic duct may cross the Cantlie line to enter the left hepatic duct in some donors, therefore care must be taken to divide the left hepatic duct to the left of the anomalous entry (Soejima et al, 2003a; Varotti et al, 2004).

Many centers choose to include the caudate lobe with a left-lobe graft, given the left portal inflow, biliary drainage, and added hepatic mass (Fig. 98B.10; Abdalla et al, 2002; Miyagawa et al, 1998; Takayama et al, 2000).

The left lobe is elevated, the caudate is dissected off of the vena cava to the base of the Cantlie line, and the caudate vein proper is encircled. The left and middle hepatic veins are isolated above the liver, utilizing the technique of Arantius for simplification. Temporary inflow occlusion may be used to delineate the transection plane at the Cantlie line. The parenchyma is transected, which may be facilitated by the so-called hanging maneuver (Belghiti et al, 2001; Broering et al, 1998). The intrahepatic middle hepatic vein is divided as it courses into segment IVa, allowing procurement of left and middle hepatic veins with the graft.

With the transection complete, the left hepatic artery and left portal vein are ligated and divided, the hepatic veins are clamped and divided, and the graft is removed. While the graft is flushed and prepared on the back table, the hepatic vein remnant is oversewn in the donor, hemostasis and biliostasis are ensured, and the donor procedure is concluded.

Laparoscopic Donor Procedure

There is extensive global clinical experience in left-lobe LDLT. Although some centers are performing laparoscopic donor hepatectomy for the left lateral section and right lobe, only limited minimally invasive left-lobe donors have been reported (Kurosaki, et al, 2006). In this report, 10 left-lobe donor procedures (5 including the caudate lobe) were reviewed, exhibiting good donor and recipient outcomes. The technique utilized is video-assisted and is summarized below.

The video access is accomplished by either the abdominal wall–lifting method or under CO_2 pneumoperitoneum. In those procedures utilizing the lifting method, a 12-cm minilaparotomy is made in the upper abdomen. A lifting retractor is used for elevating the abdominal wall, and dissection proceeds via three to five working ports, including optics by flexible laparoscopy. The surgeon is positioned at the right side of the patient with two assistant surgeons and a laparoscopist.

Mobilization of the liver is performed laparoscopically, including short hepatic veins, which are dissected and sealed using a coaptive device or clips. In left lobe/caudate lobe donors, the caudate lobe is dissected through the foramen of Winslow, mobilizing it from the inferior vena cava (IVC) to the level of a prominent caudate vein. Retraction of the caudate lobe is performed via minilaparotomy in cases without a pneumoperitoneum. The caudate hepatic vein is dissected and encircled, and the common trunk of the middle and left hepatic veins are exposed in preparation for the hanging maneuver to facilitate parenchymal transection.

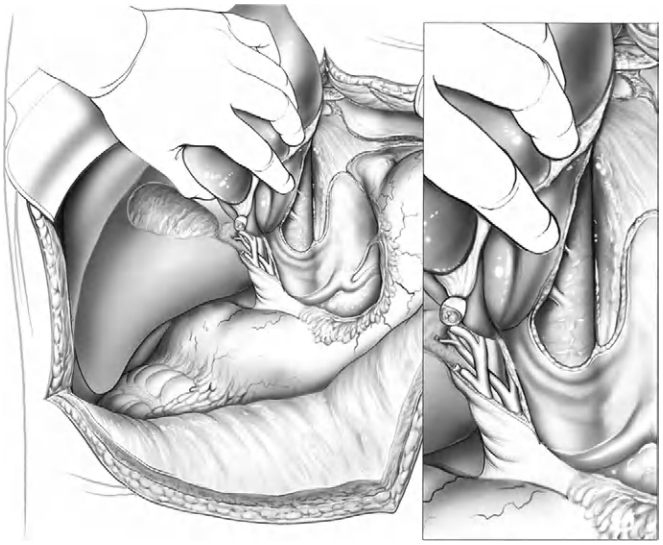

FIGURE 98B.10. Dissection of the caudate lobe off of the vena cava during preparation of a left-lobe graft.

The structures within the porta hepatis are dissected and isolated using a combination of laparoscopy and direct operation via the minilaparotomy, allowing the left portal vein and hepatic artery to be encircled. The left hepatic duct is divided after the cholangiography, and the distal end is sutured via the minilaparotomy. During parenchymal transection, space between the liver and the IVC was created using a combination of the hanging maneuver and upward traction on the falciform ligament. The left hepatic donation is made under intermittent inflow occlusion of the right liver, and the line of hepatic transection is determined by demarcation during vascular occlusion. The transection is performed using a combination of ultrasonic dissection and bipolar irrigation electrocautery, avoiding injury to the hepatic arteries, portal vein, and hepatic veins.

Initially, the caudate lobe and caudate process are divided at the base of the Cantlie line, and the tape for the hanging maneuver is relocated anterior to the porta hepatis. The deep parenchymal dissection proceeds along the tape via the minilaparotomy. Once the transection is complete, the hepatic veins and the caudate hepatic vein are skeletonized through the space created between the hemilivers. Under systemic anticoagulation, the left hepatic artery is divided at its origin, the left portal vein is clamped and divided at the bifurcation of the common portal vein, the caudate hepatic vein is divided, and finally the suprahepatic IVC is partially clamped to allow division of the common trunk of the left and middle hepatic veins. The liver graft is prepared on the back table, while the cut ends of the hepatic vessels are secured with suture, and the donor incisions are closed.

Laparaoscopic left hepatectomy is established for other clinical indications (Koffron et al, 2007b). The techniques are well defined, but its application to left-lobe donation is complicated by caudate management; therefore it seems logical that this donation procedure will evolve to a minimally invasive extent, positioned between that for the left lateral sectionectomy and right hemihepatectomy.

Recipient Procedure

As in all forms of LDLT, the recipient hepatectomy is performed with caval preservation, and the portal structures are dissected distally in the hepatic hilum. The left hepatic vein–middle hepatic vein confluence of the liver graft is typically anastomosed end-to-end to the same in the recipient. If there is a vessel size discrepancy or concern for torsion or kinking of the venous outflow, direct anastomosis to the vena cava may be performed (Egawa et al, 1997; Makuuchi & Sugawara, 2003; Sugawara et al, 2002b).

The portal vein and hepatic artery are reconstructed anatomically, and vascular conduits are used in cases of size discrepancy. Biliary enteric continuity is reestablished via a Roux-en-Y hepaticojejunostomy.

Right Hepatic Transplantation

Open Donor Procedure

Access to the abdomen is gained through either a right subcostal or bilateral subcostal incision with upper midline extension. Following exploration, the teres and falciform ligaments are divided close to the abdominal wall to facilitate reconstruction after right-lobe donation and to prevent medial-posterior rotation and torsion of the remnant liver (Miller et al, 2001). Cholecystectomy is performed, and the cystic duct is cannulated for later cholangiography. With anteromedial retraction of the extrahepatic biliary system, the peritoneum and neurolymphatic tissue of the portal hepatis is approached posterolaterally. This allows identification and isolation of the right hepatic artery from the lateral border of the common hepatic duct to its entrance into the right lobe (Fig. 98B.11; Kawarada et al, 2000).

Care is taken to avoid sacrificing any of the small arterial branches of the right hepatic artery that may supply the right hepatic duct. Once the artery is mobilized and elevated, the right portal vein is identified and isolated from the portal bifurcation to its entrance into the right lobe.

Dividing the right hepatic duct is a crucial step. If the right hepatic duct exists as a single structure, precise transection is necessary to obtain a single orifice, just proximal to division into sectorial ducts, and also avoid encroaching on the remnant liver biliary system (Huang et al, 1996; Varotti et al, 2004). To ensure accurate and safe transection, guidance with fluoroscopic cholangiography allows identification, marking, and precise transection of the right hepatic duct. The duct is transected sharply, avoiding overdissection and ischemic or thermal injury, which

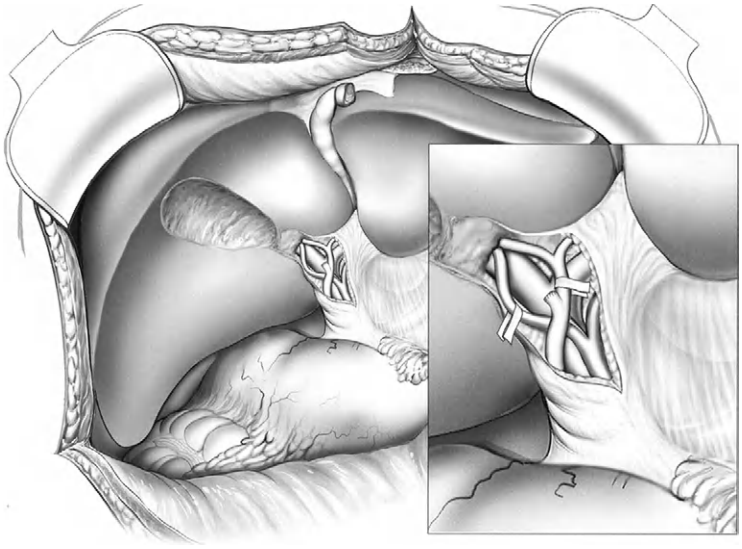

FIGURE 98B.11. After cholecystectomy is performed, the hilar structures for the right lobe graft are exposed. The right hepatic artery is identified to the right of the bile duct and is dissected from behind the duct toward the liver (*inset*).

may lead to biliary complications in the recipient (Gondolesi et al, 2004a).

The right lobe is completely mobilized by dividing the triangular ligament, bare area, and posterior vena cava ligament. The retrohepatic IVC is mobilized off the right lobe by ligating the small, short hepatic veins. Anomalous inferior hepatic veins may constitute substantial drainage of the posterior sector (segments VI and VII); therefore veins larger than 5 mm are preserved or divided in a manner—suture or staple—that allows later implantation in the recipient. Mobilization of the right lobe from the vena cava facilitates the dissection and control of the right hepatic vein.

The caudate process is divided over the IVC at the base of the Cantlie line using electrocautery; this allows passage of an umbilical tape from above the liver, between the middle hepatic vein and right hepatic vein, behind the liver, and up through the incised caudate process. The umbilical tape is lifted during hepatic parenchymal transection, guiding the division down the line of Cantlie, greatly facilitating the division of the most posterior parenchyma and simultaneously protecting the vena cava from injury (Belghiti et al, 2001; Broering et al, 1998).

The precise line of hepatic transection may be determined by temporary occlusion of the right hepatic artery and right portal vein or using ultrasound and anatomic landmarks. The intrahepatic course of the middle hepatic vein is similarly identified, particularly the segment V and VIII venous tributaries, which greatly facilitates parenchymal transection and isolation of the middle hepatic vein for later reconstruction, if necessary. The liver is transected without inflow occlusion, using any of a variety of devices—ultrasonic aspirator, water jet, bipolar saline-enhanced cautery—designed to limit bystander tissue injury. Typically, the middle hepatic vein is prepared for transection high in segment IVa near its confluence with the left hepatic vein with an attempt to preserve segment IV tributaries to the distal middle hepatic vein within the left lobe. Following parenchymal transection and achieving hemostasis, the back table and graft flush are readied.

In rapid sequence, the graft is devascularized and flushed. The right hepatic artery is ligated proximally and divided distal to the ligature to allow back bleeding. The right portal vein is then clamped (or stapled) and divided to ensure no compromise to the portal inflow to the remnant left hepatic lobe. The right hepatic vein, middle hepatic vein, and any preserved short hepatic veins are clamped or stapled and then divided, and the graft is removed. While the graft is flushed with preservation solution, and necessary vascular reconstructions are performed (Nakamura et al, 2002), the donor procedure is completed. This includes suturing clamped vessel stumps, ensuring no bile leakage, and completion cholangiogram to ensure vascularity of the remnant liver, followed by reconstruction of the falciform ligament and closure.

Laparoscopic Donor Procedure

Because of the right lobe's large size, fragility, and the consequences of graft injury, minimally invasive donation of the right lobe is usually performed by using a hybrid technique of liver resection (Koffron et al, 2007a). This technique of laparoscopic-assisted liver resection uses laparoscopic techniques to mobilize the liver while avoiding the morbid right subcostal incision. The hilar dissection and parenchymal transection proceed laparoscopically to the limits of safety or surgeon comfort level, at which time standard open techniques are used via the hand-assisted/extraction incision. This technique of right-lobe donation was first described by Koffron and colleagues in 2006 and is briefly summarized.

INITIAL MANEUVERS. The donor is placed under general anesthesia in supine position with arms adducted. Pneumoperitoneum (CO_2 at 12 mm Hg) is established through a 12-mm umbilical port, and the abdomen is explored utilizing a 30-degree 10-mm laparoscope for optimal visualization of the retrohepatic structures. Once the liver is visualized, one additional 10-mm port is placed at the right midclavicular line, and a 5-cm subxiphoid midline incision is created for hand assistance during right-lobe manipulation and for graft extraction using a hand-port device (Fig. 98B.12). This configuration enables the surgeon, who stands on the left side of the patient, to use the hand port for graft manipulation, with simultaneous use of the midclavicular line port for dissection.

RIGHT LOBE MOBILIZATION. Next, the ligamentum teres, falciform, coronary, and right triangular ligaments are divided using a coaptive laparoscopic tissue-sealing device. The hepatic bare area is completely mobilized, and the right lobe is elevated to expose the length of the retrohepatic IVC. The posterior vena cava ligament (Fig. 98B.13) and short hepatic veins are divided using a secure method—such as a sealing device, clips, or stapler (Figs. 98B.14 and 98B.15)—to separate the IVC and right lobe to allow visualization of the right hepatic vein (RHV) as it enters the IVC. An umbilical tape is passed around the RHV (Fig. 98B.16), the right lobe is allowed to return to anatomic position, and a cholecystectomy is performed.

HILAR DISSECTION AND LIVER RESECTION. The right hepatic artery (RHA) and right portal vein (RPV) are isolated posteriolaterally, with hand-assisted laparoscopy, as they enter the right lobe. Using the hand-assisted/extraction incision, under direct vision (Fig. 98B.17), the cystic duct is cannulated, cholangiogram confirms the biliary anatomy, and the right hepatic duct is isolated using fluoroscopic cholangiographic guidance. The right hepatic duct is then transected, leaving a 4-mm stump with the donor hepatic confluence, which is oversewn. The RHA and RPV branches are further dissected under

A, Endovascular stapler division of large segment VI vein entering the vena cava in preparation for donor lobectomy and later venous reconstruction in recipient. **B,** Divided segment VI vein. The staple line on the right lobe facilitates later back-table identification, preparation, and vein reconstruction prior to implantation in the recipient.

FIGURE 98B.16. Right hepatic vein isolated and encircled for later hanging technique during liver parenchymal transection.

direct vision to optimize vessel length and enhance safety (see Fig. 98B.17B). There is no hepatic inflow occlusion, and the central venous pressure is maintained at 2 to 4 mm Hg in preparation for parenchymal transection. Using the hand-assisted/extraction incision, the liver parenchyma is divided at the Cantlie line (Fig. 98B.18) in an inferior/anterior to superior/posterior direction using the transaction methods of choice. The middle hepatic vein tributaries from segments V and VIII are secured and divided using a method that allows later reconstruction, such as sutures or staples.

The retrohepatic umbilical tape is used toward the end of the parenchymal transection in the method of Belghiti (Belghiti et al, 2001; Ogata et al, 2007) to bring the transection plane closer to the abdominal wall. Once the right liver is separate, the RHA is ligated just lateral to the common bile duct and is transected sharply with scissors distally through the hand-assisted incision, allowing back-bleeding from the graft side. Immediately, the RPV is stapled using an Endo GIA (gastrointestinal anastomosis) stapler (Covidien, Mansfield, MA)

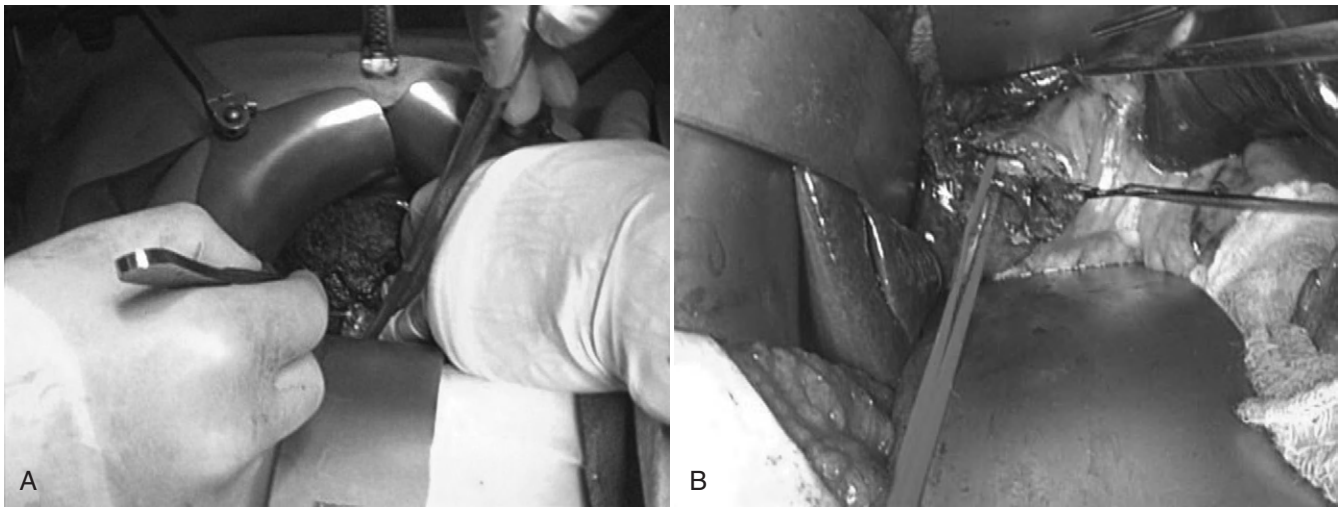

FIGURE 98B.17. A, The surgeon is using open techniques through hand-assisted/extraction incision. **B,** Overhead view of surgeon using open techniques through a hand-assisted/extraction incision. The hepatic artery and portal vein have been encircled; forceps are holding the right hepatic duct prior to division.

(Fig. 98B.19A), the right lobe is retracted laterally, and the RHV is stapled and divided at the IVC with the stapler (Fig. 98B.19B). The RPV is then transected sharply distally to the staple line; this causes the right lobe to decompress by allowing back-bleeding through the graft side of the RPV. The right lobe is gently extracted through the hand-assist subxiphoid incision (Fig. 98B.19C). A completion cholangiogram is performed, and a closed suction drain is placed and exteriorized through the right subcostal port site. The port sites and the extraction incision are closed in layers.

The initial reported series of four donors suggested equivalent donor and recipient outcomes using this technique compared with the standard open technique (Koffron et al, 2006). Later, the same group performed a retrospective, comparative analysis of 33 laparoscopic donors and 33 open donors (Baker et al, 2009). This analysis demonstrated that the laparoscopic approach can be performed as safely as the open technique, with the advantages of reduced operative times, a trend toward reduced blood loss, and comparable donor complication rates, length of stay, and hospital and surgical costs. In addition, the laparoscopic procedure provided equitable grafts for the recipient with equal patient and graft survival and complication rates. Although greater experience and wider usage of this technique is necessary to confirm these findings, such an approach intuitively can benefit donors and may lead to the increase in willingness to donate, as has been demonstrated for kidney transplantation.

FIGURE 98B.18. Dissection of significant segment V hepatic vein through the hand-assisted/extraction incision. This approach facilitates the safe dissection of intrahepatic vessels for later reconstruction on the back table.

Recipient Procedure

As in left-lobe LDLT, total hepatectomy is performed with caval preservation (Fig. 98B.20; Tzakis et al, 1989), and the structures of the portal triad are dissected high in the hilum to preserve options for subsequent reconstruction. If anticipating a duct-to-duct biliary reconstruction, avoid overdissection of the recipient common bile duct, which may devascularize the proximal extent, the site of potential anastomosis to the graft hepatic duct. In addition, maintaining the distal portion of the recipient middle hepatic vein—dissected from the cranial parenchyma of segment IVa, as the devascularized liver is being removed—leaves this available for use in graft middle hepatic vein reconstruction. This final portion of the hepatectomy is facilitated by complete occlusion of the cava, which allows division and suture control of difficult retrohepatic structures.

Once the liver is removed, or in the case of recipient instability, partial occlusion may be chosen to maintain venous return during implantation. Of course, as in whole-liver transplantation, venovenous bypass may be used as an adjunct to ensure hemodynamic stability, reduce blood loss, or inhibit visceral vascular congestion during the anhepatic phase (Fan et al, 2003; Grewal et al, 2001). Once the diseased liver is removed, hemostasis is ensured, the graft is placed in the resulting hepatic fossa, and venous reconstruction is visualized.

