SECTION II Neoplastic

A. General

CHAPTER 78

Tumors of the liver: pathologic aspects

Pierre Bedossa and Valérie Paradis

OVERVIEW

Liver tumors encompass a large spectrum of benign and malignant neoplasms, both primary and metastatic. In addition, a variety of nonneoplastic tumor-like masses deserve attention, because they can simulate neoplasms. Despite major advances in imaging procedures, the definitive diagnosis of a liver tumor is based primarily on accurate examination and interpretation of histologic material. The role of the pathologist is to establish the histologic type of the tumor, estimate its potential behavior, and assess any pertinent prognostic indicators.

According to their histogenesis, primary intrahepatic tumors are classified into three main categories—*hepatocellular, biliary,* and *mesenchymal tumors*—although additional rare entities exist. Liver tumor classification has recently been reviewed, and this chapter will present main pathologic aspects of intrahepatic liver tumors according to the 2010 World Health Organization (WHO) classification (Bosman et al, 2010).

HEPATOCELLULAR TUMORS

Hepatocellular Carcinoma

Clinical and Epidemiologic Background (See Chapter 80)

Hepatocellular carcinoma (HCC) is the most common primary malignant tumor in the adult liver. It ranks among the most frequent neoplasms—approximately 6% of all new cancer diagnosed worldwide with an estimated incidence of about 500,000 to a million new cases per year. It is a deadly malignancy and the third most frequent cause of cancer death among men, causing 600,000 deaths worldwide per year (McGlynn & London, 2005; Sherman, 2005; Parkin et al, 2005; Bruix et al, 2004).

One of the striking characteristics of HCC is the marked geographic variation in its frequency, which is mainly related to geographic distribution of chronic liver disease risk factors. East Asia and sub-Saharan Africa have a very high incidence, whereas Italy, Spain, and Latin America are at intermediate risk. A relatively low but increasing incidence is found in Western Europe, the United States, Canada, and Scandinavia. In these countries, the incidence rate is 50 times lower than in Southeast Asia (Bosch et al, 2004; Kahn et al, 2002; Seeff & Hoofnagle, 2006).

The association between cirrhosis and HCC has been well established. Indeed, 60% to 90% of HCC arises in cirrhotic livers. Conversely, approximately 1% to 3% of patients with cirrhosis will develop HCC annually (Colombo et al, 1991; Johnson & Williams, 1987; Zaman et al, 1985). Most of the epidemiologic variation in HCC prevalence is thought to reflect differences in etiologic risk factors for liver cirrhosis that encompasses a large group of environmental factors (El-Serag et al, 2008). The major known risk factors for HCC are hepatitis viruses (chronic hepatitis B and C; see Chapter 64), toxins (alcohol, aflatoxins), metabolic diseases (metabolic syndrome, α_1 antitrypsin deficiency, Wilson disease), hereditary hemochromatosis, and immune-related diseases (primary biliary cirrhosis, autoimmune hepatitis; see Chapter 70A). Given that the burden of chronic liver diseases is expected to rise along with increasing rates of alcoholism, hepatitis B and C infection, and fatty liver disease, it is expected that the incidence of HCC will also increase in the near future (Nordenstedt et al, 2010; El-Serag, 2008).

HCC is primarily a disease of older men, and its incidence generally increases with age. In Western Europe and the United States, most patients with HCC are between 50 and 75 years of age, although there are geographic differences. It occurs more frequently in men than women, with a male/female ratio ranging from 2:1 to 9:1, although the reason for this is not clear (El-Serag et al, 2008). Routine liver function tests are variably abnormal, often reflecting the underlying cirrhosis without a consistent pattern of alterations. Serum α-fetoprotein (AFP) is elevated in most symptomatic tumors, but small cancers are associated with lower or even normal levels. Thus serum AFP is not a reliable diagnostic test for HCC screening in patients with cirrhosis (Bruix & Sherman, 2005).

It is admitted that HCC usually occurs after a mean delay of 10 years following the onset of liver cirrhosis. This observation is highly consistent with the multistep process of liver cirrhosis that implies progressive malignant transformation of preneoplastic lesions, such as macroregenerative and dysplastic cirrhotic nodules. Because of the dismal prognosis of the disease, increasing emphasis has been placed on detecting early, asymptomatic HCC that is potentially curable.

Ultrasound (US) is a sensitive technique for identifying nodules larger than 1.5 cm and is thus often used for detection, whereas magnetic resonance imaging (MRI) is a more accurate procedure for liver mass characterization (Bolondi et al, 2005; see Chapters 13 and 17). Reliable and highly specific imaging criteria now allow confident diagnosis of HCC in cirrhotic patients so that liver biopsy can be avoided when hyperarterialization associated with early washout is present in dynamic imaging (Bruix & Sherman, 2005; Forner et al, 2008). Screening programs have thus been proposed to follow cirrhotic patients by repeat US. These programs have been successful in identifying small and asymptomatic HCCs in high-incidence areas such as Japan, China, and Alaska but have been less effective in regions where the tumor incidence is low (Sangiovanni et al, 2004).

Despite some progress in managing HCC, liver cancer still carries a dismal prognosis, which is partly explained by its late diagnosis and the clinical context of the patient, which may compromise potential therapeutic strategies. Prognosis is also related to the liver tumor itself, which is prone to early angioinvasion.

HCC is a peculiar tumor for several reasons. Indeed, its morphologic patterns are various, beyond the usual classification based on growth pattern and tumor differentiation. Furthermore, molecular pathogenesis of HCC is complex, involving different molecular pathways that may reflect both etiologic factors and underlying liver disease (Thorgeirsson & Grisham, 2002; Villanueva et al, 2007).

Gross Pathology

HCC can adopt a wide range of gross configurations, and several macroscopic classifications of varying complexity have been proposed, but their clinical relevance has not yet been proven. Tumor size ranges from less than 1 cm to more than 30 cm in diameter. At the time of diagnosis, mean size of HCC arising in a cirrhotic liver is usually less than those occurring in nonfibrotic liver. HCC tumors less than 2 cm are recognized as *small* or *early HCC* (International Working Party [IWP], 1995). Recently, small HCC have been subdivided into *vaguely nodular* and *well-circumscribed HCC,* two patterns with differences in prognosis; the vaguely nodular form has a better prognosis (International Consensus Group [ICG], 2009; Hytiroglou et al, 2007). Although the diagnosis of large HCC relies mainly on imaging modalities, biopsy is often requested for the diagnosis of these small nodular lesions. Upon gross examination, HCC may display a nodular, infiltrative, or diffuse macroscopic pattern (Okuda et al, 1984).

NODULAR (EXPANDING) HEPATOCELLULAR CARCINOMA. The nodular (expanding) pattern is the most common type of HCC, and it is typically seen in association with cirrhosis. This group of tumors is characterized by a sharp demarcation between the tumor mass and the compressed and partly atrophic surrounding parenchyma (Fig. 78.1). The presence of distorted hepatic vessels, including arteries, that form curved structures on the surface of the tumor mass or are visible on the cut surface support the concept of an expanding growth pattern. The nodule may be solitary or multiple across the liver, when these develop as a complication of cirrhosis. When nodules are multiple, small (<1 cm in diameter), and adjacent to the main tumor nodule, they are known as *satellite nodules* (Fig. 78.2).

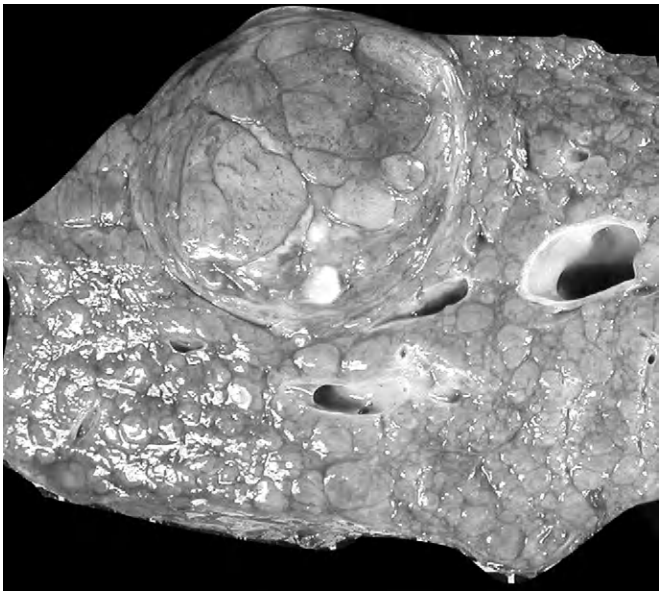

FIGURE 78.1. Hepatocellular carcinoma developed on liver cirrhosis with an expanding growth pattern. The tumor is sharply demarcated from the surrounding parenchyma and limited by a fibrous capsule.

In cases of multiple HCCs, nodules may represent either multifocal independent tumors or intrahepatic metastasis. Such a distinction is quite impossible based on pathologic study alone but could be addressed with surrogate molecular analysis (Paradis et al, 1998; Sakamoto et al, 1989). On cut section, nodular HCC is well delineated from nontumoral liver and circumscribed totally or partially by a fibrous capsule (Okuda et al, 1977). Capsule formation is considered to begin at a tumor diameter of at least 10 mm or greater, because no

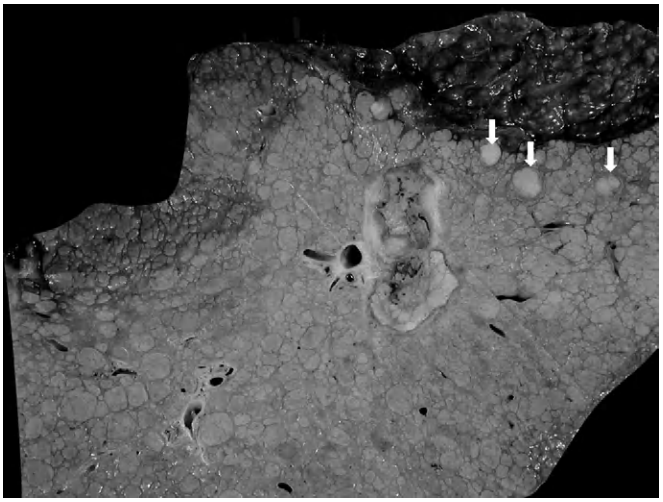

FIGURE 78.2. Hepatocellular carcinoma. The tumor is massively necrotic with minute satellite nodules in the vicinity (*arrows*).

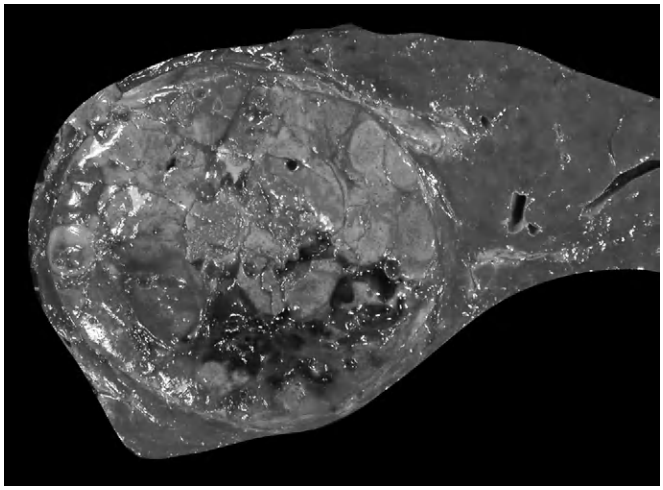

FIGURE 78.3. Hepatocellular carcinoma. The tumor forms soft masses with foci of hemorrhage or necrosis.

distinct capsule has been noted in lesions less than 10 mm (Nakanuma et al, 1986). The prognostic significance of capsule formation has not yet been definitively settled. HCC typically forms soft masses that vary in color from gray, light brown, or yellow-green, often punctuated by foci of hemorrhage or necrosis when the tumor reaches a significant volume (Fig. 78.3).

INFILTRATIVE (MASSIVE) HEPATOCELLULAR CARCINOMA. The infiltrative (massive) pattern is usually characterized by a large, solitary mass that occupies a substantial portion of the liver. The lesion is poorly circumscribed with ill-defined, invasive borders (Fig. 78.4). This pattern has been associated more commonly with noncirrhotic livers (Smalley et al, 1988; Grando-Lemaire et al, 1999). On cut section, the tumor extends into and distorts the adjacent nontumor tissue, interdigitating with surrounding parenchyma. Vessels are incorporated into, not displaced by, the tumor mass so that tortuous vessels around the tumor are not so obvious (Okuda et al, 1982).

DIFFUSE HEPATOCELLULAR CARCINOMA. The diffuse pattern is the least common type of HCC and represents a widespread infiltration by numerous small nodules that virtually replace the entire liver. In this pattern, tumor consists of

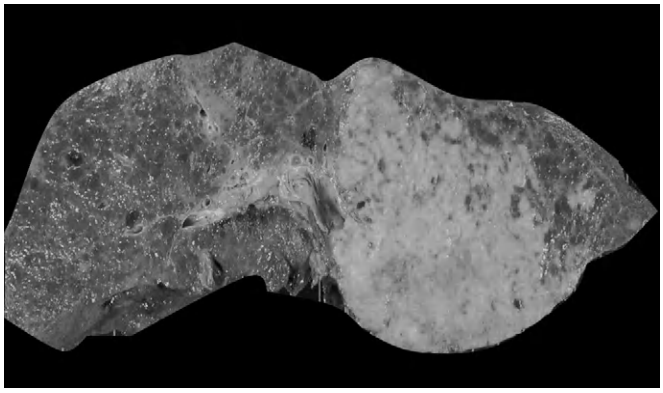

FIGURE 78.4. Hepatocellular carcinoma with an infiltrative growth pattern. The tumor is poorly circumscribed and extends into the surrounding parenchyma. No rim of compressed tissue or capsule is visible.

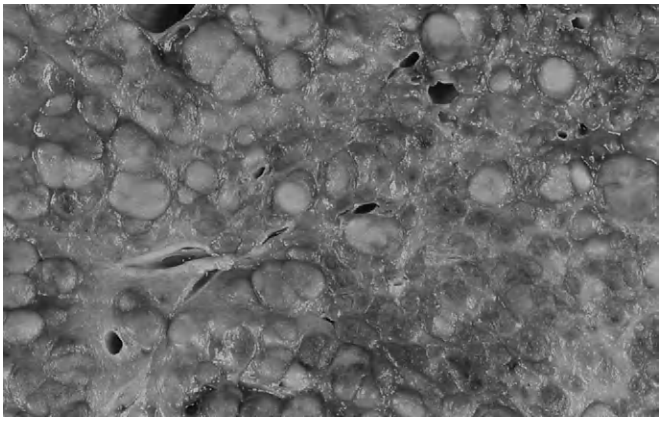

FIGURE 78.5. Hepatocellular carcinoma with a diffuse pattern of growth. The liver is totally replaced by numerous small, round tumor nodules.

several unconnected small tumors of roughly similar size. Multicentric origin or intrahepatic spread after portal vein invasion have been discussed as pathogenic mechanisms (Fig. 78.5; Nakashima & Kojiro, 1986).

PEDUNCULATED HEPATOCELLULAR CARCINOMA. Pedunculation is noted in rare instances, presumably reflecting an origin from an accessory hepatic lobe (Horie et al, 1983). The identification of the pedunculated form of HCC is significant, because even in the case of large tumors, limited resection may give excellent results.

LIMITS OF GROSS CLASSIFICATION. This gross classification has limits, because categorization of a tumor within one single growth pattern may be difficult; for example, expanding HCC may show areas of infiltrative pattern. Furthermore, the reproducibility of this categorization among different pathologists has not been shown. Finally, besides the diffuse pattern, which is associated with a dismal prognosis, the differentiation between expanding and infiltrative patterns does not appear as a prognostic indicator in multivariate analysis.

In nodular, advanced, and infiltrative HCC, invasion of large veins is common even at gross examination. The portal vein is more often involved than hepatic veins, inferior vena cava, or right atrium (Fig. 78.6). Portal vein invasion may be associated with thrombosis, and vascular invasion should be determined with care at the initial gross examination (macrovascular invasion). In some instances, intravascular tumor plugs in the close periphery of a large tumor may be difficult to distinguish from satellite tumor nodules. Invasion of large bile ducts may produce biliary obstruction, and hemobilia might be occasionally found.

Histopathology

Histopathologic evaluation is no more systematic, because dynamic imaging has high diagnostic accuracy for tumors larger than 3 cm. When imaging is not diagnostic, US-guided biopsy must be performed. This is often the case for HCC smaller than 2 cm, when biomarkers have low predictive values, and hyperarterialization may be incomplete or absent. For nodules smaller than 1 cm, biopsy is generally not recommended because of its limited performance. These diagnostic criteria have been endorsed by most international liver disease associations (Bruix & Sherman, 2005; Bruix et al, 2001). Nevertheless,

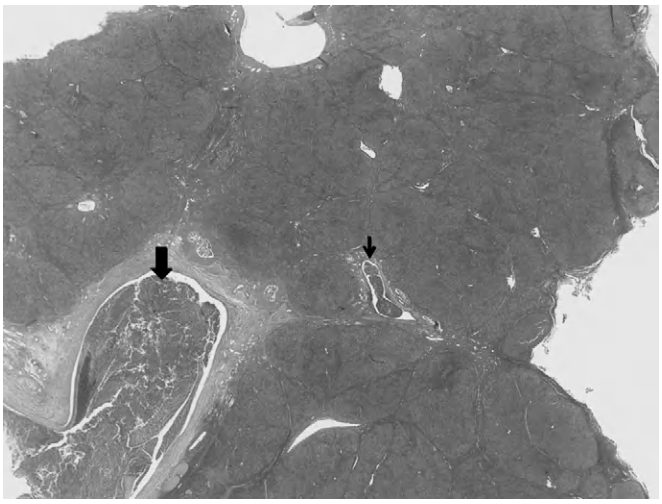

FIGURE 78.6. Invasion of a dilated large portal vein (*large arrow*) and a small vein (*small arrow*) by a tumoral thrombus in a cirrhotic liver close to a hepatocellular carcinoma.

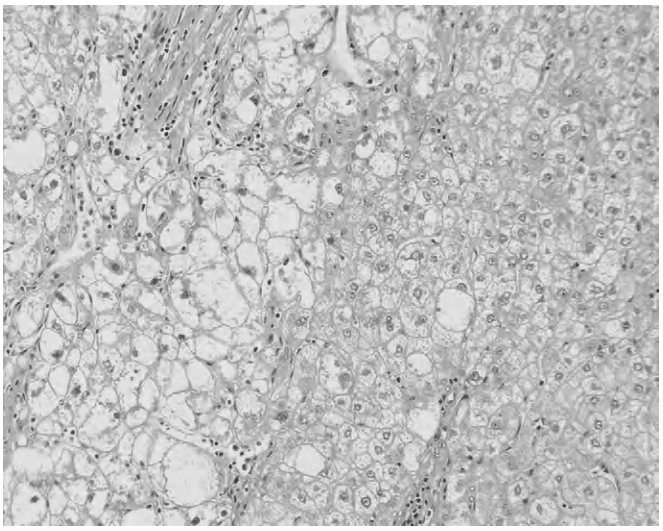

FIGURE 78.8. Hepatocellular carcinoma with a clear-cell pattern. Malignant tumor cells of various sizes are enlarged with a clear cytoplasm.

despite the major advances in radiologic procedures, the definitive diagnosis continues to be based primarily on accurate examination and interpretation of histologic material for any small or atypical nodule.

Histopathologically, the diagnosis of HCC is based on the distinction between tumor cells and normal hepatocytes (Anthony, 1973). Therefore, the microscopic evaluation entails assessment of cytologic characteristics of tumor cells and evaluation of their architectural pattern.

Tumor cells may be seen in varying degrees of hepatocellular differentiation within a single tumor. Nuclei are usually basophilic and often irregular, with prominent nucleoli and a high nuclear/cytoplasmic ratio. In well-differentiated HCC, the tumor cells may closely resemble normal hepatocytes, with a polygonal shape, distinct cell membranes, and eosinophilic granular cytoplasm (Fig. 78.7). Bile canaliculi can often be seen by light microscopy or can be demonstrated by immunostaining. When dilated, they might contain bile pigment, a characteristic feature of hepatocellular differentiation. Accumulation of glycogen or fat in tumor cells may produce a clear-cell appearance (Fig. 78.8). Cytoplasmic fat droplets might be more common in small HCCs. Mallory-Denk bodies, hyaline globules, and eosinophilic or so-called *ground-glass cytoplasmic inclusions* may also be observed.

As the tumor evolves to a poorly differentiated phenotype with cell-to-cell heterogeneity, bizarre nuclei or giant tumoral cells may appear. Mitosis and apoptotic bodies can be observed (Fig. 78.9). Different degrees of cellular differentiation are usually present within a single large tumor, although small HCC tend to be more homogeneous.

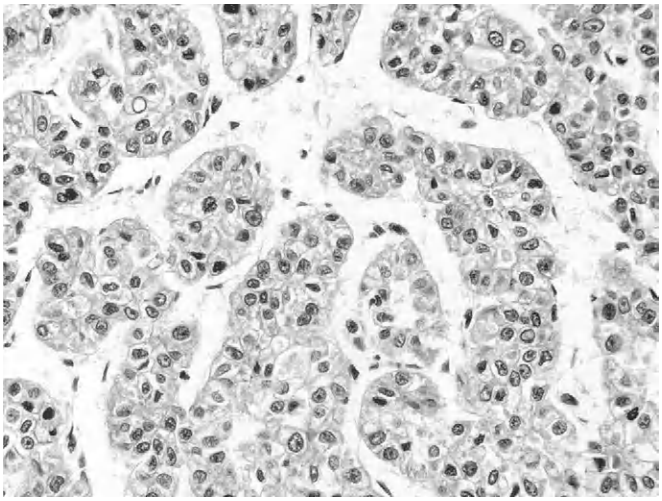

FIGURE 78.7. Well-differentiated hepatocellular carcinoma. Tumor cells are organized in large trabeculae and resemble normal hepatocytes with a polygonal shape, distinct cell membranes, and clear cytoplasm with a high nuclear/cytoplasmic ratio.

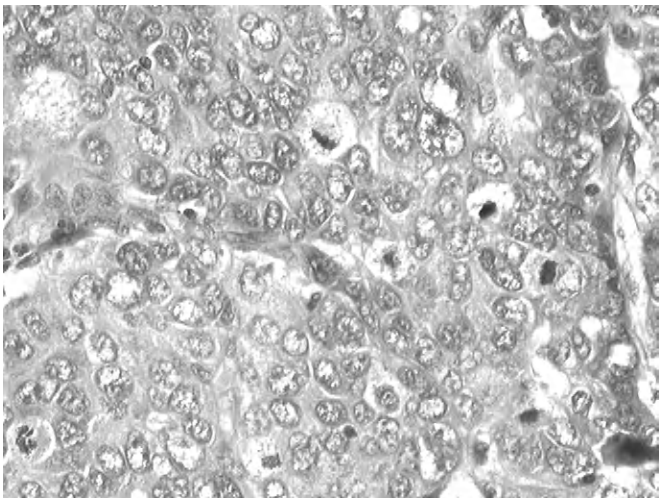

FIGURE 78.9. Poorly differentiated hepatocellular carcinoma. The tumor is highly cellular with tumoral cells organized in large trabeculae with bizarre nuclei, mitosis, and apoptotic bodies.

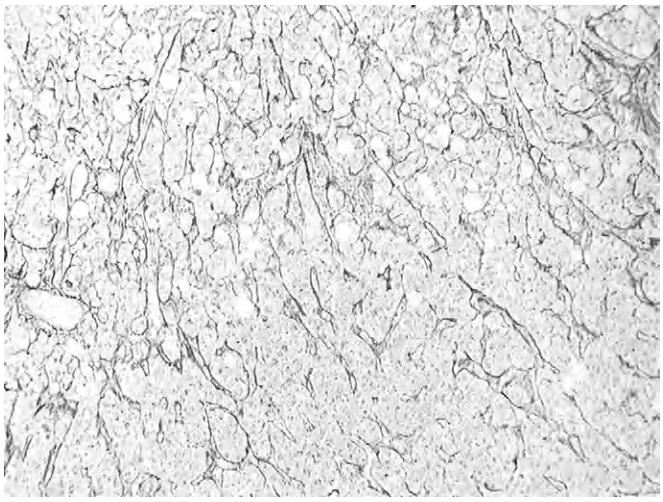

FIGURE 78.10. Reticulin staining in hepatocellular carcinoma. The lower part of the figure displays fragmentation and rarefaction of the reticular framework.

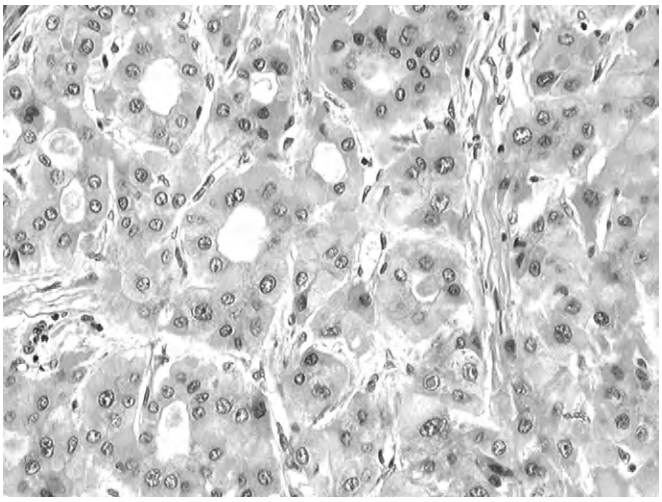

FIGURE 78.11. Hepatocellular carcinoma with a pseudoglandular pattern. Hepatocytes display glandlike organization around dilated canaliculi between tumor cells.

Growth Patterns

The arrangement of the cells contributes to the variability in the microscopic appearance. On this basis, several types of tumor have been categorized, but it has not yet been fully established whether these variations reflect differences in behavior and influence prognosis (Qin & Tang, 2002). The three main architectural patterns of growth of HCC are *trabecular; acinar,* or *pseudoglandular;* and *scirrhous.*

TRABECULAR GROWTH. Trabecular growth occurs when tumoral hepatocytes are arranged in plates in varying thicknesses from 2 to more than 20 cells (see Fig. 78.7). This feature resumes the normal trabecular arrangement of liver plates. Neoplastic cells are organized along simplified sinusoids lined by flat endothelial cells with few or no Kupffer cells. Compared with normal liver plates, the reticulin framework is commonly sparse or absent (Fig. 78.10). A compact or solid pattern occurs when the trabeculae are closely aligned, and the sinusoids become compressed and unapparent.

ACINAR (PSEUDOGLANDULAR) GROWTH. The *acinar*, or *pseudoglandular, pattern* results either from glandlike dilation of the canaliculi between tumor cells, in which the lumens can contain bile, or central degeneration of trabeculae, in which the lumens contain mainly degenerative products with fibrin (Fig. 78.11). As with the trabecular pattern of growth, stroma is typically sparse. The lack of a desmoplastic stroma reaction is a helpful diagnostic clue, when other glandular malignant epithelial neoplasms, especially cholangiocarcinomas, are discussed. On occasion, large vascular lakes resembling peliosis can develop within the pseudoglandular formations.

SCIRRHOUS GROWTH. The scirrhous pattern of HCC is rare, characterized by tumor cells with cytologic and phenotypic features of otherwise typical HCC but within an abundant fibrous stroma. This pattern is different from a subset of so-called fibrolamellar HCC, which will be discussed below.

PUSHING AND MERGING CONFIGURATIONS. At the interface with adjacent nonneoplastic parenchyma, HCCs typically adopt either pushing or merging histologic configurations. With pushing growth, the tumor is completely or partially limited by a fibrous capsule made of dense collagen fibers, often encircling dilated veins. With progressing growth, the tumor steps across the capsule and merges directly into adjoining nonneoplastic cell plates, replacing the normal hepatocytes.

Histologic Variants

FIBROLAMELLAR HEPATOCELLULAR CARCINOMA. This subset, which differs from other types of HCC in clinical features and prognosis, is the only variant with clinical significance. It was first delineated as a distinct entity in 1980 (Craig et al, 1980). In a population-based study, fibrolamellar HCC constituted 0.85% of all cases of primary liver cancer and 13.4% of all cases in patients younger than age 40 (El-Serag & Davila, 2004). The clinical presentation is similar to other HCCs, except that it occurs in young people with equal gender ratio and has no association with chronic liver disease, cirrhosis, or any other known predisposing risk factors.

On gross examination, fibrolamellar HCC is a firm, mostly well-defined but unencapsulated single nodule that can range from 5 cm to more than 20 cm (Saab & Yao, 1996). On cut section, the tumor is gray to brown with scalloped borders and a solid consistency (Fig. 78.12). Prominent fibrous septa subdivide the mass and may connect with a central zone of scarring. Such features may be confused with focal nodular hyperplasia. In addition, several reports in the literature describe fibrolamellar HCC spatially associated with focal nodular hyperplasia, although filiation between these two lesions has never been convincingly demonstrated (Saul et al, 1987). Calcifications may also be observed.

The distinctive histologic features are fibrous stroma and large, eosinophilic tumor cells (Fig. 78.13; Berman & McNeill, 1988). The stroma comprises dense, fibrous bands of varying thickness organized around nests, cords, and sheets of neoplastic cells (Nerlich et al, 1992). The tumor cells are usually larger

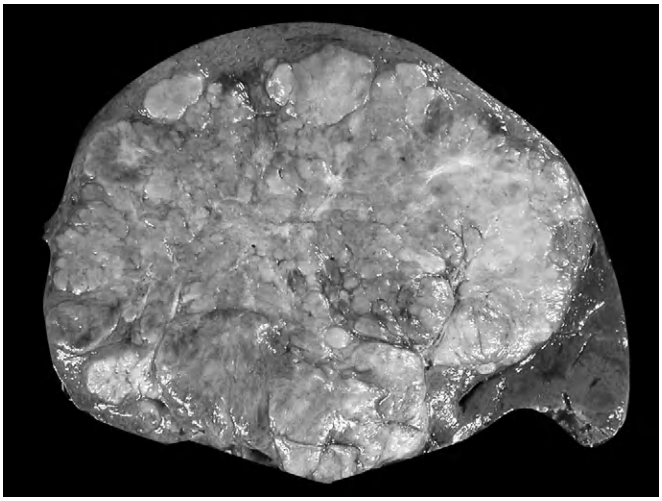

FIGURE 78.12. Fibrolamellar hepatocellular carcinoma. Large lobulated tumor is well delineated from normal surrounding liver.

than normal hepatocytes and display abundant, granular, and deeply eosinophilic cytoplasm with prominent nucleoli. Bile pigment is common, and fat or glycogen accumulation is sometimes seen. Most fibrolamellar carcinomas are histologically low grade, mitoses are usually sparse, and nuclear pleomorphism and multinucleation are infrequent. Cytoplasmic inclusions of various types are common, including ground-glass pale bodies (Fig. 78.14), eosinophilic cytoplasmic globules of variable periodic acid-Schiff positivity, and rarely Mallory-Denk bodies. In contrast to most HCC, fibrolamellar HCC seems to abundantly express type 7 cytokeratin (CK) and, in some cells, biliary-type CK19 (Van Eyken et al, 1990).

Fibrolamellar HCC tends to be slow growing and frequently resectable with a better prognosis than other types of carcinoma. However, when adjustment is made for tumor stage, all series do not demonstrate this better prognosis. Successfully resected patients have good chance of long-term survival despite extrahepatic recurrences.

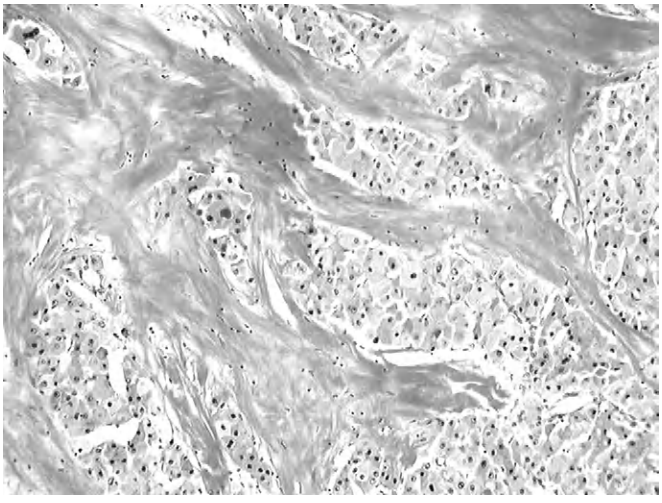

FIGURE 78.13. Fibrolamellar hepatocellular carcinoma. The tumor is composed of large eosinophilic tumor cells organized in cords between dense, acellular fibrous bands.

CLEAR-CELL CARCINOMA. This predominant tumoral cell type is rich in glycogen or lipid and accordingly has a clear cytoplasm (Buchanan & Huvos, 1974). The clear-cell variant has been associated with a better prognosis, but the survival advantage, if present, is minor and has not been confirmed (Kishi et al, 1983). Clear-cell HCC may be associated with hypoglycemia and hypercholesterolemia, and sudden death from severe hypoglycemia has been reported (Sasaki et al, 1981; Ross & Kurian, 1985).

SARCOMATOID HEPATOCELLULAR CARCINOMA. This variant is characterized by a sarcomatous-appearing component of spindle-shaped or giant tumor cells (Kojiro et al, 1989). The elongated spindle cells are arranged in bundles, occasionally with interlacing or storiform patterns. The giant cells are multinucleated, markedly pleomorphic, and cytologically anaplastic, and osteoclast-like giant cells are described in some instances (Kuwano et al, 1984). These tumors have often been referred to as *carcinosarcomas*. The sarcomatoid component varies in its extent, and histologic transitions with the carcinomatous elements are often noted. The spindle-shaped cells are typically immunoreactive for keratin and α-fetoprotein (Kakizoe et al, 1987).

SCLEROSING HEPATOCELLULAR CARCINOMA. Sclerosing HCC is a rare but distinctive variant characterized by abundant, diffusely distributed fibrous stroma and compressed, sometimes elongated malignant hepatocytes. The tumor tends to occur in an older age group, affects men and women equally, and might be associated with hypercalcemia (Omata et al, 1981). A large, firm, gray-white mass is found on gross examination. The hepatocellular nature of the lesion is best appreciated on a cytologic, rather than architectural, basis. Individual tumor cells, especially at the periphery of the mass, correspond to those of the usual HCC. Although generally smaller in size, they exhibit granular eosinophilic cytoplasm, vesicular nuclei, and conspicuous nucleoli. Bile pigment can sometimes be discerned.

Other Morphologic Patterns of Hepatocellular Carcinoma

It is well known that HCCs that arise in hemochromatosis fail to show accumulation of stainable iron, and iron-free foci in siderotic macroregenerative nodules in human cirrhotic livers have been suggested to be a marker for incipient neoplastic lesions (Hirota et al, 1982; Deugnier et al, 1993). Some HCCs accumulate copper, which can be detected using histochemical methods. Accumulation of large amounts of copper and copper-binding protein (orcein-positive) has been found chiefly in the fibrolamellar variant of HCC (Lefkowitch et al, 1983).

There are some unusual instances in which HCC produces substances that occur in some rare metabolic disorders (e.g., black HCC in a patient without Dubin-Johnson syndrome; Roth et al, 1982). A granulomatous sarcoid-like reaction may be encountered within HCC, the granulomas being characterized by epithelioid cells, Langerhans-type giant cells, and varying numbers of lymphocytes (Nakashima & Kojiro, 1986). Massive lymphoid stroma may also circumscribe otherwise typical HCC.

Hepatocellular Carcinoma in Noncirrhotic Liver

HCC in noncirrhotic liver encompasses several entities. It may develop during the evolution of a chronic fibrosing liver disease at the stage of incomplete cirrhosis (septal fibrosis). This is

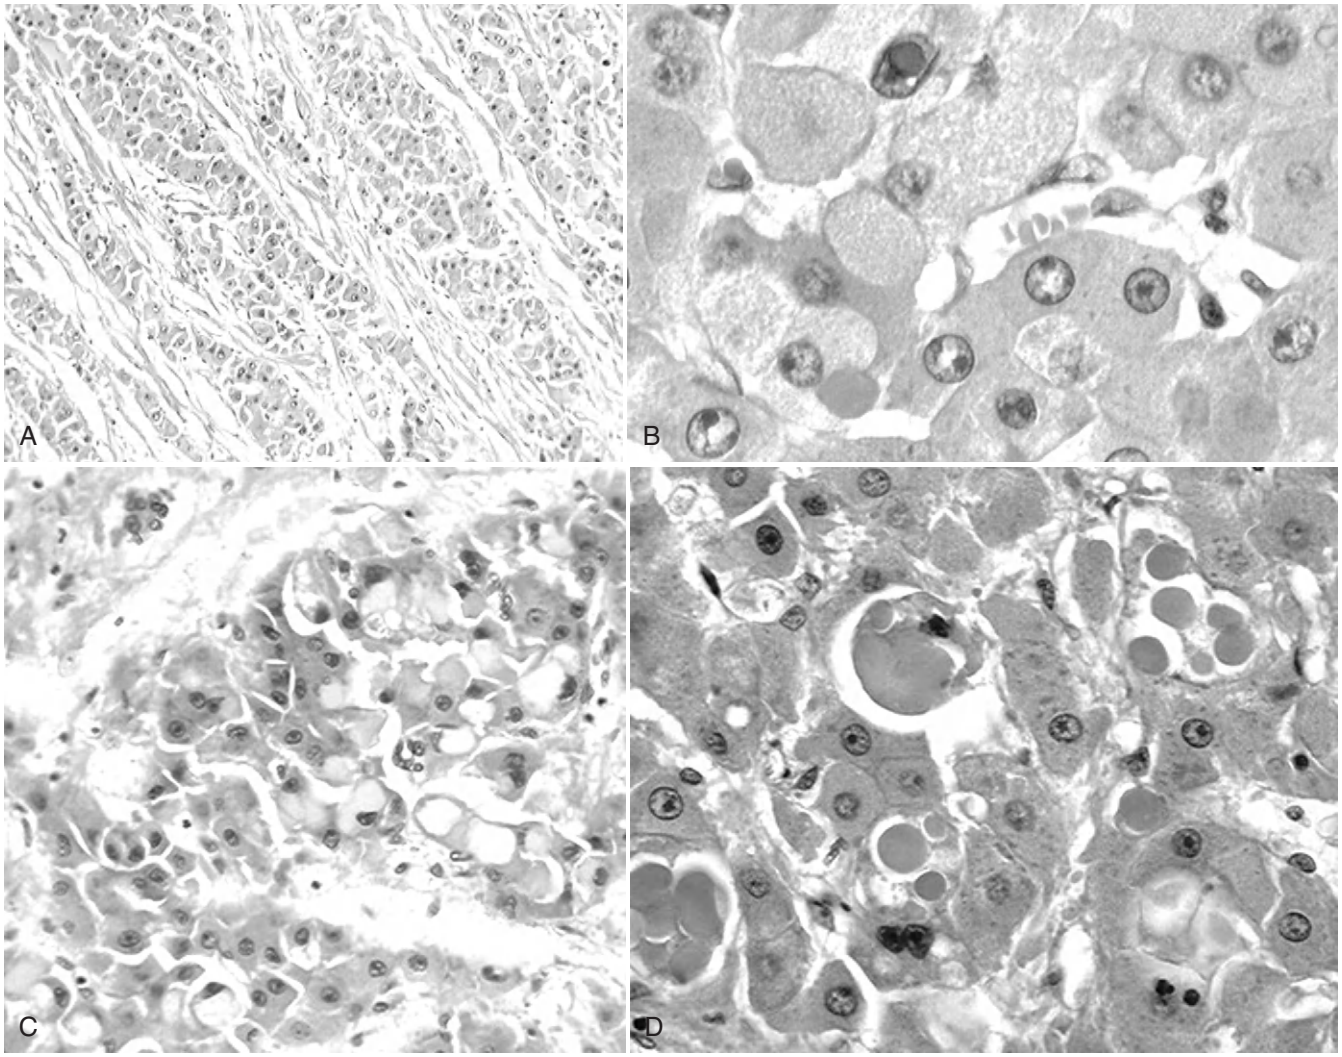

FIGURE 78.14. Fibrolamellar hepatocellular carcinoma. **A,** Tumoral cells organized in trabeculae along fibrous septa. **B,** High magnification showing large eosinophilic tumor cells with intracytoplasmic ground-glass pale bodies. **C,** Intracytoplasmic pale bodies. **D,** Intracytoplasmic eosinophilic globules of various size.

especially common in the context of chronic hepatitis B (Lam et al, 2004). Because of the possible reversibility of cirrhosis, it is not known whether HCC in incomplete cirrhosis develops during an ongoing fibrogenesis or along with the reversion of cirrhosis. In this context, HCC does not show any specific morphologic criteria. HCC may also develop in strictly normal liver or in liver with mild changes, such as steatosis. This group includes the fibrolamellar variant of HCC, that arising from malignant transformation of liver cell adenoma (see below), and a group that develops in the context of other chronic liver disease, including nonalcoholic fatty liver disease (Paradis et al, 2009; Marrero et al, 2002).

Grading and Other Pathologic Prognostic Factors

Grading of HCC relies on the Edmondson and Steiner system, which subdivides HCC into four grades, from I to IV, on the basis of histologic and cytologic resemblance to normal liver (Edmonson & Steiner, 1954). This grading has been shown to correlate with the DNA content and cellular proliferation indices of the tumor (Grigioni et al, 1989). Grade I is the well-differentiated type, in which hepatocyte-like cells are arranged in thin trabeculae. Small HCC tends to be grade I, although these are often not uniform in their differentiation. Grade II HCC is composed of larger tumor cells with abnormal nuclei; glandular structures may also be present. In grade IV, neoplastic cells are much less differentiated, with hyperchromatic nuclei and loss of trabecular pattern. In fact, most HCC seen initially is grade II or III (Kenmochi et al, 1987). Therefore, and as for other carcinomas, the general tendency is to summarize the grading using a three-tiered system comprising well-, moderately, and poorly differentiated HCC.

Nonetheless, tumor grade is a weak independent predictor of the clinical course and conveys little prognostic information (Lai et al, 1979; Chuong et al, 1982). Furthermore, grading of HCC is often heterogeneous alongside the tumor so that liver biopsy might have limited performance for grading HCC. Consequently, the histologic grading of HCC is useful, but rather as a descriptive tool; its practical value is limited (Pawlik et al, 2007).

Besides grading, other histologic features of HCC, such as architectural pattern, have little or no independent prognostic

value. However, several staging systems have been proposed for HCC (Llovet et al, 1999; Marrero et al, 2005). The main prognostic factors are related to general health status; tumor stage, specifically the number and size of nodules, presence of vascular invasion, and extrahepatic spread; liver function, defined by the Child-Turcotte-Pugh classification system and by serum bilirubin and serum albumin levels; and portal hypertension. Etiology has not been identified as an independent prognostic factor.

Size is a major prognostic factor: small or minute carcinomas have a better prognosis, although with larger cancers, the tumor size does not directly correlate with outcome. Presence of satellite nodules around the main tumor has been also recognized as a prognostic factor in several studies. Improved survival has been associated with tumors that are encapsulated or fail to invade surrounding hepatic parenchyma (Ohnishi et al, 1987; Arii et al, 2000; Sutton et al, 1988).

Macroscopic and microscopic vascular invasion are important histoprognostic criteria that deserve special mention. Vascular invasion is a known predictor of recurrence and survival, directly associated with histologic differentiation, degree, and size of the main nodule (Nathan et al, 2009; Pawlik et al, 2005). Characteristically, the prevalence of microscopic vascular invasion increases with tumor size, with up to 60% to 90% in nodules larger than 5 cm. Other histologic findings are not consistently correlated with outcome, although occasional series have reported a better prognosis with clear-cell HCC and tumors of low histologic grade.

Using microarray technology, recent studies have shown that a subset of adult HCC displays phenotypic traits of hepatoblasts. These tumors retent stem cells markers and express CK7 and CK19. Interestingly, worse survival was demonstrated for this subgroup (Lee et al, 2004). Although the significance of CK7 and CK19 expression in HCC is still unclear, it might represent a relevant prognostic factor, although a larger study with multidimensional analysis should be performed.

A major influence on clinical status of the patient is the presence or absence of cirrhosis, which thus becomes a leading indicator for survival. Therefore, simultaneous biopsy of nontumoral liver is of major importance and should be systematically performed for consideration in the therapeutic decision and to help the pathologist in the diagnosis of very well-differentiated HCC.

Molecular Genetics

From experimental hepatic carcinogenesis and epidemiologic studies, it appears that liver carcinogenesis follows a multistep process (see Chapter 8C). Although a few cases of HCC arise in normal liver, the vast majority of them develop from the stepwise pathway: normal liver progresses to fibrosis then to cirrhosis and finally to HCC. Therefore, cirrhosis is recognized as a precancerous lesion (IWP, 1995).

As a result of careful follow-up of cirrhotic patients and detailed pathologic analysis of cirrhotic explanted livers, relevant insights have been gained into the early pathogenesis of HCC. Data are less clear when associated molecular events are concerned; however, a consensus supports the idea that HCC results from cumulative genetic and epigenetic events (Thorgeirsson & Grisham, 2002). Although recurrent gene abnormalities have been reported in fully developed HCC, the early molecular events are far less unknown.

Several studies using different approaches have looked for early molecular abnormalities in regular cirrhosis. Several molecular markers have been evaluated in macronodules, and none of the oncogenes or tumor suppressor genes involved in advanced HCC have been repeatedly found altered in the precancerous lesions. By contrast, proliferation markers, neoangiogenesis, telomerase expression, allelic losses, and clonality have been studied with more consistent results. Interestingly, these studies convincingly demonstrate, using clonal analysis, that among cirrhotic micronodules that looked similar on light microscope, some are already monoclonal (neoplastic), and others are polyclonal (regenerative; Paradis et al, 1998, 2000). Telomerase, an enzyme that allows unrestricted cell proliferation and that is specifically expressed in cancer, can be detected in some but not all of these clonal micronodules without any remarkable histopathologic features (Oh et al, 2003). In the same orientation, and using cell-cycle markers, studies have shown that cirrhosis associated with HCC, or that will give rise to HCC, already expresses increased cell-cycle markers. Therefore even in regular cirrhosis with a bland histopathologic appearance, foci of neoplastic clonal proliferation of liver cells with a limitless capacity of proliferation clearly are already present.

Most genomic studies address advanced HCC, and several efforts have been made to provide molecular classification of HCC based on gene expression (Villanueva et al, 2007; Chuma et al, 2003). Global gene-expression profiling may be the most appropriate technology to unravel the pathogenesis of HCC and explore its heterogeneous origin (Lee et al, 2004; Wurmbach et al, 2007; Llovet et al, 2006; Hoshida et al, 2008). In fact, application of gene-expression profiling of HCC has identified subgroups of patients according to etiologic factors, different stages of the disease, recurrence, and survival (Villanueva et al, 2008; Ladeiro et al, 2008; Boyault et al, 2007). The diversity of these tumors is also found at the molecular level, and a large number of genetic and epigenetic alterations have been described, some of them specific of risk factors. Recently, several comprehensive studies have shown that a molecular classification of HCC can be drawn, linking the transcriptomic pattern of gene expression (Boyault et al, 2007), micro-RNA profiling (Ladeiro et al, 2008), promoter methylations, chromosome gains, and deletions (Xue et al, 2008) to mutation of oncogenes and tumor suppressor genes (de la Coste et al, 1998). Major classes of tumors emerging from these comprehensive analyses are also related to important carcinogenesis pathways, such as activation of ß-catenin (de la Coste et al, 1998), AKT/mTOR (Villanueva et al, 2008), or inactivation of TP53 and RB1. Whether this molecular subclassification may provide a clue to personalized, targeted treatment or to prognosis is under active investigation (Villanueva et al, 2008). Interestingly, using genome-wide expression profiling of formalin-fixed, paraffin-embedded tissues, a recent study demonstrated that a reproducible gene-expression signature correlating with survival was only described in liver tissue adjacent to the tumor in patients with HCC (Hoshida et al, 2008).

Premalignant Hepatocellular Lesions and Small Hepatocellular Carcinomas

It is commonly accepted that in the context of cirrhosis, there is a stepwise progression from cirrhotic nodule to HCC. Several terms have been used in the past to define the intermediate lesions, such as *adenomatous hyperplasia* and *atypical adenomatous hyperplasia*; but in 1995, the IWP proposed a unified nomenclature that has gained wide acceptance and is still

currently used. This classification was recently reviewed and completed by an international group that added definitions of the early and small HCC (ICG, 2009).

Macroregenerative Nodules

A *macroregenerative nodule* (MRN) is a tumor-like hepatocellular mass that can arise in the setting of cirrhosis. These lesions have increasingly been detected, the result of both improved radiographic imaging techniques and more widespread screening of cirrhotic patients. Most MRN are large, discrete nodules that range from 1 to 3 cm in diameter. There is no minimum size threshold for definition; MRNs have to be appreciated according to the size of background cirrhotic nodules, which may be twofold to threefold larger than cirrhotic nodules (Theise et al, 1992; Terada et al, 1993). Macronodules are often well demarcated and surrounded by condensed connective tissue. MRNs are common, and they have been found after careful inspection in about 10% of cirrhotic livers at autopsy or at transplantation (Theise et al, 1992; Furuya et al, 1988; Mion et al, 1996). Histologically, most MRNs are indistinguishable from the usual parenchymal nodules seen in cirrhosis: normal-appearing hepatocytes are arrayed in plates one or two cells thick, limited by a regular sinusoid lining and bounded by typical fibrous septa containing blood vessels, bile ductules, and varying degrees of inflammatory infiltration (Fig. 78.15).

Dysplastic Nodules

Dysplastic nodules (DNs) are sizable lesions arising in cirrhosis, and they differ from the surrounding liver parenchyma with regard to size, color, texture, and degree of bulging of the cut surface. Based on microscopic features, DNs are further subdivided into *low grade* (LGDN) and *high grade* (HGDN), the latter being closer to HCC in the spectrum of hepatocarcinogenesis (IWP, 1995; ICG, 2009). Briefly, LGDNs display features suggestive of a clonal cell population but lack architectural atypia, whereas HGDNs show cytologic and architectural atypia but insufficient for a diagnosis of malignancy.

The premalignant nature of DNs is supported by different clues, including the common association with HCC in resected and explanted end-stage cirrhotic livers (Theise et al, 1992; Furuya et al, 1988; Libbrecht et al, 2005; Sakamoto et al, 1991); the presence of hepatocellular cyto-architectural abnormalities, featuring a lesion on the way to HCC (Ferrell et al, 1992; Ganne-Carrie et al, 1996; Takayama et al, 1990); the morphologic evidence of neoangiogenesis under the form of unpaired arteries supporting the abnormally ongoing vascular supply (Roncalli et al, 1999; Park et al, 2000; El-Assal et al, 1998); the detection of both genetic and epigenetic changes, greater than those in the surroundings but less frequent and consistent than in HCC; and a natural history showing an increased risk for malignant transformation compared with control cirrhotic nodules (Maggioni et al, 2000; Kobayashi et al, 2006; Terasaki et al, 1998; Seki et al, 2000).

Among the various cytologic alterations that characterize DNs are enlarged, crowded, or irregular nuclei with patent nucleoli and an increased nuclear/cytoplasmic ratio. Atypical architectural findings involve expansile proliferative zones, sometimes located within an MRN (nodule-in-nodule formations); focal loss of associated reticulin framework; and foci of abnormal structural patterns that includes irregular thickening of hepatic plates (IWP, 1995; Fig. 78.16). According to Eastern pathologists, *stromal invasion,* defined as the presence of tumor cells invading into the portal tracts or fibrous septa, is the most relevant feature distinguishing HGDN from early HCC (International Consensus Group for Hepatocellular Neoplasia, 2009). The degree and extent of these features vary greatly among patients, thus forming a histologic continuum that stretches between ordinary MRNs and obvious hepatocellular carcinoma.

Dysplastic nodules must be differentiated from *dysplastic foci,* microscopic changes incidentally recognized in cirrhotic tissue. According to histopathologic criteria, dysplastic foci are split into two groups: those with large-cell changes or those with small-cell changes. Although large liver cell change, previously

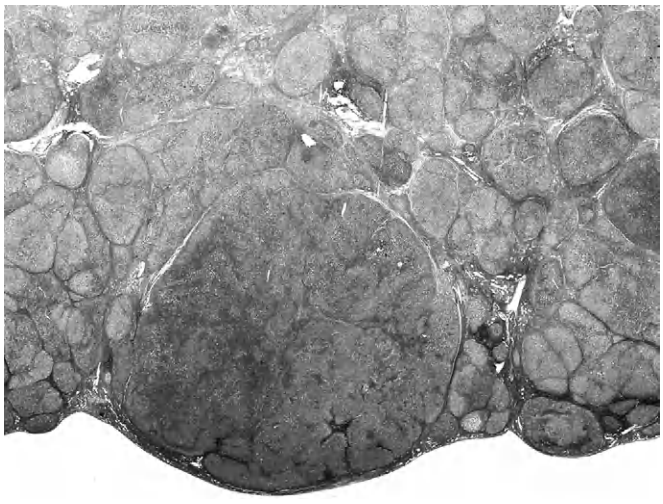

FIGURE 78.15. Low magnification of a benign regenerative macronodule in a cirrhotic liver. The macronodule is well-demarcated from surrounding liver. Fibrous septa and portal tracts are still present within the macronodule.

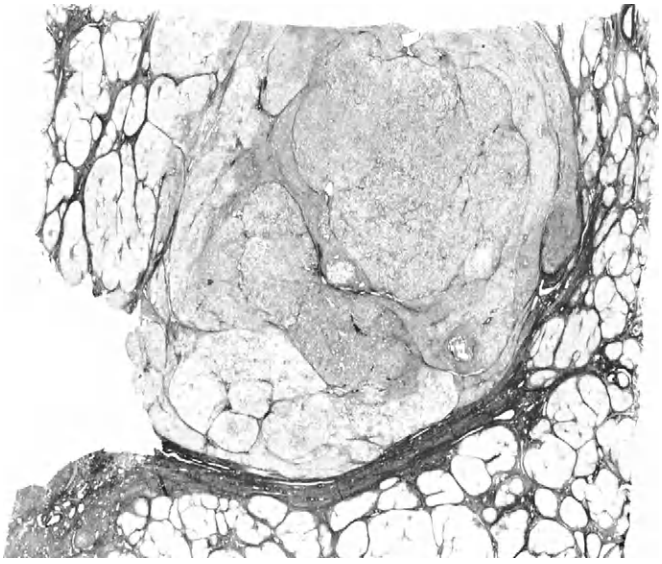

FIGURE 78.16. A macronodule with a nodule-in-nodule pattern of growth. An expansile proliferative basophilic zone is located within a macronodule.

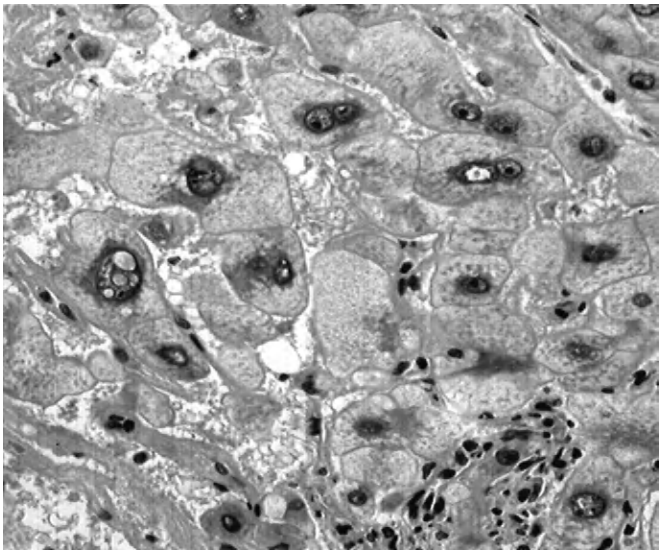

FIGURE 78.17. Large liver cell changes. Cluster of abnormal large liver cells with dystrophic nuclei.

called *large liver cell dysplasia* (Fig. 78.17) consists of abnormal but nonneoplastic hepatocytes that are predictors of HCC development; small liver cell dysplasia is composed of neoplastic cells that are direct precursors of HCC (Lee et al, 1997; Borzio et al, 1995).

Small Hepatocellular Carcinoma

A "small" liver cancer is currently defined as HCC with a maximum diameter of less than 2 cm (Nakashima & Kojiro, 1986). However, the lack of a widely accepted definition has led to confusion, and HCCs smaller than 3 to 5 cm have also been included in this group by others. Small HCCs are usually clinically silent and are often discovered incidentally on explanted liver or at autopsy (Mion et al, 1996). Small HCCs are most often a well-differentiated lesion, sometimes still containing portal triads, growing without substantial destruction of the preexisting hepatic framework and seldom showing angioinvasion (Sakamoto et al, 1991).

Small HCCs have been subdivided into two different entities: those with indistinct margins, called *vaguely nodular HCC,* and those with distinct margins, called *distinctively nodular HCC* (ICG, 2009). Whereas vaguely nodular HCC is the earliest, most indolent, and least angioinvasive type of HCC, distinctively nodular HCC is thought to have already acquired an ability to invade the vessels and to metastasize (Hytiroglou, 2007; Kojiro & Roskams, 2005; Theise et al, 2002). Therefore small HCC with distinct margins seems to be a progressed cancer in spite of its small size. On the liver biopsy, the difference between these two entities cannot be appreciated, because it requires the notion of gross features, which are not recognizable in small fragments. Therefore the term *well-differentiated HCC* may be better used in the biopsy report.

Natural History of Premalignant Lesions and Diagnostic Challenges

Few prospective studies have been conducted in large series of histologically proven nonneoplastic nodules detected by US during surveillance programs in cirrhosis. Taken together, these studies have shown that only a minority of macroregenerative or dysplastic nodules became malignant, those transforming are mostly in the group of HGDN. Furthermore, 40% to 60% stabilized, and a few definitely disappeared during follow-up (Borzio et al, 2003; Kondo et al, 1990). Most of these nodules are 1 to 2 cm, so they seldom display a diagnostic pattern at imaging. Therefore histologic assessment is needed at baseline, and it is worth repeating when sampling is not adequate.

Whether HCC regularly develops from DNs in a low grade–high grade–small and early–small HCC sequence in individual patients is still unclear. This hypothesis is supported by the feature of so-called nodules in nodules, which have been mainly reported in the Eastern literature (Kojiro, 2004; Roncalli et al, 2004, 2007). However, HCC has also been found to originate from outside dysplastic nodules during the surveillance of cirrhotic patients, supporting the notion that HCC can also develop "de novo," by skipping the gradual transition of the sequence (Borzio et al, 2003).

From a clinical point of view, correct classification of hepatocellular nodules, as well as the exact number of truly malignant nodules, is crucial in order to plan the most appropriate therapy. However, the diagnostic approach to these small nodular lesions is a challenge. The prevalence of HCC is closely dependent on the size of the lesion. Indeed, almost half of those lesions smaller than 1 cm are nonmalignant, whereas the large majority of lesions exceeding 2 cm are HCC, so that in the group of lesions greater than 2 cm, a diagnosis of nonmalignancy should suggest the suspicion of a diagnostic error. It has been well established that, in cirrhosis, the progression from nonmalignant nodules to dysplastic to early and advanced HCC is characterized by the progressive loss of the portal blood with a "de novo" arterial vascularization (Hayashi et al, 2002). However, in the group of lesions sized 1 to 2 cm, about 20% of small HCC is hypovascular, so that histology is required in most of these cases, either at baseline or during follow-up, to confirm the nature of the lesions (Forner et al, 2008).

In clinical practice, liver biopsy is today mostly performed to classify small hepatocellular nodules (Bruix & Sherman, 2005). Diagnosis has to be made on tiny and often fragmented material, and clinicians need a conclusive report as to whether lesions are benign or malignant. Nevertheless, the diagnosis is not always straightforward, and other techniques may be required in addition to standard staining. Fortunately, immunocytochemical tools useful to distinguish malignant from nonmalignant nodules within the group of well-differentiated hepatocellular lesions have been developed recently, such as glypican-3 antibody (Di Tommaso et al, 2007).

Hepatoblastoma

Hepatoblastoma is the most common primary liver tumor of childhood, accounting for 45% of the malignant hepatocellular neoplasms of infants and young children (Stocker, 2001; see Chapter 82). Almost all cases of hepatoblastoma occur during the first 3 years of life, although rare cases have been described in older children (Lack et al, 1982). Hepatoblastoma has been associated with congenital or genetic disorders, including Beckwith-Wiedeman syndrome, Wilms tumor, familial adenomatous polyposis, glycogen storage disease, and various congenital anomalies (Ishak & Glunz, 1967).

Hepatoblastomas are typically solitary, well-circumscribed, and occasionally encapsulated masses mostly located in the right lobe; size ranges from 5 to 20 cm in diameter (Stocker,

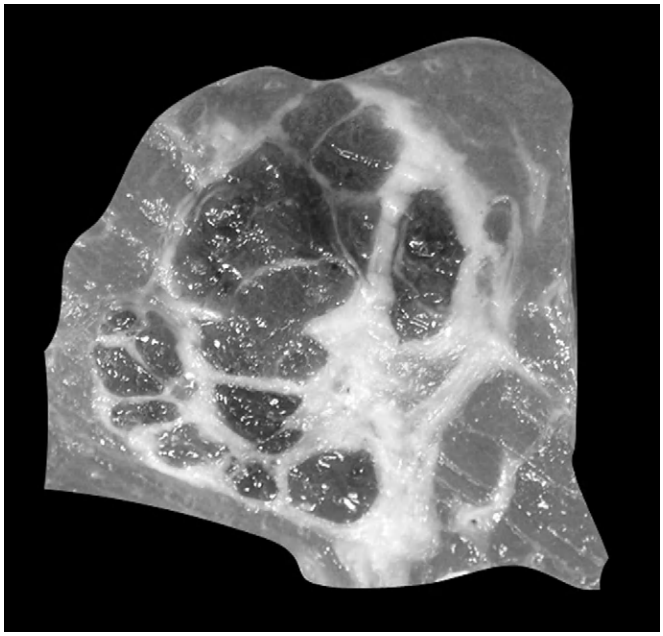

FIGURE 78.18. Hepatoblastoma. Well-delineated tumor with lobulation and hemorraghic foci and areas of cystic degeneration. *(Image courtesy Dr A. Fabre.)*

2001). The cut surface of hepatoblastoma has a bulging, lobulated contour and a variable tan to light brown to gray-white appearance with occasional foci of hemorrhage, cystic degeneration, necrosis, or calcification (Fig. 78.18; Stocker, 2001; Lack et al, 1982).

Histologically, hepatoblastoma is composed predominantly of immature liver cells resembling either fetal or embryonic hepatocytes. In addition, hepatoblastoma may be of either the pure epithelial type or the mixed epithelial and mesenchymal type.

Fetal-type cells are smaller than normal hepatocytes with a uniform monotonous appearance, an abundant polygonal cytoplasm, and round, regular nuclei with inconspicuous nucleoli (Fig. 78.19). The cells are organized in irregular plates; nuclear

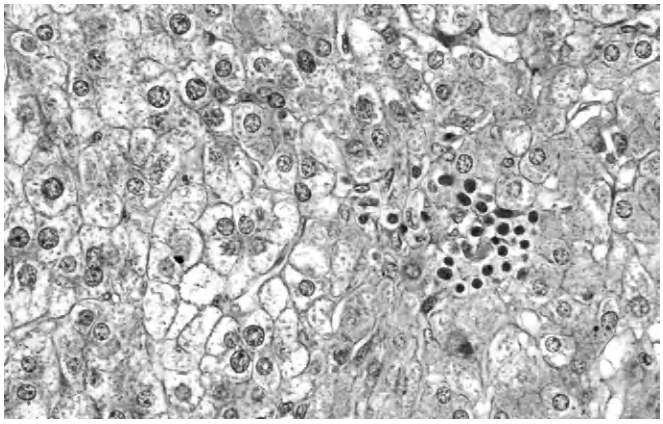

FIGURE 78.19. Hepatoblastoma, fetal type. Tumoral hepatocytes are smaller than normal with an abundant polygonal cytoplasm and round, regular nuclei organized in thin, irregular plates with dark foci of extramedullary hematopoiesis. *(Image courtesy Dr A. Fabre.)*

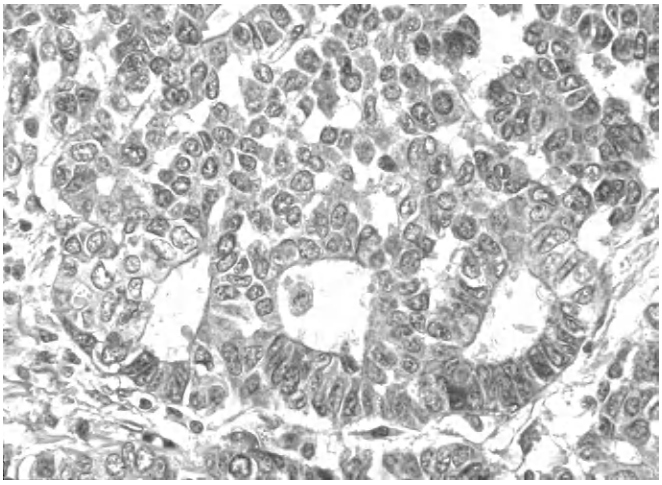

FIGURE 78.20. Hepatoblastoma, embryonal type. Tumoral cells are less mature and made of small, dark, angular cells with compact cytoplasm and poorly defined outlines. *(Image courtesy Dr A. Fabre.)*

pleomorphism is minimal, and mitoses are few, but foci of extramedullary hematopoiesis are a common finding. The embryonal-type cell is composed of less mature tumoral cells—dark, angular cells with compact cytoplasm and poorly defined outlines (Fig. 78.20). Scattered mitoses are regularly noted, and foci of necrosis are occasionally seen.

Fetal-type and embryonal-type cells often coexist, and transitions between the two are frequently present. In addition to the two major patterns, other types are described. The anaplastic type consists of small uniform cells similar to those of neuroblastoma with scanty cytoplasm, hyperchromatic nuclei, and frequent mitoses (Haas et al, 2001).

The mixed hepatoblastomas combine the epithelial component with mesenchymal-derived tissues of various differentiations. Usually this consists of osteoid-like material, sometimes focally calcified, or primitive spindle cells occurring in fasciculated or loose myxoid arrangements. Rarely, trabecular bone formation or cartilaginous or rhabdomyoblastic differentiation is identified.

Hepatoblastoma is an aggressive neoplasm that invades locally and spreads to regional lymph nodes, lungs, adrenal glands, brain, and bone marrow. The most important predictor of outcome is the tumor stage at presentation. Once stage is taken into account, the various histologic subtypes become less important prognostic indicators (Conran et al, 1992). Nonetheless, tumors of pure fetal-type histology tend to have the best prognosis (Haas et al, 1989).

Benign Liver Tumors (See Chapter 79)

Benign hepatocellular lesions encompass two main entities that strongly differ in terms of pathogenesis, clinical presentation, and behavior: *focal nodular hyperplasia* (FNH) and *hepatocellular adenoma* (HCA). Both groups are mainly observed in young women, usually in the context of oral contraception, and lesions develop in an otherwise normal liver. Whereas HCA is a neoplastic, clonal, and proliferative lesion, there is now consensus on the polyclonal, nonneoplastic, and reactive origin of FNH (Paradis et al, 1997; Bioulac-Sage et al, 2007a).

Focal Nodular Hyperplasia

FNH is ten times more common than HCA and is the second most common benign liver process after hemangioma. It is predominantly diagnosed in women 30 to 50 years of age. Most FNH is found incidentally, but some is revealed by clinical symptoms or biologic alterations such as pain, liver mass, or increased γ-glutamyltransferase (GGT) levels. However, complications such as rupture or bleeding are exceptional, and no evidence of malignant transformation has been reported. In contrast to HCA, the diagnosis of FNH is strongly suggested by imaging techniques, so that histopathologic examination is required for diagnosis in a minority of cases. When performed, fine needle biopsy of FNH can be difficult, because fibrous septa and thick abnormal arteries, the hallmarks of FNH, are usually missing (Fabre et al, 2002; Makhlouf et al, 2005).

On gross examination, FNH appears usually as a solitary, discrete, rounded mass, pale to beige, and well-delineated from background normal liver but without a defined fibrous capsule (Fig. 78.21). On cut surface, FNH displays a variegated and partly nodular organization, and frequently, but not always, a central stellate scar with radiating fibrous cords are also visualized at imaging (Wanless et al, 1985; Nguyen et al, 1999).

The typical histopathologic features of classical FNH include fibrous septa, which contain large dystrophic arteries with a peripheral ductular reaction, and an absence of interlobular bile ducts (Fig. 78.22). Hepatocytes are usually unremarkable, arranged in normal or mildly thickened plates without cytologic atypia, lined by a well-preserved sinusoidal framework. Steatosis or cholestatic degeneration with Mallory-Denk bodies may be seen.

FNH has been divided into *classic* and *nonclassic* forms (Nguyen et al, 1999). In forms of FNH other than the classic one, the diagnosis may prove difficult, because some of the distinguishing pathologic features may be unapparent. Such forms consist of FNH without a central scar, a mixed hyperplastic and adenomatous form, FNH with massive steatosis, and a form with atypia of the large-cell type (Nguyen et al, 1999). Strong evidence has been found, based on clonal features and the angiopoietin gene-expression profile, that the previously so-called telangiectatic variant of FNH may, in fact, belong to the HCA group (see below; Paradis et al, 2004).

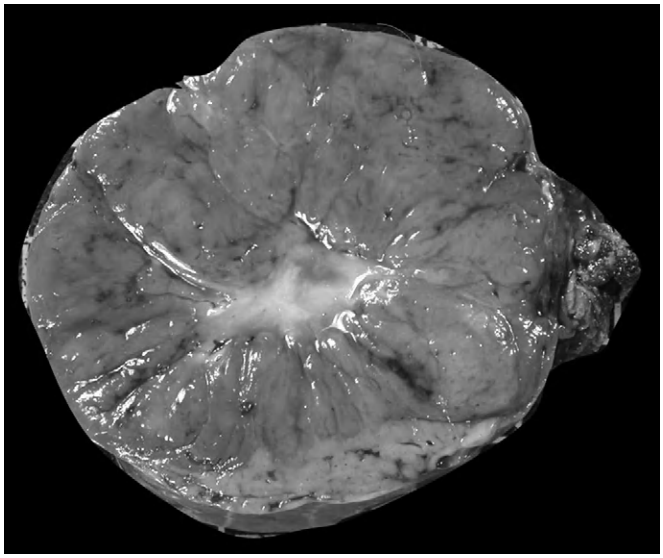

FIGURE 78.21. Focal nodular hyperplasia. A well-circumscribed nodular lesion with a central stellate scar and radiating fibrous cords.

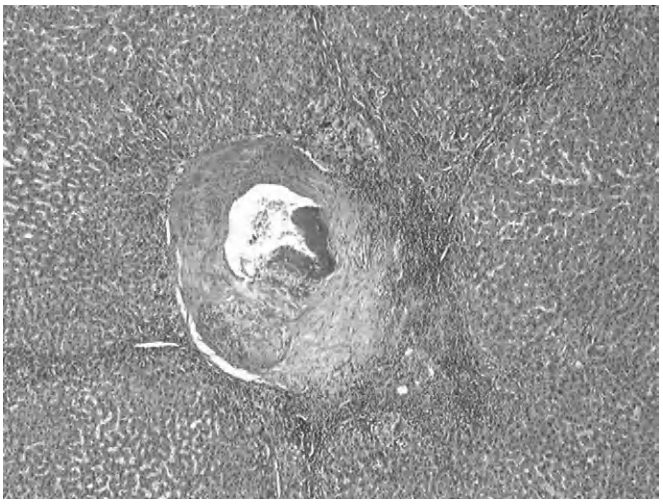

FIGURE 78.22. Focal nodular hyperplasia. Fibrous septa contain often large, dystrophic arteries with thick walls and thin, fibrous septa.

Immunohistochemistry may provide interesting information. Immunostaining with glutamine synthetase that shows focal positive hepatocellular areas, usually centered by hepatic veins and described as a maplike pattern, is highly consistent with the diagnosis of FNH and suggests a focal maintenance of lobular organization (Bioulac-Sage et al, 2009a). In addition, the perisinusoidal spaces in FNH exhibit an aberrant extracellular matrix associated with abnormal fibrillin-1 expression (Lepreux et al, 2004). Further study showed that the phenotype of endothelial cells lining the vascular channels in FNH differs from those in the remaining liver, associated with a downregulation of angiotensin I–converting enzyme/CD143 (Grantzdorffer et al, 2004).

FNH and FNH-like nodules are now well known to develop in the context of hepatic venous outflow obstruction, including Budd-Chiari syndrome (Maetani et al, 2002; Rangheard et al, 2002), and in other circulatory disorders of the liver such as portal vein thrombosis, portal vein agenesis, hereditary telangiectasia, and even in cirrhosis; this supports the concept of a vascular trigger in the pathogenesis of FNH (Kondo, 2001; Kondo et al, 2004; Bureau et al, 2004). Evidence supports that FNH is a hyperplastic reaction resulting from an arterial malformation related to increased arterial blood flow (Wanless et al, 1985).

Similar to HCA, FNH has been observed in association with the use of oral contraceptives, although the relationship remains controversial (Scott et al, 1984). FNH may occur together with HCA (Grange et al, 1987), and it has been found to be associated with a variety of nonhepatic tumors and tumorlike conditions, such as HCA, hemangioma of the liver, and several other tumors (e.g., in siblings with glioblastoma; Handra-Luca et al, 2006). The significance of these associations is unclear, but it suggests that the pathogenesis of FNH is probably heterogeneous.

Hepatocellular Adenomas

HCA is a rare, benign liver cell neoplasm strongly associated with oral contraceptive (OC) use and androgen steroid therapy

FIGURE 78.23. Hepatocellular adenoma. External view of a superficial tumor with large subcapsular and dilated vessels.

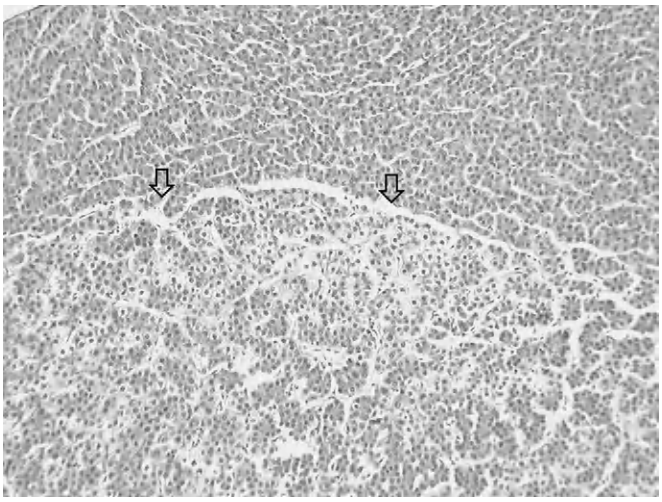

FIGURE 78.25. Hepatocellular adenoma. Proliferation of benign hepatocytes of normal size with a normal nuclear/cytoplasmic ratio pushing the normal liver parenchyma (*arrows*).

(Coombes et al, 1978; Nime et al, 1979). Its estimated incidence is 0.1 per year per 100,000 in non-OC users and reaches 3 to 4 per 100,000 in long-tem OC users. HCA can also occur spontaneously or in association with underlying metabolic diseases, including type 1 glycogen storage disease, iron overload related to β-thalassemia, and diabetes mellitus. Therefore, HCA represents a heterogeneous group of tumors in which histopathologic features may vary according to the etiologic background (Bioulac-Sage et al, 2007b).

HCA is usually solitary, sometimes pedunculated, with size ranging from a few millimeters to 30 cm. Large subcapsular vessels are commonly observed with large superficial tumors (Fig. 78.23). On analysis of cut sections, the tumor is soft, white to brown, and well delineated with little or no fibrous capsule (Fig. 78.24). Heterogeneous areas of necrosis or hemorrhage may be observed, especially in larger tumors. Histologically, HCA consists of a proliferation of benign hepatocytes of normal size or slightly enlarged with a normal nuclear/cytoplasmic ratio. Hepatocytes are arranged in a trabecular pattern without any residual portal tracts; a pseudoglandular growth pattern is possible but rare. Small, thin, and unpaired vessels without other portal tract elements—including connective tissue, bile ducts, or ductular reaction—are usually found throughout the tumor (Fig. 78.25). The cytoplasm of hepatocytes may be normal, glycogen-rich, or fatty, and cellular atypia can be impressive, especially in patients who have taken steroids for many years. In that context, differential diagnosis with HCC may be difficult. Vascular changes are frequent and include sinusoidal dilation, peliosis, infarcts, and hemorrhage. These changes may leave edematous or fibrotic regions, often with hemosiderin-laden macrophages.

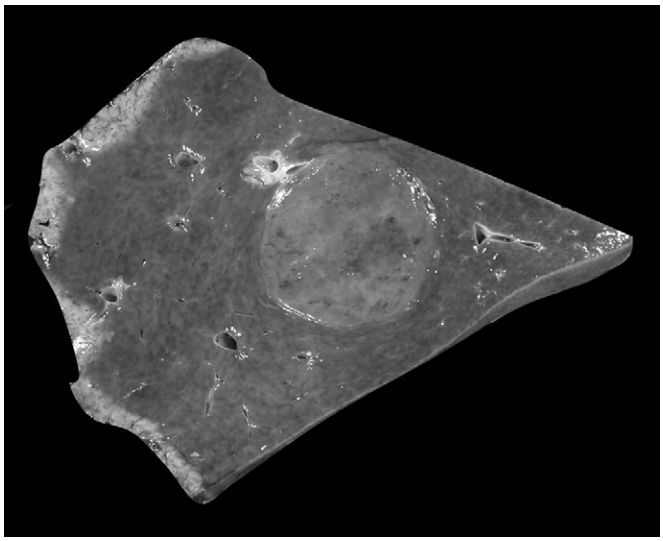

FIGURE 78.24. Hepatocellular adenoma. Soft, well-delineated tumor with little or no fibrous capsule and small, heterogeneous foci of hemorrhage.

Compared with patients with FNH, those with HCA are more likely to come to medical attention with symptoms such as spontaneous bleeding and hemorrhage, with an increased risk according to size for tumors larger than 5 cm in diameter (Dokmak et al, 2009). The risk for malignant transformation of HCA ranges between 4% to 10%, with a higher rate in males and in large HCA (Bioulac-Sage et al, 2007; Dokmak et al, 2009). In addition, recent evidence suggests that metabolic syndrome may favor development of HCC in a preexisting HCA (Paradis et al, 2009). Increased incidence of metabolic syndrome may partly explain the rising incidence of malignant transformation of HCA, especially in the male population (Farges et al, 2011).

Multiple HCA and so-called *adenomatosis* are not so rare (Fig. 78.26). Patients with multiple HCAs are predominantly female, but the use of OC appears to be less prevalent (Fléjou et al, 1985). Patients with glycogen storage disease type I are also at risk of developing multiple HCA (Labrune et al, 1997). Nevertheless, these tumors share the same clinical and imaging characteristics independent of their number (Dokmak et al, 2009; Lewin et al, 2006). In addition, a recent study supports that the risk of complications, including bleeding and malignant transformation, is similar to that in patients with solitary HCA, and it is not influenced by the number of tumors (Dokmak et al,

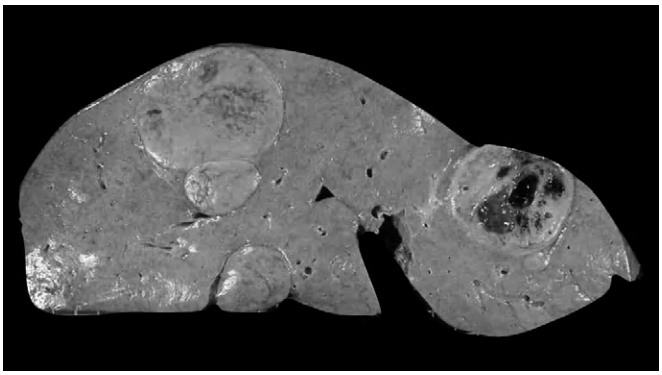

FIGURE 78.26. Adenomatosis. Multiple hepatocellular adenomas of various sizes are dispersed throughout the liver.

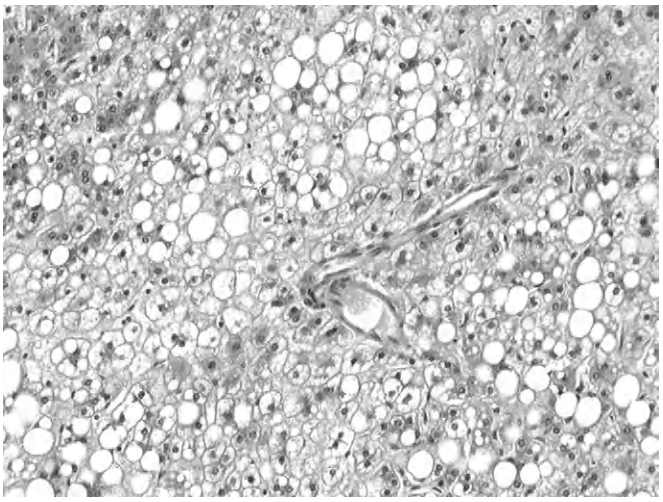

FIGURE 78.27. Steatotic adenoma. Most liver cells display marked steatosis. Unpaired arteries are visible between tumoral cells, but no portal tract.

2009; Bioulac-Sage et al, 2009b). The three main morphologic patterns of liver adenomatosis have been described: 1) *steatotic,* 2) *peliotic/telangiectatic,* and 3) *mixed* (Lewin et al, 2006). To note, the proportion of steatotic HCA is higher, and presence of microadenomatous foci in the "nontumoral liver" is more often observed in patients with liver adenomatosis (Dokmak et al, 2009).

MOLECULAR CLASSIFICATION OF HEPATOCELLULAR ADENOMAS. Molecular comprehensive studies have recently garnered further insights into the structure of HCA, demonstrating some degree of molecular and histologic heterogeneity among the group of HCAs. Today, HCAs are subdivided into three main subtypes according to phenotypic and molecular features: 1) *hepatocyte nuclear factor (HNF) 1α–mutated steatotic,* 2) *telangiectatic/inflammatory,* and 3) *β-catenin–mutated* (Paradis et al, 2004; Rebouissou et al, 2008; Zucman-Rossi et al, 2006). In addition, a small group of HCA that does not display any specific morphologic or genotypic features remains unclassified.