The right hepatic vein is reconstructed in a manner that allows maximal possible venous outflow. This is achieved either by anastomosis to the residual cuff of the recipient right hepatic

FIGURE 98B.19. **A,** Liver transection is complete, the hepatic artery is divided, and the right portal vein is secured using an Endo GIA stapler. **B,** The right hepatic vein is sealed and divided using the stapler. **C,** The portal vein has been incised distal to the staple line to allow decompression of the right lobe graft, which is then gently extracted and taken to the back table.

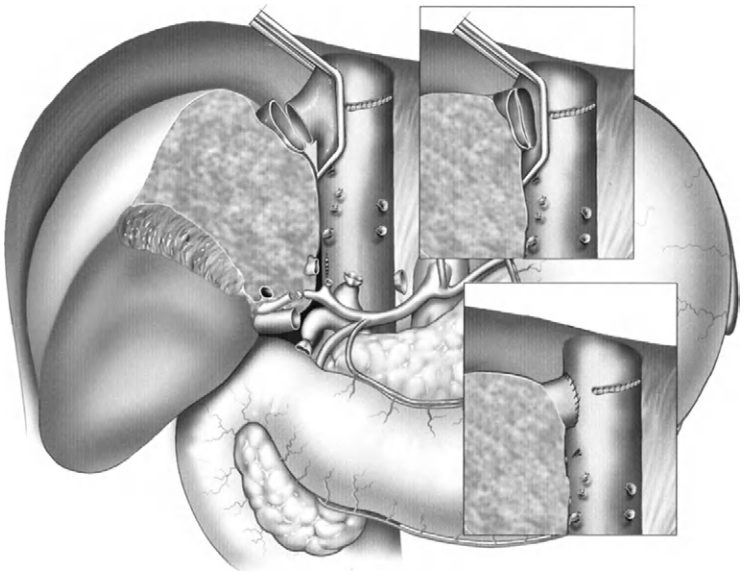

FIGURE 98B.20. The hepatectomy has been performed using a vena cava–sparing technique, and the right lobe graft is implanted. The right hepatic vein can be sewn to the stump of the recipient right hepatic vein, or cavoplasty can be performed to extend the orifice and reduce the risk of outflow obstruction. Short hepatic veins greater than 5 mm in diameter are anastomosed directly to the cava.

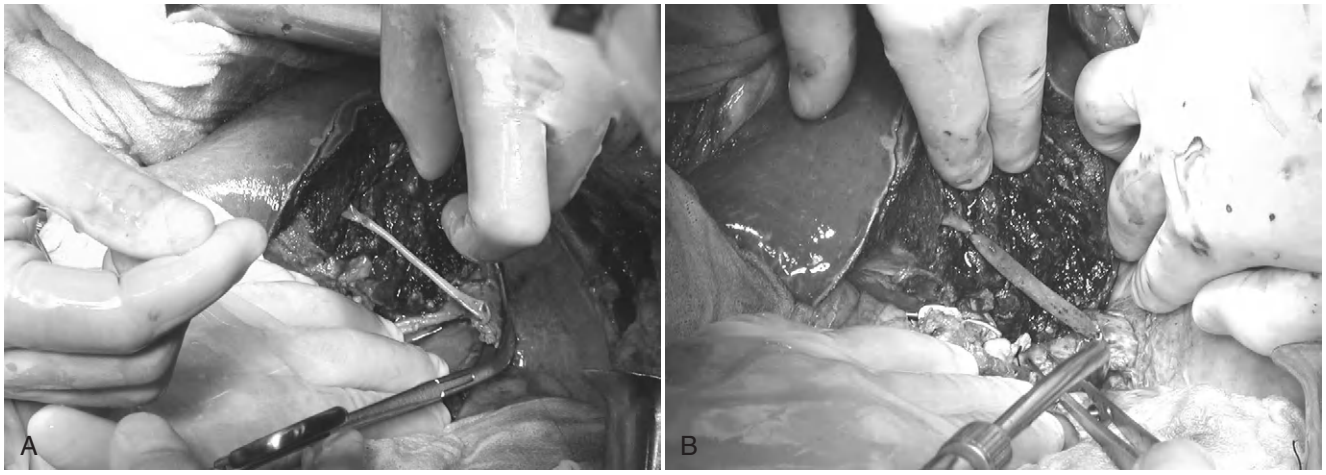

FIGURE 98B.21. **A,** Reconstruction of segment V vein to the orifice of the middle hepatic vein using a segment of the donor inferior mesenteric vein as interposition graft, before reperfusion. **B,** Segment V venous interposition graft after reperfusion.

vein or to an enlarged cavotomy created by enlarging the right hepatic vein orifice (see Fig. 98B.20; Liu et al, 2003; Sugawara & Makuuchi, 2001). This reconstruction should be performed anticipating acute and delayed enlargement of the graft following reperfusion/engorgement and hepatic regeneration, respectively.

Compensatory hepatic regeneration occurs within the space confined by the vena cava, diaphragm, and lateral thoracoabdominal wall. As the hepatic graft enlarges, this can change the geometry of the venous anastomosis over time and can potentially lead to outflow obstruction (Hata et al, 2004; Humar et al, 2004; Olthoff, 2003). Accessory inferior hepatic veins over 5 mm in diameter are anastomosed directly to the side of the vena cava (see Fig. 98B.20).

Once the dorsal-most hepatic veins have been addressed, reconstruction of segment V or VIII middle hepatic vein tributaries, if required, can be performed (Fig. 98B.21). Many techniques for reconstruction are available, depending on the surgical anatomy and vessel availability (Kinkhabwala et al, 2003; Marcos et al, 2001b; Sugawara et al, 2004). The use of vascular interposition grafts, if needed, is facilitated by placement during graft back table preparation and may include cadaveric iliac vein, recipient saphenous vein, preserved vascular allograft, and synthetic vascular conduit.

The donor right portal vein is anastomosed to the recipient main or right portal vein, accounting for size discrepancy and/or vessel length. As in whole-organ transplantation, recipient portal vein thrombosis is treated by thromboendovenectomy or portal vein resection and venous interposition graft (Dumortier et al, 2002; Kadry et al, 2002; Moon et al, 2004). The donor right hepatic artery usually is anastomosed to the recipient right or proper hepatic arteries in an attempt to prevent redundancy or kinking, which may occur as the arterial spasm subsides following reperfusion.

The methods of biliary reconstruction depends on the size, number, and configuration of the donor and recipient ducts. This may include direct duct-to-duct anastomosis, Roux-en-Y hepaticojejunostomy, or a combination of these techniques in cases of biliary complexity (Fig. 98B.22; Azoulay et al, 2001; Testa et al, 2000).

BILIARY COMPLICATIONS (SEE CHAPTER 100)

Biliary complications remain the largest contributor to morbidity following LDLT. Despite further understanding of the anatomy and both donor and recipient surgical techniques, biliary leak and stenosis rates range from 20% to 40% (Gondolesi et al, 2004a; Pomfret, 2003) up to 60% (Kawachi et al, 2002). The A2ALL cohort study reported a 31.8% biliary leak rate across the nine participating transplant centers (Freise et al, 2008). Studies investigating the methods of biliary reconstruction found no difference in overall complications, but one advantage of duct-to-duct reconstruction is that it allows future endoscopic access and management of these complications. Leaks generally manifest early after transplantation (Popescu et al, 1994) and are associated with significant morbidity and mortality (Gondolesi et al, 2004a). Bile leak from the cut liver edge may be treated successfully with percutaneous drainage, but anastomotic leaks invariably require endoscopic and/or operative management.

As in DDLT, biliary strictures are generally diagnosed by noting an increase in biliary enzymes. Evaluation of strictures usually involves US, MRC, and in some cases, direct cholangiography, either endoscopic or percutaneous transhepatic cholangiography (PTC). The treatment strategy is similar to biliary stricture in general (see Chapter 42A), although operative management in LDLT recipients is technically difficult as a result of the neighboring vascular reconstructions.

POSTOPERATIVE CARE OF LIVING LIVER DONORS

Because donors are healthy individuals, the donation event may represent their initial significant medical or surgical experience. Therefore, despite thorough preoperative education, their postoperative course is out of proportion to their expectations. Although discussions with previous donors may help prepare donors mentally during recovery, even routine surgical care, and complications in particular, have a heightened impact on healthy volunteers. Most notably, the degree of postoperative

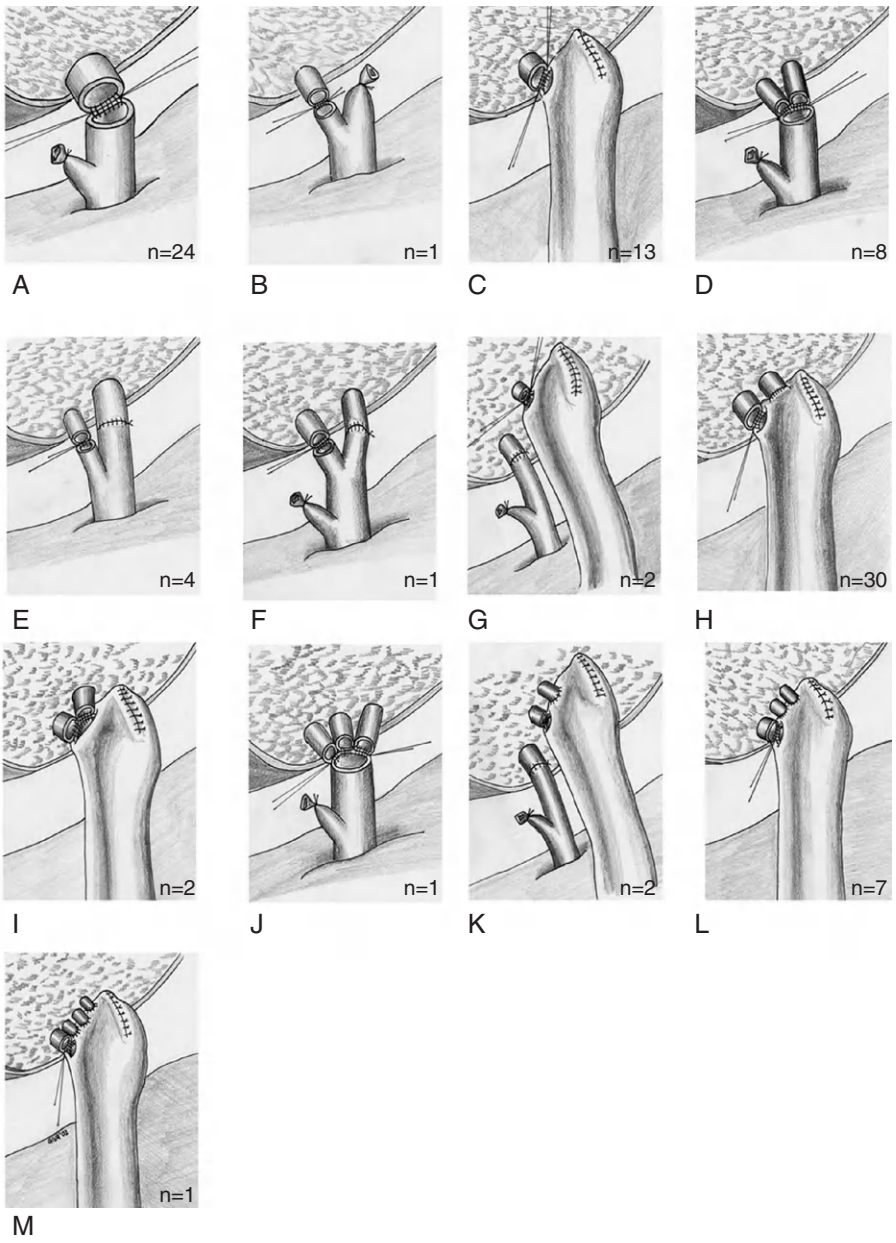

FIGURE 98B.22. A to **M,** Different types of biliary reconstructions and number of cases for each applied in a series of 96 right-lobe living donor liver transplantations. *(From Varotti G, et al, 2004: Anatomic variations in right liver living donors. J Am Coll Surg 198:577-582.)*

pain is usually unexpected, and every effort to maintain adequate analgesia, such as via patient-controlled analgesia or epidural analgesia, is key for both the donor's comfort and to enable recuperation free of preventable nosocomial complications. Postoperative care is similar to that for any liver resection, however, all established prophylactic measures—pulmonary hygiene, deep venous thrombosis prophylaxis, and other such measures—should be included to reduce donor risk to the lowest point achievable.

Despite meticulous surgical postoperative care, right-lobe donor hepatectomy is associated with considerable morbidity, with up to 50% of donors experiencing complications in some series (Pomfret, 2003). The A2ALL retrospective cohort study found that out of 393 donors, 82 (21%) had one complication, and 66 (17%) had two or more complications Although most were of low-grade severity, such as respiratory and wound-related complications, a significant proportion were severe (26%), life threatening (2%), or even fatal (0.8%; Ghobrial et al, 2008).

Some degree of hepatic insufficiency is clinically identified after surgery, presenting as transient prolonged prothrombin time and nonobstructive cholestasis. Management of biliary leakage with right hepatectomy is similar to right hepatectomy for other indications, but the surgical team should be aware that delayed reoperation could occur because of the logical desire to avoid reoperating on a donor. Vascular complications such as hemorrhage and portal thrombosis are rare but logically require rapid detection and surgical correction to avoid injury to the remnant liver. Fortunately, uncommon instances of biliary stricture (Lee et al, 2004), incisional hernia, and small bowel obstruction have been treated by standard surgical means.

The psychiatric effects on liver donors is not insignificant. The A2ALL study group identified one or multiple psychiatric complications in 16 (4.1%) of 392 donors, including three

severe complications: suicide, accidental drug overdose, and attempted suicide (Trotter et al, 2007). These findings stress the importance of both preoperative screening assessment and monitoring of liver donors to prevent such tragic events.

LIVING DONOR TRANSPLANTATION: FUTURE DIRECTIONS

Outcomes analysis, multicenter collaboration (A2ALL cohort study), and communication among living donor transplantologists have promoted advancement of this valuable treatment option. Further experience will continue to refine surgical techniques, reduce vasculobiliary surgical complications, and hone the clinical indications for many disease entities, especially malignancy. The role of laparoscopy in LDLT will continue to expand, as experience in laparoscopic liver resection techniques increases. As with liver resection, we should be mindful to avoid liberalization of indications simply because a less invasive approach to donation is available. Clinical decisions must be based on the limits for the recipient and the risk to the donor, despite the shortage of cadaveric donors and waiting-list mortality. Continued contributions by participating centers and study groups such as the A2ALL will continue to clarify the role and application of LDLT in the treatment of liver disease.

ACKNOWLEDGMENTS

We are grateful to M. Rasm Alsibae, MD, who selflessly provided guidance and insight during the preparation of this chapter.

CHAPTER 98C

Liver transplantation in children and segmental transplantation

Susan Logan, Christopher D. Anderson, and Jeffrey A. Lowell

HISTORICAL OVERVIEW

Thomas Starzl attempted the first human liver transplantation in 1963 in a 3-year-old child with biliary atresia. Unfortunately, the child died in the operating room from uncontrollable hemorrhage (Starzl, 1992), but subsequently, in 1967, Starzl successfully performed liver transplantation in eight children. All survived the operation, and half survived more than 1 year (Starzl et al, 1968).

Since those heroic beginnings 4 decades ago, advances in immunosuppression, surgical technique, and critical care have made liver transplantation a reliable, lifesaving procedure performed every day at liver transplant centers throughout the world. In children with end-stage liver disease (ESLD), liver transplantation has become the accepted therapy, and its use is limited only by the availability of suitable grafts.

In 2007, there were 5887 adult liver transplantations and 602 pediatric transplantations (Organ Procurement and Transplantation Network/Scientific Registry of Transplant Recipients [OPTN/SRTR], 2008). Currently, approximately 15,500 adults and 540 children are awaiting liver transplantation (United Network for Organ Sharing [UNOS], 2009). Potential recipients who are infants, toddlers, or young children have narrow constraints with regard to graft size. Historically, the lack of size-matched organ availability, coupled with the disproportionate number of adults on the waiting list, has significantly disadvantaged children awaiting transplantation. Compared with adults who have liver disease, children have much less time to await transplantation; an infant with decompensated liver disease from cirrhosis typically cannot survive on a waiting list for several years (McDiarmid, 2002). Furthermore, waiting-list mortality for children younger than 1 year continues to far exceed that of other children and adults (OPTN/SRTR, 2008), in part because of the lack of size-matched organs.

The shortage of donor organs has motivated surgeons to develop innovative techniques to increase the number of potentially usable organs for pediatric transplantation. Initially, adult cadaveric livers were made smaller by removing the right lobe and medial section of the left lobe to enable grafting of the left lateral section into small recipients. In this way, the size restrictions imposed on any particular donor-recipient combination could be overcome. The application of reduced-size grafts led to a shift of cadaveric livers to children and small adults, but it did not increase the total graft pool.

Progressive improvements in surgical technique have evolved such that now the left lateral section and the right trisegment graft each can be used, meaning that a single liver potentially can be divided and transplanted into two recipients. With this innovative technique, the *split-liver procedure*, important progress in the effort to expand donors available to children has been accomplished without disadvantaging adult recipients. Except in unusual circumstances, the use of a reduced-size liver allograft in which the remnant is discarded is theoretically rarely justified. In 2007, partial or split-liver transplantations accounted for approximately 4% of all deceased-donor liver transplantations (OPTN/SRTR, 2008). The use of reduced-size liver grafts declined from 23% to 16% of pediatric liver transplantations over the last decade, but during this same time, split-liver allografts increased from 9% to 16% (Anderson et al, 2008).

Favorable outcomes transplanting reduced-size and split livers led to the development of techniques for using liver segments from living donors for pediatric grafts. With increasing experience, donations from living donor livers are no longer confined to left lateral sections or left hepatic lobes but have expanded to include full right hepatic lobe grafts, which contributes to the adult organ pool as well (Hong et al, 2008). Today, living-related and unrelated living-donor liver transplantation (LDLT) accounts for approximately 10% of all pediatric liver transplantations and 4% of adult liver transplants (OPTN/SRTR, 2008), and it has been one of the most exciting and challenging advances in liver transplantation.

INDICATIONS

Box 98C.1 lists common indications for pediatric liver transplantation. Biliary atresia is a progressive, inflammatory, fibrosing cholangiopathy of unclear pathogenesis (see Chapter 40). It occurs in only 1 in 8000 to 18,000 live births; and although it is rare, it remains the most common cause of infant death owing to hepatic disease and accounts for approximately 50% of all pediatric liver transplantations (Bassett & Murray, 2008; Bezerra, 2005; Perlmutter & Shepherd, 2002). Most children with this disease lack an extrahepatic biliary tree, resulting in impaired bile flow, conjugated hyperbilirubinemia, acholic stools, and hepatomegaly. The hepatic parenchyma becomes congested, and progressive damage leads to secondary biliary cirrhosis. Although portoenterostomy, also known as the *Kasai procedure* (Kasai & Suzuki, 1959), may yield some clinical improvement and is the first-line treatment (Ohi, 2000; Ryckman et al, 1998), approximately 70% to 80% of children with biliary atresia eventually require liver transplantation (Karrer et al, 1996; Lowell et al, 1996).

Other causes of cholestasis in children include idiopathic neonatal hepatitis; infection by both viral and bacterial pathogens, including toxoplasmosis and syphilis; progressive familial intrahepatic cholestasis (Byler disease); metabolic and genetic diseases; familial arteriohepatic dysplasia (Alagille syndrome); choledochal cyst; and ischemia-reperfusion injury. Cholestasis

Box 98C.1

Indications for Pediatric Liver Transplantation

Cholestatic Hepatic Failure

Biliary atresia
Primary sclerosing cholangitis
Alagille syndrome
Byler disease
Total parenteral nutrition–induced liver failure
Idiopathic disease

Infectious Hepatic Failure

Viral infection, such as with hepatitis A, B, or C
Toxoplasmosis
Syphilis
Bacterial infection

Genetic or Metabolic Hepatic Insufficiencies

α_1-Antitrypsin deficiency
Cystic fibrosis
Wilson disease
Glycogen storage disease
Tyrosinemia
Primary hyperoxaluria
Hereditary hemochromatosis
Crigler-Najjar syndrome
Neoplastic hepatic primaries
Hepatoblastoma
Hepatocellular carcinoma

Extrahepatic Diseases

Hemophilia
Familial hypercholesterolemia

Other Causes of Hepatic Failure

Autoimmune hepatitis
Budd-Chiari syndrome
Toxicity
Giant arteriovenous malformation

may progress to cirrhosis and has also been associated with parenteral nutrition in children with short bowel syndrome (Baker et al, 1998).

Pediatric liver transplantation is also indicated in cases of noncholestatic liver failure secondary to infectious, metabolic, genetic, and neoplastic etiologies. Although less frequent in children than in adults, postnecrotic liver cirrhosis is the indication for transplantation in approximately 10% of pediatric patients and is most commonly the result of viral hepatitis or idiopathic cryptogenic cirrhosis (Malatack et al, 1983).