The first group of HCA displays biallelic mutations of the *TCF1* gene, inactivating the HNF-1α transcription factor. This homogeneous group is phenotypically characterized by marked steatosis and absence of cytologic abnormalities or inflammatory infiltrates (Fig. 78.27). Whereas both *HNF-1α* mutations are somatic in most cases, patients with inherited mutation in one allele of *HNF-1α* and an additional somatic mutation may develop HCA in the context of maturity-onset diabetes of the young type 3 (MODY3) and are predisposed to familial liver adenomatosis (Bluteau et al, 2002; Bacq et al, 2003).

The second group of HCA displays β-catenin–activating mutations and is characterized by increased risk for malignant transformation into HCC. These HCAs are mostly encountered in male patients and frequently show significant cell atypias and pseudoglandular formations (Fig. 78.28; Zucman-Rossi et al, 2006).

The third group of HCA is the inflammatory/telangiectatic adenoma group. These tumors, previously called *telangiectatic variant of FNH,* are well-delineated, unencapsulated tumors with areas of vascular changes without any fibrous scar (Fig. 78.29; Paradis et al, 2004; Wanless et al, 1989; Bioulac-Sage et al, 2005). Histologically, the hepatocellular proliferation contains small clusters of arteries embedded in collagen, often associated with an inflammatory infiltrate (lymphocytes and macrophages) and occasionally with ductular proliferation. In addition, foci of sinusoidal dilation and peliotic changes are usually present, and mild or significant steatosis may also be observed within tumoral cells. Although commonly observed in women using OC, telangiectatic/inflammatory HCA is often reported in patients with increased body mass index (BMI) associated with inflammatory syndrome (increased C-reactive protein [CRP] or fibrinogen serum levels; Paradis et al, 2004). Interestingly, in approximately 60% of these lesions, the interleukin (IL)-6 signaling pathway was found to be activated in relation to mutations in the *IL6ST* gene that encodes the signaling coreceptor gp130. As a matter of fact, the gain-of-function somatic mutations in *gp130* may result in the inflammatory phenotype of HCA, which would explain activation of the acute inflammatory phase observed in tumoral hepatocytes (Rebouissou et al, 2009).

The fourth group includes HCAs without any characteristic morphologic features or any of the genetic abnormalities previously described.

Surrogate immunophenotypic markers related to the genetic abnormalities may be used for the classification of the main subtypes of HCA (Bioulac-Sage et al, 2007b). Indeed, expression of liver fatty acid binding protein (LFABP), a protein positively regulated by HNF-1α, is absent in steatotic HNF-1α–mutated HCA, whereas it is expressed in nontumoral liver. Similarly, telangiectatic/inflammatory HCA displays positive immunostaining with acute-phase inflammatory proteins, such as serum amyloid A (SAA) and CRP. Most β-catenin–mutated HCA presents abnormal and cytoplasmic and/or nuclear staining of β-catenin in tumoral hepatocytes, usually with a focal positivity restricted to a few isolated tumoral hepatocytes. Immunostaining with glutamine synthetase, a β-catenin–targeted gene, showing a strong and diffuse cytoplasmic staining increases the sensibility for diagnosis of β-catenin–mutated HCA.

In surgical series of HCA, steatotic and telangiectatic/inflammatory subtypes appear to be equally distributed, accounting for 85% of overall HCA, whereas β-catenin-mutated HCA is reported in 10% to 15%.

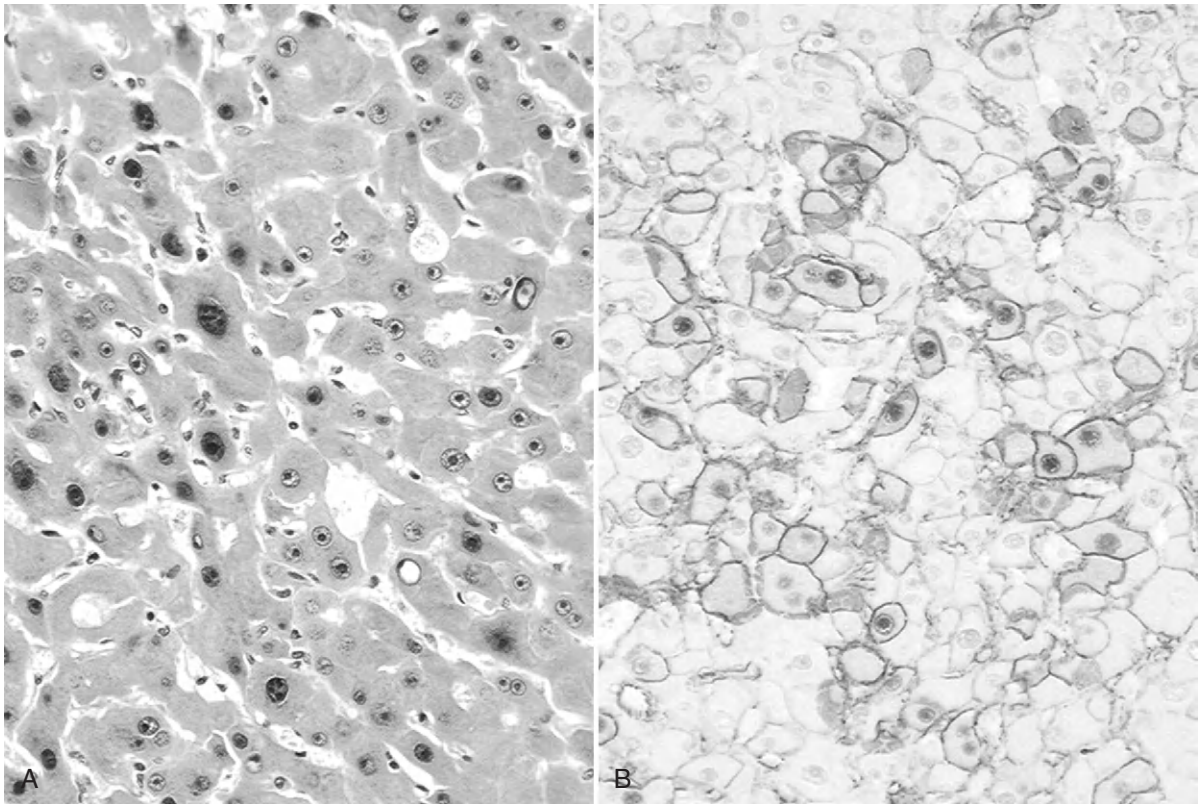

FIGURE 78.28. Hepatocellular adenoma with β-catenin–activating mutations. Liver cells display marked atypia **(A)**; β-catenin immunostaining **(B)** shows that some tumoral cells display abnormal cytoplasmic and nuclear staining.

BILIARY CELL TUMORS

Cholangiocarcinoma

Epidemiology and Clinical Background (See Chapters 50A and 50B)

Cholangiocarcinoma (CC) is a malignancy with biliary differentiation that develops along the biliary tree. It is the second most frequent primary malignant tumor of the liver (5% to 15% of liver primary malignancies; Malhi & Gores, 2006; Welzel et al, 2006). CC is mainly observed in adults with a peak incidence between 60 and 70 years and a male/female ratio of 1.5:1 (Parkin et al, 2005). CC is classified according to the anatomic location, either *intrahepatic* (IH-CC) or *extrahepatic* (EH-CC; Welzel et al, 2006). CC within the intrahepatic bile ducts is referred to as *peripheral cholangiocarcinoma,* arising in the bifurcation of the common bile duct as hilar CC, or Klatskin tumor; those in the extrahepatic bile ducts are extrahepatic CC (Klatskin, 1965). The updated WHO classification divides CC into *IH-CC, hilar CC,* and *EH-CC* (Bosman et al, 2010).

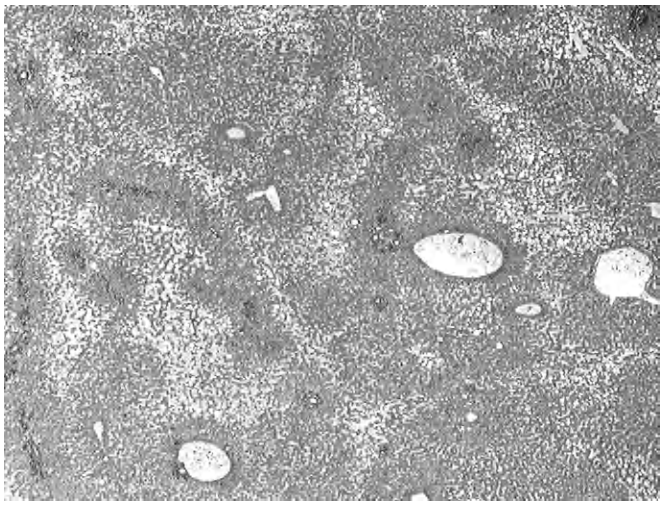

FIGURE 78.29. Telangiectatic/inflammatory adenoma. Extended foci of sinusoidal dilation are visible at low magnification.

Hilar tumors are the most common, accounting for 60% to 70% of CC; peripheral lesions and tumors located in the extrahepatic bile duct represent 5% to 10% and 20% to 30% of CC respectively (Malhi & Gores, 2006; Patel, 2006). Although hilar CCs are usually considered an IH-CC, their characteristics in terms of clinical presentation, morphology, and phenotype are closer to EH-CC.

Prevalence of CC shows a wide geographic distribution largely as a result of variations in regional environmental risk factors, with the highest incidence observed in Asian countries where parasitic infections—namely, *Opisthorchis viverrini* and *Clonorchis sinensis*—are endemic (Kim et al, 1989; Lim et al, 2006; Watanapa & Watanapa, 2002; see Chapter 45). Importantly, incidence of CC is rising in most countries, even in nonendemic areas. Such an increase is specifically observed for IH-CC, including hilar tumors, whereas incidence of EH-CC is stable or even decreased (Khan et al, 2002; Patel, 2001, 2006; Shaib et al, 2004).

Although several risk factors for CC are well established, most occur in patients without evident predisposing factors (Chapman, 1999). Primary sclerosing cholangitis (PSC) associated with ulcerative colitis is one of the most recognized risk factors (see Chapter 41). Indeed, patients with PSC display a 1.5% cumulative annual risk of developing CC, and 10% to 20% will eventually develop CC (Boberg et al, 2002). Fibropolycystic liver diseases that include choledocal cyst, Caroli syndrome, and congenital hepatic fibrosis are also common risk factors (Yamato et al, 1998; see Chapter 46); infections with parasitic liver flukes, such as *Opisthorchis viverrini* and *Clonorchis sinensis,* contribute to the high incidence of CC in Asia (Curado & Shin, 2007; Lim et al, 2006; see Chapter 45). Hepatholithiasis (see Chapters 39 and 44), cholelithiasis, cholangitis, chronic pancreatitis, and Thorotrast exposure are also risk factors (Chapman, 1999; Lipshutz et al, 2002). More recently, associations of CC with obesity, diabetes, human immunodeficiency virus (HIV) and hepatitis C virus (HCV) infection, and alcoholic liver disease have been reported in large population databases (Shaib et al, 2005; Welzel et al, 2007).

Clinical symptoms at diagnosis are dependent on the anatomic location, the growth types of the CC, and the tumor-node-metastasis (TNM) stage (Malhi & Gores, 2006). Although IH-CC is usually discovered at a late stage, hilar CC and EH-CC usually are found earlier with cholestasis (Ebata et al, 2009). The prognosis of CC is dismal, partly related to its propensity to invade directly adjacent liver parenchyma and to spread along the portal pedicles. Presence of perineural and vascular invasion is frequent in the hilar tumors. In the intraductal growth type, tumor often spreads intraluminally along the ducts, and intrahepatic metastases develop in nearly all advanced cases. The incidence of metastases to regional lymph nodes is higher than in HCC. Blood-borne spread occurs later, particularly to the lungs (Jiang et al, 2009; Patel, 2001; Suzuki et al, 2002).

Pathology (See Chapter 47)

Most CC develops in noncirrhotic liver. The Liver Cancer Study Group proposed a classification of CC based on growth patterns, and three main types emerged: 1) *mass forming,* 2) *periductal infiltrating,* and 3) *intraductal growing* (Yamasaki et al, 2003). These patterns are associated with different clinical evolution, the intraductal growing and the periductal infiltrating showing the best and worse prognoses, respectively (65% survival at 5 years vs. <5%; Jiang et al, 2009; Suzuki et al, 2002).

The mass-forming variation is the main type of IH-CC, accounting for approximately two thirds of cases. It is a solitary, nodular lesion developed in the liver parenchyma. The tumor is usually well delineated, not encapsulated, and gray to white with a firm and solid consistency (Fig. 78.30). In cases with large tumors, adjacent satellite tumoral nodules are commonly observed. The periductal infiltrating type spreads along the portal tracts with stricture of the involved ducts, potentially leading to obstructive dilation and cholangitis of the peripheral bile ducts (Fig. 78.31). The intraductal growing type is a polypoid or papillary tumor developed within dilatated bile duct lumen (Fig. 78.32). This type represents malignant progression of biliary papillomatosis or intraductal papillary neoplasm (IPN) of the bile duct (see below). These three patterns may overlap in the same tumor. Although most CC occurs in a background normal liver, recent reports suggest that independently to its origin, cirrhosis increases the risk 10-fold for patients

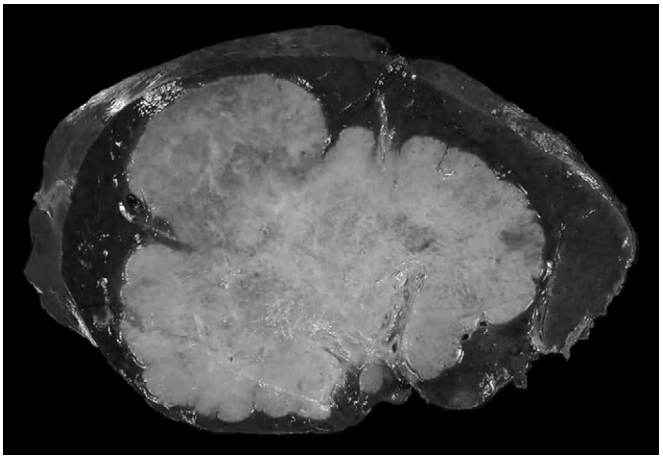

FIGURE 78.30. Cholangiocarcinoma, mass-forming type. Well-circumscribed, unencapsulated tumor is gray to white with a fibrous aspect developed in normal liver.

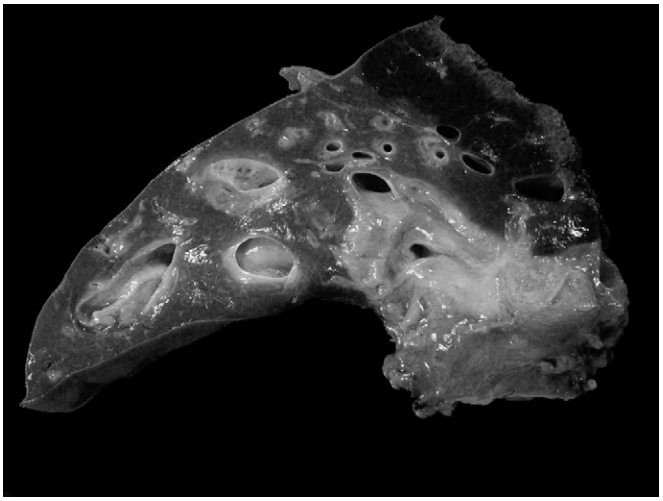

FIGURE 78.31. Cholangiocarcinoma, periductal infiltrating type. On cut section, infiltrating tumor developed along the portal tract and led to narrowing bile duct and obstructive dilation of peripheral intrahepatic bile ducts.

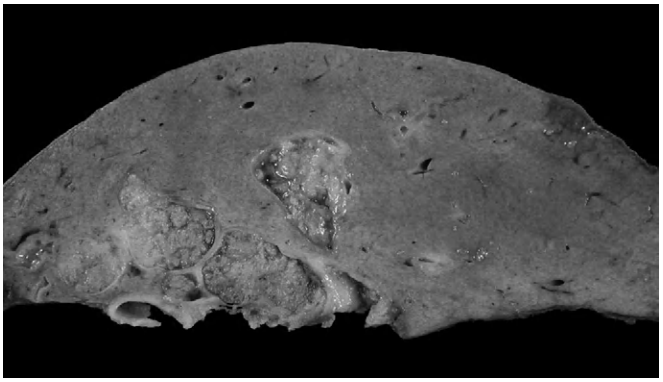

FIGURE 78.32. Cholangiocarcinoma, intraductal growing type. On cut section, endoluminal papillary proliferation growing into the bile ducts in a normal liver.

to develop CC (Fig. 78.33; Shaib et al, 2005; Kobayashi et al, 2000).

The next most common form is mixed mass forming and periductal infiltrating CC, observed in 25% of cases. The pure peri-infiltrating type and the intraductal growth pattern are seldom observed (Guglielmi et al, 2009). CC arising in the intrahepatic small bile ducts or ductules is usually the mass-forming type, whereas CC arising in the intrahepatic large bile ducts (hilar CC) may be any of the three types (Nakanuma et al, 2008).

Most CCs are adenocarcinomas with a prominent, fibrous stroma. CC can be graded as well-, moderately, or poorly differentiated adenocarcinoma according to morphology. Most CCs are well-differentiated tumors with a glandular or tubular pattern of growth, although micropapillary, acinar, or cordlike patterns also occur. Similar to their normal counterparts, tumor cells are small or medium sized, cuboidal or columnar, with small nuclei and nucleoli (Fig. 78.34). Cytoplasm is usually pale, slightly eosinophilic, and sometimes more abundant and clear. Mucus secretion may be highlighted by Alcian blue staining, though the amount is usually small. Less differentiated tumors may show cribriform formations and/or a cordlike pattern, and poorly differentiated cancers are characterized by marked cellular pleomorphism. Hilar and EH-CC are more often well differentiated compared with peripheral CC (Guedj et al, 2009). Presence of dense, hyaline, fibrous stroma is a key feature of CC. Usually, the center of the tumor is densely sclerotic and hypocellular with focal calcifications, whereas the periphery of the tumors is more cellular. CC frequently infiltrates into portal tracts, invading portal vessels, and perineural invasion is a frequent finding in hilar CC (Fig. 78.35; Guedj et al, 2009).

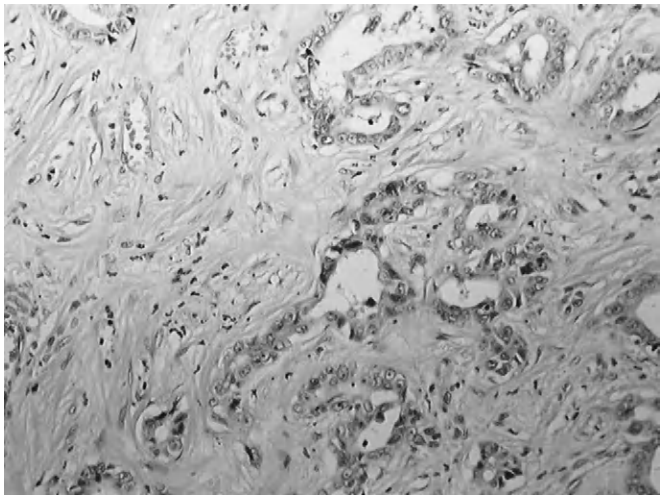

FIGURE 78.34. Cholangiocarcinoma: well-differentiated adenocarcinoma with a glandular pattern composed of small, cuboidal eosinophilic cytoplasm into a prominent fibrous stroma.

Several histologic variants have been reported, including adenosquamous and squamous carcinoma, mucinous carcinoma, signet-ring cell carcinoma, clear-cell carcinoma, mucoepidermoid carcinoma, lymphoepithelioma-like carcinoma, and sarcomatous CC.

Because CC originates from biliary epithelial cells, tumor cells display immunostaining with anti–CK7 and anti–CK19, carcinoembryonic antigen (CEA), and epithelial membrane antigen (EMA). The keratin profile is particularly useful for the differentiation of IH-CC from metastatic carcinoma derived from colorectal origin: CK7 is constantly expressed in CC, and CK20 is constantly expressed in metastatic colon carcinoma (Rullier et al, 2000). The diagnosis of IH-CC may be a challenging main diagnostic issue concerning the differential diagnosis between CC and metastatic carcinoma. In that setting, fine needle aspiration, and especially cytologic smears, have been shown as performant as core biopsy with a specificity of 100%, a sensitivity of 84%, and no false-positive cases of CC (Pupulim et al, 2008). In contrast, performance of biopsy is much more limited in cases of extrahepatic strictures. Additional approaches, including evaluation of ploidy and fluorescence in situ hybridization (FISH), have been shown to increase sensitivity up to 34% and specificity up to 98% (Kipp et al, 2004; Levy et al, 2008).

Biliary Papillomatosis and Biliary Intraepithelial Neoplasia

Biliary papillomatosis is closely associated with the intraductal growing pattern of CC. It is a rare condition characterized by the multicentric proliferation of columnar epithelium within the large bile ducts, although it can diffuse anywhere in the large intrahepatic or extrahepatic bile ducts (Padfield et al, 1988; Mercadier et al, 1984; Gouma et al, 1984). Biliary papillomatosis is a disease of middle-aged or older adults, and men are affected about twice as often as women. Grossly, the neoplasm invades the bile duct lumen, which is filled with soft pink to tan papillary excrescences, although skipped areas may be present (Zen et al, 2006). The surface epithelial cells covering these papillae are pancreatobiliary-, gastric-, or intestinal-type cells (Fig. 78.36). According to the WHO classification, and in similarity with pancreatic lesions, biliary papillomatosis has been renamed *biliary intraepithelial papillary neoplasm* (IPN). Although often cytologically benign, the cells can display greater degrees of nuclear atypia; in situ or invasive carcinoma is occasionally noted (Gouma et al, 1984; Neumann et al, 1976). Specific differentiation of the epithelial lining may be observed, including that of the pancreatobiliary type, intestinal type, oncocytic type, and gastric type. This invasive tumor may be a conventional, tubular-type adenocarcinoma, or in 10% to 15% of cases, it may be a mucinous (colloid) adenocarcinoma (Zen

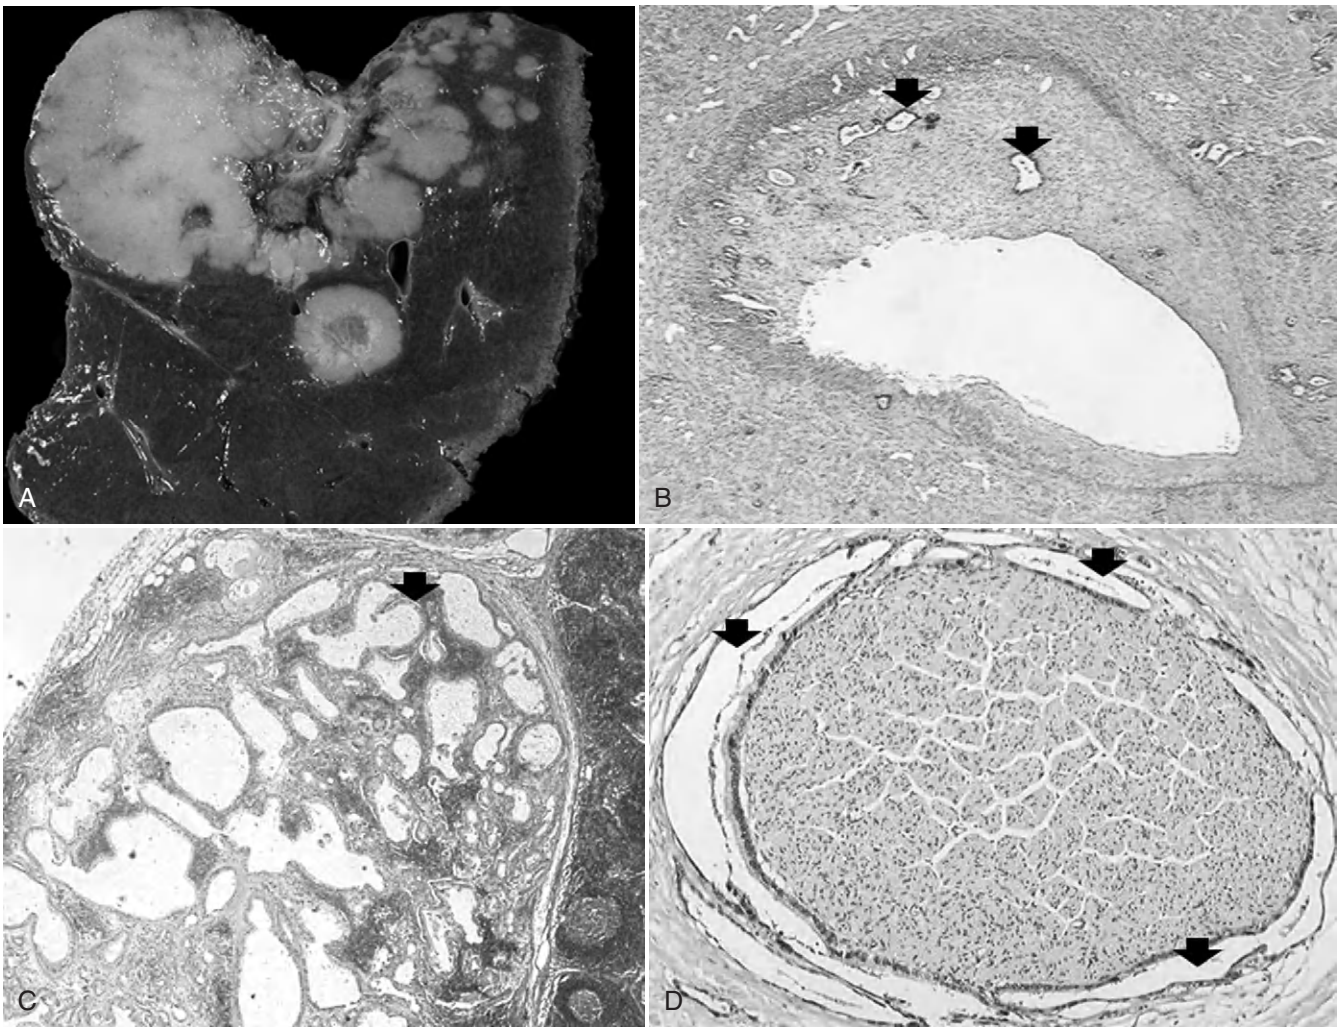

FIGURE 78.35. Histoprognostic factors of cholangiocarcinoma (CC): **A,** Gross macroscopy showing a mass-forming type of CC with satellite nodules. **B,** Lymph node metastasis (*arrows*). **C,** Vascular section invaded by carcinomatous glands (*arrow*). **D,** Perineural invasion with tumoral cells lining the nerve structure (*arrows*).

et al, 2006; Lee et al, 2004). Oncocytic variants of biliary papillomatosis have also been reported that share similar clinical features with their nononcocytic counterparts. The invasive tumors associated with these oncocytic papillary lesions are also oncocytic, as a result of the presence of abundant cytoplasmic mitochondria (Rouzbahman et al, 2007).

A precancerous lesion may also develop on flat bile duct epithelium. This lesion is now termed *biliary intraepithelial neoplasia* (BilIN). BilINs are characterized by abnormal epithelial cells with multilayering of nuclei and micropapillary projections into the duct lumen (Zen et al, 2007). The abnormal cells have an increased nuclear/cytoplasmic ratio, partial loss of nuclear polarity, and nuclear hyperchromasia. They are divided according to degrees of atypia into *low-grade* (BilIN-1), *moderate* (BilIN-2), and *high-grade* dysplastic lesions (BilIN-3) (Fig. 78.37; Zen et al, 2005).

Hepatocholangiocarcinoma

Hepatocholangiocarcinoma—also known as *combined hepatocellular cholangiocarcinoma*, or mixed HCC-CC—is a rare but increasingly recognized neoplasm of the liver, accounting for approximately 5% of primary liver malignancies (Allen & Lisa, 1949; Aoki et al, 1993; Maeda et al, 1995). It shares unequivocal features of both HCC and CC as defined by the WHO classification. Depending on various investigations, patients with combined HCC-CC share similar clinical and pathologic features with patients with HCC (Maeda et al, 1995; Ng et al, 1998) or CC (Tickoo et al, 2002; Jarnagin et al, 2002), or their tumors are clinicopathologically different from those of CC or HCC. Caution must be exercised when interpreting the results of these studies, regarding how combined HCC-CCs were defined in the studies, and there may have been population and etiology differences as well. Taken together, it appears that combined HCC-CCs lack a specific clinical parameter, and this may be explained by various studies across different geographic regions, etiologies, and populations.

Although a unified histopathologic criteria for combined HCC-CC is still not available, it is generally accepted that a firm diagnosis of combined HCC-CC requires evidence of HCC differentiation—a trabecular growth pattern, bile production, or bile canaliculi—and clear evidence of CC, such as true

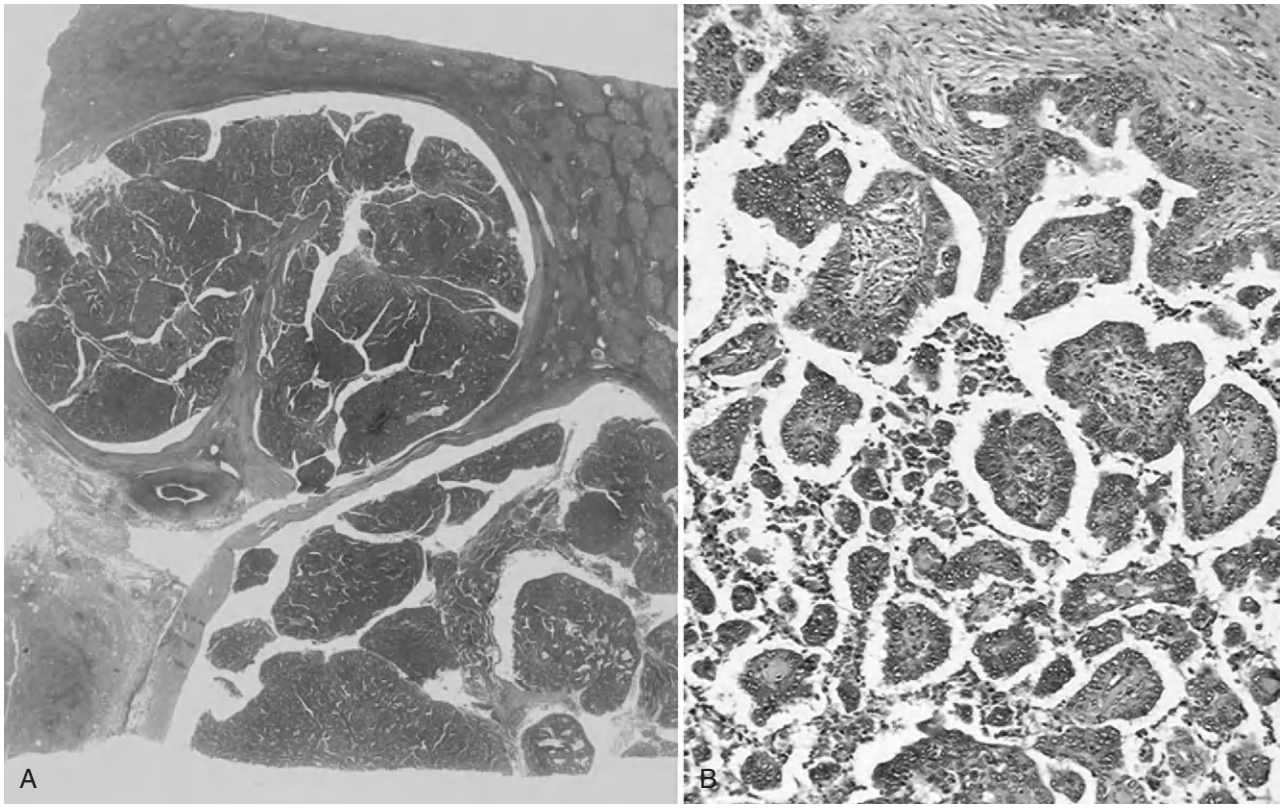

FIGURE 78.36. Biliary papillomatosis. **A,** Low magnification. Bile duct lumen is covered by papillary excrescences. **B,** Tumoral papillae with fibrous stalk covered by proliferation of cuboidal cells.

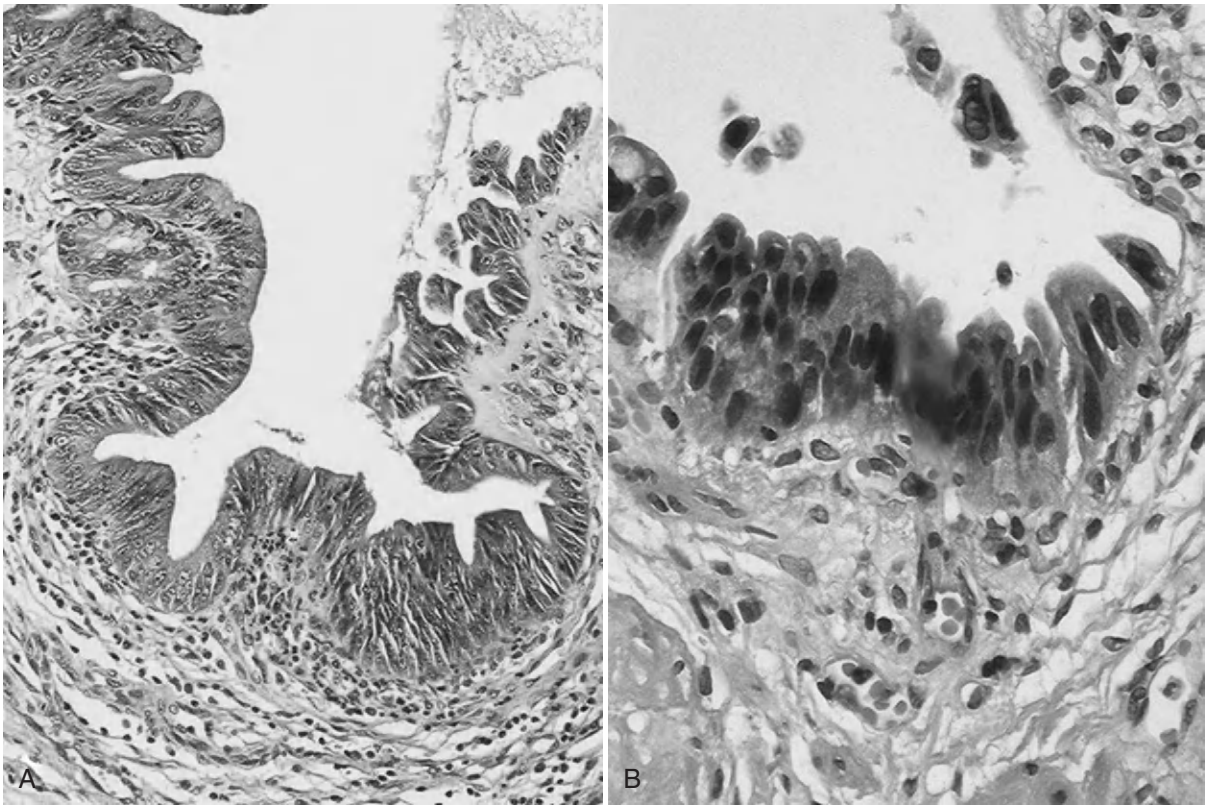

FIGURE 78.37. Biliary intraepithelial neoplasia (BilIN). **A**, BilIN-2 is characterized by micropapillary projections lined by multilayered cells with cell atypias. **B,** BilIN-3 with atypical cells showing increased nuclear/cytoplasmic ratio, loss of nuclear polarity, and nuclear hyperchromasia.

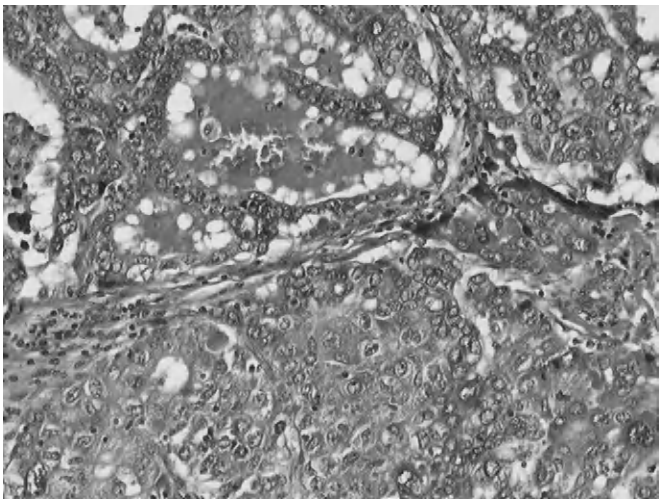

FIGURE 78.38. Hepatocholangiocarcinoma. Association of a hepatocellular differentiation (*top half*) with trabecular and solid growth pattern and cholangiocarcinoma differentiation (*bottom half*) with glandular structures lined by biliary-type epithelium.

glandular structures formed by biliary-type epithelium, mucin production, or prominent desmoplastic stroma (Fig. 78.38; Maeda et al, 1995; Yano et al, 2003; Goodman et al, 1985). Separate HCC and CC coincidentally found in the same liver is generally considered a collision tumor and is excluded by the WHO classification of combined HCC-CC. This has been further supported by the genetic findings that two independent neoplastic clones develop at close proximity, hence no histologic transitions exist (Fujii et al, 2000).

The cell of origin of combined HCC-CC has been a matter of debate. The fact that the HCC and CC elements intermingle with each other in a transitional area strongly supports that both components of the cancer derive from hepatic progenitor cells. Recent molecular investigations support this hypothesis, because single clonal tumors with a homogeneous genetic background in both HCC and CC components of combined HCC-CC have been demonstrated, suggesting that histologic diversity of HCC-CC is a phenotypic expression of the divergent differentiation potential of a single clone (Fujii et al, 2000; Theise, 2002; Cazals-Hatem et al, 2004).

Cholangiolocellular Carcinoma

Cholangiolocellular carcinoma is a very rare neoplasm, accounting for less than 1% of primary liver cancers (Komuta et al, 2008; Steiner & Higginson, 1959). In this tumor, more than 90% of the neoplasm is composed of small, monotonous glands that represent residual ductular proliferation with an antler-like anastomosing pattern (Fig. 78.39). In addition, HCC and CC components may also be present, altogether comprising less than 10% of the neoplasm, although these three histologic components showed transitions among each other (Komuta et al, 2008). The relationship between cholangiocellular carcinoma and combined HCC-CC remains to be clarified, however, they may overlap to some degree and belong to a spectrum of the primary liver neoplasms that arise from the hepatic progenitor cells.

Biliary Cystadenoma and Cystadenocarcinoma (See Chapter 79B)

Biliary Cystadenoma

Biliary cystadenoma is an uncommon cystic neoplasm that accounts for less than 5% of all intrahepatic biliary cysts (Ishak et al, 1977; Van Roekel et al, 1982). The histogenesis of biliary cystadenoma remains uncertain, although an origin from embryonic foregut rests has been advanced (Akwari et al, 1990). Almost all of these tumors occur in middle-aged women, with a peak incidence in the fifth decade (Devaney et al, 1994).

Biliary cystadenomas are characteristically large (2.5 to 28 cm), multiloculated cysts without communication with the intrahepatic biliary system (Fig. 78.40). The tumor is solitary and spherical and contains white to yellow to brown mucinous or gelatinous material. Individual locules vary in size, and the internal surface is typically smooth with occasional

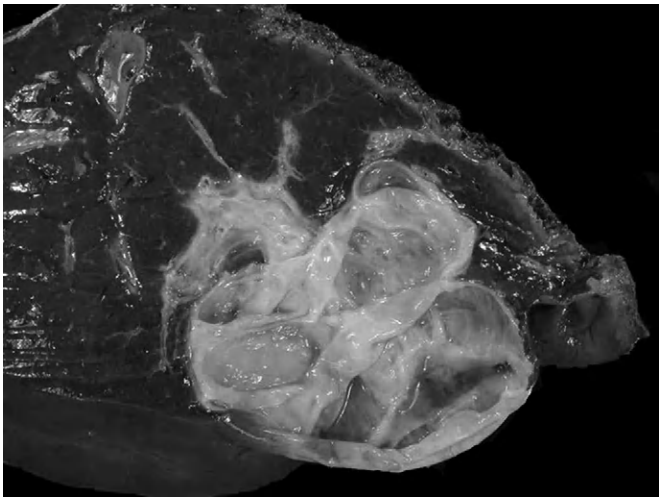

FIGURE 78.40. Cystadenoma. The tumor is cystic, solitary, and spherical with a smooth, white internal surface.

trabeculations or papillations (Ishak et al, 1977). If solid areas are present, concern should be raised for an invasive component (Devaney et al, 1994; Buetow et al, 1995).

Histologically, the cysts are lined by a simple columnar to cuboidal epithelium with mucin-filled cytoplasm. On occasion, the epithelium may be pseudostratified or focally ulcerated, and goblet cells or squamous cells are sometimes seen. Nuclear atypias and mitoses are rare, and their presence should raise the possibility of complicating cystadenocarcinoma. Also recognized is a serous variant of biliary cystadenoma, which is distinguished by a single layer of glycogen-rich cuboidal cells similar to those seen in microcystic adenomas of the pancreas.

Underneath is an ovarian type stroma, which is absent in cases arising in men (Devaney et al, 1994). Typically, this stroma is densely cellular and composed of closely packed spindle cells reminiscent of ovarian stroma. This stroma stains with antibodies to estrogen and progesterone receptor, and growth can occur during hormone replacement therapy and pregnancy (Daniels et al, 2006). As dysplasia may be patchy, and invasive tumors may arise in as many as 25% of cystadenomas (Ishak et al, 1977), the gross specimens of cystic tumors need to be carefully examined for suspicious areas, and extensive sampling of the cyst should be performed.

Biliary Cystadenocarcinoma

This rare malignancy generally develops as a complication of a biliary cystadenoma, which may or may not demonstrate the distinctive mesenchymal stroma (Ishak et al, 1977; Wheeler & Edmondson, 1985b; Woods, 1981). Most patients are between 45 and 70 years of age, and men and women are equally affected. Cysts are generally multilocular and range in size from 5 cm in diameter to more than 20 cm. Although the gross appearance can be difficult to distinguish from a biliary cystadenoma, the suspicion of malignancy should be raised if areas of large, solid, thickening papillary masses are present (Ishak et al, 1977).

Histologically, cystadenocarcinomas are usually well-differentiated adenocarcinomas, often with an intracystic papillary component, and they are composed of malignant epithelial cells with varying degrees of nuclear stratification, pleomorphism, and hyperchromasia; often, the benign epithelium of the preexisting cystadenoma can be identified. Transitions can sometimes be discerned with varying degrees of epithelial dysplasia (Woods, 1981). The tumor infiltrates the underlying cyst wall, and vascular invasion and extension into adjoining hepatic parenchyma or adjacent organs are characteristic of malignancy. These tumors tend to grow slowly, but they eventually invade adjacent structures and metastasize to distant sites. In rare cases the carcinoma demonstrates adenosquamous, oncocytic, or spindle-cell (pseudosarcomatous) differentiation (Moore et al, 1984; Unger et al, 1987; Wolf et al, 1992).

Other Benign Cystic and Bile Duct Lesions: Ciliated Hepatic Foregut Cyst, Biliary Adenoma, and Biliary Hamartoma

Ciliated Hepatic Foregut Cysts

A ciliated hepatic foregut cyst is a rare lesion that is generally solitary and unilocular (Terada et al, 1990). This lesion is smaller than 3 cm and lined by a characteristic ciliated pseudostratified columnar epithelium with mucous cells and an underlying fibrous wall that contains abundant smooth muscle (Fig. 78.41; Vick et al, 1999a). Occasional cases of squamous carcinoma arising in a ciliated hepatic foregut cyst have been reported (Vick et al, 1999b). Because these features are similar to those seen in bronchial and esophageal cysts, an analogous origin from the embryonic foregut is suggested (Wheeler & Edmondson, 1984).

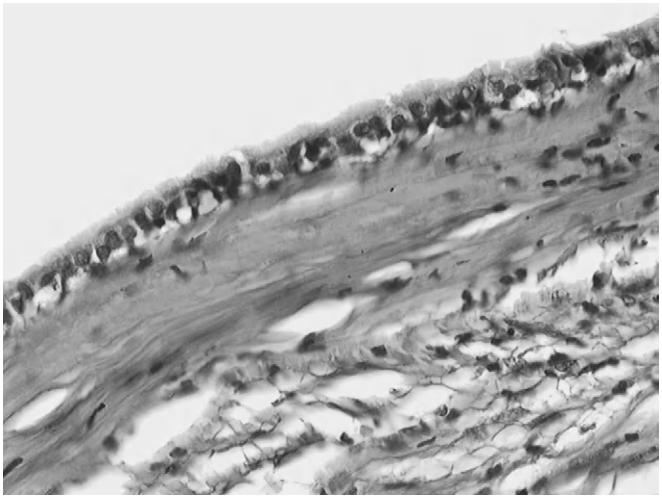

FIGURE 78.41. Ciliated hepatic foregut cyst. The cystic wall is lined by a characteristic ciliated pseudostratified columnar epithelium with an underlying fibrous wall.

Bile Duct Adenoma

Bile duct adenoma is an incidental finding, often discovered at surgery, because most develop superficially under the Glisson capsule (Gold et al, 1978; Allaire et al, 1988). It is an inconsequential lesion that may be mistaken for bile duct hamartoma or metastatic carcinoma (Govindarajan & Peters, 1984). Almost all bile duct adenomas are less than 1 cm in diameter, although cases up to 4 cm have been recorded (Govindarajan & Peters, 1984). The lesion typically appears as a discrete white nodule, usually solitary and subcapsular in location, with a firm consistency and unencapsulated margin. Histologically, bile duct adenoma is made of a compact proliferation of small ductules with small or inapparent lumens lined by cuboidal epithelium with slightly basophilic cytoplasm and bland, regular nuclei (Fig. 78.42). Mitoses, cytologic atypia, and nuclear pleomorphism are absent. Ductular structures are surrounded by a fibrotic, hyalinized stroma that can distort ductal structures, portal tracts are often entrapped within the tumor, and scattered inflammatory cells are sometimes seen. Malignant transformation has not been clearly documented.

Biliary Microhamartoma

Biliary microhamartoma, also known as a *von Meyenburg complex*, is a developmental malformation resulting from the aberrant remodeling of the ductal plate. The lesion is relatively common; it occurs in about 3% of all autopsied patients and is generally found incidentally. Microhamartomas are often multiple, but when numerous, this raises the possibility of early autosomal dominant polycystic disease or congenital hepatic fibrosis (Desmet, 1992). The lesions appear as small, subcapsular white or green nodules that seldom exceed 0.5 cm in diameter, often located within or close to portal tracts. Microscopically, biliary

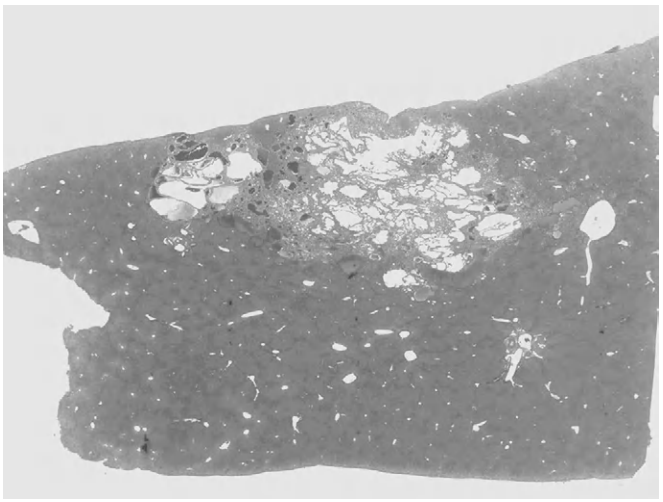

FIGURE 78.44. Hemangioma, low magnification. The lesion is made of vascular cavities, some filled with blood, and is well demarcated from the surrounding liver.

microhamartomas are composed of numerous bile duct–like structures with an angulated or branching configuration with varying degrees of dilation. These structures are lined by a single layer of low columnar or elongated epithelium, and their lumens contain bile plugs or eosinophilic proteinaceous debris; ducts are embedded within a dense, fibrous stroma (Fig. 78.43). In rare cases, microhamartomas have been complicated by the development of cholangiocarcinoma (Burns et al, 1990; Honda et al, 1986).

MESENCHYMAL TUMORS

Benign Mesenchymal Tumors

Hemangioma

Hemangioma is the most common primary tumor of the liver, with a prevalence in autopsy surveys that ranges from 0.4% up to 20% (Karhunen, 1986). This lesion is discovered in all ages and both sexes, although hemangiomas are more frequent in older age groups, and in most series they favor women (Bioulac-Sage et al, 2008).

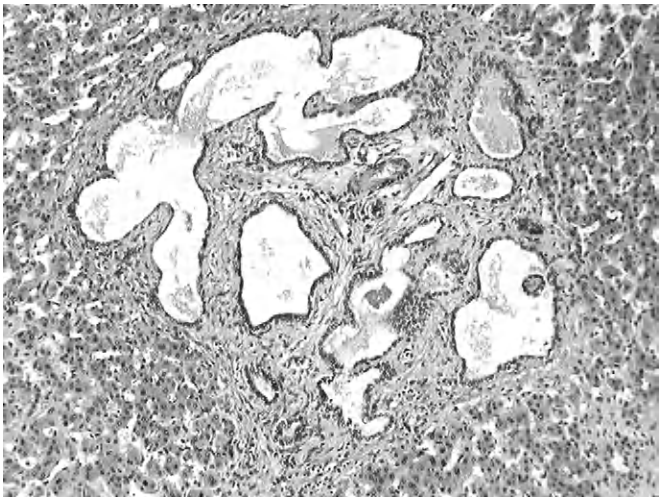

FIGURE 78.43. Biliary microhamartoma. Focal proliferation of bile duct–like structures with an angulated or branching configuration and varying degrees of dilation embedded within a dense, fibrous stroma.

Most hemangiomas are clinically silent and are discovered incidentally during radiologic examination, surgery, or autopsy. However, larger tumors can occasionally become clinically evident with abdominal discomfort, hepatomegaly, or a palpable abdominal mass (Schnelldorfer et al, 2010). Rare reports describe spontaneous rupture with hemoperitoneum or a bleeding diathesis with hypofibrinogenemia or platelet sequestration and consequent thrombocytopenia (Kasabach-Merritt syndrome; Gandolfi et al, 1991). Hemangiomas can be correctly identified in most instances by radiographic imaging (see Chapter 17). Needle biopsy is not necessary and is, in fact, contraindicated because of the risk of severe hemorrhage (Trastek et al, 1983).

Most hemangiomas are solitary lesions less than 4 cm in diameter (Fig. 78.44). Multiple tumors are seen in up to 25% of cases, and hemangiomas up to 30 cm have been recorded. The tumors can occur anywhere in the liver but are frequently located immediately beneath the hepatic capsule. The cut surface demonstrates a soft, dark red, spongy mass with blood-filled cavities and occasional foci of thrombosis, scarring, or calcification. Most are well demarcated from the surrounding liver. Histologically, hemangiomas are composed of dilated vascular spaces lined by flattened endothelial cells and supported by connective tissue septa. The septa consist of poorly cellular fibrous bands with varying degrees of myxoid change and scarring. Thick-walled blood vessels and scattered bile ducts are sometimes found in larger septa, and the vascular spaces are frequently the sites of thrombi in various stages of organization. Hemangiomas may also demonstrate involutional changes with extensive hyalinization, obliteration of the vascular channels, and sometimes calcification.

Infantile Hemangioendothelioma

Infantile hemangioendothelioma is a benign pediatric vascular proliferation of the liver (see Chapter 82). Although uncommon, it is nonetheless the predominant hepatic neoplasm of the first year of life, and only a few cases have been reported in

adults. Most cases manifest clinically with hepatomegaly, diffuse abdominal enlargement, or a palpable abdominal mass. The prognosis is generally good, because the tumors usually undergo spontaneous involution and can completely regress (Dachman et al, 1983); however, a potentially life-threatening feature is not uncommon because of arteriovenous shunting through the tumor that may result in cardiac failure, with a reported mortality rate of about 25% (Vorse et al, 1983).

Infantile hemangioendothelioma typically appears as sharply defined but unencapsulated masses, ranging between 1 and 15 cm in diameter. On cut section, the lesion is well delineated with a gray-tan to pink color and a firm or spongy appearance. Central hemorrhage, necrosis, fibrosis, and calcification may be noted in larger lesions.

Histologically, the tumor is characterized by a proliferation of small, irregular vascular channels lined by a single layer of plump endothelial cells. These channels display small, often compressed lumens and contain varying quantities of red blood cells. The endothelial cells are uniform, with almost no mitoses. The fibrous stroma is composed of scattered fibroblasts and collagen fibers, and small bile ducts are scattered through the mass. The tumor generally grows by expanding into adjacent liver, although hepatic plates can sometimes be entrapped along its advancing edge.

Some hemangioendotheliomas may demonstrate atypical histologic features with atypical crowded and multilayered endothelial cells that show hyperchromatic nuclei and occasional mitoses. This atypical pattern has been referred to as *type 2,* in contrast with the more common *type 1* pattern (Dehner, 1978). Most of the type 2 tumors pursue a benign course, but some exhibit more aggressive behavior with extensive local growth and, in some instances, metastases. Consequently such tumors have been considered by some investigators as a low-grade childhood form of angiosarcoma (Dehner & Ishak, 1971).

Mesenchymal Hamartoma

Mesenchymal hamartoma is a tumor-like lesion arising in young children, usually those younger than 2 years, although sporadic examples are described in adolescents and adults (see Chapter 82; Dehner, 1978; Gramlich et al, 1988). It is thought to represent a developmental anomaly, probably arising from the aberrant formation of primitive portal mesenchyme together with secondary degenerative changes (Siddiqui & McKenna, 2006). Although some cases are discovered incidentally, most are clinically evident because of their large size, causing progressive abdominal distension or a palpable abdominal mass (Srouji et al, 1978).

Mesenchymal hamartoma appears grossly as a solitary mass that ranges from 3 to 30 cm in diameter. Typically, the tumor is well demarcated from the adjacent liver, although an infiltrative border and satellite lesions are not so rare (Stocker & Ishak, 1983). On cut surface, the lesion is composed of multiple small cysts filled with clear or mucoid fluid, lined by a smooth surface, and surrounded by a myxoid tissue with fibrous bands (Dehner et al, 1975).

Histologically, mesenchymal hamartoma is characterized by the association of immature myxoid mesenchymal tissue, bile ducts, blood vessels, and mature hepatocytes. The mesenchymal component consists of elongated bland cells within an edematous myxoid stroma that contains varying amounts of collagen. Focally, this stroma undergoes cystic degeneration, yielding a lymphangiomatous appearance and giving rise to the grossly visible cysts. In addition, numerous thick-walled veins, foci of extramedullary hematopoiesis, and scattered bile ducts can be observed. The ducts often exhibit branching or cystically dilated lumina. Bile duct cells can be atrophic or hyperplastic, and small clusters of unremarkable hepatocytes that lack a lobular arrangement are interspersed within the tumor (Stocker & Ishak, 1983).

Angiomyolipoma

Angiomyolipoma (AML) is a rare tumor that occurs at a median age of about 45 years; it is predominant in women by a ratio of 5:1 (Goodman & Ishak, 1984; see Chapter 79A), and 10% of cases occur in the setting of tuberous sclerosis, usually associated with coexisting renal AML (Petrolla & Xin, 2008). Size ranges widely, from 1 cm in diameter to more than 20 cm. Tumors are usually single, but multiple tumors in the liver and multiorgan involvement have been described (Nonomura et al 1994, 1995). Only one malignant degeneration in a liver AML has been reported in the literature (Dalle et al, 2000).

Most AMLs are well circumscribed but not encapsulated (Fig. 78.45). AMLs have three key components: 1) *tortuous vessels*, 2) *fat*, and 3) *myoid cells.* Liver AMLs demonstrate solid growth with a variable amount of fat and myoid elements. Hematopoietic cells may also be seen in some cases. Myoid cells may be epithelioid or spindled. The fat component is typically mature, but lipoblast-like cells may be found. A hallmark of this lesion is the existence of tortuous, thick-walled vessels that are usually lacking in elastic lamina and are often rimmed by epithelioid myoid cells (Fig. 78.46; Tsui et al, 1999). The diagnosis of AML may be confirmed by immunohistochemistry, because myoid cells are reactive to HMB-45 (Sturtz & Dabbs, 1994).

The histogenesis of AML is unclear, but recent studies suggest AML is a clonal proliferation that favors a neoplastic process (Flemming et al, 2000). Strong arguments suggest that the three cell types are derived from a single precursor cell in the perivascular space, the *perivascular epithelioid cell* (PEC; Tsui et al, 1999; Hornick & Fletcher, 2006). AMLs composed of a large number of epithelioid cells have been termed *PEComas* (perivascular epithelioid cell tumors; Bonetti et al, 1997).

Lipoma

Lipomatous tumors are rarely found in the liver. Most occur in adults as asymptomatic lesions, incidentally detected by

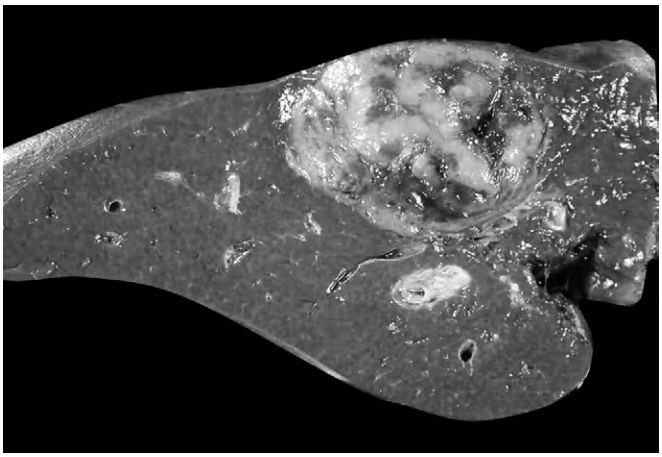

FIGURE 78.45. Angiomyolipoma. A well-circumscribed, soft, white nodular lesion with foci of hemorrhage.

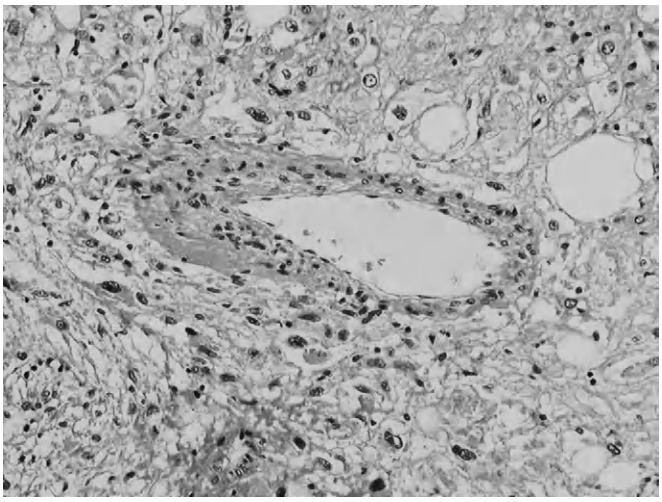

FIGURE 78.46. Angiomyolipoma, light microscopy. The lesion is composed of myoid cells with fat droplets and thick-walled vessels.

radiographic imaging (Roberts et al, 1986). Typically, the tumors are solitary masses ranging from 1 to 20 cm. Microscopically, they are composed of mature adipose tissue, either pure or accompanied by a vascular, hematopoietic, or myeloid component. Depending on the constituents, the tumor is designated a *pure lipoma, angiolipoma,* or *myelolipoma* (Nishizaki et al, 1989; Peters et al 1983).

Coelomic fat ectopia consists of a rounded nodule of fat attached to the hepatic capsule, usually on the anterior diaphragmatic aspect of the right lobe (Komori et al, 2008). The histologic features accordingly entail mature adipose tissue with various degenerative changes, including calcification (Wheeler & Edmonson, 1985b).

Fibrous Tumors

Localized fibrous tumors of the liver have been reported under a variety of names, including *fibroma, solitary fibrous mesothelioma,* and *benign mesothelioma.* Similar to their pleural counterparts, these tumors arise from submesothelial connective tissue and form large masses, from 5 cm in diameter to more than 25 cm, that protrude from the hepatic surface (Komori et al, 2008). The histologic features entail interlacing bundles of bland spindle cells with variable cellularity and intermixed collagen fibers (Kim & Damjanov, 1983; Kottke-Marchant et al, 1989).

Other Benign Mesenchymal Tumors

Sporadic cases of hepatic leiomyoma, lymphangiomatosis, chondroma, hemangioblastoma, and myxoma have been recorded (Rojiani et al, 1991; Van Steenbergen et al, 1985; Fried et al, 1992; Santos et al, 2010).

Malignant Mesenchymal Tumors

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma is a low-grade malignant tumor of endothelial origin that can occur in several sites, including the liver. At diagnosis, most patients are in their fourth or fifth decade of life, and about 60% are women (Ishak et al, 1984). Unlike hepatic angiosarcoma, no strong etiologic associations or predisposing factors have been identified, although a relationship with long-term OC use has been suggested (Dean et al, 1985).

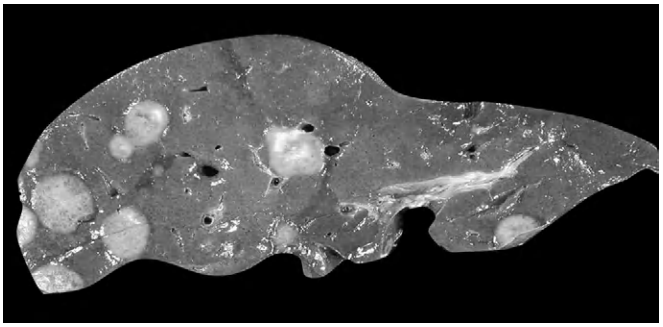

FIGURE 78.47. Epithelioid hemangioendothelioma, characterized by diffuse involvement of both lobes by white to tan tumor nodules of various sizes with a firm consistency.

Epithelioid hemangioendothelioma tends to be an indolent and slowly growing tumor, but the natural history can vary considerably (Woodal et al, 2008). Most patients have a prolonged survival, whereas others suffer rapid deterioration with early death from hepatic failure or extensive tumor spread (Dean et al, 1985; Dietze et al, 1989). Metastases commonly involve the lung, spleen, abdominal lymph nodes, omentum, and peritoneum. Even with metastatic disease, some patients can survive for many years, although the distinction between metastatic spread and multicentric disease is sometimes difficult to make (Mehrabi et al, 2006).

In about 80% of cases, the tumor is multifocal with involvement of both lobes by tumor nodules of various sizes. Nodules are white to tan and have a firm consistency (Fig. 78.47), and the background liver is generally normal (Ishak et al, 1984).

Histologically the tumor comprises small groups of tumor cells surrounded by a distinctive and often abundant stroma of varying myxoid or sclerotic character. The neoplastic cells display abundant eosinophilic cytoplasm and large vesicular and hyperchromatic nuclei with variable nucleoli. These cells reveal their endothelial origin by displaying one or more intracytoplasmic vacuoles that represent intracellular vascular lumina. In addition, they can form small capillary-like lumina, which sometimes contain red blood cells (Makhlouf et al, 1999).

At the actively proliferating margin of the tumor, the neoplastic cells infiltrate the sinusoids, resulting in ductular transformation, atrophy, and eventual obliteration of the adjacent hepatic plates. The underlying lobular architecture is frequently preserved, and remnants of portal tracts can be identified. The tumor also invades the central veins, portal vein branches, and larger blood vessels. This intravascular growth appears as intraluminal papillary clusters or tuftlike projections (Bioulac-Sage et al, 2008). Infiltrating tumor cells are accompanied by a prominent stromal matrix that is initially fibrillar or hyaline, and an attendant mixed inflammatory infiltrate is often also present. Toward its center, the tumor ultimately becomes densely sclerotic, often with focal calcification, and the tumor cells can be difficult to discern (Weiss et al, 1986).

Angiosarcoma

Hepatic angiosarcoma is the most common primary sarcoma of the liver (Brady et al, 1977). Association with exposure to Thorotrast, vinyl chloride monomer, or inorganic arsenic

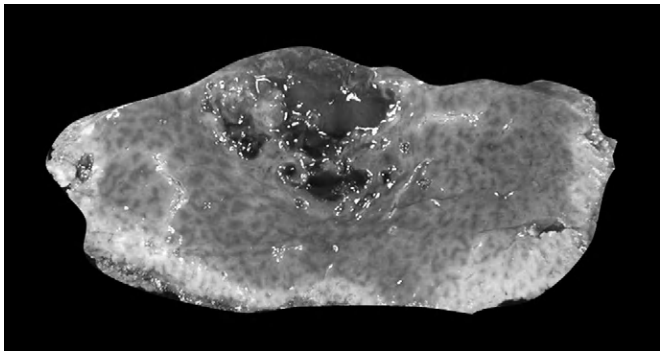

FIGURE 78.48. Angiosarcoma is a hemhorragic mass, ill limited from surrounding liver.

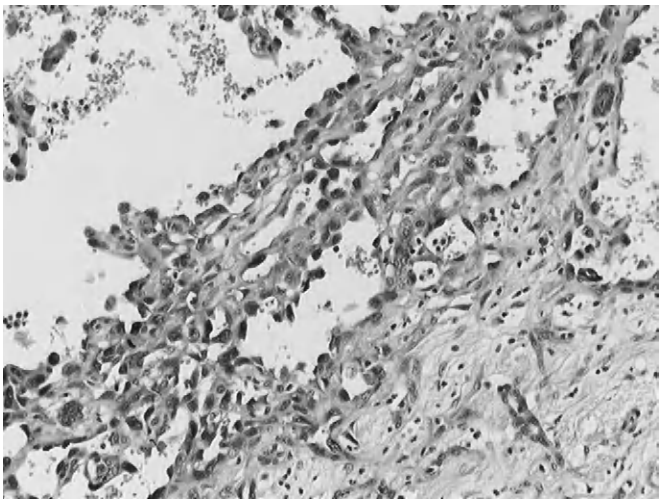

FIGURE 78.49. Angiosarcoma, light microscope. Proliferation of malignant endothelial cells with pale, ill-defined cytoplasm and enlarged, pleomorphic, and hyperchromatic nuclei.

compounds have been identified in 25% to 40% of angiosarcomas (Brady et al, 1977; Falk et al, 1981a; Kojiro et al, 1985; Sherman, 2009). Although these agents either have been discontinued or are under stricter controls, the prolonged latency period suggests that associated angiosarcomas will continue to be encountered for many years (Falk et al, 1981a). The peak incidence is in the sixth and seventh decades of life, and approximately 75% of the patients are men. Rare cases have been reported in children, most in association with infantile hemangioendothelioma (Strate et al, 1984).

The prognosis of patients with hepatic angiosarcoma is very poor. Most patients deteriorate rapidly and die within 6 months of diagnosis, usually from hepatic failure, extensive tumor burden, or tumor rupture. Distant metastases are noted in more than half the patients, most commonly to the lungs, regional lymph nodes, spleen, or bone marrow (Locker et al, 1979).

On gross examination, angiosarcomas typically appear as multiple gray or hemorrhagic masses scattered throughout both liver lobes (Fig. 78.48). The size varies greatly, between 0.1 and 5 cm, and tumors have a spongy consistency with irregular, ill-defined borders. Less often, the tumor is represented by a large solitary mass, typically more than 15 cm in diameter.

The histologic appearance is characterized by a proliferation of malignant endothelial cells with pale, ill-defined cytoplasm and enlarged pleomorphic and hyperchromatic nuclei (Fig. 78.49). The cells usually assume an elongated orientation, but they can also appear rounded or polygonal with conspicuous cytoplasm and prominent nucleoli. Mitoses, although in variable number, are often numerous and bizarre: in some cases the cells show evidence of phagocytic behavior (Bioulac-Sage et al, 2008; Ludwig & Hoffman, 1975).

The tumor infiltrates preexisting vascular structures and eventually destroys the hepatic parenchyma. With early involvement, the malignant cells line the sinusoids and separate the hepatic plates. With progression, the hepatocytes atrophy and are ultimately replaced by fibrosis, and the sinusoids dilate, producing irregular pelioid-like vascular spaces of varying size. These spaces are lined by multilayered tumor cells, sometimes in a papillary arrangement, and contain blood and necrotic debris. Extramedullary hematopoiesis is often present (Kojiro et al, 1985). The tumor also invades central veins or portal vein branches, which can lead to luminal occlusion with subsequent hemorrhage, necrosis, and infarction.

In angiosarcomas associated with Thorotrast, vinyl chloride, and arsenic exposure, an initial precursor stage that precedes the development of overt tumor has been recognized, with hypertrophy and hyperplasia of endothelial cells together with reactive hepatocyte alterations (Tamburro et al 1984).

Undifferentiated (Embryonal) Sarcoma

Embryonal sarcoma of the liver is a highly malignant childhood neoplasm (Stocker & Ishak, 1978; see Chapter 82). It is the third most common hepatic malignancy in the pediatric population after hepatoblastoma and hepatocellular carcinoma. The peak incidence is between 6 and 10 years with an age range that extends from newborn infants to almost 30 years of age (Stocker & Ishak, 1983, 1978; Pachera et al, 2008). The prognosis of undifferentiated sarcoma is very poor. Death often occurs because of massive local tumor growth with direct extension into contiguous structures and even through the diaphragm.

On gross examination, the tumors are large, well-demarcated masses, usually 10 to 30 cm in diameter with a soft gelatinous consistency. Most of the tumors occupy the right lobe of the liver. The cut surface is variegated with areas of solid gray-white tumor interrupted by foci of cystic degeneration, hemorrhage, and necrosis (Stocker & Ishak, 1978).

Histologically, the tumors are composed of malignant spindle-shaped cells separated by myxoid stroma. The neoplastic cells are grouped into closely packed sheets or fascicles or scattered loosely in the stroma. They vary greatly in size and have pleomorphic, hyperchromatic nuclei; inconspicuous nucleoli; and poorly defined borders. Mitoses are often numerous and bizarre, and multinucleated tumor giant cells can be seen. A characteristic finding is the presence of periodic acid-Schiff–positive, diastase-resistant eosinophilic globules within tumor cells and in the extracellular stroma (Ma et al, 2008). The myxoid stroma dominates the less cellular portions of the tumor and harbors numerous thin-walled veins and often contains foci of extramedullary hematopoiesis. Areas of hemorrhage and necrosis are abundant, and bands of dense, hyalinized collagen are occasionally noted. The periphery of the tumor typically entraps bile ducts that are cystically dilated and lined by a cuboidal epithelium that often displays hyperplastic or atypical features. The tumor lacks histologic evidence of cellular differentiation, and its histogenesis remains uncertain

(Lack et al, 1991). Embryonal sarcoma represents a primitive mesenchymal neoplasm capable of divergent differentiation (Choi et al, 2010).

Other Sarcomas

Most primary hepatic sarcomas occur in adults between 40 and 60 years of age who are seen with signs and symptoms indicative of a hepatic mass. These primary hepatic sarcomas should be distinguished from metastatic involvement by sarcomas of other organs and from sarcomatoid hepatocellular carcinoma (Kakizoe et al, 1987). The overall prognosis is poor, and most patients die within a year of diagnosis.

Hepatic sarcomas histologically resemble their soft-tissue counterparts. Among the types reported are fibrosarcoma, follicular dendritic cell sarcoma, desmoplastic nested single-cell tumor, malignant fibrous histiocytoma, hemangiopericytoma, osteosarcoma, malignant schwannoma, and dedifferentiated liposarcoma (Choi et al, 2010; Hill et al, 2005; Li et al, 2008; Kim et al, 1987; Lederman et al, 1987). Leiomyosarcomas are described arising within the hepatic parenchyma, from the ligamentum teres, and from the hepatic vein, where they have been associated with Budd-Chiari syndrome (Shamseddine et al, 2010; Kuma et al, 2008; Fong & Ruebner, 1974; Hilliard et al, 2005).

Kaposi sarcoma is seen primarily in the setting of the acquired immunodeficiency syndrome (AIDS). Histologically, the tumor is characterized by multifocal nodules composed of proliferated spindle cells with slit-like spaces that contain extravasated erythrocytes. These lesions are predominantly centered on portal tracts, but they also spread into and destroy the parenchyma (Bioulac-Sage et al, 2008; Friedman, 1988).

Hepatobiliary rhabdomyosarcoma is a rare neoplasm that usually arises from the common bile duct (Ali et al, 2009). Most patients are young children, with exceptional cases reported in adults (Stocker, 2001; Lack et al, 1981). Histologically the tumor resembles botryoid-type embryonal rhabdomyosarcomas that occur elsewhere in the body. Soft polypoid masses protrude into the ductal lumen and are covered by intact, ulcerated, or inflamed biliary epithelium. The tumor is composed of small hyperchromatic cells with variable eosinophilic cytoplasm and rare cross-striations. Beneath the biliary epithelium, the cells are densely packed and form a so-called cambium layer, whereas deeper in the tumor, they are separated by a loose myxoid stroma. The diagnosis is secured by immunohistochemical demonstration of desmin, muscle-specific actin, or myoglobin expression or with the ultrastructural finding of the characteristic myofilaments.

MISCELLANEOUS TUMORS

Inflammatory pseudotumors of the liver are nonneoplastic masses of unknown etiology (see Chapter 48). They occur at any age and clinically manifest with abdominal pain together with various systemic manifestations that include low-grade fever, weight loss, leukocytosis, anemia, and inflammatory syndrome (Tang et al, 2010). Although the cause is unknown, an as yet unidentified infectious or immunoglobulin G4 autoimmune-related process have been suggested (Horiuchi et al, 1990; Yamamoto et al, 2009).

The masses are often solitary and range between 2 and 25 cm in diameter. They have a variable histologic appearance and consist of proliferated fibroblasts and myofibroblasts, lymphocytes (sometimes with lymphoid follicles), plasma cells, eosinophils, and neutrophils. Fibrosis or granulation tissuelike zones can be conspicuous, particularly in the central portions of the mass. Multinucleated or foamy macrophages, phlebitis, and granulomas are sometimes noted. Inflammatory pseudotumors may regress spontaneously.

Neuroendocrine Tumor

Neuroendocrine tumors in the liver are almost always metastatic, and a primary lesion in the gastrointestinal tract or pancreas is usually identified (see Chapter 81B). In rare cases, however, primary hepatic endocrine tumors have been described in which no extrahepatic site of involvement can be identified (Sioutos et al, 1991; Miura & Shirasawa, 1988). Because of the normal presence of endocrine cells in biliary epithelium, an origin from intrahepatic bile ducts has often been suggested. Histologically, the tumor is composed of small, uniform tumor cells with regular round nuclei and moderate granular cytoplasm arranged in nests, cords, and pseudoglandular patterns. Dense core neurosecretory granules are found on immunostaining.

Other Tumors

Several examples of malignant rhabdoid tumors of the liver have been recognized. These tumors are highly aggressive neoplasms with a distinctive histologic appearance (Hunt & Anderson, 1990). Rare cases of primary hepatic germ-cell tumors of several types—including teratomas, yolk sac tumors, and choriocarcinoma—have been described. The combination of yolk sac tumor and hepatoblastoma has also been described (Cross & Variend, 1992); these tumors exhibit malignant behavior, although occasional long-term survival has been obtained with cancer chemotherapy.

Squamous carcinoma of the liver is uncommon, with most cases developing within simple hepatic cysts, in various forms of fibropolycystic liver disease, or in teratomas (Gresham & Rue, 1985). Adrenal rest tumor and pancreatic heterotopia have also been described and might be misleading (Wolf et al, 1990; Contreras et al, 1985).

HEMATOPOIETIC NEOPLASMS

Primary Hepatic Lymphoma

The liver may represent the sole site of involvement by malignant lymphoma, but these primary hepatic lymphomas are uncommon, although hepatitis C infection may be a risk factor (Santos et al, 2003).

On gross examination, most cases are characterized by a single large mass or, less often, by multiple discrete nodules (Anthony et al, 1990). Rarely, the liver is diffusely infiltrated without a well-defined mass lesion. The tumors are predominantly classified as non-Hodgkin lymphomas of diffuse large cell type, with occasional examples of small cleaved or uncleaved varieties such as mucosa-associated lymphoid tissue (MALT) tumors (Deshald et al, 2010; Doi et al, 2008). Most of the tumors are phenotypically of B-cell lineage, although occasional T-cell lymphomas have also been described (Noronha et al, 2005; Andreola et al, 1988). The neoplastic lymphocytes expand the portal tracts and invade into adjacent parenchyma from large infiltrative nodules. The lobules are otherwise little affected, although occasional cases, particularly with T-cell

lymphomas, demonstrate sinusoidal infiltration (Farcet et al, 1990).

Secondary Involvement

All varieties of lymphomas, leukemias, and hematopoietic proliferations can secondarily affect the liver, usually as a manifestation of disseminated disease and often in conjunction with splenic involvement. As a general rule, the low-grade non-Hodgkin lymphomas tend to produce multiple portal-based infiltrates, whereas the intermediate- and high-grade types give rise to large, irregular tumor masses. Sinusoidal involvement is uncommon except with peripheral T-cell lymphomas (Farcet et al, 1990; Gaulard et al, 1986).

Hepatic involvement in Hodgkin disease can manifest as large, irregular masses or as small, diffusely distributed nodules. The characteristic infiltrate, which predominantly affects portal tracts, consists of a polymorphous collection of Reed-Sternberg cells or variants together with small lymphocytes, large mononuclear cells, plasma cells, eosinophils, and neutrophils in varying numbers (Dich et al, 1989).

Leukemias of both acute and chronic types tend to permeate the sinusoids with malignant cells, with involvement of the portal tracts additionally noted with the lymphoid varieties. Hepatic involvement is especially common and conspicuous in hairy cell leukemia (Zafrani et al, 1987).

Langerhans cell histiocytosis involves the liver in about 40% of cases (Iwai et al, 1988). The most important clinical manifestations include jaundice and portal hypertension, resulting in part from infiltration of large bile ducts to produce a sclerosing cholangitis-like picture.

The liver is commonly involved in generalized mastocytosis. Mast cells accumulate principally in the portal tracts and are accompanied by varying degrees of periportal fibrosis and, on occasion, cirrhosis.

METASTASIS

Metastatic cancers are by far the most common form of hepatic malignancy, accounting for more than 95% of the total (see Chapter 81). In autopsy series, liver metastases are noted in about 40% of patients with malignant tumors, and the sites of origin include virtually every organ in the body (Schulz & Hort, 1981). The more frequent primary sites include carcinomas of the colon, pancreas, lung, and breast in adults and neuroblastoma, Wilms tumor, and rhabdomyosarcoma in pediatric patients (Strohmeyer & Schultz, 1986). Although the origin of the tumor is often known when metastases are biopsied, carcinomas of the pancreas, stomach, and lung are particularly notorious for being occult primary neoplasms.

FIGURE 78.50. Liver metastasis. Confluent and infiltrative masses of varying size made of pale nodules with central necrosis.

Grossly, metastatic tumors in the liver are almost always multiple, but they may appear as solitary nodules, confluent masses, or as small, diffusely infiltrative lesions that can mimic cirrhosis (Fig. 78.50; Borja et al, 1975). The size range varies considerably. Typically these tumors are gray to yellow nodules, sometimes complicated by central necrosis, umbilication, or cystic change, and they can occur anywhere within the parenchymal mass (Strohmeyer & Schultz, 1986). Some metastases may display prominent fibrous changes.

In general, metastatic tumors maintain the histologic features seen in their primary location. A desmoplastic stroma is common with metastatic adenocarcinomas, especially those from the pancreas or breast, and the overall picture cannot be distinguished from cholangiocarcinoma. Some metastatic tumors tend to infiltrate the sinusoids, and tumors such as small-cell carcinoma and melanoma can grow within the hepatic plates and replace the liver cells.

CHAPTER 79A

Benign liver lesions

Jacques Belghiti, Safi Dokmak, Valerie Vilgrain, and Valérie Paradis

OVERVIEW

One of the consequences of extensive use of imaging for an ever-increasing number of indications is the detection of asymptomatic tumors. In the absence of underlying chronic liver disease or a history of cancer, the vast majority of these lesions correspond to benign liver tumors, including cystic and solid lesions. Cystic tumors will be covered in Chapter 69A and 69B. Solid benign lesions include a broad spectrum of regenerative and true neoplastic processes (Table 79A.1). Based on the cell of origin, most solid, benign tumors can be classified into two groups: *epithelial lesions* include hepatocellular (focal nodular hyperplasia [FNH] and adenoma) and cholangiocellular tumors (bile duct adenoma); *mesenchymal tumors* include those lesions that originate from blood vessels (hemangioma), adipose tissue (angiolipoma), and muscle (leiomyoma). Except hepatocellular adenoma (HA), which may be associated with serious complications that may require surgery, the vast majority of solid, benign liver lesions remain asymptomatic and do not increase in volume; therefore they do not require any treatment or follow-up.

The understanding of clinical, biologic, radiologic, and pathologic characteristics of each tumor is important for accurate diagnosis and appropriate management. Advances in imaging studies allow an accurate diagnosis in the majority of cases, reducing the use of percutaneous biopsy to only a few patients and limiting the number of resections for final diagnosis to exceptional cases. The most frequent benign liver cell lesions include hemangioma, FNH, and HA. Because radiologic imaging is of critical importance in diagnosis and management, there is considerable emphasis on the role of radiologic study, and this section should be read in conjunction with Chapters 13, 16, and 17.

CAVERNOUS HEMANGIOMA

Hepatic hemangiomas are probably the most common of all liver tumors. These tumors occur at all ages, however, because of the difference of histologic structure between the adult and the infantile forms (see Chapter 82) and the different clinical presentation, they must be regarded as separate entities (Hobbs, 1990). Only hemangioma of the liver in adults will be considered in this chapter.

Pathogenesis and Pathology

The prevalence of hemangioma in the general population ranges from 1% to 20% (Semelka & Sofka, 1997), but it is predominant in women by a 5:1 ratio (Mergo & Ros, 1998; Trotter & Everson 2001; Biecker et al, 2003). In adults, hemangiomas are usually found in patients at a mean age of 50 years and equally in the left and right lobes of the liver; the majority are less than 5 cm in diameter and are rarely pediculated, but hemangiomas measuring 10 cm or more are referred to as *giant hemangiomas* and can present with fibrosis, thrombosis, and calcifications (Fig. 79A.1).

The pathogenesis of hemangioma is not well understood. Some of these tumors have estrogen receptors, and accelerated growth has been observed with high-estrogen states, such as those associated with puberty, pregnancy, oral contraceptive use, and with androgen treatment. These findings suggest that hormonal effect may be one of the pathogenic mechanisms (Trotter & Everson, 2001; Cobey & Salem, 2004). Macroscopic examination demonstrates well-delineated, flat lesions of red-blue color that may partially collapse on sectioning. Some degree of fibrosis, calcification, and thrombosis may be observed, most commonly in the largest lesions (Fig. 79A.2). Microscopically, hemangiomas are made of cavernous vascular spaces lined by flattened endothelium underlying fibrous septa of various widths (Fig. 79A.3). Small hemangiomas may become entirely fibrous, appearing as a solitary fibrous nodule.

Clinical and Biologic Data

The vast majority of hemangiomas are less than 5 cm and are found incidentally during ultrasound (US) or computed tomography (CT) examination of the abdomen for unrelated reasons (Trotter & Everson, 2001). Hemangiomas remain stable in size

Table 79A.1

Histologic Classification of Benign Liver Lesions and Main Clinical Data

Lesion	Type	Comments
Epithelial Lesions		
Hepatocytes	Hepatocellular adenoma	Very rare Associated with oral contraceptives High rate of complications (bleeding, malignant transformation)
	Focal nodular hyperplasia	Rare Female predominance No risk of complication
	Nodular regenerative hyperplasia	Very rare Associated with systemic diseases and drugs Portal hypertension
	Focal fatty change	Common Associated with diabetes, obesity, hepatitis C virus, and malnutrition No risk of complication
Biliary cells	Bile duct adenoma	Rare No risk of complication
	Biliary hamartoma (Von Meyenburg complex)	Very rare Development anomaly No risk of complication
Nonepithelial Lesions		
Mesenchymal	Hemangioma	Common Female predominance Very low risk of complication
	Angiomyolipoma	Rare Associated with tuberous sclerosis No risk of complication
	Lipoma, myelolipoma	Exceptional No risk of complication
Heterotopia	Adrenal, pancreatic, or spleen tissues	Exceptional Very low risk of complication
Others	Peliosis hepatis	Exceptional Associated with androgens, oral contraceptives, drugs, malignancies, and tuberculosis No risk of complication
	Inflammatory pseudotumor	Very rare Associated with general syndromes No risk of complication

(Takayasu et al, 1990) or demonstrate minimal increase in diameter over time (Nghiem et al, 1997). Pain related to an uncomplicated hemangioma is most probably due to associated disorders, such as gallbladder disease, liver cysts, gastroduodenal ulcers, or a hiatal hernia (Farges et al, 1995). Large hemangiomas may be asymptomatic or may manifest with an abdominal mass or pain (Erdogan et al, 2007). Large lesions located in the left lobe of the liver may cause pressure effects on adjacent structures with resulting symptoms. Jaundice as a

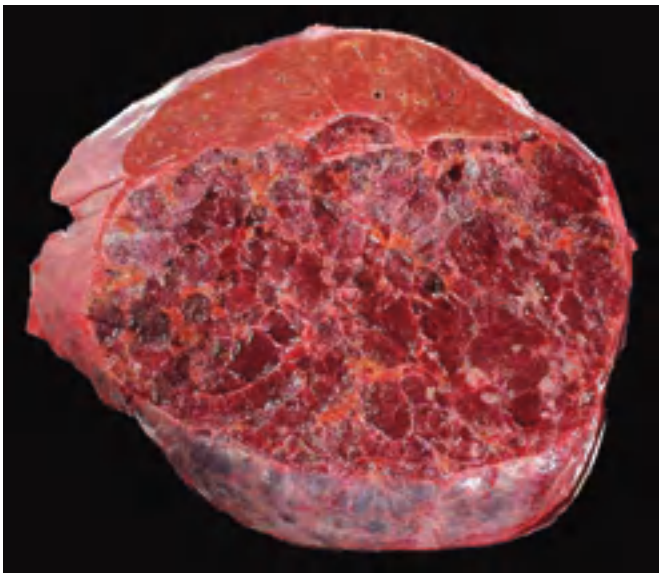

FIGURE 79A.2. Macroscopic view of hemangioma.

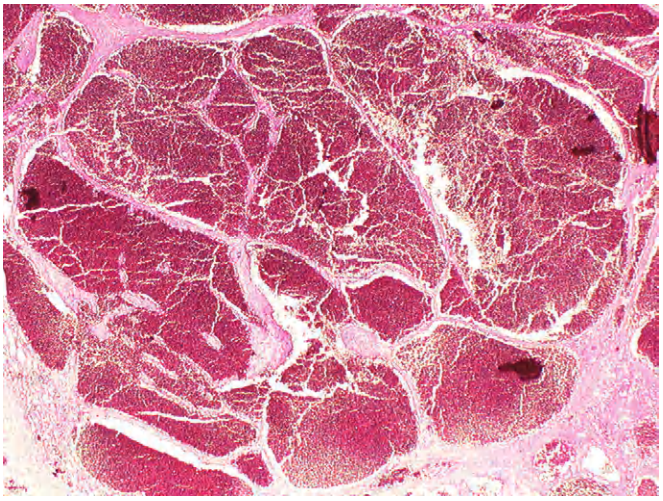

FIGURE 79A.3. Microscopic view of hemangioma showing cavernous vascular spaces lined by flattened endothelium underlying fibrous septa of various widths. The vascular spaces are filled with red blood cells.

result of compression of bile ducts by hemangioma has also been observed, but this is rare (Losanoff & Millis, 2008).

Liver biologic tests, including alkaline phosphatase and γ-glutamyltransferase (GGT), are normal. Normal laboratory tests associated with a large hepatic tumor with mild symptoms could be of help in the diagnosis of hemangioma.

Complications are mostly observed in large hemangiomas and can be divided into 1) alterations of internal architecture, such as with inflammation; 2) coagulation abnormalities, which could lead to systemic disorders such as hemorrhage and subsequent hemoperitoneum; and 3) compression of adjacent structures.

Some cases of inflammatory processes complicating giant hemangioma have been reported (Bornman et al, 1987; Takayasu et al, 1990), and the prevalence is probably underestimated. Signs and symptoms of an inflammatory process include low-grade fever, weight loss, abdominal pain, accelerated erythrocyte sedimentation rate, normal white blood cell count, anemia, thrombocytosis, and increased fibrinogen level. The imaging features are those of giant hemangioma. Clinical and laboratory abnormalities disappear after surgical excision of the mass (Bornman et al, 1987; Pateron et al, 1991; Pol et al, 1998).

Kasabach-Merritt syndrome is an exceptional complication of hepatic hemangioma in adults (Hall, 2001; see Chapter 82). This coagulopathy consists of intravascular coagulation, clotting, and fibrinolysis within the hemangioma, and it may progress to secondary increased systemic fibrinolysis and thrombocytopenia (Concejero et al, 2009); the syndrome is reversible after removal of the hemangioma. Although rarely encountered in hepatic hemangioma, intratumoral hemorrhage can occur spontaneously or after anticoagulation therapy. Spontaneous rupture of a hemangioma is exceptional, and very few indisputable cases have been reported (Corigliano et al, 2003); taking into account the high prevalence of these tumors, the extremely low incidence of this complication should not interfere with the therapeutic management, nor should it influence the specific advice to patients, who are often worried by the presence of a vascular liver tumor (Plackett & Lin-Hurtubise, 2008).

Imaging

The vast majority of hemangiomas are diagnosed accurately by imaging studies alone because of characteristic imaging features. On US the classic appearance of hemangioma is that of a homogeneous hyperechoic mass less than 3 cm in diameter with acoustic enhancement and sharp margins (Fig. 79A.4; see Chapter 13). No vascular pattern is usually identified on color Doppler. Other investigations are required when US does not show typical patterns. Contrast-enhanced US reveals peripheral

FIGURE 79A.4. Hemangioma. **A,** Ultrasound shows a hypoechoic liver lesion with posterior acoustic enhancement. **B** and **C,** Contrast-enhanced ultrasound demonstrates peripheral puddling followed by complete and delayed enhancement.

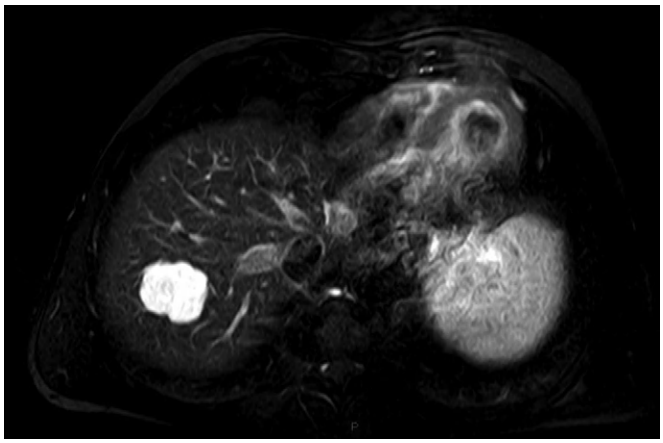

FIGURE 79A.5. Hemangioma. T2-weighted magnetic resonance imaging shows typical bright signal.

globular enhancement in the portal phase and isoechoic pattern on the late phase in most atypical hemangiomas (Quaia et al, 2002).

On CT, the criteria for the diagnosis of hemangioma are the following: 1) low attenuation on noncontrast CT, 2) peripheral and globular enhancement of the lesion followed by a central enhancement on contrast CT, and 3) contrast enhancement of the lesion on delayed scans (Freeny & Marks, 1986; see Chapter 16). Among these criteria, the presence of peripheral puddles on the arterial phase has a sensitivity of 67%, a specificity of 99%, and a positive predictive value of 86% for hemangioma (Nino-Murcia et al, 2000). Magnetic resonance (MR) imaging is the key imaging modality in the characterization of liver hemangiomas (Itai et al, 1985; Starck et al, 1985; see Chapter 17). The classic appearance of a liver hemangioma is that of a hypointense lesion on T1-weighted sequences, a strongly hyperintense lesion on heavily T2-weighted sequences, with a "light-bulb" pattern (Fig. 79A.5). Dynamic multiphasic T1-weighted sequences after gadolinium chelate administration show findings similar to that of contrast-enhanced CT phases (Fig. 79A.6; Semelka et al, 1994). Hemangiomas can be multiple in 10% of cases, and in exceptional cases, the presence of innumerable hemangiomas are called *hemangiomatosis* (Ishak & Rabin, 1975; Keegan et al, 2001).

The two most common imaging atypias are found in giant hemangiomas and in rapidly filling hemangiomas. Giant hemangiomas, which are defined when they exceed 6 or 12 cm in diameter, are often heterogeneous with marked central areas that correspond to thrombosis, extensive hyalinization, and fibrosis (Danet et al 2003; Coumbaras et al, 2002). However, usually the typical early, peripheral, nodular enhancement is observed along with strong hyperintensity on T2-weighted MR images at the periphery. Although present, the progressive centripetal enhancement of the lesion does not lead to complete filling. Rapidly filling hemangiomas are not uncommon and occur significantly more often in small lesions (42% of hemangiomas are <2 cm in diameter) (Hanafusa et al, 1995). CT and MR imaging show an immediate homogeneous enhancement in the arterial phase, which makes differentiation from other hypervascular tumors difficult. Their diagnosis is based on strong hyperintensity on T2-weighted images, the parallel enhancement with arterial structures, and the persistent enhancement on delayed-phase imaging; it is important to note that these rapidly filling hemangiomas may induce arterial–portal venous shunts (Kim et al, 2001). The other atypical hemangiomas are very uncommon and include very slow filling, calcified, hyalinized cystic and pedunculated hemangiomas, those with fluid-fluid levels, and hemangiomas with capsular retraction.

Hemangiomas associated with inflammatory response syndrome are usually due to acute thrombosis of a part or all the hemangioma. These can be diagnosed by showing spontaneous hyperattenuation on unenhanced CT scans. Hemangiomas developing in abnormal liver are difficult to diagnose, and those in fatty liver usually appear isoechoic or hypoechoic at US and hyperattenuating at unenhanced CT (Marsh et al, 1989). MR imaging with fat-suppressed, in-phase and opposed-phase T1-weighted sequences is the key to the diagnosis and is more helpful than CT; strong hyperintensity on T2-weighted images is also a reliable finding.

With progressive cirrhosis, hemangiomas are likely to decrease in size and become more fibrotic and difficult to diagnose radiologically (Brancatelli et al, 2001). In this clinical setting, US cannot be used to confidently make the diagnosis of hemangioma, as half of the hyperechoic lesions are hepatocellular carcinomas (HCCs) (Caturelli et al, 2001). The association of hepatic hemangioma and FNH can be observed in about 25% of cases and is not fortuitous (Mathieu et al, 1989; Vilgrain et al, 2003). FNH is considered to be a hyperplastic response as a result of focal increased arterial flow in the hepatic parenchyma and, like hemangioma, it is thought to have a vascular origin.

Imaging, and especially MR imaging, is therefore able to diagnose liver hemangiomas in nearly all cases, and liver biopsy should be restricted to exceptional cases. Liver hemangioma, which has been considered a contraindication to needle biopsy for many years, is possible without significant risk of hemorrhage (Heilo & Stenwig, 1997; Caldironi et al, 1998). However, as in other tumors, a cuff of normal hepatic parenchyma should be interposed between the capsule and the margin of the hemangioma.

Management

Whatever the size, there is no treatment for *asymptomatic hemangioma*. When the diagnosis is established, it is not necessary to adopt therapeutic or specific measures. The patient should be reassured about the rare occurrence of growth and the extremely low risk of complication; therefore oral contraceptives need not be interrupted, nor should the patient be counseled to avoid pregnancy or discontinue any sporting activity, and follow-up is not justified. Although in specialized centers, liver resection mortality for benign lesions is essentially nil, there is a risk of intraoperative bleeding and postoperative biliary fistula, which should be considered unacceptable given the benign nature of these lesions; indeed, it could be stated that the main complication of hemangioma is surgical operation.

Indications for treatment include severe symptoms, complications, and inability to exclude malignancy (Yoon et al, 2003; Duxbury & Garden, 2010). Symptoms are more frequently encountered with huge hemangioma (Erdogan et al, 2007). Surgical resection remains the definitive treatment, but other less effective options include hepatic artery ligation and radiation therapy; radiation therapy can reduce the size of the lesion (Gaspar et al, 1993), but long-term effects of radiation therapy

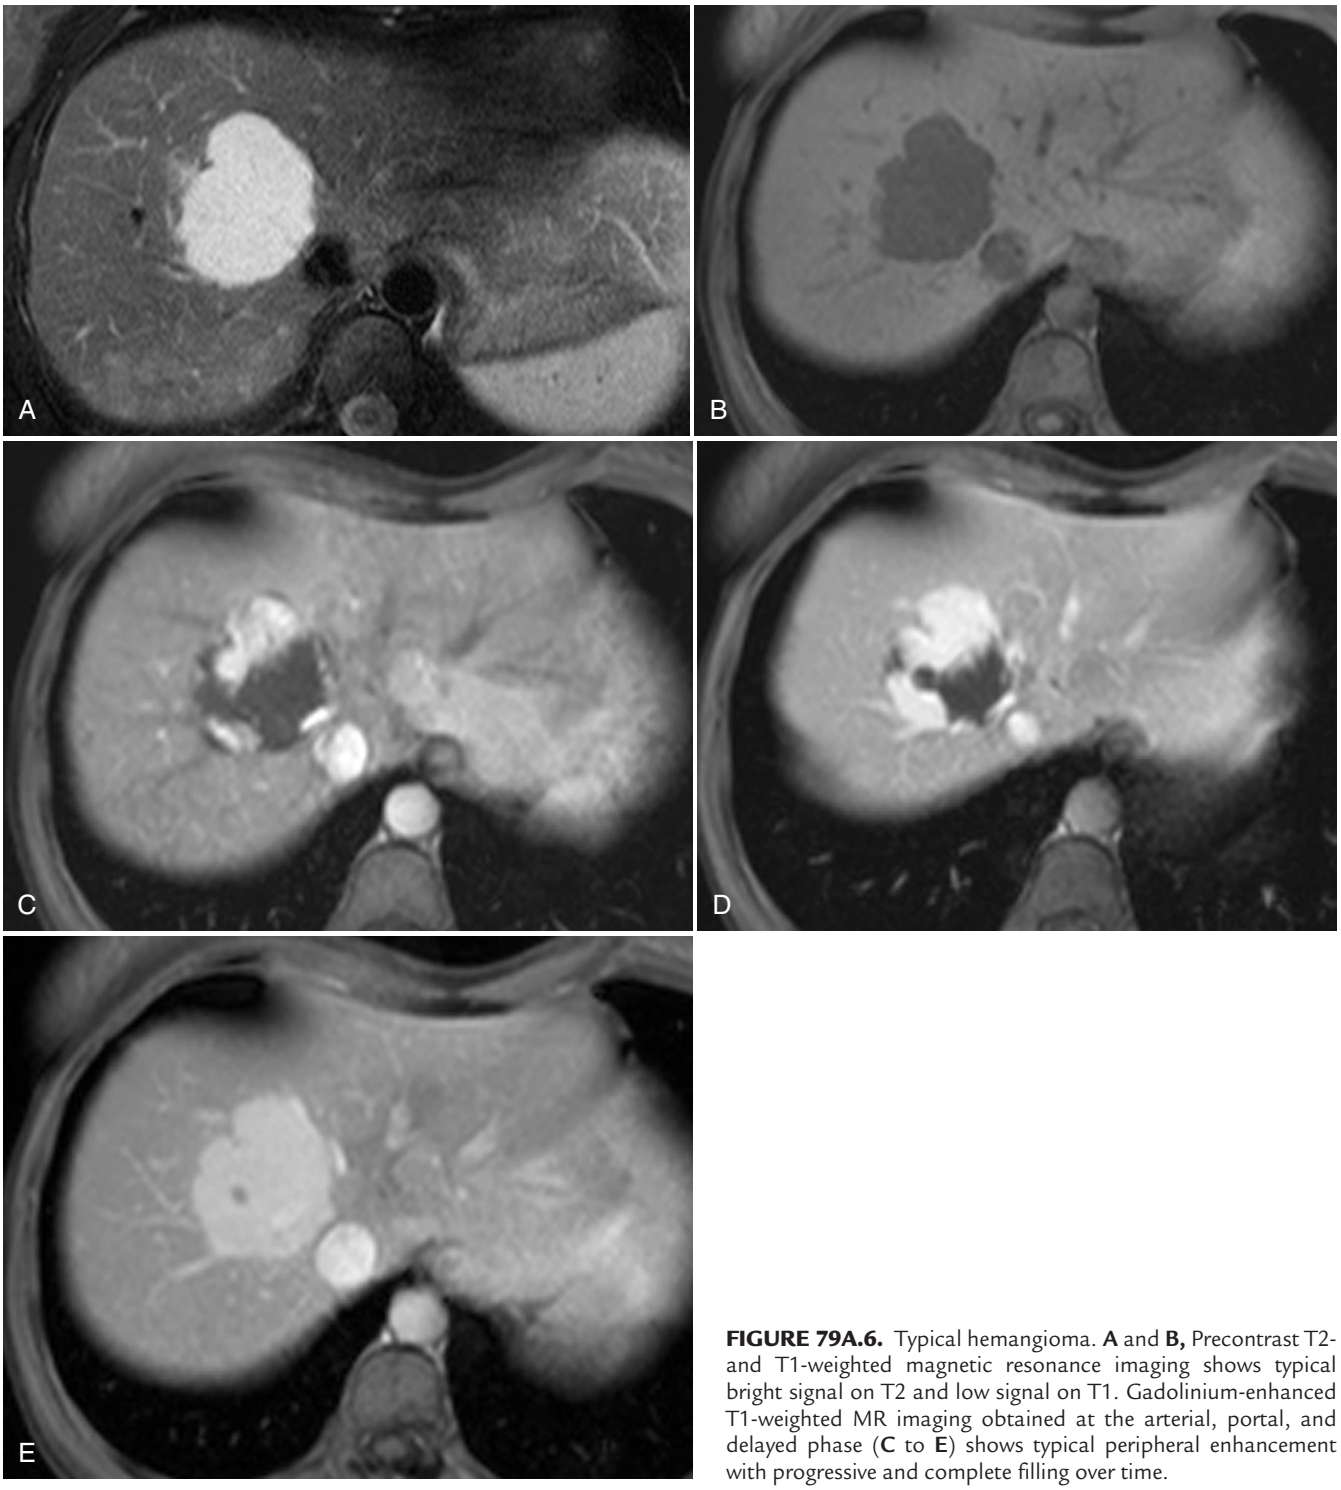

FIGURE 79A.6. Typical hemangioma. **A** and **B,** Precontrast T2- and T1-weighted magnetic resonance imaging shows typical bright signal on T2 and low signal on T1. Gadolinium-enhanced T1-weighted MR imaging obtained at the arterial, portal, and delayed phase (**C** to **E**) shows typical peripheral enhancement with progressive and complete filling over time.

on the liver and adjacent structures can be deleterious. In addition, relief of symptoms is not well documented. Arterial embolization, which may be considered for the temporary control of hemorrhage, has limited success and is occasionally associated with morbidity (Reading et al, 1988). Arterial ligation may be considered during surgical procedures to allow manual decompression of large hemangiomas and facilitate their manipulation and enucleation (Yoon et al, 2003).

When indicated, the only treatment to be considered is resection (Herman et al, 2005; Erdogan et al, 2007), and it should be performed in specialized units, where a variety of techniques and approaches can be used. The choice between enucleation and resection requires consideration of the size and anatomic location of the lesion. Hemangioma located in the peripheral liver area is preferably treated by enucleation, whereas tumors deeply located are more safely resected with a

formal anatomic liver resection (Kuo et al, 1994; Gedaly et al, 1999; Fu et al, 2009). In the majority of cases, patients showed symptoms relief after resection of a symptomatic hemangioma (Erdogan et al, 2007). Although laparoscopic resection is safe for peripheral hemangioma (Karahasanoglu et al, 2001; Jiang et al, 2007), this approach should not extend the rare indication for surgery. Liver transplantation has also been used successfully to treat symptomatic patients with a technically unresectable, complicated giant hemangioma or hemangiomatosis with cardiopulmonary complications (Browers et al, 1997; Tapetes et al, 1995; Ferraz et al, 2004; Keegan et al, 2001; Ercolani et al, 2010).

FOCAL NODULAR HYPERPLASIA

Pathogenesis and Pathology

FNH accounts for the second most common benign liver process, after hemangioma. It is a benign, tumor-like condition predominantly diagnosed in women 30 to 50 years of age, and it is not influenced by oral contraceptives (International Working Party, 1995; Ishak, 1979). FNH is considered a hyperplastic reaction resulting from arterial malformation (Wanless et al, 1985). This hypothesis, suggesting that increased arterial flow hyperperfuses the local liver parenchyma and leads to secondary hepatocellular hyperplasia, has been reinforced by molecular data showing that FNH is a polyclonal regenerative process (Gaffey et al, 1996; Paradis et al, 1997; Rebouissou et al, 2008). This regenerative process induced in a specific vascular territory could explain the absence of size changes in the vast majority of cases. However, an involution of this lesion is possible after menopause (Kuo et al, 2009), which explains the occurrence of this lesion in patients with vascular disorders of the liver, including Budd-Chiari syndrome (Cazals-Hatem et al, 2003), hereditary hemorrhagic telangiectasia (Gincul et al, 2008), congenital absence of portal flow (Kim T, et al, 2004), or portal thrombosis with subsequent hepatic arterialization (Bureau et al, 2004).

Such focal regenerative processes are also described in cirrhotic tissue with the so-called FNH-like macronodules. FNH displays a typical pathologic pattern for both radiologists and pathologists. Grossly, it is a well-circumscribed, unencapsulated, usually solitary mass characterized by a central fibrous scar that radiates into the liver parenchyma (Fig. 79A.7). Histologically, FNH is composed of benign-appearing hepatocytes arranged in nodules, usually partially delineated by fibrous septa that originate from the central scar. The main diagnostic feature is the presence of large and dystrophic vessels in the fibrous septa, which can be accompanied by several degrees of ductular proliferation and inflammatory cells. The hepatocytes

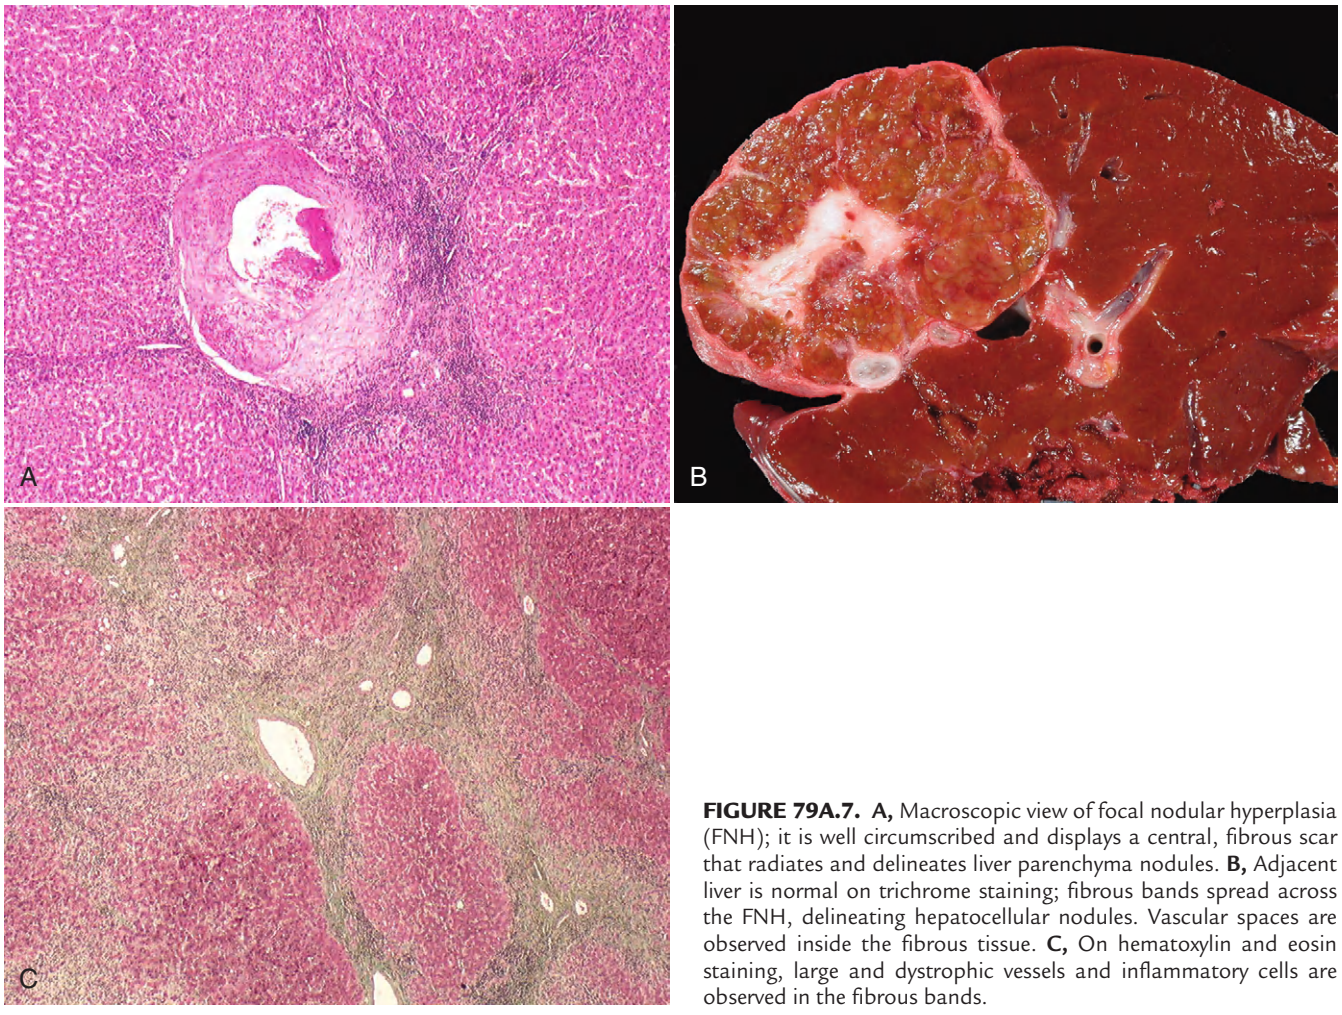

FIGURE 79A.7. A, Macroscopic view of focal nodular hyperplasia (FNH); it is well circumscribed and displays a central, fibrous scar that radiates and delineates liver parenchyma nodules. **B,** Adjacent liver is normal on trichrome staining; fibrous bands spread across the FNH, delineating hepatocellular nodules. Vascular spaces are observed inside the fibrous tissue. **C,** On hematoxylin and eosin staining, large and dystrophic vessels and inflammatory cells are observed in the fibrous bands.

are hyperplastic, arranged in liver plates of normal or slightly increased thickness (see Chapter 78). Hepatocytes may be hydropic, related to cholestatic changes, or they may display some degree of steatosis.

Performance of biopsy in the diagnosis of FNH is often a challenge, because fibrous septa and thick abnormal arteries are usually missing on biopsy specimen (Makhlouf et al, 2005). In that context, glutamine synthetase showing focal positive hepatocellular areas, usually centered by hepatic veins and described as a maplike pattern, is a helpful surrogate marker (Bioulac-Sage et al, 2009a).

Besides this classic form of FNH, several variant lesions are described with increased frequency and commonly classified as *nontypical FNH* by radiologists. This group of lesions is somewhat heterogeneous, including FNH without a central fibrous scar and FNH containing fat (Nguyen et al, 1999). However, molecular studies have demonstrated that in this group of atypical FNH, lesions that display telangiectatic changes, the so-called *telangiectatic* form of FNH, are clonal processes that should be rather regarded as a variant form of liver cell adenoma; it is classified as a specific subgroup of adenoma other than FNH (Paradis et al, 2004; Bioulac-Sage et al, 2005).

Clinical and Biologic Data

FNH represents the second most frequent benign lesion, with an estimated prevalence around 1% (Vilgrain, 2006); it is seen predominantly in women (9:1) and often is discovered in patients aged 30 to 40 years, although men with FNH are usually older than 40 years (Nguyen et al, 1999). The vast majority of FNH is asymptomatic, usually discovered incidentally during liver US examination. In a few patients with large tumors, FNH can be discovered by abdominal pain or discomfort. Large lesions located in the left lobe of the liver may cause pressure effects on adjacent structures with resulting symptoms. The lesion may be felt when it is pedunculated, and it can be responsible for acute episodes of pain because of torsion on the pedicle. Large FNH below the Glisson capsule could also be responsible for pain (Buetow et al, 1996), but in most cases pain related to FNH is probably due to associated disorders.

Complications of FNH, such as rupture or bleeding, are exceptional and are usually related to atypical forms of FNH with specific imaging and biologic features, the so-called telangiectatic FNH, which should be classified as an adenoma. No malignant transformation of FNH has been demonstrated. A reduction in size after menopause may be observed, but in the vast majority of cases, FNH remains stable in size, even after interruption of oral contraception or after pregnancy (Mathieu et al, 2000).

Liver biologic test results are normal in nearly 80% of cases (Belghiti et al, 1993). Abnormalities include mild elevation of GGT and alkaline phosphatase in patients with a large FNH that caused extrinsic compression of intrahepatic biliary ducts. The presence of a slight elevation of serum transaminase levels could be due to the presence of associated steatosis in the underlying liver parenchyma.

Imaging

FNH is usually slightly hypoechoic or isoechoic at US (see Chapter 13). Some lesions are only detected because they displace the surrounding vessels. Lobulated contours and a hypoechoic halo are often observed; the central scar is slightly hyperechoic but is often difficult to visualize at US (20% of cases; Shamsi et al, 1993). Typical findings at color Doppler include the presence of a central feeding artery with a stellate or spoke-wheel pattern that corresponds to the artery running from the central scar to fibrous septa (Fig. 79A.8). Doppler spectral analysis shows, in most cases, an intralesional pulsatile waveform with high diastolic flow and low resistive index (Uggowitzer et al, 1997). Large draining vessels may be identified in the periphery at the tumor margins. US contrast agents and nonlinear continuous imaging modes at a low mechanical index are very interesting tools to better characterize FNH. Most lesions enhance at the arterial phase (Kim MJ, et al, 2004; Dietrich et al, 2005) with a central vascular supply and a centrifugal filling to the periphery. The lesion becomes homogeneously isoechoic in the late portal and delayed phases in the vast majority of the cases (Kim MJ, et al, 2004), and very little FNH is evident with washout; when the central scar is detected, it appears hypoechoic on both arterial and portal phases. By showing centrifugal enhancement with radiated vascularization, differentiation from hepatocellular adenoma is possible in most cases (Kim T, et al, 2008).

On precontrast CT scans, FNH is demonstrated as a focal hypodense or isodense mass. A central hypodense scar is depicted in only one third of the patients (Shamsi et al, 1993). Calcifications within the central scar are very rare and are observed in only about 1% (Caseiro-Alves et al, 1996). Because of the prominent arterial supply to the FNH, the lesion enhances rapidly at the arterial phase of contrast-enhanced CT in most cases (Brancatelli, et al 2001). Lesion enhancement decreases at the portal venous phase, and the lesion may be either isodense or slightly hyperdense relative to normal liver. Additional findings are lesion homogeneity, a lobulated contour, and the absence of a capsule. A central scar is observed more often in large lesions than in small ones, and it enhances over time (Carlson et al, 2000). It has been shown that the enhancement of FNH in the arterial phase is significantly higher than in HA (Ruppert-Kohlmayr et al, 2001).

On MRI, typical FNH is isointense or hypointense on T1-weighted images and isointense or slightly hyperintense on T2-weighted images (Vilgrain et al, 1992; Buetow et al, 1996; see Chapter 17). The central scar is hypointense on T1-weighted images and strongly hyperintense on T2-weighted images (Mortelé et al, 2000; Kehagias et al, 2001). Another key finding is the lesion homogeneity apart from the central scar. After administration of gadolinium chelates, the enhancement is similar to that observed on contrast-enhanced CT. On delayed-phase imaging, 5 to 10 minutes after injection, the central scar shows high signal intensity because of the accumulation of contrast material in the fibrous tissue. Hepatobiliary contrast agents can be used to highlight the hepatocellular origin of the lesions and to differentiate FNH from hepatocellular adenomas; however, the biokinetics are different among those specific contrast agents (Ba-Ssalamah et al, 2002; Grazioli et al, 2005). On diffusion-weighted MR sequences, FNH is often hyperintense on high b values, but their apparent diffusion coefficient (ADC) values are close to that of the liver.

Atypical forms of FNH that are difficult to diagnose include FNH without a scar, especially in lesions measuring less than 3 cm in diameter. In some cases, scars do not enhance on delayed imaging, or they are hypointense on T2-weighted images; this leads the clinician to suspect the diagnosis of

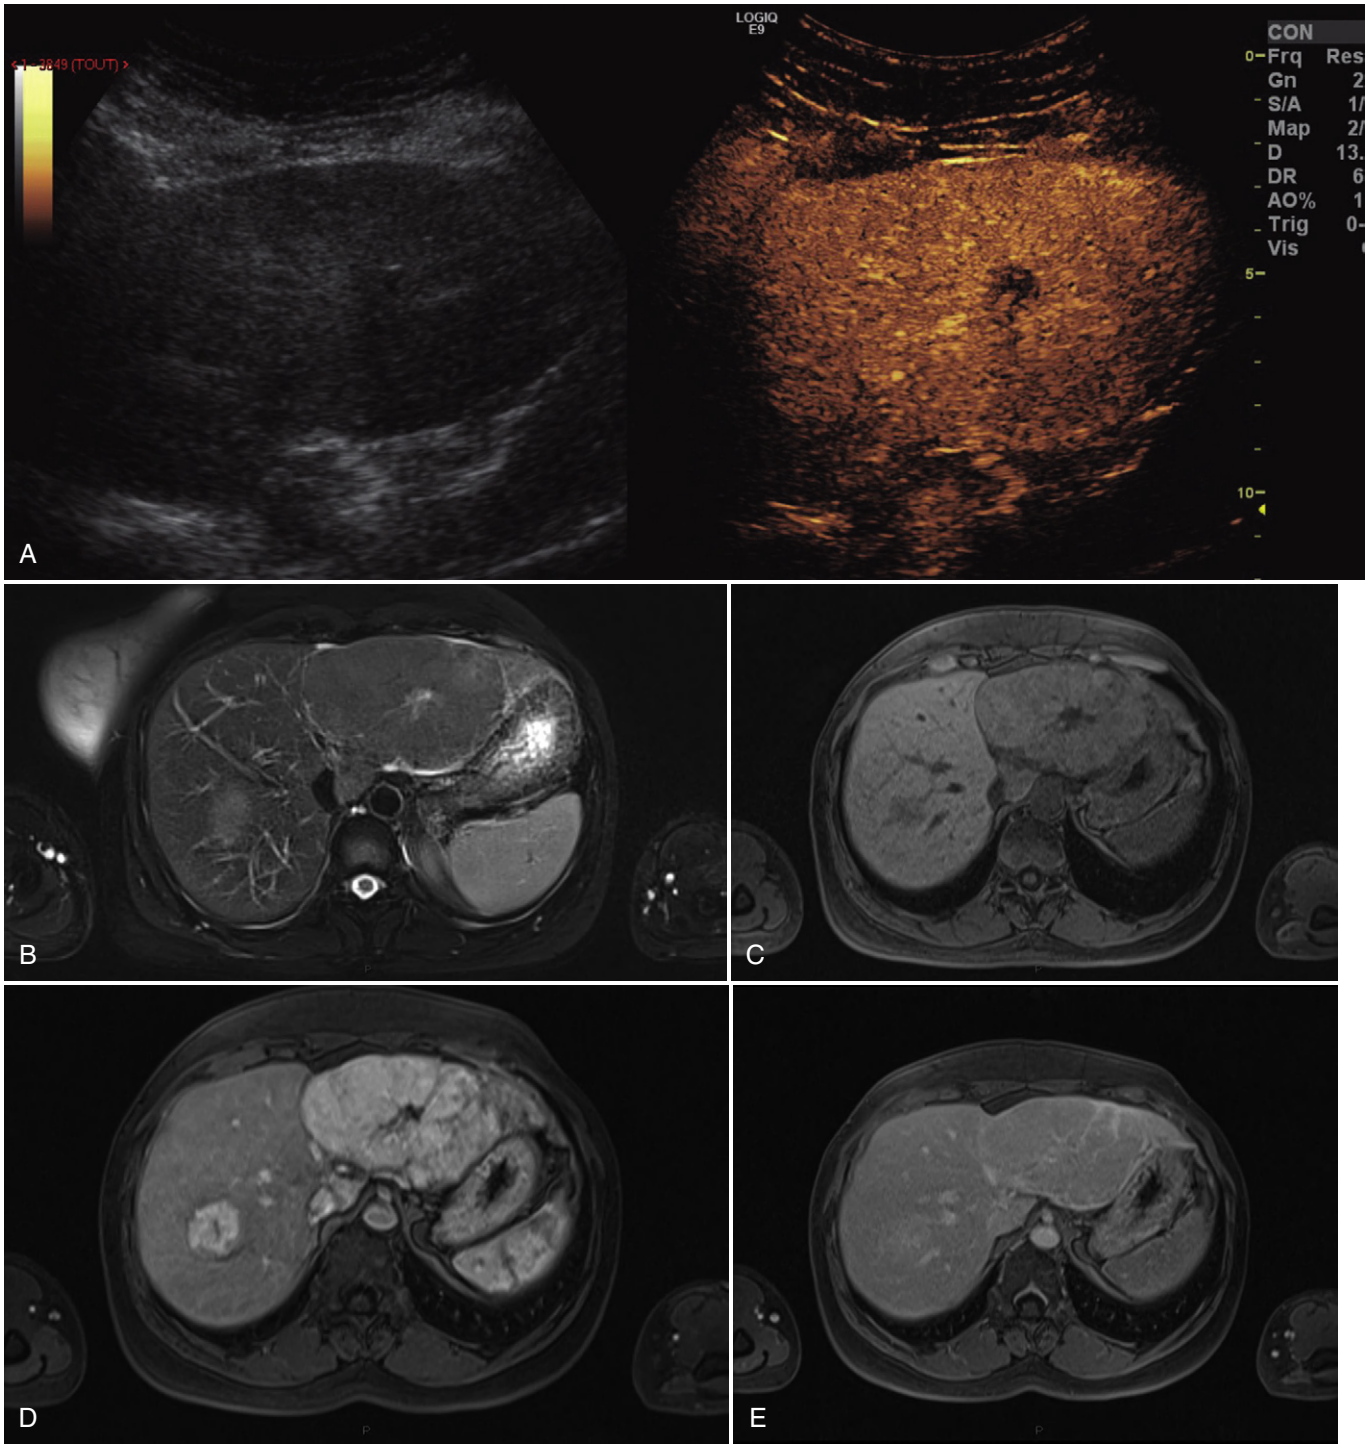

FIGURE 79A.8. Typical focal nodular hyperplasia (FNH). **A,** Contrast-enhanced ultrasound demonstrates strong and homogeneous enhancement apart from the central scar, which remains hypoechoic. Precontrast T2- and T1-weighted magnetic resonance (MR) imaging shows two hyperplastic focal nodules, which are isointense on T2 (**B**) and hypointense on T1 (**C**). Gadolinium-enhanced T1-weighted MR imaging obtained at the arterial and delayed phase (**D** and **E**) shows strong and homogeneous enhancement of the lesion with progressive fading. The central scar is hyperintense on T2 and enhances on delayed imaging. Note that the central scar is more evident in the large FNH.

fibrolamellar carcinoma. Other atypical findings include hyperintensity on T1-weighted imaging, which may be caused by various pathologic changes that include fat deposition (mostly in patients with steatosis; Stanley et al, 2002). FNH heterogeneity is exceptional and should make the diagnosis doubtful.

Although FNH is mainly a solitary lesion, multiple FNH lesions may be observed in 20% of cases and may be associated with hemangiomas or more seldom with HA (Mathieu et al, 1989; Vilgrain et al, 2003; Laurent et al, 2003). Accuracy of contrast-enhanced US has been established, and MR imaging

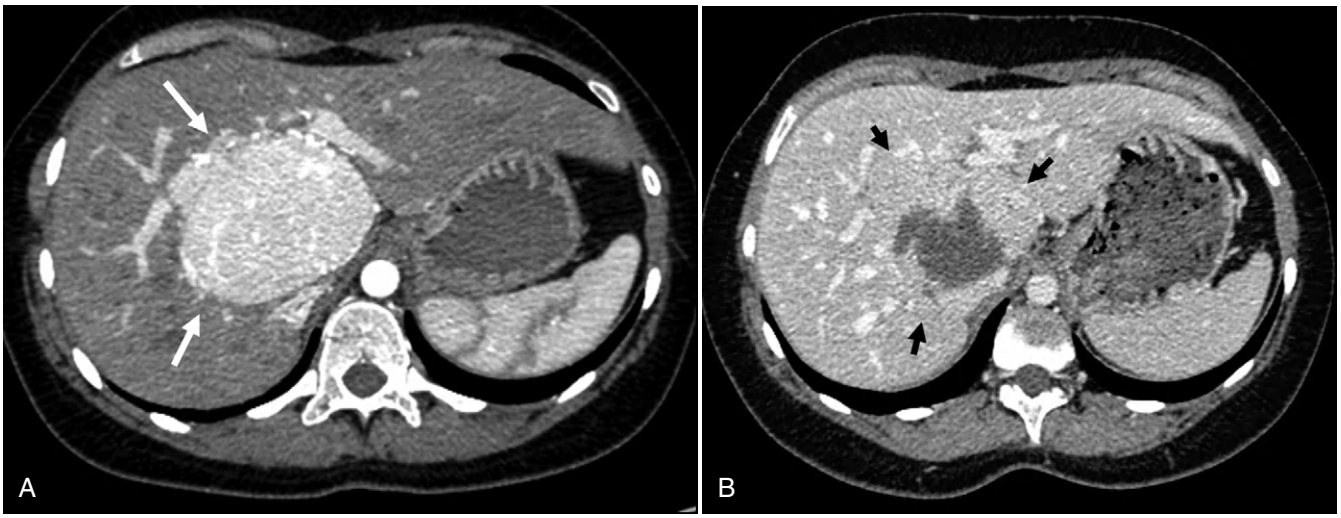

FIGURE 79A.9. Focal nodular hyperplasia (FNH) before and after arterial embolization. **A,** Abdominal computed tomographic scan with contrast injection on arterial and portal phases. Homogeneous centrohepatic FNH shows an immediate and intense enhancement during the arterial phase (*white arrows*). **B,** Postembolization aspect of the lesion. Note the size decrease and complete devascularization of the center of the lesion, appearing as a homogeneous unenhanced central area (*black arrows*).

has the higher sensitivity (70%) and specificity (98%) (Soussan et al, 2010). However, the diagnosis of FNH is based on a combination of features, and none of them are specific for FNH. When imaging cannot establish a firm diagnosis, liver biopsy plays a role in diagnosing FNH (Fabre et al, 2002; Makhlouf et al, 2005).

Management

Whatever the size and number of lesions, no treatment is necessary for asymptomatic FNH, when the diagnosis has been firmly established. This lesion should be considered a regenerative procedure rather than a tumor. In addition, the occurrence of this lesion in men should not modify the indication of conservative treatment; FNH has no risk of malignant potential and no risk of complications. The patient should be reassured about the absence of potential complications and the natural history of this lesion, which remains stable; advise that it could decrease and even disappear after the fifth decade; therefore no argument can even be made for interrupting oral contraceptives or avoiding pregnancy, and a follow-up is not justified.

Surgical resection is restricted to symptomatic patients. Symptomatic patients with confirmed FNH should be thoroughly investigated to exclude other pathology before attributing symptoms to the liver lesion. The development of a liver laparoscopic approach should not extend the indication for resection, which should be performed in specialist hepatobiliary units, as it is clearly indicated in patients with large, symptomatic FNH located in the left liver and in those with a pedunculated lesion. The safer resection procedure is liver resection with a surgical margin, rather than enucleation, because large veins often surround FNH, which renders enucleation difficult. In some symptomatic patients with large FNH located in the right liver or in segment I and necessitating difficult or risky resection, transarterial embolization has been advocated to determine the relationship between the lesion and symptoms (De Rave & Hussain, 2002; Kehagias et al, 2001). Data in the literature (Amesur et al, 2009) and our experience have shown that this is an attractive treatment with reduction of size in conjunction with relief of symptoms (Fig. 79A.9). Percutaneous radiofrequency ablation (RFA) has also been described as an effective treatment modality for symptomatic FNH (Hedayati et al, 2010).

HEPATOCELLULAR ADENOMA

Pathogenesis and Pathology

Hepatocellular adenoma (HA) is a rare, benign liver neoplasm strongly associated with oral contraceptive (OC) use (Rosenberg, 1991). The most important complications of HA are hemorrhage and malignant transformation into HCC. HA is mainly observed in women of childbearing age, and it is rare in men (sex ratio 9:1). Its incidence is estimated to be 0.1 per year per 100,000 in non-OC users, and it reaches 3 to 4 per 100,000 in long-term OC users (Wittekind, 1995). HA is directly related to OC use, and the risk for developing adenoma increases with the duration and estrogen content of the medication (Rosenberg, 1991; Dokmak et al, 2009). This tumor can also occur in men receiving anabolic steroids (Socas, et al 2005), or it may be associated with underlying metabolic disease, including type 1 glycogen storage disease, and iron overload related to β-thalassemia and hemochromatosis (Barthelemes & Tait, 2005; Bioulac-Sage et al, 2008). The prevalence of obesity was high in patients with HA (Dokmak et al, 2009), and it was recently described in patients with nonalcoholic fatty liver disease (Watkins et al, 2009). HA can also occur in patients with portacaval shunt or portal deprivation, and familial cases have been reported in patients with mellitus onset diabetes type 3 (Chiche et al, 2000; Bioulac-Sage et al, 2008).

HA is usually solitary, sometimes pedunculated, with a diameter that can vary from a few millimeters up to 30 cm. The widespread use and technical progress in imaging techniques has revealed that one third of patients have multiple HAs (Dokmak et al, 2009; Deneve et al, 2009; Bioulac-Sage et al, 2009b). Patients with more than 10 HAs are subclassified as having *liver adenomatosis*, considered to be more common in

men and to have an increased risk of complications (Fléjou et al, 1985). However, review of the literature and our experience do not support this arbitrary classification based on clinical and imaging characteristics (Ribeiro et al, 1998; Jovine et al, 2004; Barthelemes & Tait, 2005; Dokmak et al, 2009; Bioulac-Sage et al, 2008). The risk of bleeding and of malignant transformation is similar to that in patients with solitary adenoma and is mainly related to the size and subtype of tumors (Dokmak et al, 2009; Bioulac-Sage et al, 2008; Deneve et al, 2009; Stoot et al, 2010). It also appears that the prevalence of HA is rising in men, mainly as a result of the rising incidence of metabolic syndrome (Farges et al, 2011). Such HA displays a significantly higher risk of malignant transformation to HCC, reaching 47% in the last few years in our experience (Farges et al, 2011); therefore patients should not be managed according to the number of HAs, but rather according to the risk of complications, which is related to sex, the histologic subtype, and mainly to the size of the HA.

Large subcapsular vessels are commonly found on macroscopic examination. On cut sections, the tumor is well delineated, sometimes encapsulated, and has a fleshy appearance; it ranges in color from white to brown (Fig. 79A.10). HA frequently displays heterogeneous areas of necrosis and hemorrhage. Histologically HA consists of a proliferation of benign hepatocytes arranged in a trabecular pattern; however, the normal liver architecture organization is absent (Chapter 78). Hepatocytes may have intracellular fat or increased glycogen. Malignant transformation to HCC may be difficult to assess, especially on biopsy specimen (Deneve et al, 2009; Stoot et al, 2010), but it is observed in 4% to 10% of cases in published series (Barthelemes & Tait, 2005; Bioulac-Sage, 2008; Deneve et al, 2009; Zucman-Rossi et al, 2006).

Four subtypes of HA could be named according to genotype/phenotype classification (Bioulac-Sage et al, 2009). Group 1 includes HA with mutation in the hepatocyte nuclear factor (HNF)-1α gene (*H-HA*). Observed in approximately 35% to 40% of patients, almost exclusively in women and often with multiple HAs, this group corresponds to a histologically homogeneous group of tumors characterized by marked steatosis, no cytologic abnormalities, no inflammatory infiltrates, and a very low risk of complications. Group 2 includes HA with mutation of the β-catenin gene. Observed in approximately 10% of cases, mostly in men, this group is characterized by the presence of cytologic abnormalities with the greater risk of malignant transformation. Group 3 corresponds to telangiectatic/inflammatory HA. Observed in more than 50% of cases, these lesions usually occur in overweight women patients with inflammatory syndrome; tumors are characterized morphologically by the presence of inflammatory infiltrates, marked sinusoidal dilation or congestion, and numerous isolated or clustered arteries. The risk of complication in this group is high. The last group corresponds to HA that does not express any of the above-mentioned phenotypic or morphologic features. Besides the morphologic features associated with the different subtypes of HA, additional immunohistochemical markers have been described that provide significant assistance in the classification of HA, especially in biopsy specimens (Bioulac-Sage et al, 2009).

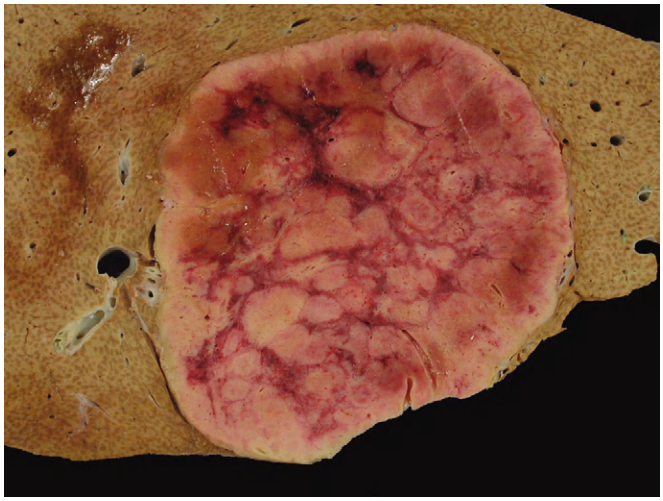

FIGURE 79A.10. Macroscopic aspect of hepatocellular adenoma. The lesion is well delineated, unencapsulated, and tan to yellow with some vascular changes.

Clinical and Biological Data

Although patients with HA can come to medical attention with symptoms, the majority are asymptomatic, especially if they have small tumors (Trotter & Everson, 2001; Weimann et al, 2000; Bioulac-Sage et al, 2009; Dokmak et al, 2009). Tumors are discovered during diagnostic workup of elevated liver enzymes or during liver imaging monitoring in pregnancy or for other reasons. A large adenoma may cause a sensation of right upper quadrant fullness or discomfort.

Adenoma is of clinical importance because of its tendency to bleed spontaneously and result in hemorrhage and infarction in the tumor. The risk of spontaneous bleeding is likely to be between 20% and 40% (Barthelemes & Tait, 2005; Dokmak et al, 2009; Bioulac-Sage et al, 2009; Deneve et al, 2009). Although the risk of bleeding is increased in pregnant women and in those taking OC, this risk is quite exclusively observed in patients with lesions larger than 5 cm (Dokmak et al, 2009; Deneve et al, 2009). About 10% of patients are seen with acute, severe abdominal pain from intraperitoneal rupture and hemoperitoneum, which may be associated with hypovolemic shock. Hemorrhage results in acute pain and discomfort accompanied by anorexia, nausea, vomiting, and fever. Although tumor rupture with hemoperitoneum represents an alarming manifestation, hemodynamic instability is rare, except in patients treated with anticoagulation (Marini et al, 2002). The presence of sudden right upper quadrant pain with some respiratory manifestation leads some clinicians to erroneously suspect the diagnosis of pulmonary embolism; they then treat the patient with anticoagulant therapy, which can exacerbate the bleeding.

The risk of malignant transformation of HA in women is on the order of 5% (Barthelemes & Tait, 2005; Bioulac-Sage et al, 2009; Deneve et al, 2009; Dokmak et al, 2009; Stoot et al, 2010). No clinical or radiologic signs can predict preoperatively the diagnosis of degenerated HA; it is almost exclusively made on the pathologic specimen of resected HA. Malignancy displays well-differentiated HCC, and vascular extension or satellite nodules are exceptional. α-Fetoprotein (AFP) level is usually normal. Most cases of HCC develop at the site of the liver cell adenoma. The risk of malignancy is very high in men (50%), whatever the size of the tumor, and in women with a large HA (>8 cm) (Dokmak et al, 2009; Stoot et al, 2010; Farges et al, 2011). Moreover, HA with β-catenin activation carries a higher risk of malignant transformation (Bioulac-Sage

et al, 2009; Farges et al, 2011). These cases of malignancy developed in HA should be differentiated from exceptional cases of multiple degenerated HA occurring in young women with symptomatic hepatomegaly associated with severe asthenia and high AFP level. The prognosis is poor, because surgical resection is not feasible, and liver transplantation is inevitably followed by rapid and fatal relapse of the disease.

In two thirds of cases, liver function tests are abnormal, including elevated cholestatic enzymes and mild elevation of transaminases (Dokmak et al, 2009). In case of malignancy, serum AFP is generally normal.

Imaging

For years, imaging features of HA were nonspecific and unlikely for FNH. Now, it is well established that the different molecular features correspond to distinct phenotypic features.

The key imaging feature of HNF-1α–inactivated HA is the presence of marked and diffuse fat within the lesion. Fat is responsible for lesion hyperechogenicity on US and strong hypoattenuation on unenhanced CT scan (see Chapter 16). Because of the fat content, the lesion does not enhance markedly and shows rapid washout on multiphasic examination. MR plays a crucial role in demonstrating the presence of diffuse fat (see Chapter 17). The striking finding is a diffuse and homogeneous signal dropout on chemical-shift T1-weighted sequences with a high specificity (Laumonier et al, 2008; Fig. 79A.11).

The key imaging feature of telangiectatic/inflammatory HA is the presence of telangiectatic components (Fig. 79A.12). The lesion is often hyperechoic at US but is also heterogeneous, and Doppler signals are commonly seen. Unlike other HAs, central arteries that could mimic FNH may be seen on contrast-enhanced US (Soussan et al, 2010). On unenhanced CT, telangiectatic/inflammatory HAs are hypoattenuating but often heterogeneous. The characteristic lesion behavior on multiphasic examination is a strong arterial enhancement and a persistent enhancement in the delayed phase (Laumonier et al, 2008). MR imaging is also very important because it shows a strong hyperintense signal on T2-weighted images. On T1-weighted sequences, lesion signal intensity is variable and is often hyperintense. This hyperintensity is not related to fat and persists on fat-suppressed and opposed-phase sequences (Attal et al, 2003; Lewin et al, 2006). Considering two imaging findings—a markedly hyperintense signal on T2-weighted images and persistent enhancement on the delayed phase—Laumonier and colleagues (2008) observed a positive predictive value for the diagnosis of telangiectatic/inflammatory hepatocellular adenoma of 88.5%, a negative predictive value of 84%, a sensitivity of 85.2%, and a specificity of 87.5%. Some of telangiectatic/inflammatory HAs may contain some fat deposition. The two other subtypes, β-catenin–activated and unclassified HA, are less characteristic on imaging. To note, some telangiectatic/inflammatory HA may display β-catenin activation and may therefore have imaging findings similar to classic telangiectatic/inflammatory HA. The others share findings of hepatocellular tumors, strong arterial enhancement with no delayed enhancement after gadolinium injection, and may have heterogeneous content.

Treatment

The management of patients with HA should be mainly tailored according to the patient's gender and the size of the tumor. The follow-up and treatment in some patients can also be influenced by the histologic classification of their HA.

Whatever the size, HA in men represents an indication for resection because of the high risk of malignancy. Whatever the number of HAs, women with small lesions less than 5 cm in diameter have a low risk of complication and could be safely observed after cessation of OC; however, the influence of the discontinuation of OC on the regression of HA is a subject of debate (Gordon et al, 1986), justifying serial imaging examinations in patients with HA managed conservatively. Indeed, long-term follow-up evaluation for nearly 20 years of patients with small residual HAs after surgery showed that HA remains stable or involved in more than 90% of cases (Dokmak et al, 2009). Regression and even disappearance of HAs seem to occur more frequently in older patients. Reappearance or increase in size occurs in 15% of patients, but serious complications are rarely described in this subgroup (Dokmak et al, 2009). It was usually recommended that pregnancy be avoided in patients with a history of HA (Deneve et al, 2009); however, in our experience, pregnancies in several women treated for HA were not associated with reappearance or enlargement of residual HA; this led us to not contraindicate pregnancy in patients with HA (Dokmak et al, 2009).

Resection of HA greater than 5 cm is indicated. The operative approach should be tailored to the location and the size of the tumor. A large resection margin is not needed, allowing complete resection through a laparoscopic approach when feasible (Descottes et al, 2003). In some patients with large bilobar tumors, resection could be performed in two steps. Tumors located in one lobe are resected during a first procedure, followed some weeks later by a second procedure to resect tumors located in the remnant liver. Small tumors need not be resected, and liver transplantation is no longer indicated in patients with multiple HAs (Dokmak et al, 2009). Malignant transformation is often discovered on the pathologic analysis of the resected specimen, because no radiologic features are specific, and AFP level is almost always normal. Vascular invasion is absent, and lymph nodes are not involved. Complete resection of malignant HA is a safe and efficient therapeutic option.

Although surgical resection remains the standard of care of HA, other treatment modalities such as arterial embolization (Kobayashi et al, 2009; Stoot et al, 2007), percutaneous RFA (Atwell et al, 2005), or combinations of both are performed more and more with encouraging results in recent publications. Such modes of treatment are now proposed for tumors around 5 cm in diameter, in case of recurrence after surgical resection, and if the estimated risk of malignancy is very low (see Chapters 83 and 85).

Patients with ruptured HA should be treated electively. After stabilization of the patient and selective hepatic artery embolization, the patient can be observed for several months, until resorption of the hematoma surrounding the tumor (Terkivatan et al, 2001; Marini et al, 2002). The absorption of the hematoma surrounding the tumor allows an easier and parenchyma-sparing elective liver resection with a low risk of transfusion (Marini et al, 2002; Deneve et al, 2009). The involvement of these hemorrhagic HAs, which decrease dramatically in size and even disappear after embolization, may even bring into question the need for subsequent resection, because exceptional cases of hemorrhagic HA had a malignant component.

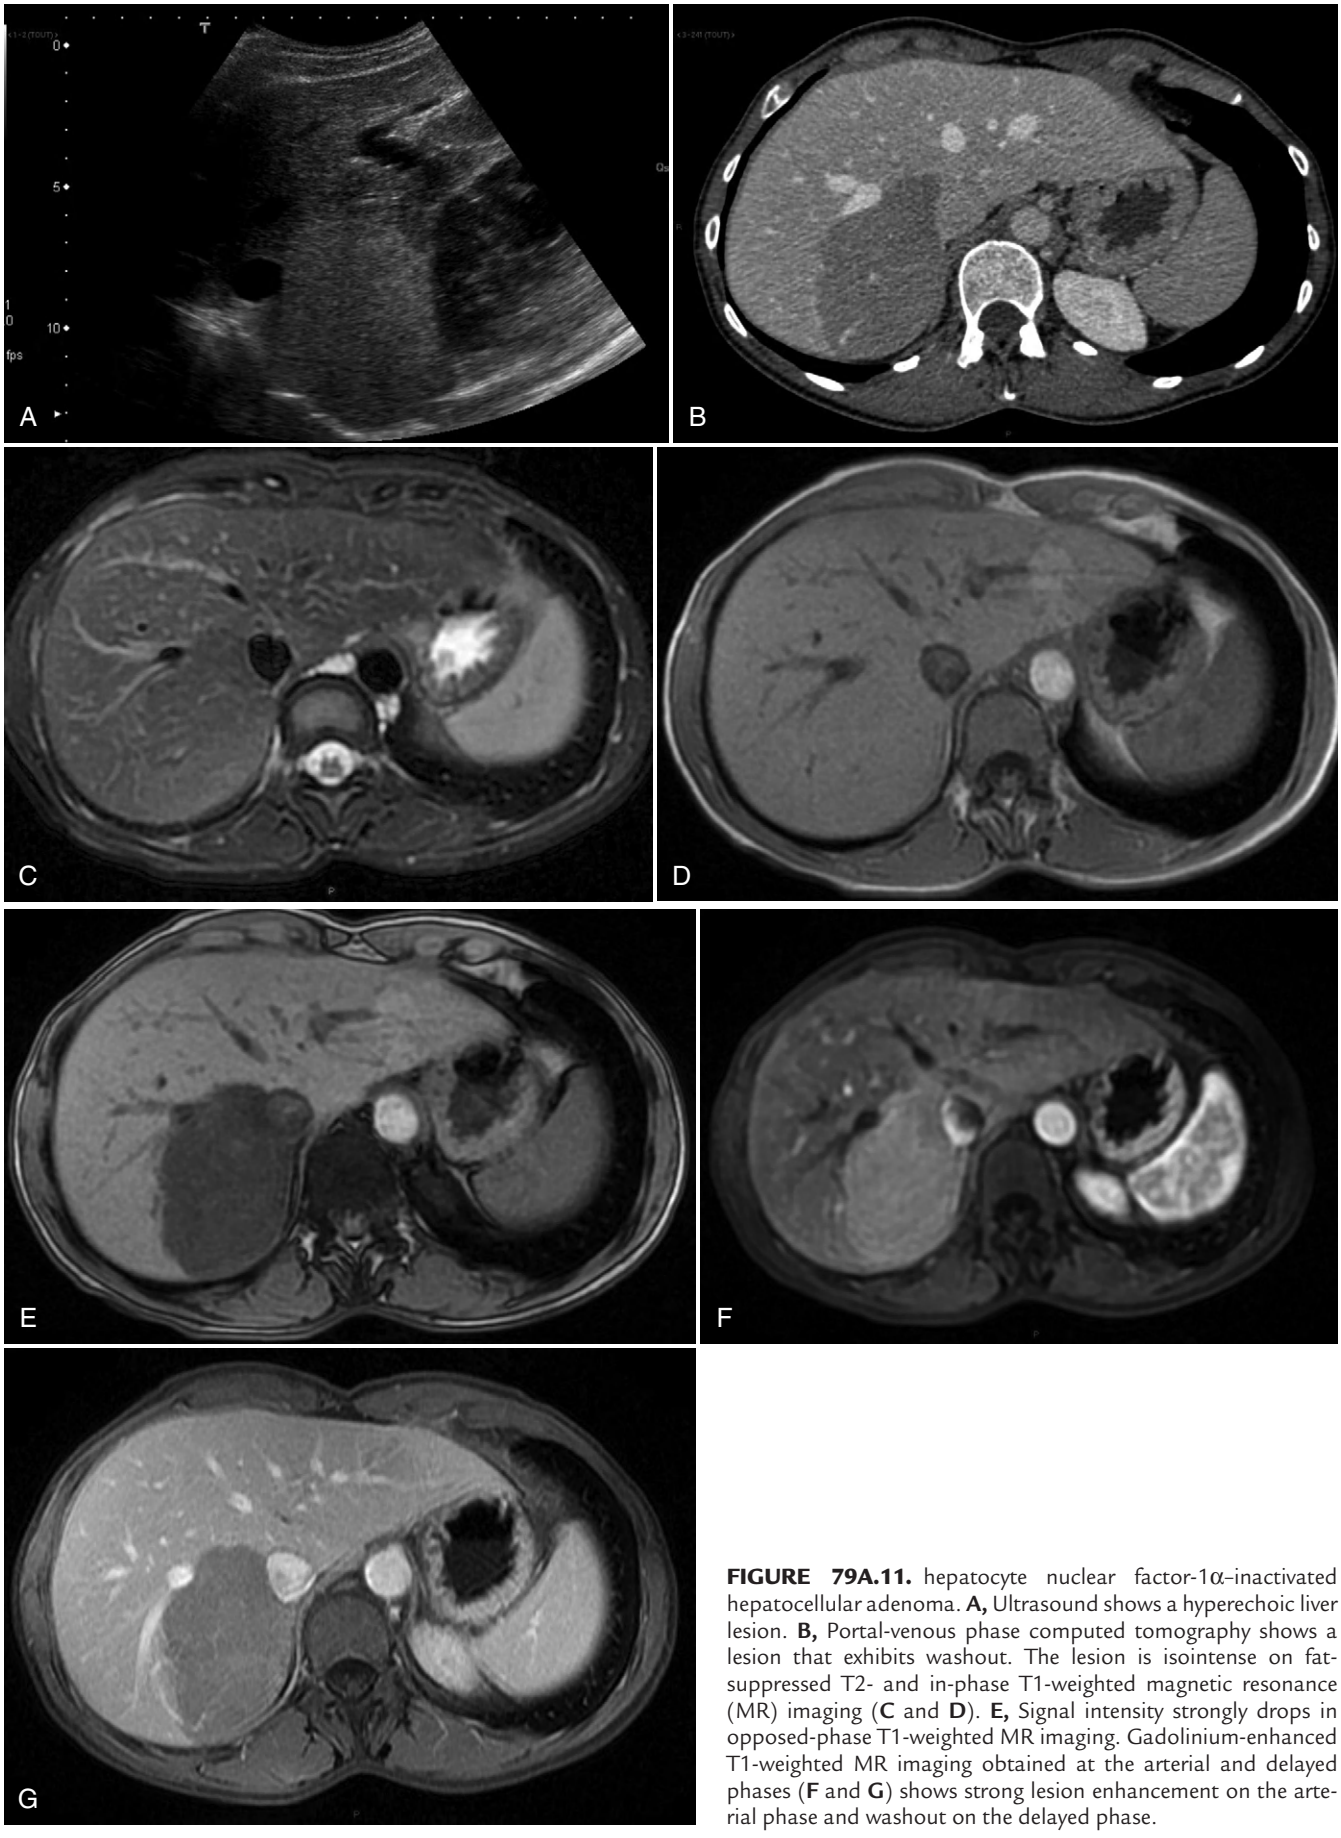

FIGURE 79A.11. hepatocyte nuclear factor-1α–inactivated hepatocellular adenoma. **A,** Ultrasound shows a hyperechoic liver lesion. **B,** Portal-venous phase computed tomography shows a lesion that exhibits washout. The lesion is isointense on fat-suppressed T2- and in-phase T1-weighted magnetic resonance (MR) imaging (**C** and **D**). **E,** Signal intensity strongly drops in opposed-phase T1-weighted MR imaging. Gadolinium-enhanced T1-weighted MR imaging obtained at the arterial and delayed phases (**F** and **G**) shows strong lesion enhancement on the arterial phase and washout on the delayed phase.

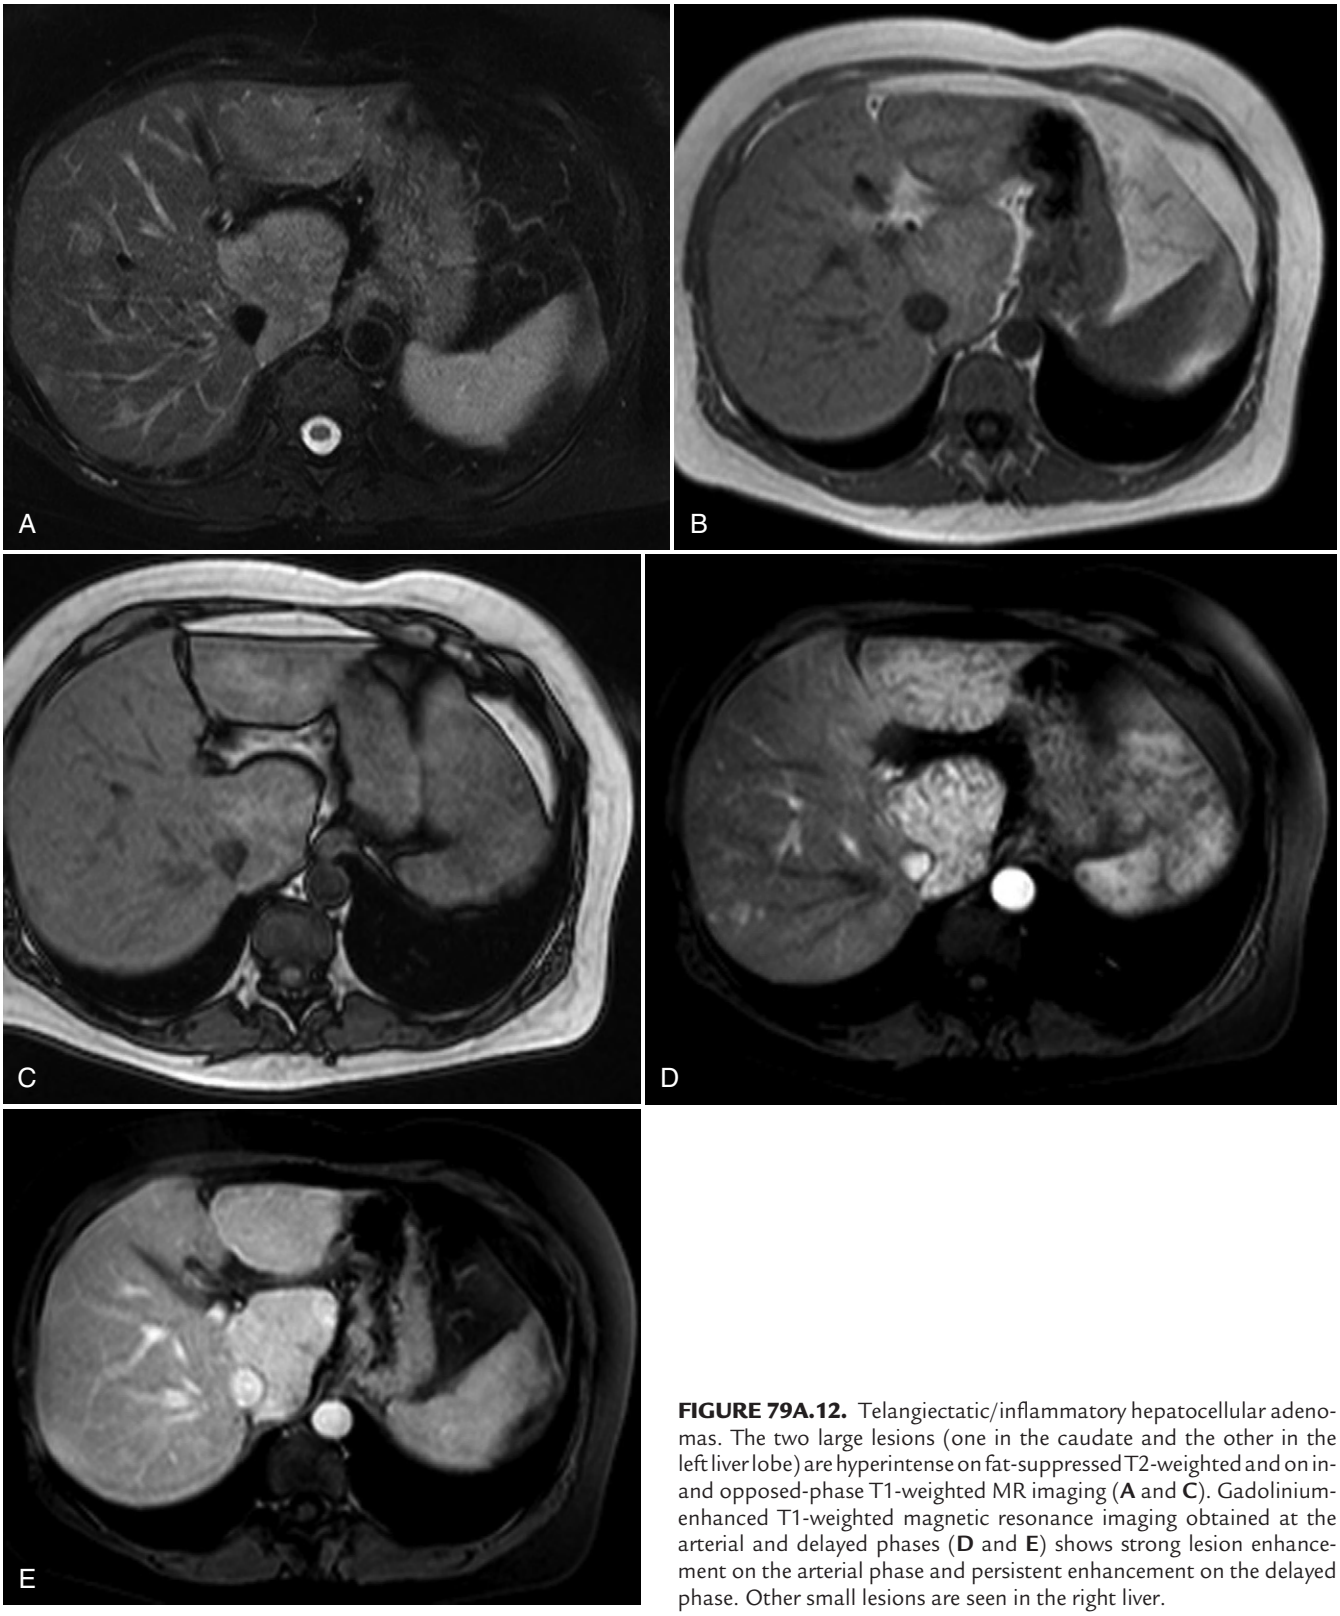

FIGURE 79A.12. Telangiectatic/inflammatory hepatocellular adenomas. The two large lesions (one in the caudate and the other in the left liver lobe) are hyperintense on fat-suppressed T2-weighted and on in- and opposed-phase T1-weighted MR imaging (**A** and **C**). Gadolinium-enhanced T1-weighted magnetic resonance imaging obtained at the arterial and delayed phases (**D** and **E**) shows strong lesion enhancement on the arterial phase and persistent enhancement on the delayed phase. Other small lesions are seen in the right liver.

The impact of the genotype/phenotype classification on the management of HA remains unclear (Terkivatan & Ijzermans, 2009). We are in favor of preoperative biopsy in patients with large (>5 cm) steatotic HA, considering a conservative approach with observation if the HA belongs to group 1, with H-HA mutation. Patients with HA approximately 5 cm, which could be treated by transarterial embolization or RFA, should undergo a biopsy before employing a conservative approach, so that close follow-up or even systematic resection can be considered if the HA belongs to group 2 with β-catenin mutation.

OTHER LESIONS

Fatty Lesions of the Liver

Angiomyolipoma

Hepatic angiomyolipoma is a rare, benign mesenchymal tumor composed of smooth muscle cells, adipose tissue, and proliferating blood vessels in various combinations. It belongs to the group of tumors derived from the *perivascular epithelioid cell,* referred to as *perivascular epithelial cell tumors* or *PEComas* (Tsui et al, 1999). Hepatic angiomyolipoma occurs frequently in the kidney but rarely in liver. This rare tumor may occur as a solitary mass (Zhou et al, 2008; Zeng et al, 2010) or as an associated finding with tuberous sclerosis (Hooper et al, 1994), which is present in about 15% of cases. In this situation, angiomyolipomas are usually multiple.

Hepatic angiomyolipoma predominantly affects women between 30 and 50 years of age, and lesions are often larger than 5 cm in diameter (Yang et al, 2007), and it can increase in size (Zeng et al, 2010). This tumor was once considered benign, but malignant transformation has been reported (Zhou et al, 2008; Rouquie et al, 2006; Dalle et al, 2000). Patients usually have no symptoms, and liver tests are normal; most of these tumors are found incidentally on routine imaging studies. The accuracy of preoperative diagnosis is low as a result of variable imaging appearance because of the varying content of the three components and the rarity of the lesion. The fat component of angiomyolipoma varies between 10% and 90% (Hooper et al, 1994).

Typically, angiomyolipoma appears hyperechoic and hypoattenuated on unenhanced CT scans and markedly enhanced on the arterial phase with central vascular opacification (Fig. 79A.13). The presence of large central vessels, the so-called macroaneurisms, within the lesion is characteristic of angiomyolipoma. On contrast-enhanced US, the vast majority of angiomyolipomas enhance on the arterial phase without washout on the portal or delayed phase (Wang et al, 2010). MRI is also an important diagnostic technique that allows fat suppression and multiphase dynamic contrast-enhanced scanning. In general, MR shows a marked hypersignal in T1-weighted images, which drops on fat-suppressed sequences. However, the lesions have various imaging characteristics because of the different proportions of smooth muscle, fat, and vessels (Yan et al, 2002). The amount of fat may be too small to be detected (<5%), and some angiomyolipomas, especially those with a prominent epithelioid myoid component, may mimic hepatocellular lesions, mostly HA and HCC (Arblade et al, 1996). The accuracy of needle biopsy is reinforced by using the antibody anti–HMB-45, which stains the myoid component (Arblade et al, 1996); the positivity of this antibody in the cytoplasm of smooth cells is characteristic of angiomyolipoma (Arblade et al, 1996). When the diagnosis is established, careful observation with serial follow-up is recommended in asymptomatic patients with lesions less than 5 cm (Hoffman et al, 1997; Sawai et al, 1998). Because some degenerated cases have been reported in patients with large tumors, especially when major epithelioid content was present, liver resection is indicated in large (>5 cm) hepatic angiomyolipoma (Zeng et al, 2010; Fig. 79A.14).

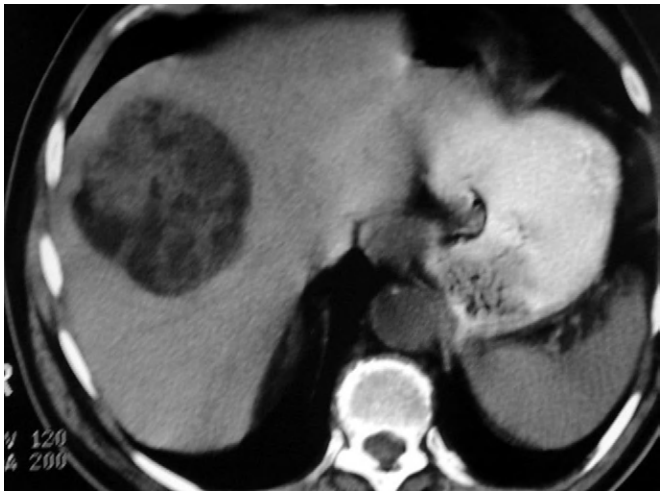

FIGURE 79A.13. Typical angiomyolipoma. Precontrast computed tomography shows a heterogeneous lesion that contains fat.

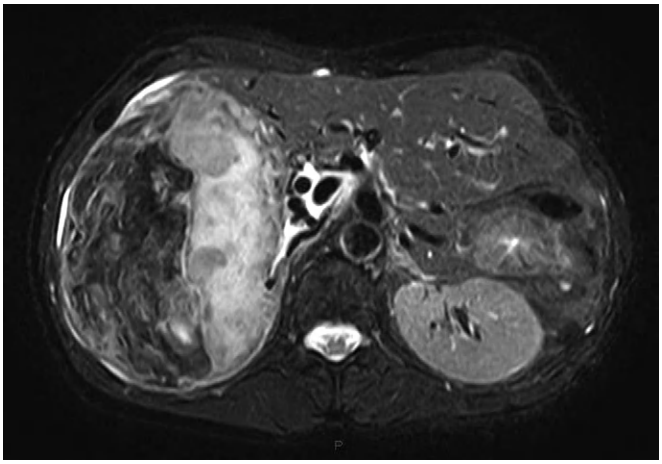

FIGURE 79A.14. Large hepatic angiomyolipoma requiring resection for the risk of malignant components. Lesion heterogeneity is well demonstrated on magnetic resonance imaging.

Lipoma

Hepatic lipoma is a very rare liver tumor that can mimic angiomyolipoma. Lesions of hepatic lipoma are homogeneous and circumscribed, show fat attenuation on CT, and do not enhance after intravenous (IV) administration of contrast material. On MRI imaging, lipomas are hyperintense on T1-weighted images and moderately hyperintense on T2-weighted images. The key finding is the drop in signal intensity on fat-suppressed MR sequences (Horton et al, 1999). Unlike hepatocellular tumors that contain fat, lipomas do not drop in signal intensity on opposed-phase T1-weighted MR images. Microscopic analysis shows well-differentiated adipose tissue without any significant changes. There is no need to resect lipomas (Nakamura et al, 2009).

Bile Duct Adenoma

Bile duct adenoma, also called *benign cholangioma,* is a benign and asymptomatic mass that is typically discovered incidentally at imaging studies, surgery, or at autopsy (Kim et al, 2010). This rare benign lesion of the liver is usually a well-circumscribed,

subcapsular nodule with a diameter of less than 1 cm consisting of a proliferation of noncystic biliary structures within a dense, fibrous stroma (Allaire et al, 1988). No relationship between this tumor and cholangiocarcinoma has been shown, and resection is unnecessary; its only clinical significance lies in the possible confusion with metastatic carcinoma during surgery (Hornick et al, 2005).