Metabolic liver diseases are genetic disorders that lead to the production of aberrant transport proteins or enzymes and altered metabolic pathways. These inborn errors of metabolism, such as α_1-antitrypsin (AAT) deficiency or Wilson disease, may cause direct injury to the liver and result in liver failure, with or without injury to other organs; it may also lead to abnormal liver metabolism, including urea cycle disorders or oxalosis, that can lead to injury of other organs. Altogether, such diseases account for approximately 10% of all pediatric liver transplantations (Hansen & Horslen, 2008).

AAT deficiency is a genetic disorder that leads to defective production of the serine protease α_1-antitrypsin (see Chapter 70A), an enzyme produced in the liver to protect the lungs from neutrophil elastase. The abnormal protein accumulates in the liver, apparently causing liver damage, although the mechanism of injury remains unclear. Synthetic AAT has some utility in the treatment of AAT deficiency–related lung disease, but it has no role in the treatment of the associated liver disease (Köhnlein & Welte, 2008; Silverman & Sandhaus, 2009).

Wilson disease is an inborn error of metabolism characterized by defective copper excretion and the accumulation of toxic amounts of copper in the liver, basal ganglia, kidney, and cornea, which may lead to the characteristic Kayser-Fleischer rings (see Chapter 70A). The defect is located on chromosome 13, is inherited in an autosomal recessive fashion, and affects 1 in 50,000 births. Initial symptoms are nonspecific and include lethargy, anorexia, vague abdominal pain, and weight loss. Some patients present with asymptomatic hepatomegaly, and others present with fulminant hepatic failure (FHF) (Riordan & Williams, 2001).

Other metabolic liver diseases—such as urea cycle disorders, Crigler-Najjar (CN) syndrome, or familial hypercholesterolemia—do not result in primary hepatic disease but cause extrahepatic disease as a result of dysfunctional hepatic gene products or metabolites that affect extrahepatic tissue. Urea cycle defects result in the accumulation of nitrogenous waste and severe, potentially lethal hyperammonemia. Two diseases within this group of disorders are described by their respective enzyme deficiencies: *carbamyl phosphate synthetase* (CPS) *deficiency* and *ornithine transcarbamylase* (OTC) *deficiency*. Three others are described by the primary metabolite that accumulates in affected individuals: *citrullinemia, argininosuccinic aciduria* (AS), and *argininemia* (AL).

CN syndrome is caused by mutations of the gene that codes uridine diphosphate glucuronosyltransferase-1, resulting in unconjugated hyperbilirubinemia. Untreated neonates develop a condition of severe neuronal damage called *kernicterus.* Homozygous familial hypercholesterolemia (HFH) is a rare disease caused by mutations in the gene that codes the low-density lipoprotein (LDL) receptor. The receptor may be defective or completely absent, and affected individuals have dramatically elevated plasma cholesterol levels, leading to accelerated atherosclerosis, childhood coronary artery disease, and premature death from myocardial infarction (Hansen & Horslen, 2008). Liver transplantation corrects these conditions by providing the required cellular machinery to synthesize the correct gene product or metabolite (Florman & Shneider, 2001; Meyburg & Hoffmann, 2005). Occasionally, auxiliary hepatic transplantation has been performed in these circumstances (Bismuth et al, 1996; Sze et al, 2009; Van Hoek et al, 1999). In AAT deficiency, the potential for development of hepatocellular carcinoma (HCC) precludes auxiliary liver transplantation and mandates total hepatectomy.

Cystic fibrosis (CF) is an autosomal recessive multiorgan disorder that is the most common lethal inherited disease affecting the white population. As management of these patients continues to improve, CF liver disease (CFLD) is increasingly recognized as a significant cause of morbidity and mortality. Approximately 5% to 10% of CF patients will progress to cirrhosis, with the most frequently recognized complications attributable to portal hypertension with an associated nutritional and pulmonary decline. A significant number of patients with CFLD may be helped with an isolated liver transplantation or a concomitant liver and lung transplantation; however, the debate is ongoing in the literature regarding the timing of liver transplantation in these patients (Colombo et al, 2006; Fridell et al, 2003; Nash et al, 2008).

Although more common in adult patients, chronic Budd-Chiari syndrome with severe hepatic congestion and focal

areas of liver fibrosis or cirrhosis may be an indication for liver transplantation in older children (see Chapter 77). Pretransplantation evaluation should be performed to recognize predisposing factors or underlying diseases such as myeloproliferative disorders, primary hepatic protein deficiencies—of proteins C and S, antithrombin III, and activated protein C resistance—or secondary protein deficiencies, such as increased intestinal protein loss in inflammatory bowel disease (Slakey et al, 2001).

FHF (see Chapters 73 and 97C) is associated with a mortality rate greater than 70%. It is essential to transfer children with FHF to a transplant center immediately for management and urgent evaluation and listing for liver transplantation. Because cerebral edema develops rapidly, careful monitoring and intensive supportive care are required. Mild elevation of intracranial pressure (ICP) may be managed acutely by hyperventilation and elevation of the patient's head, although maintenance likely requires strict sodium and osmolar and intravascular volume control. Placement of an ICP monitor should be considered, but regardless, attention to maintenance of cerebral perfusion pressure (CPP) is paramount. Transplantation in patients with signs of cerebral edema is urgent, as edema may lead to irreversible brain damage or death (Tanaka et al, 1994). Poor prognostic factors for liver transplantation in children with FHF include age younger than 10 years, liver disease other than viral hepatitis, grade 2 or 3 hepatic encephalopathy, coagulopathy (prothrombin time >30 seconds), and increasing jaundice (bilirubin >9 mg/dL) (Uemoto et al, 2000).

Liver tumors account for less than 3% of all indications for pediatric liver transplantation (Austin et al, 2006). Hepatoblastoma, HCC, and fibrolamellar HCC represent the most frequent tumors (see Chapter 82). In contrast to adults, the predisposing factors for malignant liver tumors in children are not viral hepatitis or alcoholism but are more often metabolic disorders, such as AAT deficiency, tyrosinemia, or glycogen storage disease. In patients without cirrhosis, hepatic resection is the treatment of choice. Liver transplantation should be considered in the case of unresectable tumors confined to the liver (Chen et al, 2006; Otte et al, 2004). In patients with advanced cirrhosis and HCC meeting Milan criteria, transplantation is indicated (Austin et al, 2006; Beaunoyer et al, 2007; Perilongo et al, 2004). Rarely, giant arteriovenous malformations and benign liver tumors—when they replace the whole liver, or when they have the potential for malignancy (e.g., hepatic adenomatosis or multiple adenomas in glycogen storage disease [Fig. 98C.1])—may be indications for total hepatectomy and liver transplant (Malatack et al, 1987; Wellen et al, 2009; see Chapter 79A).

FIGURE 98C.1. Multiple giant adenomas in an explanted liver.

EVALUATION OF THE POTENTIAL RECIPIENT

A multidisciplinary evaluation of a child with decompensated liver disease should be completed with the involvement of surgeons, hepatologists, nurses, anesthesiologists, psychologists, and social workers. Early referral to a transplant center allows maximum time to develop a management strategy and to optimize pretransplantation clinical status. The timing of liver transplantation is crucial, because late referral of patients with significant hepatic complications and malnutrition results in a poorer outcome. The expected waiting time on the transplant list may vary based on the geographic region, and this should be taken into account. In infants younger than 2 years who weigh less than 10 kg, it is often difficult to maintain metabolic and nutritional support. Ideally, children should be considered for liver transplantation before the complications of malnutrition, such as weight loss and growth failure, occur (Kimura et al, 2004; McDiarmid et al, 2004). With chronic liver disease, prolonged clotting times, intractable ascites, recurrent variceal bleeding secondary to portal hypertension, and recurrent cholangitis with severe cholestasis are indications for liver transplantation (Hendrickson et al, 2004).

The prognosis after liver transplantation for chronic liver disease is influenced by preoperative comorbidities. The advent of the Pediatric End-Stage Liver Disease (PELD) and Model for End-Stage Liver Disease (MELD) scores (Malinchoc et al, 2000; Wiesner et al, 2001) has made it possible to better predict mortality and progression of liver disease while awaiting transplantation (Desai et al, 2004; Barshes, et al, 2006). The pertinent factors in the PELD score are the international normalized ratio (INR), total bilirubin, serum albumin, age younger than 1 year, and weight or length less than 2 standard deviations (SDs) from the mean for age and gender. The PELD score is used for patients younger than 12 years, and the scores range from a negative value (−10) to 50. Adolescents aged 13 to 18 years are allocated organs based on the MELD score, similar to adults. Box 98C.2 presents the formulas for calculating the MELD and PELD scores.

Box 98C.2

MELD and PELD Calculations

MELD

$$10\times[0.957\ln(\text{Creatinine}[\text{mg/dL}])+0.378\ln(\text{Total bilirubin }[\text{mg/dL}])+1.120\ln(\text{INR})+0.643]$$

PELD

$$10\times[0.480\times\log_e(\text{Bilirubin}[\text{mg/dL}])+1.857\times\log_e(\text{INR})-0.687\times\log_e(\text{albumin}[\text{g/dL}])+0.436(\text{if the patient is}<1\text{ year old})+0.667(\text{if the patient has growth failure}[<2\text{ SD}])]$$

The resulting score is rounded to the nearest whole number.
MELD, Model for End-Stage Liver Disease; PELD, Pediatric End-Stage Liver Disease; INR, international normalized ratio; SD, standard deviation

Box 98C.3

Contraindications to Pediatric Liver Transplantation

Absolute

Uncontrolled systemic sepsis
Irreversible brain edema
Uncorrectable symptomatic heart defects
Nonreversible pulmonary hypertension
Extrahepatic malignancy

Relative

Portomesenteric thrombosis
HIV-positive status
Severe psychosocial impediments

HIV, human immunodeficiency virus

Comparing the periods before and after the introduction of the MELD and PELD scores, a similar percentage of children are being transplanted, but mortality rates have decreased (Freeman et al, 2004; Yao et al, 2004). Small size and young age are no longer contraindications, and many transplantations for biliary atresia are now done in infants who weigh less than 10 kg (Colombani et al, 1996; Sokal et al, 1990). Whereas post-transplantation mortality has improved, waiting-list mortality for infants younger than 1 year remains high, unfortunately (OPTN/SRTR, 2008). Consideration should be given to referring these young and small infants to pediatric specialty centers that have expertise with these challenging cases. Contraindications to pediatric hepatic transplantation are listed in Box 98C.3.

RECIPIENT HEPATECTOMY

The recipient hepatectomy is typically difficult, because more than half of the pediatric patients have had a prior laparotomy. Severe portal hypertension with abdominal wall and perihepatic venous collaterals is common, and these technical challenges may be exacerbated by severe coagulopathy and thrombocytopenia. Thrombosis of the portal vein can be an additional complicating factor, and preservation of the retrohepatic inferior vena cava contributes to hemodynamic stability during the hepatectomy.

Before beginning the transplantation, a Broviac central venous catheter is placed for intraoperative and postoperative fluid resuscitation, monitoring, and postoperative laboratory draws, the same as an arterial catheter. Pressure points are well padded, and convective heating blankets are used. The abdomen is entered through a curved transverse subcostal incision. Meticulous hemostasis must be maintained throughout the procedure, because ongoing bleeding may lead to dilutional coagulopathy and fibrinolysis. Abdominal wall venous collaterals must be carefully controlled as they are encountered, and adhesions to the liver are carefully dissected to allow access to the portal region (Fig. 98C.2).

If the child has had a previous Kasai procedure, the jejunal loop is taken down, the enterostomy is closed, and the Roux-en-Y loop is preserved for later biliary drainage of the graft, if it is of suitable quality. The porta hepatis is dissected carefully with isolation of the hepatic artery and portal vein. Although transection of the hepatic artery is performed early in hepatectomy, the portal vein is divided after total mobilization of the liver, just before removal of the native liver, to avoid unnecessary congestion in the mesentericoportal system. Alternatively, a temporary portocaval anastomosis may be performed by ligating and dividing the portal vein at the level of the bifurcation and creating an end-to-side anatomosis to the infrahepatic vena cava. This avoids mesenteric venous congestion and also helps maintain venous return and hemodynamic stability.

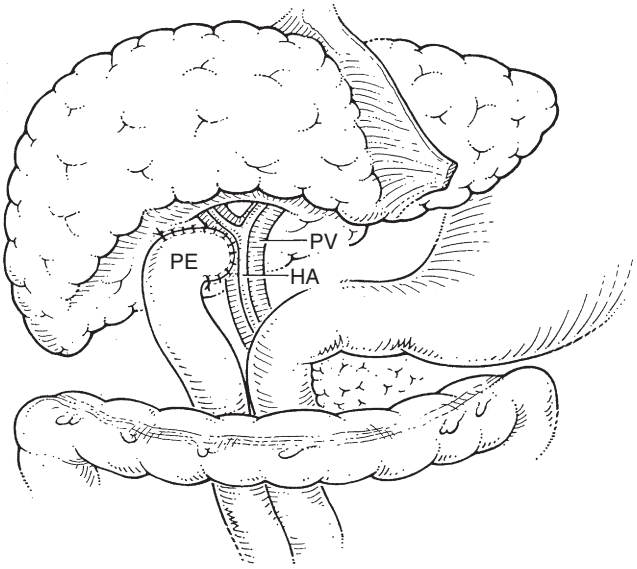

FIGURE 98C.2. Recipient hepatectomy. The hilum is examined carefully, and a previous portoenterostomy (*PE*) is taken down. The portal vein (*PV*) and hepatic artery (*HA*) are divided high in the porta hepatis.

The hepatic artery and portal vein are dissected high in the hilum to preserve adequate length for later anastomosis with the graft. The portal vein may be quite small; in this setting, dissection to the level of the confluence of superior mesenteric vein and splenic vein posterior to the pancreas may allow for anastomosis to a larger inflow vessel. The liver is mobilized further by dividing the ligamentous attachments and the short hepatic veins that drain the right liver and caudate directly into the vena cava.

For orthotopic whole-liver transplantation, the small retrohepatic caval segment can be removed with the native liver, or the vena cava can be preserved and the donor liver anastomosed in a piggyback fashion to the confluence of the recipient's right, middle, and left hepatic veins. With a segmental graft, the recipient inferior vena cava must be preserved. A vascular clamp is placed across the hepatic veins so that they can be joined to form a common opening to sew to the donor suprahepatic cava or, in case of segmental grafts, the left hepatic vein (Fig. 98C.3). Complete hemostasis of the retroperitoneum should be accomplished before removing the donor liver from cold storage.

GRAFT PROCUREMENT AND ENGRAFTMENT

The techniques used for recovering whole, deceased-donor livers for transplantation from children are similar to the techniques used in adult-adult transplantation. Special attention should be paid to donor serum sodium levels and to dynamic liver function tests. High sodium levels (>170 mmol/L) may be

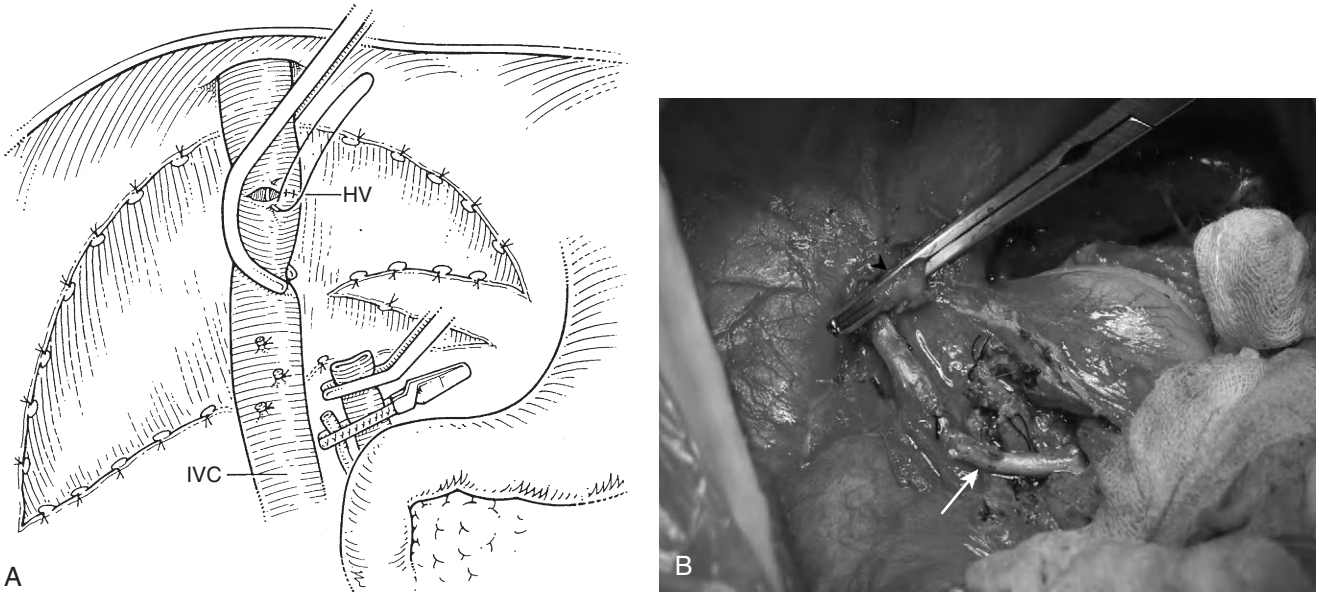

FIGURE 98C.3. Recipient hepatectomy. **A,** The liver has been removed, and the inferior vena cava (*IVC*) is preserved in preparation to receive a segmental graft. **B,** Note the portocaval shunt (*arrow*) and vascular clamp occluding only the hepatic veins (*arrowhead*), allowing venous return from both the systemic and mesentericoportal systems. Sutures mark the ligated hepatic artery and bile duct. HV, hepatic vein.

associated with severe reperfusion injury and poor graft function (Totsuka et al, 1999).

The donor liver is anastomosed using the full vena cava—or the left hepatic vein, with or without the middle hepatic vein, in the case of a reduced-size left graft—to the confluence of the recipient hepatic veins. Before securing the final caval sutures, the donor liver is flushed through the donor portal vein with cold Ringer's lactate to flush out the preservation solution, usually Viaspan (University of Wisconsin solution) or Custodiol (histidine-tryptophan-ketoglutarate [HTK]), which may be high in potassium. The portacaval shunt is taken down and oversewn, and the portal venous anastomosis is completed, leaving a large growth factor in the continuous suture to prevent a waist, or narrowing of the anastomosis, when the vessels are refilled with portal blood.

The arterial anastomosis is performed with sutures of fine (7-0 or 8-0) monofilament material using microsurgical loupes. A microscope may be useful in anastomosing arteries with a diameter smaller than 1 to 2 mm. The anastomosis is performed most commonly in an end-to-end fashion directly to the native hepatic artery. If the native artery is not of adequate size, or if there is an intimal dissection, an extension allograft using saphenous vein or donor iliac artery from the infrarenal or supraceliac aorta may be used (Yamaoka, 1996).

The bile duct anastomosis is the final step in the procedure. If present, the donor gallbladder is removed. If the recipient has an intact bile duct that is of suitable size, an end-to-end choledochocholedochostomy can be performed with or without placement of a T-tube or an internal stent; however, most children who undergo transplantation have either biliary atresia or common bile ducts that are very small or sclerotic, so a choledochojejunostomy is necessary. Use of a segmental allograft requires hepaticojejunostomy, if the common bile duct has been resected. In case of a previous Kasai procedure, the jejunal loop of the portoenterostomy can be used again, although it must be shortened, and a fresh segment must be anastomosed.

REDUCED-SIZE SEGMENTAL LIVER TRANSPLANTATION AND SPLIT-LIVER TRANSPLANTATION

Reduced-Size Segmental Liver Transplantation

The use of reduced-size grafts for pediatric recipients is one of the most important advances in liver transplantation. The disproportionate shortage of grafts for very young children, compared with older children, motivated surgeons to develop innovative operative techniques to overcome the restrictions imposed by donor and recipient size mismatch. With these techniques, livers can be reduced to a functional unit of appropriate size for the recipient. The optimal ratio between the required volume of liver and the actual "tailored" hepatic mass is between 1:1 and 1:2. In this way, livers from donors 10 or 20 times the size of the recipient can be used (Broelsch et al, 1988).

The liver comprises eight anatomically defined segments, each with its own arterial and portal blood inflow and separate biliary drainage (Strasberg, 1997; see Chapter 1B). Similarly, segmental hepatic venous outflow is independent, but major liver veins run along sectional borderlines, receiving blood from several adjacent segments (Couinaud, 1954). For purposes of transplantation, the liver can be divided into several functional grafts. The most commonly used reduced-size graft is the left lateral section graft, composed of segments II and III (Fig. 98C.4; Botero & Strasberg, 1998). To preserve a single donor portal vein, the liver is transected just to the right of the falciform ligament, and branches of the ascending (umbilical) portion of the left portal vein to segment IV are carefully suture ligated. The left hepatic vein is used for hepatic venous drainage. It is anastomosed directly to the recipient's vena cava, which must be preserved during hepatectomy. The full left graft (segments I, II, III, and IV or segments II, III, and IV) is used in small adults or older children who require a graft slightly larger than the left lateral section.