Biliary Hamartoma

This lesion, also known as a *Von Meyenburg complex,* is a development anomaly of small intrahepatic bile ducts composed of bile ductules, inflammatory cells, and fibrosis (Table 79A.1; Neri et al, 2004). The main practical problem raised by this tumor is for the pathologist, because its possible discovery during surgery for carcinoma of another abdominal organ leads the surgeon to perform a biopsy for frozen-section diagnosis (Guiu et al, 2009). The pathologist who is unaware of this rare entity may be puzzled and may be tempted to call the lesion metastatic carcinoma. Otherwise, hamartomas are easily recognized on heavily T2-weighted MR images and appear as multiple small lesions that are strongly hyperintense. The presentation is often mistaken for Caroli disease, but the lesions in biliary hamartoma do not communicate with bile ducts (Thomé-Noun et al, 2008). Treatment is not required.

Inflammatory Pseudotumors

Inflammatory pseudotumor of the liver (IPL) is a rare benign tumor that can mimic cholangiocarcinoma (Deng et al, 2010; see Chapter 48). Commonly found in the lung, IPL is a reactive fibroblastic proliferation infiltrated by polymorph inflammatory cells: plasmocytes, lymphocytes, and histiocytes. IPLs are also referred to as *inflammatory myofibroblastic tumors, plasmocytic granuloma, histiocytoma, fibroxanthoma, pseudolymphoma,* and *necrotic tumor of the liver* (Milias et al, 2009). They are more common in men than in women, are more frequently seen in the non-European population, and have an average age at presentation of 50 years (Goldsmith et al, 2009). The majority of patients with IPL typically experience vague constitutional symptoms such as fever (50%), abdominal pain (48%), weight loss (37%), and jaundice (Zamir et al, 1998; Goldsmith et al, 2009). Hematologic tests are generally normal, but one third of patients are seen with inflammatory syndrome. Liver function tests are abnormal in 15% of cases with mild elevations in cholestatic tests (alkaline phosphatase and GGT). The etiology of this pathology is not well known, but the predominantly inflammatory pattern and the associated systemic reaction suggest an underlying infectious agent (Koea et al, 2003) with microorganisms coming from the gut to the liver via the portal vein (Jover Díaz et al, 2009). This etiology can explain the response to antibiotics in some cases. Some authors have suggested an autoimmune etiology such as immunoglobulin G (IgG)-4 sclerosing cholangitis with histologic findings similar to autoimmune pancreatitis (Uchida et al, 2007), and in this case, treatment with steroids can be effective (Anthony, 1993; Kamisawa & Okamoto, 2008). In the tumoral hypothesis, authors suggest that some IPL may be of follicular dendritic cell origin (Shek et al, 1998).

Imaging studies often show diffuse and infiltrative large tumors, although multiple forms can be found (Jover Díaz et al, 2009). The majority of these lesions are located near the gallbladder or are related to the biliary tree, sometimes mimicking a malignant biliary stricture (Koea et al, 2003; Locke et al, 2005; Terada, 2010).

According to clinical and morphologic presentations, three different forms can be distinguished:

1) *Inflammatory form:* Revealed by abdominal pain and fever, inflammatory syndrome can be found in half of patients; weight loss, nausea, and vomiting may also occur but are rare. At imaging, the lesion is generally solitary, ill-defined, large, heterogeneous, and hypervascular. On MRI, the lesion is hypointense on T1-weighted sequences and isointense or hyperintense on T2-weighted sequences. At histology, spindle cells with a dense inflammatory and polymorphic population are seen, associated with anomalies of the portal branches in contact with the lesion (fibrotic portal endophlebitis).

2) *Encapsulated form:* Clinically, this lesion is small and is usually discovered fortuitously. Inflammatory syndrome is absent. At CT, the lesion is hypoattenuating and presents with a peripheral capsule, and no enhancement is depicted within the lesion. On MRI, the lesion is well limited, hypointense on T1 imaging, isointense on T2 imaging, and surrounded by a capsule that enhances on delayed phase. This encapsulated form resembles a lesion called a *solitary necrotic nodule of the liver* (Abbey-Toby et al, 2003), and it can be a chronic sequela of an inflammatory process that has partially healed, circumscribed by a fibrotic capsule.

3) *Infiltrating periportal form:* Frequently revealed by jaundice (Venkataraman et al, 2003), this is a poorly demarcated lesion with periportal infiltration on imaging. The lesion is hypointense on T1-weighted sequences and moderately hyperintense on T2-weighted sequences with dilated bile ducts (Venkataraman et al, 2003). A progressive enhancement is seen after injection of gadolinium chelates. Lymphadenopathy can be observed along the hepatoduodenal ligament and in the retroperitoneum, mimicking cholangiocarcinoma (Fig. 79A.15; Chirica et al, 2005). On histology, periportal inflammation is associated with destruction of bile ducts and intrahepatic extension of inflammatory processes.

On gross sections, IPL is tan, usually unencapsulated, and may show indistinct borders with the surrounding parenchyma. When the diagnosis is suspected, a liver biopsy is often necessary to differentiate IPL from other tumors.

The optimal management has not been well established, with many types of treatment described, from simple observation to surgical resection and even liver transplantation (Milias et al, 2009). In the literature, most patients have been surgically treated, because the diagnosis was not made preoperatively because of the possible destructive nature of IPL, or because its malignant potential leads some authors to propose liver resection (Li et al, 1989). The outcome of patients treated surgically is very good (Goldsmith et al, 2009), but IPL can be associated with some risk, especially IPL that occurs as hilar lesions, necessitating major liver resection. Recurrence can be observed after resection (Lopez-Tomassetti Fernandez et al, 2006). However, IPLs are benign lesions with no malignant potential; once the diagnosis has been made, medical treatment by antibiotics, steroids (Maze et al, 1999), or observation can be undertaken with very good results. A number of reports exist that suggest the natural history of these lesions is of spontaneous complete resolution or regression (Levy et al, 2001; Koea et al, 2003; Goldsmith et al, 2009); therefore IPL can be safely managed nonoperatively.

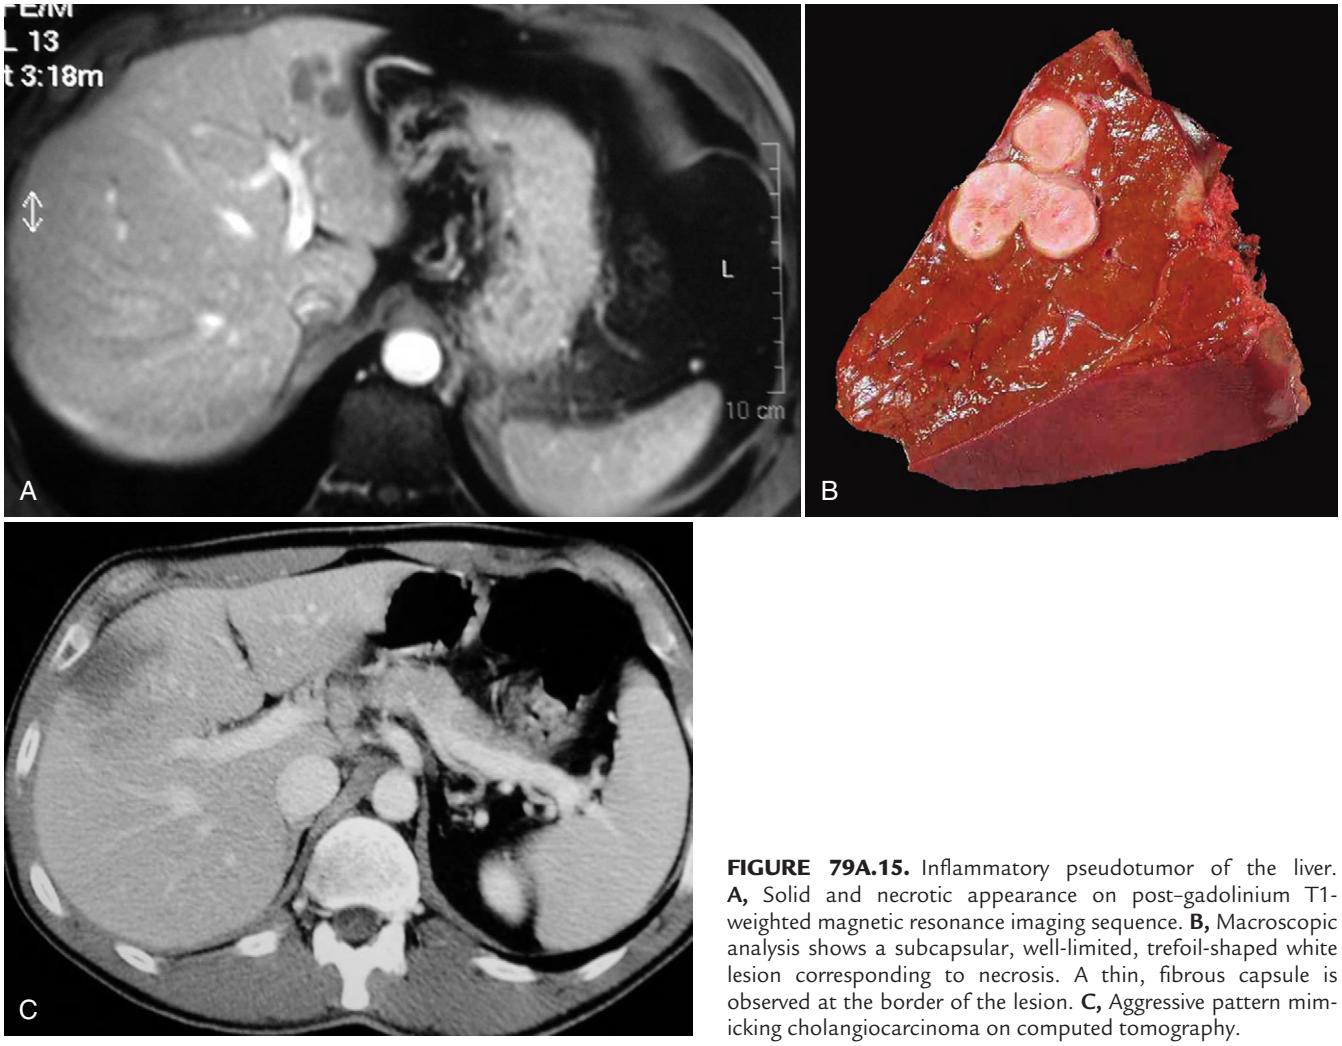

FIGURE 79A.15. Inflammatory pseudotumor of the liver. **A,** Solid and necrotic appearance on post–gadolinium T1-weighted magnetic resonance imaging sequence. **B,** Macroscopic analysis shows a subcapsular, well-limited, trefoil-shaped white lesion corresponding to necrosis. A thin, fibrous capsule is observed at the border of the lesion. **C,** Aggressive pattern mimicking cholangiocarcinoma on computed tomography.

Rare Tumors and Pseudotumors

Solitary Fibrotic Tumor

Also known as a *solitary necrotic tumor,* a *solitary fibrotic tumor* of the liver is rare with only about 100 cases reported in the literature. Slightly more frequent in men, these tumors are found at a mean age of 60 years, and the majority of patients are asymptomatic (Deniz & Coban, 2010). The solitary fibrotic tumor is usually a unique, well-circumscribed, small (<2 cm) lesion (Zhou et al, 2008). Histologically, it is composed in varying degrees of necrosis and fibrosis comprising abundant collagen fibers, and it can contain calcifications. This lesion can mimic liver malignancy, especially metastases (Delis et al, 2009; De Luca et al, 2000).

The etiology of this lesion is still uncertain, but possible causes included thrombi, hemangioma, trauma, and infection, especially parasitic infection such as with a hydatid cyst (Clouston et al, 1993; Deniz & Coban, 2010). On imaging, no findings are characteristic except a progressive enhancement that is related to abundant collagen (Moser et al, 2005), which can be very intense on delayed phase. It is assumed to be benign, but more than half the time, this lesion is associated with extrahepatic malignancy, especially colonic cancer and small metastatic adenocarcinoma; this justifies resection (Deniz & Coban, 2010).

Lymphangioma

Lymphangiomas are benign neoplasms located within the liver parenchyma, regarded as malformations that arise from sequestrations of lymphatic tissue that fail to communicate with the normal lymphatic system during embryogenesis (Weiss et al, 2008). Lymphangiomas are frequently found in the neonatal period and childhood but rarely in adulthood. The occurrence of a solitary lymphangioma in the liver is extremely rare, and very few reported cases—fewer than 10—have been described in the literature (Matsumoto et al, 2010). Contrary to neonatal (Shahi et al, 2009) or childhood cases with symptomatic, large tumors, lymphangiomas are generally small (<4 cm) and asymptomatic in adults. On imaging, this lesion has a solid and cystic component and can contain small peripheral calcifications; histologically, it is composed of vascular lymphatic spaces lined by regular cells. Immunohistochemistry using D2-40, LYVE-1, and Prox-1 are helpful to establish the diagnosis of lymphangioma, as they are able to discriminate between lymphatic and vascular endothelium (Matsumoto et al, 2010).

Leiomyoma

Leiomyomas are very rare, benign liver tumors developed from the smooth muscles of the vessels or bile ducts (Belli et al, 2001;

Urizono et al, 2006) with lesions of variable size. It can be observed in patients with immunosuppression or AIDS (Prévot et al, 1994; Sclabas et al, 2002). On imaging, lesions appear hypoechoic on US and hypoattenuating on CT scan with variable enhancement after injection of contrast material. On MR imaging, leiomyoma is hypointense on T1-weighted sequences and strongly hyperintense on T2-weighted sequences (Santos et al, 2010). Histologic features include spindle-cell proliferation without nuclear atypia, hemorrhage, and necrosis. Immunoreactivity with mesenchymal markers shows positivity of the cell proliferation with vimentin and smooth muscular actin. Because radiologic findings are nonspecific, liver resection is usually recommended.

Heterotopic Tissue

The presence of heterotopic tissue within the liver has been described, and diagnosis is usually established after surgical excision (see Chapter 48). The most frequent is liver splenosis, which corresponds to autotransplantation of splenic tissue; it occurs after traumatic splenic rupture or, less frequently, after surgical rupture during splenectomy (Davidson & Reid, 1997; Labat-Debelleix et al, 2008). Splenosis is asymptomatic, most often localized in the left liver, with a mean size of approximately 4 cm. On imaging, the lesion shows features of a hypervascular tumor but with less enhancement on the delayed phase. These radiologic features make the differential diagnosis with another hypervascular liver tumor very difficult, and this can be misinterpreted in a standard preoperative evaluation as HCC or breast metastatic disease (d'Angelica et al, 1998; Foroudi et al, 1999; Labat-Debelleix et al, 2008; Abu Hilal et al, 2009). Diagnosis can be suspected with scintigraphy using technetium (Tc) 99m–labeled heat-denatured red blood, and it can be established with liver biopsy (Lu et al, 2008; Labat-Debelleix et al, 2008). Other heterotopic tissues include adrenal and pancreatic tissues located around the bile ducts (Suzuki et al, 1999; Heer et al, 2010).

Hepatic Pseudolesions

The development of imaging techniques using thin slices and multiphasic study permits the discovery of many intrahepatic anomalies, especially after injection of contrast material on CT scan and MRI; some anomalies are not really liver lesions but can mimic liver tumors.

1) *Perfusion disorders:* These anomalies are the result of hyperarterialization of a liver segment as a result of decreased or absent portal vein flow. These anomalies are seen on CT after injection of contrast; they predominate on arterial or portal phase images and disappear or attenuate on the delayed phase. These perfusion disorders result from portal obstruction, compression, or arterioportal shunt (Tamura et al, 1997). In general, they have typical straight borders that correspond to segmental or subsegmental locations. The diagnosis can be more difficult in patients with small peripheral or central "pseudonodular" lesions, such as in cirrhotic patients as a result of arterioportal shunts. In patients with hepatic vein obstruction, these abnormalities are not systematized (mosaic form) because of the rapid development of interhepatic venous shunts (Vilgrain et al, 2007).

2) *Localized parenchymal compression:* This can display aspects of pseudolesion because of impaired enhancement in the compressed territory in the portal phase but without hyperarterialization on the arterial phase. In this case, the pseudolesion has no vascular topography and can be exacerbated by deep inspiration with compression by the ribs and diaphragm (Vilgrain et al, 2007).

3) *Confluent fibrosis:* This lesion can also mimic a tumor, and it is mainly observed in chronic liver disease; it corresponds to parenchymal extinction and is located in segments IV and VIII with capsular retraction (Vilgrain et al, 2007).

4) *Radiation:* Pseudolesion of liver parenchyma can be observed after radiation exposure. Previous history of radiation therapy and the appearance of straight borders without anatomic distribution are highly suggestive of this etiology. As a result of associated fibrosis, atrophy of the involved segment can be observed with compensatory hypertrophy (Vilgrain et al, 2007).

Peliosis

Peliosis is a rare condition characterized by multiple, small, blood-filled pools in liver parenchyma that vary from 1 mm to several centimeters without lobular systematization. This lesion results from focal rupture of sinusoidal walls and is mostly observed in adult patients after systemic chemotherapy for colorectal liver metastases using oxaliplatin (Rubbia-Brandt et al, 2010). It can also be associated with androgenic anabolic steroids (Tsirigotis et al, 2007), OC use (Gutiérrez Santiago et al, 2007), HIV infection (Radin & Kanel, 1991), or severe tuberculosis and malignancies such as Hodgkin's lymphoma (Kleger et al, 2009).

Imaging findings often mimic those of true tumors, because lesions are well limited and strongly hyperintense on T2-weighted MR images, and they enhance with arterial phase CT or MR. The persistent contrast uptake within the lesion is due to the blood-pooled condition (Verswijvel et al, 2003). This lesion can lead to extensive fibrosis resulting from parenchymal destruction and collapse (Cavalcanti et al, 1994), which is revealed on histology.

In general, this lesion is asymptomatic, but severe complications such as liver rupture, subsequent bleeding (Choi et al, 2009; Wang et al, 2001; Fidelman et al, 2002), and hepatopulmonary syndrome have been reported (Kallel et al, 2008). Treatment includes withdrawal of the possible causative agents, which can lead to regression of the disease.

Focal Fatty Changes

Hepatic steatosis is generally a diffuse process; however, heterogeneous focal fat distribution seen as spared liver areas, without steatosis, or areas that are fattier than the rest of liver parenchyma may also be present (Wanless, 2002). Although the pathogenesis is not well understood, regional hypoxia of hepatic tissue is thought to play a role (Zeppa et al, 2002). The majority of patients have underlying disease such as diabetes, obesity, hepatitis C, nonalcoholic steatohepatitis, and malnutrition; lesions are often discovered incidentally on imaging studies. Focal steatosis is mainly localized in segment IV, around the gallbladder and the round ligament (Vilgrain et al, 2007). A nodular aspect can mimic liver metastasis (Tom, et al 2004; Rubaltelli et al, 2002).

REGENERATIVE PROCESSES

Nodular Regenerative Hyperplasia

Nodular regenerative hyperplasia (NRH) is a relatively rare, benign, diffuse micronodular transformation of the liver that

has been referred to by many names in the literature, including *nodular transformation*, *noncirrhotic nodulation*, and *partial nodular transformation*. It is a distinct disease entity characterized by diffuse involvement of the liver with nodules composed of hyperplastic hepatocytes, and it should not be confused with the regenerative nodules of cirrhosis or FNH (Federle & Brancatelli, 2001).

The pathogenesis of NRH is not well known, but one of the proposed theories hypothesizes that a primary vascular process leads to obliteration of portal vein, which in turn induces ischemia, atrophy of hepatocytes in the central zone, and the proliferation of hepatocytes (Al-Mukhaizeem et al, 2004). The other theory proposes that a preneoplastic process leads to NRH in association with the reported high prevalence of hepatocyte dysplasia (20% to 42%) and HCC formed in livers of patients with NRH (Nzeako et al, 1996; Dogan et al, 2003). The prevalence of NRH was reported to be around 2% (Biecker et al, 2003).

NRH was classically associated with a wide spectrum of systemic diseases, processes, and drugs; these include myeloproliferative and lymphoproliferative disorders, chronic vascular disorders, rheumatologic and collagen vascular diseases (rheumatoid arthritis, Felty syndrome, polyarteritis nodosa, amyloidosis, and primary biliary cirrhosis) (Morris et al, 2010), primary hypogammaglobulinemia (Malamut et al, 2008), HIV infection (Tateo et al, 2008; Bihl et al 2010), hereditary hemorrhagic telangiectasia (Brenard et al, 2010), hepatoportal sclerosis, congenital absence of the portal vein (Peker et al, 2009), portal veinopathy (Hillaire et al, 2002), malignant disease (Al-Hamoudi et al, 2009), and after solid organ transplantation (Devarbhavi et al, 2007). NRH is also associated with the use of drugs such as steroids (Mortelé & Ros, 2002), azathioprine for inflammatory bowel disease (Vernier-Massouille et al, 2007; Seksik et al, 2010), and chemotherapeutic agents. This lesion is considered the most severe induced histologic liver lesion in patients treated with oxaliplatin-based chemotherapy for colorectal liver metastases, with an incidence up to 24% (Hubert et al, 2007; Wicherts et al, 2010; Rubbia-Brandt et al, 2010); it can be associated with high postoperative morbidity in cases of major liver resection (see Chapter 65).

Clinically, NRH usually causes no symptoms, and lesions are discovered incidentally, mainly on liver biopsy. More than two thirds of reported patients had abnormal liver test results, but liver function was preserved (Arvanitaki & Adler, 2001; Morris et al, 2010); the risk of liver insufficiency leading to liver transplantation is rare (Tateo et al, 2008). The main clinical presentation is portal hypertension, observed in 30% of patients, with subsequent esophageal varices, splenomegaly, and ascites (Arvanitaki & Adler, 2001; Dogan et al, 2003; Morris et al, 2010). Fatal bleeding from varices has been observed (Morris et al, 2010), but the risk of transformation to HCC is rare (Nzeako et al, 1996; Kataoka et al, 2006). Because of these clinical features, the diagnosis of NRH should be considered in patients with clinical signs of portal hypertension and normal or mildly abnormal liver function test results, in whom other causes of portal hypertension have been excluded.

Imaging findings are not specific for NRH. On imaging, three presentations are possible: first, liver imaging is unremarkable; second, imaging shows signs of noncirrhotic portal hypertension without any liver nodules, because the nodules are typically very small; third, NRH appears as multiple liver nodules with or without portal hypertension. In most cases, imaging shows normal hepatic parenchyma. When nodules are seen, they have a variable enhancement, and they are hyperintense on T1-weighted images and isointense or hypointense to normal liver on T2-weighted images (Clouet et al, 1999; Mortelé & Ros, 2002; Casillas et al, 1997; Horita et al, 2002). Contrary to FNH, the central scar is lacking. Differences between these two lesions are mainly based on the presence of multiple small nodules, signs of portal hypertension, and clinical context. Accurate diagnosis should be confirmed with histologic examination prior to treatment. In highly suspicious cases, percutaneous needle biopsy can establish the diagnosis (Hubert et al, 2007). In doubtful cases with negative percutaneous biopsy, open biopsy is indicated to obtain an adequate sample of hepatic tissue, because percutaneous needle biopsies may give falsely normal results (Biecker et al, 2003).

Management depends on the clinical symptoms. In asymptomatic patients, no treatment is recommended. The effect of the withdrawal or specific treatment of the possible causative disease or agents on the course of this entity is not well known. In patients with complications of portal hypertension, appropriate management includes drug therapy, endoscopic therapy, transjugular intrahepatic shunt, or portacaval shunt if necessary (Biecker et al, 2003). Rarely, patients may progress to liver failure and may ultimately require liver transplantation (Trotter & Everson, 2001; Tateo, 2008). Because of the high postoperative morbidity with major liver resection in cases of NRH associated with oxaliplatin-based chemotherapy (Wicherts et al, 2010), it is recommended in this group of patients, who underwent many cycles of preoperative chemotherapy, to perform a liver biopsy—either systematically or in case of portal hypertension—to search for NRH. If NRH is diagnosed, major liver resection should be avoided or prepared for by portal vein embolization.

FNH-like Lesions

FNH-like lesions histopathologically resemble FNH but are seen in patients with liver disease or liver vessel abnormalities. The most common causes of liver diseases responsible for the development of FNH-like lesions are Budd-Chiari syndrome (Cazals-Hatem et al, 2003), hereditary hemorrhagic telangiectasia (Gincul et al, 2008), and congenital hepatic fibrosis (Vilgrain et al, 1999; Zeitoun et al, 2004; Buscarini et al, 2004). All these diseases induce severe liver flow alterations with decreased portal vein blood flow and marked increased hepatic artery blood flow (Kim et al, 2004; Bureau et al, 2004). FNH-like lesions may be a hepatic response to increased arterial inflow. Similarly, FNH-like lesions have been reported in patients with cavernous transformation of the portal vein (Bureau et al, 2004); imaging findings of FNH-like lesions are similar to the FNH that arises on normal liver, and they may contain a central scar. Because the liver signal is abnormal in Budd-Chiari syndrome, the FNH-like lesions are mostly hyperintense on T1- and hypointense on T2-weighted images; however, they still enhance strongly at the arterial phase. Unlike most FNH, they may become more numerous and grow over time.

CHAPTER 80

Hepatocellular carcinoma

Alejandro Forner, Maria E. Reig, Carlos Rodriguez De Lopes, and Jordi Bruix

OVERVIEW

Hepatocellular carcinoma (HCC) is the most common primary liver tumor. It currently represents the sixth most common cancer worldwide and is the third major case of cancer death. Its incidence presents marked geographic differences (Table 80.1; Ferlay et al, 2010). Asia and sub-Saharan Africa constitute high-risk areas with yearly rates exceeding 20 per 100,000 population. Southern Europe and Japan have intermediate rates, and rates are low in Northern Europe and North America (Bosch et al, 2004; El-Serag, 2004; Ferlay et al, 2010). Several registries have shown that the incidence figures have changed slightly during the past several years. Vaccination plans against hepatitis B virus (HBV) and improvement in health standards have decreased the incidence in some high-risk areas, such as Taiwan (Chang et al, 1997; see Chapter 64). The incidence is decreasing in Japan, where the risk of HCC is linked significantly to chronic infection with hepatitis C virus (HCV) that was acquired decades ago, when health care was less concerned by blood-borne viral disease. By contrast, HCC incidence is increasing in the United States (El-Serag & Mason, 1999) and in Northern Europe (Bosch et al, 2004), probably reflecting the different timing in the appearance of risk factors, mostly HCV infection (Tanaka et al, 2002; see Chapter 64). Another major risk factor for HCC is alcohol intake, and this also varies widely in different countries (Morgan et al, 2004). Aflatoxin B1 uptake (Colombo & Donato, 2005), cigarette smoking, and heavy alcohol consumption are independent risk factors and may have synergistic effects (Kuper et al, 2000; see Chapter 64). Finally, recent studies have suggested that coffee intake reduces the risk (Bravi et al, 2007).

In all areas of the world, cirrhosis underlies HCC in almost 90% of the cases (Bruix et al, 2004; Fattovich et al, 2004). Cirrhosis is related to chronic HBV and HCV, which contribute to HCC development in 80% of cases. Alcohol consumption is a frequent cofactor, and surveys indicate that a significant proportion of HCC in cryptogenic cirrhosis is due to nonalcoholic fatty liver disease (Calle et al, 2003; Clark, 2006; El-Serag et al, 2001; Marrero et al, 2005; Regimbeau et al, 2004), a condition associated with diabetes or obesity (Day, 2002; Marchesini et al, 2003; see Chapter 65). Because of the obesity epidemic, this factor may gain greater relevance in the near future. Follow-up studies have disclosed that HCC development is now the most frequent cause of death in patients with cirrhosis (Benvegnu et al, 2004; Degos et al, 2000; Forner et al, 2009; Sangiovanni et al, 2006). Prevention, diagnosis, and treatment of this neoplasm are major areas of clinical and research activity.

The mean annual incidence of HCC in cirrhotic patients in the West is 3% to 4%, and this figure increases in parallel to liver function impairment (Benvegnu et al, 2004; Bolondi et al, 2001; Bruix & Sherman, 2011; Degos et al, 2000; Forner et al, 2009; Sangiovanni et al, 2006). Some specific characteristics have been associated with a higher risk. The most consistent are male sex; advanced age, this being a surrogate for the duration of the underlying liver disease; and increased α-fetoprotein (AFP) concentration (Bruix & Sherman, 2011). HBV and HCV coinfection imply a higher risk (Fattovich et al, 2004).

Data of patients coinfected with the human immunodeficiency virus (HIV) suggest that the incidence of HCC has increased in this population, liver function deteriorates more rapidly, and the HCC appears in younger ages and frequently in symptomatic, advanced stages (Brau et al, 2007) associated with poorer outcome (Puoti et al, 2004). In addition, several authors have reported higher potential of tumoral progression before and after liver transplantation in HIV/HCV-coinfected patients despite similar pathologic findings (Vibert et al, 2011). Further studies are needed to confirm whether HIV coinfection increases the HCC incidence, and if it is an independent prognostic factor. Irregular regeneration, high proliferative stage, and presence of dysplastic foci in biopsy samples also have been correlated with higher HCC incidence during follow-up, but the need for tissue sampling has prevented their robust validation and wide clinical acceptance (Bruix et al, 2004).

Table 80.1

Incidence of Hepatocellular Carcinoma According to Geographic Area and Distribution of Risk Factors

GEOGRAPHIC RISK FACTORS		AGE-ADJUSTED INCIDENCE RATE (%)			
Area	**Male/Female**	**Hepatitis C Virus**	**Hepatitis B Virus**	**Alcohol**	**Other**
Europe		60-70	10-15	20	10
Western Europe	5.8/1.6				
Southern	9.8/3.4				
Northern	2.6/1.3				
North America		50-60	20	20	—
Northern	4.1/1.6				
Southern	4.8/3.6

RISK FACTORS AND PREVENTION

All types of cancer are the consequence of genetic changes that accumulate through time, ultimately conferring a survival advantage to cells with an abnormal phenotype. The relationship between chronic hepatitis and long-lasting liver damage with HCC development suggests that persistent inflammation is a key factor leading to cancer. Maintained injury and repair with high proliferation rate increase the risk for DNA mutation (Arbuthnot & Kew, 2001). In addition to genetic damage secondary to inflammation, HBV itself may have direct genetic or epigenetic effects, being able to integrate into the host genome (Brechot, 2004; Farazi & DePinho, 2006). This integration into the host genome is accompanied by rearrangement and increased mutagenesis that may affect crucial target genes (Farazi & DePinho, 2006; Ferber et al, 2003; Ryu, 2003; Villanueva et al, 2007). HCV is an RNA virus and does not integrate into host DNA (see Chapter 8C).

The most effective prevention of HCC is avoidance of viral infection or of toxin intake. Effective vaccination for HBV exists, and the vaccination plans in Taiwan have shown the efficacy of this action in diminishing cancer rates in children and adults (Chang et al, 1997). Proper controls in health care settings prevent HCV dissemination through blood transmission. Alcohol intake should be the target of health campaigns in the community; in addition, aflatoxin contamination of food can be prevented by avoiding grain storage in humid conditions. The epidemic of obesity with associated nonalcoholic steatohepatitis leading to HCC must be controlled by health education.

If viral infection is already present, it has been shown that a decrease in viral replication and subsequently of chronic hepatic damage could result in a reduced incidence of HCC in the long term (Liaw et al, 2004). Effective therapy is available for HBV and HCV, and prevention may be feasible for both agents; however, if chronic liver disease already has caused cirrhosis, it is unclear whether antiviral therapy has any preventive capacity, because cell damage and transformation may already be present (Bruno et al, 2007). Recent studies have shown that long-term interferon administration in does not reduce the risk of HCC in patients with cirrhosis (Bruix et al, 2011; Di Bisceglie et al, 2008). In patients with HBV infection, the genetic damage may occur in the absence of major liver insult, and this would explain the appearance of HCC in an otherwise healthy liver (Pollicino et al, 2004). This circumstance is more frequent in areas where viral transmission occurs early after birth or in childhood, stressing the benefits of HBV vaccination. Secondary prevention in patients with chronic liver disease requires the prior recognition of affected individuals, but currently no proof of the cost-effectiveness of population screening for viral liver disease has been offered, and this is not recommended (Bruix & Sherman, 2005; see Chapter 64).

SCREENING AND RECALL OF HIGH-RISK INDIVIDUALS

A single randomized controlled trial performed in China recruited HBV patients to compare screening versus no screening; it showed the positive impact of screening on survival (Zhang & Yang, 1999). Unfortunately, such proof of efficacy is lacking in the West, and the establishment of surveillance for HCC in patients with cirrhosis is based on expert opinion (Bruix & Sherman, 2011; Bruix et al, 2001). The aim of screening is to detect HCC at an early stage, when the tumor is potentially curable (Bruix & Sherman, 2011; Forner et al, 2010).

Success of screening depends on several factors that include adequate ultrasound (US) performance, accurate diagnostic and staging criteria, and timely availability of curative treatments. If these requirements are not met, screening will never result in an increase of life expectancy. Even when accounting for the potential lead-time bias (i.e., patients apparently survive longer simply because their tumors were diagnosed earlier) and length-time bias (i.e., the interval between screenings misses the more aggressive tumors that will be detected when symptoms appear), it is assumed that screening results in more frequent detection of early stage HCC with more common application of effective treatment and improved outcome (Sangiovanni et al, 2004).

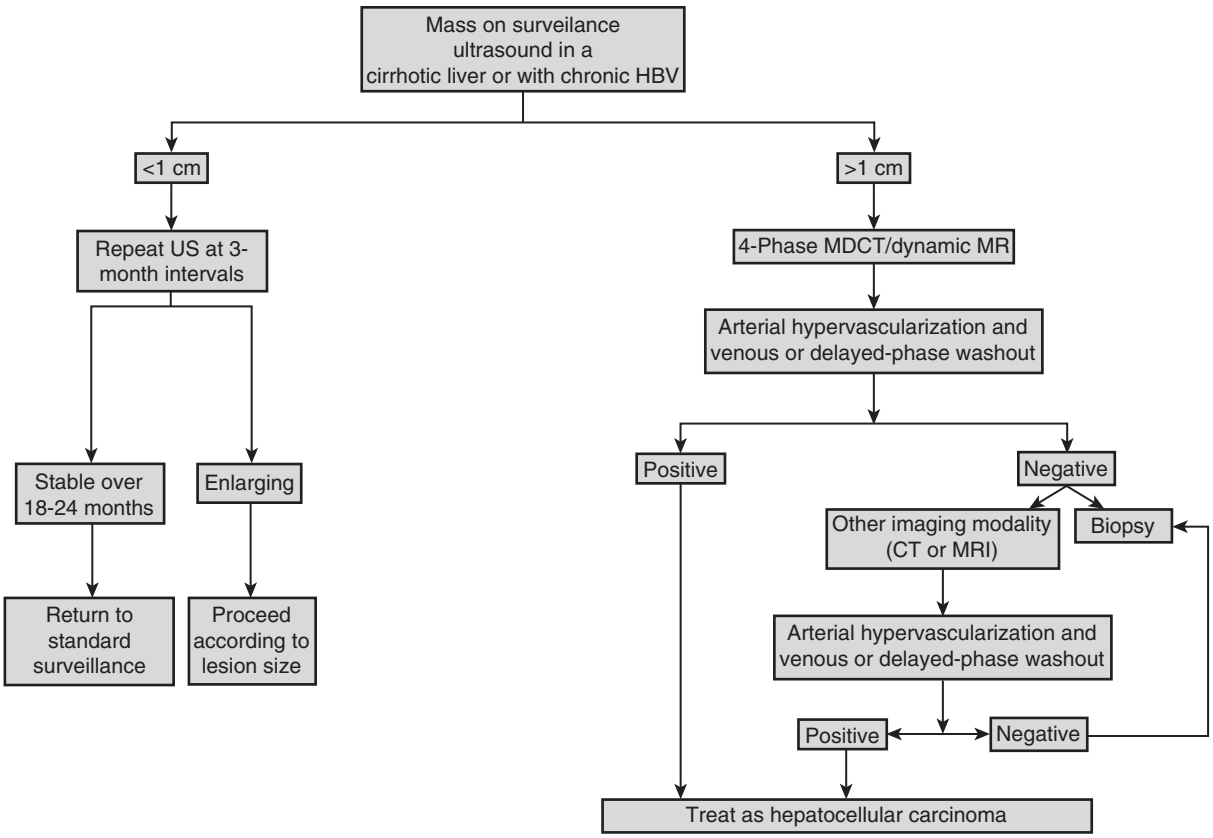

FIGURE 80.1. Screening strategy as proposed in the American Association for the Study of Liver Diseases Practice Guidelines. CT, computed tomography; HBV, hepatitis B virus; MDCT, multidetector computed tomography; MR, magnetic resonance; MRI, MR imaging; US, ultrasound. *(From Bruix J, Sherman M, 2011: Management of hepatocellular carcinoma: an update. Hepatology 53:1020-1022.)*

Effective treatment of HCC and long-term cure are feasible only with early detection; diagnosis at the symptomatic stage reflects an advanced stage and lack of effective treatment. Based on these arguments, the European Association for the Study of the Liver (EASL) panel of experts suggested abdominal US scanning and AFP measurements every 6 months for patients with liver cirrhosis who would be treated if diagnosed with HCC (Bruix et al, 2001). Because of the suboptimal accuracy of AFP (Marrero et al, 2009; Trevisani et al, 2001), the determination of this marker is no longer recommended, and screening is currently based on regular US (Bruix & Sherman, 2011). The screening recommendation excludes patients with severe associated conditions and those with advanced liver disease who are already candidates for transplantation. If this is not an option, screening for HCC aiming to detect early tumor will never be followed by treatment, and it makes no clinical sense.

On detection of an abnormal finding, patients must be evaluated. Figure 80.1 depicts the recall strategy proposed by the American Association for the Study of Liver Diseases (AASLD) panel, and Box 80.1 summarizes proposed diagnostic criteria (Bruix & Sherman, 2011). Nodules measuring less than 1 cm in a cirrhotic liver may not correspond to a malignant focus in more than 60% of cases (Forner et al, 2008); even so, confident diagnosis is difficult with current diagnostic tools. Close follow-up to detect any increase in size is therefore recommended (Bruix & Sherman, 2005). Nodules in a cirrhotic liver that are larger than 1 cm can be diagnosed as HCC if the vascular profile on imaging techniques is characteristic of this neoplasm—that is, intense contrast uptake is seen in the arterial phase followed by contrast washout in the delayed venous phase (Bruix & Sherman, 2005; see Chapters 16 and 17). In a tumor larger than 1 cm in diameter, a single dynamic imaging technique can establish the diagnosis (e.g., computed tomography [CT] or magnetic resonance imaging [MRI]; Fig. 80.2). Contrast ultrasound is no longer recommended because it is not able to differentiate cholangiocarcinoma from HCC (Chen 2010; Vilana 2010). If the characteristic dynamic profile is not recognized by imaging techniques, it is recommended that the

Box 80.1

Diagnostic Criteria for Hepatocellular Carcinoma

Cytohistologic criteria
Noninvasive criteria (cirrhotic patients)
Focal lesion >2 cm: one imaging technique (e.g., dynamic computed tomography, magnetic resonance imaging) with arterial hypervascularization and venous washout

From Bruix J, Sherman M, 2011: Management of hepatocellular carcinoma: an update. Hepatology 53:1020-1022.

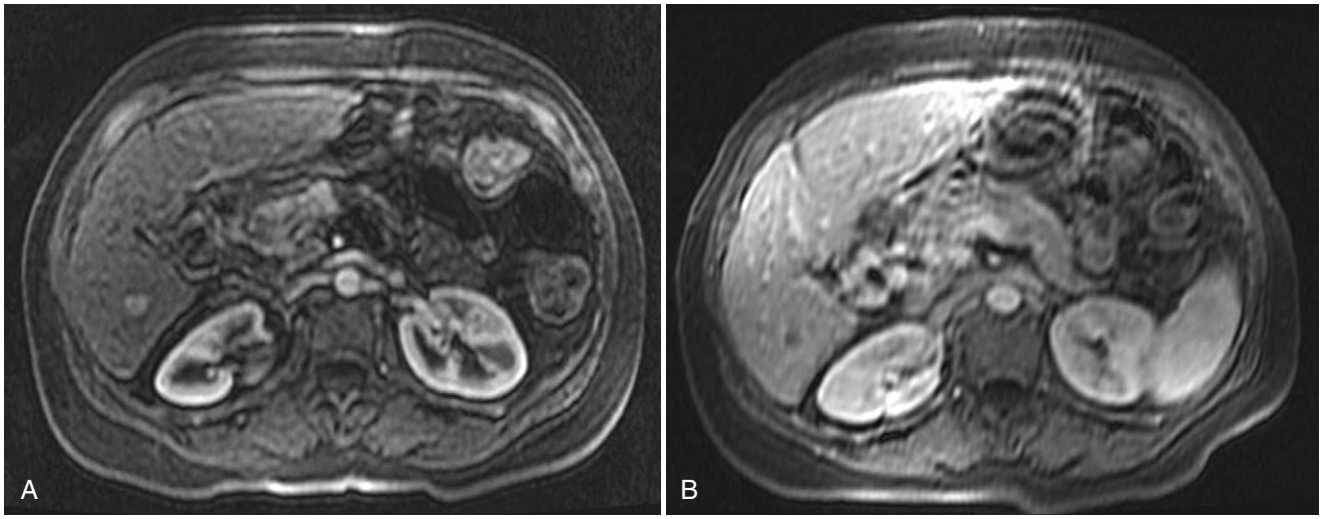

FIGURE 80.2. A, Magnetic resonance imaging depicts a small nodule with arterial enhancement after contrast administration. **B,** The nodule exhibits washout of the contrast material in the venous phase, the characteristic pattern of hepatocellular carcinoma. *(Courtesy Dr. Carmen Ayuso.)*

diagnosis be based on fine needle biopsy (Fig. 80.3; see Chapter 20). This is so even in the presence of increased AFP values, because cholangiocarcinoma and hepatic metastases may produce AFP (Bruix & Sherman, 2011; Rimola et al, 2009). It must be stressed that biopsy is not 100% sensitive, hence a negative result does not exclude HCC (Forner et al, 2008). Tumor staging is done through spiral CT and MRI (see Chapters 13, 16, and 17); MRI is the most sensitive to detect nodules smaller than 2 cm (Burrel et al, 2003). The technical advances in these techniques have made angiography unnecessary for diagnosis and staging (see Chapter 19). Other tumor markers, such as protein induced by vitamin K absence (Marrero et al, 2009), glypican-3 (Capurro et al, 2003), and AFP fractions (Marrero et al, 2009), have been proposed to be used alone or in combination with AFP, but their usefulness in routine clinical practice has not been established (Bruix & Sherman, 2011).

FIGURE 80.3. Small nodule measuring >2 cm located in the right lobe. The nodule is heterogeneous and appears as a thin, hypoechoic capsule. Fine needle aspiration biopsy established the diagnosis of hepatocellular carcinoma. Early detection of this small tumor allows effective therapy to be initiated. *(Courtesy Dr. Luis Bianchi.)*

STAGING AND PROGNOSTIC EVALUATION

Staging systems are crucial tools to stratify patients into different subgroups according to prognosis. Ideally, they should establish a link with treatment and predict outcome after therapy. A well-validated and internationally accepted staging system is lacking for HCC. In most tumors, the prognosis is related mainly to tumor stage at the time of diagnosis. The presence of underlying liver disease makes prognostic evaluation of patients with HCC more complex, because liver disease influences outcome and the possibility of treatment (see Chapters 2 and 70). This must take into account tumor stage and liver function and explains why one-dimensional systems taking into account one of the two aspects have no power to predict outcome or to establish the best treatment (Forner et al, 2010). This is the case for the tumor-node-metastasis (TNM) system used by the American Joint Commission on Cancer (2002) and the Child-Turcotte-Pugh (CTP) classification (Pugh et al, 1973). Despite several modifications over time, the TNM system is still not valid, because it relies predominantly on pathologic findings. Combination with a rough assessment of the underlying liver status (cirrhosis versus no cirrhosis; Vauthey et al, 2002) offers some advantages, but it still lacks accuracy to predict prognosis in nonsurgical cases.

The Okuda classification is based on rough assessment of tumor burden, either on imaging or by surgery, and liver function. It stratifies patients into three groups with different outcomes (Okuda et al, 1985), but its main capacity is to identify end-stage patients. Several additional scoring systems have been proposed in Uganda (Primack et al, 1975), the United States (Stuart et al, 1996), Barcelona (Calvet et al, 1990), France (Bonnetain et al, 2008; Chevret et al, 1999), Italy (1998), Austria (Schoniger-Hekele et al, 2001), Hong Kong (Leung et al, 2002), and Japan (Kudo et al, 2003; Omagari et al, 2004; Tateishi et al, 2005; Table 80.2). The relevant prognostic parameters are not the same in all systems, and despite their capacity to stratify subjects, none of them has shown transportability; that is, strata of patients do not have the same survival in different settings. The major usefulness of

Table 80.2

Prognostic Scores Proposed for Stratification of Hepatocellular Carcinoma Patients According to Expected Outcome

these systems is the identification of end-stage patients with a poor prognosis, but none of these systems provides any link to treatment indication. This lack of reproducibility indicates major heterogeneity among the different studies, and no widely accepted universal scoring and staging system is currently available.

The Barcelona Clinic Liver Cancer (BCLC) Staging Strategy avoids the use of a single scoring system for all patients. Instead, it divides patients into four major groups: 1) *very early/early,* 2) *intermediate,* 3) *advanced,* and 4) *end stage*. It then develops a prognostic model within each group, taking into account the impact of treatment (Fig. 80.4; Forner et al, 2010, 2012; Llovet et al, 1999a). This model was constructed based on the results obtained in the setting of several cohort studies and randomized controlled trials. The proposal constitutes a regularly updated staging classification derived from the combination of the data of several independent prognostic studies in different disease stages and treatments. Because it links staging with treatment indication, it has become a widely used clinical tool for treatment decision making (Bruix & Sherman, 2011; Llovet et al, 2008b). It considers variables related to tumor stage, liver functional status, physical status, and cancer-related symptoms. Patients at an early stage present with solitary tumors (usually <5 cm) or two or three nodules (none >3 cm). Depending on the degree of liver function impairment, patients may benefit from curative therapies, such as resection, transplantation, or percutaneous ablation (see Chapters 83, 85, 90, and 97D). The 5-year survival ranges from 50% to 70%. The intermediate stage comprises patients with large or multifocal tumors with preserved liver function and no cancer-related symptoms or vascular invasion. The only treatment that has shown survival benefit is transarterial chemoembolization, which achieved a 50% survival at 3 years. Patients at an advanced stage have cancer-related symptoms, vascular invasion, or extrahepatic spread, and their median survival is less than 1 year. They may benefit from sorafenib treatment, the sole agent that has been confirmed to improve the survival of HCC patients (see Chapter 88). Finally, end-stage patients have major impairment of liver function or major cancer-related symptoms with severe deterioration of physical condition as reflected by a performance status (PS) greater than 2. Their short-term prognosis is poor, and they should receive palliative care (Forner et al, 2010).

TREATMENT STRATEGY

The selection of the best treatment in patients with HCC is the result of the evaluation of several factors, the most relevant among which are the status of the underlying liver and the tumor stage. Accurate definition of the status of the nontumor liver is crucial. The few patients in whom HCC appears in a noncirrhotic liver are good candidates for liver resection (see Chapter 90). Major lobectomies are well tolerated, and resection is the first-line option (Llovet et al, 2005). By contrast, in most patients, cirrhosis underlies HCC, and the degree of functional impairment may preclude safe surgery. In these patients, the first-line treatment should be liver transplantation (see Chapter 97D); if this is not feasible, these patients should be considered for percutaneous ablation through any of the available techniques: ethanol injection, radiofrequency, cryotherapy, or microwave (see Chapters 83, 84A, and 85). These options are thought to offer potential long-term cure (Forner et al, 2010). The sole palliative approaches that have been shown to have a positive impact in survival are transarterial chemoembolization (TACE) (Forner 2012; Llovet & Bruix, 2003; see Chapter 83) and sorafenib administration (Cheng et al, 2009; Llovet et al, 2008a; see Chapter 88). Most of these approaches are discussed in other chapters; we briefly discuss the Barcelona strategy to select the best option for each patient (see Fig. 80.4).

Liver function is assessed initially through the CTP classification, and this is combined with a detailed evaluation of tumor extent (Forner et al, 2010; see Chapters 2 and 70). This assessment has to search for the presence of daughter nodules, vascular invasion, extrahepatic disease, and portal vein thrombosis.

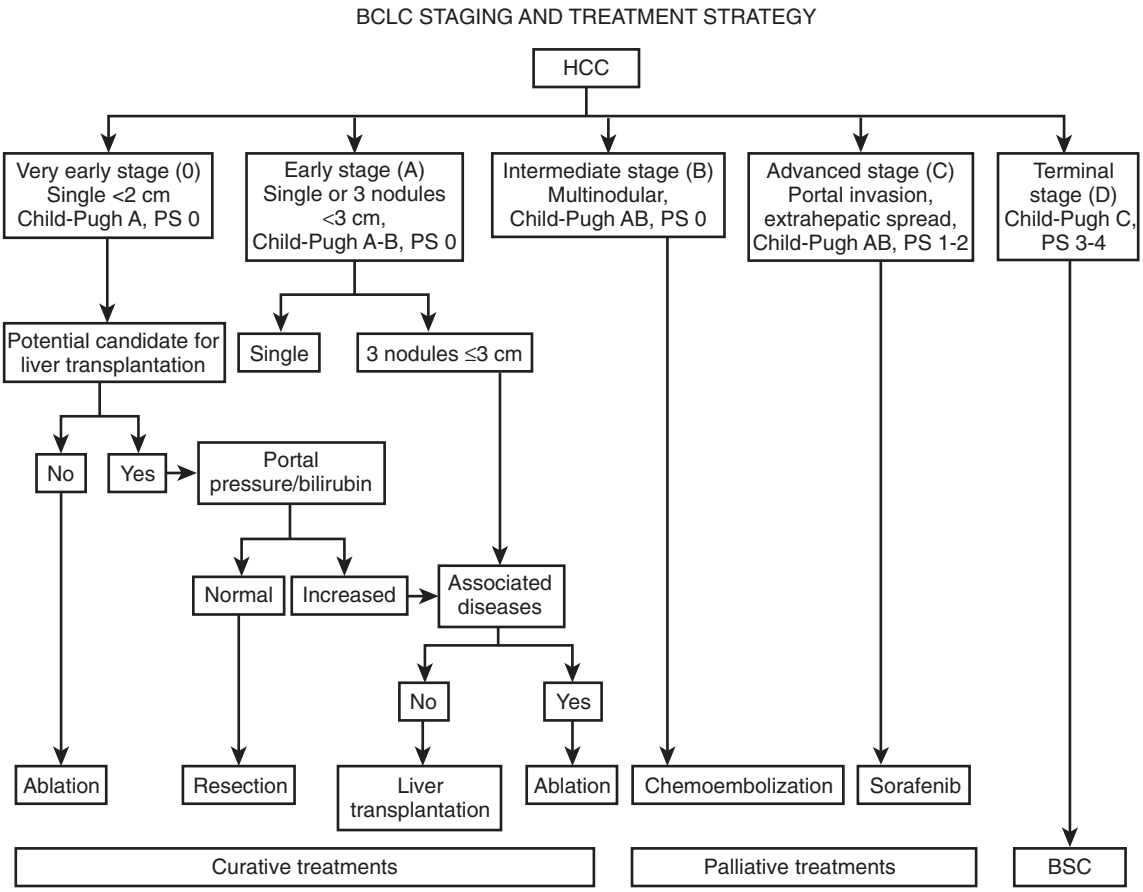

FIGURE 80.4. Staging system and treatment strategy according to the Barcelona Clinic Liver Cancer criteria. Patients are stratified according to clinical, tumor, and biochemical characteristics into four major groups: 1) *early,* 2) *intermediate,* 3) *advanced,* and 4) *terminal.* Treatment selection is decided according to stage allocation. HCC, hepatocellular carcinoma; PEI, percutaneous ethanol injection; PS, performance status; PST, PS test; RF, radiofrequency. *(Modified from Forner A, et al, 2010: Current strategy for staging and treatment: the BCLC update and future prospects. Semin Liver Dis 30:61-74.)*

Extrahepatic disease is ruled out by chest CT scan and bone scintigraphy. The general condition of the patient not only includes consideration of comorbid conditions that may increase perioperative or intervention-related morbidity and mortality but also the assessment of cancer-related symptoms as reflected by performance status (Sorensen et al, 1993). This provides an evaluation similar to the Karnofsky index (Schag et al, 1984) but simpler. Heavily affected patients (PS 3 to 4) belong in a terminal disease stage and should receive palliative treatment.

Liver resection (see Chapter 90) is the first-line treatment in patients with solitary tumors who do not present with underlying cirrhosis and in patients with HCC in well-compensated cirrhosis (Belghiti et al, 2002; Forner et al, 2010). This status cannot be assessed through the CTP classification. Only patients with normal bilirubin concentration and an absence of clinically relevant portal hypertension should be considered optimal candidates for resection (Llovet et al, 1999b). These patients tolerate the intervention without risk of hepatic decompensation, and survival at 5 years is approximately 70%. Hepatic vein catheterization is the most accurate tool to measure portal pressure, and a hepatic pressure gradient less than 10 mm Hg is the best cutoff value. Patients with portal hypertension are at high risk of liver decompensation and death after surgery, and their survival at 5 years drops to 50% (Ishizawa et al, 2008; Llovet et al, 1999b).

Liver transplant (see Chapter 97) is offered to patients who do not fit the optimal profile for resection, and the best candidates are those with solitary tumors less than 5 cm, or those with two or three nodules, each less than 3 cm (Mazzaferro et al, 1996). Vascular invasion and extrahepatic dissemination should be ruled out, and patients should not have general contraindications for liver transplantation. Percutaneous treatment is proposed if expected waiting time exceeds 6 months, and all patients also are proposed to enter the live donor program (Sala et al, 2004b; see Chapters 97D and 98B).

If patients are not candidates for surgery, they are offered percutaneous ablation (Forner et al, 2010). Radiofrequency ablation (RFA) is the main technique, but ethanol injection can be used in the presence of contraindications for RFA, such as tumor in a subcapsular location or in the vicinity of the gallbladder or heart. The best results of ablation are achieved in solitary tumors smaller than 2 cm, where these techniques may achieve complete necrosis, and recurrence rates are similar to resection in 90% of the cases (Livraghi et al, 2008; Sala et al, 2004a). Accordingly, ablation may compete with resection in patients with solitary nodules smaller than 2 cm and it has become the preferred treatment option in patients with HCC at a very early stage who are not potential candidates for liver transplantation (Forner et al, 2012).

Patients with more advanced disease (large or multifocal HCC) without portal vein invasion are candidates for TACE

(see Chapter 83), if liver function is preserved, and they are still free of cancer-related symptoms. Response to this locoregional approach is associated with improved survival, and it is the sole locoregional palliative therapy that has a statistically significant impact on outcome at this stage of the disease (Llovet & Bruix, 2003; Llovet et al, 2002; Lo et al, 2002). If chemoembolization is not feasible, but patients still have preserved liver function (CTP class A or B) without major cancer-related symptoms, they should be considered for sorafenib administration (see Chapter 88). Current trials explore the combination of other molecular therapies with sorafenib and the usefulness of second-line alternatives. If patients are diagnosed at a terminal stage, identified by severe liver function deterioration (CTP class C), and the extent of the tumor prevents transplantation and has induced severe cancer-related symptoms (performance status >2), patients are offered palliative care.

FUTURE PROSPECTS

Major research in recent years has been devoted to allowing an earlier diagnosis of HCC and more accurate staging at the time of diagnosis. The improvements in treatment have had a minor impact, because most patients still are diagnosed at an advanced stage, when there is no option for long-term cure. Most of the effective treatments available today should be considered invasive, and it is hoped that active laboratory research translates into new instruments to predict the biology of the tumor and identify new treatment targets. As happened years ago in breast cancer (Perou et al, 2000; Somiari et al, 2003; van de Vijver et al, 2002), prostate cancer (Dhanasekaran et al, 2001; Grubb et al, 2003), lung cancer (Yanagisawa et al, 2003), non-Hodgkin B lymphoma (Alizadeh et al, 2000), and melanoma (Bittner et al, 2000), this is now a reality in HCC; additional molecular profiling is evolving, using gene or protein profiling (Boyault et al, 2007; Chiang et al, 2008; Hoshida et al, 2008) that will further affect how we face diagnosis, evaluation, and treatment of patients with liver cancer (Hoshida et al, 2010; Villanueva et al, 2010).

SUMMARY

The incidence of HCC has a marked geographic heterogeneity. Although years ago HCC was considered an infrequent neoplasm in Europe and North America, more recent epidemiologic surveys have shown that its incidence in these areas has increased significantly. HCC is associated with chronic liver diseases, usually related to viral infection or toxic agents, such as alcohol. Despite major advances in detection, diagnosis, and treatment, only a few patients currently are diagnosed at early stages and become candidates for treatments that offer potential long-term cure: resection, transplantation, and percutaneous ablation. Most patients with this malignancy still are diagnosed at an intermediate or advanced stage, such that the only therapies that have been shown to offer a significant survival benefit are TACE and sorafenib administration, but these can be applied in only a few cases. Better detection and diagnostic strategies are urgently needed, aimed at increasing the proportion of patients diagnosed at an early stage who could receive effective therapy. In addition, active translational research should help to develop new therapeutic tools that could result in a significant improvement of the long-term survival of patients diagnosed at advanced stages.

CHAPTER 81A

Metastatic malignant liver tumors: colorectal cancer

Jordan Winter and Rebecca Ann C. Auer

OVERVIEW

The liver is the most common site for hematogenous metastasis from colorectal cancers (CRCs). One quarter of patients with primary colorectal carcinoma present with synchronous hepatic metastasis, and nearly half of the patients resected of their colorectal primary will eventually develop metachronous liver metastasis (Bozzetti et al, 1987; Ekberg et al, 1987). In patients with isolated hepatic metastases, the extent of liver disease is the principal determinant of survival, and when left untreated, survival is measured in months (Norstein & Silen, 1997). Despite recent improvements in regional therapies, systemic chemotherapies, and biologic agents, survival is rarely over 3 years in the absence of surgical intervention (Table 81A.1).

Over the past 3 decades, surgery has been clearly demonstrated to be a safe and potentially curative modality in the treatment of colorectal metastases to the liver. The current 5-year survival following a margin-negative hepatic resection is 40%, with a 10-year survival approaching 20%. Although no prospective randomized trials comparing liver resection to systemic, regional, or other local therapies have been performed, the outcome for patients after liver resection for metastatic CRC is sufficiently favorable that surgery is now considered the primary therapy in selected patients (Pawlik & Choti, 2007; Ito et al, 2010).

This chapter will review the data supporting the use of liver resection in the treatment for metastatic colorectal carcinoma. It will review the most 1recent studies describing patient outcomes after hepatic resection. Specifically, current results with operative morbidity, operative mortality, and long-term survival after liver resection are presented. We review current staging systems and discuss the role of various imaging modalities in the preoperative patient; controversies are discussed, such as resection of extrahepatic metastases; and we review a number of systemic medical and biologic therapies that have been approved in the past 2 decades for use in CRC and address their effectiveness in the adjuvant setting.

NATURAL HISTORY OF METASTASES FROM COLORECTAL CANCER

Invasive CRC principally spreads through two mechanisms: cancer cells can metastasize to regional lymph nodes and then through central lymphatics into the systemic circulation, or they can spread directly to the liver via portal venous drainage (Knosel et al, 2004). This has been tested experimentally for CRC. In one study, investigators measured circulating transcripts of guanylyl cyclase C as a surrogate marker for circulating tumor cells and detected these two mechanisms at work in patients. During surgery for stage I or stage II primary CRC, circulating cancer cells were more frequently detectable in the portal blood as opposed to in the periphery, suggesting that the portal route may be more important in early stage patients; however, in some patients with documented lymph node spread, circulating cells were evident in peripheral blood samples but not in the portal blood (Tien et al, 2002).

When cancer spreads through the portal system, the liver acts effectively as a filter and minimizes or even prevents spread to distant sites (Picardo et al, 1998; Wang et al, 2004). At a cellular level, this process has been imaged through the labeling of cancer cells with green fluorescent protein, transplanting them into the ascending colon in mice. In this model, metastatic foci in the liver emerge within days after transplantation (Wang et al, 2004). The importance of portal spread is further validated by clinical data. Liver metastases were not observed in patients with cirrhosis (0 of 40 patients) but were observed in patients without cirrhosis (46 of 210, $P < .001$) in a Japanese study. The authors speculated that decreased portal flow to liver parenchyma in cirrhotic patients accounted for this phenomenon (Uetsuji et al, 1992).

It is unclear why some cancers spread via lymphatics and others spread via the portal circulation, although some theories based on experimental data have been suggested. One study found that in colon primaries, tumors located on the mesenteric side of the colon had a higher rate of lymph node spread than those on the antimesenteric side (207 cases, 51% vs. 30%; $P = .004$), probably related to the distribution and density of lymphatic vessels in the mesocolon (Boni et al, 2007). A separate group analyzed chromosomal copy number in primary and metastatic cancer foci using comparative genomic hybridization and found that certain reproducible allelic losses or gains were observed in hematogenous deposits, as compared with lymph node metastases.

The outcome of untreated metastatic CRC to the liver has been well documented in the older metastatic CRC literature and has been summarized in detail elsewhere (Norstein & Silen, 1997). The median survival of untreated CRC with synchronous liver metastases is just 5 to 10 months, and 3-year survival is very unusual. Survival at 5 years is essentially limited to patients who are seen initially with solitary liver metastases.

The extent of liver disease is an important determinant of prognosis. In a highly cited retrospective study by Wood and colleagues, 113 patients from the Glasgow Royal Infirmary with stage IV CRC were followed. The 1-year survival rate was 5.7% in the setting of widespread liver disease, 27% for those with metastases localized to a single segment or lobe of the liver, and 60% for patients with a solitary metastasis (Norstein & Silen, 1997). The patients with solitary metastases had a 3-year

Table 81A.1

Natural History of Liver Metastasis from Colorectal Cancer

Study	No. Patients	MEDIAN SURVIVAL			
		Mean (mo)	1 Year (%)	3 Years (%)	5 Years (%)
Bengmark & Hafstrom, 1969	40	–	5.7	0	0
Cady et al, 1970	269	13	–	–	–
Oxley & Ellis, 1969	112	–	27	4	1
Wood et al, 1976	113	6.6	15	3	1
Bengtsson et al, 1981	25	–	–	–	–

Scheele et al, 1990	921	–	–	9	0
Stangl et al, 1994	484	7.5	–	–	1
Rougier et al, 1995	318	5.7	–	–	–

survival of 13% and a median survival of 17 months. A similar study by Wagner and colleagues (1984) found that 20% of patients who had an unresected solitary liver lesion lived 3 years.

The authors of these two retrospective natural history studies attempted to distinguish potentially resectable disease from unresectable disease and determined that the survival was substantially better in the former. In the study by Wood and colleagues (1976), 13 patients were believed to have had resectable disease; the 1-, 3-, and 5-year survival of these untreated patients were 77%, 23%, and 8%, respectively, compared with 15%, 0%, and 0% for the unresectable group. Similarly, Wagner and colleagues (1984) reported 3- and 5-year survivals for untreated resectable disease of 14% and 2%, respectively, compared with 4% and 0% for patients with unresectable disease. Notably, even patients with resectable, solitary liver metastases consistently have very poor long-term survival (<10%).

RESULTS OF RESECTION FOR COLORECTAL LIVER METASTASES

The stepwise spread of cancer from primary site to liver through the portal circulation, and from the liver to other organs, provides an opportunity to prevent dissemination of tumor to other sites by direct treatment of hepatic metastases. In addition, the remarkable ability of the liver to regenerate after hepatic resection has enabled aggressive surgical options for hepatic metastases. In patients with normal hepatic reserve, removal of up to 80% of the liver is possible, and regeneration largely occurs in the first few weeks.

Long-Term Results

Since the studies of Wood and Wagner and colleagues, numerous large, single institutional and multicenter reports from around the world have demonstrated that liver resection is safe and results in long-term survival (Table 81A.2). In recent series, 5-year survival rates approach 40%, and median survival exceeds 40 months (Fong et al, 1999; Choti et al, 2002); this represents a dramatic improvement from the seminal study by Foster (1978) on liver resection, when the reported 5-year survival was 20%.

Based on the favorable data reported by these studies, liver resection has now become the standard treatment for metastatic lesions from colorectal primaries. Even in the premodern

chemotherapy era—in studies from the 1990s, before FOLFOX and FOLFIRI were given routinely—long-term survival in patients undergoing resection for metastatic disease far exceeded the survival of unresected patients. This improvement in survival was striking, even in patients with unresectable, low-volume metastatic disease: 20% to 40% 5-year survival with metastasectomy versus less than 10% for patients with unresected solitary metastases.

With newer multimodal treatments and careful patient selection, it is anticipated that 5-year survival approaching 70% can be achieved after resection (Nikfarjam et al, 2009), and comparable outcomes are likely to be reported in larger studies in the near future. Many patients with CRC at stage IV are cured by surgery. A recent review of actual 10-year survivors indicated that one third of actual 5-year survivors will eventually succumb to a cancer-related death; however, 10-year survival is tantamount to a cure in all but the rarest cases (<1%) (Tomlinson et al, 2007).

No prospective, randomized trials have been done that directly compare surgery with nonoperative therapy for metastatic CRC, and such a trial is unlikely to ever occur. The strikingly favorable outcome for surgical patients in retrospective studies compared with patients managed nonoperatively renders such a trial unethical.

Outcome and Surgical Volume

A number of studies have correlated perioperative outcome to hospital volume for hepatectomy. Choti and colleagues (1998) and Glasgow and colleagues (1999) used the state registries in Maryland and California, respectively, and found that hepatectomy performed at a high-volume center resulted in improved outcomes. Surgery at high-volume centers was also associated with reductions in perioperative mortality, length of hospital stay, and cost. A recent study by Fong and colleagues (2005) based on a national Medicare database provides further support for superior outcomes at high-volume centers. The authors demonstrated that perioperative outcome correlated with the expertise of the institution, and the survival advantage persisted after the perioperative period. These data lend support to the concept of regionalization of hepatectomy to high-volume centers.

MEDICAL TREATMENT OF METASTATIC COLORECTAL DISEASE TO THE LIVER

Over the past 3 decades, the most widely used chemotherapeutic agent in the treatment of metastatic CRC has been 5-fluorouracil (5-FU), used either alone or in combination with other chemotherapies. Randomized clinical trials and meta-analyses in advanced CRC during the 1980s and 1990s established that 5-FU was best administered in combination with leucovorin (LV) and that 5-FU should be given as a continuous infusion over several days, as opposed to a series of daily bolus injections (ACCMAP, 1992; D'Angelica et al, 2002; de Gramont et al, 1997; MAGIC, 1998). Tumor response rates with the optimized 5-FU/LV dosing regimen reached 30%, with a median survival around 12 months. This response rate was a substantial improvement over what had been previously reported for 5-FU alone (10% to 15%), although the overall survival rates were similar (ACCMAP, 1992; MAGIC, 1998).

In 2000, two studies compared systemic therapy using irinotecan (CPT-11) in combination with 5-FU/LV with 5-FU/LV alone. Patients had stage IV CRC and had not received treatment for their metastatic disease (Douillard et al, 2000; Saltz et al, 2000). In the study by Saltz and colleagues, patients who recived the irinotecan-containing regimen—referred to as the *IFL regimen,* because it used bolus 5-FU—had a longer progression-free survival (PFS; 7.0 vs. 4.3 months), a higher response rate (39% vs. 21%), and a longer overall survival (median, 14.8 months vs. 12.6). Similar results were observed by Douillard and colleagues; in their study, irinotecan was combined with infusional 5-FU/LV (FOLFIRI). Based on these studies, combination therapy using irinotecan, 5-FU, and LV became the standard treatment for unresectable stage IV CRC. Subsequently oxaliplatin plus 5-FU/LV (FOLFOX) was accepted as second effective first-line combination regimen (de Gramont et al, 2000; Goldberg et al, 2004). In the study by de Gramont and colleagues (2000), PFS was 9.0 months versus 6.2 months with 5-FU/LV alone; the response rate was 50.7%, versus 22.3%; overall survival was 16.2 months versus 14.7 months (P = .1). In the study by Goldberg and colleagues (2004), outcomes were consistently superior with FOLFOX, including an overall survival of 19.5 months versus 15.0 months (P = .0001). This latter trial further demonstrated that FOLFOX was superior to a combination regimen consisting of irinotecan and oxaliplatin.

Two randomized controlled trials have compared FOLFOX and FOLFIRI against each other. Both trials concluded that the regimens had similar efficacy for metastatic CRC as a first-line treatment (Tournigand et al, 2004; Colucci et al, 2005). In the study by Tournigand and colleagues, patients were randomized to one of the two regimens and were crossed over to the opposite treatment arm upon progression. Overall survival was 21.5 months and 20.6 months in the FOLFIRI-first and FOLFOX-first treatment arms, respectively (P = .99). Roughly 15% of the patients in the trial became resectable during treatment and underwent metastasectomy. This was a more frequent occurrence in the FOLFIRI-first arm. In the second trial, no crossover was built into the study design, although a high proportion of patients received second-line treatment. The overall survival in the FOLFIRI and FOLFOX arms were 14 and 15 months, respectively (P = .28; Colucci et al, 2005). Secondary surgery was performed in about 5% in each group. Based on these studies, FOLFOX and FOLFIRI are widely considered to be equivelent in the metastatic setting and are generally selected according to the toxicity profile. The FOLFOX regimen is characterized by a higher rate of grade 3 and 4 neurotoxicity (30% vs. 5%) and neutropenia (44% vs. 24%). The FOLFIRI is associated with more nasuea and vomiting (20% vs. 5%), mucositis (10% vs. 0%), and alopecia (50% vs. 20%).

Falcone and colleagues (2007) explored an aggressive regimen with all three chemotherapeutic agents (FOLFOXIRI) and compared this treatment with FOLFIRI, and an increased rate of neutropenia and neurotoxicity was observed with FOLFOXIRI treatment; however, the more aggressive regimen was associated with better PFS (9.8 vs. 6.9 months), response rate (66% vs. 41%), and overall survival (22.6 vs. 16.7 months). In the FOLFOXIRI group, 15% of patients had secondary metastasectomy compared with 6% in the FOLFIRI group (P = .03). The difference was even greater when patients with liver-only disease were considered (36% vs. 12%, P = .02) (Falcone et al, 2007). In the above trials that evaluated the standard first-line combination regimens, the complete response rate was consistently around 5%.

Several small-molecule and antibody therapies have been developed that target growth factors or cell surface receptors important to CRC biology. Bevacizumab (Avastin), for instance, is a monoclonal antibody against vascular endothelial growth factor (VEGF) and has been approved in the first-line treatment of metastatic CRC in combination with 5-FU–based chemotherapy. FDA approval was a response to a study that compared bevacizumab and FOLFIRI to FOLFIRI alone (Hurwitz et al, 2004). The bevacizumab-containing regimen was associated with longer overall survival (median 20.3 vs. 15.6 months, $P < .001$) and a higher response rate (44.8 vs. 34.8%; $P = .004$). Bevacizumab was also evaluated in the context of oxaliplatin-based chemotherapy using either FOLFOX or XELOX (capecitabine and oxaliplatin; Saltz et al, 2008). Although the PFS was superior in the bevacizumab group (9.4 vs. 8.0 months; $P = .0023$), no improvement in overall survival was found (21.3 vs. 19.9 months; P .077). The response rates were the same in both arms (47% vs. 49%; $P = .3$). The pattern of increased PFS with novel biologic agents despite equivalent response rates is a common finding in trials with targeted agents. This phenomenon suggests that targeted therapies may improve PFS through stabilization of disease or perhaps by causing tumor necrosis, which is a confounding factor with conventional Response Evaluation Criteria in Solid Tumors (RECIST) (Tuma, 2006).

Cetuximab (Erbitux) and panitumumab (Vectibix) are both monoclonal antibodies against the epidermal growth factor receptor (EGFR) and are now an important part of the treatment algorithm for unresectable colorectal metastases (Cunningham et al, 2004; Jonker et al, 2007; Van Cutsem et al, 2007). Cetuximab is a chimeric monoclonal antibody approved for treatment of metastatic CRC in combination with irinotecan in patients with disease refractory to irinotecan (Cunningham et al, 2004) or as a single agent in patients who cannot tolerate irinotecan or oxaliplatin (Jonker et al, 2007).

Cunningham and colleagues (2004) established the first indication in their study, which tested the addition of cetuximab to irinotecan-based treatment in patients who were progressing and compared this strategy with cetuximab therapy alone. The response rates in the two groups were 22.9% and 10.8% ($P = .007$), and the times to progression were 4.1 and 1.5 months ($P < .001$), respectively. Overall survival was not significantly different between the two groups (8.6 vs. 6.9 months; $P = .5$; Cunningham et al, 2004). Jonker and colleagues demonstrated that cetuximab montherapy was superior to best supportive care in patients who were unable to take irinotecan or oxaliplatin-based therapy (Jonker et al, 2007). Overall survival was 6.1 months in the cetuximab group compared with 4.6 months in the control group ($P < .001$). The response rate was 8% with cetuximab, and disease stabilization occurred in 31.4% versus 10.9% in the control group ($P < .05$).

Panitumumab is a fully humanized monoclonal antibody and therefore appears to have a lower rate of serious infusion reactions compared with cetuximab (Van Cutsem et al, 2007). Like cetuximab, panitumumab is approved for single-agent therapy in patients who have progressed on standard chemotherapy (Van Cutsem et al, 2007). Patients on panitumumab had an 8-week PFS compared with 7.3 weeks with best supportive care ($P < .0001$), and it was associated with a 10% response rate; however, the overall survival was 7 months in both groups ($P = .99$). Panitumumab was also evaluated as part of a first-line regimen for metastatic CRC, but a benefit was not apparent in the absence of *KRAS* mutation profiling (Hecht et al, 2009). Hecht and colleagues (2009) compared standard FOLFOX or FOLFIRI plus bevacizumab with or without panitumumab. Interestingly, patients receiving panitumumab had significantly inferior progression-free and overall survival compared with the control arms.

Although both cetuximab and panitumumab are antibodies directed against EGFR, there is no evidence that EGFR expression influences response rate; however, there appears to be a strong treatment interaction with both medications, and *KRAS* is mutated in 40% of CRCs (Bos et al, 1987). A prospective trial of first-line treatment comparing FOLFIRI with and without cetuximab demonstrated prolonged PFS in patients with a wild-type *KRAS* in their tumors (Van Cutsem et al, 2009). Similarly, a recent trial evaluating first-line treatment using FOLFOX with and without panitumumab showed prolonged PFS in the setting of wild-type *KRAS*. Those patients with a *KRAS* mutation actually had significantly worse PFS (Douillard et al, 2010). Peeters and colleagues (2010) evaluated FOLFIRI plus panitumumab versus FOLFIRI alone in chemorefractory patients, demonstrating improved PFS with second-line chemotherapy in patients having wild-type *KRAS* tumors. Additionally, when administered as monotherapy as salvage treatment for metastatic CRC, EGFR inhibitors again were only found to be effective in patients with tumors with wild-type *KRAS*. In the two trials described earlier that compared EGFR inhibitor monotherapy with best supportive care (Jonker et al, 2007; Van Cutsem et al, 2007), cetuximab and panitumumab were associated with improvements in tumor response, PFS, and overall survival (Amado et al, 2008; Karapetis et al, 2008). Based on these studies, EGFR inhibitors are now used just in those patients with tumors that do not have a mutated *KRAS* gene. This paradigm, in which the genotype of a tumor dictates therapy, is likely to become even more prevalent in the future.

In summary, patients who have yet to receive treatment for metastatic CRC, even if adjuvant treatment was previously administered for the colorectal primary, have a 50% or greater chance at responding to modern systemic chemotherapy and can expect a median survival around 18 to 20 months in the absence of resection. Unresected patients, however, still seldom live more than 3 years after the diagnosis of metastatic disease. After a patient fails first-line therapy, the results are discouraging. Response rates of 20% or less are typically seen, regardless of the second-line treatment selected (Bensmaine et al, 2001; Comella et al, 2002; Cunningham et al, 1998, 2004; Falcone et al, 2007).

PROGNOSTIC VARIABLES AND STAGING SYSTEMS

Although all patients with colorectal metastases are grouped as stage IV in the tumor-node-metastasis (TNM) staging system, considerable heterogeneity is observed within this group. For instance, the prognosis for a patient who comes to medical attention with a solitary liver metastasis, found several years after resection of a lymph node–negative right colon cancer, is different than that of a patient with synchronous and bilateral liver-metastatic disease noted during exploration of a perforated lymph node–positive colon cancer. Therefore, a classification system that can discriminate between these patients and provide additional prognostic information is paramount. Such a classification system should also be capable of facilitating

comparisons across studies, and it should guide patient selection for adjuvant therapy or clinical trials.

The development of a sophisticated staging and prognostic classification scheme is dependent on a thorough understanding of the clinical and pathologic variables associated with long-term survival in patients with stage IV CRC. Prognostic variables in the population of patients who develop hepatic metastases from CRC can be classified into three categories: 1) clinical and pathologic variables associated with the primary tumor; 2) clinical variables associated with the liver metastases, such as response to neoadjuvant chemotherapy; and 3) pathologic characteristics of the liver metastases.

Characteristics of the Patient and Primary Tumor

Age has not been found to be a significant prognostic variable for long-term survival, although analyses examining the role of age are confounded by the fact that older patients are carefully selected for surgery (Cady et al, 1992; Ballantyne & Quin, 1993). The location of primary cancer has not been shown to affect outcome, as metastatic rectal and colon cancer have similar prognoses (Doci et al, 1991). On the other hand, the stage of the primary tumor is quite useful in staging metastatic disease. Patients who had positive lymph nodes associated with their primary CRC do worse, as do patients who present with synchronous liver disease. Histologic grade of the primary cancer is not a significant predictor of long-term survival in patients with metastatic disease (Doci et al, 1991; Ballantyne & Quin, 1993).

Clinical Characteristics of Liver Metastases

The most important clinical predictor of outcome related to the liver metastases themselves is the disease-free interval: the shorter the interval, the worse the prognosis (Rosen et al, 1992; Scheele et al, 1995). Other negative factors include multiple liver metastases—four lesions is a commonly used cutoff—bilateral disease, tumor size greater than 5 cm, and a markedly elevated preoperative carcinoembryonic antigen (CEA >200 ng/mL; Nordlinger et al, 1996).

The prognostic value of response to neoadjuvant chemotherapy is controversial, and opinions vary in the literature. In a study by Adam and colleagues (2004), the 5-year disease-free survival was so poor following progression during neoadjuvant chemotherapy—3% versus 20% in patients who had a response or stable disease—the authors proposed that such a finding should preclude liver resection. This phenomenon was confirmed in our own experience (Allen et al, 2003). Although other groups have not found this to be true, such studies were based on patients who received older chemotherapy regimens. Roughly half of the patients only received 5-FU, which might account for the high rate of progression (Gallagher et al, 2009; Neumann et al, 2009). With modern chemotherapy, the expected rates of progression would be less than 20% compared with 60% in the studies mentioned above that used 5-FU (Nordlinger et al, 2008).

Operative and Pathologic Characteristics of Liver Metastases

Higher operative blood loss and transfusion requirements have been found to be associated with an increased number of perioperative complications and mortality but not with a worse long-term survival (Table 81A.3; Kooby et al, 2003). Anatomic resections are believed to indirectly improve long-term outcomes, because this approach is associated with a significantly lower rate of positive margins. In a retrospective analysis from our institution, patients who had an anatomic segmental resection had a better outcome than patients subjected to wedge resections (DeMatteo et al, 2000). In an anatomic resection, planes are developed along major hepatic veins, and inadvertent disruption of the tumor is avoided. Wedge resections are usually guided by palpation and can be complicated by inadequate exposure or retraction. The attendant problems of poor visibility and impaired tactile sense at the depth of the resection will often lead to tearing of the specimen along the hard tumor–soft liver interface, thus resulting in a positive margin.

Perhaps the most informative surgical prognostic factor is the finding of extrahepatic disease (Rosen et al, 1992; Fong et al, 1999; Abdalla et al, 2006). The existence of nonpulmonary extrahepatic disease has long been considered by many surgeons to be a contraindication to hepatectomy (Fong et al, 1999; Abdalla et al, 2006); however, the approach to extrahepatic disease has been reevaluated in recent years, as some studies have demonstrated acceptable survival in selected patients with limited extrahepatic disease managed with resection, particularly in the setting of low-volume pulmonary metastases. The two largest studies on this question evaluated combination resection of liver and lung metastases and noted 5-year survival rates of 30% (Headrick et al, 2001; Miller et al, 2007).

The presence of metastatic disease to the portal lymph nodes remains a particularly poor prognostic factor. Portal metastases are found in 3% to 30% of patients with metastatic CRC to the liver (Abdalla et al, 2006), and disease recurs in virtually all patients with resected portal lymph nodes (Carpizo et al, 2009). A consensus paper on the management of extrahepatic disease concluded that no convincing data suggest that therapeutic portal lymphadenectomy for metastatic CRC improves survival (Abdalla et al, 2006). In contrast to portal lymph node metastases, there appears to be a role for hepatic resection in conjunction with metastases to other sites. The question has been examined in the form of large retrospective studies that included resections of the peritoneum or mesentery, retroperitoneal lymph nodes, and a variety of solid organs (Minagawa et al, 2000; Elias et al, 2003; Carpizo et al, 2009). The 5-year survival rates reported in these series range from 20% to 28%. Based on these studies, hepatectomy combined with surgical resection of extrahepatic disease is believed to be appropriate in selected patients.

A macroscopic positive margin, or R2 resection, is widely accepted as a poor prognostic factor. The presence of microscopic disease at the resection margin (R1 resection) or the precise thickness of the negative margin (R0 resection) is perhaps more controversial. For instance, the preponderance of data on the impact of an R1 resection suggests that a microscopically positive margin is associated with worse survival. The 5-year survivals are consistently above 30% for negative margins but are 20% or less with microscopic disease at the margin (Fong et al, 1999; Pawlik et al, 2005; Nuzzo et al, 2008); however, multivariate analyses that include R1 resection status often do not find it to be a significant predictor of outcome after adjusting for other competing risk factors, which suggests that a positive microscopic margin is merely a marker of poor biology

(Pawlik et al, 2005; Nuzzo et al, 2008). As adjuvant therapy improves, patients with R1 resections will likely have outcomes that more closely approach patients with negative resection margins. Indeed, a recent report suggests that a microscopic positive resection margin obtained out of necessity does not negatively impact the 5-year survival, although the recurrence rate is increased (de Haas et al, 2008).