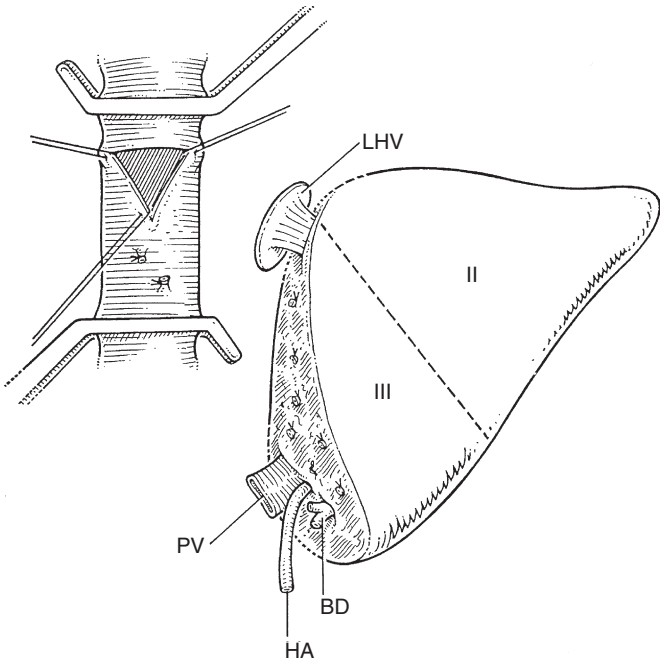

FIGURE 98C.4. The most commonly used segmental graft uses segments II and III of the left liver. The recipient's inferior vena cava (*IVC*) is preserved, and the left hepatic vein (*LHV*) is sutured to a large triangular venotomy cut on the anterior aspect of the IVC. The portal vein (*PV*), hepatic artery (*HA*), and bile ducts (*BD*) are depicted before anastomosis.

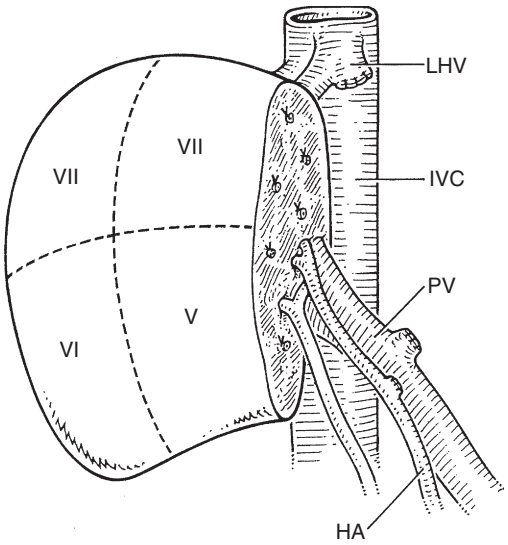

FIGURE 98C.5. Segmental graft. The full right liver incorporating segments V through VIII is used. The left hepatic artery (*LHV*) is shown and represents the oversewn left and middle hepatic veins. HA, hepatic artery; IVC, inferior vena cava; PV, portal vein.

Bismuth and Houssin (1984) first reported success with transplantation of a left hepatic allograft; in the same year, Broelsch and colleagues (1984) reported the successful grafting of the left lateral section. Since then, most pediatric transplant centers have adopted segmental transplant techniques using reduced-size livers. The results after these segmental grafts are comparable to the results achieved with whole-organ orthotopic liver transplants (Hong et al, 2008). Although reduced-size grafts can overcome the donor-recipient size discrepancy by distributing cadaveric livers to the advantage of children, and to small adults, they do not increase the absolute number of grafts. The advent of the split-liver technique not only allowed the donor liver to be tailored to fit a small child, but it also allowed for the remaining donor graft to be used, which increased the actual organ pool; however, routine use of reduced-size grafts is discouraged except in unique situations.

Split-Liver Transplantation

In the split-liver procedure, a single cadaveric liver is divided into two grafts to be transplanted into two patients (Cintorino et al, 2006; Strasberg et al, 1999; Zamir et al, 2002). The first successful split-liver transplantation was performed by Pichlmayr and colleagues in 1988, utilizing a right extended graft (segments IV, V, VI, VII, and VIII) and a left lateral graft (segments II and III). Leaving segment IV with the right graft rarely leads to an impaired arterial and portal venous perfusion, despite the fact that the vascular supply of this segment belongs to the left liver. Very rarely, resection of segment IV may be required because of poor perfusion. The liver also may be dissected along the principal plane, dividing it into right and left livers. The vena cava and the full length of main portal vein and celiac artery typically are included with the right graft (segments V through VIII), which is then anastomosed to the recipient in a manner similar to a whole-liver graft (Fig. 98C.5). By contrast, the left lobe has a left hepatic vein, left hepatic artery, and left portal vein, which have been divided at the branching points from the vena cava, common hepatic artery, and portal vein.

Broelsch and coworkers (1990) reported the first successful split-liver transplantation series. Since then, other groups have developed and refined the technique (Azoulay et al, 2001a, 2001b; Busuttil & Goss, 1999; Rela et al, 1998); however, the initial enthusiasm for this procedure faded, because the preliminary results were inferior, mainly owing to technical and organ-preservation problems. In addition, progress in split-liver transplantation was hampered by tremendous practical and logistical problems, because this procedure requires two full teams of surgeons, anesthesiologists, and operating room staff to be available almost simultaneously. The initial reported patient survival at 1 year was 67%, and graft survival was reduced to 55% (Broelsch et al, 1990). The most frequent complications during the initial experience with this procedure were bleeding, primary poor function, and biliary fistulae and strictures. In adult recipients of right-lobe grafts, liver insufficiency became a major problem because of long ischemic times and borderline size matching.

With surgical refinements of liver splitting and transplantation techniques and better patient selection, results improved (Goss et al, 1997; Malago et al, 1997; Yersiz et al, 2006). The introduction of the in situ split-liver technique, developed by Rogiers in 1994, significantly reduced ischemic time of the liver (Rogiers et al, 1996). Using this technique, the liver is divided in situ in the heart-beating deceased donor before cold perfusion starts (Yersiz et al, 2003). While arterial and portal blood supply and venous drainage are preserved, the liver is divided by careful transection of the hepatic parenchyma, most commonly by separating the future left lateral section allograft from the future right trisegment graft. The splitting procedure requires

meticulous hemostasis, which also affects the recipient operation, because little or no bleeding occurs at the cut surface of the graft after reperfusion.

Although the split-liver technique remains a procedure confined to large transplant centers that have experience in segmental grafting, the possibility of transferring a partial graft to another center has now become reality. Today, split-liver transplantation has gained wide acceptance, with results comparable to those of whole-organ transplantation (Deshpande et al, 2002; Diamond et al, 2007; Hong et al, 2009); now a standard procedure, it represents an important technical advance in expanding the total number of transplantable organs. Together with living-related liver transplantation, the split-liver technique has had a substantial impact on the inequities of the pediatric donor organ shortage.

LIVING DONOR TRANSPLANTATION

The success of many centers performing reduced-size and split-liver grafting provided a strong surgical basis for using segments from living donors (Strong et al, 1990; see Chapter 98B), particularly in the treatment of small children with ESLD (Broelsch et al, 1994; Edmond et al, 1993; Otte, 1995; Otte et al, 1998; Raia et al, 1989). Donors are most commonly the parents or other close relatives of the recipient, but nonrelated living donor liver transplantation (LDLT) procedures also are performed (OPTN/SRTR, 2008).

For ethical reasons, adequate and thoughtful selection of donors is a major prerequisite of LDLT, and most centers have adopted stringent donor evaluation protocols (Chen et al, 2003; Surman & Hurtl, 2003). The segmental liver donation must be deemed by the transplant team to be a purely voluntary, altruistic act with no motive of secondary gain, and a complete psychologic and social evaluation of the donor is performed. Potential donors and their families are extensively counseled, and they are evaluated by an independent physician, who acts as the donor advocate and explains the risks of the procedure in detail (Trotter, 2000). Any objections regarding the psychosocial background of the potential donor result in withdrawal from consideration for organ donation (Singer et al, 1989; Surman, 2002; Ghobrial et al, 2008).

Of paramount concern, however, is the medical risk to healthy donors; everything possible must be done to minimize risks of donor morbidity and mortality. As much as possible, the donor must be fully apprised of all the risks, possible complications, and potential sequelae; with the donor so informed, they must accept these possibilities before undertaking the procedure (see Donor Risk in Living Donor Liver Transplantation).

The success of LDLT depends partly on adequate graft volume (Kiuchi et al, 1999). The required graft volume should be determined individually and can be assessed with the use of computed tomography (CT) or magnetic resonance imaging (MRI) (Kamel et al, 2000, 2001). The left lateral section provides the most straightforward dissection, but full left- and right-lobe grafts have been used successfully. The size of the living donor's left lateral section is assessed by volumetric CT or MRI (Urata et al, 1995), the hepatic vasculature is assessed by CT angiography or MRI angiography, and the biliary anatomy is assessed by MR cholangiography or endoscopic retrograde cholangiopancreatography (ERCP). Rarely, percutaneous liver biopsy is done, but only if imaging suggests hepatic steatosis in the donor. The type and size of graft should be decided on an individual basis. In general, a full left-lobe liver graft (segments II through IV) can overcome a disparity between recipient and donor size of about 1:4. With a left lateral segment graft, a disparity of 1:10 or more can be managed. In infants weighing less than 10 kg, left lateral segment grafts are used almost exclusively.

Procedure

The donor liver is approached in the usual manner, through a standard bilateral subcostal incision or a right subcostal incision with upper midline extension. Recently, laparoscopic-assisted or hybrid laparoscopic and open techniques have been described (Baker et al, 2009; see Chapter 98B). Regardless of method, the surgical procedure begins by identifying the structures in the hilum. It is imperative to dissect close to the falciform ligament to avoid injuries to the hilar structures running to the right lobe. The left hepatic artery is isolated and followed to the liver parenchyma, and the left portal vein is dissected free and encircled with a vessel loop. The dissection continues by dividing portal and arterial branches to the caudate, which increases the length of the left hepatic artery and left portal vein. The portal branches to segment IV are ligated, and the left hepatic vein is identified above the liver and encircled with a vessel loop as it enters the vena cava. The hepatic parenchyma is transected just to the right of the falciform ligament, with suture ligation of all vessels and ducts, until the left lateral section is completely separated from the rest of the liver; the segment is still perfused with arterial and portal blood and has drainage via the left hepatic vein.

The parenchymal transection is performed without any vascular control of the graft or the remaining liver to maintain maximal viability. Hepatic transection continues until the hilar plate is reached. At this point, the section II and III bile duct is divided sharply, and its distal end is oversewn with fine, absorbable monofilament suture. With the plane of transection 0.5 to 1.0 cm to the right of the umbilical fissure, approximately 90% of left lateral section grafts will be obtained with a single section II and III bile duct (Renz et al, 2000).

The graft is now ready to be removed. The left portal vein, the left hepatic artery, and the left hepatic vein are simultaneously clamped after giving systemic heparin, and the vascular structures are divided. The left lateral section graft is removed, and the portal vein and the hepatic artery are immediately flushed with cold, heparinized preservation solution. After removing the left lateral section, rarely there may be concern for the viability of segments I and IV, because branches to these segments may be interrupted during the dissections. If there is any doubt about viability, resection may be performed after removal of the graft and a period of observation in the operating room.

As discussed previously, during the recipient hepatectomy, the vena cava is left in situ, and a temporary portacaval shunt may be used. The recipient hepatic vein–vena cava junction is modified to accommodate the anastomosis with the donor hepatic vein. A generous triangular venous anastomosis to ensure adequate drainage of the graft is recommended; the donor hepatic venous cuff should be kept short to provide an anastomosis that is not susceptible to kinking. Portal vein reconstruction is done in an end-to-end fashion. In children with biliary atresia, the recipient's portal vein is often small and may be phlebosclerotic. In these cases, an anastomosis to the confluence of the superior mesenteric and splenic veins may be

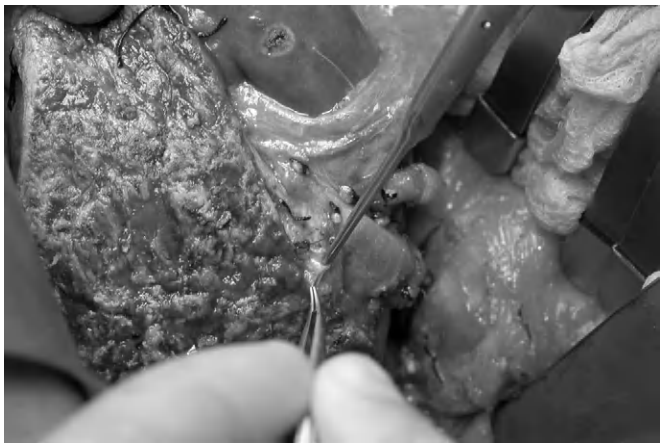

FIGURE 98C.6. Common trunk formed by segments II and III bile ducts from a left lateral section graft.

preferred (Saad et al, 1998). Hepatic artery reconstruction usually can be achieved by an end-to-end anastomosis to the recipient's proper hepatic artery via a microsurgical technique using surgical loupes or a microscope (Inomata et al, 2000). In some cases, a venous interposition graft from the recipient's infrarenal aorta, using donor saphenous vein, is needed to achieve a tension-free arterial anastomosis.

Care must be taken to identify correctly the bile ducts from segments II and III (Fig. 98C.6); such ducts are not obtained with a common trunk up to 10% of the time (Renz et al, 2000; Salvalaggio et al, 2005). The biliary drainage is fashioned using a Roux-en-Y loop of the jejunum with or without a stent. After completion of all anastomoses, the liver rotates slightly to the right and occupies a more central position than it does in the donor (Fig. 98C.7). This slight shift must be taken into account

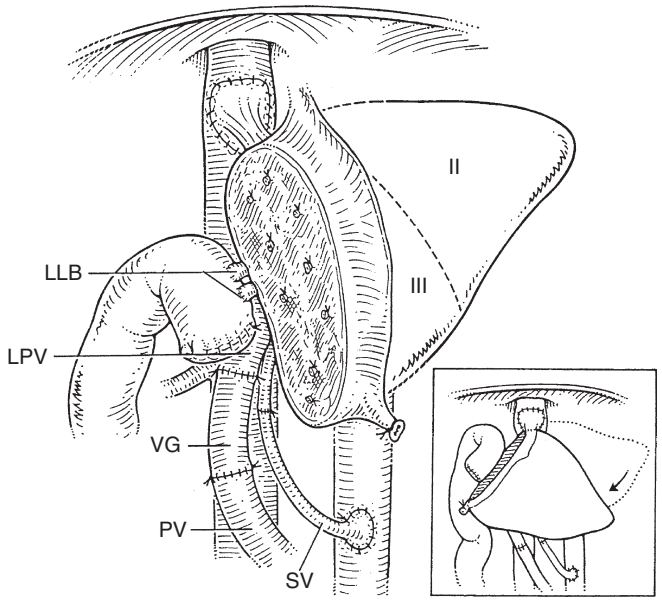

FIGURE 98C.7. Completed recipient implantation. The variant with two bile ducts is depicted. Interposition grafts are used for the hepatic artery and the portal vein to ensure adequate length. The *inset* shows the final position of the graft after abdominal closure. LLB, reresents segment II and III bile ducts; LPV, left portal vein; PV, portal vein; SV, saphenous vein graft to the hepatic artery from the aorta; VG, vein graft.

when performing the vascular and biliary anastomoses. The graft should be resuspended to the anterior abdominal wall by the falciform ligament to prevent further right shift and vascular torsion.

Donation and transplantation of a living donor full left liver lobe (segments II, III, and IV with or without segment I) is similar to that of a left lateral section graft, with a few technical variations. After cholecystectomy, the resection follows the principal plane. The venous outflow of the graft can be provided by the left hepatic vein or preferentially by use of a common patch of the left and middle hepatic vein (Makuuchi & Sugawara, 2003). Devascularization of the main left hepatic bile duct is less of a concern when the caudate is preserved with the allograft.

Although the primary goal of LDLT is the relief of organ shortage, numerous additional benefits are associated with this procedure (Sindhi et al, 1999). The most important advantage for the recipient of a living-donor transplant is a much shorter waiting period leading up to transplantation (Tanaka et al, 1994). Timing of the procedure can be planned, and the operation can be performed under elective conditions, which results in decreased operative risk. Careful donor evaluation and a short cold ischemic time offer uniformly good grafts and can minimize the risk for initial nonfunction (Farmer et al, 2001).

ADULTS

After the encouraging results of living donor left lateral section transplantation in children, this innovative technique was extended to try to solve another problem: the shortage of donor organs for adults (Renz et al, 2003; Strasberg et al, 1999). Especially in countries where cadaveric donor organ transplantation has not been established, either by law or for religious or cultural reasons, living-donor organ donation offers the only chance of liver transplantation for patients with ESLD. In 1991, the first LDLT to an adult was performed in Kyoto by Tanaka, using a left liver graft (Hashikura et al, 1994). This technique has been expanded to the use of full right hepatic lobe grafts, which are now the preferred grafts in adult-adult living donor transplants (Kawasaki et al, 1998; Seek et al, 2002; Brown, 2008).

The right lobe graft (segments V through VIII) comprises approximately 50% to 60% of total liver volume and presents the advantage of fitting exactly in the right hepatic fossa (Fig. 98C.8). Problems with this graft include a large cut parenchymal surface and an irregular biliary, arterial, portal, and hepatic venous anatomy (Trotter et al, 2002). Variations of portal vein anatomy, such as a trifurcation, and variations in arterial anatomy, such as an accessory right hepatic artery, are relative contraindications to living donation of segments V through VIII (Erbay et al, 2003; Imamura et al, 2000). Most often, the right hepatic artery has a large diameter, unless there is an additional right artery arising from the superior mesenteric artery. The hepatic artery and portal vein usually can be anastomosed directly to the recipient's vessels. In most cases, venous drainage of the right graft is achieved exclusively via the right hepatic vein, and a careful anastomosis of this vessel with the vena cava or the orifice of the recipient's right hepatic vein must be performed to prevent compromised venous outflow and congestion of the graft. If necessary, the orifice should be enlarged longitudinally to provide an exact anastomosis.

In the case of a second right hepatic vein, such as an inferior right hepatic vein, two independent anastomoses are

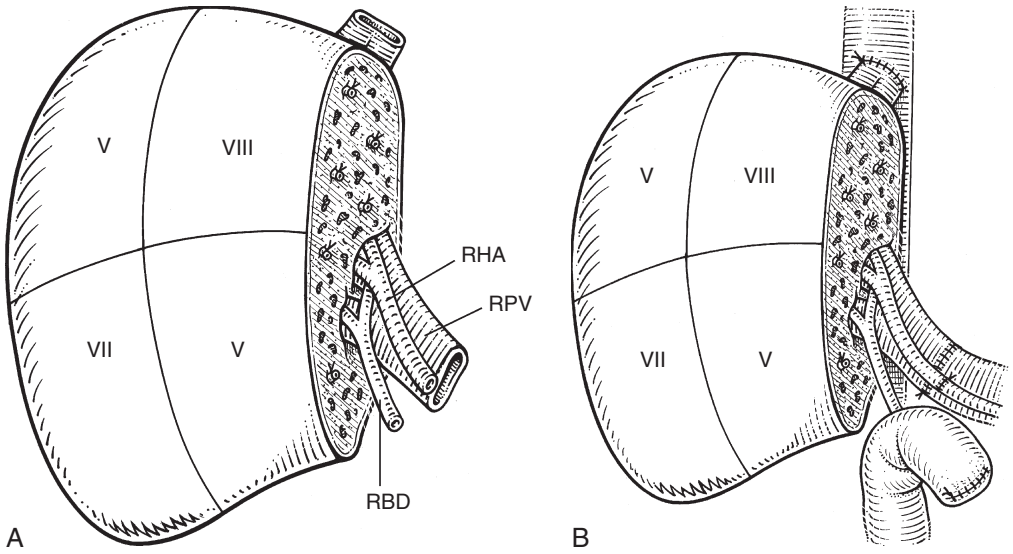

FIGURE 98C.8. **A,** Right graft from a living donor with short hilar structures and a short right hepatic vein (*RHV*). **B,** Completed recipient implantation of a right graft. RBD, right bile duct; RHA, right hepatic artery; RPV, right portal vein.

recommended for uncompromised venous drainage (Ghobrial et al, 2001). The inclusion of the donor middle hepatic vein with the graft is controversial (Fan et al, 2003). Biliary reconstruction can be challenging, because bile ducts from segments V through VIII may not form a common trunk, and two or more ducts may be present (Fan et al, 2002). Reconstruction with a Roux-en-Y hepaticojejunostomy is standard. A direct biliary anastomosis to the recipient's bile duct using a T-tube may be considered when a large, single right hepatic bile duct is present.

One dilemma of LDLT in adults centers on the maximum extent of liver resection that can be safely tolerated by the donor and the minimum amount of hepatic mass necessary for the recipient to survive (Fan et al, 2000). The definition of small-for-size grafts is vague, because the minimal amount of liver compatible with life is unknown, and variables such as ischemia-reperfusion injury, steatosis, or rejection may reduce further the initially transplanted liver mass (Hill et al, 2009). Many reports have indicated that grafts corresponding to no more than 40% of the recipient's standard volume may not be expected to function well (Pomfret, 2003). At present, a graft/body weight ratio of 0.8% or a graft volume greater than 50% of the standard liver volume are suggested values for successful grafting (Kiuchi et al, 1999; Sugawara et al, 2001). The use of an extended right liver with the middle vein retained with the graft lowers the risk of liver insufficiency in the recipient but is associated with greater donor morbidity and possible mortality. Because this procedure requires a major hepatectomy with the donation of about two thirds of total liver volume, transient impairment of donor liver function is common (Lo et al, 1999; Pomfret et al, 2003).

Prolonged cholestasis in the absence of rejection or mechanical bile duct obstruction is a hallmark of small-for-size grafting. In such patients, the perioperative management is focused on avoiding any further damage to the graft. Unless retransplantation is considered, optimal supportive care is currently the only therapy for small-for-size liver transplantation. Temporary liver support systems, such as artificial liver devices or extracorporeal perfusion, are under investigation, but their clinical use is not yet available in the United States (Demetriou et al, 2004; see Chapters 73 and 97C). In the future, it may be desirable to combine temporary liver support systems with small-for-size organs. This could be one option to improve organ shortage in adults by an extended use of LDLT.

Although there are several advantages for the recipient of an LDLT, an adult-adult LDLT subjects the donor, a healthy individual, to all of the risks of a major abdominal operation. Risk minimization begins with careful selection of appropriate candidates during the donor evaluation; however, despite careful donor and patient selection, LDLT still has significant risks for the donor, as well as potential added complications to the recipient, compared with a full-sized cadaveric donor graft (Man et al, 2003; Sugawara et al, 2003).

DONOR AND RECIPIENT RISK IN LIVING DONOR LIVER TRANSPLANTATION

Early enthusiasm for adult-adult LDLT has been tempered by growing concern for donor morbidity and mortality. Following one high-profile donor death reported in 2002 (Trotter et al, 2006), the annual number of LDLTs in the United States declined steadily, from a high of 522 in 2001 to only 266 in 2007 (OPTN/SRTR, 2008). Quantifying the risk associated with LDLT has been difficult, because no formal international registry exists to prospectively collect data on donors worldwide. UNOS has only recently mandated reporting of outcomes for all LDLT donors who are taken to the operating room for a donor hepatectomy, but this data set is not yet mature enough to be informative (Trotter et al, 2006). Most published reports of complications associated with adult-adult LDLT have come from single-center experience, and reports vary widely, with complication rates as low as 9% and as high as 67% (Ghobrial et al, 2008; Marsh et al, 2009). Estimates of donor mortality rates range from 0.1% for left lateral section grafts to 0.5% for right lobe grafts (Ringe & Strong, 2008).

In an effort to provide an unbiased assessment of the risks and severity of complications for both donors and recipients of LDLT, the nine-center, NIH-funded Adult-to-Adult Living

Donor Liver Transplantation (A2ALL) cohort study was initiated in 2002 (Ghobrial et al, 2008). The first phase of the A2ALL study utilized a retrospective, observational design and included 405 potential donors accepted for LDLT from 1998 through 2003. Among this cohort, 393 underwent donation, 12 procedures were aborted (3%), and 148 donors (38%) experienced a total of 220 complications. The most common postoperative complication was bacterial infection (12.5%), followed by biliary leak (9.2%), incisional hernia (6%), pleural effusion requiring drainage (5%), neuropraxia (4%), repeat laparotomy (3%), wound infection (3%), and intraabdominal abscess (2%). One patient died from gastric gas gangrene, sepsis, and multiorgan failure on the third postoperative day; another died from a drug overdose, and a third died from suicide, more than a year after operation; and a fourth donor died in a nonsuicide pedestrian-train accident 2 years after operation (Ghobrial et al, 2008; Trotter et al, 2006).

In addition to examining donor morbidity, the A2ALL cohort study examined complications to recipients of adult-adult LDLT relative to recipients of deceased-donor liver transplantation (DDLT). Overall, the complication rate after LDLT was not significantly higher than after DDLT (82.8% vs. 78.2%; $P = .17$), but the severity of complications was greater. Among a cohort of 384 LDLTs and 216 DDLTs, the complications that occurred more frequently in recipients of LDLT included bile leak (31.8% vs. 10.2%), unplanned laparotomy (26.2% vs. 17.1), hepatic artery thrombosis (6.5% vs. 2.3%), and portal vein thrombosis (2.9% vs. 0%). Complications leading to retransplantation or death with or without retransplantation also occurred more often after LDLT than after DDLT (15.9% vs. 9.3%); however, in a separate analysis that factored in center experience, the authors found a significant decline in LDLT complications after a center had performed at least 20 procedures (Freise et al, 2008).

The systematic data collection, analysis, and reporting methods used in the multicenter A2ALL cohort study have helped to more accurately characterize and quantify both the benefits and risks associated with adult-adult LDLT. One limitation of the study thus far has been its retrospective design, but a prospective phase of the A2ALL cohort study was initiated in 2004.

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS AFTER PEDIATRIC LIVER TRANSPLANTATION (SEE CHAPTER 100)

In the immediate postoperative period, monitoring of graft function is achieved by evaluation of acid-base status, blood glucose, mental status, coagulation time, liver enzymes, and cholestasis parameters. Doppler ultrasound frequently is performed to ascertain patency of hepatic vessels, in particular of the hepatic artery.

Primary nonfunction of the graft occurs in 2% of patients and requires immediate retransplantation (Doyle et al, 1996). With regard to pediatric recipients, retransplantation with a reduced size graft from a cadaveric donor or a living donor may offer emergency options (Seiders et al, 2002). The most frequent complication after liver transplantation is hemorrhage, which may occur during the transplant procedure or in the immediate perioperative period. If a child becomes unstable or hypotensive in the postoperative course, it is prudent to reexplore immediately. The use of the protease inhibitor aprotinin (Trasylol) and an antifibrinolytic agent such as aminocaproic acid (Amicar) may help reduce diffuse bleeding, but the debate continues concerning potential increased risk of arterial thrombosis after their use (Himmelreich et al, 1992; Kang et al, 1987; Xia & Steadman, 2005).

Hepatic artery thrombosis (HAT) is the most common vascular complication in pediatric OLT and is a major cause of early graft failure and retransplantation. Previously published rates of HAT were over 25% (Dalgic et al, 2003; Heffron et al, 2003), but more recent large series report rates ranging from 5% to 19% (D'Alessandro et al, 2007; Diamond et al, 2007; Duffy et al, 2009; Farmer et al, 2007; Salvalaggio et al, 2005; Yilmaz et al, 2007). Decreases in the incidence of HAT are attributed to improved surgical techniques. Careful anticoagulation and rheologic management and avoidance of rejection also may diminish the risk of HAT. Doppler ultrasound, used routinely or with a low threshold based on clinical indications, is essential for early diagnosis and possible thrombectomy and revascularization. Portal vein thrombosis occurs less frequently than HAT but is estimated to occur in 3% to 8% of all pediatric OLTs, and incidence increases with segmental grafts (Chardot et al, 1997; Diamond et al, 2007; Millis et al, 1996).

Similar to HAT, graft rejection or preservative injury with swelling of the liver increases the risks for portal vein thrombosis. Large-for-size transplantation is another risk factor for thrombosis (Kiuchi et al, 1999), if elevated intraabdominal pressure is not lowered using a patch abdominoplasty. Early portal vein thrombosis rarely may be treated successfully by emergency thrombectomy and revascularization. Late portal vein thrombosis with complications of portal hypertension may be an indication for retransplantation (Dalgic et al, 2003; Vilca-Melendez & Heaton, 2004).

Biliary strictures are the most common complication of segmental OLT (10% to 35%) (Bhatnagar et al, 1995; Reichert et al, 1998). In partial grafts, the biliary complication rate can be as high as 40% (Anderson et al, 2010; Diamond et al, 2007; Salvalaggio et al, 2005). It is important to recognize biliary complications early and to treat them aggressively, because biliary complications account for approximately 8% of late graft loss in pediatric OLTs. With widespread use of percutaneous radiologic intervention, such as transhepatic balloon dilation and stenting, the need for surgical reintervention and reconstruction has decreased (Heffron et al, 2003; Ko et al, 2008; Moreira et al, 2010).

Many children who undergo liver transplantation have had a prior portoenterostomy and are at risk for iatrogenic bowel injury as a result of the adhesiolysis during native hepatectomy. A high index of suspicion and early repeat laparotomy and primary closure of any perforation are crucial to prevent systemic complications of sepsis. Many children have compromised pulmonary function before the transplant procedure because of significant arteriovenous pulmonary shunting, pulmonary infections, or pleural effusions. Postoperatively, respiratory problems may be worsened as a result of diaphragmatic splinting or temporary right hemidiaphragm paralysis, pulmonary edema secondary to perioperative fluid shifting, or atelectasis. In children with high intraabdominal pressure secondary to a relatively large liver, a tension-free temporary closure of the abdomen with a prosthetic graft is advisable (Fig. 98C.9). This abdominal wall graft may be reduced in size over several days, similar to when an abdominal wall silo is used in newborns with gastroschisis (Cacciarelli et al, 1997; Noble-Jamieson & Barnes, 1999).

FIGURE 98C.9. A, Temporary abdominal closure, using a prosthetic patch, after transplantation of a left lateral section graft into a neonate. **B,** The graft is reduced in size over several days and is finally removed altogether, and the abdomen is closed.

Peritransplant impairment of renal function is common but is usually reversible. Reduction or temporary cessation of nephrotoxic immunosuppressive medications (e.g., cyclosporine or tacrolimus) may help to improve renal function. Less than 5% of children need temporary dialysis after transplantation, unless this was already a pretransplantation requirement (Bartosh et al, 1997; Berg et al, 2001).

Septic complications and infections are lifelong risks in an immunocompromised patient. In the initial postoperative course, bacterial infections with *Enterococcus faecalis, Pseudomonas* species, and *Staphylococcus aureus* are most common, often related to central venous lines or bacterial translocation from the gut (Deen & Blumberg, 1993; Fishman, 1999). Viral infections, which usually occur in children immunologically naive to cytomegalovirus (CMV) or Epstein-Barr virus (EBV) before transplantation, typically manifest about 6 weeks after transplantation and may be effectively prevented or treated by ganciclovir. Fungal infections may occur frequently in patients seen with acute hepatic failure, and the use of prophylactic oral antifungal medication is recommended (Gladdy et al, 1999; Kahn et al, 1988).

IMMUNOSUPPRESSION

Much of the progress in pediatric liver transplantation is attributable to improvements in immunosuppression (Evrard et al, 2004; see Chapter 97B), and treatment regimens are constantly in development, even as new drugs become available. Children generally have a higher incidence of rejection and require higher levels of immunosuppressive agents compared with adults. Baseline immunosuppression consists of a corticosteroid and a calcineurin inhibitor (cyclosporine or tacrolimus; van Buren et al, 1998). Tacrolimus has the advantage of requiring lower steroid dosage than cyclosporine for the same level of immunosuppression and less risk of hirsutism and gingival hyperplasia. Mycophenolate commonly is used to minimize the nephrotoxic effects of cyclosporine and tacrolimus. The initial 12-hour trough levels should be about 250 to 300 ng/mL for cyclosporine and about 10 ng/mL for tacrolimus.

In the early postoperative period, levels of immunosuppressive drug should be maintained at a higher level to avoid rejection periods; elevated drug levels can result in severe graft edema with subsequent arterial or portal vein thrombosis, so drug levels are tapered over time (Mazariegos et al, 1997), and most children can be weaned off the steroid component within 1 year. Recent studies have shown excellent graft survival in pediatric OLT patients maintained on tacrolimus (Prograf) monotherapy. Additional benefits of reduced immunosuppression include decreased infection rates and improvements in renal function and growth (Turmelle et al, 2009) with reports of complete withdrawal of immunosuppressants in children several years after transplantation (Diem et al, 2003; Reding et al, 2003; Riordan & Williams, 1999).

RESULTS OF PEDIATRIC LIVER TRANSPLANTATION

The application of split-liver grafts and LDLT has led to significant relief of the organ shortage in pediatric liver transplantation, particularly among small infants with ESLD (Hong et al, 2009; Sindhi et al, 1999). In the decade from January 1998 through December 2007 in the United States, 5762 pediatric liver transplantations were performed. LDLT accounted for approximately 14% of these transplantations (OPTN/SRTR, 2008). The overall survival rates after liver transplantation in children are good, and most centers report 1-year rates greater than 80% (OPTN/SRTR, 2008). In the United States, 5- and 10-year actuarial survival of children who have undergone liver transplantation for biliary atresia is 87.2% and 85.8%, respectively. For elective transplantation in children with stable metabolic disease, the 1-year survival is 95% (Abt et al, 2004; SPLIT Research Group, 2001; OPTN/SRTR, 2010).

Extremely young age, low body weight, and anatomic abnormalities all increase the complexity and complication rate of pediatric OLT (Anderson et al, 2008). A series from Hamburg of 12 infants weighing less than 5 kg had a survival of 75% at 1 year (Lang et al, 2000; Rogiers et al, 1997). This series showed the feasibility of liver transplantation in small infants. Children with FHF who undergo emergency hepatic transplantation have 1-year survival rates of approximately 60% (Lee et al, 2001; Uemoto et al, 2000). Likewise, infants with vascular and other anomalies associated with biliary atresia have increased complication rates and decreased survival (Anderson et al, 2008).

There is no doubt that outcome in liver transplantation is related directly to the severity of illness and the physical condition of the child (Farmer et al, 2007; Kimura et al, 2004). Early referral to a pediatric transplant center, along with early liver grafting before the clinical condition deteriorates significantly, remains the most decisive factor for success.

Living donation not only leads to a relief of organ shortage, it also offers the advantage of careful timing and the performance of transplantation under elective conditions. Although, LDLT is a valuable strategy to minimize waiting times in children, the ultimate goal of the successful pediatric transplant center should be to decrease waiting-list mortality while maintaining excellent posttransplant outcomes; this is most often accomplished using a strategy that utilizes all donor types.

CHAPTER 91B

Vascular reconstruction techniques

Patrick Pessaux and Jacques Belghiti

OVERVIEW

Improvements in our understanding of the anatomy and function of the liver, expertise stemming from liver transplantation, and the advances of hepatic imaging have allowed extension of the surgical limits in the area of hepatic resection. Extensive liver resection for malignant tumors, which requires a sufficient functional liver remnant volume for patient recovery, may be performed with concomitant vascular reconstruction to ensure oncologically adequate resection and adequate liver function (see Chapter 94). Parenchymal resection can be performed with caval, portal, and, exceptionally, arterial resection to improve resectability of many tumor types. Hepatic vein (HV) reconstruction has been more recently emphasized for improving postoperative liver function and regeneration.

VENA CAVA AND HEPATIC VEIN RESECTION

Complete Obstruction of the Inferior Vena Cava

When liver tumor is associated with complete inferior vena cava (IVC) obstruction, collateral circulation usually provides sufficient venous drainage (Fig. 91B.1), therefore obstruction symptoms, such as edema of the lower extremity, are uncommon. Leiomyosarcoma of the retrohepatic IVC is the main etiology of a complete obstruction of the IVC. In this situation, liver resection with concomitant IVC resection is appropriate, providing preservation of the collaterals can be performed without restoration of caval flow. IVC replacement is considered in patients who have poor development of collateral circulation and in those who require wide retroperitoneal resection for lymph node dissection, which can disrupt preexisting venous channels and reduce collateral venous return (Beck & Lalka, 1998; Yoshidome et al, 2005).

After IVC resection, lower-limb venous thrombosis occurs in about 25% of patients, and reduction of the collateral circulation may increase this risk (Mingoli et al, 1991). After caval flow interruption, postoperative renal dysfunction occurs in 0% to 40% (Daylami et al, 2010). Because the left renal vein has multiple collateral venous developments—gonadal, adrenal, and lumbar—ligation of the left renal vein is not deleterious (Griffin & Sterchi, 1987); however, the right renal vein has few collateral venous systems, and its ligation can be harmful and often necessitates reimplantation into the IVC or into the left renal vein.

Partial Obstruction of the Inferior Vena Cava

Colorectal liver metastasis and intrahepatic cholangiocarcinoma (see Chapters 50A and 81A), which are best treated by R0 resection, may involve the IVC. Preoperative morphologic assessments are generally inaccurate to differentiate malignant infiltration of the vena cava wall from a simple tumoral adhesion; therefore concomitant hepatic and IVC/HV resection should be considered when tumor involvement of the IVC or the venous confluence is suspected. Invasion of the vena wall is found in 22% to 72% of patients and can be assessed intraoperatively by palpation, ultrasonography, or even by intravascular ultrasonography (Azoulay et al, 2006; Hemming et al, 2002; Kaneko et al, 1996; Kikumori et al, 2003). Experience in living donor liver transplantation (LDLT) has shown that congestion of the remnant liver territory is underestimated (Scatton et al, 2008). Impairment of venous outflow of the remnant liver has deleterious consequences on postoperative liver function and regeneration, emphasizing the need for reconstruction of the corresponding draining HV, especially when the volume of the remnant liver is marginal (Nakamura et al, 1990). In addition, maintaining the normal anatomy of the hepatic veins in the remnant liver may be beneficial to preserve the possibility of repeat hepatectomy for tumor recurrence, particularly in patients resected for colorectal liver metastasis (Pessaux et al, 2006).

Many studies report the technical aspects of vascular resection with hepatectomy, but few report the long-term results with survival rate. Venous involvement is a poor prognostic factor, but given the poor results of nonsurgical treatment, aggressive surgical resection that includes major vascular resection offers the best results in selected patients (Aoki et al, 2004; Miyazaki et al, 1999).

Hepatocellular carcinoma (HCC) has a strong propensity for vascular invasion and direct intravascular extension (see Chapter 80). Autopsy series report IVC involvement from 9% to 26% and right atrium involvement from 2.4% to 6.3% (Sung et al, 2008). Most patients are seen initially with symptoms of portal hypertension or right-sided heart failure (diuretic-resistant lower extremity edema). Efficient treatment requires liver parenchymal resection associated with vascular resection and thrombectomy under vascular exclusion (see Chapter 91A). This procedure, which requires expertise in both vascular and liver surgery, usually includes simultaneous hepatectomy and thrombectomy under vascular exclusion (Sung et al, 2008). Major bleeding and difficult vascular reconstruction are associated with the risk of thrombus migration into pulmonary arteries (Shirabe et al, 2001). When tumor thrombus extends to the right atrium, liver resection associated with cardiopulmonary bypass should be considered.

Resection

According to the extent and location of the IVC involvement, various approaches, including thoracoabdominal access, have been described (Torzilli et al, 2007). Because complete mobilization of the liver could be hazardous, an anterior approach to

FIGURE 91B.1. Complete obstruction of the inferior vena cava with development of collateral circulation.

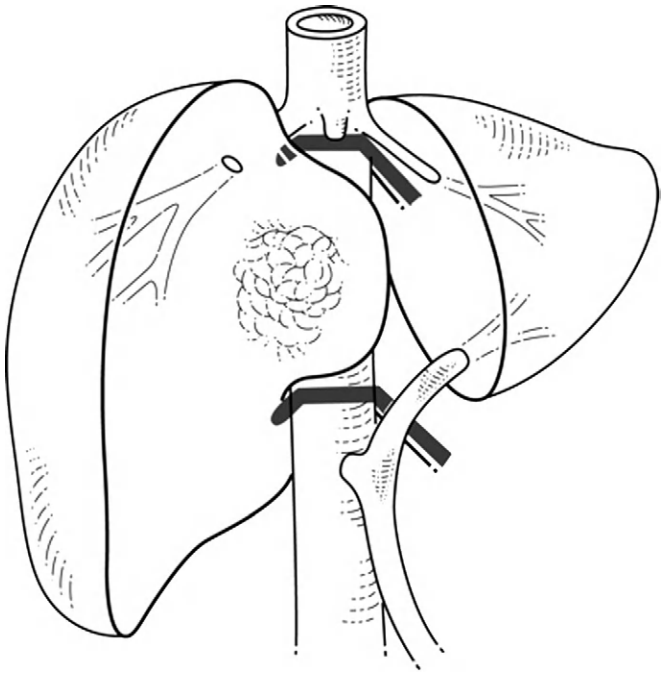

FIGURE 91B.2. Clamps placed above and below the area of tumor involvement on the inferior vena cava.

the IVC can be performed (Liu et al, 2000). After extrahepatic control of the IVC below and in the upper liver, the anterior approach includes initial liver resection toward the IVC.