With regard to the extent of negative margin, a 1-cm rim of normal liver parenchyma surrounding a resected tumor was traditionally espoused in the older literature (Shirabe et al, 1997); however, recent studies suggest that subcentimeter margins are acceptable (Are et al, 2007) and are perhaps even associated with equivalent outcomes to R0 resections (Scheele et al, 1995; Pawlik et al, 2005; Hamady et al, 2006; Figueras et al, 2007). Low rates of micrometastastic disease, or satellitosis, were found in resection specimens in two Japanese studies, further supporting this idea (Yamamoto et al, 1995; Kokudo et al, 2002). Anatomic segmental resection, as opposed to wedge resections (DeMatteo et al, 2000), and neoadjuvant chemotherapy are two proposed strategies to improve R0 resection rates in patients with colorectal liver metastases (Parikh et al, 2003).

In summary, the prospect of a positive microscopic or close microscopic margin is not a contraindication to liver metastasectomy in appropriately selected patients with modern chemotherapy. In addition to a macroscopically positive resection margin, the findings of hepatic satellite lesions and intrabiliary invasion have also been shown to predict tumor recurrence (Gayowski et al, 1994; Scheele et al, 1995; Okano et al, 1999; Povoski et al, 2000; Kubo et al, 2002).

Predictive Models and Clinical Risk Scores

Four large studies have enabled robust multivariate analyses of prognostic factors with metastatic CRC and design of useful predictive models for favorable survival after metastasectomy (Nordlinger et al, 1996; Fong et al, 1999; Kattan et al, 2008; Rees et al, 2008). Nordlinger and colleagues (1996) reported on a multicenter series of more than 1500 patients. Fong and colleagues (1999) reported on a single institutional series of 1001 patients and later on a cohort of 1477 patients (Kattan et al, 2008), and Rees and colleagues (2008) evaluated long-term survival in 929 patients from a tertiary referral center in the United Kingdom.

In the series by Fong and colleagues (1999), seven parameters were found to be independent predictors of an unfavorable prognosis: 1) the presence of extrahepatic disease, 2) a positive resection margin, 3) nodal metastases associated with the primary CRC, 4) a short disease-free interval, 5) largest liver metastasis greater than 5 cm, 6) more than one liver metastasis, and 7) a serum CEA greater than 200 ng/mL. The presence of extrahepatic disease and a postive resection margin are generally determined intraoperatively. When presumed preoperatively, these two variables are often considered relative contraindications to metastasectomy. A preoperative clinical risk score (CRS) system was therefore created using the last five factors (Box 81A.1), with each positive criterion counting as one point. This CRS is a simple and facile staging system used to classify patients with liver-exclusive metastatic CRC (Fig. 81A.1).

The presence of any one of these characteristics was still associated with a 5-year survival of 24% to 41%; therefore no single criteria can be considered a contraindication to

Box 81A.1

Prognostic Scoring System for Hepatic Colorectal Metastases

Node-Positive Primary Tumor

Disease free interval <12 months between colon resection and appearance of metastases
Size of largest lesion >5 cm

>1 Tumor

Carcinoembryonic antigen >200 ng/dL
Sum of points, with a point assigned for each positive criterion

resection; rather, the total score out of 5 is highly predictive of outcome, with a score of 2 or less suggestive of a particularly favorable prognosis—the optimal candidate for liver metastasectomy. Patients with a CRS of 3 or 4 have less favorable outcomes and may be appropriate for clinical trials involving adjuvant chemotherapy. Long-term disease-free survival is rare in patients with a CRS of 5, and these patients are also typically best served in clinical adjuvant chemotherapy trials. Importantly, actual 10-year survival has been observed in patients with even the highest CRS, as patients with a CRS of 3 to 5 have a 10% disease-specific survival (DSS). This is roughly equal to the cure rate of treatment in these patients; therefore a high CRS should not be considered a contraindication to hepatic resection (Tomlinson et al, 2007).

Current Use of Clinical Risk Score

The above prognostic scoring system has been validated by an independent group from Norway (Mala et al, 2002), which demonstrated that the CRS is generalizable to populations outside of the index cohort from a single, large, tertiary American center. In addition to appropriate patient selection for surgery, the CRS has proven useful in selecting patients for neoadjuvant treatment, ablation, and stratification in clinical trials (Table 81A.4).

*In Mala et al, no patients were classified with a clinical risk score of 5.

Additionally, the CRS has been shown to be useful in guiding the preoperative evaluation of a patient with metastatic CRC. As the number and cost of available tests increases, there is a growing need to develop effective ways to stratify patients so as to determine which tests are necessary for a given individual. For instance, a CRS of 1 or more was associated with a 14% rate of occult metastatic disease detectable by fluorodeoxyglucose (FDG) positron emission tomography (PET) imaging but not by conventional imaging (Schussler-Fiorenza et al, 2004). PET scanning did not have any utility in patients with a CRS of 0. Similarly, laparoscopy can be helpful for staging patients with a high CRS (>2). The finding of extrahepatic disease at laparoscopy in more than 40% of patients with elevated risk scores can prevent the added morbidity associated with an unnecessary laparotomy; however, the yield of laparoscopy is sufficiently low in the setting of a low CRS (~10% incidence of occult unresectable disease) that the added procedure is unnecessary (Jarnagin et al, 2001).

Predictive models with added sophistication have been developed recently, such as a nomogram (Kattan et al, 2008) and a multifactorial predictive index (Rees et al, 2008). Although these models are based on the same basic prognostic factors as the earlier models described above, they are more complex and difficult to use; however, as computer software and accessible handheld technology progresses, improved and more accurate predictive models will likely achieve clinical relevance in the near future.

MOLECULAR DETERMINANTS OF OUTCOME

Molecular profiling of CRC is an evolving area and will likely become an essential component of prediction models for cancer recurrence in the future. As stated earlier, variable response to EGFR inhibitors based on tumor *KRAS* status is well documented (Bos et al, 1987; Amado et al, 2008; Karapetis et al, 2008; Van Cutsem et al, 2009; Peeters et al, 2010). Similarly, response rate and the presence of microsatellite instability in the tumor are associated (Ribic et al, 2003; Nash et al, 2010). In a manner akin to the *HER2* amplification and breast cancer, it is

easy to imagine that these and other molecular factors will be incorporated into postoperative prognostic scales in the future.

Preoperative Investigations

The selection of patients for hepatic metastasectomy depends upon patient operability and tumor resectability. The criteria for patient operability are similar to those considered for any major laparotomy. A significant history of cardiac and pulmonary disease must be investigated, as these patients are at significant risk for perioperative complications. Pulmonary compromise as a result of a long upper abdominal incision and the development of a right sympathetic pleural effusion may predispose to pneumonia. In addition, dramatic intravascular fluid shifts and electrolyte imbalances may occur perioperatively that can precipitate cardiac ischemia and arrhythmia. Finally, any previous liver disease that might have impaired hepatic function should be evaluated, as this will determine the volume of liver than can be safely resected.

Preoperative investigations prior to resection of metastatic colon cancer are directed at 1) establishing the diagnosis, 2) anatomic definition of the liver lesion for surgical planning, and 3) staging to rule out extrahepatic disease. A confirmatory biopsy of hepatic lesions is only indicated to confirm the diagnosis when the clinical picture is unclear. The differentiation between metastatic tumors and benign hepatic lesions can usually be done with imaging modalities, including ultrasound (US), magnetic resonance imaging (MRI), and PET scan as discussed below (see Chapters 13, 15, and 17). The risk of tract seeding from percutaneous fine needle aspiration appears to be quite small, with only a few case reports in the literature. The workup to determine the extent of disease includes imaging, as outlined below, and recent colonoscopy (within 6 months). Although a detailed discussion of each imaging modality is beyond the scope of this chapter, the following sections will focus on the practical aspects of imaging for preoperative workup of patients with hepatic colorectal metastases.

THE ROLE OF PREOPERATIVE IMAGING

Computed Tomographic Scans

Computed tomographic (CT) scans have become indispensable in the staging of patients with metastatic CRC (see Chapter 16). A contrast-enhanced CT scan of the chest, abdomen, and pelvis are routinely obtained, although the yield from scanning the chest with regard to detecting metastatic disease is limited to just a few percent (Kronawitter et al, 1999). The most important images in the evaluation of the liver in the setting of metastatic CRC are obtained in the portal venous phase, because the lesions are not typically well vascularized. Arterial phase images are principally used to distinguish metastatic disease from benign vascular lesions, such as hemangiomas, or to better define the arterial anatomy of the liver. Such a step is necessary when planning for the placement of hepatic arterial infusion pumps. Standard CT scanning involves a triple-phase protocol through the liver that includes arterial, portal venous, and delayed phases. Slices are usually 5 to 7 mm thick through the liver, but these are reduced to 1.5-mm thick overlapping slices when high-resolution hepatic angiography is desired. Coronal and sagittal reconstructions are performed to further delineate the anatomy.

Metastatic lesions from colorectal primaries tend to push structures away, rather than invade directly, respecting the liver capsule and intersegmental planes (Baer et al, 1989; Scheele, 1989). Even when large lesions appear to involve the inferior vena cava on preoperative imaging, they often do not on surgical exploration; therefore such a finding on CT should not preclude an operation. Diaphragmatic invasion is a rare event as well (Weinbren & Blumgart, 1986).

Magnetic Resonance Imaging

MRI is most useful to evaluate indeterminate hepatic lesions and to better define the relationship of tumors to the hepatic vasculature and biliary tree using magnetic resonance cholangiopancreatography (MRCP; see Chapter 17). In particular, MRI is excellent at distinguishing between benign lesions such as hemangiomas, adenomas, and fibronodular hyperplasia. Moreover, MRI is better than CT for investigating pathology in the background of a fatty liver, such as in patients who have a history of obesity, diabetes, alcoholism, or previous chemotherapy treatment (Bipat et al, 2005; Fernandez et al, 2005). Because MRI is much more expensive than CT, this modality is not used routinely; however, it is warranted to better characterize indeterminate lesions or for the patient with an elevated CEA and a fatty liver with no evidence of disease on CT.

Ultrasonography

Ultrasonography is a relatively inexpensive test that can provide detailed information about the number, extent, and anatomic relationships of liver metastases (see Chapter 13). Duplex US can define the proximity of the tumor to the portal vessels, hepatic veins, and inferior vena cava, and US is particularly useful for characterizing cystic lesions within the liver. In expert hands, it can be very sensitive at detecting small metastatic lesions, although the test is highly operator dependent.

Hepatic Angiography and Computed Tomographic Portography

Direct hepatic angiography has largely been replaced by CT and MR angiography, which are less invasive alternatives (see Chapter 19). The main role for direct angiography in the modern era of high-resolution cross-sectional imaging is CT portography. In this technique, contrast is administered directly into the splanchnic bed by injection into the superior mesenteric artery, and a CT portal venogram of the liver is acquired after a suitable delay. This technique is highly sensitive at detecting small metastatic tumors (Sica et al, 2000); however, because the test requires arterial catheterization and is associated with a relatively high false-positive rate because of perfusion abnormalities, its primary role is in the setting of a planned portal vein embolization (PVE; see Chapter 93).

Positron Emission Tomography

The role of whole-body positron emission tomography as an adjunct to CT in the evaluation of metastatic CRC has been growing in recent years (see Chapter 15). In the United States, the use of FDG PET for staging and diagnosis of CRC was approved by Medicare in 2001 (Kelloff et al, 2005). The imaging test utilizes an intravenously administered radioactive tracer,

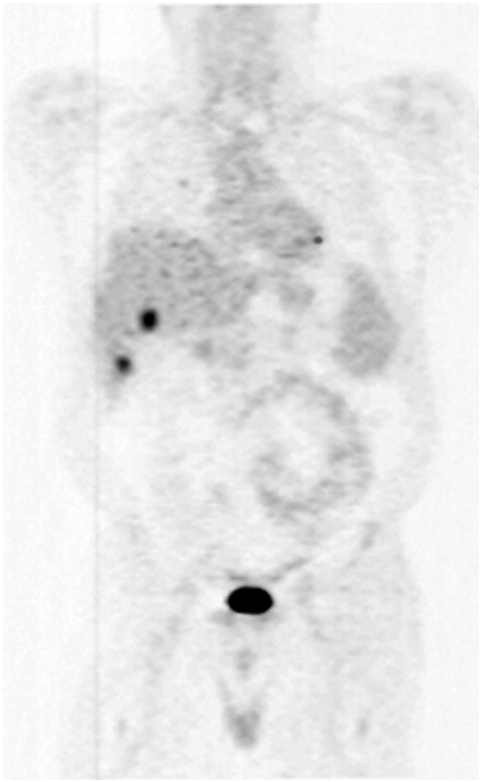

FIGURE 81A.2. A patient with two potentially resectable hepatic metastases in the right lobe of the liver. An FDG PET scan identified abnormal uptake in the left ligula of the lung, which was biopsied and found to represent an extrahepatic colorectal cancer metastasis.

which in most cases is ^{18}F-FDG. The radioactive glucose analogue cannot proceed down the glycolytic pathway and therefore accumulates within glucose-avid cancer cells. PET capitalizes on this phenomenon, as ^{18}F-FDG reveals the distribution of metabolically active metastases overexpressing cell surface GLUT1 transporters (Fig. 81A.2). The limitations of PET include poor sensitivity for lesions less than 1 cm, that some larger lesions are not FDG avid, and that the test lacks a high degree of anatomic detail. Moreover, false positives occur in the setting of inflammation, which may exist early after surgery and radiotherapy, or in the context of an infectious process. Integration of FDG PET imaging and CT addresses some of these limitations, particularly with regard to anatomic details.

PET has emerged as a relevant test in several areas of metastatic CRC management. Reported applications include patient selection for metastasectomy, evaluation of a patient with a suspected recurrence, radiotherapy planning, response assessment, and the discovery of incidental colorectal lesions (Herbertson et al, 2007). With regard to the initial staging of patients with metastatic CRC, FDG PET imaging leads to a change in management in 2% to 36% of patients. For instance, Strasberg and colleagues (2001) examined the utility of PET in evaluating patients with hepatic colorectal metastases for possible hepatic resection. Out of 43 patients, the authors identified 6 with unresectable disease detected by PET imaging, which amounted to a 14% rate of occult disease detection by PET. Futile surgery was avoided in these patients. This improved detection rate is comparable to the experience described above by Schussler-Fiorenza and colleagues (2004) in the section on uses of the CRS. Interestingly, Strasberg and colleagues (2001) report quite favorable outcomes after metastasectomy, which they attribute to improved patient selection from the use of preoperative PET imaging: the resectability rate, 3-year disease-free survival, and 3-year overall survival were 95%, 40%, and 77% respectively. A meta-analysis on the subject found that the sensitivity and specificity of FDG PET were 91.5% and 95.4% for extrahepatic disease compared with 60.9% and 91.1% for CT (Wiering et al, 2005). The advantage of FDG PET over CT alone in the evaluation of a patient with a suspected recurrence, in the setting of a rising serum CEA, is similar to the experience described above for the patient undergoing a complete staging workup for stage IV disease (Huebner et al, 2000). FDG PET may also be particularly useful at identifying omental or peritoneal disease. Finally, the prospect of using functional imaging to assess treatment response is a promising application of PET technology. For instance, multiple studies have demonstrated that early metabolic response to chemotherapy correlates with eventual RECIST response, based on CT imaging, for both CRC and other cancer types (Findlay et al, 1996; Weber et al, 2003; Juweid & Cheson, 2006). One can imagine treatment adjustments based on FDG PET scans after just a few cycles of chemotherapy.

The National Comprehensive Cancer Network (NCCN) guidelines do recommend that an FDG PET scan be considered in the follow-up of a patient with CRC in the setting of CEA elevation and suspected recurrence and also in the setting of a resectable synchronous or metachronous liver metastasis. The utility of preoperative staging with FDG PET in metastatic CRC is the focus of a currently accruing randomized Phase III trial (PET START). Enrollment for this 400-patient study is nearing completion, with results expected in the near future.

THE ROLE OF LAPAROSCOPIC STAGING (SEE CHAPTER 21)

Laparoscopy has been shown to have a role in staging patients with metastatic CRC, particularly in patients with associated poor prognostic factors or an elevated CRS (Babineau et al, 1994; John et al, 1994; Jarnagin et al, 2000). The principal advantage of laparoscopy is that it allows the detection of occult peritoneal or periportal disease that would preclude resection, but it is not appreciated on preoperative imaging. In a study by Jarnagin and colleagues (2001), laparoscopic evaluation identified the majority of cases of unresectable metastatic disease (14 of 26), sparing a laparotomy in many instances. Moreover, the authors demonstrated that laparoscopic detection of extrahepatic or unresectable disease resulted in decreased surgical morbidity, a shorter hospital stay, decreased hospital costs, and shorter delay to systemic therapy.

Of course, a negative laparoscopy lengthens anesthetic time and increases operating costs; therefore the technique is typically reserved for patients deemed to be at high risk for having unresectable or extrahepatic disease. Such patients include those with findings on imaging that are suspicious, but not diagnostic for, extrahepatic disease and those with a CRS greater than 2 (Jarnagin et al, 2001).

SYNCHRONOUS METASTASES AND TIMING OF RESECTION

The timing of hepatic resection in patients presenting with liver metastases during workup for the primary tumor is

controversial. Certainly, studies have demonstrated that synchronous metastatic disease portends a worse prognosis compared with metachronous metastases (Scheele et al, 1995), which factors into the discussion of whether to resect the primary and metastatic disease in one operation. Several factors related to perioperative and long-term outcome should be considered when deciding between simultaneous and delayed liver resection for metastatic CRC to the liver. With regard to surgical morbidity, de Haas and colleagues (2010) demonstrated that fewer complications were observed in patients who underwent simultaneous colorectal and liver resection (11% vs. 24%), but perioperative mortality was the same. Patients in this study were included if their liver resection involved three segments or less. A similar or decreased complication rate associated with simultaneous resection has also been validated by other groups (Vogt et al, 1991; Martin et al, 2003; Chua et al, 2004; Capussotti et al, 2007).

In the above mentioned study by de Haas and colleagues (2010), the 3-year overall survivals were 74% and 70% in the two groups, respectively; however, the simultaneous resection group experienced more recurrences (85% vs. 63%; $P = .002$), resulting in a decreased 3-year PFS compared with the staged resection patients (8% vs. 26%, respectively). The authors concluded that although simultaneous resection is safe, there is an associated detriment in PFS. When interpreting such a study, it is important to recognize that the group of patients who underwent simultaneous resection may have included some patients who would have progressed to unresectabilty during the interval between removal of the primary and metastasectomy. This would bias the long-term results in favor of the delayed resection group. Indeed, Lambert and colleagues (2000) showed that roughly two thirds of patients can be spared unnecessary hepatic resection by using a delayed-resection approach to liver metastases. Taking the data together, it is reasonable to perform a simultaneous resection in patients with low-volume disease in the liver, when the risk of early and rapid progressive disease is relatively low. Simultaneous resection should be avoided in patients who appear frail and in certain clinical scenarios in which the liver disease is best addressed in a delayed fashion, such as with obstruction or bleeding.

PREOPERATIVE ALGORITHM

The preoperative preparation and planning before hepatic resection of colorectal metastases should be thorough and carried out with the intent to avoid unexpected findings at the time of laparotomy. A systematic approach to the CRC patient who is referred for consideration of hepatic resection both facilitates the preoperative evaluation and minimizes unnecessary investigations.

OPERATIVE MANAGEMENT

The principles of hepatic resection are similar for colorectal metastases as for any other hepatic surgery (see Chapter 90B). The immediate preoperative preparation includes a single dose of prophylactic antibiotics and placement of sequential compression devices to prevent the development of deep vein thromboses. The choice of incision includes a subcostal, long midline, or short midline incision with a rightward extension approximately 3 cm above the umbilicus. The latter is most frequently used at our institution, as it provides excellent exposure while minimizing the length of the midline incision in the upper abdomen, potentially reducing postoperative pulmonary compromise. The maintenance of a low central venous pressure (<5 mm Hg) reduces operative blood loss by decreasing bleeding from the hepatic venous radicles during dissection (Cunningham et al, 1994; see Chapter 22). This is facilitated by performing the dissection with the patient in a 15-degree Trendelenburg position, which increases the venous return to the heart and improves cardiac output.

Intraoperative Staging and the Role of Intraoperative Ultrasound (See Chapters 21 and 95)

As with any laparotomy for cancer, the abdomen should be carefully explored for evidence of extrahepatic metastases. In particular the celiac axis and portocaval and hilar lymph nodes must be palpated, and any suspicious nodes should be removed and examined by frozen section. Most surgeons routinely use intraoperative US after mobilization of the liver. With experience this practice may detect 5% to 10% of lesions missed on noninvasive imaging with CT, MRI, and transabdominal US (Boldrini et al, 1987; Machi et al, 1987, 1991; Olsen, 1990; Stone et al, 1994). In addition, intraoperative US is useful to delineate the interior anatomy of the liver, such as the intrahepatic vessels; therefore hepatic resection can be performed more safely with an anatomic approach. Intraoperative US is also useful throughout parenchymal transection, so that the resection line can be viewed in relation to the lesion and blood vessels. Prior to the development of PET imaging, several reports demonstrated that surgical management of hepatic tumors was influenced by intraoperative US in 30% to 50% of operations (Castaing et al, 1986; Rifkin et al, 1987).

Recently, interest is mounting with regard to contrast-enhanced intraoperative liver US with contrast agents that consist of microbubbles of air or gas that create greater contrast between tumors and normal liver parenchyma. Typically, the contrast is delivered in the form of a 4-mL intravenous bolus of SonoVue, sulfur hexafluoride gas stabilized by a phospholipid shell (Bracco SpA, Milan, Italy), followed by a flush of normal saline. In a series of 60 patients from the United Kingdom with metastatic CRC, the acccuracy of preoperative MRI/CT, standard intraoperative US, and contrast-enhanced US were 74%, 79%, and 96% respectively. The median size of lesions identified on contrast-enhanced US, but not on preoperative imaging, was 0.8 cm. In 17 patients (29%), findings on intraoperative contrast-enhanced US changed the surgical plan (Leen et al, 2006). In a second study from the United Kingdom, contrast-enhanced US altered the management plan in 4 (19%) of 21 patients compared with standard intraoperative US (Shah et al, 2010).

POSTOPERATIVE MANAGEMENT

Immediate Postoperative Care (See Chapter 22)

Metabolic derangements are common in the postoperative period following liver resection and are due to both hepatic insufficiency and hepatic regeneration. Hypoproteinemia and hypoglycemia may indicate early hepatic insufficiency, but they are usually transient. Hypokalemia and hypophosphatemia occur on the second postoperative day, as the liver begins to

consume these electrolytes for regeneration. Such metabolic abnormalities should be treated supportively. We prefer maintenance intravenous fluid with 5% dextrose and half-normal saline with the addition of 15 to 30 mEq/L of potassium phosphate. Alkaline phosphatase and transaminase elevations are common, and hyperbilirubinemia may occur. Abnormalities in coagulation or platelets may also occur and should be treated when the international normalized ration (INR) exceeds 1.5, or the platelets are less than 50,000/μL. Hepatic regeneration occurs rapidly after surgery. DNA synthesis is initiated in hepatocytes within 10 to 12 hours after surgery, and most of the hepatic mass returns within 1 week. Subsequent architectural rearrangements continue over the next few weeks, and in the majority of cases, this process is complete in 6 weeks.

Perioperative Mortality and Morbidity

For a surgical approach to be widely accepted, it must be efficacious, safe, and feasible. Without a doubt, major liver resection can be performed with acceptable mortality and morbidity. Using proper patient selection, preoperative staging, and surgical expertise, metastatic hepatectomies can be performed safely and result in prolonged disease-free survival and cure.

Mortality

The mortality associated with an elective liver resection for colorectal metastases has decreased significantly over the past 3 decades, and in the last 10 years, it has been shown to be less than 10% across major series (Butler et al, 1986; Hughes et al, 1986; Pagana, 1986; Cobourn et al, 1987; Nordlinger et al, 1987; Schlag et al, 1990; Scheele et al, 1991; Younes et al, 1991; Rosen et al, 1992). Advances in the understanding of liver anatomy, resection techniques, and anesthetic care have translated into favorable survival rates even with major resections. At the highest volume centers, operative mortality rates are now 3% to 5% (see Table 81A.2). The majority of deaths occur from perioperative hemorrhage or liver failure. Further improvements in mortality rates will be challenging, despite ongoing advances in surgical technique, as surgeons have taken an increasingly aggressive approach to hepatic resections.

Morbidity

The complication rate associated with hepatectomy is attributable in large part to the metabolic and immunologic derangements associated with liver surgery. The reported complication rate in most series is over 20% (see Table 81A.3), but this is likely an underestimate and reflects the fact that these reports are retrospective. Nonspecific or nonliver morbidities include cardiac, pulmonary, and infectious complications. The incidence of cardiovascular complications is around 9%, but the overwhelming majority of these are arrhythmogenic in nature (Jarnagin et al, 2002). The low rate of severe cardiac complications reflects careful selection of patients for liver resection. Pulmonary complications occur in close to 20% of patients and are related to the large upper abdominal incision and postsurgical sympathetic pleural effusions. Specifically, symptomatic pleural effusions occur in 10% of cases, pneumonia in 3%, and pulmonary embolism in 1% (Jarnagin et al, 2002).

Liver insufficiency and liver failure remain the most dangerous liver-related complications and occur in 3% to 8% of major hepatic resections (Schlag et al, 1990; Doci et al, 1991; Scheele et al, 1991; Cunningham et al, 1994; Jarnagin et al, 2002). Other hepatobiliary complications include bile leak in 4% of patients and perihepatic abscess in 2% to 10% (Schlag et al, 1990; Scheele et al, 1991; Jarnagin et al, 2002). Significant hemorrhage is rare (1% to 3%) but can be an important cause of perioperative mortality.

It is worth emphasizing that a high complication rate does not always translate into a prolonged hospital stay. If recognized and treated promptly, most complications do not result in a poor outcome. For instance, in the experience by Jarnagin and colleagues (2002), with more than 1800 liver resections performed at a single center, the median hospital stay was 8 days, and intensive care unit (ICU) admission was required for only 112 patients (6%). On the other hand, an association between the development of complications and decreased long-term outcome, both disease-free and overall survival, has been observed for liver surgery (Ito et al, 2008; Farid et al, 2010); this is similar to the findings in a large, population-based analysis of patients undergoing surgical procedures (Khuri et al, 2005), a finding that again underscores the importance of safe liver surgery.

Follow-up After Resection

No consensus exists regarding the extent and frequency of follow-up after surgery for primary CRC, as no specific strategy has been shown to conclusively improve survival (Makela et al, 1995; Ohlsson et al, 1995; Kjeldsen et al, 1997; Schoemaker et al, 1998). Similarly, no conclusive data demonstrate improved survival with close follow-up after hepatic resection for CRC metastases (Metcalfe et al, 2004). Nevertheless, patients who have undergone hepatic resection are usually monitored closely with the goal to identify early and potentially curable resectable recurrences. Our paradigm is as follows: physical examination, serum CEA level, and CT of the abdomen and pelvis every 3 to 4 months for the first 2 years and then every 6 months thereafter, and patients undergo chest imaging annually. We continue surveillance for more than 5 years, because roughly a third of 5-year survivors will still recur (Tomlinson et al, 2007).

ROLE OF ADJUVANT THERAPY

Patterns of Recurrence

Although the cure rate for liver metastasectomy is now considered to be roughly 20% (Tomlinson et al, 2007), the majority of patients with metastatic CRC to the liver die from recurrent disease. It stands to reason that these patients harbored occult disease at surgery that ultimately progressed and led to their demise. The most common sites for failure include the liver and lung (Table 81A.5). Indeed, the recurrences occur within the liver in 60% of patients (de Jong et al, 2009) and exclusively in the liver in up to 40% (Nordlinger et al, 1987).

Adjuvant Systemic Chemotherapy

A number of nonrandomized studies have evaluated the utility of perioperative systemic chemotherapy in the setting of hepatic resection for CRC metastases with equivocal results. Most of these studies compared patients receiving 5-FU–based chemotherapy with or without irinotecan or oxaliplatin. A large retrospective cohort study from European and American centers compared 792 patients who underwent hepatic resection alone to hepatic resection with perioperative 5-FU chemotherapy.

Table 81A.5

Sites of Initial Recurrence after Liver Resection for Colorectal Metastasis

Fortner, 1988	69	45	—	8 (12)	—	16 (23)	—	—	—

The basis for receiving chemotherapy was largely a function of where the patients were treated, thereby removing the bias toward chemotherapy in higher risk patients, which confounds other studies (Hewes et al, 2007). In this study, chemotherapy was associated with an improved 5-year overall survival (37% vs. 31%; Parks et al, 2007). Postoperative systemic 5-FU chemotherapy was evaluated in two prospective, randomized, controlled trials, the Fédération Francophone Cancerologie (FFCD) trial 9002 and the ENG trial, but both studies were closed early as a result of poor accrual. The pooled results included 278 patients randomized to surgery alone or surgery with 6 months of 5-FU. The authors demonstrated a marginal improvement in PFS (18.8 vs. 27.9 months; $P = .058$) without an improvement in overall survival at 3 or 5 years (Mitry et al, 2008).

More recently, Nordlinger and colleagues (2008) reported the results of the European Organization for the Research and Treatment of Cancer (EORTC) intergroup trial 4098. This prospective and randomized trial included 364 patients with resectable hepatic colorectal metastases who were treated by surgery alone or surgery with perioperative FOLFOX chemotherapy, six preoperative cycles and six postoperative cycles (Nordlinger et al, 2008). Based on an intention-to-treat analysis, an insignificant improvement was seen in PFS at 3 years of 7.3% (28.1% vs. 35.4%; $P = .058$); however, when only eligible patients were analyzed, the absolute difference in 3-year PFS was 8.1% and reached statistical significance ($P = .041$). The difference was 9.2% when just patients who underwent surgical resection were included ($P = .025$). This was technically a negative study, because the groups were statistically equivalent in the intent-to-treat analysis, but this is frequently quoted as a study demonstrating that perioperative chemotherapy improves PFS in patients undergoing hepatic resection for CRC metastases. Furthermore, one cannot comment on the role of neoadjuvant therapy from this study, because patients received chemotherapy before and after surgery in the adjuvant arm. No prospective and randomized study to date has examined the role of newer, biologic agents in the adjuvant setting in patients with resectable metastatic CRC.

Adjuvant Hepatic Arterial Infusion Chemotherapy (See Chapter 86)

Although regional liver-directed chemotherapy is not universally used, some liver surgeons and gastrointestinal oncologists support a role for this strategy in the setting of metastatic CRC to the liver. The rationale for this approach is that the liver is the most common site for tumor recurrence after liver resection, and it is often the only site of recurrence. Moreover, most metastatic liver tumors preferentially derive their blood supply from the hepatic artery, as opposed to normal hepatic tissue, which relies on the portal venous blood supply. In addition, the hepatic parenchyma can extract and metabolize chemotherapy drugs to less toxic byproducts, which allows the administration of very high doses to tumor cells with minimal systemic toxicity. For a more detailed discussion of the technical aspects of regional chemotherapy, refer to Chapter 86.

The most extensively studied agent used in hepatic artery infusional therapy is 5-FU-2-deoxyuridine (FUDR). This agent is a 5-FU analogue, which is concentrated 100 to 400 times in the liver as a result of its 95% hepatic extraction ratio (Ensminger et al, 1978). Most of the data on regional hepatic chemotherapy focuses on unresectable metastatic CRC. Randomized trials have clearly demonstrated that the technique is safe and is associated with a higher response rate than systemic chemotherapy alone; responses are 48% to 62% versus 0% to 21%, respectively (Chang et al, 1987; Kemeny et al, 1987; Hohn et al, 1989; Martin et al, 1990; Rougier et al, 1992); however, improved treatment response has translated into an improved survival in just a single study (Chang et al, 1987). Four relatively large randomized trials of adjuvant regional chemotherapy have been completed, and three were positive trials in favor of regional chemotherapy (Kemeny et al, 1999; Lygidakis et al, 2001; Kemeny et al, 2002). The fourth trial by Lorenz and colleagues (1998) found no difference in outcome for patients treated with resection alone versus resection plus regional 5-FU chemotherapy in an intention-to-treat analysis; however, the patients randomized to regional therapy had a very high operative mortality (8%), and 5-FU was used instead of FUDR, which has a much higher hepatic extraction rate and therefore less systemic toxicity. In addition, implanted ports were used as opposed to pump devices. Technical complications prevented chemotherapy administration in many of the patients randomized to regional therapy, so that just 74% and 30% of patients in the experimental arm initiated and completed treatment, respectively. These findings highlight the importance of technical expertise with regional liver chemotherapy (Lorenz et al, 1998).

Two of the positive adjuvant trials were large American studies. The Eastern Oncology Cooperative Group/Southwest Oncology Group (ECOG/SWOG) study consisted of 109

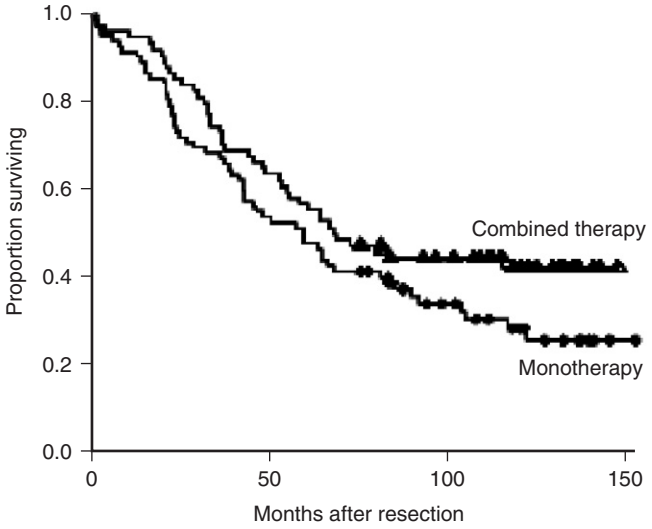

FIGURE 81A.3. Overall survival among patients with metastatic colorectal cancer treated with hepatic arterial infusion plus systemic chemotherapy (combined therapy) or systemic chemotherapy alone (monotherapy). *(From Kemeny N, Gonen M, 2005: Hepatic arterial infusion after liver resection N Engl J Med 352[7]:734. Copyright 2005 Massachusetts Medical Society All rights reserved. Reprinted with permission.)*

patients randomized to surgery alone or surgery plus hepatic arterial infusion (HAI) with FUDR. The 4-year hepatic disease-free survival was significantly better in the HAI group (67% vs. 43%; $P = .03$) (Kemeny et al, 2002). No difference in overall survival was found, although the study was insufficiently powered to test this end point. In a larger single-institution study from Memorial Sloan-Kettering Cancer Center (MSKCC), 156 patients were randomized to resection plus systemic 5-FU or resection plus combined systemic 5-FU and HAI with FUDR. The patients who were treated with regional therapy had a significantly higher 2-year survival (86% vs. 72%; $P = .03$) and markedly improved liver disease control, and 10-year follow-up demonstrated significantly improved PFS associated with regional therapy (31.3 vs. 17.2 months; Fig. 81A.3). Survival rates at 10 years were 41.1% and 27.2% in the two groups, although the difference was not statistically significant ($P = .1$) (Kemeny & Gonen, 2005).

Future prospective trials should explore regimens combining HAI chemotherapy with FUDR and modern systemic chemotherapy with agents such as irinotecan (CPT-11), oxaliplatin, bevacizumab, and cetuximab. Phase I and II studies combining systemic CPT-11 and HAI-FUDR or systemic oxaliplatin with HAI-FUDR are presently ongoing. As second-line therapy in the palliative setting for unresectable hepatic colorectal metastases, systemic CPT-11 and/or oxaliplatin combined with HAI-FUDR was associated with a response rate of over 70% (Kemeny et al, 2001; Kemeny & Gonen, 2005). This compares quite favorably to second-line systemic chemotherapy, which has a response rate of only 20%.

Recent Phase I and II studies of HAI with floxuridine and dexamethasone combined with systemic irinotecan (Kemeny et al, 2003) or oxaliplatin (Kemeny et al, 2009) demonstrated safety and feasibility in the adjuvant setting. Active investigation is now directed at determining the efficacy of this strategy. While awaiting the results of larger scale trials, regional FUDR should be considered an option in the adjuvant setting in patients at high risk for liver recurrence, particularly after failure of first-line systemic therapy.

Neoadjuvant Chemotherapy for Downstaging of Unresectable Disease

Several practical and conceptual advantages attend neoadjuvant chemotherapy for metastatic CRC involving the liver. Improved efficacy of modern chemotherapy has the potential to convert unresectable metastatic CRC into resectable disease, or it may reduce the extent of resection required to remove the hepatic disease (see Chapters 65 and 87). In addition, neoadjuvant chemotherapy can treat micrometastatic disease early as opposed to addressing it in a delayed fashion. Finally, this strategy may function as an in vivo test of chemoresponsiveness to a particular agent. Bismuth and colleagues (1996) were the first to publish this observation in a study of 330 consecutive patients with unresectable disease. They found that a combination of 5-FU/LV and oxaliplatin converted 53 patients to resectability (16%). Furthermore, the long-term outcome of these individuals after resection was similar to patients who were initially resectable. Since then, the potential to downstage unresectable into resectable disease with neoadjuvant chemotherapy has been validated in a number of studies and ranges between 3% and 41% of patients (Giacchetti et al, 1999; Adam et al, 2001; Wein et al, 2001; Clavien et al, 2002; Adam et al, 2004; Pozzo et al, 2004; Vauthey et al, 2006; Adam et al, 2009). Patients who undergo complete resection have a median survival between 30 and 60 months. Of course, patient selection plays a vital role when estimating the potential benefit of neoadjuvant treatment. In the largest prospective study to date, 138 of 1104 unresectable patients (12%) became resectable after a course of neoadjuvant chemotherapy using either FOLFIRI or FOLFOX. Factors associated with a poor long-term outcome in these patients included large tumors, an increased number of tumors (≥3), increased preoperative CEA, and periportal or celiac lymph node metastases (Adam et al, 2004).

Regional chemotherapy alone or in conjunction with systemic chemotherapy may also convert unresectable disease into resectable disease. For example, 6 (26%) of 23 patients became resectable after HAI-FUDR treatment (Clavien et al, 2002). The 3-year actual survival rate was 84% for the patients who responded to HAI treatment compared with 40% for nonresponders. As part of a Phase I trial conducted at MSKCC, 21 patients with unresectable metastastic CRC received systemic oxaliplatin and CPT-11 in conjunction with HAI-FUDR. Seven of these patients (33%) became resectable after treatment (Kemeny et al, 2005).

Chemotherapy-Induced Liver Damage (See Chapters 65 and 87)

Neoadjuvant chemotherapy has been shown to cause liver injury in some patients. Specifically, oxaliplatin is associated with hepatic sinusoidal obstruction (Rubbia-Brandt et al, 2004), and CPT-11 is associated with hepatic steatosis (Kooby et al, 2003; Parikh et al, 2003); these agents can even cause severe steatohepatitis (Fernandez et al, 2005). Obese patients are at increased risk, and a preoperative liver biopsy should be considered to evaluate the liver parenchyma in such patients. When a major hepatic resection is planned in a patient

suspected of having impaired liver function after exposure to systemic chemotherapy, preoperative portal vein embolization may be warranted to induce hypertrophy in the future liver remnant. In some instances, concern about the function of the future liver remnant should push the liver surgeon to proceed straight to surgery, and plan for chemotherapy postoperatively, after the liver has regenerated. In addition to steatohepatitis, the treated liver may become fibrotic and may develop perivascular adhesions, which can complicate a planned resection.

Despite well-documented histologic changes in the liver that can occur with chemotherapy, the actual clinical impact is not entirely clear. Indeed some studies have demonstrated a negative impact of oxaliplatin or irinotecan chemotherapy on postoperative morbidity (Karoui et al, 2006; Vauthey et al, 2006; Nakano et al, 2008) and mortality (Vauthey et al, 2006), whereas other studies have not confirmed these findings (Hewes et al, 2007; Mehta et al, 2008).

Disappearing Hepatic Metastases

A *radiologic complete response*, defined as the disappearance of a lesion on cross-sectional imaging, occurs in approximately 6% to 9% of lesions treated with neoadjuvant chemotherapy (Benoist et al, 2006; Elias et al, 2007; Auer et al, 2010). A lesion that disappears during chemotherapy may represent a pathologic complete response or a reduction in the sensitivity of cross-sectional imaging secondary to chemotherapy-induced steatosis. When a hepatic metastasis is present in a segment of the liver that cannot be removed, disappearance of this lesion during chemotherapy may preclude wedge resection or ablation and thereby jeopardize a complete resection. Moreover, in some patients, resection is only a consideration because previously apparent liver disease had disappeared during chemotherapy. When approaching such a patient, surgeons must understand that removal of visible disease is likely to be ineffective if occult and viable tumor remains in the foci that correspond to the "vanished" lesions.

Three institutions have published retrospective studies on the significance of liver metastases that disappear with chemotherapy (Benoist et al, 2006; Elias et al, 2007; Auer et al, 2010), and although all three studies agree that a complete radiologic response does not often equate to a true clinicopathologic response, the strength of this association varied across the studies. Benoist and colleagues (2006) found the lowest rate of true clinicopathologic response. The authors identified 38 patients with at least one or more disappearing liver metastases, a total of 66 complete radiologic responses, by CT scan (Benoist et al, 2006). All of these patients eventually underwent surgical exploration after a lesion disappeared. In 20 of 66 instances, macroscopic disease was appreciated at the site of disappearance. In 15 cases, the area of disappearance was resected, even though no residual disease was observed at surgery, and viable tumor cells were seen on histologic examination in 12 of these specimens. The remaining 31 sites were left in situ, and 23 recurred within 1 year of surgery. In summary, a true and durable response was only appreciated in 17% of the disappearing lesions.

Elias and colleagues reviewed data from 16 patients who had complete disappearance for at least 3 months during HAI or systemic chemotherapy in at least one liver metastasis in the future liver remnant on cross-sectional imaging. The disappearing lesion reappeared in 6 patients (38%) but represented a complete response in 10 patients (62%) based on a minimum of 2 years of follow-up. Interestingly, none of the lesions that disappeared with HAI therapy reappeared in follow-up. In the most recent study by Auer and colleagues, 38 patients had 118 disappearing liver metastases; a total of 68 disappearing lesions were resected, and 50 were followed clinically (Auer et al, 2010). In the resected liver that harbored the 68 vanished lesions, a complete pathologic response was observed in 44 patients (65%). Similarly, there were 31 recurrences (62%) in the 50 disappearing lesions that were followed clinically for a median of 41 months. Factors associated with a true complete response included HAI chemotherapy, inability to visualize the disappearing lesion on MRI, and normalization of serum CEA with treatment.

RE-RESECTION FOR RECURRENCE AFTER RESECTION

As stated previously, the most common site of recurrence after hepatic resection for colorectal metastases is the liver, and the liver is the sole site of recurrence in 15% to 40% of cases (see Table 81A.5). In the absence of extrahepatic disease, and in the patient with a good performance status and adequate hepatic reserve, a repeat hepatectomy may be considered. In approximately one third of liver recurrences, such an operation is feasible (Table 81A.6). The presence of adhesions and the altered anatomy of the liver, particularly the position of the vasculature and biliary system, make these operations very challenging from a technical standpoint. Series of repeat liver resections report an operative mortality rate less than 3% and a perioperative complication rate that is similar to initial resections (Lange et al, 1989; Bozzetti et al, 1992). The most common complications include biliary fistula, hepatic duct stenosis, hemorrhage, hepatic failure, and subphrenic abscess. Reported 5-year overall survival was 30% to 40%, and the median survivals were often more than 30 months after repeat resection.

The largest published series of repeat liver resection for metastatic CRC is a combined series of 126 patients from MSKCC and the University of Frankfurt Medical Center (Petrowsky et al, 2002). The operative procedures included 90 minor resections and 36 major hepatic resections. The 1-, 3-, and 5-year survivals were 86%, 51%, and 34%, respectively, and there were 19 actual 5-year survivors (15%). On multivariate regression analysis (proportional hazard model), the number of lesions greater than 1 ($P = .01$) and tumor size greater than 5 cm ($P = .04$) were independent prognostic indicators of reduced survival. Contrary to previous smaller studies (Bozzetti et al, 1992; Adam et al, 1997), the interval between the first and second liver resection was not associated with long-term survival.

In summary, for selected patients with a low tumor burden, a repeat liver resection is feasible, and safe and long-term survival is possible. We believe that repeat hepatic resection should be considered the standard of care for resectable metastatic recurrences in the absence of other distant sites of disease or medical contraindications. Notably, the risk of future recurrence remains high; therefore adjuvant therapy is often appropriate when good systemic options remain for the patient.

CONCLUSION

Hepatic resection for metastatic CRC to the liver is the standard of care for patients with resectable hepatic disease in the

NED, no evidence of disease

absence of extrahepatic disease. Hepatic metastasectomy can be performed with an acceptable morbidity and mortality, and it results in prolonged survival and offers the best possibility for cure. The advent of more effective chemotherapy will continue to extend the therapeutic options and increase the number of patients who might benefit from resection, which is particularly true given the prospect of new and potentially more effective targeted agents. Aggressive surgery combined with improved adjuvant treatments will likely continue to improve the cure rate in a disease that was believed to be terminal just a few decades ago.

CHAPTER 82

Hepatic tumors in childhood

Barrie S. Rich and Michael P. La Quaglia

OVERVIEW

An appreciation of hepatic segmental anatomy (see Chapter 1) has led to major advances in hepatic surgery, especially for tumors. In addition, the irresistible but still mysterious stimulus to hepatic regeneration has allowed larger and more extensive resections. In small infants, 85% of the liver can be removed safely, greatly increasing the scope for cure. Advances have also been made in understanding tumor biology and clinical behavior. This chapter addresses benign and malignant tumors of the liver and biliary tract encountered in infancy, childhood, and adolescence.

HISTORY

Between 310 and 280 BCE, Herophilus and Erasistratus first presented a description of hepatic anatomy. In the late 1880s, hepatic resection was attempted, but advances in anesthesia and antisepsis would be required before a successful outcome could be realized. Wendel used avascular anatomic planes in the liver to perform a hepatic resection in 1910 (McClusky et al, 1997), and progress in hepatic surgery has been based on an appreciation of hepatic segmental anatomy as described by Couinaud (Bismuth, 1982; Couinaud, 1986, 1992; see also the Introduction to this text). The distribution of the portal and hepatic veins delimits each hepatic segment, which has a unique portal vein and hepatic artery branch and bile duct. Knowledge of this anatomy allows control of the vascular structures before division of the hepatic parenchyma, making major hepatic resections feasible (see Chapter 1).

Bloodless hepatic dissection is crucial in infants and small children, who may have a total blood volume of less than 1 L. In the pediatric literature, Martin and Woodman (1969) reported that hepatoblastomas could be treated by hepatic lobectomy, and modern hepatic resection is soundly based on principles of segmental hepatic anatomy.

A second important historic finding was the sensitivity of some tumors, especially hepatoblastoma, to systemic chemotherapy (Fegiz et al, 1977). Chemotherapy caused significant reductions in tumor volume, and previously unresectable hepatoblastomas became resectable (Filler et al, 1991; Reynolds, 1995). Presently, the standard of practice is to administer neoadjuvant systemic chemotherapy to patients with hepatoblastoma, unless the tumor is clearly resectable at diagnosis.

In addition, appreciation of the biology of hepatic epithelial malignancies has increased, especially the differences between hepatoblastoma and hepatocellular carcinoma (HCC). These differences include the relatively good prognosis of hepatoblastoma compared with HCC in childhood, the importance of complete surgical resection of the primary hepatic tumor, and the association of hepatoblastoma with certain clinical syndromes (Exelby et al, 1975; Koishi et al, 1996; Schneid et al, 1997; Simms et al, 1995; Tsai et al, 1996; Vaughan et al, 1995). Finally, the first application of hepatic transplantation to a childhood liver tumor was reported by Heimann and colleagues in 1987, and a series of pediatric liver tumor patients treated by hepatic transplantation was reported by Tagge and colleagues in 1992. There is continued interest in using this modality for unresectable hepatic malignancies in childhood and adolescence (Pichlmayr et al, 1995; Pinna et al, 1997; Superina & Bilik, 1996).

MALIGNANT TUMORS

Primary malignant liver tumors constitute approximately 1.1% of childhood malignancies in Western nations. The overall incidence of primary liver cancer, as published by the Surveillance Epidemiology and End Results (SEER) program, is 5 cases per 1 million children in the 0 to 4 year age group and 1 case per 1 million in the 5 to 9, 10 to 14, and 14 to 19 year age groups (National Cancer Institute, 1995). Liver cancers constitute 0.5% to 2% of all pediatric solid tumors and about 5% of abdominal tumors in childhood (Weinberg & Finegold, 1983). The distribution of the most common malignant hepatic tumors is depicted in Figure 82.1. Hepatoblastoma is the most common, and its treatment is a success story in pediatric oncology.

Hepatoblastoma

Incidence

Hepatoblastomas are the most common primary hepatic tumors of childhood, constituting 43% to 64% of all hepatic neoplasms in one large series (Mann et al, 1990; Stocker, 1994; Weinberg & Finegold, 1983). Hepatoblastoma accounts for 91% of primary hepatic tumors in children younger than 5 years (Darbari et al, 2003) but comprises less than 1% of hepatic malignancies when adult age groups are included (Kaczynski et al, 1996). The Liver Cancer Study Group (LSCG) of Japan (1987) identified 30 hepatoblastomas (0.6%) in a cohort of 4,658 patients of all ages diagnosed over a 2-year period.

Hepatoblastoma affects 1 child younger than 15 years old in 1 million per year (Finegold, 1994), and approximately 50 to 70 new cases per year are reported in the United States, with a male/female ratio of 1.7:1 (Lampkin et al, 1985). Although hepatoblastoma has been reported sporadically in adults (Bortolasi et al, 1996; Harada et al, 1995; Inoue et al, 1995; Kacker et al, 1995; Parada et al, 1997), the median age at diagnosis is about 18 months, and most cases occur before the age of 3 years (Exelby et al, 1975). Hepatoblastoma is the most prevalent malignant neoplasm of the fetus and neonate and results in death within 2 years if not treated (Dehner, 1978; DeMaioribus 1990; Isaacs, 1985, 2007; Patterson et al, 1985). Finally,

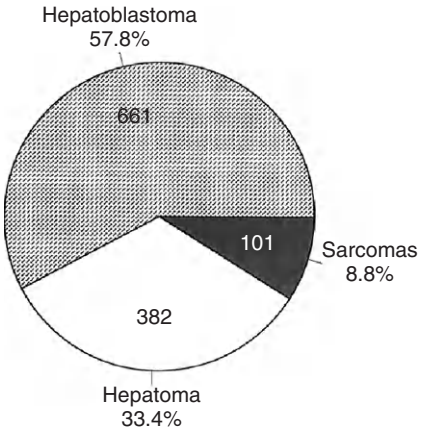

FIGURE 82.1. The frequency distribution of malignant hepatic tumors in childhood as compiled from reported large series. *(From Exelby PR, et al, 1975: Liver tumors in children in the particular reference to hepatoblastoma and hepatocellular carcinoma: American Academy of Pediatrics Surgical Section Survey 1974. J Pediatr Surg 10:329-337; and Weinberg AG, Finegold MJ, 1983: Primary hepatic tumors of childhood. Hum Pathol 14:512-537.)*

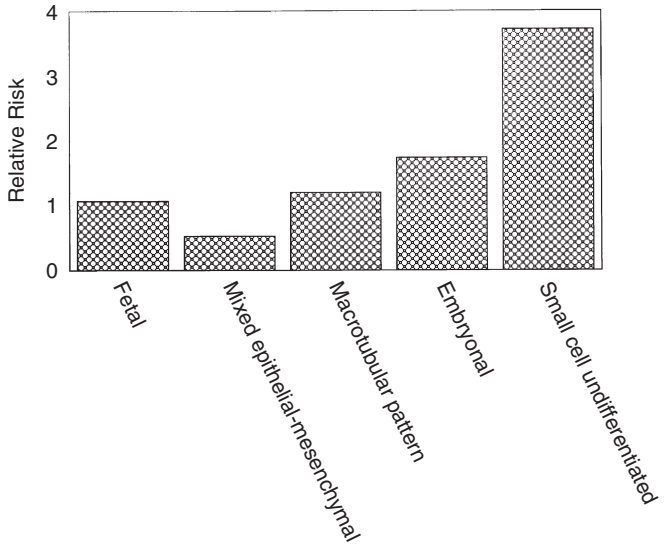

FIGURE 82.2. Graph depicts the risk of death for patients with fetal histology hepatoblastoma adjusted for age, sex, and stage and compared with other histopathologic subtypes.

the incidence of hepatoblastoma may be increasing (Blair & Birch, 1994). The incidence of hepatoblastoma was 0.6 per 1 million in the years 1973 through 1977, and it increased to 1.2 per 1 million from 1993 through 1997 (Darbari et al, 2003).

Hepatoblastoma may occur in siblings (Fraumeni et al, 1969; Ito et al, 1987; Napoli & Campbell, 1977; Surendran et al, 1989). It is most strongly associated with familial polyposis (Giardiello et al, 1996; Iwama & Mishima, 1994), Gardner syndrome (Hartley et al, 1990), and Beckwith-Wiedemann syndrome (Koishi et al, 1996; Tsai et al, 1996). In familial polyposis, incidence of hepatoblastoma seems to be increased in first-degree relatives of the patients with polyposis. Beckwith-Wiedemann syndrome is associated with Wilms tumor, rhabdomyosarcoma, adrenocortical carcinoma, and hepatoblastoma with a possible association between hepatoblastoma and trisomies 2, 8, 18, and 20 (Bove et al, 1996; Tomlinson, 2005).

Hepatoblastoma is also associated with low birth weight (Ikeda et al, 1997; Reynolds et al, 2004). It is unknown whether the causative agent is developmental abnormalities associated with prematurity or interventions, such as early total parenteral nutrition. These tumors also are reported in patients with congenital anomalies, such as cleft palate, and cardiovascular and renal anomalies, including multicystic kidney and absence of the right adrenal gland (Rao et al, 1989). There are also at least two reports of hepatoblastoma occurring in patients with biliary atresia (Taat et al, 2004). No evidence associates hepatoblastoma with hepatitis B or C infection or any other chronic viral hepatitis. These patients usually do not have cirrhosis or inborn errors of metabolism.

Pathology

Hepatoblastomas are large tumors that can contain fibrous bands, producing a spoked-wheel appearance (Jha et al, 2009). The five histologic subtypes observed in hepatoblastoma are 1) fetal, 2) embryonal, 3) mixed epithelial, 4) mesenchymal/macrotubular, and 5) anaplastic or small-cell undifferentiated. These subtypes are differentiated based on the findings with light microscopy, but all tumor cells appear smaller than nonneoplastic hepatocytes. Extramedullary hematopoiesis is notably present and may be related to constitutive cytokine production by the tumor cells (von Schweinitz et al, 1995a). The fetal type grows in trabeculae and resembles fetal hepatic cells, whereas embryonic hepatoblastoma cells grow in incohesive sheets and resemble embryonic cells. Some hepatoblastomas contain mesenchymal tissue along with the epithelial component. Calcification also may appear in these tumors, and one patient was reported with osteosarcomatous elements in the hepatoblastoma and associated pulmonary metastases (Alcantar, 1985). The anaplastic or small-cell type consists of small, round blue cells reminiscent of neuroblastoma. This subtype is rare but particularly virulent, with a strong metastatic potential (Dehner & Manivel, 1988). The importance of subtyping in hepatoblastoma is due to the association between prognostic risk and subtype, illustrated in Figure 82.2 (Gonzalez-Crussi et al, 1982; Lack et al, 1982). Some studies have indicated that the fetal histologic subtype has a better prognosis; in contrast, patients with the rare anaplastic variant usually do poorly (Dehner & Manivel, 1988).

Basic Biology

Few cellular models of hepatoblastoma exist, and immortalized cell lines have been difficult to establish. One cell line, isolated from a human hepatoblastoma, clearly expresses the MYC and Hras1 oncogenes and epidermal growth factor receptor (EGFR) (Manchester et al, 1995). Antibodies that blocked the EGFR inhibited cell growth, but the significance of oncogene expression remains to be determined. A new cell line was established from primary hepatoblastoma tumor tissue and contains an identical genotype to tumor cells, with morphologic, molecular, and immunohistochemical confirmation.

In immunodeficient mice, hepatoblastoma is tumorigenic (Chen, 2009). Elevated hepatocyte growth factor levels have been demonstrated in the serum of 10 (45%) of 22 patients with hepatoblastoma (von Schweinitz et al, 1997a). Addition of hepatocyte growth factor causes proliferation in hepatoblastoma-derived cell lines.

Small epithelial cells, characteristic of hepatic stem cells, have been observed in human hepatoblastomas of various

subtypes (Ruck & Xiao, 2002). Additionally, various genetic abnormalities have been reported in hepatoblastoma. Chromosome 8q amplification is associated with a worsened prognosis and has been correlated with overexpression of the transcription factor pleomorphic adenoma gene 1 (PLAG1) (Zatkova et al, 2004). Telomerase and its regulatory protein expression levels have been correlated with poor outcome in human hepatoblastoma (Hiyama et al, 2004), and tamoxifen may inhibit hepatoblastoma cells by reducing telomerase levels (Brandt et al, 2005).

Loss of heterozygosity on chromosome 11p15.5, the region associated with Beckwith-Wiedemann syndrome, and on chromosome 1p36 has been described in hepatoblastoma (Albrecht et al, 1994; Kraus et al, 1996). Investigations into both of these regions suggest that each may contain a tumor suppressor gene, but this has not been proven. Trisomy 20 and trisomy of all or part of chromosome 2 also have been reported (Swarts et al, 1996). In addition, an abnormality of chromosome 2q may provide a common genetic link between hepatoblastoma and rhabdomyosarcoma (Rodriguez et al, 1991). Finally, frequent genetic losses found using comparative genomic hybridization included regions 13q21-q22 (28%) and 9p22-pter (22%), and the most frequent genetic gains were on chromosomes 2q23-q23 (33%) and 1q24-q25 (28%; Gray et al, 2000). Recently, differentially expressed microRNA has been shown to be deregulated in hepatoblastoma (Magrelli et al, 2009), and mutations of β-catenin have also been recognized (Curia et al, 2008).

Perhaps the most exciting insight is the association between hepatoblastoma and familial adenomatous polyposis syndrome (Bala et al, 1997; Cetta et al, 1997). In one study of 13 hepatoblastomas obtained from nonfamilial adenomatous polyposis patients, 69% had mutations in the adenomatous polyposis coli (*APC*) gene (Oda et al, 1996). In one case of siblings with hepatoblastoma, a shared *APC* gene mutation was identified (Thomas et al, 2003). In addition, the well-known thrombocytosis associated with untreated hepatoblastoma is fascinating, as is the presence of extramedullary hematopoiesis in these tumors. It was shown that hepatoblastoma cells secrete interleukin (IL)-1β, which causes secretion of IL-6 from surrounding fibroblasts and endothelial cells (von Schweinitz et al, 1993). Other factors, such as erythropoietin and stem cell factor, have been localized to the cytoplasm of hepatoblastoma cells. Thrombopoietin has been identified in hepatoblastoma tissue and serum from a patient, but its correlation with the thrombocytosis associated with this neoplasm is unclear (Komura et al, 1998).

Clinical Findings

The most common presenting sign of hepatoblastoma is an asymptomatic abdominal mass. The child is often in good health, and the tumor usually is discovered incidentally, when an attentive parent, grandparent, or clinician discovers the mass on a routine examination or while bathing the child (Fabre et al, 2004). Patients with the anaplastic variant of hepatoblastoma, who often have distant metastases at diagnosis, are more frequently symptomatic. Accompanying symptoms such as pain, irritability, minor gastrointestinal disturbances, fever, and pallor occur in smaller numbers of patients. Significant weight loss is unusual, although patients may fail to thrive. In most series of hepatoblastomas and HCCs, a few patients present acutely with tumor rupture and intraperitoneal hemorrhage (Brown et al, 1993). Rarely, hepatoblastoma manifests with sexual precocity secondary to a β-human chorionic gonadotropin (hCG)-secreting tumor (Muraji et al, 1985), and one patient with a hepatoblastoma was reported presenting with a biliary fistula (Daniel & Kifle, 1989). Finally, hepatoblastoma may present as a cardiac tumor (Wang et al, 2003).

A mild anemia associated with a markedly elevated platelet count is observed in most patients at diagnosis, and the platelet count can range into the millions. As noted previously, the cause is probably secondary to abnormal cytokine release.

Measurement of serum α-fetoprotein (AFP) is well established as an initial tumor marker in the diagnosis of hepatoblastoma and a means of monitoring the therapeutic response (Van Tornout et al, 1993). The normal level in most laboratories is less than 20 ng/mL, whereas the AFP level at diagnosis in hepatoblastoma patients can range from normal to significantly elevated (7.7×10^6 ng/mL); it is estimated that the AFP is elevated in 84% to 91% of patients with hepatoblastoma (Lack et al, 1982). One study reported a mean AFP level in hepatoblastoma of 3 million ng/mL, whereas the mean in pediatric patients with HCC was about 200,000 ng/mL (Ortega et al, 1991). In infants younger than 1 year, the AFP is normally elevated and is highest at birth (Fig. 82.3).

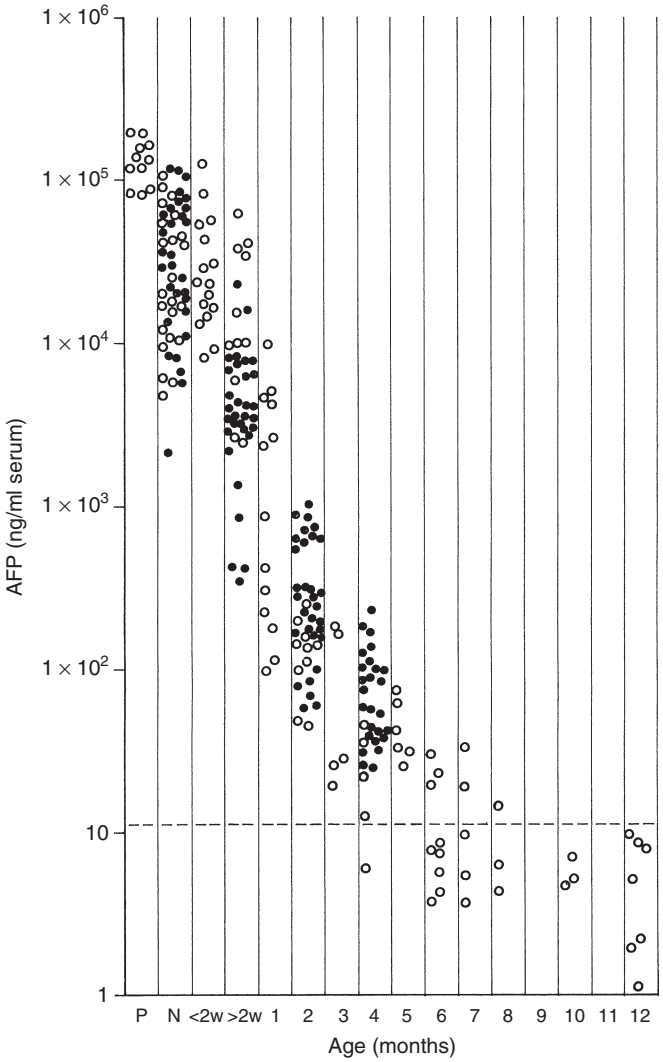

FIGURE 82.3. Graph shows the time decay of α-fetoprotein (*AFP*) levels in normal infants during the first year of life. *(Data from Wu JT, et al, 1981: Serum alpha fetoprotein [AFP] levels in normal infants. Pediatr Res 15:50-52.)*

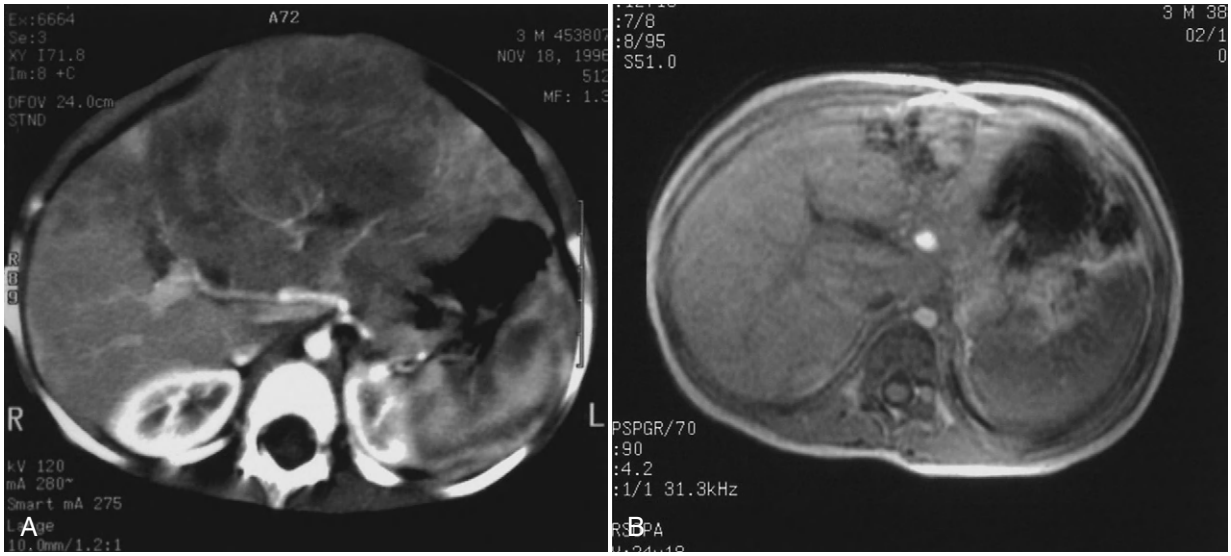

FIGURE 82.4. A, Computed tomographic image of a patient with hepatoblastoma before induction chemotherapy. **B,** Magnetic resonance image of the same patient after four courses of vincristine, cisplatin, and 5-fluorouracil.

Some authors suggest that subfractionation more reliably indicates whether the increased AFP is secondary to a hepatoblastoma or HCC, an endodermal sinus tumor, or benign liver disease (Tsuchida et al, 1997). The half-life of AFP is about 6 days, and in one study, 24 (77%) of 31 patients had levels decline by at least 1 log before second-look surgery (Walhof et al, 1988). Of these patients, 16 (50%) of 32 eventually had AFP levels decline to normal at the end of therapy and had no clinical or radiographic evidence of hepatoblastoma at this point. Finally, 15 (94%) of 16 patients who attained a complete response also showed a decline in AFP levels of 2 logs or more before second-look surgery (Van Tornout et al, 1997). A large, early decline in AFP levels was an independent predictor of survival in multivariate analysis; it has also been stated that a low initial AFP level is associated with worse survival (von Schweinitz et al, 1995b), but this has not been confirmed in multivariate analysis (von Schweinitz et al, 1994a). Anaplastic hepatoblastomas may also be associated with lower AFP levels (Tsunoda et al, 1996).

When interpreting the AFP level, it is important to realize that normal levels are very high at birth and decrease over the first 6 months of life. Premature newborns may have AFP levels in the range of 100,000 ng/mL. Term newborns also can have relatively high levels (10^4 to 10^5 ng/mL). By 2 months of age, most infants have levels ranging from 100 to 1000 ng/mL, and by 6 months, levels should be less than 100 ng/mL. Usually, levels decrease to normal (<20 ng/mL) after 6 to 7 months, but levels may remain elevated for 1 year after birth (Ohama et al, 1997). AFP may also be elevated in the setting of liver damage, liver regeneration, or in the presence of another tumor.

Imaging

The first imaging study is usually an abdominal ultrasound (US) (see Chapter 13). If duplex technique is used, tumor vascularity can be gauged, and the hepatic veins can be assessed (Bates et al, 1990). The ultrasonographer also should search for anomalies of the genitourinary system and rule out tumor thrombus in either the vena cava or the hepatic veins. Computed tomography (CT) (see Chapter 16) is useful to identify pulmonary metastases, identify diffuse hepatic involvement, and determine resectability. Oral and intravenous contrast material is used (Fig. 82.4A). CT scans can be performed quickly and can be completed in less than 2 minutes in helical scanners; this greatly shortens the required period of sedation for infants or small children, and it has the added advantage of being a quick and reliable screening method for pulmonary metastases. Hepatoblastoma will appear as a well-demarcated tumor, without a capsule. CT angiography (CT portography) uses CT with fine cuts and an increased amount of intravenous contrast material to image hepatic tumors and the hepatic venous anatomy. CT portography may provide as much information as magnetic resonance imaging (MRI) (see Chapter 17), which is useful for evaluating hepatic lesions and their relationship to vascular structures. MRI can show the hepatic veins, vena cava, and bile ducts (Ohnuma et al, 1991). MRI of a hepatoblastoma patient after neoadjuvant chemotherapy is shown in Figure 82.4B. Positron emission tomography (PET) has been used to identify hepatoblastoma recurrence and to search for sites of metastatic disease, but it may not be reliable for lesions smaller than 6 to 10 mm (Wong et al, 2004).

Staging

In the United States, the commonly used staging system is that from the Children's Oncology Group (COG), based on operative findings (Table 82.1). A tumor-node-metastasis (TNM) classification has also been used (Table 82.2; Brower et al, 1998). The *PRE-T*reatment *EXT*ent (PRETEXT) system of disease staging has been used extensively by the International Society of Pediatric Oncology liver group (SIOPEL) (Fig. 82.5; Aronson et al, 2005). It relies on radiographic findings prior to any therapy, including surgery, and does not take into account the independent surgeon's judgment at the time of surgery regarding resectability. This staging system is based on Couinaud's system of segmentation of the liver and is thought to predict the degree of tumor infiltration, the extent of surgical resection, and the complexities involved in the resection

Table 82.1

Children's Oncology Group Staging for Hepatoblastoma

Stage I	Complete Resection
Favorable histology	Purely fetal histology with a low mitotic index
Other histology	All other stage I tumors
Stage II	Gross total resection with microscopic residuals or total resection with preoperative or intraoperative rupture
Stage III	Unresectable tumors as determined by the attending surgeon, partially resected tumors with macroscopic residual involvement or any tumor with lymph node involvement
Stage IV	Measurable metastatic disease to lungs or other organs

From Finegold MJ, et al, 2008: Liver tumors: pediatric population. Liver Transpl 14(11):1545-1556.

(Couinaud, 1992; Otte, 2010). This system classifies the tumor into one of four categories, depending on which sections of the liver do not include tumor (Table 82.3; Roebuck et al, 2007). Additional criteria added in 2005 (Table 82.4) further classify these tumors (Otte, 2010; Roebuck, 2007).

PRETEXT was compared with pathologic findings in 110 patients and was correct in 51%, overstaged in 37%, and understaged in 12%. The authors compared this system with the Children's Cancer Group/Pediatric Oncology Group (CCG/POG) and TNM schemes and claimed a better correlation with risk status. This study analyzed data from patients who had

Table 82.2

Tumor-Node-Metastasis Staging for Hepatic Malignancies

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Solitary tumor without vascular invasion		
T2	Solitary tumor with vascular invasion or multiple tumors, none >5 cm		
T3a	Multiple tumors >5 cm		
T3b	Single tumor or multiple tumors of any size involving a major branch of the portal vein or hepatic vein		
T4	Tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of visceral peritoneum		
Stage Grouping			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage IIIA	T3a	N0	M0
Stage IIIB	T3b	N0	M0
Stage IIIC	T4	N0	M0
Stage IVA	Any T	N1	M0
Stage IVB	Any T	Any N	M1

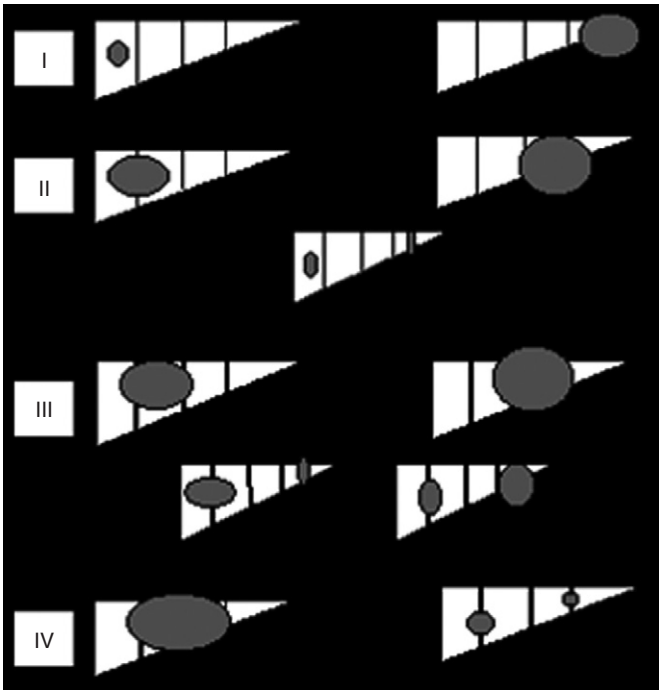

FIGURE 82.5. The PRE-Treatment EXTent (PRETEXT) staging system used by the International Society of Pediatric Oncology.

neoadjuvant chemotherapy, whereas a recent study from the COG analyzed data from patients with a hepatoblastoma at diagnosis and reported that both the COG stage and PRETEXT were useful prognostic indicators. The PRETEXT system has been described as showing improved predictive value for survival compared with other staging classifications (Aronson et al, 2005). Moreover, this system can be valuable for recognizing patients who are surgical candidates (PRETEXT stages I and II) and those who may benefit from lower dose chemotherapy (Meyers et al, 2009). It is recommended that all liver tumor patients in future COG studies undergo PRETEXT staging.

Treatment

Multiple studies support the effectiveness of systemic chemotherapy combined with complete surgical resection of the primary hepatic tumor (Gauthier et al, 1986; von Schweinitz et al, 1994a, 1994b, 1995b). Survival depends on removal of

Table 82.3

PRETEXT Staging System

PRETEXT Number	Definition
I	One section is involved, and three adjoining sections are free
II	One or two sections are involved, but two adjoining sections are free
III	Two or three sections are involved, and no two adjoining sections are free
IV	All four sections are involved

PRETEXT, PRE-Treatment EXTent

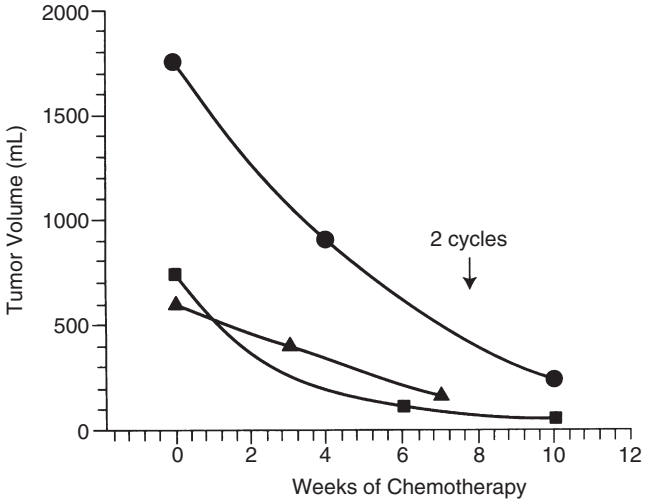

FIGURE 82.6. Tumor volumes of three hepatoblastoma patients are plotted versus time from initiation of chemotherapy. A significant reduction in tumor volume is apparent that is most rapid during the first two cycles of induction chemotherapy. *(Data from Medary I et al, 1996: Kinetics of primary tumor regression with chemotherapy: implications for the timing of surgery. Ann Surg Oncol 3:521-525.)*

the primary liver tumor, when imaging suggests that complete resection is feasible.

The first clinical decision is whether to initiate neoadjuvant chemotherapy or proceed with resection. Often, resection is not feasible if tumors are large and involve both hepatic lobes. Preoperative (neoadjuvant) chemotherapy results in tumor shrinkage and makes subsequent resection easier (Reynolds, 1995). In one study, the rate of shrinkage was high after initiation of chemotherapy, but it declined after two cycles had been administered (Fig. 82.6; Medary et al, 1996). Exquisite clinical judgment and good communication between members of the multidisciplinary team are crucial, because about 60% of hepatoblastomas are resectable at diagnosis.

To confirm the diagnosis, an initial biopsy is required. For unresectable tumors, the initial surgical procedure should include a diagnostic biopsy and placement of a vascular access device for chemotherapy. A second laparotomy is performed after four cycles of chemotherapy, if imaging studies show a good response, and the tumor appears resectable.

Complete resection of the primary tumor is necessary for survival and may require extended hepatic lobectomies or complex biliary reconstructions. For hepatoblastoma, reports have suggested that gross total resection of the primary lesion may be adequate for cure in chemoresponsive tumors (Dicken et al, 2004; Schnater et al, 2002).

For resected tumors (stage I) with fetal histology, further therapy is not recommended. All other stage I tumors without pure fetal histology, in addition to stage II patients, should receive four cycles of cisplatin, 5-fluorouracil (5-FU), and vincristine (C5V). Patients with stage III and IV disease should receive four cycles of chemotherapy, followed by resection or transplantation, followed by two more cycles of chemotherapy. C5V is administered, followed by doxorubicin if there is minimal response to C5V. Recent reports have suggested the use of doxorubicin from the start in this subgroup (Finegold et al, 2008; Malogolowkin et al, 2008). The combination of cisplatin plus doxorubicin was compared with cisplatin plus 5-FU plus C5V in a combined CCG/POG (intergroup) study (Ortega et al, 2000). The efficacy was thought to be similar, but more complications resulted with the regimen containing doxorubicin, accounting for equivalent event-free survivals; however, a more detailed review of the analysis suggested that the doxorubicin-containing arm had an improved disease-specific survival. This finding implied that with better management of toxicity, patient outcome might be better with a doxorubicin-containing regimen. In addition, a clinical trial that used a combination of cisplatin and carboplatin had to be terminated because of poor tumor response, suggesting that platinum-based monotherapy, as proposed by SIOPEL, was not as effective as combination chemotherapy. Clinical trials by the COG and SIOPEL are planned to evaluate the use of doxorubicin, irinotecan, and other agents, especially in high-risk patients.

In patients with unresectable primary tumors, the use of liver transplantation is increasing. A recent analysis stated an approximate 80% long-term disease-free survival in those receiving transplantation in large, solitary, or multifocal tumors invading all four sectors of the liver (Otte et al, 2005). The

United Network for Organ Sharing (UNOS) database consists of over 200 patients, with a median age of 2.9 years, who underwent orthotopic liver transplantation (OLT) for hepatoblastoma between 1987 and 2006. Approximately half of the patients had a recurrence. Overall survival was 80%, 69%, and 66% at 1, 5, and 10 years, respectively (Austin et al, 2006). In a recent multicenter review, 147 patients with hepatoblastoma were analyzed after liver transplantation. In almost three quarters of these patients, the original surgery was OLT; the remaining patients either had residual disease after prior resection or had recurrent tumor. The first group of patients had an improved outcome, with 82% overall disease-free survival, compared with 30% in the second group. Smaller, single-center reports have reinforced findings that liver transplantation for hepatoblastoma has the best outcome when done as the primary procedure rather than as a salvage (D'Alessandro et al, 2007; Otte et al, 2004; Pham et al, 2007; Reyes et al, 2000).

Transplantation, however, does require the use of immunosuppressive treatment, which comes along with its own set of side effects. Moreover, there is in increased chance of thrombosis of the hepatic artery after transplantation in children (Jain et al, 2006). The main causes of mortality after transplantation, accounting for 54% of this population, are metastases and recurrence (Austin et al, 2006). The COG is continuing to investigate the role of liver transplantation in hepatoblastoma. A global database has been instituted to aid in this endeavor.

In one study, the 1-year survival for patients presenting with metastases was no different from that in patients with localized tumors (Van Tornout et al, 1997). In another study by SIOPEL, the 5-year overall and event-free survival for children with hepatoblastoma who presented with pulmonary metastases were 57% and 28%, respectively (Perilongo et al, 2000). This study suggested that 25% to 30% of patients with synchronous pulmonary metastases are curable. It is still necessary to resect the primary liver tumor, and pulmonary metastasectomy should be done only if the primary site is controlled (Schnater et al, 2002). Many pulmonary metastases resolve with chemotherapy, but thoracotomy and resection are sometimes required for larger or persistent metastatic lesions (Passmore et al, 1995).

No current prospective studies are underway for pulmonary metastasectomy, but one recent study describes the advantage of pulmonary metastasectomy for diagnosed lesions that remain after neoadjuvant therapy (Meyers, 2007). Some radiation oncologists have treated pulmonary metastases with external-beam radiotherapy in an approach similar to that used for Wilms tumors, but with 18 to 20 Gy administered (Habrand et al, 1992); however, this may be associated with significant pulmonary toxicity and has not resulted in cure. There is no reported cure in patients with spread to sites outside of the lung or local lymph nodes.

Outcome

Following a gross total resection, the 5-year event-free survival is 83%, but this drops to 41% in patients with tumor remaining after surgery (Ortega et al, 2000). Some patients with microscopic residual tumor are curable with continued chemotherapy and may benefit from external-beam radiotherapy to the primary hepatic site. Resection of many hepatoblastomas may be easier after chemotherapy, and complete resection of the primary hepatic tumor is necessary for survival. In multivariate analysis, factors that have been independent predictors of worse prognosis include a high TNM stage, unresectable tumor, bilobar involvement and multifocality, AFP less than 100 ng/mL or greater than 10^5 ng/mL, distant metastases, embryonal versus fetal histology, and vascular invasion (von Schweinitz et al, 1997b). The COG has reported a 3-year event-free survival of 90%, 50%, and 20% for stage I to II, III, and IV, respectively (Malogolowkin et al, 2008).

Future Directions

Advances in hepatic anatomy have allowed more extensive resections so that even very large and bilobar tumors can be removed successfully. Segmental resection is also feasible and may allow resection of multifocal lesions.

The uses of various novel treatments are currently being investigated. First, transcatheter selective arterial chemoembolization, which involves the direct injection of chemotherapeutic agents to the tumor, hypothetically decreases systemic toxicity. The average decrease in tumor size was 84% in one study (Clouse et al, 1994), and unresectable hepatoblastomas may become resectable with this intervention (Berthold et al, 1986). Doxorubicin, cisplatin, and fluorodeoxyuridine have been promising, as these agents have a high hepatic extraction; case reports exist with striking results. For example, Yokomori and colleagues (1991) describe the total regression of a tumor in a 4-month-old infant with fetal hepatoblastoma treated for 1.5 years with 5-FU, vincristine, doxorubicin, and cisplatin. No recurrence was seen after 6 years of follow-up. Risks involved with this technique include infection, thrombosis, or shifting of the catheter. Furthermore, it is challenging to carry out in children, and prospective studies are needed. Other new approaches include treatment with anti-AFP antibodies, IL-2, and viral transfection vectors to attack malignant hepatic cells (Geiger, 1996; Huber & Richards, 1996; Ji & St, 1997; Ramani et al, 1997).