If the portion of the IVC involved by the tumor is below the hepatic veins, the hepatic parenchyma is divided using intermittent inflow occlusion if necessary (Belghiti et al, 1999). Once the IVC is exposed, portal inflow occlusion is released if used, the patient is volume loaded, and clamps are placed above and below the area of tumor involvement (Fig. 91B.2; see Chapter 91A). This caval clamping allows resection of the portion of the liver involved by tumor with the portion of vena cava involved by tumor, followed by partial or total reconstruction of the IVC. Positioning the clamps below the hepatic veins allows perfusion of the remnant liver and minimizes ischemic time.

In cases of lateral IVC involvement, a single clamp may be applied tangentially to the IVC to preserve a vena caval flow (Fig. 91B.3), but this procedure is not applicable when the tumor involves the whole hepatocaval confluence. In such cases, are two different approaches may be applied. The first one includes a total vascular exclusion of the liver with subsequent infrahepatic IVC, pedicular, and suprahepatic IVC clamping (Fig. 91B.4; see Chapter 91A). Total vascular exclusion induces a decrease of 40% to 50% in the cardiac index and may be not well tolerated in some patients (Azoulay et al, 2006; Hemming et al, 2004). The second one includes use of an active venovenous bypass between the portal and axillary vein and between IVC and axillary vein can also be used (Azoulay et al, 2006; Hemming et al, 2004). When a biopump is used, in situ hypothermic perfusion of the liver parenchyma can be added to prevent postoperative liver failure as a result of prolonged ischemia (Azoulay et al, 2006; Hemming et al, 2004; see Chapter 94).

Extrahepatic control of the IVC can be attained without using total hepatic vascular exclusion (Varma et al, 2007). The suprahepatic IVC is taped just below the diaphragm, the

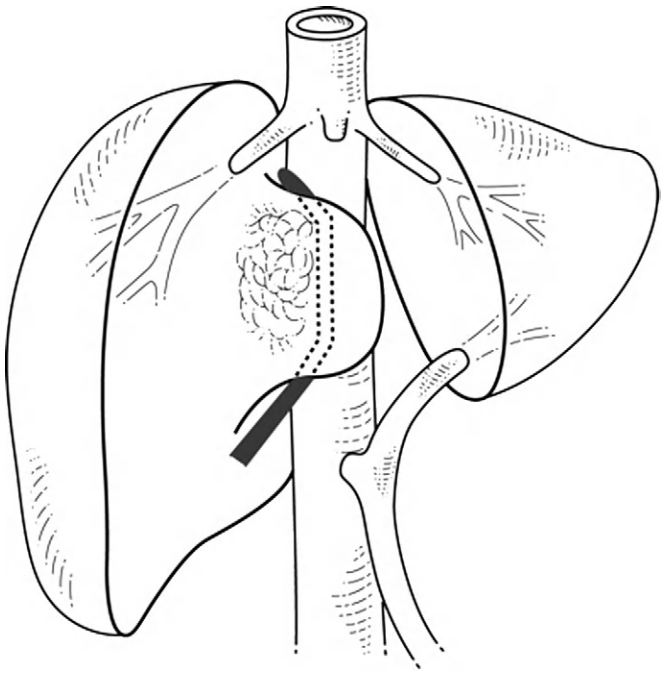

FIGURE 91B.3. A single clamp could be applied tangentially to the inferior vena cava to preserve vena caval flow in case of lateral wall involvement.

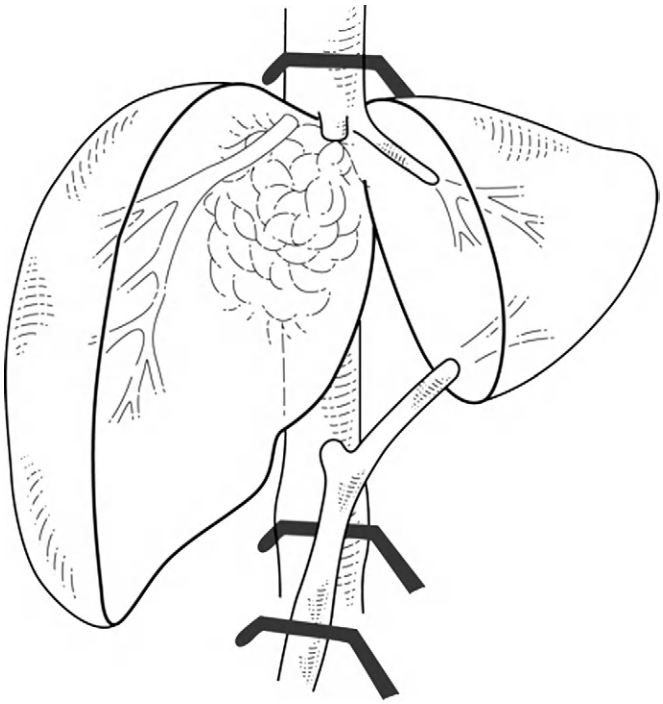

FIGURE 91B.4. Total vascular exclusion of the liver: the infrahepatic vena cava, hilum, and suprahepatic vena cava are serially clamped.

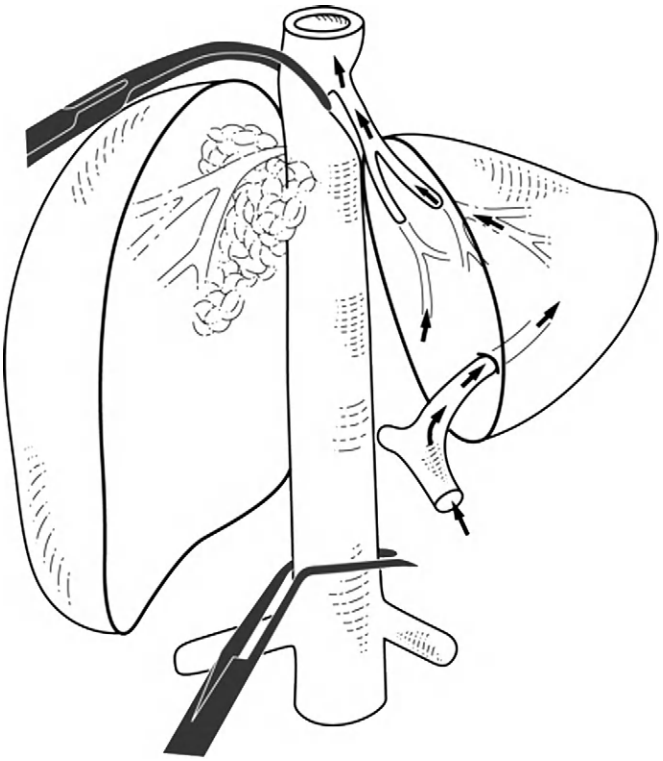

FIGURE 91B.5. The infrahepatic vena cava is clamped, and a clamp is placed obliquely on the suprahepatic inferior vena cava to occlude right hepatocaval confluence and juxtahepatic vena cava.

common trunk of the left and middle hepatic veins is dissected, and a previously deployed suprahepatic tape is rotated to the right side between the vena cava and common trunk; this isolates the right hepatocaval confluence and juxtahepatic vena cava, leaving the common trunk and the rest of IVC free. The infrahepatic IVC is clamped, and concerning the suprahepatic IVC, a clamp is placed obliquely to occlude the right hepatocaval confluence and juxtahepatic vena cava (Fig. 91B.5). When right the hepatocaval junction is uninvolved, this procedure can be used in patients with left-sided neoplasms by reversing the caval tape to the left side (Maeba et al, 2001). The remnant liver receives complete inflow with uninterrupted outflow through the uninvolved hepatocaval confluence, the patency of which is maintained. This technique may also be used when synchronous involvement of the IVC and any one of the hepatocaval confluences is apparent, with at least one HV being free of tumor. This procedure has the potential disadvantage of incomplete vascular control during parenchymal transection in the presence of large veins from the caudate lobe, which leads to backflow venous bleeding. This problem can be overcome by associated resection of segment I.

Advances in liver transplantation techniques have allowed expansion of the ex vivo procedure in selected resections (see Chapter 94). This challenging technical procedure, described by Pichlmayr and colleagues (1988), is seldom performed (Hemming & Cattrall, 1999; Miyazaki et al, 2007b; Yanaga et al, 1993). Although a biopump ensures venous return to the supradiaphragmatic venous system, the liver is completely removed and perfused with preservation solution. Bloodless transection of hepatic parenchyma can then be performed, allowing complex reconstruction of hepatic veins or portal structures before reimplantation of the liver. A simplified technique was proposed with preservation of the continuity of the portal triad (Sauvanet et al, 1994). This technical modification reduces the duration of the anhepatic phase and avoids the risks of artery and biliary reconstruction.

Reconstruction

Hepatic Vein

Autologous vein graft using the external iliac, superficial femoral, saphenous, ovarian, portal, and left renal vein has been used for hepatic vein reconstruction (Nakamura et al, 1990, 1993; Ohwada et al, 1998; Takayama et al, 1996). The quality of the anastomosis itself and the blood flow volume through the graft are a concern in the long-term patency after a hepatic vein reconstruction. The selection of an optimal graft size is also important. Hepatic reconstruction using autologous vein grafts obtained from the upper abdominal cavity could be performed without requiring an additional skin incision. In addition, the portal vein or uninvolved hepatic vein from the resected specimen could be used (Hemming & Cattral, 1999), provided it is not involved with tumor; however, it has been reported that interposition grafts are complicated by thromboses in about 25% of patients (Nakamura et al, 1993). Venous graft must be kept as short as possible to avoid kinking, a risk factor for occurrence of thrombosis; however, grafts are not always necessary (Hemming et al, 2002; Nakamura et al, 1997). Even if cut flush with the liver surface, an HV can be anastomosed without an extension graft to either the origin of the same HV or, if necessary, lower down on the IVC. It is necessary to fashion a long, isolated segment of the HV (Oshita et al, 2009).

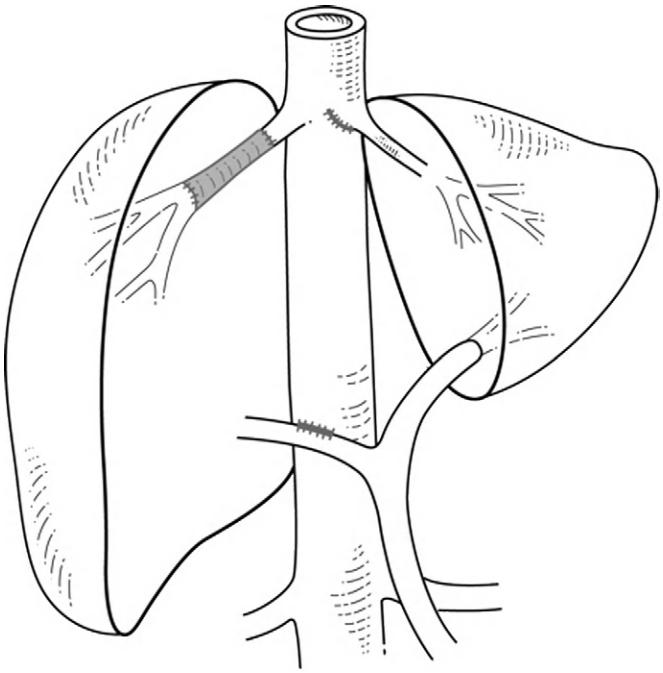

FIGURE 91B.6. Central hepatectomy with resection of the right hepatic vein reconstructed by extended polytetrafluoroethylene graft.

The advantage of expanded polytetrafluoroethylene (ePTFE) graft is the range of lengths and diameters that can be easily obtained (Fig. 91B.6). Potential disadvantages include long-term stricture and thrombosis. A synthetic graft carries a high risk of infection in cases of hepatic resection, especially with concomitant bilioenteric anastomosis or in cases with high risk of postoperative bile leakage, such as after segment VIII resection or after a resection close to the portal bifurcation (Yamashita et al, 2001).

Vena Cava

Repair of the resected IVC may be performed by three different modalities: 1) primary closure, 2) patch repair, and 3) prosthetic replacement, depending on the extent of the defect. In the literature, infection of prosthetic caval grafts has been reported (Bower et al, 2000; Yoshidome et al, 2005). An omental wrap has been described to protect prosthetic caval grafts from infection (Hemming et al, 2004). The second problem is the long-term patency of the prosthetic graft. The ringed, reinforced ePTFE graft is currently recommended, because it provides the best results, given the length of the missing segment and the need for strength to resist compression in the abdomen to prevent graft collapse. It remains to be demonstrated whether anticoagulation is required. Some authors (Hardwigsen et al, 2001) have proposed an arterialization of the graft to enhance its patency between either the remaining left renal vessels or the right renal artery and homolateral gonadic vein.

PORTAL VEIN RESECTION

Complete Obstruction

The complete obstruction of the portal vein with cavernous transformation remains a contraindication for the resection. In cases of HCC involving portal veins, the liver Cancer Study Group of Japan classifies the tumor invasion of the first branch of the portal vein and tumor in the main portal trunk or the opposite-side portal branch into two groups, vp3 and vp4 (Liver Cancer Study Group of Japan, 2003), because there might be a crucial difference between both groups in terms of therapeutic and prognostic aspects. Tumor thrombus of vp3 can be completely removed by a major hepatectomy with the division of the ipsilateral portal branch near the bifurcation, but vp4 tumor thrombus must be removed by a thrombectomy or via an en bloc combined resection and reconstruction of the main portal vein with the hepatectomy.

The difference in outcome between thrombectomy and partial portal vein resection is clear: Konishi and colleagues (2001) reported a 2-year survival rate of 34% with a 0% postoperative mortality rate following thrombectomy. Wu and colleagues (2000) reported a 2-year survival rate of 48% with 0% postoperative mortality following hepatectomy with combined partial portal vein resection. These results were confirmed by Inoue and colleagues (2009), who reported no survival difference in patients with macroscopic portal tumor thrombus undergoing a thrombectomy and a portal vein resection. Tumor thrombus derived from HCC grows expansively and rarely infiltrates the portal wall. It is logical to assume that if the tumor thrombus does not infiltrate into the portal venous wall, thrombectomy is a viable treatment option.

Partial Obstruction

Hilar or intrahepatic cholangiocarcinoma and liver metastases could involve the portal bifurcation (see Chapter 50). An en bloc portal vein resection may be necessary to achieve local tumor clearance and to increase resectability. In cases of hilar cholangiocarcinoma, infiltration or perivascular involvement after portal vein resections are present only in 22% and 13%, respectively (Neuhaus et al, 1999). No-touch techniques are generally used in oncologic surgery to prevent dissemination of tumor cells. Right-sided liver resections follow this principle, all the more so if the resection line is extended to the left portion of the hepatoduodenal ligament by portal vein resection. It is unnecessary to strip the right portal vein branch of the hepatic duct bifurcation, and the portal bifurcation can be left undisturbed as well, which further decreases the required extent of hepatoduodenal dissection. Recent studies have reported improved postoperative outcomes similar to those in patients without portal vein resection with a mortality rate of less than 10% (Bachelier et al, 2011; Kondo et al, 2003; Miyazaki et al, 2007a; Neuhaus et al, 1999). Neuhaus and colleagues (1999) reported a 5-year survival rate of 65% for patients who underwent hepatectomy with en bloc portal vein resection.

Resection (See Chapters 50B and 90B)

After completion of a lymphadenectomy down to the celiac trunk, the common bile duct and the portal trunk are dissected and encircled by a loop just above the pancreas. The right hepatic artery generally crosses behind the tumor and is isolated close to the proper hepatic artery. The left hepatic artery courses some distance to the tumor and is isolated up to the umbilical fissure. The bile duct is divided at the superior margin of the pancreas, and the right hepatic artery is divided. The proper and left hepatic arteries are fully isolated from the tumor region. The only connections of the hepatic hilum with the tumor to

the surrounding structures are the main portal vein trunk and the left portal vein branch. Parenchymal transection is then performed. In case of bleeding during liver transaction, the hepatic pedicle is occluded by intermittent clamping (10 minutes clamping, 5 minutes clamping release). The specimen is attached to the portal vein bifurcation only; both parts of the portal vein are occluded with vascular clamps, superior to the duodenal bulb and within the umbilical fissure, respectively. Portal vein reconstruction is performed under portal vein occlusion only, in order to preserve the arterial hepatic flow.

Some authors have reported portal vein resection and reconstruction before hepatic dissection (Kondo et al, 2003). The risk of this technique is that surgical maneuvers after portal vein reconstruction might produce tension on the portal anastomosis, leading to its disruption.

Reconstruction

In most portal vein resections, end-to-end reconstruction can be performed without using segmental grafts. A continuous suture should be used, and an oblique cut on the left portal vein branch is performed to allow for the difference in caliber of the two ends. To avoid stricture, the surgeon should carefully reconstruct the portal vein without kinking in the reconstruction portion. This is achieved by maintaining precise anterior-posterior orientation when placing vascular clamps. Sufficient expansion of the reconstructed vein should be obtained by release of a proximal vascular clamp before the suture is tied, which should be done relatively loosely to allow for expansion. The right colon and the root of the mesentery are mobilized to obtain enough length to perform a tension-free anastomosis. In the literature, autologous vein grafts have been reported, such as external and internal iliac, jugular, or left renal veins.

ARTERIAL RESECTION

Indication

Hilar cholangiocarcinoma and advanced gallbladder cancer (see Chapters 49 and 50B) have the propensity to invade extensively, not only along the bile duct but also into adjacent organs via lymphatics and perineural spaces. Regions of the portal vein and right hepatic artery bifurcations are often involved, because these vessels run just behind the bile duct and to the left of the gallbladder neck. Hepatic artery resection is less common, because the reconstruction is more complicated, and microvascular techniques are required. Furthermore, this level of invasion is often associated with advanced disease that is not amenable to resection, particularly in cases of gallbladder cancer; however, hepatectomy with combined portal vein/hepatic artery resection and reconstruction has been reported (Miyazaki et al, 2007a; Shimada et al, 2003). Hepatic artery resection may result in a higher postoperative mortality rate than portal vein resection, because hepatic artery resection has been combined with portal vein resection in most patients: the mortality rate could reach 33% to 56% (Gerhards et al, 2000; Miyazaki et al, 2007a, 2007b).

The survival rate is very poor after hepatic artery resection. Miyazaki and colleagues (2007b) reported 1- and 3-year survival rates of 11% and 0%, respectively, similar to unresectable patients, with survival rates of 15% and 0% at 1 and 2 years. A surgical team reported controversial results, with acceptable mortality, by an experienced surgeon (2%) and acceptable long-term survival in selected patients (30.3% at 5 years) (Nagino et al, 2010). The authors explained these good results by the fact that arterial vascular reconstruction was performed by plastic or vascular surgeons under a surgical microscope, they had previous experience with portal resection, and they practiced meticulous perioperative management.

Resection

To avoid long-term ischemic liver injury during both the resection and reconstruction of the hepatic artery and the portal vein, simultaneous resection and interruption of both vessels should be avoided. The portal vein should be resected first and reconstructed prior to hepatic artery resection. Then immediately after the reconstruction of the portal vein, the hepatic artery can be resected with the surgical specimen.

Reconstruction

The hepatic artery can be reconstructed in an end-to-end fashion in most patients, and the use of the gastroduodenal artery has been reported as a conduit. The anastomosis may be difficult or impossible to perform, when the arterial stump is small or when there are multiple vessels. Experimental studies using dogs subjected to hepatobiliary dearterialization demonstrated that arterioportal shunting reduced acute hypoxic hepatic injury and improved hypoxia in the bile duct, permitting successful choledochojejunostomy (Munemura, 1995), enhancing hepatic regeneration, and resulting in improved survival (Shimizu et al, 2000). In the literature, few clinical cases report the feasibility and safety of arterioportal shunting as an alternative procedure (Kondo et al, 2004; Young et al, 2008). Hepatopetal arterial collaterals develop within 1 month, and the shunt could be closed when still patent to prevent portal hypertension (Kondo et al, 2004).

CONCLUSION

Combined liver resection and vascular reconstruction expands the role of liver resection for malignancy, and these procedures may be performed with acceptable morbidity and mortality rates. This approach, using extensive surgery, is worth attempting in selected patients, because surgical resection provides the only hope of cure.

Seoul National University College of Medicine
Seoul, Korea

Bryan Clary, MD
Associate Professor of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Andrei Cocieru, MD
Chief Resident in Surgery
Danbury Hospital
Danbury, Connecticut

Carlos M. Contreras, MD
Department of Surgical Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Kendra D. Conzen, MD
Research Fellow
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Carlos U. Corvera, MD
Associate Professor
Section Chief, Upper GI Surgery
University of California-San Francisco;
Staff Surgeon
Department of General Surgery
VA Medical Center
San Francisco, California

Anne M. Covey, MD
Associate Professor of Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Jeffrey S. Crippin, MD
Marilyn Bornefeld Chair in Gastrointestinal Research and Treatment
Department of Internal Medicine
Washington University School of Medicine
St. Louis, Missouri

Hany Dabbous, MD
Louisiana State University Health Sciences Center-Shreveport
Shreveport, Louisiana

Michael I. D'Angelica, MD, FACS
Associate Professor of Surgery
Weill Medical College of Cornell University;
Assistant Attending Surgeon
Memorial Sloan-Kettering Cancer Center
New York, New York

Michael Darcy, MD
Professor of Radiology
Washington University School of Medicine;
Chief of Interventional Radiology
Mallinckrodt Institute of Radiology
St. Louis, Missouri

Mark Davenport, ChM, FRCS(Paed), FRCS(Eng)
Professor of Paediatric Surgery
King's College Hospital
London, United Kingdom

Jeroen De Jonge, MD, PhD
Gastro-intestinal and Transplant Surgery
Erasmus Medical Center
Rotterdam, The Netherlands

Ronald P. DeMatteo, MD, FACS
Vice Chair, Surgery
Chief, Division of General Surgical Oncology
Leslie H. Blumgart Chair in Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Achilles A. Demetriou, MD, PhD
Executive Vice President and Chief Operating Officer
University Hospitals Health System
Cleveland, Ohio

Niraj M. Desai, MD
Assistant Professor of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Eduardo De Santibañes, MD, PhD
Professor and Chairman
Department of General Surgery and Liver Transplantation
Hospital Italiano
Buenos Aires, Argentina

Terry S. Desser, MD
Associate Professor
Department of Radiology
Stanford University School of Medicine
Stanford, California

Kiran K. Dhanireddy, MD
Assistant Professor of Surgery
Division of Hepatobiliary/Pancreatic and Abdominal Organ Transplant Surgery
University of Southern California
Keck School of Medicine
Los Angeles, California

Safi Dokmak, MD
HPB Surgery & Liver Transplantation
Hôpital Beaujon
Clichy, France

M.B. Majella Doyle, MD, FRCS(Ire)
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Truman M. Earl, MD
Department of Surgery
Barnes Jewish Hospital
Washington University in St. Louis
St Louis, Missouri

Tomoki Ebata, MD, PhD
Asisstant Professor and General Manager
Division of Surgical Oncology
Department of Surgery
Nagoya University Graduate School of Medicine
Nagoya, Japan

Yousef El-Gohary, MD, MRCS(Glasg)
Pediatric Surgery Fellow
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Andrew S. Epstein, MD
Fellow, Medical Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

N. Joseph Espat, MD
Professor of Surgery
Boston Unversity School of Medicine;
Chief, Surgical Oncology
Department of Surgery
Roger Williams Medical Center
Providence, Rhode Island

Sheung Tat Fan, MD, PhD, DSc
Chair and Professor of Surgery
Queen Mary Hospital
University of Hong Kong
Hong Kong, China

Olivier Farges, MD, PhD
Professor of HPB Surgery
Hospital Beaujon
Clichy, France

Carlos Fernandez-Del Castillo, MD
Professor of Surgery
Harvard Medical School;
Director
Pancreas & Bilary Surgery Program
Massachusetts General Hospital
Boston, Massachusetts

Cristina R. Ferrone, MD
Assistant Professor of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Mary Fischer, MD
Clinical Member
Anesthesiology and Critical Care
Memorial Sloan-Kettering Cancer Center
New York, New York

James E. Fisher, MD
General Surgery Resident
Mayo School of Graduate Medical Education
Rochester, Minnesota

Yuman Fong, MD
Murray F. Brennan Chair in Surgery
Memorial Sloan-Kettering Cancer Center;
Professor of Surgery
Weill Medical College of Cornell University
New York, New York

Alejandro Forner, MD, PhD
Liver Unit, BCLC Group;
Biomedical Research Centre Network of Hepatic & Digestive Diseases (CIBERehd)
University of Barcelona
Barcelona, Spain

Scott L. Friedman, MD
President
American Association for the Study of Liver Diseases;
Chief, Division of Liver Diseases
Fishberg Professor of Medicine
Mount Sinai School of Medicine
New York, New York

Stefan Fritz, MD
Certified Surgeon
Fellow in Visceral Surgery
University Clinic of Heidelberg
Heidelberg, Germany

John R. Galloway
Department of Surgery
Barnes Jewish Hospital
Washington University in St. Louis
St. Louis, Missouri

Hans Gerdes, MD
Attending Physician
Department of Medicine
Memorial Hospital for Cancer and Allied Diseases;
Professor of Clinical Medicine
Weill Cornell Medical College of Cornell University
New York, New York

George Getrajdman, MD
Associate Professor of Clinical Radiology
Weill Medical College of Cornell University;
Clinical Director
Interventional Radiology Section
Department of Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Paula Ghaneh, MB ChB, MD, FRCS
Senior Lecturer
Division of Surgery and Oncology
University of Liverpool
Liverpool, United Kingdom

Giorgia Ghittoni, MD
Interventional Ultrasound
Pavia, Italy

George Gittes, MD
Professor of Surgery
Department of Pediatric Surgery
University of Pittsburgh;
Surgeon-in-Chief
Children's Hospital of Pittsburgh
Pittsburgh, Pennsylvania

Karyn A. Goodman, MD
Assistant Member
Radiation Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

Gregory J. Gores, MD
Reuben R. Eisenberg Professor of Medicine
Gastroenterology and Hepatology
Mayo Foundation
Rochester, Minnesota

Eduardo Gotuzzo, MD
Istituto de Medicina Tropical Alexander von Humboldt
Universidad Peruana Cayetano Heredia
Lima, Peru

Dirk J. Gouma, MD
Academic Medical Center
Amsterdam, The Netherlands

Paul D. Greig, MD, FRCSC, FACS
Professor
Department of Surgery
University of Toronto
Toronto, Ontario, Canada

Christopher M. Halloran, MBBS, MD, FRCS(Eng), FRCS(Gen Surg)
Division of Surgery and Oncology
University of Liverpool
Royal Liverpool University Hospital
Liverpool, United Kingdom

Neil A. Halpern, MD, FACP, FCCP, FCCM
Attending Physician, Critical Care Medicine
Medical Director, Respiratory Therapy
Chief, Critical Care Medicine Service
Memorial Sloan-Kettering Cancer Center;
Professor of Medicine in Clinical Anesthesiology and Clinical Medicine
Attending Physician
New York-Presbyterian Hospital
Weill Medical College of Cornell University
New York, New York

Lucy E. Hann, MD
Director of Ultrasound
Department of Radiology
Memorial Sloan-Kettering Cancer Center;
Professor of Radiology
Weill Medical College of Cornell University
New York, New York

Ewen M. Harrison, MBBS, MRCS, PhD
Lecturer in General Surgery
University of Edinburgh
Royal Infirmary of Edinburgh
Edinburgh, United Kingdom

Werner Hartwig, MD
Department of General and Visceral Surgery
University of Heidelberg
Heidelberg, Germany

Julie K. Heimbach, MD
Department of Surgery
Mayo Clinic College of Medicine
Rochester, Minnesota

William S. Helton, MD
Department of Surgery
Virginia Mason Medical Center
Seattle, Washington

Alan W. Hemming, MD, MSc
Professor and Chief
Transplantation & Hepatobiliary Surgery
University of California at San Diego
San Diego, California

J. Michael Henderson, MBBS
Chief Quality Officer
Professor of Surgery
Cleveland Clinic
Cleveland, Ohio

Amelia J. Hessheimer, MD
Resident, General Surgery
Barnes Jewish Hospital
Washington University in St. Louis
St. Louis, Missouri;
Research Fellow
Liver Transplant Unit
Instituto de Enfermedades Digestivas y Metabólicas (IMDM)
CIBERehd
Hospital Clinic, University of Barcelona
Barcelona, Spain

Asher Hirshberg, MD, FACS
Professor of Surgery
SUNY Downstate College of Medicine
Director of Emergency Vascular Surgery
Kings County Hospital Center
Brooklyn, New York

Alice Ho, MD, MBA
Assistant Attending Physician
Department of Radiation Oncology
Memorial Sloan-Kettering Cancer Center
New York, New York

Michael G. House, MD
Assistant Professor of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Chung-Bao Hsieh, MD
Director, Organ Transplantation
Tri-Service General Hospital;
Associated Professor of Surgery
National Defense Medical College
Taipei, Taiwan

Kuo-Feng Hsu, MD
Department of Surgery
Tri-Service General Hospital
Taipei, Taiwan

David A. Iannitti, MD
Chief
HepatoPancreatoBiliary Surgery
Carolinas Medical Center
Charlotte, North Carolina;
Clinical Associate Professor of Surgery
University of North Carolina
Chapel Hill, North Carolina

Hiroshi Imamura, MD, PhD
Lecturer
Division of Hepato-Pancreatic-Biliary Surgery
Department of Surgery
Tokyo University Graduate School of Medicine
Tokyo, Japan

Clem W. Imrie, MBBS, FRCP
Professor
Lister Department of Surgery
West of Scotland Pancreatico-biliary Unit
Glasgow Royal Infirmary
Glasgow, United Kingdom

William R. Jarnagin, MD, FACS
Professor of Surgery
Weill Medical College of Cornell University;
Chief, Hepatopancreaticobiliary Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Roger L. Jenkins, MD
Professor of Surgery
Tufts Medical School
Boston, Massachusetts;
Chief of Surgery
Division of Hepatobiliary Surgery and Liver Transplantation
Lahey Clinical Medical Center
Burlington, Massachusetts

Stefan Kahl, MD
University of Magdeburg
Magdeburg, Germany

Ivan Kangrga, MD, PhD
Associate Professor
Department of Anesthesiology
Washington University School of Medicine
St. Louis, Missouri

Kaitlyn Kelly, MD
Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Nancy E. Kemeny, MD
Professor of Medicine
Weill Medical College of Cornell University;
Attending Physician
Solid Tumor–GI Division
Memorial Sloan-Kettering Cancer Center
New York, New York

Eugene P. Kennedy, MD
Associate Professor of Surgery
Thomas Jefferson University
Philadelphia, Pennsylvania

Robert K. Kerlan Jr, MD, FSIR
Professor of Clinical Radiology and Surgery
Chief of Interventional Radiology
Department of Radiology
University of California-San Francisco
San Francisco, California

Adeel S. Khan, MD
Washington University School of Medicine
St. Louis, Missouri

Saboor Khan, MBBS, PhD, FRCS (Eng)(Gen)
HPB Scholar
Department of Surgery
Mayo Clinic
Rochester, Minnesota;
Consultant HPB and General Surgeon
Department of Surgery
University Hospitals Coventry and Warwickshire
Coventry, United Kingdom

T. Peter Kingham, MD
Assistant Attending Physician
Division of Hepatopancreatobiliary Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Allan D. Kirk, MD, PhD
Associate Professor of Surgery
Uniformed Services, University of Health Sciences
F. Edward Hebert School of Medicine;
Senior Investigator and Chief
Transplantation Branch
National Institutes of Diabetes and Digestive and Kidney Diseases
National Institutes of Health
Bethesda, Maryland

Yuichi Kitagawa, MD
Staff Specialist for Surgery
National Center for Geriatrics and Gerontology
Obu, Japan

David S. Klimstra, MD
Chief, Surgical Pathology Service
Department of Pathology
Memorial Sloan-Kettering Cancer Center;
Professor, Department of Pathology and Laboratory Medicine
Weill Medical College of Cornell University
New York, New York

Michael D. Kluger, MD
Assistant Professor
Division of Hepatobiliary Surgery and Liver Transplantation
Weill Medical College of Cornell University
New York, New York

Stuart J. Knechtle, MD
Professor of Surgery
Emory University School of Medicine
Atlanta, Georgia

Peter J. Kneuertz, MD
Clinical Research Fellow
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Jonathan Koea, MHB(Hons), MD, FACS, FRACS
Department of Surgery
Auckland Hospital
Auckland, New Zealand

Alan J. Koffron, MD
Director, Transplantation
Department of Surgery
William Beaumont Hospital;
Professor of Surgery
Oakland University Beaumont School of Medicine
Royal Oak, Michigan

Norihiro Kokudo, MD, PhD
Professor
Division of Hepato-Biliary-Pancreatic Surgery
University of Tokyo
Tokyo, Japan

David A. Kooby, MD
Associate Professor of Surgery
Director of Minimally Invasive Gastrointestinal Oncologic Surgery
Emory University School of Medicine
Atlanta, Georgia

Kevin Korenblat, MD
Associate Professor of Medicine
Washington University School of Medicine
St. Louis, Missouri

Robert M. Krasny, MD
Co-founder
Resolution Imaging
Santa Monica, California

Jake Krige, MBBS, MSc, FACS, FCS(SA), FRCS(Ed)
Professor and Head
HPB and Surgical Gastroenterology Unit
Department of Surgery
University of Cape Town Health Sciences Faculty
Groote Schuur Hospital
Cape Town, South Africa

Robert C. Kurtz, MD
Chief, Gastroenterology and Nutrition Service
Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Matthew P. Landman, MD
Resident Physician
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Michael P. La Quaglia, MD
Chief, Pedatric Surgery
Memorial Sloan-Kettering Cancer Center;
Professor of Surgery
Weill Medical College of Cornell University
New York, New York

Nicholas F. LaRusso, MD
Director, Center for Innovation
Charles H. Weinman Professor of Medicine, Biochemistry and Molecular Biology
Mayo Clinic
Rochester, Minnesota

Kwan N. Lau, MD
Department of Surgery
Carolinas Medical Center
Charlotte, North Carolina

Konstantinos N. Lazaridis, MD
Division of Gastroenterology & Hepatology
Center for Basic Research in Digestive Diseases
Mayo Clinic College of Medicine
Rochester, Minnesota

Markus M. Lerch, MD, FRCP(Glasg)(Lon)
Professor and Chairman
Department of Medicine
Ernst-Moritz-Arndt University
Greifswald University Hospital
Greifswald, Germany

Joseph B. Lillegard, MD, PhD
Instructor of Surgery
Department of Gastrointestinal and General Surgery
Mayo Clinic
Rochester, Minnesota

Keith D. Lillemoe, MD, FACS
Surgeon-in-Chief
Department of Surgery
Massachusetts General Hospital;
W. Gerald Austen Professor of Surgery
Harvard Medical School
Boston, Massachusetts

David C. Linehan, MD
Professor of Surgery
HPB Surgery
Washington University School of Medicine
St. Louis, Missouri

Susan Logan, MD
Division of Abdominal Solid Organ Transplantation
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Benjamin Loveday, MB ChB
Research Fellow
Department of Surgery
University of Auckland
Auckland, New Zealand;
Surgical Registrar
Department of Surgery
Waikato Hospital
Hamilton, New Zealand

Jeffrey A. Lowell, MD
Professor of Surgery and Pediatrics
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

David C. Madoff, MD, FSIR
Professor of Radiology
Chief, Division of Interventional Radiology
New York Presbyterian Hospital
Weill Cornell Medical Center
New York, New York

Shishir K. Maithel, MD
Assistant Professor of Surgery
Division of Surgical Oncology
Winship Cancer Institute
Emory University
Atlanta, Georgia

Ali W. Majeed, MD, FRCS
Department of Surgery
Sheffield Teaching Hospitals
Sheffield, United Kingdom

Masatoshi Makuuchi, MD, PhD
President, Japanese Red Cross Medical Center
Shibuya-ku/Hiroo
Tokyo, Japan

Peter Malfertheiner, MD
Department of Gastroenterology
University of Magdeburg
Magdeburg, Germany

Mark Mamlouk, MD
Department of Radiology
University of California-Irvine
Orange, California

Giovanni Marchegiani, MD
Department of Surgery
Verona University Policlinico Borga Roma
Verona, Italy

Luis A. Marcos, MD
Clinical Fellow
Division of Infectious Diseases
Department of Internal Medicine
Washington University School of Medicine
St. Louis, Missouri;
Associate Investigator
Istituto de Medicina Tropical Alexander
von Humboldt
Universidad Peruana Cayetano Heredia
Lima, Peru

James F. Markmann, MD, PhD
Associate Professor of Surgery
University of Pennsylvania School of Medicine;
Director, Pancreas Transplant Program
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

J. Wallis Marsh, MD, MBA
Professor of Surgery
Thomas E. Starzl Transplantation Institute
Pittsburgh, Pennsylvania

Maureen Martin, MD, FACS, FRCSC
Chairman, Department of Surgery
Kern Medical Center
Bakersfield, California;
Clinical Professor
Department of Surgery
University of California at San Diego
San Diego, California

Robert C.G. Martin II, MD, PhD, FACS
Sam and Lolita Weakley Chair in Surgical Oncology
Director, Division of Surgical Oncology
Professor of Surgery
Director of the Upper GI and HPB Multi-Disciplinary Clinic
University of Louisville School of Medicine
Louisville, Kentucky

Dipen M. Maru, MD
Associate Professor
Department of Pathology
University of Texas
M.D. Anderson Cancer Center
Houston, Texas

Francisco Juan Mattera, MD
Surgeon
Liver Transplantation Unit
Hospital Italiano
Buenos Aires, Argentina

Julia V. Mayerle, MD
Assistant Professor
Department of Medicine A
Ernst-Moritz-Arndt University
Greifswald, Germany

Oscar M. Mazza, MD
Staff Surgeon
Hepato-Biliary-Pancreatic Unit
Hospital Italiano
Buenos Aires, Argentina

Ian D. McGilvray, MD, PhD
Associate Professor of Surgery
Department of Surgery
University of Toronto
Toronto, Ontario, Canada

Colin J. McKay, MD, FRCS
Consultant
Lister Department of Surgery
West of Scotland Pancreatico-biliary Unit
Glasgow Royal Infirmary
Glasgow, United Kingdom

Jose A. Melendez, MD
Associate Chair of Anesthesiology and Associate Professor of Anesthesiology
University of Colorado School of Medicine;
Senior Medical Director of Perioperative Services
University of Colorado Hospital
Denver, Colorado

James J. Mezhir, MD
Assistant Professor of Surgery
Division of Surgical Oncology and Endocrine Surgery
Holden Comprehensive Cancer Center
University of Iowa Hospitals and Clinics
Iowa City, Iowa

George Miller, MD
Assistant Professor
Departments of Surgery and Cell Biology
New York University School of Medicine
New York, New York

Klaus Mönkemüller, MD
University of Magdeburg
Magdeburg, Germany

Tricia A. Moo-Young, MD
NorthShore University Health System
Chicago, Illinois

Satish N. Nadig, MD, PhD
Fellow and Clinical Lecturer
Section of Transplant Surgery
University of Michigan
Ann Arbor, Michigan

Masato Nagino, MD
Associate Professor
Division of Surgical Oncology
Department of Surgery
Nagoya University Graduate School of Medicine
Nagoya, Japan

Alexander Nagle, MD
Assistant Professor
Department of Surgery
Northwestern University
Chicago, Illinois

David M. Nagorney, MD
Professor of Surgery
Mayo Clinic
Rochester, Minnesota

Atilla Nakeeb, MD
Professor
Department of Surgery
Indiana University of School of Medicine
Indianapolis, Indiana

Hector E. Nazario, MD
Transplant Hepatologist and Gastroenterologist
Department of Transplant Hepatology
The Liver Institute at Methodist-Dallas
Dallas, Texas

Geir Nedredal, MD, PhD
Division of Transplantation Surgery
Department of Surgery
Mayo Clinic
Rochester, Minnesota

John P. Neoptolemos, MB, BChir, MD, FRCS, FMedSci
Owen and Ellen Evans Chair of Surgery
Head, Section of Surgery and Oncology, Department of Molecular and Clinical Cancer Medicine
Institute of Translational Medicine at the University of Liverpool;
Honorary Consultant Surgeon
Royal Liverpool and Broadgreen University Hospitals NHS Trust
Liverpool, United Kingdom

James Neuberger, DM, FRCP
Consultant Physician
Liver Unit
Queen Elizabeth Hospital
Birmingham, United Kingdom;
Medical Director
Organ Donation and Transplantation
NHS Blood and Transplant
Bristol, United Kingdom

Douglas L. Nguyen, MD
Resident
Department of Internal Medicine
Mayo Clinic
Rochester, Minnesota

Yuji Nimura, PhD
President
Department of Digestive Surgery
Aichi Cancer Center
Nagoya, Aichi, Japan

Scott L. Nyberg, MD, PhD
Professor
Department of Surgery
Mayo Clinic
Rochester, Minnesota

John G. O'Grady, MD, FRCP(Ire)
Institute of Liver Studies
King's College Hospital
London, United Kingdom