Hepatocellular Carcinoma (Hepatoma)

Epidemiology

HCC (see Chapter 80) accounts for 23% of pediatric liver tumors but is rare in infancy (Finegold, 1994). Approximately 1.4 cases per 1 million children exist in the United States (Ni et al, 1997). The LCSG (1987) reported no cases in children age 4 years or younger in a series of 2286 patients with histologically reviewed tumors. Historic series without pathologic review may report a higher rate of infantile HCC owing to misdiagnosis of some early hepatoblastomas (Exelby et al, 1975). We have had personal experience of infants with well-documented HCC, and it affects about 0.5 children younger than age 15 years per 1 million annually. SEER data indicate that HCC accounts for 87% of primary hepatic malignancies in the 15- to 19-year age group (Darbari et al, 2003). The incidence is bimodal, with an early peak that is lower than that of hepatoblastoma. Most of these early cases occur before 5 years of age. A second peak occurs between 13 and 15 years of age. The median age at presentation of fibrolamellar carcinoma, a variant of HCC, is 20 years, and it is rarely observed before age 10 years. HCC has a male predominance (1.3 to 3.2:1), and in areas endemic for hepatitis B, the male/female ratio may be reversed, at 0.2:1. Approximately 35 to 40 new HCCs are diagnosed per year in the pediatric age group in the United States. Incidence reported for the years 1973 through 1977 versus 1993 through 1997 showed a decrease from 0.45 to 0.29 cases per 1 million (Darbari et al, 2003).

Hepatitis B and C infection correlates with the incidence of HCC. In Asia, 85% of HCC patients, both adult and pediatric, are hepatitis B surface antigen positive, whereas this is found in only 10% to 25% of patients in the United States. The relative risk for the development of HCC is 250:1 for patients with chronic active hepatitis compared with patients without hepatitis surface antigen positivity (Brower et al, 1998). Hepatitis C antibodies are found in 20% of patients with HCC. In one report, an infant with a history of neonatal hepatitis developed HCC (Moore et al, 1997a). Other conditions associated with the development of HCC include cirrhosis, α_1-antitrypsin deficiency, tyrosinemia, aflatoxin ingestion, hemochromatosis, hepatic venous obstruction, androgen and estrogen exposure, Alagille syndrome (arteriohepatic dysplasia), and Thorotrast administration (Wegmann et al, 1996). One case of childhood HCC developing in a patient with neurofibromatosis has also been reported (Ettinger & Freeman, 1979).

A universal vaccination program against hepatitis B has reduced the incidence of HCC in Taiwan. The average annual incidence of HCC in children 6 to 14 years old declined from 0.70 per 100,000 children in the years 1981 through 1986 to 0.36 in the years 1990 through 1994 ($P < .01$) coincident with widespread administration of the hepatitis B vaccine (Chang et al, 1997). The mortality rate also decreased during this period. Antiviral therapy with lamivudine reduced the risk of development of HCC in patients with chronic hepatitis B infection and cirrhosis or fibrosis (Liaw et al, 2004). In contradistinction to HCC in adults, however, conditions associated with cirrhosis occur in only 30% to 40% of children with HCC; the remaining 60% to 70% of tumors are present without any cirrhosis (De Potter et al, 1987; Fattovich et al, 2004; Ismail et al, 2009; Llovet & Beaugrand, 2003; Marsh et al, 2004; Reynolds, 2001).

In one comparative study of pediatric HCC and hepatoblastoma, numerous discriminating features were reported (Chan et al, 2002). The mean age at presentation was 18 months for hepatoblastoma versus 10 years for HCC. The initial resectability of HCC was 45% and did not improve with chemotherapy, whereas 91% of hepatoblastomas could be completely resected before or after chemotherapy. Tumor rupture occurred in 36% of hepatoblastomas versus 9% of HCCs. Most importantly, the survival of patients with HCC was much worse.

Pathology (See Chapter 78)

HCCs are highly invasive and often multicentric at diagnosis with frequent hemorrhage and necrosis. Nuclear pleomorphism, nucleolar prominence, and the absence of extramedullary hematopoiesis are observed, and the cells are larger than normal hepatocytes. Low-grade HCCs may look similar to normal hepatocytes, especially if a limited amount of tissue is sampled. Invasiveness, and vascular invasion in particular, is a hallmark of these tumors. Extrahepatic dissemination to portal lymph nodes, lungs, and bones is frequent at diagnosis and strongly affects survival. HCCs naturally progress from capsular invasion to extracapsular extension, then vascular invasion, and finally to intrahepatic metastases (Toyosaka et al, 1996). A strong correlation has been found between intrahepatic metastases and portal vein thrombosis; this suggests that efferent tumor vessels anastomose to the portal, rather than the hepatic, veins, allowing intrahepatic spread and explaining the multicentricity that is a hallmark of HCC. Fibrolamellar HCC is a histologic variant seen in older children and young adults. It was once thought that this variant was associated with a better prognosis (Greenberg & Filler, 1989); however, studies indicate that when stage is controlled for, the survival is similar between standard HCC and its fibrolamellar variant.

Biology and Molecular Biology

Most investigations into the basic biology of HCC involve the study of hepatitis B and its relationship to carcinogenesis (Scaglioni et al, 1996). In one in vivo model in which rats developed HCC after prolonged feeding with glyceryl trinitrate, *KRAS* point mutations were identified in 8 of 18 animals that developed tumors (Tamano et al, 1996), and no *TP53* mutations were seen. Cytogenetic data indicate that chromosomal abnormalities are complex, but no consistent patterns have been established (Terris et al, 1997).

Clinical Findings

Children and adolescents with HCC are often seen initially with palpable abdominal masses (40%), but many are symptomatic at diagnosis (Ni et al, 1997). Pain is frequent (38%) and may occur in the absence of an obvious mass. Constitutional disturbances such as anorexia, malaise, nausea and vomiting, and significant weight loss occur with greater frequency. Jaundice is an uncommon feature of either disease, but AFP is elevated in approximately 85% of patients, with most levels greater than 1000 ng/mL (Brower et al, 1998). Although elevated, these levels are usually less than those measured in hepatoblastoma patients; 10% may come to medical attention with tumor rupture and a hemoperitoneum (Brower et al, 1998).

Staging

The staging schemes listed for hepatoblastoma also are used for HCC in childhood.

Treatment

In over a quarter century, no significant progress has been made in treatment of the pediatric population with HCC (Ismail et al, 2009). This tumor remains extremely resistant to current chemotherapy agents, and long-term survival is impossible without complete resection. Because of a high incidence of multifocality within the liver, extrahepatic extension to regional lymph nodes, vascular invasion, and distant metastases, complete resection is often impossible. Infiltration with thrombosis of portal and hepatic venous branches is common, and even the vena cava may be involved. Furthermore, the cirrhosis found in a number of HCC livers may preclude an extensive resection. Most analyses report a 10% to 20% resectability rate among children with HCC. In contrast, patients with a fibrolamellar histologic pattern have a higher resection rate and essentially do not have cirrhotic livers. Even with complete resection, however, the prognosis remains poor secondary to the high rate of recurrence.

Historically, the same chemotherapy protocols used for hepatoblastoma were also applied to HCCs in childhood; however, HCC is rather unresponsive to chemotherapy overall, although cisplatin in particular has shown activity against it (Bower et al, 1996). The utility of external-beam radiation therapy is unclear; it can aid with temporary control of gross disease, but it has not been shown to reduce the risk of relapse in patients with residual disease after resection. Because of the poor survival of patients with HCC, present thinking is to apply new and innovative approaches to these cancers.

Unresectable HCCs can be palliated with embolization with or without added chemotherapeutic agents or radioisotopes (Maini et al, 1996; see Chapter 83). Percutaneous intralesional injection of ethanol also has been of palliative benefit when lesions are small (Ryu et al, 1997; see Chapter 85A). Radiofrequency ablation (RFA) of these tumors, percutaneously or at laparoscopy/laparotomy, has been associated with tumor resolution and prolonged survival (Inamori et al, 2004; Koda et al, 2004; Raut et al, 2005; Santambrogio et al, 2003; see Chapter 85C). Lin and colleagues (2004) reported that radiofrequency ablation was superior to ethanol injection in HCCs 4 cm or less in diameter. Moreover, preliminary research using metronomic chemotherapy and adjuvant antiangiogenic treatments is currently underway (Gille et al, 2005; Meng et al, 2007; Meyers, 2007; Pang & Poon, 2006).

As standard therapies have proven unsuccessful, liver transplantation has been used more widely. The Milan criteria used for adults have been extrapolated to children. They stipulate a single tumor no larger than 5 cm in diameter, or up to three tumors each 3 cm or less in diameter, an absence of macroscopic portal vein invasions, and absence of extrahepatic disease; however, no current data support the efficacy of using the Milan criteria in this population. The UNOS database analyzed 41 patients with HCC who received OLT from 1987 through 2006. The overall survival was 86%, 63%, and 58% for 1, 5, and 10 years, respectively. Analogous to hepatoblastoma, mortality was mainly secondary to recurrence, which occurred even more often than it did in hepatoblastoma (86% vs. 54%) (Austin et al, 2006).

Outcome

The overall survival from HCC in childhood approaches zero, and it remains a therapeutic problem (Table 82.5). Occasionally, resection of localized lesions results in long-term survival. Results from the LCSG (1987) are consistent with these findings, showing a 1-year survival rate of 40% for resectable disease and 10% for unresectable lesions. The trend is to separate HCC from hepatoblastoma in clinical studies because of its greatly differing biologic behavior.

Future Directions

Gene therapy with viral vectors that attack dividing cells is being investigated. Hepatocytes rarely divide unless stimulated by liver resection. Viruses such as herpes attack dividing cells and can be molecularly manipulated to contain cytotoxic genes, and modified herpesvirus can be transfected efficiently into hepatoma cells (Carew et al, 1998; Tung et al, 1996). One group has used an adenovirus vector to deliver murine endostatin to tumors in nude mice injected with HCC cells with a resultant reduction in tumor growth (Li et al, 2004).

Rhabdomyosarcoma of the Extrahepatic Bile Ducts

Incidence

Although embryonal rhabdomyosarcoma of the extrahepatic bile ducts is extremely rare, it is the most frequently seen malignancy in the biliary tree of children (Martinez et al, 1982). Ten cases were reported in intergroup rhabdomyosarcoma studies I and II, constituting 0.8% of confirmed tumors in those studies (Ruymann et al, 1985). Fewer than 50 cases have been reported since 1975 (Zampieri et al, 2006).

Pathology

Most tumors are of the embryonal histopathologic subtype. They often show botryoid characteristics similar to other rhabdomyosarcomas that arise in a hollow viscus. Immunohistochemistry and nuclear staining are informative for diagnosis of embryonal rhabdomyosarcoma (Ali et al, 2009; Morotti et al, 2006). About 40% of patients develop distant metastases, but mortality is most often due to the effects of local invasion (Lack et al, 1981). Rhabdomyosarcoma of the liver and the ampulla of Vater, but not involving the bile ducts, also has been reported but is very rare (Horowitz et al, 1987; Perera et al, 2009).

Presentation

Patients range in age from 1 to 9 years at diagnosis, and this tumor is seen more frequently in males. The typical presentation includes intermittent jaundice and may include loss of

appetite and episodes of cholangitis (Charcot's triad) (Perisic et al, 1991). Hepatomegaly and a palpable abdominal mass are usual (Lack et al, 1981; Nagaraj et al, 1977). The diagnosis may be confused with hepatitis with resultant delay in specific therapy, but rhabodmyosarcoma of the bile ducts can also be mistaken for a choledochal cyst (Sanz et al, 1997).

Imaging

Ultrasonography (US) shows a hilar or intrahepatic mass that may be confused with a choledochal cyst (Friedburg et al, 1984; Geoffray et al, 1987). Although CT or MRI may provide information about extension and metastases (Ng et al, 1997), they do not establish the diagnosis. Imaging may be more accurate for extrahepatic ductal involvement (Roebuck et al, 1998).

Treatment

Surgical exploration and biopsy are necessary to establish the diagnosis in most cases. Often a hilar lymph node provides diagnostic material, but carefully sampling the primary tumor may be necessary. A core needle biopsy or aspiration cytology may be adequate for diagnosis, and entry into the bile ducts should be avoided if possible. Intraoperative US (see Chapter 21) is helpful in identifying the course of biliary structures. Initial complete resection before chemotherapy may be difficult or impossible because of the extensive nature of these tumors. Also, microscopic submucosal extension is common, and resection margins are often microscopically positive despite the normal appearance of the intrahepatic bile ducts.

It is probably better to first establish the diagnosis with a biopsy and then begin systemic chemotherapy, which reduces the tumor size and allows a cleaner resection at second-look surgery. During the initial biopsy, hilar and left gastric lymph node sampling is performed to determine whether these nodal echelons require added radiotherapy. In the series reported from the intergroup rhabdomyosarcoma study, six of the 10 patients underwent initial resection, but all had microscopic or minimal gross disease left behind (Ruymann et al, 1985). The only four survivors were in this group; however, none of the four patients survived in whom resection was not attempted. In another report of three consecutive cases from a single institution, all patients presented with jaundice, cachexia, and abdominal mass (Martinez et al, 1982). The tumor arose in the common hepatic duct in two children and in the left hepatic duct in the third. The technical difficulty of prechemotherapy resection is illustrated by the fact that intrahepatic extension was noted in all, making complete resection impossible. Two of these patients are alive and disease-free at 9 months and 14 years, whereas the third died as a result of progressive disease at 33 months. All received radiotherapy in addition to multiagent chemotherapy. Jaundice was not a late problem.

The need for aggressive surgical resection of biliary rhabdomyosarcomas was challenged in a report by Spunt and colleagues (2000). They reported 25 patients with this diagnosis from intergroup rhabdomyosarcoma studies I through IV and noted that although only 29% of these patients underwent a gross total resection before or after multiagent chemotherapy, the overall 5-year survival rate was 78%. They concluded that surgery was important for diagnosis and staging but that it was not necessary for long-term survival with present chemotherapeutic agents. They also noted that the use of biliary drains in patients undergoing aggressive surgery was associated with a high rate of serious infections.

The surgical approach is a bile duct resection, and a Roux-en-Y jejunostomy is the favored reconstruction. Intraoperative cholangiography is recommended to ensure adequate bile drainage. The four of these 10 patients who survived were alive and free of disease free from 6 months to over 6 years from diagnosis.

Future Directions

Presently, the need for radiation, or even surgical resection, has been questioned. In the future, some of these patients may be treated by chemotherapy alone after establishment of the diagnosis. If a complete radiologic response is documented after neoadjuvant chemotherapy, no further intervention except observation may be needed, although this requires further study. Embryonal rhabdomyosarcoma of the extrahepatic bile ducts is rare, locally invasive, and requires multidisciplinary treatment. Initial biopsy followed by chemotherapy and resection at a second-look procedure is the standard course.

Embryonal Sarcoma

Incidence

Embryonal sarcoma, also known as *malignant mesenchymoma* or *undifferentiated sarcoma* in the older literature, is a rare primary hepatic neoplasm that occurs in older children. In one study, two cases were reported out of 1102 (0.2%) primary liver tumors analyzed (Flemming et al, 1995). The age at diagnosis ranges from 5 to 16 years (Newman et al, 1989; Vetter et al, 1989). Embryonal sarcoma constitutes 14% of malignant liver tumors occurring in children 6 to 10 years of age (Yedibela et al, 2000).

Pathology

Microscopically these tumors appear as a pleomorphic or undifferentiated sarcoma, and areas of the liver may be entrapped. Primitive mesenchymal cells with occasional small cysts and ducts lined with benign-appearing epithelium are sometimes present at the periphery (Gallivan et al, 1983). Some reports have suggested that embryonal sarcoma of the liver may represent malignant degeneration of a mesenchymal hamartoma (Begueret et al, 2001; O'Sullivan et al, 2001).

Clinical Presentation

A right upper quadrant abdominal mass and pain are significant presenting symptoms, and fever also may be prominent. Spontaneous rupture has been reported (Yedibela et al, 2000).

Imaging

Embryonal sarcoma often appears hypodense (dark) on CT and has a bright peripheral fibrous pseudocapsule, as shown in Figure 82.7. They can be very bulky tumors and sometimes are confused with cystic liver disease (Orozco et al, 1991; Tozzi et al, 1992). These tumors may have the appearance of a solitary liver cyst in childhood (Chowdhary et al, 2004) or may mimic a hydatid cyst (Aggarwal et al, 2001).

Treatment and Outcome

Embryonal sarcomas of the liver are treated with resection and adjuvant chemotherapy (Kadomatsu et al, 1992). Cisplatin, doxorubicin, cyclophosphamide, dacarbazine, actinomycin, and other agents have been used in combination with radiotherapy (Newman et al, 1989; Vetter et al, 1989). Complete

FIGURE 82.7. Computed tomographic image showing the radiologic characteristics of embryonal sarcoma (malignant mesenchymoma).

surgical resection should be attempted and usually requires a major hepatectomy for tumor clearance. Although past reports have cited a poor prognosis, we have seen long-term survival with a combination of modern multiagent chemotherapy and complete resection.

Leiomyosarcoma

Patients with human immunodeficiency virus (HIV) infection experience an increasing incidence of smooth muscle tumors (Norton et al, 1997; Ross et al, 1992). Leiomyosarcoma of the liver has been reported in more than 20 patients; the youngest was 9 years old. Adjuvant therapy is ineffective; these tumors must be resected for control. They tend to be low grade or have an indeterminate malignant potential. Supportive and antiretroviral therapy is given through the perioperative period. A case of HIV-associated leiomyosarcoma is shown in Figure 82.8.

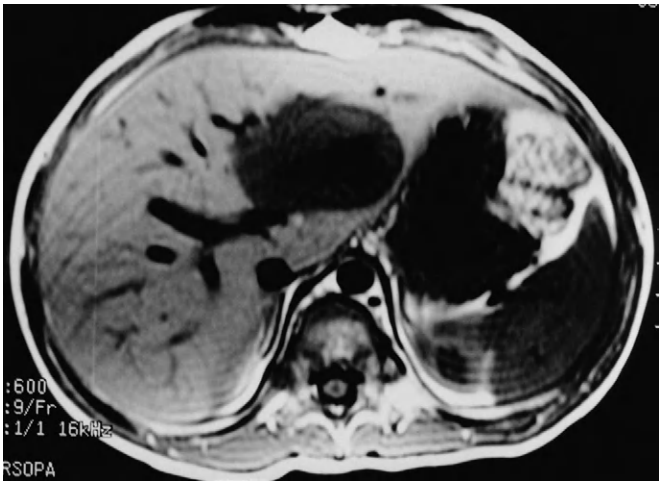

FIGURE 82.8. Leiomyosarcoma of the liver in a patient with acquired immunodeficiency syndrome (computed tomographic scan).

Primary Hepatic Rhabdoid Tumor

Incidence

Rhabdoid tumors are very rare, highly malignant, sarcoma-like neoplasms that usually involve the kidney or central nervous system (Vujanic et al, 1996). They can be primary in extrarenal sites, including extremity, paraspinal, and cervical soft tissues and the liver (Honda et al, 1996; Jimenez-Heffernan et al, 1998; Kelly et al, 1998). In a recent literature review of 19 cases of primary hepatic rhabdoid tumor, the median patient age was 16.7 months, and 89% of patients were younger than 2 years. The overall mortality rate was 89%, and the median time to death was 15.3 weeks (Yuri et al, 2004).

Pathology

Histopathologic examination shows a high-grade round-cell neoplasm with abundant cytoplasm and containing cells with cytoplasmic filamentous inclusions (White et al, 1999). The cells are frequently positive for vimentin and cytokeratins, and deletions at chromosome 22q11 are often seen (White et al, 1999).

Imaging

Rhabdoid tumors have no distinct radiologic features.

Clinical Presentation

The diagnosis may be suspected if widespread metastases, including central nervous system dissemination, are found with a hepatic mass. Cases with spontaneous rupture have been reported (Clairotte et al, 2006; Kelly et al, 1998; Ravindra, 2002; Yuri et al, 2004).

Treatment

These tumors are highly resistant to treatment. Disease confined to the liver should be resected if possible. Treatment with dose-intense, antisarcoma-type chemotherapy is also warranted.

Outcome

Although an initial period of control is feasible, these tumors are likely to recur and metastasize.

Angiosarcoma

Some authors describe angiosarcoma as the malignant form of hemangioendothelioma in children (Falk et al, 1981; Noronha & Gonzalez-Crussi, 1984). Arsenic exposure has been associated with malignant progression from hemangioendothelioma to hemangiosarcoma (Falk et al, 1981); however, no clear association has been reported between angiosarcoma and arsenic, Thorotrast, or vinyl chloride (Dimashkieh et al, 2004). Angiosarcoma is typically evidenced by a swiftly growing liver. Histologically, hypercellular whorls of spindled sarcoma cells are observed interspersed with bile ducts, blood vessels, and collagen. Intracellular periodic acid-Schiff–positive globules are present in most cases, and focal factor VIII staining may be seen.

Complete resection is required for cure of angiosarcoma, but recurrence rates are high, and the tumor is often not resectable; it is typically present in both lobes of the liver, and consideration should be given to adjuvant chemotherapy. Early metastasis, most commonly to the lung, is seen frequently (Awan et al, 1996; Falk et al, 1981; Kaufmann & Stout, 1961; Selby et al,

1992; Weinberg & Finegold, 1983). A recent review stated an average survival of 16 months (Dimashkieh et al, 2004). In one report of 10 cases of hepatic angiosarcoma in childhood, six patients were female, and four were male (Selby et al, 1992). The median age at diagnosis was 3.7 years (range, 1.5 to 7 years), with a mean follow-up of 10 months, and six of seven patients with follow-up died from disease.

Malignant Germ Cell Tumors

Primary malignant germ cell tumors of the liver are very rare and may present as teratomas, choriocarcinomas, or yolk sac tumors (Theegarten et al, 1998). In childhood, these may respond well to neoadjuvant chemotherapy followed by resection. Usually, a regimen containing cisplatin, ifosfamide, and bleomycin is employed.

Primary Hepatic Non-Hodgkin Lymphoma

Primary non-Hodgkin lymphoma of the liver occurs in childhood and may comprise 5% of primary hepatic malignancies in this age group (Gururangan et al, 1992). Burkitt lymphoma and other types of small-cell, noncleaved lymphoma have been reported (Huang et al, 1997; Mills, 1988). One or many lesions may be involved (Mantadakis et al, 2008). The primary treatment of lymphoma in childhood is chemotherapy, which usually results in complete resolution of the hepatic mass. Resection is rarely, if ever, indicated.

Hepatic Metastases

The liver is a relatively frequent site of metastatic disease in childhood. Non-Hodgkin lymphoma, neuroblastoma, rhabdomyosarcoma, rhabdoid tumors, Wilms tumor, desmoplastic small round-cell tumor, adrenal cortical carcinoma, osteogenic sarcomas, and a host of other malignancies may metastasize to the liver. Few data are available to determine the correct surgical approach to these lesions. Criteria for surgical removal of hepatic metastases include control of the primary site, a solitary or limited number of metastases, adequate hepatic reserve, good performance status, and a reasonable expectation of prolonged survival or cure. A helpful finding is some response of the metastatic lesions to adjuvant chemotherapy, and MRI is helpful in the diagnosis and evaluation of hepatic metastases.

We have had experience with 11 patients (age range, 4.3 to 21 years) who underwent hepatic metastasectomy. The overall survival in this group was 20%, but local hepatic control was greater than 85%. Advantages of hepatic metastasectomy include amelioration of liver function abnormalities, improvement of biliary obstruction, and possibly prolonged survival (Su et al, 2007).

Neuroblastoma

Hepatic metastases from neuroblastoma may be encountered in stage IV neuroblastoma and in newborns and infants with stage IV-S disease. In the latter situation, the liver involvement is a hallmark of the disease (Komuro et al, 1998). In stage IV-S, hepatic tumors generally resolve, although they may increase alarmingly in size before this happens. The increase in size usually causes pulmonary and vena caval impairment and may require relief by placement of an abdominal silo similar to that used for congenital abdominal wall defects. For stage IV disease, it may be advantageous for patients to undergo hepatic metastasectomy, which may aid in diminution of treatment or prolonged survival (Su et al, 2007). One patient with neuroblastoma and hepatic metastasectomy had disease-free survival with a follow-up time of 59 months (Su et al, 2007).

Wilms Tumor

Wilms tumor metastasizes to the liver in about 12% of patients (Cohen & Siddiqui, 1982), and this usually is associated with unfavorable histology (Breslow et al, 1986; Thomas et al, 1991). Resection of localized residual disease may be beneficial in well-selected cases. In one report, 15 cases of metastatic Wilms tumor with hepatic metastasectomy were analyzed and showed a 2-year survival of 62% and a 5-year survival of 44% (Foster, 1978). In one report, four patients with Wilms tumors metastatic to the liver underwent hepatic resection with a 2-year survival of 80%, and two patients survived 14 and 17 years, respectively (Morrow et al, 1982). This experience is also noted in other reports of Wilms tumor (Hagiwara et al, 1982). Experience with three patients, however, did not show survival greater than 9 months (Su et al, 2007).

Osteogenic Sarcoma

Calcified hepatic metastases sometimes may be observed in patients with osteogenic sarcoma (Shapiro et al, 1988). Although pulmonary metastasectomy for this disease is well described (La Quaglia, 1993; Saltzman et al, 1993; Torre et al, 2004), the role for hepatic metastasectomy has not been clarified. We reported a case of a child with osteogenic sarcoma with isolated liver metastases resected by a formal right lobectomy. This patient remained without disease for 2 years afterward and then developed recurrence in a limb, which required amputation. Hepatic metastases returned 46 months after this, and the patient died thereafter (Su et al, 2007).

Desmoplastic Small Round-Cell Tumor

Hepatic involvement with desmoplastic small round-cell tumor is frequent and is usually associated with a fatal outcome (Kushner et al, 1996; Mazuryk et al, 1998; Ordonez, 1998). The pattern of metastases is diffuse, leaving no spared segments that would allow resection, and complete resection is associated with a significant survival advantage in this disease (Schwarz et al, 1998). Future strategies include chemoembolization and arterial infusion therapy. Hepatic radiation to a level of 3000 cGy is ineffective.

Rhabdomyosarcoma

The liver follows regional lung, lymph nodes, and bone as a site of rhabdomyosarcoma metastases (Shimada et al, 1987). Resection of liver metastases is usually not feasible because of diffuse hepatic involvement and the presence of metastases in other sites.

Colon Cancer

Colon cancer can occur in childhood (La Quaglia et al, 1992). About 50% of these patients have signet ring tumors. The pattern of spread is over peritoneal surfaces, rather than through

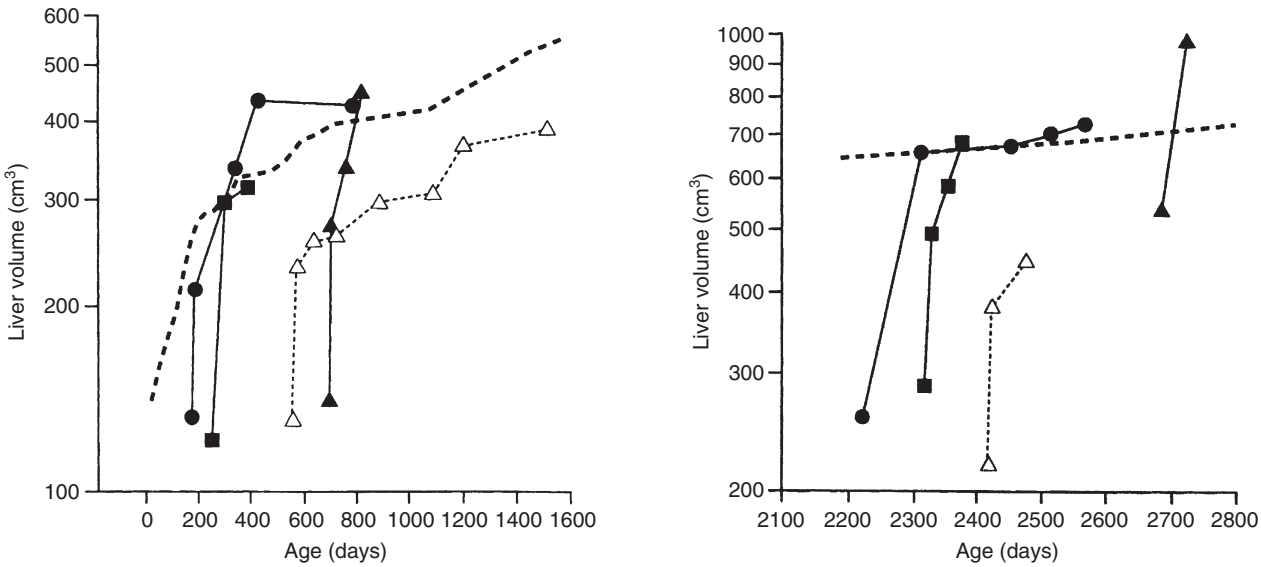

FIGURE 82.9. Graphs show the rapid recovery of hepatic volume to normal levels for age after major resections in childhood. The graphs show regeneration in two different age groups. *(Data from Wheatley JM, et al, 1996: Liver regeneration in children after major hepatectomy for malignancy: evaluation using a computer-aided technique of volume measurement. J Surg Res 61:183-189.)*

the portal system, and hepatic metastases usually occur late despite massive peritoneal disease.

Malignant Peripheral Nerve Cell Tumor

Malignant peripheral nerve cell tumors are likely to metastasize to the liver in childhood and adolescence. The pattern of metastases is usually miliary, and the tumors do not respond well to chemotherapy (Probst-Cousin et al, 1997).

Adrenocortical Carcinoma

Adrenocortical carcinoma also may metastasize to the liver, although concomitant pulmonary and retroperitoneal metastases are usually also present (Arico et al, 1992). Treatment is usually with platinum-based chemotherapy, and surgery is rarely done.

Rhabdoid Tumor

Rhabdoid tumor most commonly originates from the kidney and can metastasize to liver (White et al, 1999). It also may be primary to the liver, but this is rare. The pattern for hepatic metastases is usually diffuse and is not amenable to surgical resection. Chemotherapy protocols suitable for sarcoma are usually used (Vujanic et al, 1996).

Hepatic Evaluation and Resection

Surgical Anatomy

The schema of hepatic anatomy most useful for the surgeon is based on the work of Couinaud; this is described in other chapters (see Chapter 1). The principles of hepatic resection in small children and infants are the same as those for adults (see Chapters 90A through 90F).

Hepatic Regeneration

The liver in a child is able to regenerate quickly, even after massive resection (see Chapter 5) and administration of systemic chemotherapy (Shamberger et al, 1996; Wheatley et al, 1996). In most patients, recovery to the normal volume for age is rapid (Fig. 82.9).

EVALUATION OF A CHILD WITH A HEPATIC MASS

Patients presenting with a suspected hepatic mass first undergo a thorough history and physical examination. Blood work should include a complete blood count, liver function tests, coagulation studies, and tumor markers that should include serum AFP and β-hCG. Doppler US is done to determine whether a mass is cystic or solid, determine the patency of the portal and hepatic veins and vena cava, and identify satellite lesions. At present, MRI provides the greatest amount of information concerning the lesion and surrounding veins and bile ducts, and CT portography has been shown to give anatomic information equal to MRI. If a malignant tumor is suspected, thoracic CT is done to identify metastases. A tissue diagnosis is mandatory if malignancy is suspected after the workup. Percutaneous needle core or aspiration biopsy is useful for hepatoblastomas but may not be definitive in the case of HCC; open or laparoscopic biopsy is acceptable if necessary. Before exploration, the surgeon must do a thorough diagnostic workup to determine resectability. Often a team approach with a pediatric surgeon and an experienced hepatobiliary surgeon is helpful.

BENIGN HEPATIC TUMORS

Benign hepatic tumors (see Chapter 79A) accounted for less than 35% of 1250 pediatric liver tumors in one study (Finegold, 1994). Benign tumors of the liver that occur in childhood

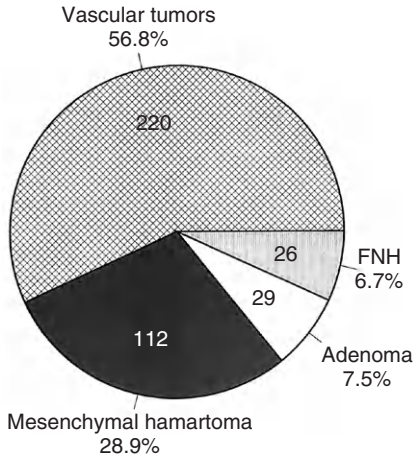

FIGURE 82.10. The frequency distribution of benign hepatic tumors in childhood (Exelby et al, 1975; Weinberg & Finegold, 1983). This graph is based on surgical or pathologic series of patients. With modern imaging techniques, the frequency of asymptomatic vascular tumors discovered incidentally is undoubtedly much higher (Flemming et al, 1995). FNH, focal nodular hyperplasia.

include hemangiomata or vascular malformations, hepatocytic adenomas, focal nodular hyperplasia, mesenchymal hamartomas, and various types of cysts and cystic disease. The distribution of common benign hepatic tumors of childhood is illustrated in Figure 82.10.

Hemangiomata and Vascular Malformations

Hemangiomata are lesions characterized by endothelial-lined vascular spaces that vary in size and extent (Ehren et al, 1983; Ishak, 1976). They are sometimes classified as hamartomas and are the most common skin lesions observed in childhood. Hemangioendotheliomas are highly proliferative cellular lesions of variable malignant potential. In contrast, venous malformations and cavernous hemangiomata are distinguished by a lack of cellularity and large vascular spaces. Arteriovenous malformations are the rarest pathologic subtype and are distinguished by abnormal anastomoses between arteries and veins. Venous malformations, cavernous hemangiomata, and arteriovenous malformations may be associated with significant shunting that results in congestive heart failure.

Incidence

The overall incidence of endothelial-lined vascular tumors of the liver in childhood is probably unknown, because many are asymptomatic. Vascular lesions taken together represent 13% to 18% of symptomatic hepatic tumors in childhood (Exelby et al, 1975; Finegold, 1994). Hepatic hemangiomata are more common in girls by 2:1 (Mulliken, 1988).

Presentation and Diagnosis

An abdominal mass is probably the most frequent sign of a vascular tumor of the liver. Multiple hemispheric, cutaneous hemangiomata may be present and warn the physician of possible visceral lesions. A systolic bruit sometimes can be heard over the enlarged liver. Infants with large, actively perfused vascular lesions may come to medical attention with congestive heart failure. Rarely, jaundice, disseminated intravascular coagulation (DIC), or hemorrhagic shock from intraperitoneal rupture may be present, and rupture can be precipitated by percutaneous needle biopsy (Hobbs, 1990).

Imaging studies are usually all that is required to confirm the diagnosis. Tumor extent and tissue characterization are assessed using MRI with standard spin echo T1-weighted and T2-weighted imaging (Powers et al, 1994). Intravenous administration of gadopentetate dimeglumine (gadolinium) can produce greater resolution. Vascular lesions can be seen as intensely white on T2-weighted images, and this study is often accurate enough to be definitive. Contrast-enhanced CT scan will demonstrate a focus with decreased density, with contrast enhancement from the edges toward the middle of the tumor, which will then be homogeneously enhanced (Meyers et al, 2007). Arteriography is rarely indicated given the detail and accuracy of modern imaging techniques, and open biopsy can result in massive hemorrhage.

Treatment

Asymptomatic lesions do not require treatment, and many hepatic hemangiomata regress after the first year of life. Patients with congestive heart failure are admitted to the intensive care unit and treated with digitalis and furosemide. If the heart failure remains refractory to these maneuvers, hepatic artery embolization or direct surgical ligation may be necessary (de Lorimier et al, 1967; Herlin et al, 1988). Hepatic arterial embolization may be successful in controlling symptoms, but rapid development of collateral vessels can make subsequent resection or embolization difficult. Transfusion of blood and platelets may be required for DIC. Interferon-alfa therapy for symptomatic angiomatosis and hemangioendothelioma is being used with success in individual patients (Le Luyer et al, 2000).

Patients who are seen in hemorrhagic shock with rupture of a vascular tumor usually require hepatic resection; however, initial hepatic arterial embolization may control bleeding temporarily and may allow stabilization and safer surgery (Takvorian et al, 1988). Hepatic resection may also be required in some patients in association with congestive heart failure. Blood loss in these complicated procedures may be reduced using hemodilution techniques (Kitahara et al, 1995; Schaller et al, 1984).

Outcome

The overall prognosis for benign hepatic vascular lesions is good. Most patients do not require operative intervention, and most cellular lesions start to regress after the first year of life. Angiosarcomatous degeneration of benign hemangioendotheliomas has been reported in five patients from one institution (Weinberg & Finegold, 1983). Three of the five were treated with radiotherapy to the benign hemangioendotheliomas before the development of angiosarcoma. This and other reports from the literature have correlated radiotherapy of benign vascular tumors with subsequent malignant degeneration, usually to angiosarcoma (Costello & Seywright, 1990).

Hemangioendothelioma

The incidence of hemangioendothelioma is 1%, and it is the most prevalent hepatic vascular tumor in pediatric patients younger than 6 months (Sari et al, 2006). In one report of 16 infants and children with hemangioendothelioma, 15 were seen

initially with hepatomegaly, 7 with congestive heart failure, and 4 with associated cutaneous lesions (Holcomb et al, 1988). Kasabach-Merrit syndrome, a platelet-trapping coagulopathy, also has been observed (von Schweinitz et al, 1995c). These lesions may appear very cellular, but they do not metastasize. If a primary lesion produces symptoms, resection is indicated for relief.

Hemangioblastoma

Hemangioblastoma of the liver usually is associated with von Hippel-Lindau disease (Rojiani et al, 1991). In infancy and childhood, these lesions appear very cellular, but distant metastases are uncommon. Complete resection should be performed and is usually curative. Hemangioblastomas of the central nervous system and retina have been treated with interferon alfa-2a, but without striking resolution, although two retinal lesions showed shrinkage (Niemela et al, 2001).

Mesenchymal Hamartoma

Mesenchymal hamartomas are usually solitary hepatic masses occurring in infants. They are usually multicystic, and the cysts are lined with flattened biliary epithelium or endothelium. Actively growing mesenchyme is abundant, associated with distended lymphatics. It is postulated that mesenchymal hamartomas arise in areas of focal intrahepatic biliary atresia; this results in distal bile duct obstruction and hepatocellular necrosis (Cooper et al, 1989). Others have hypothesized that these lesions arise in conjunction with anomalies of vascular development. This explains the occurrence of small hemangiomata observed in close proximity to mesenchymal hamartomas (Srouji et al, 1978). Cytogenetic analysis has only rarely been performed on these tumors, but a consistent 19q13.4 breakpoint has been identified (Mascarello & Krous, 1992).

Epidemiology

Mesenchymal hamartomas account for 6% of primary liver tumors in childhood, and a male predominance is reported. In one study, four of 134 patients with space-occupying liver lesions had mesenchymal hamartomas (Yen et al, 2003). Two thirds of these tumors are diagnosed in infants younger than 1 year, although presentation in the teenage years has been described. In one study of 18 such tumors, the mean age at diagnosis was 16 months (DeMaioribus et al, 1990).

Presentation and Diagnosis

Most mesenchymal hamartomas are seen as an enlarging abdominal mass or hepatomegaly and are usually not otherwise symptomatic (Srouji et al, 1978), but they can grow to great size and may cause respiratory distress or evidence of caval obstruction. Mesenchymal hamartomas are typically found within the right lobe of the liver, and US, CT, and MRI are the most useful diagnostic studies, although an open biopsy is often necessary to make the diagnosis. Figure 82.11 shows an MRI of a huge mesenchymal hamartoma. Giant hepatic cysts in fetuses also have been diagnosed on ultrasound (Tsao et al, 2002).

Treatment

Anatomic resection (hepatic lobectomy) is effective treatment, especially for large lesions. Because of the mesenchymal component, these lesions have a definite capsule that facilitates enucleation of large, central mesenchymal hamartomas not amenable to lobectomy. Enucleation was done in the case illustrated in Figure 82.11. Occasionally, it is necessary to marsupialize a large cystic lesion, but only if it is not feasible to remove this lesion completely. This approach may not be successful (Meinders et al, 1998). One report using sequential CT scans documented initial expansion followed by involution of a mesenchymal hamartoma (Barnhart et al, 1997). Because many reports exist describing spontaneous regression, the role of surgery is being contested in the asymptomatic patient (Meyers, 2007; Leary et al, 1989). It has been postulated that in utero decompression of giant hepatic cysts would improve the outcome in these patients (Tsao et al, 2002).

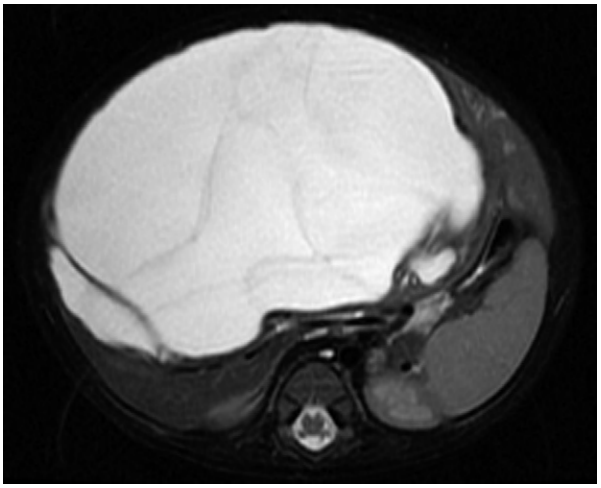

FIGURE 82.11. T2-weighted magnetic resonance image of a massive mesenchymal hamartoma.

Outcome

Patients with mesenchymal hamartomas do well with all forms of therapy. In one study of 18 patients, 13 who were available for follow-up were alive and well 1 month to 24 years after treatment (mean, 5 years; DeMaioribus et al, 1990).

Focal Nodular Hyperplasia and Hepatocellular Adenoma

Focal nodular hyperplasia (FNH) and hepatocytic adenomas are benign hepatocellular proliferations that are more common in adults than in children (see Chapter 79A). Hepatic adenomas are expected with type I glycogen storage disease after the first decade of life and may be multiple (Saito et al, 1984). FNH has also been described in a patient with type I glycogen storage disease (Sakatoku et al, 1996). Hepatic adenomas also have grown in patients undergoing androgen therapy for hematologic disorders, after danazol use, and in woman on oral contraceptives (Fermand et al, 1990). Both tumors have been correlated with a high-estrogen environment (Sakatoku et al, 1996). One report in the literature is of FNH developing in children treated for other solid malignancies (Bouyn et al, 2003). These authors postulated that a vascular injury secondary to chemotherapy or radiation was the causal factor.

FNH is distinguished from adenoma by the presence of fibrous septa that contain bile ducts and an inflammatory

infiltrate. In one report, five of 39 unresected hepatic adenomas developed HCC (Foster & Berman, 1994).

Epidemiology

Less than 2% of hepatic tumors in childhood are FNH or hepatocellular adenomas (Weinberg & Finegold, 1983). Both lesions have been described in infants and teenagers. Most patients are younger than 5 years at presentation and predominantly female (Nagorney, 1995). An association with contraceptive use has been found in adults, but no defined association between exogenous hormone administration in childhood and adolescence has been reported, although FNH has been reported in an infant antenatally exposed to corticosteroids (Prasad et al, 1995). In one report of 48 benign liver tumors in childhood, there were three cases (6%) of FNH and two cases of hepatocellular adenoma (4%) (Ehren et al, 1983).

Presentation and Diagnosis

Patients with hepatocellular adenomas usually come to medical attention with an asymptomatic abdominal mass; they are more likely to be symptomatic and may present with rupture and resultant hemorrhage, causing an acute abdomen. Both FNH and adenoma are well encapsulated on imaging studies. Because FNH is associated with fibrous septa, abdominal US and CT may show a distinctive central "scar." Hepatic adenomas may show encapsulation on imaging studies, but histologic sections may be difficult to distinguish from HCC. In childhood, these tumors may attain great size, contributing to symptoms. In one report of six cases in childhood, the average tumor size was 7.5 cm (range, 2.5 to 10 cm) (Lack & Ornvold, 1986). The tumor was localized to the right lobe in four of the six and was bilobar in the remaining two. Superparamagnetic oxide-enhanced MRI may discriminate between hepatic adenoma and FNH (Beets-Tan et al, 1998).

Treatment

It is best to remove adenomas because of the difficulty of differentiating them from low-grade HCCs, uncertainty about future malignant degeneration, and the possibility of rupture and hemorrhage (Westaby et al, 1983). Resection also results in relief of preoperative symptoms (Hutton et al, 1993). An anatomic liver resection usually is required, and we have employed extended left hepatectomy successfully in children to treat this lesion (Glick et al, 2000). Laparoscopic resection of these lesions has also has been done (Marks et al, 1998; Samama et al, 1998), and percutaneous RFA has recently become an option for treatment (Rocourt et al, 2006). Embolization of unresectable lesions is another alternative, if the masses are large or symptomatic. Unresectable and asymptomatic cases of FNH are observed using serial abdominal US, MRI, and clinical examination. Spontaneous regression has been documented, and patients with symptoms are typically treated with either surgical resection or ablation (Meyers, 2007).

Outcome

Most patients do well after hepatic resection, and in general, anatomic resection provides the best result. In one study of six patients with FNH and two with an adenoma, six were long-term survivors (Lack & Ornvold, 1986). Three patients with FNH were alive 4 to 17 years after hepatic lobectomy, and two other patients were followed with observation alone and were alive and well 13 and 15 years later. The one death in this group was from leukemia with an incidental finding of FNH. One of the two patients with an adenoma survived for 10.5 years after lobectomy, whereas the second died as a result of postoperative hemorrhage.

Cysts and Cystic Disease (See Chapter 69)

Multiple cases of solitary, congenital, nonparasitic liver cysts in childhood have been reported (Hernandez-Siverio et al, 1988; Pul & Pul, 1995). They are extremely rare but have been increasingly noted as incidental findings on US and CT performed for other reasons. Cysts are simple and not multilocular, they often have a bluish appearance at laparotomy, and the wall usually has three layers. The lining is generally cuboidal or columnar, although mucinous or squamous epithelium is reported. The middle layer comprises vascular elements, and the outer layer comprises compressed hepatocytes, collagen, muscle fibers, and bile ducts (Jones, 1994). The central contents are straw-colored and clear and are not under high pressure, as is the case with parasitic cysts. Most of these cysts are located in the right, anteroinferior hepatic lobe (segment V), and occasionally they are pedunculated.

Most solitary cysts are asymptomatic and do not require therapy. Older patients sometimes complain of abdominal pain or sensations of fullness. Rarely, a large cyst ruptures; torsion of a pedunculated cyst has been reported, and 9% of solitary cysts may be associated with extrahepatic biliary obstruction and jaundice secondary to external bile duct compression by the cyst. These cysts do not affect longevity, although malignant degeneration has not been reported. This must be considered when planning therapy. Solitary, asymptomatic cysts do not require therapy. If the cyst is symptomatic or doubt persists about the diagnosis, simple percutaneous aspiration usually is followed by recurrence, but aspiration followed by ethanol injection (sclerotherapy) may also be an effective treatment. More commonly, operative intervention is required.

Preoperative MRI or Doppler US is necessary to determine proximity to the portal and hepatic veins. Cysts that are neither adherent nor in proximity to these vascular structures are excised. Hepatic lobectomy may be necessary for symptomatic cysts that adhere to major veins, and marsupialization is sometimes a viable alternative. Injection of contrast media into the cyst can rule out a rare communication with the biliary tract. Cysts discovered incidentally at laparotomy should be left alone when less than 5 cm in diameter, but aspiration of cysts that are between 5 cm and 10 cm in diameter should be performed to confirm the diagnosis. Aspiration is followed by excision of the cyst wall. For large cysts—especially if there has been previous inflammation, or the cyst wall is near major venous or biliary branches—an anatomic liver resection is indicated (Iwatsuki et al, 1990). This resection avoids unnecessary bleeding and risk of postoperative biliary fistula.

Adult-type polycystic disease involving the liver has been reported with right lobar replacement and sparing of the left hepatic lobe (Marcellini et al, 1986); this was effectively treated by right hepatic lobectomy. Embryonal sarcoma of the liver sometimes can be confused with a solitary cyst (Chowdhary et al, 2004), and percutaneous needle aspiration and biopsy may be required to establish the diagnosis.

CHAPTER 83

Hepatic artery embolization and chemoembolization of liver tumors

Chang Jin Yoon and Jin Wook Chung

OVERVIEW

Primary and secondary liver tumors cause tremendous neoplastic morbidity and mortality. Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most common cause of cancer-related death in the world (Bosch et al, 2005). The highest incidences of HCC are found in Eastern Asia and sub-Saharan Africa, where hepatitis B is endemic; however, the incidence of HCC has been increasing steadily in the United States and Western Europe, largely owing to increased prevalence of viral hepatitis C in the past 2 decades (El-Serag et al, 2003). The majority of metastatic cancers involve the liver at some point as disease progresses. Despite the presence of extrahepatic spread, many patients with liver involvement die as a consequence of local tumor growth and hepatic parenchymal destruction.

Although surgery remains the best treatment in patients with most primary and secondary liver tumors, less than one third of patients are candidates for surgery when the diseases are initially found. This may be due to the extent or distribution of disease, underlying liver function, or general condition of the patient. Therefore, in the absence of effective systemic therapy, much effort has been put into developing and testing liver-directed therapies for local tumor control. Hepatic artery embolotherapy (HAE) has been outstanding among these methods as the most commonly used procedure to palliate symptoms and prolong survival.

BASIC PRINCIPLES OF HEPATIC ARTERIAL EMBOLOTHERAPY

Blood Supply of Liver Tumors

The basic physiologic principle that makes HAE feasible in patients with liver tumors is the dual blood supply to the liver (see Chapter 1B). The portal vein provides more than 75% of the blood flow to the normal hepatic parenchyma and is the primary trophic blood supply. Conversely, most of the blood supply (90% to 100%) to liver tumors comes from the hepatic artery (Breedis & Young, 1954), thus embolization of tumor-feeding arteries leads to selective ischemic damage of the tumor, while sparing the normal liver parenchyma, mainly supplied by the portal vein. Moreover, the pharmacokinetic advantage of locoregional drug administration enhances the theoretic benefit. For example, hepatic drug exposure has been estimated to be double for doxorubicin, 7 times greater for cisplatin, 8 times greater for mitomycin, 10 times greater for 5-fluorouracil, and up to 400 times higher for 5-fluorodeoxyuridine, when these were given through the hepatic artery rather than through the systemic veins (Ensminger & Gyves, 1983; see Chapter 86).

Hepatocarcinogenesis is a multistep process that causes gradual arterialization in blood supply to tumors (Pang & Poon, 2006), therefore the blood supply of liver tumors can be variable, according to the carcinogenetic stage of the tumors. For example, encapsulated nodular HCC is almost exclusively supplied by the hepatic artery, and well-differentiated HCC and the extracapsular infiltrating edge of advanced HCC can be supplied by the portal vein or both the portal vein and the hepatic artery (Goseki et al, 1995). Similar observations have been made in metastatic liver tumors; in its early stage, less than 200 μm is supplied almost exclusively by sinusoidal blood. As the tumor grows, its blood supply becomes progressively arterialized, but even in the advanced stage, most liver metastases still have a distinct portal blood supply (Strohmeyer et al, 1987); therefore early stage tumors and some fraction of advanced tumors may be resistant to hepatic arterial embolotherapy.

Chemoembolization

In the past 3 decades, many papers have been published describing a myriad different techniques for performing HAE; combined with intraarterial chemotherapy (chemoembolization), HAE has been paramount among them as the most

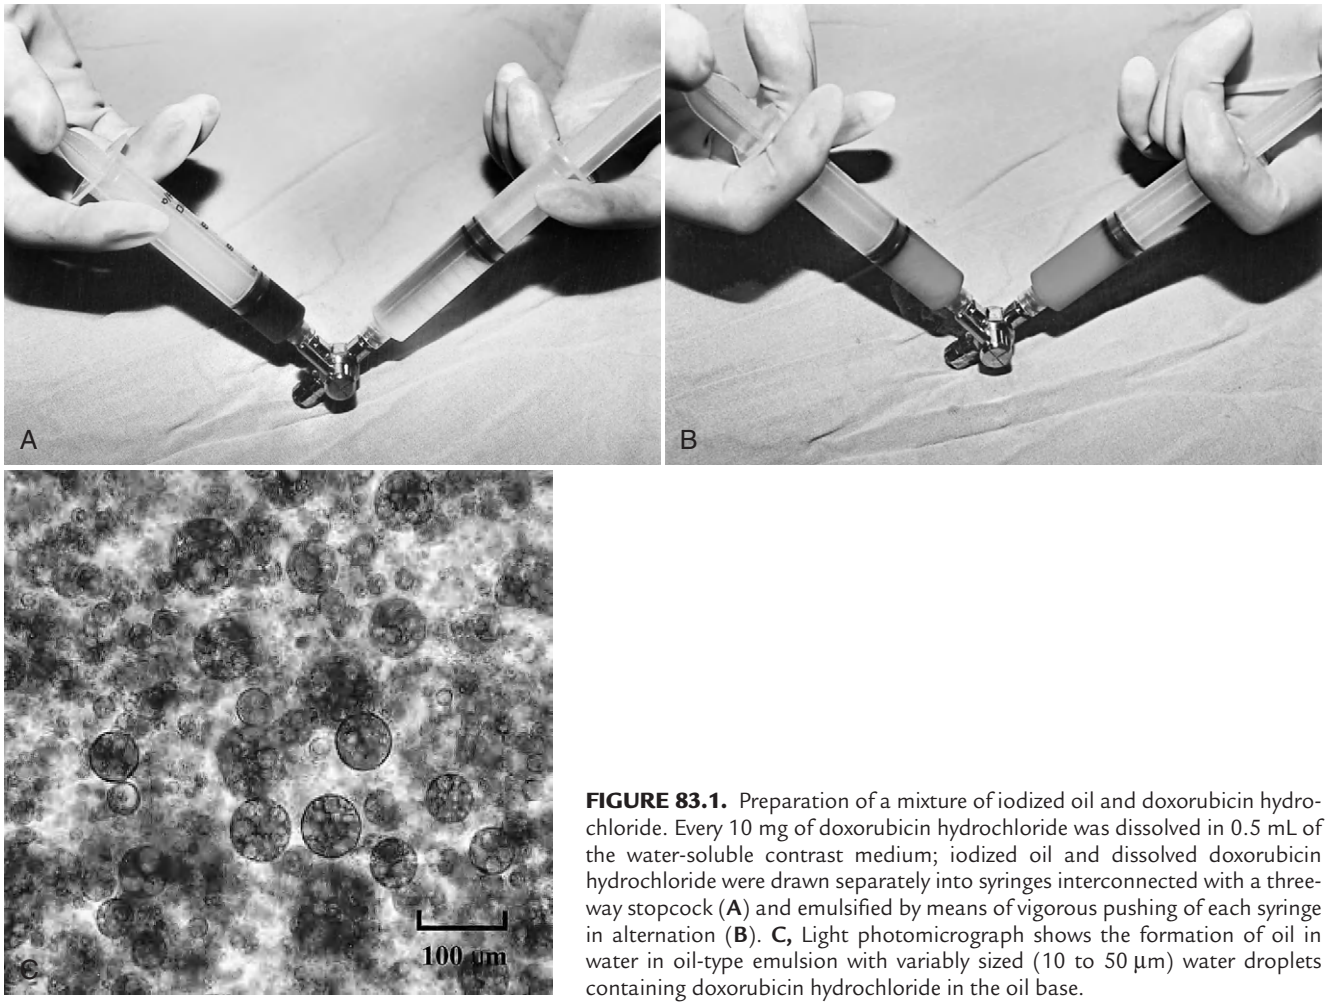

FIGURE 83.1. Preparation of a mixture of iodized oil and doxorubicin hydrochloride. Every 10 mg of doxorubicin hydrochloride was dissolved in 0.5 mL of the water-soluble contrast medium; iodized oil and dissolved doxorubicin hydrochloride were drawn separately into syringes interconnected with a three-way stopcock (**A**) and emulsified by means of vigorous pushing of each syringe in alternation (**B**). **C,** Light photomicrograph shows the formation of oil in water in oil-type emulsion with variably sized (10 to 50 μm) water droplets containing doxorubicin hydrochloride in the oil base.

widely used procedure. The goal of chemoembolization is to combine the effects of targeted tumor ischemia by embolization with intraarterial chemotherapy. To date, the most common sole-agent chemotherapeutic drug has been doxorubicin, followed by cisplatin, epirubicin, mitoxantrone, mitomycin C, and a chemical conjugate of a synthetic copolymer of styrene maleic acid and neocarcinostatin (SMANCS) (Marelli et al, 2007). The chemotherapeutic drug is dissolved in water or water-soluble contrast agent and is then mixed with iodized oil (Lipiodol; Laboratoire Guerbet, France) and administered as an emulsion (Fig. 83.1). When injected into the hepatic artery, iodized oil is trapped selectively in the tumor because of the hemodynamic difference between the tumor and normal liver parenchyma and presumably the absence of Kupffer cells in the tumor (Kan et al, 1993; Nakajo et al, 1988). Thus mixing iodized oil with a chemotherapeutic drug allows slow release of the chemotherapeutic drug over a period of 6 to 12 weeks (Raoul et al, 1992). In contrast, in the normal liver parenchyma, the iodized oil does not occlude the hepatic artery; rather it accumulates in the peripheral portal vein through arterioportal communications and subsequently passes through sinusoids into the systemic circulation (Chung et al, 1993). HAE after infusion of chemotherapeutic drugs increases drug dwelling time in the tumor by slowing the rate of efflux from the hepatic circulation. Furthermore, ischemic damage by embolization potentiates absorption of chemotherapeutic drugs by impeding the function of transmembrane pumps in tumor cells (Yu & Keeffe, 2003).

After infusion of the chemotherapeutic drug and iodized oil mixture, tumor-feeding peripheral hepatic arteries are embolized. Proximal arterial occlusion is not desirable, because it will not only induce development of intrahepatic and extrahepatic collateral vessels, it will also preclude repeat procedure. Thus it is important to select embolic materials of the proper size. The optimal size should be small enough to reach and occlude the capillaries to the tumor but bigger than the arteriovenous shunt and peribiliary plexus, to avoid the risk of pulmonary embolization and bile duct necrosis. To date, gelatin sponge particles have been the most frequently used agent, but polyvinyl alcohol (PVA) particle (Ramsey et al, 2002), absolute ethanol (Matsui et al, 1993), starch microspheres (Maluccio et al, 2008), cyanoacrylate (Berghammer et al, 1998), and even autologous blood clot (Gunji et al, 2002) have also been used.

Gelfoam is used as 500- to 1000-μm cubes, which only occludes the artery temporarily, with recanalization taking place within 2 weeks (Coldwell et al, 1994). It was proved not to cause serious hepatic damage in patients with good hepatic functional reserve (Kan et al, 1993; Sonomura et al, 1997);

however, gelfoam powder should not be used, as it may cause biliary stenosis and biloma resulting from embolization and necrosis of small arteriolar branches, which may cause biliary damage (Makuuchi et al, 1985). PVA particles cause a permanent or semipermanent arterial occlusion and can achieve more distal obstruction because of their smaller size (50 to 250 μm in diameter; Coldwell et al, 1994). Autologous blood clot achieves the same temporary artery occlusion as a gelatin sponge. Because the clot is lysed faster after embolization, there might be less chance of arterial thrombosis after several sessions of chemoembolization (Gunji et al, 2002). In a recent comparative nonrandomized study, no difference in patient survival was found between chemoembolization using gelatin sponge particles and that using PVA particles (Brown et al, 2005).

It is important to evaluate tumor-related arteriovenous shunt for safe procedures. In patients with HCC, angiographic incidence of shunting has been reported in 31.2%, shunting into the portal vein has been reported in 28.8%, and hepatic vein shunting has been reported in 2.4% (Ngan & Peh, 1997). The more liver parenchyma is occupied by the tumor, the more arteriovenous shunts exist; these are associated with poor prognosis (Granov et al, 1992) and are frequently problematic in chemoembolization of liver tumors (Izaki et al, 2004). Severe arterioportal shunt can cause hepatofugal portal flow, ascites, and variceal bleeding. In patients with a prominent arteriovenous shunt, embolization of the shunt is recommended prior to HAE (Huang et al, 2004). After embolization for massive arterioportal shunt, hepatofugal portal flow may convert to hepatopetal flow, and performance status and ascites may be improved (Izaki et al, 2004).

PATIENT SELECTION

Chemoembolization is indicated for the treatment of unresectable hypervascular liver tumors, which receive more blood supply from the hepatic artery than normal liver parenchyma, which makes the tumor suitable to HAE. The hemodynamic characteristics of a tumor may be documented on contrast-enhanced ultrasonography (Suzuki et al, 2003), computed tomography (CT) (Tajima et al, 2002b), and magnetic resonance imaging (MRI) (Levy, 2002).

The most common indication of chemoembolization is unresectable HCC. The determination of resectability of HCC should be based on either the extent of tumor involvement, underlying liver function, or a combination of these (see Chapters 2 and 90A). The majority of patients with HCC have underlying liver cirrhosis, which often requires a larger remnant liver after surgery to maintain hepatic function than in patients without underlying liver disease; therefore tumors that might be resectable in patients with normal liver parenchyma may not be resectable in patients with cirrhosis. Hepatic dysfunction also acts as a limitation in selecting patients for chemoembolization. Patients with poor hepatic function are not likely to tolerate extensive arterial embolization, because their livers are more dependent on arterial blood supply than normal liver, and moreover, patients with severe cirrhosis are more likely to die of their underlying liver disease than of HCC. Thus chemoembolization is typically recommended in patients with reasonably preserved liver function (Child-Turcotte-Pugh [CTP] class of A or B) and performance status (Eastern Cooperative Oncology Group [ECOG] 0 or 1). In general, patients with class C cirrhosis should not undergo chemoembolization as a primary treatment.

The extent of tumor is another important consideration in selecting patients for chemoembolization. Several methods have been proposed to weigh both hepatic function and the extent of tumor. In Okuda staging, patients are given points for presence of ascites, serum bilirubin and albumin levels, and the extent of tumor, and the patient is staged as I, II, or III (Okuda et al, 1985). The Cancer of the Liver Italian Program (CLIP) group proposed a more complex scoring system that includes the CTP score, tumor morphology and extension, presence of portal vein thrombosis, and serum α-fetoprotein (AFP) levels. The CLIP score was validated worldwide in multiple clinical trials and was proven to give more accurate prognostic information and greater survival predictive power than the Okuda staging system (CLIP, 2000; Ueno et al, 2001); however, those staging systems for predicting prognosis of patients with HCC did not indicate which patients would benefit from HAE. Recently, the Barcelona Clinic Liver Cancer (BCLC) staging system was developed to allow for the indication of the best therapy for each stage of HCC (Llovet et al, 1999a). In this staging system, chemoembolization is recommended as first-line therapy for intermediate stage HCC (Okuda staging 1 to 2, performance score 0, and large or multinodular disease) and some advanced-stage HCC (Okuda 1 to 2, performance score 1, no extrahepatic disease).

Spontaneous rupture of HCC is an indication for emergency HAE, regardless of underlying liver function (Kirikoshi et al, 2009). Even in patients with advanced liver cirrhosis, nodular HCC showing exophytic growth can be managed safely by selective embolization to prevent tumor rupture without diminishing liver function. Chemoembolization plays additional neoadjuvant roles as a downstaging therapy before resection or as a bridge therapy for patients awaiting liver transplantation (see Chapter 97D).

In general, the selection criteria for patients with HCC apply to patients with metastatic liver tumors; patients with unresectable hypervascular tumors will benefit from HAE. Typical hypervascular metastatic liver tumors include neuroendocrine tumors (NETs), gastrointestinal stromal tumors (GISTs), ocular melanoma, islet cell tumors, carcinoids, and sarcomas. The goal of HAE is symptomatic relief and improvement of survival. Most common indications are rapid progression of liver tumor with stable or absent extrahepatic disease, symptoms related to tumor bulk, and symptoms related to hormonal excess, especially in metastasis from neuroendocrine tumors.

Although no absolute contraindications to HAE exist, patients with two or three major poor prognostic indicators should not be treated. Generally accepted relative contraindications are extensive tumor involvement of more than 50% to 75% of the liver and class C cirrhosis. Major portal vein invasion by the tumor has been considered another relative contraindication, but this can be safely and effectively managed by an adjustment of the embolization protocol to reduce the amount of chemoembolic agents and the extent of the embolization, especially in patients with a limited parenchymal tumor and adequate liver function (Chung et al, 1995). Recent evidence demonstrates that HAE can be safely performed, even in patients with main portal vein occlusion, if hepatopetal collateral flow is present (Lee et al, 1997; Tazawa et al, 2001; Georgiades et al, 2005). In addition, active gastrointestinal bleeding, refractory ascites, extrahepatic spread, hepatic encephalopathy, and biliary obstruction are also considered relative contraindications. Regardless of the liver tumors, anaphylactoid reaction

to contrast media or renal insufficiency, uncorrectable coagulopathy, and severe peripheral vascular disease can preclude embolotherapy.

PROCEDURE

Before any chemoembolization procedure, laboratory tests should be done that include a complete blood cell count, prothrombin time, creatinine levels, and liver function testing. The baseline serum levels of tumor markers should be measured before treatment to monitor changes after treatment. By means of cross-sectional imaging studies, the size and extent of the tumor, its growth pattern (expansile vs. replacing or infiltrating), and macroscopic angioinvasion into the hepatic or portal veins are evaluated. For successful chemoembolization, accurate segmental localization of the tumor is crucial, and cross-sectional images are useful for that purpose (Yoon et al, 2008). In addition, imaging studies of the chest, abdomen, and pelvis are recommended to assess comorbid disease and ensure the presence or absence of metastatic disease.

Patients are fasted overnight and hydrated with normal saline at a rate of 200 to 300 mL/h. Antiemetics are administered intravenously, and patients with contrast allergies receive oral prednisone 1 hour before the procedure. The use of prophylactic antibiotics is controversial except in patients with a bilioenteric anastomosis or biliary stent (Geschwind et al, 2002; Ong et al, 2004; Tarazov, 1995). After infiltration of local anesthetic, the Seldinger technique is used to gain access to the common femoral artery, and initial diagnostic visceral arteriography is performed to determine arterial anatomy to the liver and patency of the portal vein. For complete angiography, all hepatic arteries should be adequately opacified, and all feeding arteries of the tumor should be identified.

Anatomic variations of celiac trunk and hepatic arteries are commonly encountered. With the introduction of multidetector row CT, these anatomic variations can be predicted before the procedure by careful review of the arterial phase scan (Song et al, 2010). Most common hepatic artery variations are the right hepatic artery arising from the superior mesenteric artery and the left hepatic artery arising from the left gastric artery, thus celiac and superior mesenteric arteriography is mandatory to identify the variations. Frequently, additional views in different angles and magnifications and selective contrast injection with use of a microcatheter are necessary to identify small feeding arteries (Yoon et al, 2008). To avoid nontargeted embolization, it is important to recognize the origin of the cystic artery and the right gastric artery, presence of a large falciform artery, and the accessory left gastric artery originating from the left hepatic artery (Song et al, 2006).

The treatment protocol should be individualized according to the hepatic functional reserve, extent of the tumor, and major portal vein invasion. Every effort should be made to preserve nontumorous liver parenchyma from ischemic damage by embolization. The best way to maximize treatment effect and to minimize procedure-related complications is to perform embolization of all tumor feeding arteries as selectively as possible. Patients with focal lesions should undergo segmental or, ideally, subsegmental embolization, in which a catheter or microcatheter is placed more selectively into the feeding artery in closer proximity to the tumor.

After the catheter is positioned appropriately, the mixture of iodized oil and chemotherapeutic drug is injected (Figs. 83.2 and 83.3). If there is a prominent arteriovenous shunt that precludes chemoembolic agents reaching the tumor vasculature, it is recommended first to embolize the shunt before injection of chemotherapeutic drugs (Fig. 83.4). The dose of iodized oil and chemotherapeutic agent depends on the size and vascularity of the tumor. The generally accepted upper limit of iodized oil is 15 mL. For a small tumor, enough iodized oil to saturate the entire tumor neovasculature could be administered. The end point for the mixture administration is stasis in tumor-feeding arteries or appearance of iodized oil in portal

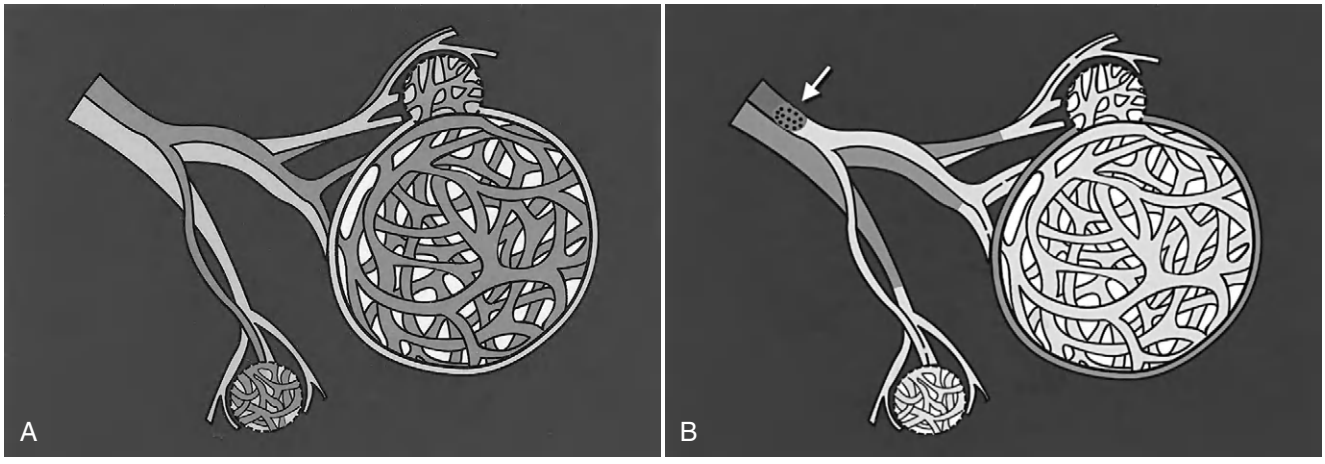

FIGURE 83.2. The concept of subsegmental or segmental chemoembolization using iodized oil. **A,** Exclusive arterial supply for encapsulated nodular hepatocellular carcinoma (HCC) and mixed arterial and portal venous supply for the portion of extracapsular invasion and small HCC without capsule formation. **B,** If a sufficient amount of a mixture of iodized oil and anticancer drug is injected through a tumor-feeding artery, not only the tumor neovasculature but also the peripheral portal veins around the tumor are filled with the emulsion. Subsequent hepatic artery embolization (*arrow*) may result in the effect of combined arterial and portal blockage; tumor fraction with mixed arterial and portal venous supply can be treated effectively by the combined effect of high-dose chemotherapy and ischemia.

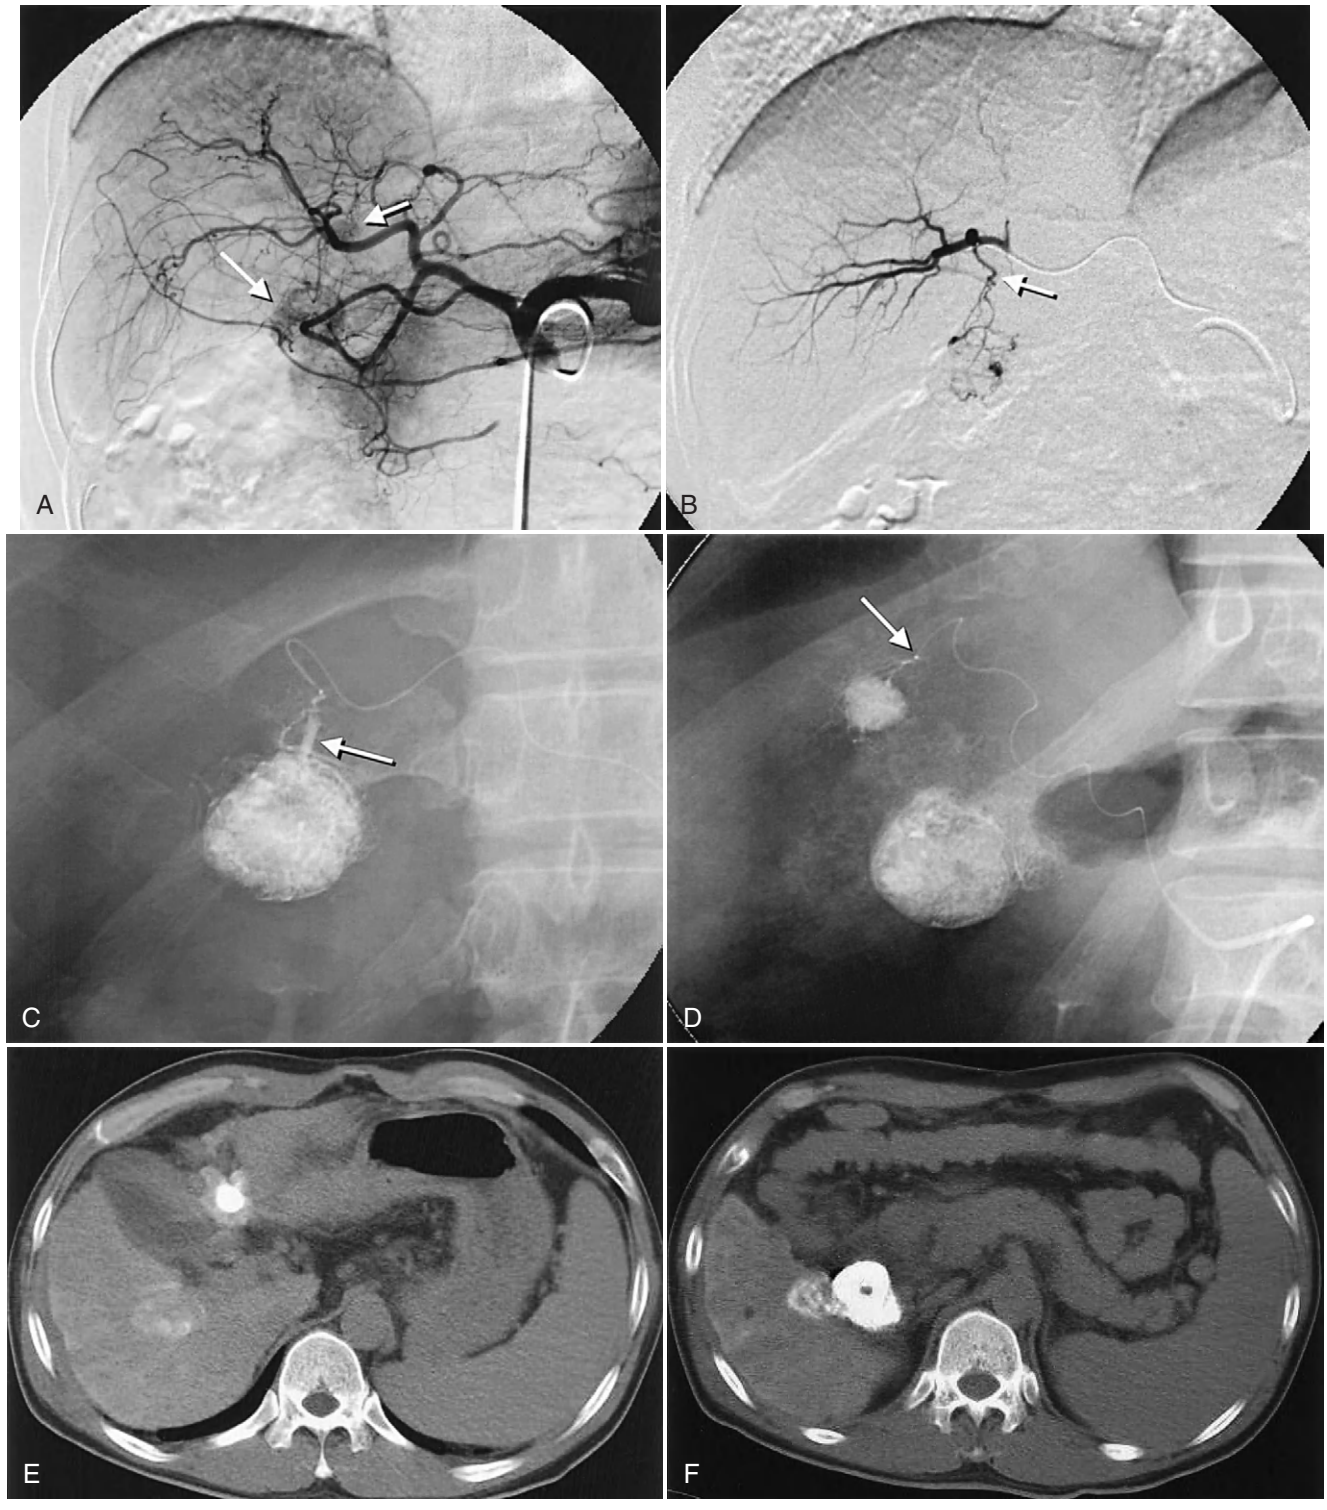

FIGURE 83.3. Subsegmental chemoembolization in a 43-year-old man with multinodular hepatocellular carcinoma. **A,** Celiac arteriogram shows two hypervascular tumor nodules (*arrows*) in the liver. **B,** The larger mass is supplied by a feeding artery (*arrow*) from the right posterior segmental branch. **C,** Subsegmental chemoembolization was performed by selective catheterization of the tumor-feeding artery and injection of an emulsion of 5 mL of iodized oil and 30 mg of doxorubicin hydrochloride. Gelfoam embolization was not performed because sufficient stagnation of blood flow was achieved after injecting the emulsion. Note the filling with iodized oil of the peripheral portal branch (*arrow*) accompanying the tumor-feeding artery. **D,** Subsegmental chemoembolization also was performed for the tumor located in hepatic segment IV by selective catheterization of the tumor-feeding artery (*arrow*). **E** and **F,** Iodized oil computed tomography (CT) reveals compact retention of iodized oil in the nodules.

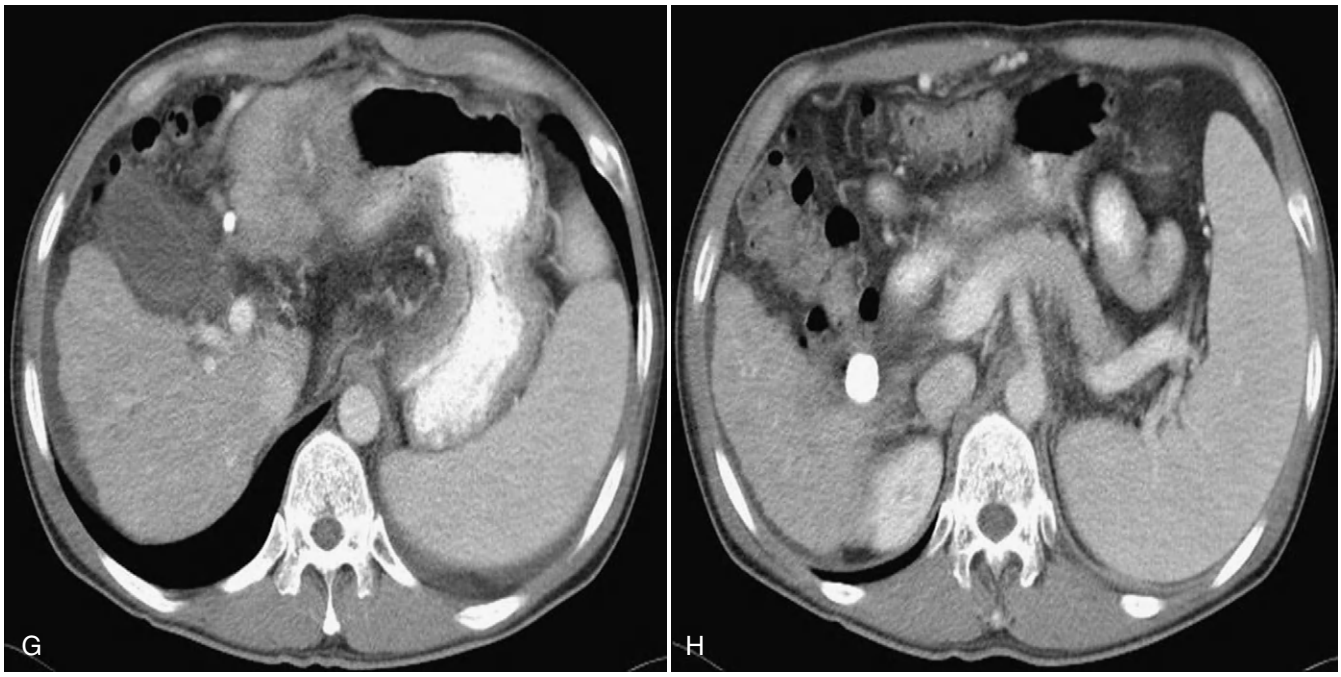

FIGURE 83.3, cont'd G and **H,** Follow-up CT scan 2 years later shows shrunken tumors without evidence of any viable portion.

vein branches (see Fig. 83.3). If flow is a persistent in the tumor-feeding arteries after infusion of chemotherapeutic drug, HAE should be performed. Gelatin sponge particles are the embolic agents most frequently used, because they degrade in a few weeks, allowing repeat treatment. PVA particle is another commonly used embolic agent, which causes a more permanent arterial occlusion (Ramsey et al, 2002).

Embolization of extrahepatic collaterals supplying the tumors is crucial to achieve successful outcomes. When a tumor is adjacent to a hepatic bare area or suspensory ligaments, or it invades into an adjacent organ, selective arteriogram of possible extrahepatic arteries should be obtained. With recent advances in CT imaging, those collateral vessels can be detected in preprocedure imaging studies (Kim et al, 2005). Common extrahepatic collaterals include the inferior phrenic artery, omental artery, internal mammary artery, colic branch of superior mesenteric artery, adrenal artery, intercostal artery, renal capsular artery, and gastric arteries (Chung et al, 2006; Kim et al, 2005, 2007, 2009; Won et al, 2003; Figs. 83.5 and 83.6). When the hepatic artery and extrahepatic collaterals supply the tumor, additional chemoembolization of the extrahepatic collaterals can be tried to increase the therapeutic efficacy of chemoembolization. These extrahepatic collaterals can be used as an access route to the tumors in patients with hepatic artery occlusion.

Recently, the use of C-arm cone-beam CT has been increasing. It can provide information about a patient's vascular anatomy, associated liver parenchyma, and the target lesion that constitutes a substantial improvement over conventional digital-subtraction angiography (DSA) and fluoroscopy (Carlson et al, 2001). C-arm cone-beam CT enables more selective catheterizations, which increases the amount of therapeutic agent delivered to the target area and decreases nontumorous liver parenchymal exposure to the agent (Meyer et al, 2007; Wallace et al, 2008; Fig. 83.7) In addition, confident identification of extrahepatic arteries supplying nontarget organs, such as supraduodenal or retroduodenal arteries, right gastric artery, phrenic artery, and falciform artery, is crucial to avoid nontarget embolization (Kim et al, 2009; Liu et al, 2005). When feeding arteries for a tumor are multiple, the portion of the tumor supplied by a catheterized feeding artery can be estimated, and the chemoembolic regimen can be proportioned accordingly. Iodized oil preferentially accumulated within tumors can be imaged without use of additional contrast media; thus completeness of therapy can be assessed immediately after treatment. If the oil has not accumulated in a portion of the tumor, the operator can search for hepatic or extrahepatic collateral tumor supply (Meyer et al, 2007; Wallace et al, 2007).

Intraarterial lidocaine and intravenous narcotic analgesics are given before the procedure to relieve pain during and after (Lee et al, 2001b). After the procedure, hydration is continued with normal saline. Narcotic analgesics, chlorpromazine, and acetaminophen are additionally supplied for 1 to 3 days as needed. Patients can be discharged once they have resumed adequate oral intake, and intravenous analgesics are no longer required.

Laboratory studies of liver function and serum levels of tumor markers should be repeated 2 to 4 weeks after the procedure. Multiphase contrast-enhanced CT or MRI is recommended 4 to 8 weeks after the procedure to evaluate the efficacy of the treatment and to detect local or remote tumor recurrences. If viable tumor is evident on imaging studies, serum levels of tumor markers are elevated, or both, patients return for another session of embolotherapy according to their hepatic functional recovery. No consensus has been reached on the ideal protocol for repeat procedures, but based on a retrospective comparison, survival rates and patient tolerance seemed to be higher when treatment was repeated, but only when progression of HCC was noted radiographically (Ernst et al, 1999).

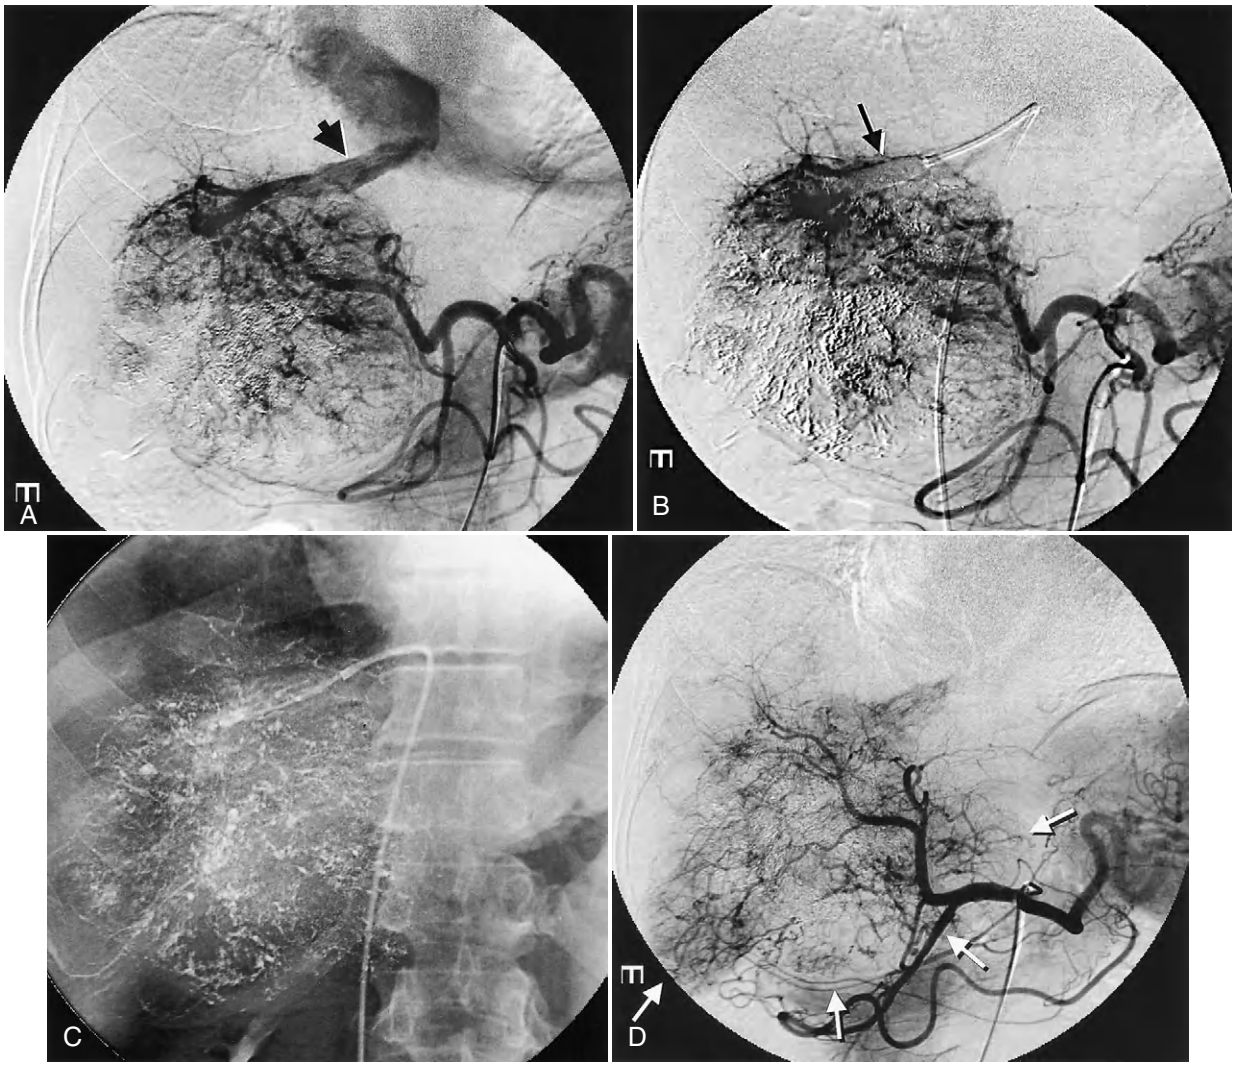

FIGURE 83.4. Severe arteriovenous shunt into the middle hepatic vein managed by chemoembolization after balloon occlusion of the middle hepatic vein in a 66-year-old man with hepatocellular carcinoma. **A,** Celiac arteriogram shows huge hypervascular mass with severe arteriovenous shunt into the middle hepatic vein (*arrow*). **B,** After balloon occlusion of the middle hepatic vein (*arrow*), celiac arteriography was repeated and confirmed the disappearance of the shunt. With the balloon inflated, chemoembolization was performed with a mixture of 10 mL of iodized oil and 50 mg of doxorubicin hydrochloride followed by Gelfoam embolization. **C,** Completion radiograph with the balloon deflated shows successful accumulation of iodized oil in the mass without untoward pulmonary embolization. **D,** Three months later, follow-up angiogram shows remarkably decreased arteriovenous shunt and the tumor fraction supplied by the hepatic arteries. An overgrowth of the tumor fraction is supplied by omental arteries (*arrows*).

THERAPEUTIC EFFICACY OF CHEMOEMBOLIZATION

Hepatocellular Carcinoma

Although the primary outcome after chemoembolization should be increased patient survival time, many other factors have been published in an effort to assess the efficacy of chemoembolization. These factors include objective response determined on imaging studies (reduction of tumor size, fraction of tumor necrosis, Lipiodol retention), biologic response (decrease in serum tumor markers), quality of life, and improvement of symptoms.

Numerous studies have shown that chemoembolization induces a significant tumor necrosis without negative influence on liver function in patients with preserved liver function. The extent of tumor necrosis has been reported to range from 60% to 100%. With introduction of subsegmental chemoembolization using a microcatheter, the tumor necrosis rate was markedly improved. Matsui and colleagues (1993) reported complete necrosis in about 70% of 100 small hypervascular HCCs less than 4 cm in diameter treated by subsegmental chemoembolization; however, especially in large tumors, even though necrosis may appear macroscopically complete, histologic examination reveals viable neoplastic cells responsible for the high rate of recurrence after treatment. During follow-up the

FIGURE 83.5. Massive hepatocellular carcinoma supplied by multiple extrahepatic collaterals in a 43-year-old man. **A,** Arterial phase computed tomographic (CT) scan shows a huge hypervascular mass in the right hepatic lobe (*arrows*). **B,** Celiac arteriogram shows a well-demarcated hypervascular mass with multinodular confluent appearance. **C** and **D,** Selective angiograms of the renal capsular artery (**C**) and the right inferior phrenic artery (**D**) also show multifocal tumor stain. Chemoembolization was performed with a mixture of 20 mL of iodized oil and 100 mg of doxorubicin hydrochloride followed by Gelfoam embolization at the right hepatic artery and extrahepatic collaterals. **E,** Postembolization plain radiograph shows diffuse uptake of iodized oil in the tumor. **F,** Follow-up CT scan shows a markedly shrunken primary tumor with a thick capsule, persistent iodized oil retention, and well-preserved, nontumorous hepatic parenchyma.

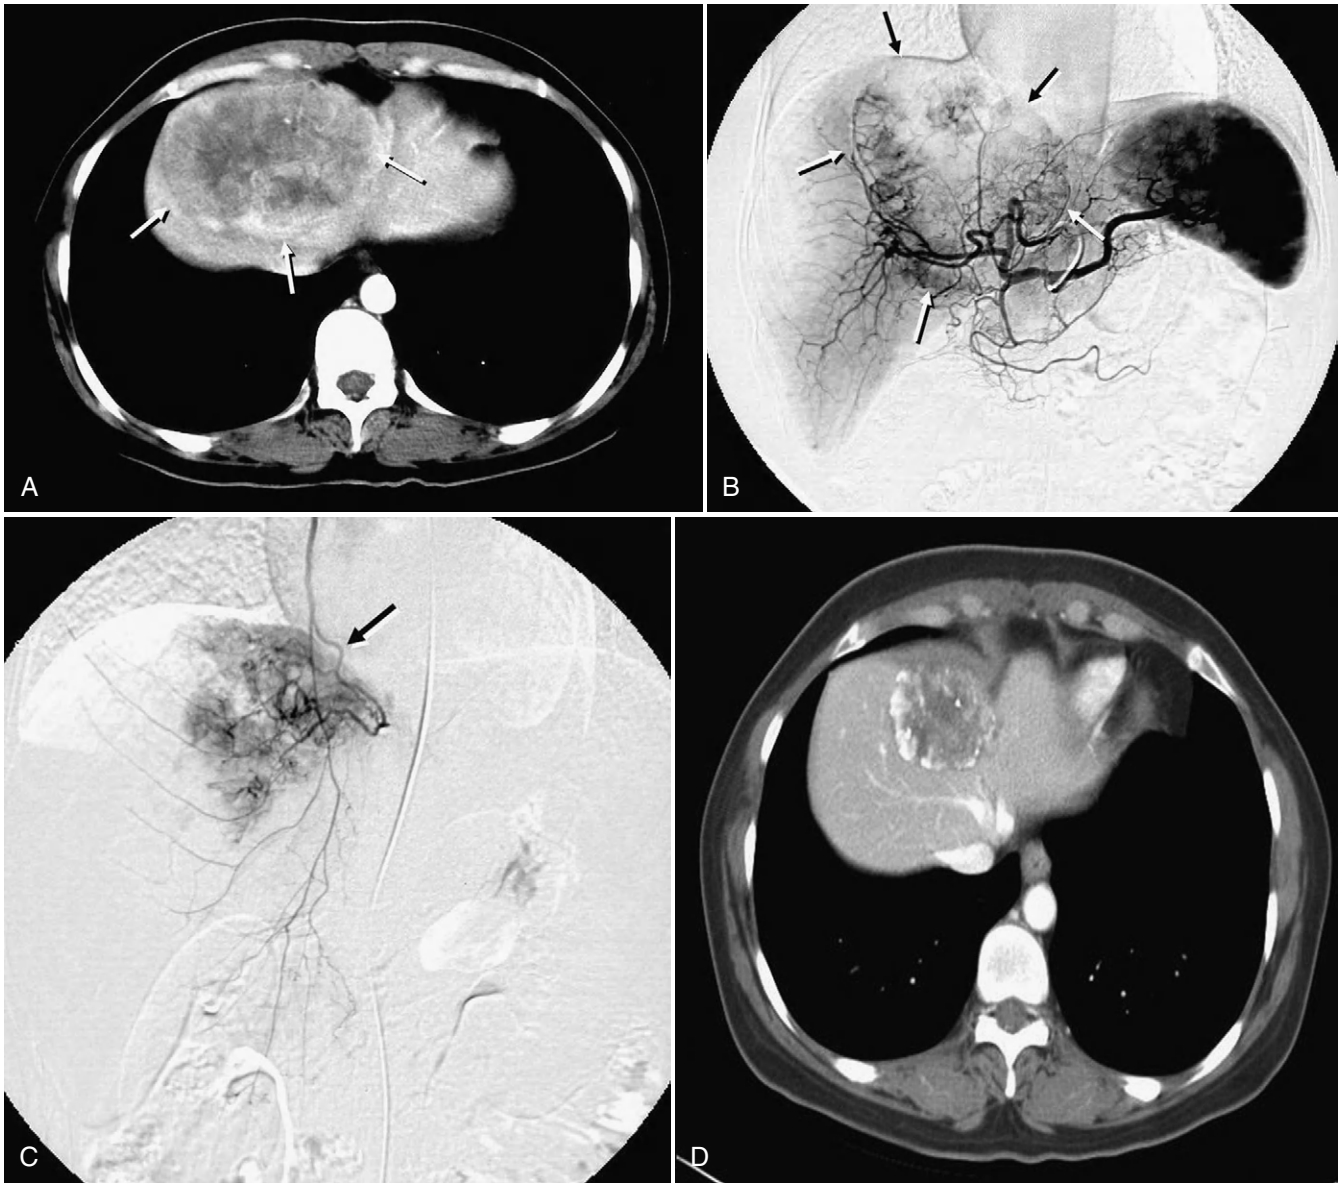

FIGURE 83.6. Hepatocellular carcinoma supplied by the right internal mammary artery as an extrahepatic collateral at its initial presentation in a 34-year-old woman. **A,** Initial computed tomographic (CT) scan shows a large tumor abutting the anterosuperior aspect of the diaphragm (*arrows*). **B,** Celiac arteriogram shows a large hypervascular mass occupying the medial segment of the left hepatic lobe and extending to the adjacent segments (*white arrows*). A defect in tumor stain appears at the superior aspect of the tumor (*black arrows*), suggesting the presence of an extrahepatic collateral supply. **C,** Right internal mammary arteriogram shows tumor stain at the area exactly matched with the defect in tumor stain on the celiac arteriogram. Chemoembolization was performed with a mixture of 15 mL of iodized oil and 50 mg of doxorubicin hydrochloride followed by Gelfoam embolization at the right hepatic artery and the diaphragmatic branch of the right internal mammary artery (*arrow*). **D,** Nine-year follow-up CT scans show a markedly shrunken tumor with no evidence of enhancing viable tumor.

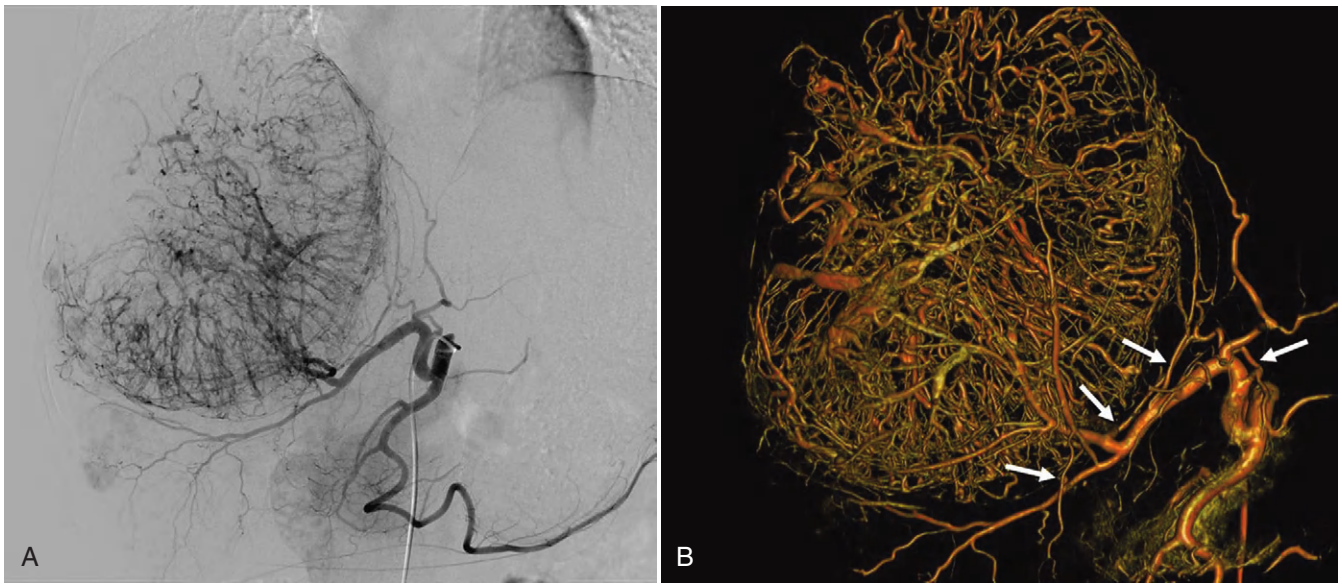

FIGURE 83.7. Application of cone-beam computed tomography (CT) for chemoembolization of hepatocellular carcinoma in a 49-year-old man. **A,** Common hepatic arteriography shows a huge hypervascular mass in the right hepatic lobe supplied by multiple feeding vessels. **B,** Three-dimensional volume-rendered image from cone-beam CT clearly demonstrates tumor feeders, including multiple, small, central feeding vessels (*arrows*). Real-time interactive anatomic information provided by cone-beam CT helps achieve successful superselective catheterization of tumor feeders and complete chemoembolization.

residual tumor nests recover their blood supply, and the tumor continues to grow. Additional treatments may be administered, either at specified intervals or as needed, but no data plainly favors either strategy (Bruix et al, 2004). Several studies have suggested that tumor characteristics lead to favorable response after chemoembolization—including small, encapsulated, expansile, hypervascular tumors—and long-term retention of iodized oil may be seen on CT (Itsubo et al, 2002; Kuroda et al, 1991; Nakamura et al, 1993). Pathologically, trabecular-type HCC showed more prominent necrosis than scirrhous, compact, or well-differentiated HCC (Jinno et al, 1992).

Several case-control and retrospective studies have shown a survival benefit in patients treated with chemoembolization compared with untreated patients or historic control subjects (Aoyama et al, 1992; Bismuth et al, 1992; Bronowicki et al, 1994; Rose et al, 1999). Bronowicki and colleagues (1994) performed a case-control study that stratifed 254 patients according to CTP classification and Okuda staging. The survival rates of the chemoembolization group were significantly higher (64%, 38%, 27%, and 27% at 1, 2, 3, and 4 years, respectively) than those of the conservative management group (18%, 6%, and 5% at 1, 2, and 3 years, respectively). The survival benefit from chemoembolization was not confirmed in early randomized, controlled trials (RCTs) performed in the 1990s (Camma et al, 2002; Groupe d'Etude et de Traitement du Carcinome Hépatocellulaire, 1995; Pelletier et al, 1990). However, two newer RCTs, one from Barcelona (Llovet et al, 2002) and one from Hong Kong (Lo et al, 2002), reported a significant positive impact of chemoembolization on patient survival. This permitted a positive result in a cumulative meta-analysis of all RCTs published from 1978 to 2002; thus, according to the guidelines published by the American Association for Study of Liver Diseases (AASLD) (Bruix & Sherman, 2005) and the European Association for the Study of the Liver (EASL) (Bruix et al, 2001), chemoembolization is recommended as first-line noncurative therapy for nonsurgical patients with large or multifocal HCC who do not have vascular invasion or extrahepatic spread. The improvement in survival in treated patients ranges from 20% to 60% at 2 years (Bruix et al, 2004), but it is clear that the relevance of the improvement, as compared with the outcome if untreated, is largely dependent on the patients' baseline characteristics regarding tumor stage, liver function, and general health status (Llovet et al, 2003). In a recent prospective cohort study that included 8510 patients with unresectable HCC, the median survival rate was 34 months, with an overall survival at 1, 3, 5, and 7 years of 82%, 47%, 26%, and 16%, respectively (Takayasu et al, 2006).

Chemoembolization as a neoadjuvant therapy in candidates for hepatic resection is controversial (see Chapter 90A). Several retrospective studies reported a possible survival benefit in patients treated with chemoembolization before resection of HCC when compared with resection alone (Gerunda et al, 2000; Zhang et al, 2000). Zhang and colleagues (2000) retrospectively analyzed postoperative outcomes of 1457 HCC patients treated with hepatectomy and concluded that effective preoperative chemoembolization can improve disease-free survival after hepatectomy. On the contrary, in a randomized trial by Zhou and colleagues (2009), preoperative chemoembolization did not improve surgical outcomes, and no significant difference was found between the preoperative chemoembolization group and the control group in disease-free survival rates and overall survival rates. Moreover, the preoperative chemoembolization group had a lower resection rate and longer operative time. Choi and colleagues (2007) studied 273 patients who underwent curative resection for HCC; 120 of them underwent preoperative chemoembolization. The 1-, 3-, and 5-year

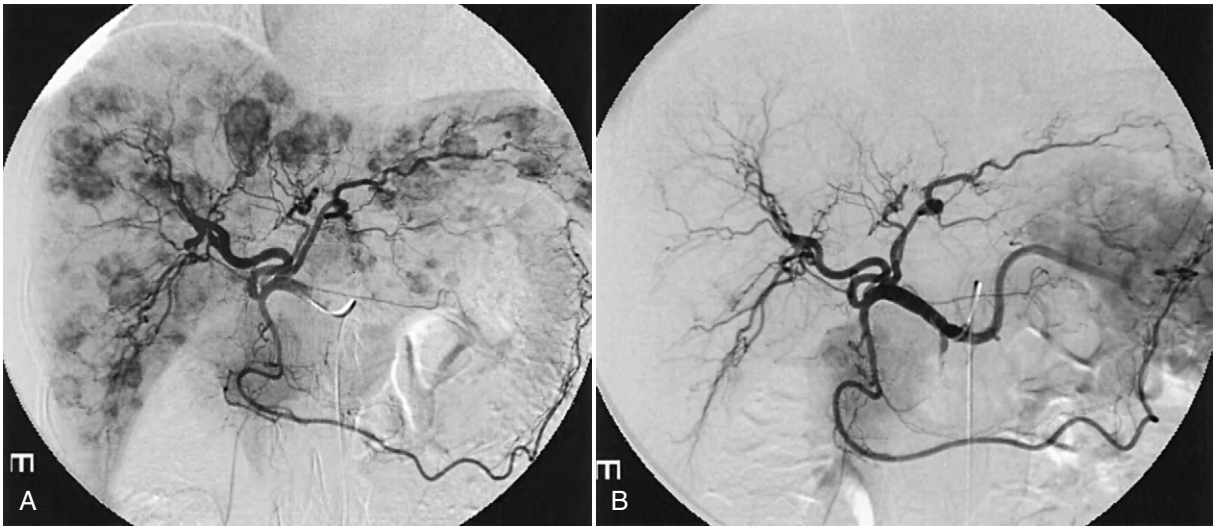

FIGURE 83.8. Liver metastasis of a rectal carcinoid in a 36-year-old woman. **A,** Celiac arteriogram shows numerous metastatic nodules scattered in both hepatic lobes. Initial chemoembolization was performed with a mixture of 7 mL of iodized oil and 40 mg of doxorubicin hydrochloride followed by Gelfoam embolization. **B,** Follow-up celiac arteriogram 2 years later after eight sessions of repeat chemoembolization shows markedly improved metastatic lesions.

disease-free survival rates were 76.0%, 57.7%, and 51.3%, respectively, in the chemoembolization group and 70.9%, 53.8%, and 46.8%, respectively, in the nonchemoembolization group. Although a difference was noted between two groups, it was not significant. Chemoembolization has also been performed to reduce tumor volume (downstaging) before hepatic resection. Majno and colleagues (1997) showed that downstaging (42%) or complete necrosis (50%) was achieved in 49 patients.

Orthotopic liver transplantation (OLT) has been shown to be the best treatment for early-stage HCC (see Chapter 97D); however, because of a steadily increasing waiting time, a noteworthy proportion of patients are excluded from OLT because of tumor progression. Llovet and colleagues (1999b) reported a 23% dropout rate as a result of tumor progression in the first 6 months of waiting for OLT without any neoadjuvant therapy. Chemoembolization has been performed as a bridge therapy prior to liver transplantation, to inhibit tumor growth while a patient awaits an organ, but no controlled study is available for comparing patients who underwent OLT for HCC with and without neoadjuvant chemoembolization. Four noncomparative studies reported dropout rates in patients who underwent chemoembolization that ranged from 0% to 46%. Other trials used chemoembolization prior to transplantation to prevent tumor dissemination during surgery, which may result in better posttransplantation outcomes (Decaens et al, 2005; Stockland et al, 2007), although the role of chemoembolization for this purpose is still being debated. In a case-control study that included 100 patients who received pretransplant chemoembolization and 100 control patients, pretransplant chemoembolization does not influence posttransplantation survival or disease-free survival (Decaens et al, 2005). Another purpose of pretransplantation chemoembolization is to downstage advanced HCC and expand selection criteria for liver transplantation. Chapman and colleagues (2008) performed pretransplantation chemoembolization in 76 patients with advanced HCC (American Liver Tumor Study Group stage III/IV). Of these 76 patients, 17 (22.4%) were successfully downstaged to qualify for OLT under the Milan criteria. Importantly, patients who are successfully downstaged and transplanted have excellent midterm disease-free and overall survival, similar to stage II HCC. Similarly, Yao and colleagues (2008) showed that successful downstaging of HCC can be achieved in the majority of carefully selected patients, and it is associated with excellent posttransplantation outcome.

Neuroendocrine Tumors (See Chapter 81B)

NETs are the most common secondary liver cancer, and they have also been managed with hepatic embolotherapy (Fig. 83.8). They are slow-growing tumors, frequently found when the disease has become metastatic. Curative surgery should always be considered as a first-line treatment, but less than 10% of patients have resectable tumors because of the diffuse nature of the disease. The development of liver metastasis causes synthesis and release of hormonal substances that lead to a constellation of symptoms, including rash, hypertension, diarrhea, and electrolyte disorders; these are collectively known as *carcinoid syndrome*. In the later stages of the disease, significant hepatomegaly by bulky metastatic tumors may cause progressive pain and dyspnea, and the primary goal of hepatic embolotherapy is to reduce liver tumor burden and palliate symptoms.

To date, partial or complete response after embolotherapy has ranged widely in reports, from 6.7% to 100%, and median survival has been reported from 13 to 80 months. Although many studies have reported median survival of more than 3 years, it is unclear whether embolotherapy significantly improves survival because of the indolent nature of the tumor; however, it is clear that outcomes are inversely related to the degree of liver replacement by tumor, and patients with carcinoid tumor have significantly prolonged survival compared with patients with islet cell tumor after embolization. Recently, Gupta and

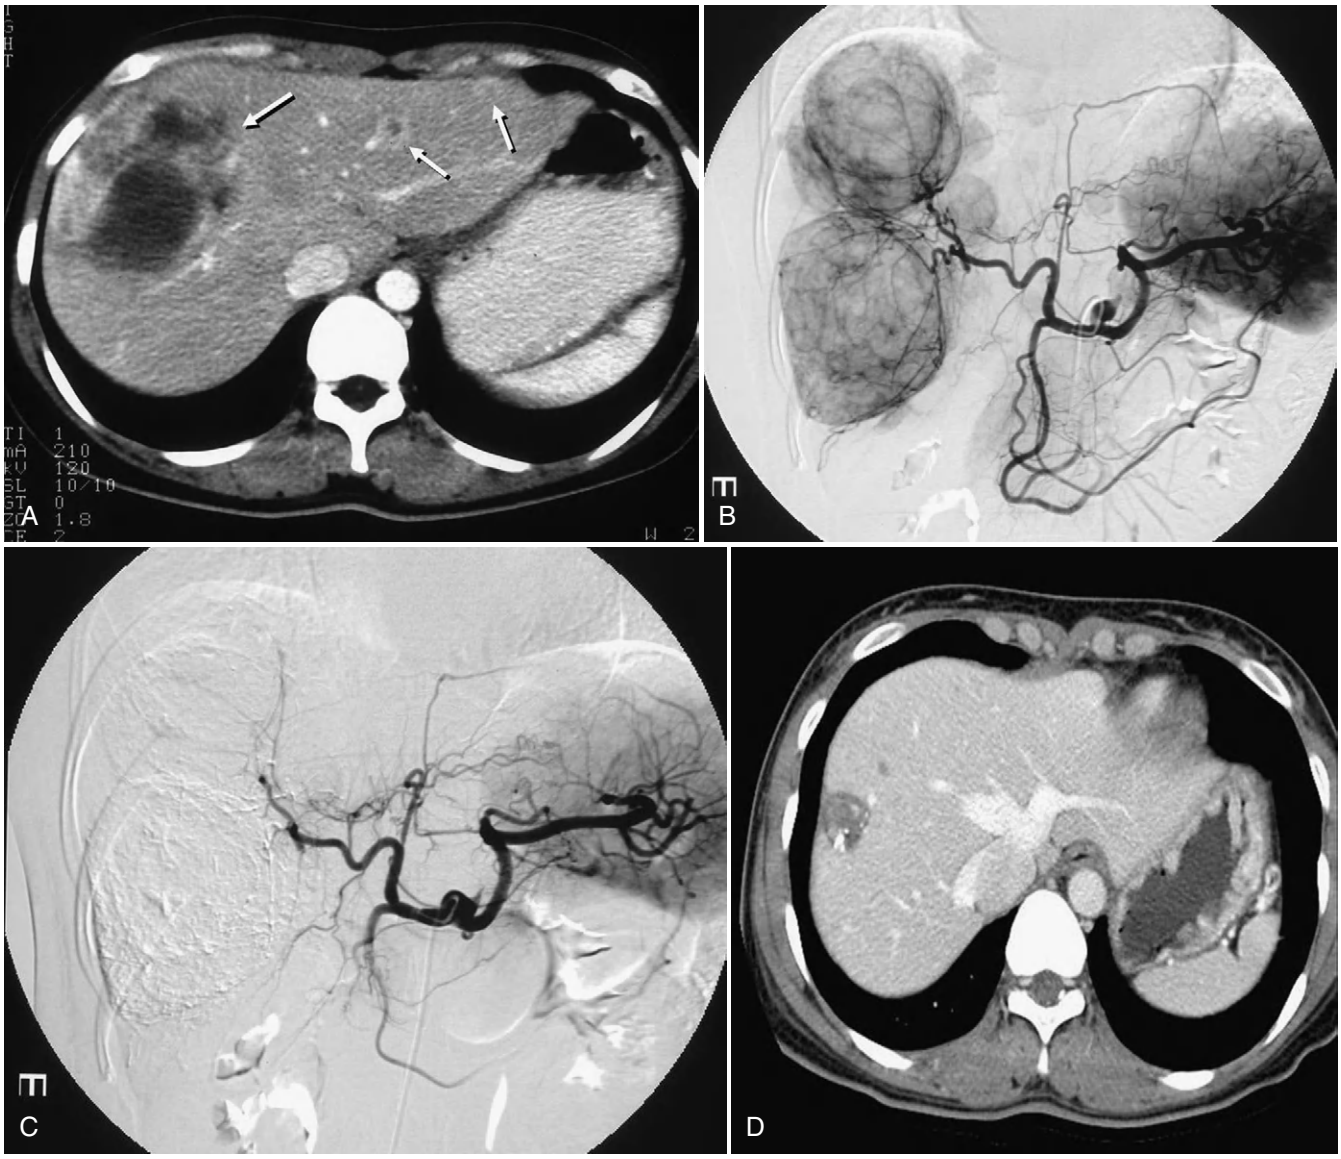

FIGURE 83.9. Liver metastasis of gastrointestinal stromal tumor of the stomach in a 34-year-old woman. **A,** Computed tomographic (CT) scan of the liver shows multiple metastatic tumors in the both hepatic lobes (*arrows*). **B,** Celiac arteriogram shows multiple and variably sized hypervascular tumors in the liver. **C,** Initial chemoembolization was performed with a mixture of 10 mL of iodized oil and 50 mg of doxorubicin hydrochloride followed by Gelfoam embolization. Completion arteriogram shows successful devascularization of the tumor. **D,** After three sessions of repeat chemoembolization, 8-year follow-up CT scan shows no evidence of viable tumor in the liver.

colleagues (2005) performed bland embolization or chemoembolization in 69 patients with carcinoid tumors and in 54 with pancreatic islet cell carcinomas. In patients with carcinoid tumors, bland embolization had a higher response rate than chemoembolization. In contrast, patients with islet cell carcinomas treated with chemoembolization had a prolonged overall survival time and improved response rate compared with those treated with bland embolization; this was not an unexpected result, because carcinoid tumors have a lower response rate to systemic chemotherapy than do islet cell tumors.

Some authors recommend a tumor burden greater than 50%, but others recommend a burden greater than 75% as an exclusion criterion for embolization, because poor outcomes and response rates have been documented. In these high-risk patients, embolotherapy should be performed in stages, with only a part of the vascular tumor embolized at each session. Using this approach, one series treated patients with greater than 75% replacement of the liver by tumor and reported response rates of 43% and 25% and overall survival of 20.1 and 16 months for patients with carcinoid tumor and islet cell carcinoma respectively. For small tumors and for patients with fewer than three tumors, hepatic embolotherapy can be combined with local ablation therapies to maximize tumor necrosis and improve local disease control.

Prior to the introduction of pharmacologic antagonists of tumor metabolites, exacerbation of the symptoms of carcinoid or carcinoid crisis was common after embolotherapy. The increased availability of somatostatin analogues has

allowed remarkable reduction of this complication after embolotherapy.

Sarcoma and Gastrointestinal Tumors (See Chapter 81C)

A small number of investigations have addressed hepatic embolotherapy for the treatment of sarcoma and GISTs. Most gastrointestinal soft-tissue neoplasms previously classified as leiomyomas, schwannomas, leiomyoblastomas, or leiomyosarcomas are today classified as GISTs on the basis of molecular and immunohistologic features. The liver is the most common site of metastasis from malignant GISTs. Surgical resection is the treatment of choice for a single metastasis, but the majority of patients with liver-dominant metastases have unresectable disease. Because this tumor is frequently hypervascular, hepatic embolotherapy has been an effective palliative treatment for unresectable liver metastases (Fig. 83.9). Mavligit and colleagues (1995) treated 15 patients with metastatic leiomyosarcoma with chemoembolization using PVA particle, cisplatin, and vinblastine, which produced a major tumor response—more than 50% regression—that lasted 8 to 31 months in 70% of patients. Similarly, in a small series by Rajan and colleagues (2001), partial response rate was 69% with a median survival of 13 months after chemoembolization. A more recent study that employed bland embolization demonstrated a radiologic response of 60% and a median survival of 24 months (Maluccio et al, 2006). A significant survival benefit was documented in patients with a radiologic response (median, 63 vs. 19 months). Because imatinib mesylate (Gleevec), a tyrosine kinase inhibitor, proved to be highly effective against GISTs (Demetri et al, 2002), hepatic embolotherapy is currently recommended for patients who failed therapy or became resistant to Gleevec.

Colorectal Metastases (See Chapter 81A)

Colon cancer is the second leading cause of cancer-related death in the Western world, and the liver is the commonest site of distant metastasis of colon cancer. Approximately 50% to 60% of patients with colorectal cancers will develop liver metastasis in their lifetime, and over half will die from their metastatic liver diseases. Surgical resection is the only potentially curative treatment for liver metastasis from colon cancer, but less than 30% of patients have resectable disease at initial evaluation (Fusai & Davidson, 2003; Meyers et al, 2003). Systemic chemotherapy remains the standard of care for this population.

Recent advances in chemotherapeutic drugs have resulted in improved survival, but overall median survival is still just more than 20 months. Bland hepatic artery embolization and chemoembolization have been used as a second-line therapy, when a liver tumor progresses during systemic chemotherapy. A limited number of series have documented that survival rates are significantly improved in selected patients with good performance status, no extrahepatic disease, and solitary lesions (Martinelli et al, 1994; Salman et al, 2002; Sanz-Altamira et al, 1997).

Preoperative chemoembolization has been proposed as a possible means of decreasing perioperative tumor dissemination and downstaging of tumor to allow resection, but only in a small number of patients. Vogl and colleagues (2003) suggested chemoembolization combined with ablation therapy as a viable treatment option. They performed sequential chemoembolization to reduce tumor size to 5 cm or less, and then treated tumors with laser-induced thermal ablation. This regimen resulted in a mean survival of more than 26 months, versus 12.8 months for patients treated by chemoembolization only.

Ocular Melanoma (See Chapter 81C)

Ocular melanoma is a rare but highly malignant disease with median survival of 2 to 6 months. Liver metastasis is found up to 40% of patients at initial evaluation, and a sole metastasis is found in more than 80% of patients. A few series used chemoembolization for local control of metastatic uveal melanoma (Feldman et al, 2004; Mavligit et al, 1988), and a retrospective study of 201 patients compared cisplatin-based chemoembolization with systemic chemotherapy and reported that chemoembolization produced a better response rate (36%) (Bedikian et al, 1995). These results were similar to those of a previous study that reported a response rate of 46% and a median survival of 11 months (Mavligit et al, 1988). Because most patients die of systemic disease, chemoembolization is unlikely to improve survival of patients.

COMPLICATIONS

Hepatic embolotherapy is associated with diverse complications. Procedure-related mortality rate is less than 5%, and the incidence of major complications has been reported to be less than 5%, including liver failure or infarction, liver abscess, biliary necrosis, and nontarget embolization (Chan et al, 2002; Ramsey et al, 2002; Song et al, 2001). Important predisposing factors for major complications are major portal vein obstruction, compromised hepatic functional reserve, biliary obstruction, previous biliary surgery, excessive use of iodized oil, and nonselective embolization (Chung et al, 1996). Recognition of predisposing factors before the procedure, selective embolization with an adequate amount of chemoembolic material, and careful postprocedure monitoring of patients is mandatory to prevent these complications.

Postembolization Syndrome

Postembolization syndrome (PES) occurs in approximately 80% of patients and consists of pain, fever, nausea, and vomiting. PES is more of a side effect than a complication of hepatic embolotherapy. The etiology of PES is not fully understood, but it is thought to be a type of tumor lysis syndrome. Abrupt tumor cell death by ischemic damage causes release of intracellular toxins into circulation, which may cause fever, nausea, and vomiting (Patel et al, 2000). Possible causes of pain are acute ischemia of liver parenchyma, distension of the liver capsule, and gallbladder ischemia secondary to inadvertent embolization of the cystic artery. Leung and colleagues (2001) reported that inadvertent gallbladder embolization and the dose of chemotherapeutic drug are associated with this syndrome. PES is treated with supportive management that includes antiemetics, analgesics, and antipyretics; it typically subsides after 1 to 3 days.

Liver Failure

The most serious complication of hepatic embolotherapy is hepatic insufficiency. In a prospective study that included 197 sessions of chemoembolization, acute liver failure developed in

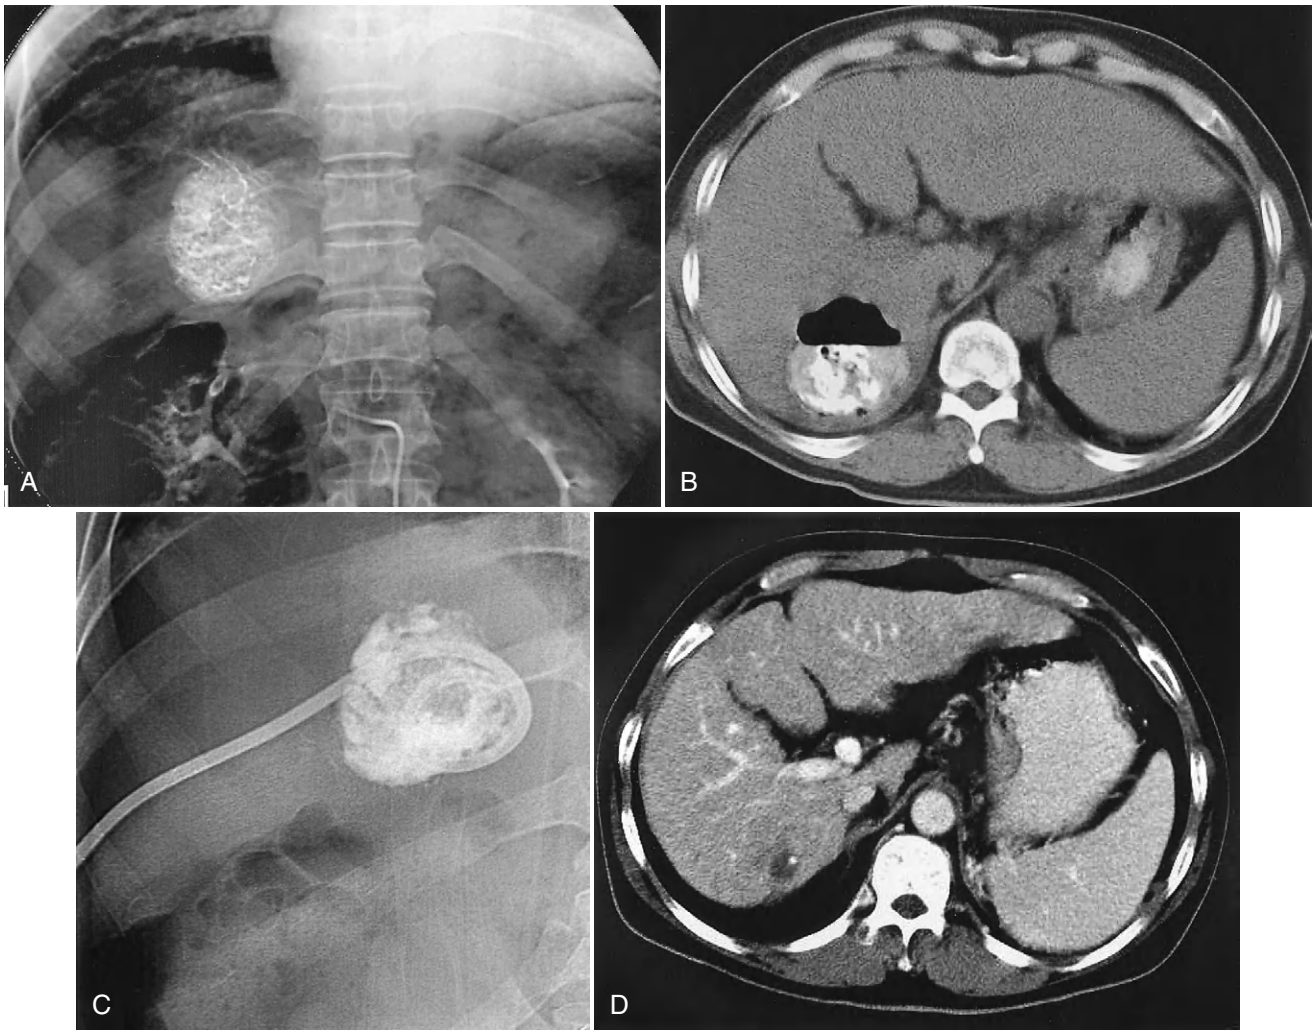

FIGURE 83.10. Liver abscess formation after chemoembolization and treatment with percutaneous drainage in a 55-year-old man. **A,** Plain radiograph obtained after chemoembolization shows selective iodized oil accumulation in the tumor. **B,** Noncontrast computed tomographic (CT) scan 2 weeks later shows air-fluid level in the tumor. **C,** The abscess cavity is drained with a percutaneous drainage catheter. **D,** Follow-up CT scan 1 month later shows remarkable shrinkage without evidence of viable tumor.

20% of patients, and 3% of these cases were irreversible. Hyperbilirubinemia, prolonged prothrombin time, higher dose of chemotherapeutic drug, and advanced cirrhosis were associated with irreversible failure (Chan et al, 2002). In general, chemoembolization does not influence liver function in patients with class A or B cirrhosis, and most liver dysfunction that requires hospitalization develops in patients with class C disease (Shah et al, 1998).

Liver Abscess (See Chapter 66)

Liver abscess is a rare (0.5% to 2%) but serious complication of hepatic embolotherapy (Kim et al, 2001). In a study by Song and colleagues (2001), predisposing factors for liver abscess included portal vein obstruction, metastatic tumors, and biliary abnormalities. Prior bilioenteric bypass surgery or sphincter of Oddi dysfunction for any reason have been reported as the most important predisposing factors for intrahepatic abscess following embolotherapy (Kim et al, 2001; Ong et al, 2004). Biliary concentrated antibiotics, such as piperacillin, with bowel preparation before the procedure is recommended to prevent liver abscess in these patients (Geschwind et al, 2002), who typically have leukocytosis and spiking fever that occur 7 to 10 days after the procedure. Liver abscess can be managed with percutaneous drainage and parenteral antibiotics (Song et al, 2001; Fig. 83.10).

Bile Duct Injury (See Chapter 42)

Intrahepatic and extrahepatic bile ducts may be damaged by hepatic arterial embolotherapy, because they are supplied by the peribiliary capillary plexus from the hepatic artery. This complication is relatively common (2% to 12.5%) and manifests as intrahepatic biloma, focal stricture of the common bile duct, or diffuse dilatation of intrahepatic bile duct (Kim et al, 2001; Kobayashi et al, 1993; Miyayama et al, 2010). The intrahepatic bile duct injury may cause obliteration of adjacent portal vein, liver parenchymal atrophy, and liver abscess (Yu

et al, 2001). Sakamoto and colleagues (2003) reported that bile duct injury is more frequent in patients with metastatic tumor, noncirrhotic liver, and in those who underwent selective embolization of distal hepatic arteries. Most patients are asymptomatic, but when signs of biliary infection are present, parenteral antibiotics and percutaneous drainage are required.

Extrahepatic Nontargeted Embolization

Nontarget embolization is the most dreaded complication of hepatic embolotherapy, but it occurs infrequently if diagnostic angiogram has been carefully performed, and the appropriate technique of embolization has been followed. The gallbladder is the most common nontarget organ, because the cystic artery is often not opacified on arteriogram. Inadvertent embolization of the cystic artery causes prolonged PES with fever, pain, nausea, and vomiting. Most cases follow a self-limited clinical course, but more serious conditions have been reported, such as gallbladder perforation and gangrenous or emphysematous cholecystitis, in which cholecystectomy or percutaneous cholecystostomy is required (Tarazov et al, 2000).

Skin complications can develop after chemoembolization of extrahepatic collateral vessels, such as the internal mammary artery and intercostal artery (Lee et al, 2001a; Hama et al, 2000). Painful induration and discoloration are often observed, but transmural necrosis that requires skin graft is rare. A supraumbilical skin rash can develop, if the emulsion of iodized oil and chemotherapeutic drug flows into the falciform artery. To avoid this complication, when a well-developed falciform artery is identified on hepatic arteriogram, it should be embolized using coils before injection of chemoembolic agent into the left hepatic artery (Ueno et al, 1995).

Gastroduodenal ulcer can occur as a result of inadvertent embolization of the accessory left gastric arteries that arise from the left hepatic artery and the right gastric artery that arises from the proper or left hepatic arteries (Morante et al, 2006). If these gastric branches are not recognized before the procedure, and appropriate protective measures are not taken, gastric complications are unavoidable. Embolization of gastric branches with coil or balloon occlusion of the proper hepatic artery can redirect the blood flow.

Chemoembolization of the inferior phrenic artery frequently results in pulmonary complications, including iodized oil accumulation in the lung field, consolidation, and pleural effusion (Tajima et al, 2002a). Diaphragmatic weakness can also develop in about one third of patients as an ischemic complication (Lee et al, 2009; Shin et al, 2006). In the presence of an arteriovenous shunt, a potential risk of pulmonary embolism or infarction exists, because the iodized oil can pass through the shunt. The incidence of pulmonary oil embolization increases to 43% when a large amount of iodized oil is used for chemoembolization (Chung et al, 1993). Respiratory symptoms of cough, hemoptysis, and dyspnea developed in 2 to 5 days and completely cleared 10 to 28 days after chemoembolization in most cases, but serious complications such as respiratory arrest may occur. To prevent pulmonary oil embolism, it is recommended to use no more than 15 mL of iodized oil, administered superselectively, and to observe arteriovenous hepatic shunts carefully on initial arteriograms and during the procedure. An intracardiac right-to-left shunt via a patent oval foramen or intrapulmonary arteriovenous shunt can lead to cerebral Lipiodol embolism (Matsumoto et al, 2007).

Iatrogenic Vascular Injury

Iatrogenic arterial injury, such as dissection, may occur in the visceral arteries during hepatic embolotherapy. The two most common sites of dissection are the celiac and proper hepatic artery. Although iatrogenic dissection of the arteries heals spontaneously in most patients, it may result in complete obstruction or pseudoaneurysm formation (Jang et al, 2009; So et al, 2003; Yoon et al, 1995).

COMBINED THERAPY WITH OTHER TREATMENT

It has been proposed that chemoembolization might be combined with other local therapeutic options to enhance therapeutic efficacy. In combination treatment, the purpose of chemoembolization is to reduce the size of tumors (downstaging) for percutaneous treatments or to obtain a synergistic effect on tumor necrosis by combining procedures. Combination with percutaneous ethanol injection (PEI), radiofrequency ablation (RFA), laser interstitial thermotherapy (LITT), and radiotherapy has been studied, and better results were reported with the combination treatment than with either of these therapies alone.

Chemoembolization enhances the diffusion of ethanol within tumor tissue, causing more extensive tumor necrosis by PEI. Several trials compared this combination therapy with stand-alone PEI or chemoembolization in small HCC (Kamada et al, 2002; Koda et al, 2001) and large HCC (Allgaier et al, 1998; Bartolozzi et al, 1995; Yamamoto et al, 1997). Koda and colleagues (2001) compared the combined therapy versus PEI alone in 52 patients with HCC 2 cm or smaller. In their study, combined therapy improved local recurrence rates (8.7% and 19.3% at 1 and 3 years, respectively) and survival rates (100%, 80%, and 40% at 1, 3, and 5 years, respectively). Kamada and colleagues (2002) compared combined therapy versus chemoembolization alone in 69 patients with HCC 3 cm smaller. The 5-year survival rates were better in the combined-therapy group than in the group that received chemoembolization alone (50% vs. 22%). In a prospective comparative study of 132 patients with unresectable large HCC, median survival time was better in the chemoembolization-PEI group (25 months) compared with the PEI group (18 months), chemoembolization group (8 months), and conservatively treated group (2 months) (Allgaier et al, 1998).

RFA is designed to destroy tumor by heating tissue to lethal temperatures, exceeding 60° C (see Chapter 85C). It has proved to be an effective treatment of small HCC, but tumor volume that can be effectively ablated is limited. HAE eliminates the heat-sink effect by blood flow, thus it induces a larger ablation area by RFA (Rossi et al, 2000; Fig. 83.11). Many reports have demonstrated this combination to be a useful therapeutic method to control large HCC. Rossi and colleagues (2000) performed RFA after bland embolization in 62 patients with HCC (3.5 to 8.5 cm) and observed a 1-year survival rate of 87% and a recurrence rate of 19%. Takaki and colleagues (2009) treated 20 patients with HCC larger than 5 cm with a chemoembolization-RFA combination and reported an encouraging 5-year survival rate of 41%. A recent retrospective study that included 104 patients with early stage HCC, defined as three or fewer tumors 3 cm or smaller each or a single tumor 5 cm or smaller, demonstrated that a chemoembolization-RFA combination resulted in a disease-free and overall survival

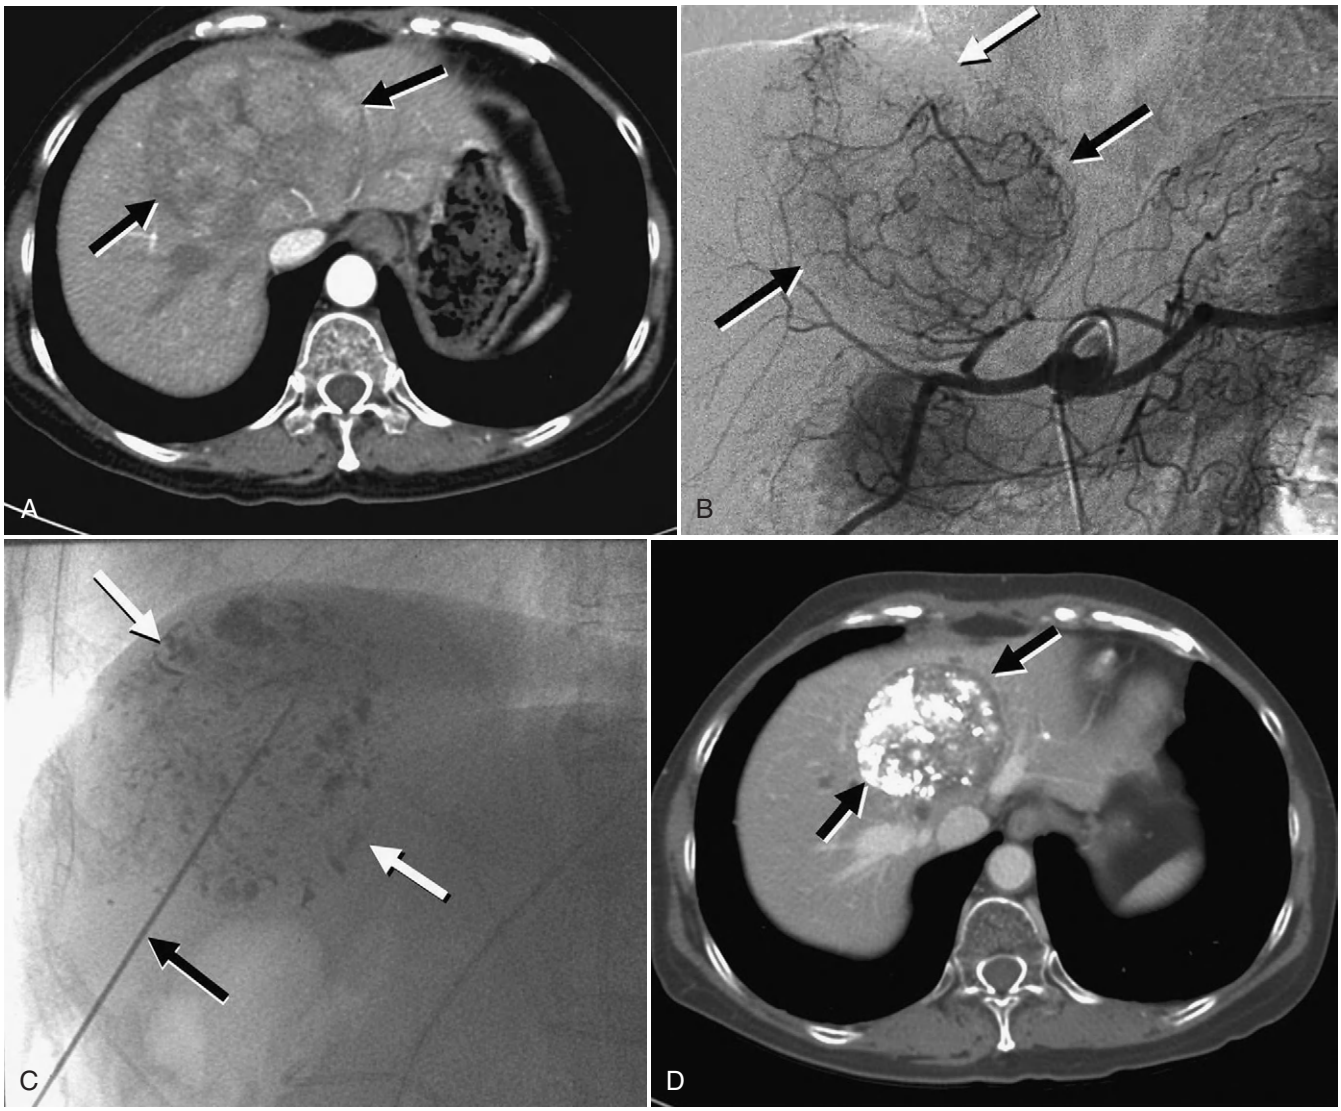

FIGURE 83.11. Combined therapy using chemoembolization and radiofrequency ablation (RFA) in a 48-year-old woman with massive hepatocellular carcinoma (HCC). **A,** Liver computed tomography (CT) arterial phase scan shows a heterogeneously enhanced massive HCC (*arrows*). **B,** Celiac arteriogram shows a hypervascular tumor stain supplied by left hepatic artery (*arrows*). Chemoembolization was performed with a mixture of 7 mL of iodized oil and 40 mg of doxorubicin hydrochloride followed by Gelfoam embolization. **C,** Immediately after chemoembolization, RFA was performed. Under fluoroscopic guidance, an expandable electrode (*black arrow*) was placed, aiming iodized oil accumulated in the tumor (*white arrows*). **D,** Follow-up CT obtained 1 year later shows remarkable shrinkage with no evidence of viable tumor (*arrows*).

similar to those achieved by surgical resection (Yamakado et al, 2008); however, the synergistic efficacy of chemoembolization with RFA has not been proven in RCTs. Recently, a prospective study did not find any survival benefit with the combined treatment compared with stand-alone RFA in HCC 3 cm or smaller (Shibata et al, 2009). Therefore, considering the increased cost and patient discomfort of additional chemoembolization, it may be reasonable to restrict this combination to large HCC or small lesions with infiltrative margins. Regarding the safety of this combination and the ability of patients to tolerate it, recent trials have demonstrated that chemoembolization and RFA can be safely performed, even in a single session (Kang et al, 2009), and it can improve quality of life scores better than chemoembolization alone (Wang et al, 2007).

Some investigators combined chemoembolization with laser thermal ablation and used chemoembolization to downsize a tumor that could be ablated with LITT. Zangos and colleagues (2007) performed repeated chemoembolization (mean, 3.5 sessions/patient) in 48 patients with HCC 50 to 80 mm in diameter to reach a favorable size for LITT, and then the patients were treated with MR-guided LITT. Repeated chemoembolization reduced the tumor size in 32 patients (66.7%), and subsequent LITT resulted in a median survival of 36 months after the first treatment. The same combination was used by Vogl and colleagues (2003), who also showed that chemoembolization can be used as a downsizing tool before LITT in 50.6% of patients with unresectable liver metastasis. Pacella and colleagues (2001) used LITT to reduce tumor volume and then performed chemoembolization in HCCs ranging from 3.5 to 9.6 cm in diameter. After combined treatment, complete response was achieved in 90% of the tumors with a local recurrence rate of 7% at 3 years.

The combination of chemoembolization and three-dimensional conformal radiotherapy (3D CRT) have involved three strategies (Hawkins & Dawson, 2006; see Chapter 84B). The most common approach is chemoembolization followed by radiotherapy (RT), in which RT is used to treat portal vein and inferior vena cava tumor thrombus to enhance the therapeutic effect by chemoembolization. From 40 Gy to 60 Gy over 5 to 6 weeks have been delivered safely to the macrovascular disease (Ishikura et al, 2002; Tazawa et al, 2001; Zeng et al, 2005). In a case-control study, 15 (34.1%) of 44 patients who underwent the combination therapy showed complete disappearance of venous tumor thrombi, and the 1-year survival rate was better in the combination group compared with the group that received chemoembolization alone (34.8% vs. 11.4%). A second approach involves RT sandwiched between chemoembolization, with RT used as a planned "consolidation" procedure to target residual viable tumor after chemoembolization (Hawkins & Dawson, 2006); in addition, the chemotherapeutic drugs retained in the tumor by chemoembolization may have a radiosensitizing effect (Seong et al, 2001). In the third approach, repetitive chemoembolization for large HCC is given until optimal response, followed by RT.

Tumor shrinkage after chemoembolization allows the use of smaller irradiation fields, which permits higher tumor doses and improves the normal liver tolerance (Guo et al, 2003). Despite the heterogeneity of disease, patients, and treatment techniques, the majority of studies have suggested a benefit of the combined therapy compared with stand-alone therapies in treatment of advanced HCC (Zeng, 2005; Guo et al, 2003; Meng et al, 2009). The introduction of molecular targeted therapies that attack pathways critical for cancer survival and progression has created a new hope against advanced HCC. Sorafenib, an oral multitarget tyrosine kinase inhibitor with antiangiogenic and antiproliferative actions, is the first systemic therapy to prolong the survival of patients with advanced HCC (Llovet et al, 2008; see Chapter 88). Currently underway are studies to investigate the effects of sorafenib as an adjuvant therapy after chemoembolization, to prevent microscopic tumor residues from reestablishing their blood supply and thus reduce tumor recurrence.

EMERGING TECHNIQUES OF HEPATIC ARTERIAL EMBOLOTHERAPY

Some controversy remains regarding the use of chemotherapeutic drugs in hepatic arterial embolotherapy. Although the concept of delivering high-dose chemotherapy to the tumor is sound, no evidence-based findings support the routine use of chemoembolization. Bland embolization with small particles has been shown to be as effective as chemoembolization in treatment of hypervascular primary and metastatic liver tumors and can be used instead of chemoembolization, thereby avoiding the added expense and systemic toxicity of chemotherapy.

In bland embolization, because the therapeutic efficacy depends on terminal vessel blockade, the smallest particles commercially available have been used. Until the late 1990s, 50-μm PVA particles were the smallest particles available, when Embospheres (BioSphere Medical, Rockland, MA), a hydrophilic tris-acyl gelatin microsphere, become available in 100- to 700-μm particles. Despite the larger size, Embospheres have several ideal characteristics of an embolic agent: they are spherical and have a hydrophilic surface that prevents aggregation, which results in a lower rate of catheter occlusion and better penetration into the more distal small vessels (Rand et al, 2005). Recently, 40- to 120-μm Embospheres became available. Maluccio and colleagues (2008) performed bland embolization using PVA particle (50 μm) or microspheres (40 to 120 μm) in 322 patients with HCC and reported 1-, 2-, and 3-year overall survival rates of 66%, 46%, and 33%, respectively. In patients without extrahepatic disease or portal vein involvement by tumor, the overall 1-, 2-, and 3-year survival rates increased to 84%, 66%, and 51%, respectively. Subgroups of patients with solitary HCC who also underwent thermal ablation the day after bland embolization had similar survival results after surgical resection (Maluccio et al, 2005). The same authors reported results of bland embolization in metastatic NETs and metastatic sarcomas that parallel those reported by others using chemoembolization (Brown et al, 1999; Maluccio et al, 2006).

Drug-eluting beads (DEBs) are specifically designed PVA beads that release chemotherapeutic drugs over an extended period. DEBs consist of nondegradable hydrogel microspheres based on PVA with a smooth surface and a precisely calibrated size that ranges from 100 to 900 μm. They are characterized by a high content of negatively charged 2-acrylamido-2-methylpropanesulfonate (AMPS). The unsaturated AMPS monomer crosslinks the PVA backbone and allows the load and release of positively charged drugs, such as doxorubicin hydrochloride or irinotecan hydrochloride, by an increased number of negatively charged sulfonate moieties (Hong et al, 2006). DEBs can achieve higher doses of the chemotherapeutic drugs and can prolong contact time with cancer cells and thus enhance therapeutic efficacy and at the same time reduce toxicity because of minimum systemic exposure (Hong et al, 2006).

The DC Bead (Biopcompatibles, Surrey, UK) is a DEB that has proven favorable kinetics and clinical characteristics (Lewis et al 2006a, 2006b; Varela et al, 2007). Malagari and colleagues (2008) treated 62 patients with single, unresectable HCC 3 to 9 cm using DC Beads impregnated with doxorubicin. After three sessions of chemoembolization, a complete response was seen in 12.2%, and an objective response was seen in 80.7%, according to EASL criteria. Lammer and colleagues (2010) conducted a prospective randomized trial to compare conventional chemoembolization with chemoembolization using DC Beads. The DEB group showed higher rates of complete response, objective response, and disease control compared with the conventional chemoembolization group (27% vs. 22%, 52% vs. 44%, and 63% vs. 52%, respectively) determined by EASL criteria at 6 months. A subgroup with more advanced disease (CTP class B, ECOG 1, bilobar disease, and recurrent disease) showed a significant increase in objective response compared with conventional chemoembolization. Moreover, DC Beads were associated with improved tolerability, with a significant reduction in serious liver toxicity and a significantly lower rate of doxorubicin-related side effects. DEBs loaded with irinotecan and oxaliplatin for treatment for metastatic liver tumors are under investigation (Martin et al, 2009; Poggi et al, 2008).

CONCLUSION

Hepatic artery embolotherapy is an effective palliative treatment in primary and secondary liver tumors. It is useful in local tumor control, prevents tumor progression, prolongs patient survival, and controls symptoms. Chemoembolization is the first-line treatment in selected patients with unresectable HCC.

The treatment protocol should be tailored according to each individual patient's condition. Most complications of hepatic embolotherapy are controllable and can be avoided by strict selection of patients and use of proper technique during the procedure. Combination with other liver-directed therapy improves local tumor control, but survival benefit has not been verified. New embolic agents that include microspheres and drug-eluting beads have shown encouraging preliminary results.

CHAPTER 84A

Radioembolization for liver tumors

Ahsun Riaz and Riad Salem

OVERVIEW

Interventional oncology is a field that is establishing its role in the management of liver tumors. The techniques used in this field are targeted to the tumors to allow delivery of toxic chemotherapeutic, radiotherapeutic, and thermal doses with minimal toxicity to normal structures; this minimizes the systemic toxicity associated with these therapeutic options and allows delivery of doses to the tumor that would not be possible using systemic delivery methods. In this chapter, the general concepts associated with radioembolization and its specific use in different primary and secondary malignancies of the liver will be discussed (Table 84A.1)

Vascular Anatomy of the Liver and Its Tumors (See Chapter 1B)

Portal Vein

The normal hepatic parenchyma is predominantly supplied by the portal vein. This unique vascularization lets the hepatocytes carry out their metabolic functions on the numerous substances absorbed from the gastrointestinal (GI) tract. It also makes the liver a common site of metastasis for GI cancers.

Hepatic Artery

The proper hepatic artery that supplies the liver is a continuation of the common hepatic artery, a branch of the celiac trunk. The proper hepatic artery branches into the right and left hepatic arteries, which supply the corresponding lobes of the liver. The cystic artery supplying the gallbladder usually arises from the right hepatic artery, and the right and left hepatic arteries give rise to the segmental branches; these eventually branch into the small vessels found in the portal triads.

Unlike the normal hepatic parenchyma, liver tumors are supplied primarily by hepatic arterial blood and are hypervascular structures compared with the surrounding uninvolved parenchyma (see Chapter 86). Hepatic tumors may parasitize arterial blood flow from the arteries that supply segments adjacent to the segment the tumor is in and those of surrounding organs, such as the stomach. This relative arterial hypervascularity of the tumors with respect to the normal parenchyma has been the basic principle behind transarterial therapies for targeting liver tumors.

HISTORY OF RADIOEMBOLIZATION

External Radiation (See Chapter 84B)

The use of external radiation for liver tumors has traditionally held limited value because of the sensitivity of the normal hepatic parenchyma to the radiation dose (Ingold et al, 1965; Geschwind et al, 2004). A dose greater than 35 Gy has led to the development of a radiation-induced liver disease (RILD); a clinical syndrome of ascites, anicteric hepatomegaly, and elevation of liver enzymes. Conformal-beam therapy, which uses a three-dimensional approach rather than broad axial plane techniques, has been shown to minimize the toxicity to normal hepatic parenchyma (Dawson et al, 1999). However, even when using conformal-beam therapy, the radiation delivered to normal hepatic parenchyma limits the maximum dose that can be delivered to the tumor without compromising safety.

External-beam radiation had limitations in treating liver tumors in specific locations; this includes tumors near the dome of the liver, which carry the risk of exposing the lungs to radiation and increasing the risk of radiation pneumonitis, and tumors in the caudate lobe in close proximity to the porta hepatis, where risk of damage to the major biliary and vascular structures is a consideration. *Dose fractionation,* dose delivery to the tumor in fractions, is beneficial in targeting radiosensitive and radioresistant malignant cells at different sessions, but multiple treatments are required. The normal tissue complications probability (NTCP) is an important parameter when calculating radiation dose delivery (Dawson et al, 2002), but its use has been challenged (Langer et al, 1998). Respiratory movement must be considered to minimize the incidence of normal tissue complications, although recent advances in the technology of external-beam radiation have been shown to increase safety and efficacy of this technique, such as stereotactic body radiotherapy, proton radiotherapy, and carbon ion radiotherapy; these are establishing the role of external-beam radiotherapy in the management of liver tumors (Dawson & Guha, 2008; Fukumitsu et al, 2009; Nomiya et al, 2008).

Radioembolization

Given the distinct vasculature of hepatic tumors described above, radioembolization provides a mode of delivering localized radiotherapy to the tumor. A radiation dose of up to 150 Gy can be administered, minimizing the complications of external radiation. Radioembolization has been shown to have promising outcomes in primary and secondary hepatic malignancies by numerous investigators.

Radioembolization was first studied by Nolan and Grady (1969) using yttrium-90 oxide ($^{90}Y_2O_3$) contained in a metal particle 50 to 100 μm in size. Their study consisted of a small number of patients but showed a favorable response, observed by the reduction in size of palpable masses. The next ^{90}Y study was published in 1982 by Mantravadi and colleagues and studied the effect and distribution of ^{90}Y after whole-liver delivery via the hepatic artery; the authors concluded that patients with hypervascular tumors are much more likely to benefit from this treatment. A dose-escalation study on animals

was performed, which formed the basis of the Phase I dose-escalation evaluations in humans (Wollner et al, 1987). Shepherd and colleagues (1992) conducted a Phase I dose-escalation study using ^{90}Y microspheres in 10 patients. Extrahepatic shunting was assessed using technetium-99m–labeled macroaggregated albumin (^{99m}Tc-MAA). In contrast to earlier studies, none of the patients in this study experienced hematologic toxicity, a fact that emphasizes the value of assessing angiographic findings and extrahepatic shunting before treatment (Shepherd et al, 1992). The technical aspects of dosimetry, radioassays, safety, and efficacy were discussed by many studies that followed (Andrews et al, 1994; Yan et al, 1993). Lau and colleagues (1994) showed that tumor response was proportional to the dose delivered, with improved survival in patients receiving more than 120 Gy. Recent data on the safety and efficacy of this treatment are discussed below.

^{90}YTTRIUM MICROSPHERES

Overview

^{90}Yttrium is the radioactive element most commonly used for radioembolization. It is a pure β-emitter with a half-life of 64.2 hours, and it decays into the stable element zirconium-90. Tissue penetration of the emissions ranges from 2.5 to 11 mm.

Pretreatment Evaluation

Clinical Evaluation

Clinical evaluation is required to stratify patients according to the Eastern Cooperative Oncology Group (ECOG) performance status, and those with a score greater than two are not considered ideal candidates for this treatment.

Laboratory Workup

The laboratory workup is important to assess the pretreatment functional status of the liver. This should include assessment of liver enzymes (alanine aminotransferase [ALT], aspartate aminotransferase [AST], alkaline phosphatase), bilirubin, albumin, and tumor markers such as α-fetoprotein (AFP).

Pretreatment Angiography and Coil Embolization

Radioembolization requires pretreatment diagnostic mesenteric angiography. The aortogram, superior mesenteric angiogram, and celiac trunk angiogram allow the interventional radiologist an opportunity to study the vascular anatomy of the liver and its surrounding structures in detail. The patency of the portal vein and the presence of arterioportal shunting are assessed. The inadvertent spread of the microspheres is prevented by a meticulous study of the vascular anatomy of the liver and collateral nontarget flow (Covey et al, 2002). Coil embolization of nontarget vessels may be necessary to decrease the unintended deposition of microspheres. Some examples of vessels that may need to be embolized are inferior esophageal, left inferior phrenic, accessory left gastric, supraduodenal, and retroduodenal arteries. The minimal incidence of complications following coil embolization and the grave clinical consequences associated with the inadvertent deposition of microspheres in the stomach, duodenum, or pancreas favor prophylactic coil embolization before radioembolization in select cases.

^{99m}Technetium Macroaggregated Albumin Scan

The ^{99m}Tc-MAA scan is used to assess splanchnic and pulmonary shunting. This pretreatment nuclear scan is important to prevent certain complications associated with the treatment. The proximity of the duodenum and stomach to the liver may make it difficult to assess shunting to these portions of the GI tract by using nuclear medicine scans alone. Thus, it is important to correlate the findings of angiography to the findings of the ^{99m}Tc-MAA scan. The lung shunt fraction (LSF) is used to calculate the dose delivered to the lungs, and adjustment for this parameter minimizes the risk of radiation pneumonitis that may be seen after radioembolization.

All hepatic vessels are assessed during the angiogram, and the arteries feeding the tumor are studied in detail. As the tumor may parasitize blood flow from surrounding vessels, it is necessary to study its vascular supply in detail. Failure to recognize a vessel supplying the tumor may lead to the incomplete targeting of the lesion and treatment failure.

Available Devices

TheraSphere

TheraSphere (MDS Nordion, Ottawa, ON, Canada) consists of nonbiodegradable glass microspheres with diameters ranging from 20 to 30 μm. It was approved by the Food and Drug Administration (FDA) in 1999 and recently has been approved for use in hepatocellular carcinoma (HCC) patients with portal

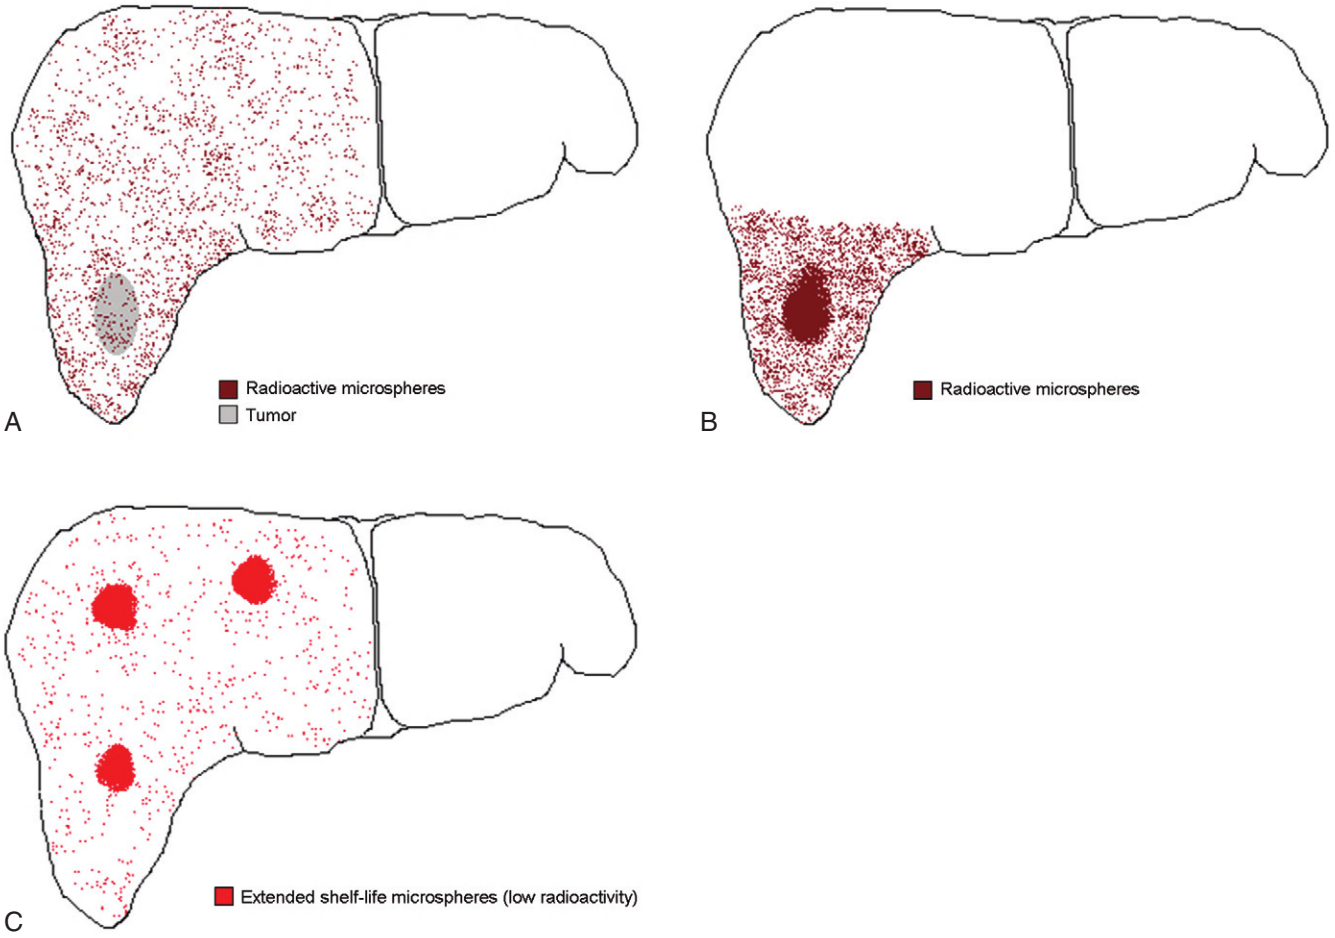

FIGURE 84A.1. A, Schematic representation of the current dosimetric model for TheraSphere (MDS Nordion), which assumes uniform distribution of the microspheres in the normal parenchyma and tumor. **B,** Schematic representation of radiation segmentectomy with highly radioactive particles preferentially accumulating in the tumor because of its arterial hypervascularity and microspheres accumulating in the surrounding parenchyma of the injected segments. **C,** Schematic representation of extended shelf life microspheres with microspheres with lower activity preferentially accumulating in the tumor, because of its arterial hypervascularity, and in the surrounding parenchyma of the injected lobe.

vein thrombosis (PVT). Vials of six different activities are available; the only difference in the vials is the number of spheres; 1.2 million microspheres are present in a vial with an activity of 3 GBq. Each microsphere has an activity of 2500 Bq at the time of calibration. The activity of the vial varies inversely with the time elapsed after calibration.

DOSE CALCULATION FOR THERASPHERE. The calculation of the dose requires the use of three-dimensional reconstruction of the target site to calculate the volume of the liver to be infused. The volume in cubic centimeters is then used to calculate the mass in grams by multiplying it by a factor of 1.03.

The activity (A) in GBq administered to the target area of the liver, assuming uniform distribution of microspheres (Fig. 84A.1A), is calculated using the following formula:

$$A = D \times m/50$$

D is the dose administered in Grays, and m is the mass in kilograms. Using this formula, it can be said that a dose of 50 Gy will be administered to 1 kg of tissue if 1 GBq of ^{90}Y is given.

The dose given to the treated mass also depends on the percent residual activity (R) in the vial after treatment and the LSF, which is calculated beforehand. These factors are accounted for in the following formula:

$$D = A \times 50 \times (1 - LSF) \times (1 - R)/m$$

SIR-Spheres

SIR-Spheres (Sirtex Medical, Woburn, MA) consist of biodegradable resin microspheres that have a slightly increased diameter and lower specific gravity per microsphere than TheraSphere. The use of SIR-Spheres was approved by the FDA for metastatic colorectal cancer to the liver in 2002. One vial of 3 GBq is available with 40 to 80 million microspheres, with each microsphere measuring from 20 to 60 μm.

As suggested by the small particle size, the embolic effect of the available microscopic spheres is minimal. They are known to lodge in the precapillary arterioles, but their small size also allows deep penetration into the tumor with minimal changes in the vascular supply to the tumor. It has been suggested that hypoxia of the tumors induced by embolization, instead of anoxia, may lead to the release of vascular endothelial growth

Table 84A.2

Empiric Method for Dose in SIR-Spheres*

Tumor Involvement of Liver (%)	Dose (Whole Liver)
≤25	2 GBq
25-50	2.5 GBq
>50	3 GBq

*Sirtex Medical, Woburn, MA

factor (VEGF) and hypoxia-inducible factor-1, which may lead to neovascularization of the tumor and subsequent incomplete necrosis and tumor recurrence.

DOSE CALCULATION FOR SIR-SPHERES. Three methods for dosimetry of SIR-Spheres are recommended by the manufacturers. The *partition method* is seldom used, as it is applicable only in special circumstances. The *empiric method* is outlined in Table 84A.2.

The model of dosimetry for SIR-Spheres is based on whole-liver infusion. The calculated gigabecquerels of the whole liver are multiplied by the percentage of the target site as a proportion of the whole liver. The most widely used body surface area (BSA) method is as follows:

$$A = BSA - 0.2 + (\%\ \text{Tumor burden}/100)$$

A is the activity in gigabecquerels, *BSA* is the body surface area in meters squared, and *% tumor burden* is the percentage of the liver involved by tumor.

New Concepts

Radiation Segmentectomy

Recently, the concept of radiation segmentectomy has been discussed. This is schematically shown in Figure 84A.1B. The current dosimetry models assume lobar infusion; however, if the tumor is localized to two or fewer liver segments, the interventional radiologist can infuse the dose at the segmental level. This maximizes the dose delivery to the tumor and minimizes delivery of radioactive microspheres to the normal parenchyma (Riaz et al, 2010), an approach that has proven to be a safe and effective method of treatment delivery.

Extended Shelf Life Microspheres

Lewandowski and colleagues (2009b) recently published a report on the concept of extended shelf life microspheres, which can be used for large or multifocal tumors. As stated above, the difference in vials of different activities is the number of microspheres. If the vials of high activities (more microspheres) are allowed to stay on the shelf longer, the activity per microsphere will decrease. This allows the delivery of a higher number of microspheres to larger volumes of the liver with minimal radiotoxicity to the normal parenchyma (Lewandowski et al, 2009b).

Radiation Lobectomy

An animal study concluded that portal fibrosis was seen after the use of radioactive microspheres (Wollner et al, 1988). Gaba and colleagues (2009) recently published a comprehensive analysis on the concept of radiation lobectomy, whereby infusion at the lobar level was used to treat the tumors. Because of fibrosis of the normal parenchyma, decreases in volumes of the treated lobe were seen. Furthermore, compensatory increases in the volumes of the untreated lobes were also observed.

New Concepts

Blood Flow Patterns for Dose Calculation

Kennedy and colleagues (2010) have recently published their analysis on computer modeling of ^{90}Y resin microsphere transport in the hepatic arterial tree. They conclude that computer simulations of both blood flow patterns and microsphere dynamics have the potential to provide insight on methods to optimize microsphere implantation into hepatic tumors while sparing normal tissue.