Risteard O'laoide, MD
Department of Radiology
St. Vincent's University Hospital
Dublin, Ireland

Kim Marie Olthoff, MD
Associate Professor of Surgery
University of Pennsylvania School of Medicine
Director, Liver Transplant Program
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Mark S. Orloff, MD
Professor of Surgery
University of Rochester School of Medicine;
Staff Physician
Division of Organ Transplantation
University of Rochester Medical Center
Rochester, New York

Marshall J. Orloff, MD
Distinguished Professor of Surgery and Chair of Surgery Emeritus
University of California, San Diego
San Diego, California

Susan L. Orloff, MD, FACS
Director and Chief, Abdominal Transplantation
Professor of Medicine
Department of Surgery
Oregon Health and Science University
Portland, Oregon

Rish K. Pai, MD, PhD
Assistant Professor
Department of Pathology
Washington University in St. Louis
St. Louis, Missouri

Katia Papalezova, MD
Fellow
Department of Surgical Oncology
Duke University Medical Center
Durham, North Carolina

Valérie Paradis, MD
Department of Pathology
Hospital Beaujon
Clichy, France

Rowan W. Parks, MB, MD, FRCS(Ire), FRCS(Ed)
Department of Clinical and Surgical Sciences
University of Edinburgh
Edinburgh, United Kingdom

Steven D. Passik, PhD
Associate Professor of Psychiatry
Weill Medical College of Cornell University;
Associate Attending Psychologist
Department of Psychiatry and Behavioral Sciences
Memorial Sloan-Kettering Cancer Center
New York, New York

Stephen M. Pastores, MD
Director, Critical Care Medicine Fellowship Program
Anesthesiology and Critical Care Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Patrick Pessaux, MD, PhD
Department of Digestive Surgery
Hospital Beaujon
Clichy, France

Maxim S. Petrov, MD, MPH
Senior Lecturer
Department of Surgery
University of Auckland
Aukland, New Zealand

Venu G. Pillarisetty, MD
Assistant Professor
Department of Surgery
University of Washington;
Attending Surgeon
University of Washington Medical Center
Seattle, Washington

James Pingpank Jr, MD
Associate Professor
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

C. Wright Pinson, MD, MBA
H. William Scott Professor of Surgery
Deputy Vice Chancellor for Health Affairs
Vanderbilt University Medical Center
Nashville, Tennessee

Sofija Pitka
Texas Tech University
Lubbock, Texas

Henry A. Pitt, MD
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

James J. Pomposelli, MD, PhD
Surgical Director of Transplantation
Department of Transplantation and Hepatobiliary Surgery
Lahey Clinic Medical Center
Burlington, Massachusetts

Wande B. Pratt, MD, MPH
Resident in Surgery
Department of Surgery
Barnes Jewish Hospital
St. Louis, Missouri

Richard A. Prinz, MD
Department of Surgery
NorthShore University Health System
Evanston, Illinois

Srinivas R. Puli, MD
Advanced Endoscopy Fellow
Division of Gastroenterology
Brigham & Women's Hospital
Boston, Massachusetts

Florencia G. Que, MD
Associate Professor of Surgery
Mayo Clinic College of Medicine;
Consultant, Department of Surgery
Mayo Clinic
Rochester, Minnesota

Valentina Ravetta, MD
Interventional Ultrasound
Pavia, Italy

Maria E. Reig, MD
Biomedical Research Centre Network of Hepatic & Digestive Diseases (CIBERehd)
University of Barcelona;
Liver Unit, BCLC Group
Hospital Clinic
Barcelona, Spain

Ahsun Riaz
Department of Surgery
Northwestern University
Chicago, Illinois

Barrie S. Rich, MD
Clinical Research Fellow
Department of Pediatric Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

David W. Rittenhouse, MD
Department of Surgery
Jefferson Medical College
Philadelphia, Pennsylvania

John Roberts, MD
Chief, Division of Transplantation
Department of Surgery
University of California-San Francisco
San Francisco, California

Piera Robson, MS, NP, OCN
Clinical Nurse IV
Interventional Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Flavio G. Rocha, MD
Staff Surgeon
Department of Surgery
Virginia Mason Medical Center
Seattle, Washington

Seaborn A. Roddenbery V, MD
St. Francis Center for Surgical Care
Department of Surgery
St. Francis Hospital
Columbus, Georgia

Carlos Rodriguez de Lopes, MD
Biomedical Research Centre Network of Hepatic & Digestive Diseases (CIBERehd)
University of Barcelona;
Liver Unit, BClC Group
Hospital Clinic
Barcelona, Spain

Garrett R. Roll, MD
General Surgery Resident and Hepatology Research Fellow
University of California-San Francisco
San Francisco, California

Alex S. Rosemurgy II, MD
Associate Dean
University of South Florida School of Medicine
The Vivian Clark Reeves/Joy McCann Culverhouse Chair in Pancreatic and Digestive Surgery
Tampa General Hospital
Tampa, Florida

Charles B. Rosen, MD
Chair, Division of Transplantation Surgery
Mayo Clinic
Rochester, Minnesota

Sandro Rossi, MD
Director
Department of Internal Medicine
Policlinico san Matteo
Pavia, Italy

Pierre F. Saldinger, MD, FACS
Chairman and Carmen & Peter Buck Chair of Surgery
Danbury Hospital
Danbury, Connecticut;
Professor of Clinical Surgery
New York Medical College
Valhalla, New York

Riad Salem, MD, MBA
Professor
Department of Radiology
Northwestern University
Chicago, Illinois

Leonard B. Saltz, MD
Head, Colorectal Oncology Section
Memorial Sloan-Kettering Cancer Center
New York, New York

Norberto J. Sanchez, MD
Clinical Research Fellow in HPB Surgery
Department of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Charbel Sandroussi, MBBS, MMSc, FRACS
Clinical Fellow
Department of Multiorgan Transplantation
University of Toronto
Toronto, Ontario, Canada

Tsuyoshi Sano, MD, PhD
Chief
Department of Surgery
Ogaki Municipal Hospital
Ogaki-City, Japan

O. Scatton, MD
Professor and Chairman
Department of Digestive and Transplant Surgery
Hospital Beaujon
Paris, France

Mark Schattner, MD
Associate Professor of Clinical Medicine
Weill Medical College of Cornell University;
Associate Clinical Member
Gastroenterology and Nutrition Service
Department of Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

William P. Schecter, MD
Professor of Clinical Surgery
University of California-San Francisco
San Francisco, California

Suzanne C. Schiffman, MD
Chief Resident
Department of Surgery
University of Louisville
Louisville, Kentucky

C. Max Schmidt, MD, PhD, MBA, FACS
Associate Professor of Surgery, Biochemistry & Molecular Biology
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Helmut Schoellnast, MD
Department of Radiology
Laboratory of Comparative Pathology
Research Animal Resource Center
Department of Neurology
Memorial Sloan-Kettering Cancer Center
New York, New York

Lawrence H. Schwartz, MD
Vice Chairman for Technology Development
Director
Department of Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Ross W. Shepherd, MD, FRACP, FRCP
Professor
Liver Research Program
Queensland Institute for Medical Research
Brisbane, Queensland, Australia;
Adjunct Professor
Department of Pediatrics
Washington University School of Medicine;
Professor Emeritus
Liver Care Center
St. Louis Children's Hospital
St. Louis, Missouri

Masafumi Shimoda, MD, PhD
Research Fellow
Division of Gastroenterology & Liver Research Center
Rhode Island Hospital
Warren Alpert Medical School of Brown
University
Providence, Rhode Island

Hosein Shokouh-Amiri, MD, FACS
Shreveport, Louisiana

Nasir H. Siddiqi, MD
Assistant Professor
Department of Radiology and Surgery
Washington University School of Medicine
St. Louis, Missouri

Stephen B. Solomon, MD
Professor
Department of Radiology
Weill Medical College of Cornell University;
Department of Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Nathaniel J. Soper, MD
Loyal and Edith Davis Professor and Chair
Department of Surgery
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Thomas E. Starzl, MD
Professor of Surgery
University of Pittsburgh Medical Center;
Director Emeritus
Thomas E. Starzl Transplantation Institute
Pittsburgh, Pennsylvania

Michael Steer, MD
Professor of Surgery
Tufts University School of Medicine
Boston, Massachusetts

Lygia Stewart, MD
Department of Surgery
San Francisco Veterans Administration Hospital
University of California-San Francisco
San Francisco, California

Oliver Strobel, MD
Associate Professor of Surgery
General, Visceral, and Transplantation Surgery
University Hospital Heidelberg
Heidelberg, Germany

Jerrold Teitcher, MD
Associate Professor of Clinical Radiology
Weill Medical College of Cornell University;
Attending Radiologist
Department of Radiology
Memorial Sloan-Kettering Cancer Center
New York, New York

Angélica Terashima, MD
Chief of Parasitology Laboratory
Istituto de Medicina Tropical Alexander von Humboldt
Universidad Peruana Cayetano Heredia
Lima, Peru

Sylvain Terraz, MD
Head, Abdominal/Interventional Radiology Unit
Department of Radiology
Geneva University Hospital
Geneva, Switzerland

William E.G. Thomas, MS, FRCS
Dean of the Faculty of Education of the International Society of Surgery
Past Vice President of Royal College of Surgeons of England
Past Clinical Director and Consultant Surgery of Sheffield Teaching Hospitals
NHS Foundation Trust
Sheffield, United Kingdom

Guido Torzilli, MD, PhD
Professor
Liver Surgery Unit
Third Department of Surgery
University of Milan School of Medicine
Istituto Clinico Humanitas, IRCCS
Milan, Italy

James F. Trotter, MD
Baylor University Medical Center
Dallas, Texas

Yumirle P. Turmelle, MD
Pediatric Liver Program
St. Louis Children's Hospital;
Department of Pediatrics
Washington University School of Medicine
St. Louis, Missouri

Christine Van Cott, MD
Attending Surgeon
Department of General Surgery
Hospital of St. Raphael
New Haven, Connecticut

Andrea Vannucci, MD, DEAA
Assistant Professor
Patient Safety Officer
Department of Anesthesiology
Washington University School of Medicine
St. Louis, Missouri

Eric vanSonnenberg, MD
Hospital Administration and Radiology
Kern/UCLA Medical Center
Bakersfield, California;
Emeritus College
Arizona State University
Tempe, Arizona

Jean-Nicolas Vauthey, MD
Professor and Chief
Liver Service
Department of Surgical Oncology
University of Texas M.D. Anderson Cancer Center
Houston, Texas

Diana Vetter, MD
Department of Abdominal Surgery
University Hospital Zurich
Zurich, Switzerland

Valerie Vilgrain, MD
Professor of Radiology
Hospital Beaujon
University Paris Denis Diderot
Paris, France

Alejandra Villamil, MD
Universidad de Buenos Aires;
Liver Transplantation Unit
Hospital Italiano de Buenos Aires;
Director
Argentine School of Hepatology
Argentine Association for the Study of Liver Disease
Buenos Aires, Argentina

Louis Voigt, MD, FCCP
Assistant Professor of Medicine
Weill College of Medicine at Cornell University;
Assistant Attending Physician
Anesthesiology and Critical Care Medicine
Memorial Sloan-Kettering Cancer Center
New York, New York

Charles M. Vollmer Jr, MD
Associate Professor of Surgery
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Jack R. Wands, MD
Rhode Island Hospital
Warren Alpert Medical School at Brown University
Providence, Rhode Island

Julia Wattacheril, MD
Fellow, Gastroenterology and Hepatology
Department of Medicine
Vanderbilt University School of Medicine
Nashville, Tennessee

Sharon Weber, MD
Section Head, Surgical Oncology
Department of Surgery
University of Wisconsin;
Chief of Surgery
William S. Middleton Veteran's Hospital
Madison, Wisconsin

Matthew Weiss, MD

PREFACE

The fifth edition of this text, *Blumgart's Surgery of the Liver, Biliary Tract, and Pancreas,* represents the most significant change since the first edition appeared in 1988. Specifically, the current edition marks the first time in three decades that Leslie H. Blumgart, MD, has not had a major hand in its creation. With his retirement from clinical practice, stewardship of the textbook, which has evolved into one of the most influential in the field, has been passed to the next generation of HPB surgeons, many of whom Leslie Blumgart has trained personally and all of whom he has influenced greatly. The title change is a fitting reminder of his status as a pioneering HPB surgeon and recognizes the many contributions he has made to the specialty. The fifth edition continues the tradition of using associate editors to cover, in a comprehensive fashion, the extraordinary growth of knowledge and advances that have taken place since the publication of the previous edition. The associate editors are all internationally renowned experts in the field and bring great insight based on extensive personal experience. Dr. Jacques Belghiti, of Paris, France, and Dr. William Chapman, of St. Louis, Missouri, assumed primary responsibility for sections dealing largely with hepatic resection and transplantation; these chapters reflect their substantial contributions in these areas. Dr. Markus Büchler, of Heidelberg, Germany, brought his extensive background in pancreatic disease management to provide a comprehensive update to the pancreas section. A great debt of gratitude is owed to my colleagues in the Department of Surgery at Memorial Sloan-Kettering Cancer Center: Dr. Ronald DeMatteo, whose basic science experience helped reinvigorate the physiology section, and Dr. Michael D'Angelica, who brought his considerable clinical experience to the chapters on biliary tract disease. A special note of thanks goes to Dr. Lucy Hann, who has been involved with liver, hepatobiliary, and pancreatic radiology for many years. Before her recent retirement, she was one of the leading practitioners of diagnostic ultrasound in the United States.

Although the organization of the book has been changed, we have maintained the general format of covering all surgical aspects of the management of hepatobiliary and pancreatic disorders. Radiologic, endoscopic, and other nonsurgical approaches are also presented in detail and are highlighted when they represent the preferred treatment. The contributors are specialists in their fields and have been asked to discuss the subject from the point of view of surgical management and to relate their views to the opinions of others. Authors with conflicting opinions have, in some cases, been chosen to give the reader an opportunity to assess divergent views. Overlap between chapters, when appropriate, was encouraged: first to allow each contribution to represent an encapsulated account that stands on its own for the reader who wishes to consult the book as a reference, and second, to allow the display of different nuances of approach to particularly difficult problems.

In addition to the organizational changes, a number of modifications have been made throughout this text. Several additions have been made, including chapters on embryologic development (to complement the anatomy chapter), hepatic fibrogenesis, and minimally invasive resection techniques. Advances in our understanding of molecular pathogenesis of neoplastic disease have been emphasized in the physiology section, and chapters highlighting ablative techniques and advances in chemotherapy, particularly as they affect the results of resection, have been added. Some chapters have been split to allow expansion on new developments, and others have been combined or eliminated. An important feature is the inclusion of considerable technical detail so that major sections of this book can be used, in conjunction with the videos available on the text's Expert Consult site, as an atlas of technique.

The initial section of the book is devoted to the applied anatomy of the liver and biliary tract, including its radiologic demonstration. Throughout this edition, the anatomic contributions of Claude Couinaud are recognized, and the liver anatomy and nomenclature of the various operative approaches are generally based on his descriptions. The anatomy chapter remains one of the most important in the entire edition; its detailed description of normal and variant anatomy, with radiologic illustrations, provides the essential basis for the reader to appreciate fully the discussions and illustrations of the operative approaches that follow. In recent years, there has been extraordinary refinement in the operative techniques pertaining to hepatic, biliary, and pancreatic resection, and these are covered in special detail. Likewise, the entire section on liver transplantation and its complications and results has been expanded to cover new developments in the field.

In summary, this work attempts to include all aspects of the anatomy, pathology, diagnosis, and surgical and nonsurgical therapeutic approaches to hepatobiliary and pancreatic disorders. The aim is to provide a text valued equally by the trainee surgeon and the established HPB surgeon as well as physicians in related disciplines. We have attempted to enlist new contributors throughout the book to give latitude to conflicting opinions and to allow the reader to form an individual approach based on contemporary opinions.

I again express my thanks to the co-editors who have collaborated with me in this endeavor and who join me in the hope that this book will prove of value as an account of the current "state of the art" in the surgical aspects of hepatobiliary and pancreatic disease as well as a stimulus to those interested in further study of the many unresolved problems that require investigation.

This book has seen the establishment and maturation of the specialty of hepatobiliary and pancreatic surgery. This evolution is due to the efforts of Leslie H. Blumgart and his contemporaries, whose vision, courage, and skill have made the field of HPB surgery what it is today. It is with pleasure that we dedicate this work to Leslie H. Blumgart and the small band of pioneering surgeons.

W.R. Jarnagin
New York, 2012

ACKNOWLEDGMENTS

We are deeply grateful to all who have contributed to this publication. Our colleagues in surgery, internal medicine, radiology, gastroenterology, pathology, and anesthesiology all responded enthusiastically and conveyed the weight of their experience. We are especially grateful to them for adding the spice of differing opinion and the aroma of international practice to the basic flavor of this work. Particular thanks goes to the members of our respective staffs in New York, St. Louis, Heidelberg, and Paris who have contributed and assisted in the preparation of this work.

Finally, thanks and appreciation are due to our esteemed publisher, Elsevier, for its great support throughout the project and for providing artistic support for the many illustrations.

Prometheus, chained to the rocky Mount Caucasus, has his liver eaten by the eagle of Zeus. (Engraving, 1566, possibly after a work by Titian. Reproduced by permission of the Hulton Getty Picture Collection, London.)

VIDEO CONTENTS

BASIC HEPATIC ANATOMY

Introduction

- Three-Dimensional Model

TECHNIQUES OF HEPATIC RESECTION

Inflow Control

- Extrahepatic Approach, Right Hepatic Artery and Portal Vein
- Extrahepatic Approach, Left Hepatic Artery and Portal Vein
- Pedicle Ligation, Right Pedicle
- Pedicle Ligation, Left Pedicle

Outflow Control

- Right Hepatic Vein
- Left and Middle Hepatic Veins
- Left Hepatic Vein

Parenchymal Transection

- Clamp Crushing
- Stapler
- Water Jet

Major Hepatic Resections

- Right Hemihepatectomy
- Extended Right Hepatectomy
- Left Hemihepatectomy
- Extended Left Hepatectomy

Segmental Resections

- Left Lateral Segmentectomy, Segments 2 and 3
- Right Posterior Sectorectomy, Segments 6 and 7
- Central Hepatectomy, Segments 4, 5, and 8
- Segment 3
- Caudate Hepatectomy, Segment 1

Vascular and Biliary Resection

- Reconstruction During Hepatectomy

Hepatic Tumors

- Enucleation of Benign Hepatic Tumors

Biliary-Enteric Anastomosis

- Running Technique
- Interrupted Technique

Resection for Biliary Malignancy

- Left Hepatectomy with En Bloc Resection of the Bile Duct and Caudate Lobe
- Right Hepatectomy with En Bloc Resection of the Bile Duct

Gallbladder Cancer

- Porta Hepatitis Lymphadenectomy with Bile Duct Preservation for Incidental Gallbladder Cancer
- Segmentectomy IVb/V for Gallbladder Cancer

Additional Techniques

- Laparoscopic Right Hepatectomy
- Pylorus-Preserving Pancreaticoduodenectomy for Adenocarcinoma of the Pancreas
- Central Pancreatectomy and Pancreaticogastrostomy for Pancreatic Endocrine Tumor
- Laparoscopic Distal Pancreatectomy
- Orthotopic Liver Transplantation
- Resection from Living Donor Transplantation: Donor Right Hepatectomy Including the MHV

inflow and outflow vascular control, 1550-1552, 1550f-1551f
inflow vascular clamping, 1547, 1547f
intermittent clamping, 1548
isolated caval clamping, 1552, 1552f
nonclamping technique, 1552-1553
preconditioning, 1549
topical hypothermia, 1549-1550, 1549f
Vascular reconstruction techniques, 1554-1558
arterial resection, 1558
indication, 1558
reconstruction, 1558
resection, 1558
Vascular reconstruction techniques *(Continued)*
portal vein resection, 1557-1558
complete obstruction, 1557
partial obstruction, 1557
reconstruction, 1558
resection, 1557-1558
vena cava and hepatic vein resection, 1554-1557
complete obstruction of inferior vena cava (IVC), 1554, 1555f
partial obstruction of inferior vena cava (IVC), 1554
reconstruction, 1556-1557, 1557f
resection, 1554-1556, 1555f-1556f
Venoocclusive disease (VOD), Budd-Chiari syndrome (BCS) and, 1188-1222
Vesalius, Andreas, 2, 2f
Volatile anesthetics, 378-379

W

Whipple, Allen O., 7-8, 8f
Whole-organ pancreas transplantation, 1796-1800
back table preparation of pancreas, 1797
complications, 1798-1799
donor operation, 1797
history and early results, 1796
indications and patient selection, 1796
recipient operation, 1797-1798, 1798f-1799f
results, 1799, 1799f
risk/benefit considerations, 1799-1800

Z

Zollinger-Ellison syndrome (ZES), 937-940
diagnosis, 938t
therapy, 939f