Transcatheter ^{90}Y Radioembolization

Radioembolization is a transcatheter therapy performed by interventional radiologists. The tumor is approached using its arterial supply, and the vial is injected into the vessel feeding the tumor. The distribution of the tumor is the factor that allows the treatment to be selective, allowing delivery to one lobe, or superselective, allowing delivery to one segment. The apparatus for the administration of ^{90}Y is designed to minimize the radiation exposure to those involved in the procedure, but a physicist should be present throughout the case to ensure that proper protocols are followed to minimize accidental radiation exposure. The procedure is performed on an outpatient basis, and the patient is discharged on the same day (Salem et al, 2002).

OTHER RADIONUCLIDES

Iodine-131–Labeled Iodized Oil and Iodized Oil (Lipiodol)

Lipiodol is a poppyseed oil that contains 38% iodine by weight. Normal hepatocytes are able to remove Lipiodol in 7 days, whereas HCC retains it for weeks. Stasis is associated with Lipiodol, hence an embolic effect is associated with this conjugate. It is a radiopaque substance and is visualized on posttreatment CT scans in the target lesion.

Overview

The half-life of ^{131}I is 8 days. This radionuclide is a β- and γ-emitter. The use of ^{131}I-Lipiodol has been studied in a prospective trial and compared in efficacy to chemoembolization (Raoul et al, 1997). The iodine moiety of Lipiodol can be substituted for the radionuclide ^{131}I.

Administration

Angiography is performed, and the ^{131}I-Lipiodol is administered only after studying the vascular anatomy of the liver. The dose is usually given via a 3-mL injection in the main hepatic artery, if the vascular anatomy is found to be normal. Extreme caution must be taken during administration, as dissolution of the plastic catheters has been seen. In addition, the thyroid gland is susceptible to the toxicity of ^{131}I; hence the thyroid is medically blocked before and after the treatment to minimize toxicity to the gland. Because the radionuclide is excreted in urine, the patient must be hospitalized for 6 to 7 days after treatment as a radioactivity safety measure. Patients are also

told to refrain from possible conception until 6 months after treatment.

Conclusion

The outcomes associated with ^{131}I-Lipiodol are comparable to those of transarterial chemoembolization (TACE; see Chapter 83), but significantly fewer serious adverse events are reported with the use of this radionuclide as compared with using TACE. ^{131}I is expensive, but the isotope has high γ-energy with a short β-range, which decreases its cytotoxic effect. Furthermore, hospitalization after the procedure decreases the cost-effectiveness of ^{131}I (Raoul et al, 1997).

Rhenium-188 HDD–Labeled Iodized Oil

Overview

Transarterial radionuclide therapy (TART) with rhenium-188 4-hexadecyl-1,2,9,9-tetramethyl-4, 7-diaza-1, 10-decanethiol (HDD)–labeled iodized oil has been recently studied for use in inoperable HCC. ^{188}Re has a shorter half-life (16.9 hours), high β-energy (maximum 2.1 MeV) and low γ-energy (155 keV) emissions, and it is available through a tungsten-188 (^{188}W-^{188}Re) generator.

Administration

The quantity of ^{188}Re-HDD iodized oil (Lipiodol) administered is based on the radiation absorbed dose (RAD) to critical organs, which is calculated after transarterial administration of a test dose of the radioconjugate (Kumar et al, 2007). The critical organs include the bone marrow, lung, and normal liver, and the dose limitations to them are 1.5 Gy, 12 Gy, and 30 Gy, respectively. A scout dose of 185 MBq activity of the radioconjugate is injected, and a whole-body nuclear scan is performed to calculate the RAD to the critical organs. The dose is then calculated and administered on the same day.

Conclusion

The incidence of serious adverse events is low with this treatment, and a survival benefit in HCC patients has been reported in published literature (Kumar et al, 2007); Liepe and colleagues (2007) have also published their experience of 10 patients. Its easy availability and published data make TART seem a promising mode of treatment of HCC; however, as of this writing, data are insufficient to recommend use of this radionuclide in metastatic disease to the liver.

OTHER ^{188}RHENIUM CARRIER COMBINATIONS. There are other ^{188}rhenium carrier combinations under study, such as ^{188}Re-bis-(diethyldithiocarbamato) Lipiodol (^{188}ReN-DEDC Lipiodol), ^{188}Re-(S_2CPh)(S_3CPh)$_2$ Lipiodol (^{188}Re-SSS Lipiodol), and ^{188}Re-labeled human serum albumin (HSA B20) microspheres (Lambert et al, 2009). ^{188}Re–hyaluronic acid combinations are also being studied as a systemically administered agent for HCC in animals, as hyaluronic acid selectively binds to CD44 receptors (Melendez-Alafort et al, 2009).

Phosphorus-32 Glass Microspheres

Overview

^{32}P is a radioisotope that emits high-energy β-particles during decay. It has a half-life of 14.28 days and a maximum tissue penetration of 8 mm, with an average of 3.2 mm (Wong et al, 1999). It is administered as an integral constituent of nonbiodegradable glass microspheres.

Administration

The dose is calculated by the following formula based on the pharmacokinetics and distribution of ^{32}P glass microspheres:

$$D = 20 \times A/m$$

D is the dose in grays, *A* is the activity in gigabecquerels, and *m* is the mass in kilograms. The administration is via a transarterial approach, after angiography has been performed to study the vascular anatomy of the liver.

Conclusion

The half-life of this radionuclide gives it the advantage of a lower required dose and a potential to have a decreased radiation exposure to handlers, compared with the other radionuclides available. It has been tolerated well in animal and human trials, although its role in the management of liver tumors is yet to be established.

Milican/Holmium-166 Microspheres

^{166}Ho is a β- and γ-emitter. This radionuclide is highly paramagnetic; hence it acts as a negative contrast agent, like iron, on magnetic resonance imaging (MRI; Bult et al, 2009). It is also radiopaque and visible on computed tomography (CT) (Bult et al, 2009).

Holmium/chitosan complex (Milican; Dong Wha Pharmaceutical, Seoul, Korea) has been shown to be effective in treating small HCC in a novel study from Korea (Kim et al, 2006). Chitosan is a unique substance derived from chitin. It has the ability to liquefy in an acidic environment and form a gel in basic environments, and the gel has embolic effects.

Microspheres of ^{166}Ho poly-L-lactic acid are being studied in animal models and have been shown to be safe, but they have yet to be studied in humans (Vente et al, 2010). ^{166}Ho has also recently been studied with hydroxyapatite as the carrier in animal models (Das et al, 2009).

PRIMARY LIVER TUMORS

The role of radioembolization has been studied in detail for the treatment of the most common primary malignant tumor, HCC. Its use in the management of cholangiocarcinoma has also been studied.

Role of Radioembolization in Management of Hepatocellular Carcinoma (See Chapter 80)

Patient Selection

The various diagnostic criteria and staging systems for HCC are beyond the scope of this chapter (Bruix et al, 2001). The management of HCC requires a multidisciplinary approach with the involvement of hepatologists, oncologists, transplant surgeons, and interventional radiologists. Patients should be selected for this treatment modality based on a consensus of the team. As discussed below, the role of radioembolization is not limited by the stage of the disease, but no survival benefit has been seen in patients with distant metastases.

Indications and Efficacy

PATIENTS WITHIN TRANSPLANT CRITERIA. The use of surgical options is the gold standard of treatment for these patients. The patients within the Milan criteria, with a single lesion less than 5 cm or three or fewer lesions all less than 3 cm, are eligible for orthotopic liver transplantation (OLT; see Chapter 97D; Mazzaferro et al, 1996). Resection is possible only if liver function is preserved (see Chapter 90F). The limited availability of donor organs for OLT and the dropout of patients as a result of tumor progression limits the number of patients who are able to undergo OLT. Thermal ablation (radiofrequency ablation) has a limited role because of the risk of tract seeding and the size and location of tumor (see Chapter 85). Radioembolization has been shown to limit progression of the disease, which allows the patient more time to wait for donor organs and thus increases their chance of undergoing OLT (Kulik et al, 2006). Thus radioembolization has a role in bridging patients to OLT.

PATIENTS BEYOND TRANSPLANT CRITERIA. Patients outside the transplant criteria as a result of the size or number of tumors but who do not have malignant PVT or metastatic HCC may also be candidates for radioembolization, which has been shown to downstage the disease in these patients to within transplant criteria. This allows patients who were initially outside Milan criteria to become eligible for OLT with an increase in overall survival reported in these patients as well (Kulik et al, 2006). Lewandowski and colleagues (2009a) recently published their experience of downstaging using transarterial therapies for HCC. Their data suggest a superior ability of radioembolization to downstage HCC compared with chemoembolization. The recurrence-free survival and overall survival after OLT in the downstaged patients has yet to be compared with that of the patients who were already within transplant criteria to determine the efficacy of downstaging.

PATIENTS WITH ADVANCED DISEASE. Patients with PVT have been shown to have a favorable response to treatment after radioembolization (Kulik et al, 2007). The presence of malignant PVT excludes these patients from transplantation, whereas its presence is not a contraindication to radioembolization with ^{90}Y. Systemic therapy with sorafenib has been shown to have a statistically significant improvement in survival in patients with advanced disease (Llovet et al, 2008; see Chapter 88). The hepatic artery is the sole vascular supply to the parenchyma in the presence of PVT, hence embolic therapies are relatively contraindicated. However, ^{90}Y may be used in these cases because of its minimal embolic effect (Kulik et al, 2007). A survival benefit (10.1 to 13.4 months from treatment) has been shown with the use of radioembolization in patients with malignant vascular involvement (Kulik et al, 2007). A survival benefit has not been shown in patients with distant metastases (Salem et al, 2010).

Conclusion

Recently, Salem and colleagues (2010) published a comprehensive analysis on the role of radioembolization in 291 patients with HCC. The data presented suggest that radioembolization is a safe and effective treatment modality. The response rate and promising survival associated with this therapy have established its role in the management of HCC in many centers around the world.

Role of Radioembolization in Management of Intrahepatic Cholangiocarcinoma (See Chapter 50A)

Resection is the best treatment option in patients who have limited disease, and it has been shown to improve survival. The role of chemoembolization for intrahepatic cholangiocarcinoma (ICC) has been studied, and an improvement in survival has been shown, but the rate of toxicity remains high. Radioembolization has been shown to be effective in the treatment of HCC, but its role in the management of ICC has not been extensively studied. A study analyzing the use of ^{90}Y in patients with ICC has shown a favorable response to treatment and favorable survival outcomes (Ibrahim et al, 2008). Patients with a better performance status according to the Eastern Cooperation Oncology Group had a significantly better survival in this study. Saxena and colleagues (2010) recently published their analysis of 25 patients with ICC who underwent radioembolization with resin microspheres. They conclude that ^{90}Y radioembolization is safe and effective, and in the absence of other therapeutic options, this treatment warrants further investigation.

SECONDARY LIVER TUMORS

Metastatic disease to the liver is common because of the liver's unique anatomy and dual vascular supply. The presence of multiple metastases and comorbidities limits the role of surgical resection in these patients (Welsh et al, 2006). The role of radioembolization alone and as a conjunct to systemic chemotherapy has been well established.

Role of Radioembolization in the Management of Metastatic Colorectal Carcinoma (See Chapter 81A)

Overview

Resection is the only curative option available for colorectal cancer (CRC) that has metastasized to the liver, although a small fraction of patients have disease that is amenable to resection (Welsh et al, 2006). Systemic chemotherapy for this disease is beyond the scope of this chapter, but some commonly used chemotherapeutic agents are 5-fluorouracil (5-FU), oxaliplatin, irinotecan (CPT-11), bevacizumab, cetuximab, and capecitabine (see Chapter 86). The favorable role of radioembolization in treatment of metastatic CRC to the liver has been published (Mulcahy et al, 2009).

Patient Selection

Patient selection criteria for radioembolization for metastatic CRC to the liver are very similar to those for HCC. Patients who have unresectable disease and are on systemic chemotherapy or those who failed to respond to first- or second-line chemotherapeutic agents are considered as candidates for radioembolization. The carcinoembryonic agent (CEA) is measured, and radiologic studies are performed prior to and following treatment to assess response. Fluorodeoxyglucose positron-emission tomography (FDG PET) has been shown to have better sensitivity in assessing tumor response to internal radiation for treatment of metastatic CRC than CT; however, more data are required before functional imaging can replace the conventional imaging techniques, such as contrast-enhanced CT, for response measurement.

Efficacy of Radioembolization

The effect of systemic chemotherapy alone has been compared to its combined effect with radioembolization in a randomized control trial. The combination has been shown to have a significantly better tumor response, a longer time to progression, survival benefit, and an acceptable safety profile (Gray et al, 2001). The use of internal radiation alone has also been published in many series and has shown promising results (Kennedy et al, 2005; Mulcahy et al, 2009), and dose-escalation studies have shown better response with increasing doses (Goin et al, 2003). A recent study on the concomitant use of irinotecan and radioembolization in fluorouracil-refractory patients with CRC hepatic metastases showed that the maximum-tolerated dose was not reached (Van Hazel et al, 2009).

Role of Radioembolization in the Management of Metastatic Neuroendocrine Tumors (See Chapter 81B)

Overview

Metastatic disease to the liver from a primary neuroendocrine tumor (NET) is common. Although most often nonfunctional, some NETs produce excessive amounts of hormones associated with debilitating clinical syndromes, such as carcinoid syndrome: vasoactive intestinal tumors (VIPomas), gastrinomas, and somatostatinomas are some examples. Systemic chemotherapy and ablative procedures have been shown to have a modest benefit in these patients, and patients with unresectable disease are candidates for radioembolization. Clinical improvement, serum chromogranin A levels, and imaging studies prior to and following treatment are used to assess response to radioembolization.

Evidence

Radioembolization of metastatic disease to the liver from a neuroendocrine neoplasia has been shown to be effective and safe. A prolonged response to treatment, greater than 2 years, has also been seen (Kennedy et al, 2008; Rhee et al, 2008b). King and colleagues (2008) recently published their experience with 34 patients and concluded that radioembolization can achieve relatively long-term responses in patients with nonresectable NET liver metastases.

Role of Radioembolization in the Management of Metastatic Mixed Neoplasia

Overview

The role of radioembolization in hepatic metastases from primary neoplasia other than the ones listed above is discussed under the heading of *metastatic mixed neoplasia*. The following secondary tumors have been treated using radioembolization, but only metastatic breast cancer has been studied in detail (see Chapter 81C).

Internal Radiation to Metastatic Breast Cancer to Liver

Breast cancer is the most common cancer in women and has a tendency to metastasize to the liver. Radioembolization presents an efficacious treatment for unresectable breast cancer metastasis to the liver (Coldwell et al, 2005). Radiologic response has been seen following radioembolization in these patients, but the survival benefit of this treatment in this population has not been established (Jakobs et al, 2008b).

Other

Radioembolization has been used to treat secondary liver tumors from various primary sources. This mode of treatment is an effective alternative to patients who have failed chemotherapy or who have become chemorefractory (Sato et al, 2008). The data suggest a similar benefit in survival and tumor response in metastatic liver tumors from the metastatic mixed neoplasia.

POSTTREATMENT ASSESSMENT

Clinical and Laboratory Parameters

The response to treatment can be monitored clinically and radiologically. The regular follow-up laboratory workup includes the hepatic panel and tumor markers—such as AFP, CEA, and carbohydrate antigen (CA) 19-9—to look for any toxicity as a result of treatment and to assess clinical improvement in the patient. Decrease in AFP in patients with HCC has recently been shown to be an indicator of prognostic benefit following transarterial locoregional therapies (Riaz et al, 2009a).

Radiologic Parameters

The first radiologic study is done 1 month after treatment. Patients are then followed with scans every 3 months to assess response to treatment or progression of disease. The use of the World Health Organization (WHO) and Response Evaluation Criteria In Solid Tumors (RECIST) are based on decreases in the size of the lesion irrespective of the amount of necrosis seen in the tumor. The European Association for the Study of the Liver (EASL) necrosis criteria are also used to assess response in the target lesions (Ibrahim et al, 2009), and the WHO and EASL guidelines have been shown to correlate well with pathologic necrosis (Riaz et al, 2009c). The conventional anatomic imaging studies are not able to assess tumor response until 6 weeks after treatment. Functional MRI may have a role in earlier detection of tumor response (Rhee et al, 2008b); however, more data are required before functional imaging can replace the conventional imaging guidelines for response assessment.

COMPLICATIONS OF RADIOEMBOLIZATION

Postradioembolization Syndrome

Patients may experience a mild postradioembolization syndrome, which comprises signs and symptoms that include fatigue, nausea, vomiting, anorexia, fever, abdominal discomfort, and cachexia. These are usually not severe enough to require hospitalization, although some serious adverse events related to radioembolization are explained below and have been discussed in detail previously (Riaz et al, 2009b).

Hepatobiliary Toxicity

Hepatic Injury

Radiation-induced liver disease (RILD) usually occurs between 4 and 8 weeks after radioembolization. Hepatic toxicity is

measured by a change in the liver enzymes and metabolites, including ALT, AST, alkaline phosphatase, albumin, and bilirubin. Using the Common Terminology Criteria version 3.0 to assess toxicity to the liver following radioembolization, the grade 3 and 4 toxicity rates following radioembolization have been low (Salem et al, 2010; Sangro et al, 2008; Young et al, 2007). The clinical appearance of ascites and jaundice is very rarely seen.

The histologic hallmark of venoocclusive disease (VOD) may be seen in severe cases (see Chapter 77). Hepatic toxicity is rarely so severe as to lead to significant morbidity and mortality (Sangro et al, 2008). The presence of factors such as a deranged hepatic function at baseline, age, and activity delivered may predispose patients to the hepatotoxic effects of radioembolization.

Biliary Injury

The biliary tract is also susceptible to toxicity by radioembolization. According to Rhee and colleagues (2008a), less than 2% of patients required intervention for the biliary toxicity induced by radioembolization. These included two cholecystectomies, drainage of three bilomas, and one abscess. Radiation-induced cholangitis has also been reported following ^{90}Y administration (Rhee et al, 2008a); however, these are not common, and meticulous technique can minimize their incidence.

Portal Hypertension

Radioembolization has been shown to cause fibrosis that may lead to portal hypertension by changing the volume of the treated lobe. The time it takes for development of portal hypertension is variable (Jakobs et al, 2008a), but it is more often associated with bilobar treatment, and its incidence is increased in patients who have chemotherapy-associated steatohepatitis (CASH; see Chapter 65). The presence of preexisting cirrhosis leading to portal hypertension in most HCC patients makes them more susceptible to the aggravation of this complication as well (Riaz et al, 2009b).

Radiation Pneumonitis

Dose adjustment is required, and caution must be exercised, when the LSF is greater than 13% (Leung et al, 1995). A restrictive pulmonary dysfunction is seen after radioembolization in a few cases with a predisposing high LSF. The LSF is used to calculate the dose that would be administered to the lung, and an absolute contraindication to radioembolization is the predicted administration of a dose greater than or equal to 30 Gy to the lungs in a single treatment or greater than 50 Gy as a cumulative dose after multiple treatments (MDS Nordion, 2004). The presence of radiation pneumonitis can be diagnosed clinically and on finding consolidation on CT, evidenced by a bat-wing appearance.

Gastrointestinal Complications

GI complications after radioembolization have been reported and are due to the inadvertent spread of microspheres to the GI tract (Carretero et al, 2007; Murthy et al, 2007a). Ulceration may occur and may require surgery for treatment; however, it can be prevented by meticulous mapping of the blood vessels to look for aberrant vasculature arising from branches of the hepatic artery that supply the GI tract. The prophylactic use of proton pump inhibitors is also recommended (Riaz et al, 2009b).

Vascular Injury

Transcatheter ^{90}Y radioembolization is a minimally invasive procedure with a low incidence of vascular injury, mostly seen in patients who were already on systemic chemotherapy (Murthy et al, 2007b), which may cause weakening of the vessel wall and predispose it to injury.

Conclusion

The adverse events that occur after radioembolization are rare and manageable. Their occurrence can be minimized by careful assessment of angiographic findings before treatment. The precautions that may minimize their incidence have been outlined previously (Riaz et al, 2009b).

SUMMARY

Radioembolization represents a novel treatment approach that has gained increased awareness and clinical use. The minimal toxicity and outpatient nature of the therapy make it an attractive alternative in the management of primary and secondary liver malignancies. Appropriate treatment planning requires certain steps that include but are not limited to 1) calculation of target liver mass to be infused and tumor burden; 2) visceral angiography to map the tumor-perfusing vessels and embolize collaterals that may lead to aberrant microsphere deposition; 3) ^{99m}Tc-MAA scan for assessment of lung shunt fraction; 4) calculation of the optimal therapeutic dose; 5) preparation of the interventional radiology suite; 6) meticulous radiation monitoring and safety procedures; and 7) calculation of residual activity and efficiency of radiation delivery. The safety and efficacy of the treatment is enhanced by following meticulous technique.

Selecting patients with adequate hepatic reserve and good functional status maximizes the beneficial therapeutic effect of this therapy with minimization of the risk of complication. Radioembolization has also been shown to be beneficial for patients with metastatic disease who have intrahepatic progression despite standard-of-care chemotherapy. This treatment modality provides an important tool for all disciplines involved in the management of liver tumors and includes hepatology, medical/radiation oncology, gastroenterology, surgery, and interventional oncology.

CHAPTER 85A

Percutaneous methods for ablating liver tumors: overview

Sandro Rossi, Giorgia Ghittoni, and Valentina Ravetta

OVERVIEW

The term *liver tumor* generally includes a variety of primary and metastatic tumors involving the hepatic parenchyma. More than 90% of the primary tumors are hepatocellular carcinomas (HCCs); the other 10% include cholangiocarcinomas and rare tumors such as hemangioendotheliomas, lymphomas, and sarcomas (McGlynn et al, 2001). Hepatic metastases (METs) can originate from all types of primary tumors, but excluding local and regional lymph nodes, the liver is usually the first organ targeted by tumors of the gastrointestinal tract (Wiess, 1986).

BACKGROUND

Percutaneous Ablation of Hepatocellular Carcinoma

HCC is the fifth most common tumor throughout the world, and its incidence is increasing worldwide because of the spread of infections caused by the hepatitis B and C viruses (see Chapters 64 and 80). Surveillance programs have been developed for patients with cirrhosis, and this approach is associated with annual HCC detection rates ranging from 3% to 8% (Bruix & Llovet, 2002). Unfortunately, although advances in imaging technology have improved the early detection of HCC, these tumors are difficult to treat and are still associated with a poor prognosis.

Conventional approaches, such as systemic chemotherapy and radiation, have proved to be ineffective in HCC, although the results of some recent randomized trials suggest that sorafenib may be associated with slightly improved survival in patients with advanced HCC (Llovet et al, 2008; Peck-Radosavljevic et al, 2010; Vitale et al, 2009; see Chapter 88). Surgical resection can result in tumor eradication and improved survival in patients with small HCCs; however, few patients are candidates for potentially curative resection, which comes with an 80% risk of recurrence (Akriviadis et al, 1998; see Chapter 90B). Liver transplantation is the ideal approach for early HCC, but it is limited by age-related contraindications and a shortage of organs (Llovet et al, 1999; see Chapter 97D). For these reasons, a number of percutaneous methods have been developed for the chemical or thermal ablation of HCC, and all have displayed satisfactory efficacy in terms of local tumor control.

Percutaneous Ablation of Hepatic Metasteses

Percutaneous ablation has been used to treat hepatic METs from primary tumors in various organs, but its systematic use has been limited to those produced by colorectal cancers (CRCs). CRC is the fourth most common tumor worldwide (Greenlee et al, 2000), and the healthy liver is the first site of metastatic involvement in patients with CRC and a source of further spread (Lenhert, 1999). Twenty-five percent of these patients already have liver METs when the primary tumor is diagnosed, and another 50% develop them within 5 years of diagnosis (see Chapter 81A). In more than 30% of the patients with liver METs, the metastatic disease appears to be confined to the liver at the time of detection.

Throughout the world, resection is considered a potentially curative approach for the treatment of CRC liver METs, and it is associated with a 5-year survival rate of 40% (Ballantyne, 1993; Greenway, 1988; Nakamura, 1997). However, more than 70% of patients are ineligible for surgical resection because of the extent of their disease, serious comorbidities, or both. For those who do undergo resection, recurrence is frequent; repeat resections are difficult to propose, and in some cases, they are ineffective. Chemical or thermal ablation methods have been proposed for patients with no surgical prospects, for those with recurrence after resection or tumor progression after systemic or local chemotherapy, and for those who refuse surgery. Chemical ablation has displayed limited efficacy in the local control of liver METs (Livraghi et al, 1991), but thermal ablation has proved to be safe and effective for the treatment of small liver METs from CRC (Lencioni et al, 2004; Livraghi et al, 2003a; Solbiati et al, 1999). It has also produced promising results in the management of lung METs (Rossi et al, 2006). Furthermore, thermal ablation coupled with open surgery seems to increase the overall number of treatable patients (Abdalla et al, 2004).

Pretreatment Studies and Patient Selection

For HCC patients, treatment eligibility screening generally involves routine laboratory tests, abdominal ultrasonography (US), contrast-enhanced US, spiral computed tomography (CT) or magnetic resonance imaging (MRI), esophagogastroduodenoscopy, and other studies as indicated. Diagnosis of cirrhosis is generally based on histology or concordant laboratory and imaging findings. Most investigators believe that HCCs more than 2 cm in diameter can be reliably diagnosed on the basis of characteristic findings documented with at least two imaging modalities. One modality is sufficient if the patient also has an α-fetoprotein (AFP) level greater than 200 ng/mL. For HCC nodules less than 2 cm in diameter, diagnosis requires typical findings of two imaging techniques and AFP levels above 200 ng/mL. Otherwise, biopsy is mandatory (Bruix & Llovet, 2002). We and others believe that diagnosis of the original tumor should be based on histologic examination of US-guided

fine needle biopsy (FNB) or laparoscopic findings (subcapsular tumors), although imaging findings can be useful for recurrences (Rossi et al, 1996, 1998). US-guided biopsy, cutting or aspirative, with an 18- to 21-gauge needle is always indicated when the AFP level is above 200 ng/mL.

Laboratory screening for CRC liver METs is similar to that described above, and diagnosis is generally based on imaging findings. In a patient with a history of CRC, a focal hepatic lesion is generally regarded as metastatic if it displays peripheral contrast enhancement in the arterial phase and complete washout in the portal and late phases on at least two types of imaging studies. US and FNB confirmation should be obtained if the diagnosis is in doubt, and it can also be used to identify the treatment-relevant receptor status of tumor cells (Midorikawa et al, 2009). Patients with CRC liver METs should always undergo colonoscopy before thermal ablation to exclude the possibility of local disease recurrence.

Candidates for percutaneous ablation have tumors with characteristics similar to those of patients who are eligible for surgical resection, but for a variety of reasons, they are not considered suitable for surgery. Thermal/chemical ablation is generally chosen to treat HCC on the basis of findings related to the tumor, residual liver function, and the patient's general health. The criteria most commonly used include documented cirrhosis; no more than three HCC nodules, measuring no more than 3.0 to 3.5 cm each in diameter; no neoplastic thrombosis of the portal or hepatic veins; and no evidence of extrahepatic metastases. Residual liver function is classified according to the Child-Turcotte-Pugh (CTP) system, and patients with scores higher than B7 to B9 are usually considered unsuitable for ablation. Candidates must also have safe coagulation parameters—prothrombin time (PT) ratio of 50% or higher, international normalized ratio (INR) no higher than 1.7, and a platelet count of 50 to 70 x 10^9/L or more—and no esophageal varices at a high risk for bleeding (Ebara et al, 1995; Rossi et al, 1998).

Similar criteria are used to select patients with CRC liver METs for percutaneous thermal ablation (Rossi et al, 1996; Solbiati et al, 1999). The patient's coagulation status still needs to be assessed, because liver disease is not the only cause of clotting defects. Compared with the criteria applied to HCCs, those used for METs are more restrictive, because metastatic tissue is more difficult to ablate than HCC tissue, so METs with diameters exceeding 2.5 to 3 cm are often considered ineligible for curative percutaneous ablation.

In terms of safety, one of the most important factors to consider is the location of the tumor. For nodules located superficially in segments III, IV, or V of the liver; on the subdiaphragmatic surface of the liver; and for exophytic nodules (surrounded by abdominal viscera) or those close to gallbladder, a laparoscopic or surgical approach is preferable, although in experienced hands, percutaneous ablation of these tumors is by no means impossible (Chopra et al, 2003). Caution must be used when the tumor is situated close to a major bile duct, because damage to these structures can lead to biliary stricture or fistula, which often requires additional interventional radiologic procedures or surgical correction (see Chapter 42).

For tumors located near a large hepatic blood vessel, risk of incomplete treatment and treatment failure is increased. Flow through these vessels can increase convectional heat loss near the tumor, thereby reducing the volume of the thermal lesion, and it can also result in more rapid clearance of the chemical ablative substances. It is often useful to devascularize these tumors before chemical or thermal ablation; this can be accomplished with selective transarterial embolization (TAE; see Chapter 83) or balloon-catheter occlusion of the vessels supplying or draining the tumor (Rossi et al, 2000).

Assessment of Local Tumor Control

Evaluation of local efficacy is based largely on evidence of complete tumor ablation that persists during the follow-up (lack of local recurrence). To achieve this, the entire tumor must be included in the volume of tissue that undergoes chemically or thermally induced coagulative necrosis, which renders it completely avascular. Shortly after the procedure, the necrotic area is surrounded by a halo of edematous, intensely hyperemic tissue. A few days later, this halo is replaced by an inflammatory halo, which persists for approximately 1 month. Thereafter, the mass of necrotic tissue shrinks and is replaced by fibrotic tissue (Rossi et al, 1990). The location, size, and evolution of this ablation zone are assessed with radiologic imaging techniques.

Evaluation of Immediate Treatment Response

The immediate response to any type of percutaneous ablation procedure is generally assessed with contrast-enhanced US (CEUS), enhanced spiral CT, or T2-weighted MRI—the gold standards for this purpose (Chen et al, 2007; Cioni et al, 2001). The presence at the ablation site of a well-defined, nonenhancing area as large or larger than the treated tumor itself is regarded as reliable evidence of a complete response, or complete radiologic necrosis. The timing of the imaging study is important. CEUS examinations performed too soon after ablation are characterized by numerous artifacts caused by gases produced during ablation or the diffusion of chemical substances within tissues surrounding tumor. Under these circumstances, it is impossible to distinguish the origin of the hyperechoic signals. If CEUS, CT, and MRI are performed in the days following the ablative procedures, it is impossible to determine whether the peripheral enhancement observed is due to residual tumor tissue or the hyperemic/inflammatory response of the liver parenchyma. This enhancement is a result of inflammatory tissue response, and it resolves within a month of tumor ablation. Therefore the persistence of an enhancing rim after this point must be considered evidence of residual tumor viability. For these reasons, the contrast-enhanced imaging studies should be scheduled at least 4 weeks after the procedure. If the results of this study are ambiguous, US-guided FNB can resolve the problem (Rossi et al, 1998).

Evaluation of Long-Term Results

Abdominal US/CEUS studies and tumor marker assays are performed every 4 to 6 months, or even more frequently if needed. Local recurrence is diagnosed when enhancement reappears within the ablation zone or within 2 cm, 1 cm according to some authors, from its margins, or when there is histologic evidence of tumor viability in this area (Berber et al, 2005). If the ablation zone remains unenhanced but fails to shrink during follow-up, or when levels of tumor markers are elevated in the absence of other intrahepatic or extrahepatic lesions, focused US-guided biopsy of the ablation zone is indicated. Nonlocal recurrence comprises extrahepatic metastases and all new intrahepatic regrowth located more than 2 cm from the ablation zone.

Assessment of Complications

Immediate and late complications have been reported after all types of percutaneous tumor ablation. They should be evaluated according to previously described guidelines (Sacks et al, 2003). Major complications are those that, if left untreated, could threaten the patient's life, produce substantial morbidity, and/or prolong the hospital stay. All other events are considered minor complications. In general, patients treated with percutaneous ethanol injection (PEI)/percutaneous acetic acid injection (PAI) are monitored for 2 to 3 hours in a dedicated recovery room and are then discharged after a postablation abdominal US examination (Ebara et al, 1995; Shiina et al, 1991). Laboratory tests and other studies are indicated only when clinical or US evidence of complications are apparent. The 24-hour study is also accompanied by measurements of hemoglobin, lactic dehydrogenase and aminotransferases levels, and blood studies to assess hepatic function.

CHEMICAL ABLATION

Chemical ablation is based on the cytotoxic properties displayed by certain chemical substances when directly injected into a tissue. The most widely used cytotoxic substance is ethanol, but in some centers, acetic acid has recently been used as an alternative in the treatment of HCCs (Huo et al, 2003), and sodium hydroxide is under evaluation in a tumor model after evaluation in rats (Lin et al, 2001). Chemical ablation has been extensively used to treat HCCs. It has also been evaluated for the treatment of METs, but this experience was abandoned based on unsatisfactory results (Livraghi et al, 1991).

Percutaneous Ethanol Injection

Physical Principles

Direct injection of ethanol into a tumor results in its distribution in the tissue by diffusion and convection. Diffusion is favored by the existence of a concentration gradient between the injection point and the surrounding tissues, by the low molecular weight of the ethanol, by the increase in local pressure determined by the injection, and by the hypervascularity of the tumor (Ho et al, 2007). Ethanol spreads through the tumor tissue, exerting cytotoxic effects that include cytoplasmic dehydration and denaturation of cellular proteins. The endothelial cell necrosis and platelet aggregation it causes occlude tumor vessels and produce ischemic damage in the neoplastic tissue (Shiina et al, 1991; Ebara et al, 1995). The final result is coagulative necrosis within the tissue around the site of injection.

Technique

PEI is usually performed on an outpatient basis. Patients are treated after an overnight fast. Prophylactic antibiotics are not usually administered, and in most cases, general anesthesia is unnecessary, but in some centers, anxious patients are moderately sedated.

The procedure is performed under real-time US monitoring. The ethanol is usually injected with a 20- to 22-gauge endhole needle (Chiba or Chiba-like) or a conical-tip needle with multiple sideholes (Livraghi et al, 1995). The tip is positioned at the desired point in the HCC nodule with the aid of real-time US guidance, and the predetermined amount of ethanol is infused slowly into the tumor. After few seconds, the HCC nodule becomes completely hyperechoic. Light aspiration is applied during withdrawal to prevent excess ethanol from leaking into the peritoneum through the insertion tract. If all goes well, the patient is kept under observation for about 2 hours.

The volume of ethanol required to ablate a tumor nodule depends on the size of the tumor, but the final decision on the total dose is based on the results of imaging studies performed at the end of each session (Livraghi et al, 1995; Shiina et al, 1991).

An alternative to this multiple-session approach is *one-shot PEI*. As the term implies, the total amount of ethanol required for the ablation, based on the calculations reported above, is injected during a single session (Giorgio et al, 1996; Livraghi et al, 1993). This technique has been proposed for HCCs with diameters exceeding 3 cm. It is more painful than conventional PEI and is therefore performed under general anesthesia. In one study, the amounts of ethanol administered with this technique ranged from 20 to 165 mL (mean, 62 mL).

Percutaneous Acetic Acid Injection

Physical Principles and Technique

After ethanol, the most widely used agent for chemical ablation is acetic acid. In vitro studies have shown that it dissolves lipids and extracts collagen from various kinds of tissues (Ho et al, 2007). Compared with ethanol, acetic acid offers certain advantages, including more effective destruction of tumor septa and capsules. In addition, the same degree of cell kill can be obtained with a smaller infusion volume (Ohnishi, 1998).

The technique of PAI is quite similar to that of PEI. The infusion consists of a 50% solution of acetic acid and sterile water injected with the same technique and needles used for ethanol. Observations in animal models and clinical explants indicate that the volume of acetic acid needed to ablate a tumor nodule is roughly one third of the volume calculated with the formula used for ethanol: ablation of a nodule measuring 3 cm in diameter would require 34 mL of ethanol but only 11.3 mL of acetic acid (Giorgio et al, 2000).

Complications of Percutaneous Ethanol/Acetic Acid Injection

Although PEI and PAI are both low-risk procedures, in rare cases they can produce severe complications. Table 85A.1 shows the complication rates reported after these procedures. The mortality rates associated with PEI/PAI are very low, ranging from 0% to 1.4%. Major complications, which ranged from 0% to 4.6%, include hemoperitoneum, hemobilia, subcapsular or intraparenchymal hematoma, hepatic abscess, cholangitis, intestinal perforation, hepatic venous thrombosis, pneumothorax or pleural effusion, hepatic infarction, and tumor seeding along the needle insertion tract.

Local Tumor Control of Chemical Ablation

Several authors have analyzed the risk factors for local recurrence of HCC after PEI, and tumor size seems to be the most accurate predictor of this outcome. The 2-year local HCC recurrence rates reported after PEI are 10% for nodules smaller than 2 cm in diameter, 18% for those between 2.1 and 3 cm, and 30% for those larger than 3 cm (Ishii et al, 1996). In other studies, local recurrence rates ranged from 33% to 38% for

HCCs smaller than 3 cm and from 43% to 68% for those exceeding 3 cm in diameter (Gaiani et al, 2003; Khan et al, 2000). Thus far, complete response rates observed after PAI seem to be similar to those obtained with PEI, but very few studies are available for comparison.

Long-Term Results

Several investigators have reported 5-year survival rates close to 50% after PEI for HCCs up to 3 cm in diameter in patients with cirrhosis; in other words, results are similar to those achieved with resection (Bruix & Llovet, 2002). In a consecutive series of 685 patients with HCC nodules measuring 3 cm or less, initial treatment with PEI was reportedly associated with a cumulative 5-year survival rate of 49% (Shiina et al, 2009). The Seventeenth Nationwide Follow-up Survey conducted by the Liver Cancer Study Group of Japan revealed survival rates of 91.3%, 77.5%, 63%, 50.2%, and 39.4% at 1, 2, 3, 4, and 5 years, respectively, for 14,726 patients whose HCCs were treated with ethanol injection (Ikai et al, 2007). A randomized trial failed to detect any significant difference in survival between HCC patients treated with PEI or surgical resection (Huang et al, 2005); however, other randomized trials have also shown that radiofrequency ablation (RFA) is superior to all types of chemical ablation for small HCCs, and the difference involved treatment responses, local tumor control, and survival rates (Bouza et al, 2009; Lin et al, 2005; Orlando et al, 2009; Shiina et al, 2005). For this reason, thermal ablation techniques are now preferred over chemical ablation for treatment of HCC. The chemical approach is still the treatment of choice when thermal ablation cannot be performed safely, such as when tumors form adhesions to the gastrointestinal tract, or when tumors are located in difficult sites or close to a bile duct.

THERMAL ABLATION

The goal of thermal ablation methods is to completely destroy a tumor without damaging the surrounding liver tissue. This can be achieved by generating killing temperatures, those exceeding 45° C or less than –40° C, within the mass of tissue that has to be ablated. The temperature reached and the duration of exposure determine how rapidly cell death occurs. Hyperthermia can be produced by delivering electromagnetic (radiofrequency, microwave), light (laser; see Chapters 85C and 85D), or mechanical (high-intensity focused ultrasound) energy into the tissue by means of dedicated probes. Hypothermia is created with cryoprobes (see Chapter 85B), which subtract heat from the tumor tissue by convection. RFA is the thermal technique most widely used for HCCs and liver METs and the one supported by the largest body of published evidence. Microwave ablation (MWA) and laser thermal ablation (LTA) have also been used in these settings, but these experiences are more limited. To date, experiences with high-intensity focused ultrasound (HIFU) have been confined to experimental studies or preliminary clinical investigations.

Radiofrequency Ablation (see Chapter 85C)

Physical Principles

Radiofrequency (RF) energy generates heat in the tissue that is in direct contact with the noninsulated tip of the needle electrode (McGahan et al, 1990; Rossi et al, 1990). The heat is the result of ionic and molecular friction, and it spreads into the surrounding tissues by a process of conduction. The highest temperatures are created in the tissue immediately adjacent to the electrode tip, and the heat rapidly decreases as the distance from the tip increases. Permanent tissue destruction occurs at temperatures of 45° C or higher (Cosman et al, 1983; Organ, 1976). Temperatures ranging from 46° C to 60° C produce irreversible cellular damage only after relatively long periods of exposure. In contrast, temperatures between 60° C and 100° C cause almost instantaneous protein coagulation with irreversible damage to mitochondria and cytosolic cell enzymes. When temperatures exceed 100° C, tissue fluids undergo boiling, vaporization, and ultimately carbonization. The final size of the thermal lesion, an area of coagulative necrosis that is gradually replaced by fibrotic tissue, depends on the total amount of heat deposited in the tissue, the thermal and electrical conductivity of the tissue, and the amount of heat lost through convection; specifically, it depends on heat lost through local blood flow, which acts as a heat sink. Tissue impedance limits the amount of heat that can be introduced into a tissue. It is inversely related to tissue hydration, which in turn reflects the ion content of the tissue (Djavan et al, 1997). During RFA the ions are quickly destroyed, and the tissue undergoes desiccation and charring, and the resultant increases in impedance ultimately prevent further delivery of RF energy.

Conventional RF electrodes used in the monopolar mode produce thermal lesions with a maximum diameter of about 1.8 cm (Rossi et al, 1996). Consequently, the ablation of a relatively small HCC nodule requires the creation of multiple, overlapping lesions. This used to mean multiple needle insertions and multiple treatment sessions; however, second-generation RF electrodes produced thermal lesions with diameters as large as 3 cm, and the volume of tissue that could be ablated with a single pulse of energy increased exponentially. These advances were achieved by increasing the active surface area of the electrode with a set of retractable hooks or prongs (expandable-tip electrodes; Rossi et al, 1998) or by cooling the electrode tip by means of an internal water-circulation system (cooled-tip electrodes) (Goldberg et al, 1998b). The expandable electrodes allow the delivery of larger amounts of RF energy, because rapid charring is less likely when the volume of tissue to be

dehydrated is large. Cooled-tip electrodes achieve the same result by preventing temperatures rising above 100° C in tissues adjacent to the active surface of the electrode. The heat dissipation prevents charring and keeps impedance low, thereby allowing the delivery of larger amounts of RF energy. Larger thermal lesions, those 4 cm or larger, have also been produced with multiple cooled electrodes combined in a cluster (Head & Dodd, 2004), cooled catheter electrodes, and expandable spiral electrodes (Rossi et al, 2006).

Other investigators have attempted to increase thermal lesion volumes by reducing convectional heat loss during the RF procedure (Goldberg, 1998a; Patterson et al, 1998; Rossi, 1999). HCCs are supplied almost exclusively by vessels arising from the hepatic artery (Breedis & Young, 1954); however, when RFA was performed after balloon-catheter occlusion of the hepatic artery, the thermal lesions produced were large as expected on the basis of experimental studies; when RFA was performed after embolization of the feeding arteries with gelatin sponge particles, the thermal lesions produced were larger than expected (Rossi et al, 2000). With this approach, in fact, HCC nodules more than 6 cm in diameter could be treated in a single RF session.

Low impedance during the procedure explains the unexpectedly large thermal lesions. Occlusion of the tumor's arterial supply with gelatin sponge particles reduces impedance in at least two ways: First, it increases the hydrostatic pressure within the HCC (Rossi et al, 2007). As a result, the boiling point of tissue fluid is higher during the thermal ablation procedure, which prolongs the delivery time and allows more energy to be deposited in the tissue, before desiccation and charring occur. Second and more importantly, a gelatin sponge is a hydrogel capable of modifying the electrical and thermal conductivity of the tissue; its presence in the ablation area markedly increases the amount of RF energy that can be delivered.

It is important to recall that liver METs are more difficult to destroy with thermal energy than HCCs. For one thing, the absence of a capsule prevents the buildup of intranodular pressure that occurs in HCCs; therefore less energy can be deposited within a MET, compared with encapsulated HCCs, with a given electrode at a given power setting. More importantly, metastatic lesions are characterized by actively proliferating tissue at the periphery and a devascularized center, and these characteristics create an inhomogeneous field in terms of impedance and conductivity, both thermal and electrical. Further studies are needed to evaluate the behavior of electromagnetic energy in a field of this type.

Technique

Patients undergoing RFA are hospitalized and treated after an overnight fast. In our department, most RFA procedures are performed without general anesthesia or conscious sedation, but some investigators prefer to perform the procedure under general anesthesia or deep sedation. A grounding pad is attached to the patient's back and connected to the RF generator to close the electrical circuit. A local anesthetic (1% lidocaine) is injected along the predefined electrode insertion line, from the skin to the peritoneum. The skin is nicked with a small lancet to facilitate insertion of the electrode, and the tip is then advanced into the HCC nodule under real-time US guidance. The RF generator is activated, and the predefined amount of energy is delivered for 8 to 12 minutes. On US, the nodule becomes hyperechoic with a posterior acoustic shadow (Rossi et al, 1996). The pull-back technique can be used to create multiple thermal lesions along the major electrode axis (Rossi et al, 2000). At the end of the procedure, the electrode is withdrawn, but the generator remains on during this phase; this way, the electrode tract itself also undergoes coagulation, which diminishes the risks of bleeding and tumor seeding.

This technique can be used for HCCs up to 3.5 cm in diameter and for CRC liver METs with diameters of 2.5 cm or less. For larger tumors, other treatment strategies have been adopted. For HCC nodules whose diameters exceed 3.5 cm, RFA has been performed with a multiple-insertion technique (Livraghi et al, 2000), an expandable triple-spiral electrode (Rossi et al, 2006), clusters of cooled electrodes (Cheng et al, 2008), and combination of RFA with other techniques (Murakami et al, 2007). As discussed above, a larger volume of necrotic tissue can also be achieved by preablation embolization of the tumor with gelatin sponge particles. Some operators perform selective transarterial chemoembolization (TACE; see Chapter 83) of larger tumors after RFA debulking. The rationale of this approach is that the amount of embolic agent will be greater in the tumor tissue if its volume was previously reduced with RFA.

Complications

RFA is a safe procedure with very low rates of death and major complications. Tables 85A.2, 85A.3, and 85A.4 show the post-RFA complication rates observed in HCC or MET series reported by our group and others. Mortality rates ranged from 0% to 3.7%, whereas major complication rates were reported in 0% to 22%. Most of the adverse outcomes reported occurred in the initial clinical experiences, and fatal and nonfatal complications have become progressively less common with the increasing experience of the investigators. Indeed, in reports published during the last 5 years, mortality rates are consistently close to 0%, and major complication rates range from 0% to 10%. The complications described include abdominal hemorrhage, hepatic abscess, pleural effusion, hepatic infarction, bronchobiliary fistula, bile peritonitis, biloma, hemobilia, thrombosis of vessels in the hepatic venous system, skin burn, and perforation of the stomach, intestine, or diaphragm. Table 85A.4 shows the complications observed by our group over the last 10 years. This series includes 706 patients with 859 HCC nodules and no procedure-related deaths, which is consistent with previous reports. Less than 1% of the procedures were associated with major complications, a percentage similar of those reported after percutaneous injection therapies. The most serious adverse effect in our series involved shearing of a branch of the hepatic artery; however, all cases were promptly detected by Doppler US studies and controlled by selective embolization of the damaged vessel. Our patients receive neither general anesthesia nor sedation, and the most frequent complication is therefore mild to moderate pain during the procedure that occurs in about 30% of all patients. The pain is easily managed with intravenous analgesia and disappears entirely shortly after the procedure. Use of local, rather than general, anesthesia has several advantages, and this approach is now used by most operators. For one thing, it simplifies the procedure and reduces the cost. More importantly perhaps, it reduces the risk of extrahepatic complications such as perforations of intestinal loops, diaphragm, and gallbladder. The frequency of these events obviously depends on the operator's skill and experience, but conscious patients can report severe pain, which almost inevitably reflects incorrect electrode placement; indeed, a conscious

patient can provide important feedback that can prevent major organ damage.

A 12% seeding rate was reported by a Spanish group during their initial experience with RFA (Llovet et al, 2001). The results contrast with those of other studies, and they may be a reflection of poor technique. Seeding along the electrode tract is virtually impossible, if the electrode is activated before and during each withdrawal. If the recommendations made in the Technique section are followed, the electrode tract itself undergoes coagulation, produced by the gases that develop during the procedure or by the heat generated by the activated electrode during its withdrawal. Our group, in fact, has observed only two cases of subcutaneous tumor seeding after a total of 1921 RFA sessions, and in both cases, it is impossible to say whether the seeding was actually caused by the RFA or by previous US-guided biopsies.

When RFA is performed during or after TAE, other complications are also possible (Rossi et al, 2000). Sporadic cases have been reported of chemical cholecystitis and intimal dissection of the hepatic artery. All patients experience transient increases in serum aminotransferase levels, but baseline values are

generally restored within a week. Some patients also display transient declines in liver function reflected by CTP scores, but these changes rarely last more than 2 weeks.

Local Tumor Control

Histologic examination of whole livers from transplant recipients who had previously been treated with RFA shows that more than 80% of HCCs measuring less than 3 cm are completely destroyed with a single RF electrode insertion (Mazzaferro et al, 2004). Complete response rates ranging from 95% to 98% have been documented in several studies; however, in numerous series of cirrhotic patients with small HCCs treated with RFA, the local recurrence rates range from 0% to 45%, as shown in Table 85A.5. In our series of 859 HCC nodules with maximum diameters of 3.5 cm, the overall local recurrence rate after a 10-year follow-up was 15.7%. The recurrence rate was 5.2% for nodules up to 2 cm in diameter, 12.7% for those with diameters of 2.1 to 3 cm, and 21% for those measuring 3.1 to 3.5 cm; however, in more than 70% of these cases, complete and persistent ablation of the recurrent disease was achieved with a single additional "clean-up" RFA session. This brought the overall local control rate close to 94%, obtained with one treatment in 82% of the cases and with two treatments in 12%.

As shown in Tables 85A.5 and 85A.6, similar complete response rates have been reported for RFA of CRC liver METs, but the recurrence rates in these cases are higher, ranging between 8% and 40%. These results are probably due in part to the use of RFA to treat METs that are too large for this type of ablation. Given the characteristics of metastatic tissue discussed above, percutaneous RFA with curative intent should probably be reserved for METs with diameters no larger than 2.5 cm. If larger METs are treated with this method, local recurrence must be expected in more than 30% of the cases.

Long-Term Results in Hepatocellular Carcinoma Patients

The long-term results reported after RFA treatment of HCCs are summarized in Tables 85A.5 and 85A.6. In our own RFA series, cumulative disease-free and overall survival was similar to those observed by others after RFA, percutaneous injection therapy, or surgical resection. Meaningful comparison of the mortality data and survival curves reported after surgical and nonsurgical treatment of HCC is virtually impossible, because only perfunctory descriptions are provided of recurrences occurring after the initial treatment. Most reports simply do not mention the characteristics of first recurrences (location, extension, etc.), how this recurrence was managed (with the same method used to treat the original tumor or with one or more other techniques), or the outcome of the treatment; even fewer details are provided on subsequent episodes of recurrence. Comparison of results reported for surgical and nonsurgical series is further complicated by the fact that cases of tumor understaging and/or positive resection margins are generally excluded from analyses of survival in surgical series, whereas cases of this type—understaged disease, tumors with persistent viability after two treatments—are usually included in the nonsurgical series (Hanazaki et al, 2000; Helling & Woodall, 2007; McCormack et al, 2005; Shimozawa & Hanazaki, 2004; Torzilli et al, 1999).

Randomized controlled studies have demonstrated that RFA is superior to chemical ablation methods in terms of both local tumor control and survival (Bouza et al, 2009; Brunello et al, 2008; Orlando et al, 2009). These findings suggest that, when possible, RFA should be the first choice for nonsurgical ablation

of HCCs. RFA was also directly compared with surgical resection in two randomized clinical trials, and neither revealed any significant differences between the local tumor control or survival rates associated with the two approaches (Chen et al, 2006; Lu et al, 2006).

Recently, HCC nodules with diameters larger than 3 cm have been treated with a cluster of cooled RF needle electrodes and a multiple-insertion technique (Goldberg, 1998a). Complete responses were observed in 61% of the nodules up to 5.0 cm in diameter and in 24% of larger nodules. These results were to be expected, because tumor volume increases exponentially with its diameter, and larger diameters are also associated with higher frequencies of daughter nodules, capsule infiltration, and neoplastic thrombosis of the portal vessels close to the tumor. Better results have been obtained with more conventional RFA electrodes during gelatin-sponge occlusion of the hepatic artery flow (see Physical Principles below). A complete response rate of 82% was achieved with this approach in 62 HCC nodules, with a mean diameter of 5.6 cm. The local recurrence rate was 19%, and the overall intrahepatic recurrence rate was 45% at 1 year (Rossi et al, 2000). RFA is now recognized as a potentially curative treatment for HCC nodules up to 3 cm in diameter, and some investigators maintain that it should be considered the treatment of choice for these cases (Choi et al, 2007; Livraghi et al, 2008; Shiina, 2009).

Long-Term Results in Patients with Metastases

Table 85A.6 shows the long-term results of RFA for resectable and unresectable CRC liver METs. Survival rates range from 33% to 46% at 3 years and from 22% to 30% at 5 years (Abdalla et al, 2004). These rates are worse than those reported after surgical resection, but it is important to recall that surgery is used in a more select population with fewer risk factors for mortality. RFA can now be considered an approach capable of improving survival in patients with limited but inoperable metastatic liver disease (Otto et al, 2010; Seidenfeld et al, 2002). RFA alone or combined with resection has also proved to be superior to other nonsurgical therapies in patients with multiple liver METs (Abdalla et al, 2004). Finally, some investigators suggest that RFA can be used as a part of a "test of time" approach. Use of RFA as the first option for limited hepatic METs would reduce the need for surgical resections by producing complete and persistent tumor necrosis in some patients. In others, RFA would be followed by new intrahepatic and/or extrahepatic METs, which means that surgery would have been a useless ordeal for the patient. And in a few, post-RFA recurrence will be limited to local regrowth at the site of the ablated MET, and in these cases, surgical resection may prove worthwhile (Livraghi et al, 2003a).

Microwave Ablation (See Chapter 85D)

The most extensive evaluations of MWA have come from Japan and China, although the method is now being studied in Western countries as well.

Physical Principles

The term *microwave* (MW) refers to electromagnetic radiation with frequencies ranging from 900 to 2450 MHz. MW radiation is emitted by the tip of a bipolar antenna electrode placed within the tissue. Microwaves cause rapid vibration and rotation of water molecules within the tissue, which immediately generates frictional heat that persists for the duration of energy delivery. The uniform distribution of this heat in all directions results in coagulative necrosis, and charring near the tip of electrode limits further heat diffusion in the tissue. The thermal lesions produced are spherical to elliptical in shape. Their diameters vary with the power delivered, the electrode caliber, and exposure time. With a 14-gauge electrode, a power output of 60 W, and an exposure time of 120 seconds, the maximum and minimum diameters of the thermal lesions were 2.4 ± 0.4 cm (length) and 1.6 ± 0.3 cm (width). Corresponding diameters

achieved with 30 minutes at 40 W were 3.6 cm (length) and 2.6 cm (width) (Seki et al, 1994).

Technique

The technique of MWA is quite similar to that described above for RFA (Seki et al, 1994). Percutaneous MWA is usually performed as an inpatient procedure after an overnight fast. General anesthesia or deep sedation is induced, and a thin (14- to 16-gauge) MW antenna is advanced directly into the tumor nodule under US guidance. The antenna is connected to the MW generator, which is activated to deliver 60 to 90 W of power. Delivery times vary from 2 to 30 minutes, depending on tumor size. In general, tumors less than 2 cm in diameter can be ablated with one or (more commonly) two electrode insertions; for larger tumors, multiple insertions are necessary. The same precautions described for RFA apply to MWA. The changes revealed by US consist of the appearance around the tip of the electrode of a hyperechoic area with a posterior acoustic shadow. This zone increases in size with exposure time and ultimately involves the entire tumor. The hyperechogenicity diminishes rapidly after the generator is switched off and disappears completely within 8 hours of the procedure.

Complications

The complications reported after MWA are quite similar to those listed above for RFA. Table 85A.7 shows the mortality and complication rates observed in the various published series. Mortality ranged from 0% to 8.3%, and complication rates from 2.6% to 14% were reported.

Local Tumor Control

MWA can produce complete tumor necrosis. Histologic examination revealed no viable tumor in 180 (92.3%) of 192 treated HCC nodules that were biopsied after MWA and in 5 (90%) of 6 HCC nodules that were surgically resected after MWA (Seki et al, 1999). None of these nodules were more than 3 cm in diameter. For HCCs of this size, the complete ablation rate is reportedly quite good, more than 90%, but it is significantly lower for larger tumors. The local recurrence rates reported by several investigators after MWA of hepatic tumors ranged from 2% to 37%, as shown in Table 85A.8.

Long-Term Results

Several clinical studies have investigated the usefulness of MWA in the treatment of HCC. The long-term results observed in these studies are summarized in Table 85A.8. The overall survival rates 3 years after the procedure ranged from 50.5% to 90%, and at 5 years from 17% to 70%. The Fifteenth Nationwide Follow-up Survey conducted by the Liver Cancer Study Group of Japan found 1-, 2-, 3, and 5-year survival rates of 94.2%, 84%, 72.9%, and 44.1%, respectively, in 1751 patients whose HCC had been treated with MWA (Ikai et al, 2004). The effectiveness of MWA and that of RFA have also been compared in randomized trials (Ohmoto et al, 2009; Shibata et al, 2002). No statistically significant differences were observed between the two treatment methods in terms of local efficacy, but RFA tended to be associated with slightly better local recurrence and complication rates; however, since RFA was introduced in 1999, use of MWA has steadily decreased, even in centers where it was once widely used (Shiina et al, 2002).

Limited data have been reported so far concerning the long-term results of MWA of liver METs (see Table 85A.8). Some investigators have reported promising results in their initial experience with several types of primary tumors (Abe et al, 2005; Liang et al, 2003). In another randomized study comparing MWA and surgical resection in patients with multiple CRC liver METs, no statistically significant differences were observed in the survival rates of the two groups (Tanaka et al, 2006).

Collectively, the data cited above indicate that MWA is an effective method for the treatment of hepatic tumors. Its major limitation is the relatively small size of the thermal lesions it produces. To ablate most tumors, multiple overlapping lesions must be created; because this requires multiple electrode insertions, it is unlikely that percutaneous MWA will be widely used to treat hepatic tumors, unless equipment and electrodes can be modified to produce a larger zone of coagulative necrosis with small caliber electrodes.

Laser Thermal Ablation (See Chapter 85D)

Physical Principles

Laser light, which has a wavelength of 800 to 1064 nm, is delivered to the tissue through the tip of a bare, flexible, quartz laser fiber (300 to 600 μm in diameter) where it is scattered, reflected, and absorbed to varying degrees, depending on its specific wavelength and the specific optical properties of the tissue. The production of heat stems from interaction between the photons of low-intensity laser energy and molecular chromophores—hemoglobin, myoglobin, bilirubin, the cytochrome pigments in mitochondria, and so on—structures ubiquitous in human tissues. This distinguishes laser thermal ablation (LTA) from RFA and MWA, which produce heat by inducing ionic and molecular friction, but the results are the same: lethal thermal injury. Temperatures between 45° C and 55° C ultimately lead to cell death if the heating is persistent. In contrast, temperatures that exceed 60° C cause immediate and irreversible cellular death with protein denaturation, breakage of chemical bonds in DNA and RNA molecules, and loss of integrity in the lipid layers (Head & Dodd, 2004; Izzo, 2002).

Use of high-power laser energy results in vaporization and rapid tissue charring around the tip of the fiber. Although temperatures near the light-emitting portion of the laser fiber can range from 300° C to 1000° C, the presence of coagulated tissue around the tip drastically reduces the optical penetration of the light into adjacent tissues and thereby limits heat diffusion. As a consequence of overheating and charring, the areas of thermal necrosis produced with LTA are often less than 1 cm in diameter. If low-power laser energy is used, tissue heating occurs slowly, which decreases vaporization and tissue carbonization around the tip of the laser fiber. This approach produces a zone of radiant and conductive tissue heating that enlarges progressively, and the area of thermal necrosis ranges from 1.0 to 1.5 cm in diameter (Germer et al, 1998).

Obviously, the relatively small volume of LTA thermal lesions limits the clinical applicability of this thermal ablation technique. To overcome this problem, a variety of strategies have been proposed. The use of sapphire-tipped laser fibers significantly reduces the occurrence of carbonization at the fiber tip, but it does not significantly increase the size of the thermal lesions (Vogl et al, 2002). The use of interstitial fibers, quartz fibers with flat or cylindrical diffusers at the tip, reduces tissue carbonization and produces thermal lesions ranging from 2.3 to 5 cm in diameter (Khan, 2008). Cooled laser application sheaths, designed to reduce temperatures around the laser fiber tip, allow the use of higher power output without carbonization and produce larger thermal lesions (Vogl et al, 2002); however, diffusers increase the caliber of the laser fiber, and water-cooled sheaths require insertion of a coaxial dilation system introduced through an 18-gauge puncture. The beam-splitting multiple-fiber LTA device offers further improvement in thermal lesion size. Most of these systems use four parallel fibers positioned 1.5 to 2 cm from each other. The simultaneous activation of all four fibers produces a thermal lesion that is larger than the sum of the individual lesions produced by each fiber, because killing temperatures are also reached in the overlapping peripheral zones. This laser device can produce thermal lesions from 4 to 7 cm in diameter; however, positioning the multiple fibers in the tumor nodule is a highly complex procedure that requires training and a great deal of practice. In addition, even for skilled investigators, it is almost impossible to place the fiber tips correctly within the three-dimensional space, and in most cases, the thermal lesion produced will be irregularly shaped.

Technique

Like other thermal ablation methods, LTA can be performed percutaneously, laparoscopically, or during open surgery. The percutaneous technique is identical to those described above for RFA and MWA, and US is the technique most commonly used to insert the Chiba or Chiba-like needle into the tumor. When the needle tip is in the correct position, the laser fiber is passed through the needle and advanced, until its tip lies about 1 cm beyond that of the needle. Laser energy is then delivered for 6 to 10 minutes.

The appearance of the thermal lesions on US is the same as that described for other methods of thermal ablation. The technique used with the beam-splitting multiple-fiber laser device is basically the same, but it involves the placement four Chiba-like needles as guides for the four laser fibers. With single and multifiber techniques, the pullback technique can be used to create multiple lesions (Pacella et al, 2009).

Unlike other thermal ablation methods, LTA can be performed under the guidance of MRI. This approach allows real-time monitoring of the temperatures reached in the tissue undergoing ablation. Several MRI sequences have been evaluated for this purpose (Botnar, 1998; Matsumoto et al, 1994; Vogl et al, 1995). The simplest and most widely used is the T1-weighted

sequence. The T1 values of a tissue decreases linearly with increasing temperatures (up to about 55° C). However, conventional MRI significantly limits access to the patient, so percutaneous insertion and placement of laser fibers is often done under US or CT guidance, and the patient is then transferred into the MRI scanner to monitor the treatment. This limitation may be overcome by the use of open MRI systems, which are becoming more and more common (Izzo, 2002).

Complications

The complications reported after LTA are also quite similar to those observed after the other percutaneous methods of thermal ablation. Table 85A.9 shows the LTA mortality and complication rates reported by several investigators. Mortality ranged between 0% and 0.8%, and complication rates were between 0% and 2%.

Local Tumor Control

LTA has been shown to be effective in producing complete ablation of tumor nodules, and as expected the probability of success depends on the size of the tumor. Increasing size is associated with decreasing rates of complete ablation; therefore all three major methods for thermal ablation can produce complete ablation in more than 90% of HCC nodules, as long as their diameters do not exceed 3 cm. As shown in Table 85A.10, the local recurrence rates reported by several investigators vary widely after LTA of hepatic tumors, from 2% to 37% (Eichler et al, 2001).

Long-Term Results

The long-term results of LTA of HCC and METs are summarized in Table 85A.10. In terms of survival, the best results were those of Vogl and coworkers (2004), who reported 3- and 5-year survival rates of 49% and 33% after LTA treatment of liver METs; however, the wide variability of the results and the limited number of reports make these data of limited value. Some investigators have reported promising 3- and 5-year survival rates after LTA of HCC (61% and 34%, respectively). On the whole, LTA is an effective method for treating hepatic tumors, but it has two major limitations: First, the small size of the thermal lesions obtained with a single laser fiber reduces the applicability of the technique and necessitates multiple treatment sessions to ablate most tumors. Second, the multiple-fiber technique is a much more complex procedure that requires a high degree of skill and experience. It also tends to produce irregularly shaped thermal lesions, therefore LTA technology needs to be improved before it gains worldwide use. At present, the available data on local recurrences and long-term survival are inadequate to allow any meaningful conclusions on the future of LTA.

Cryoablation (see Chapter 85B)

Physical Principles

Cryoablation kills tumor cells by the induction of hypothermia rather than hyperthermia. The mechanisms underlying the cellular damage produced by cryoablation depend on the freezing rate. Rapid cooling near the cryoprobe tip produces an ice ball. Water molecules are trapped within the cells and are transformed into ice crystals, which aggregate and cause cell death.

Technique

Cryoablation has been practiced during open surgery for more than 40 years. Recently, needle-like cryoprobes 3 mm in caliber

have been developed that can be used for percutaneous tumor ablation, which is generally performed under US guidance (Mala, 2006); general anesthesia is typically used, because the procedure lasts longer than 30 minutes. The tip of the cryoprobe is placed in the deepest part of the tumor under US guidance, and the freeze-thaw cycle begins. On US, the ice ball appears as an increasing hyperechoic rim with a posterior acoustic shadow. Multiple cryoprobes must be inserted to ablate tumors larger than 3 cm in diameter. In this way, ablation areas larger than 5 cm in diameter can be created (Bilchik et al, 2000).

Complications

Cryoablation is associated with a higher rate of complications than other thermal ablation techniques (Seifert & Morris, 1999). One event that is peculiar to this type of ablation is cracking of the liver parenchyma, resulting in hemorrhage. Another typical complication is a syndrome known as *cryoshock*, which involves pulmonary, renal, and coagulation abnormalities in a variety of combinations (Head & Dodd, 2004). The severity varies, and the syndrome may include diffuse intravascular coagulopathy. Severe hypothermia can occur with either intraoperative or percutaneous cryoablation, and this can be lethal when the tumor being treated is large (Sarantou et al, 1998). Other complications are similar to those reported for the other thermal ablative methods. Table 85A.11 shows the mortality and complication rates reported by several investigators after cryoablation of hepatic tumors; they range from 0% to 4% and from 1.5 % to 29%, respectively.

Local Tumor Control

Cryoablation can completely destroy hepatic tumors, but the complete response rates, as shown in Table 85A.12, are lower than those reported for RFA or MWA. Local recurrence rates

*Hepatocellular carcinoma
†Metastases from colorectal cancer
‡Miscellaneous

(6.4% to 58%) also seem to be higher than those observed after RFA.

Long-Term Results

In several centers, cryoablation has been used to destroy liver tumors, for the most part liver metastases from CRC. Only limited initial experiences have been reported for HCC, but for these tumors, RFA has surpassed cryoablation in terms of local tumor control (Adam et al, 2002). The long-term results documented in several studies are shown in Table 85A.12, but these data are characterized by a degree of variability that precludes any meaningful assessment of the efficacy of cryoablation.

The major drawbacks of cryoablation are the large caliber of the cryoprobes, which are not suitable for percutaneous insertion, and the long exposure times required to ablate even small tumors. These aspects need to be substantially improved before cryoablation can compete with the other thermal ablation methods.

CHAPTER 86

Regional chemotherapy for liver tumors

Nancy E. Kemeny and Andrew S. Epstein

OVERVIEW

The liver is an organ with a rich blood supply, therefore it serves as the destination of metastases for many tumors. As the portal vein drains the entire gastrointestinal (GI) tract, malignancies arising from these organs frequently produce liver metastases. Because of the dual blood supply and the large volume of blood flow in the liver, extraabdominal tumors—such as bronchogenic carcinoma, breast cancer, and malignant melanoma—spread hematogenously and also metastasize to the liver with some frequency. This chapter focuses on the use of intraarterial chemotherapy and associated surgical issues for the treatment of liver metastases from colorectal cancer (CRC), which is the third most common malignancy in the United States, with 141,210 new cases and 49,388 deaths in 2009. Additionally, because CRC often presents with or develops isolated spread to the liver, most major studies of hepatic intraarterial chemotherapy address liver metastases deriving from CRC. The use of systemic therapy is discussed briefly to put in perspective the relative response rates and survival with intrahepatic therapy.

SYSTEMIC CHEMOTHERAPY

Responses to systemic chemotherapy (SYS) vary with the type of tumor; for example, patients with liver metastases from a breast primary may have high response rates with SYS (Harris et al, 1997), in contrast to metastases from a gastric or pancreatic primary tumor. Despite 20% response rates and median survivals less than 1 year, fluoropyrimidines represented the standard of care for metastatic CRC for decades (Thirion et al, 2004). More recently, patients with metastatic colon carcinoma have had response rates greater than 30%. With the development of newer drugs, such as irinotecan and oxaliplatin, response rates have increased to 35% to 40% with median survivals of 15 to 19 months (Goldberg et al, 2002; Saltz et al, 2000). The use of targeted agents, such as bevacizumab and cetuximab (Cunningham et al, 2004), has further improved outcomes, and bevacizumab demonstrated overall survival of 20 months (Hurwitz et al, 2004). Many chemotherapy trials do not differentiate patients with liver-only metastases to show how these patients respond to chemotherapy. In tumors with high response rates, such as breast carcinoma, a reasonable response to SYS is found even in patients with liver metastases, although the response is lower with liver metastases than with soft-tissue metastases (George & Hoogstraten, 1978). In patients with CRC, the liver is the most common site of dissemination, and 60% of patients (Daly & Kemeny, 1986) develop liver metastases during the course of their disease.

RATIONALE FOR HEPATIC ARTERIAL CHEMOTHERAPY

The rationale for hepatic arterial infusion (HAI) is based upon anatomic and pharmacologic principles.

1. Liver metastases are perfused almost exclusively by the hepatic artery, whereas normal hepatocytes derive their blood supply from the portal vein and the hepatic artery (Breedis & Young, 1954). After injection of floxuridine (FUDR) into either the hepatic artery or the portal vein, mean liver concentrations of the drug do not differ based on the route of injection; however, mean tumor FUDR levels are significantly increased (15-fold) when the drug is injected via the hepatic artery (Sigurdson et al, 1987).
2. The use of drugs that are largely extracted by the liver during first-pass metabolism results in high local concentrations of drug with minimal systemic toxicity. Ensminger and colleagues (1978) showed that 94% to 99% of FUDR is extracted by the liver during the first pass compared with 19% to 55% of 5-fluorouracil (5-FU). FUDR is therefore an ideal drug for hepatic arterial infusion (HAI), with a 400-fold increase in hepatic exposure with FUDR. The pharmacologic advantage of various chemotherapeutic agents for HAI is summarized in Table 86.1 (Ensminger & Gyves, 1983).
3. Drugs with a steep dose-response curve are more useful when given by the intrahepatic route, because small increases in the concentration of administered drug result in a large improvement in response. FUDR follows linear kinetics and is not saturated at high dose rates.
4. Drugs with a high total body clearance are more useful for hepatic infusion. The area under the concentration-versus-time curve is a function not only of drug clearance but also of hepatic arterial flow. Because hepatic arterial blood flow has a high regional exchange rate (100 to 1500 mL/min), drugs with a high clearance rate are needed (Collins, 1984). If a drug is not cleared rapidly, recirculation through the systemic circulation mitigates the advantage of intraarterial therapy over systemic therapy (Collins, 1986).
5. Another rationale for hepatic arterial chemotherapy, especially for patients with metastatic CRC, is the concept of a stepwise pattern of metastatic progression (Weiss, 1989; Weiss et al, 1986). This theory states that hematogenous spread occurs first via the portal vein to the liver, then from

Table 86.1

Estimated Increase in Hepatic Exposure for Drugs Given by Hepatic Arterial Infusion

Estimated Increase by Drug	Half-Life (min)	Hepatic Arterial Exposure
Fluorouracil	10	5- to 10-fold
Floxuridine	10	100- to 400-fold
Bis-chloroethyl-nitrosourea	5	6- to 7-fold
Mitomycin C	10	6- to 8-fold
Cisplatin	20 to 30	4- to 7-fold
Doxorubicin	60	2-fold
Dichloromethotrexate	—	6- to 8-fold

the liver to the lungs, and then to other organs. Aggressive treatment, either resection or hepatic infusion, of metastases confined to the liver yields prolonged survival for some patients.

The development of an implantable infusion pump allowed for the safe administration of hepatic arterial chemotherapy in the outpatient setting (Blackshear et al, 1972). Early trials using an implantable pump and continuous FUDR therapy produced a median response rate of 47% (Johnson & Rivkin, 1985) and a median survival of 17 months (Weiss et al, 1983). To further show that HAI had a therapeutic benefit, several randomized studies were conducted.

FIRST-LINE THERAPY IN UNRESECTABLE LIVER METASTASES

One of the first randomized trials was conducted at Memorial Sloan-Kettering Cancer Center (MSKCC) (Kemeny et al, 1987). Before randomization, patients were stratified for extent of liver involvement by tumor and baseline lactate dehydrogenase level, two factors that have been shown to be important prognostic indicators of survival (Table 86.2; Kemeny & Braun, 1983; Kemeny et al, 1989). This prospective randomized trial compared HAI with SYS using the same chemotherapeutic agent (FUDR), drug schedule (a 14-day continuous infusion), and method of administration (internal pump) in both groups.

Of the 99 evaluable patients, two complete responses and 23 partial responses (53%) were observed in the group receiving HAI, and 10 partial responses (21%) were reported in the SYS group ($P = .001$). Of the patients randomized to SYS, 31 (60%) crossed over to HAI after tumor progression, and 25% of these patients went on to a partial response after the crossover, and 60% had a decrease in carcinoembryonic antigen (CEA) levels.

Toxicity differed between the two groups. An increase in hepatic enzymes and serum bilirubin levels occurred in the HAI group. In the SYS group, diarrhea occurred in 70% of patients, and 9% required admission for intravenous hydration. Mucositis occurred in 10% of patients receiving SYS.

The median survival for the HAI and SYS groups was 17 and 12 months, respectively ($P = .424$). The interpretation of survival in this study is difficult because 60% of the patients in the systemic group crossed over. The patients who did not cross over usually had clots of the hepatic arterial system and had a median survival of only 8 months compared with 18 months for the patients who crossed over to hepatic infusion ($P = .04$). An analysis of baseline characteristics in the crossover and noncrossover groups revealed no significant differences.

Two subsequent European randomized trials using HAI therapy in this setting have been published. The first was conducted by the Medical Research Council (MRC) and European Organization for the Research and Treatment of Cancer (EORTC) groups, which compared HAI 5-FU/leucovorin (LV) with intravenous 5-FU/LV. Crossover from the intravenous to the HAI arm was not allowed. Of 290 patients randomized, only 66% on the HAI arms received treatment. Response rates were 22% for HAI and 19% for intravenous

5-FU/LV. This trial used subcutaneous ports rather than implantable pumps and had significant catheter-related problems (36% of HAI patients) (Kerr et al, 2003). The median survival was 14.7 months and 14.8 months in the HAI and SYS groups, respectively ($P = .79$).

The second trial was by a German cooperative group that randomized 168 patients with unresectable colorectal liver metastases to HAI of FUDR, HAI of 5-FU/LV, or intravenous 5-FU/LV (Lorenz & Muller, 2000). Response rates were higher in the two HAI arms, with no significant differences in time to progression, the primary end point, or overall survival (OS) between the arms. Only 70% of patients on the HAI arms actually received assigned treatment. The study also used ports instead of pumps.

The Cancer and Leukemia Group B (CALGB) (Kemeny et al, 2006) completed trial 9481, which compared systemic 5-FU/LV via the Mayo Clinic regimen, considered standard of care at the time of trial design, with HAI of FUDR, LV, and dexamethasone, a regimen that had produced high response rates (78%) and lower toxicity (3% biliary sclerosis) in a phase II study (Kemeny et al, 1994). An earlier trial randomized patients to HAI of FUDR with or without dexamethasone, which demonstrated less biliary toxicity and a trend toward median OS (23 months vs. 15 months, respectively, $P = .06$) in the dexamethasone-containing arm (Kemeny et al, 1992). In CALGB 9481, no crossover was permitted, and a total of 134 patients were randomized. Most patients (70%) had greater than 30% liver involvement, synchronous metastases (78%), and were chemotherapy naive (97%). Response rates were higher in the HAI group (47% vs. 24%; $P = .012$), although time to progression was not significantly different (5.3 months vs. 6.8 months; $P = .8$); time to hepatic progression was better in the HAI arm (9.8 months vs. 7.3 months; $P = .017$) and in the systemic arm (7.7 months vs. 14.8 months; $P = .029$). Median OS was significantly better in the HAI arm (24.4 months vs. 20 months; $P = .0034$; Kemeny et al, 2006). Resource use, quality of life, and molecular markers of prognosis, such as thymidylate synthase (TS) and p21 gene expression, were examined prospectively in this study, and final analysis of these factors were presented. At 3- and 6-month follow-up, physical functioning was improved in the HAI group. TS levels correlated with survival in HAI patients (24 months if TS >4, 14 months if TS ≤4), but these differences were not significant ($P = .17$).

A total of 10 randomized phase III trials have been done, most of which demonstrate a higher response rate with HAI versus SYS in patients with hepatic metastases from CRC (see Table 86.2). Whether this increase in response rate translates into increased survival is controversial. Several factors complicate this issue. Importantly, most of the trials contain relatively few patients; therefore the power to observe differences in survival rates is low. Also, because of early successes with intrahepatic infusion, some of these studies allowed patients in the systemic arm to cross over to intrahepatic therapy after tumor progression on systemic therapy. This crossover may have negated any difference in survival between the two groups. The studies show a survival advantage for those who received subsequent HAI, with a mean 1-year survival of 69% for the patients who had crossed over from SYS to HAI versus 35% for the patients who did not cross over (Table 86.3). Additionally, some trials included patients with extrahepatic disease, complicating survival analyses in the absence of systemic treatment. Other factors to consider are that some patients randomized to HAI did not receive it but were included in the survival analysis, and an absence of modern toxicity-based dose-titration schema may have resulted in fewer cycles of treatment.

The European studies are difficult to interpret, because in the first two studies, the SYS group received SYS only when they became symptomatic. The two new European studies used ports instead of pumps, which resulted in more technical complications.

Two meta-analyses of the original seven trials were conducted and included more than 600 patients. The Meta-Analysis Group in Cancer (MAGIC, 1996) confirmed the increased response rates seen with HAI over SYS (41% vs. 14%); however, survival differences were deemed only statistically significant in the trials that included a control group treated only when symptoms arose. With the statistical methodology used, the authors were unable to include the data from Hohn and colleagues (1989); however, a second meta-analysis published the same year did incorporate the results from that study and found an absolute survival difference of 12.5% at 1 year ($P = .002$) and 7.5% at 2 years ($P = .026$) in favor of HAI (Harmantas et al, 1996). The authors omitted the trial by Allen-Mersch and colleagues (1994) given the fact that most patients in the SYS arm of that study received best supportive care only. Furthermore, they analyzed their results to show that, when

omitting the data from Rougier and colleagues (1992)—because, like the study from Allen-Mersh and others (1994), only half of the patients in the SYS arm received chemotherapy—survival was only statistically significantly higher at the 1-year time point. Nonetheless, factoring only those six studies without crossover, the survival differences at 1 and 2 years were accentuated, and actually both significantly favor of HAI.

As mentioned above, CALGB 9481 permitted no crossover, and with the incorporation of dexamethasone, it demonstrated survival with HAI that compares well to published results with modern SYS regimens; however, a recent and well-orchestrated third meta-analysis that accounted for the design flaws discussed above examined all 10 randomized trials to date and failed to demonstrate a survival benefit with HAI (Mocellin et al, 2007). This report and the published commentary that followed demonstrated that, although there may be no clear survival benefit in using HAI instead of SYS, combining HAI and SYS has led to high response rates with acceptable toxicity profiles.

Subsequent sections of the chapter discuss how newer management principles, such as the incorporation of dexamethasone for toxicity abrogation and the use of combination HAI and SYS, may improve overall outcomes. This underscores the need to examine response and OS data in the context of modern treatment paradigms.

TOXICITY OF INTRAHEPATIC THERAPY

Table 86.4 summarizes the GI toxicities noted by investigators using the implantable pump. The side effects of SYS are almost never observed with HAI, and myelosuppression does not occur with intrahepatic FUDR (Kemeny et al, 1984). Although intrahepatic mitomycin C or bis-chloroethyl-nitrosourea may depress platelet counts, the absolute depression and frequency of depression are less than with systemic administration. Nausea, vomiting, and diarrhea do not occur with HAI of FUDR. If diarrhea does occur, shunting of the chemotherapeutic agent to the bowel should be suspected (Gluck et al, 1985).

The most common problems with HAI are ulcer disease and hepatic toxicity (Hohn et al, 1985; Kemeny et al, 1984). Severe ulcer disease results from inadvertent perfusion of the stomach and duodenum with drug via small, unligated branches from the hepatic artery, but this can be prevented by meticulous dissection at the time of pump placement (Hohn et al, 1985); however, even without radiologically visible perfusion of the stomach or duodenum, mild gastritis and duodenitis can occur. This toxicity can be reduced by careful dose reductions when any GI symptoms arise. Hepatobiliary toxicity is the most problematic toxicity seen with HAI. Although some evidence of hepatocellular necrosis and cholestasis has been found on liver biopsy specimens (Doria et al, 1986), most studies point to a combined ischemic and inflammatory effect on the bile ducts as the most important cause of this toxicity. The bile ducts are particularly sensitive to HAI; this is because the bile ducts derive their blood supply almost exclusively from the hepatic artery, similar to hepatic tumors (Northover & Terblanche, 1979).

In patients with severe toxicity, endoscopic retrograde cholangiopancreatography (ERCP) shows lesions resembling primary sclerosing cholangitis (Kemeny et al, 1985). Because the ducts are sclerotic and nondilated, ultrasound usually is not helpful. In some patients, the strictures are more focal, and they are usually worse at the bifurcation, and drainage procedures by endoscopic or by percutaneous transhepatic intubation may be helpful. Duct obstruction from metastases should be excluded first by computed tomography (CT) of the liver.

Close monitoring of liver function tests is necessary to avoid biliary sclerosis. If the serum bilirubin becomes elevated, no further treatment should be given until the bilirubin returns to normal, and then treatment should proceed with only a small test dose (0.05 mg/kg/day). In patients who cannot tolerate even a low dose for 2 weeks, it may be possible to continue treatment by giving the FUDR infusion for 1 week rather than the usual 2 weeks. At MSKCC, we modify treatment as outlined in Table 86.5.

In older trials, cholecystitis occurred in 33% of patients receiving HAI (Kemeny et al, 1986a). In more recent series, the gallbladder was removed at the time of catheter placement to prevent this complication and to avoid the confusion of these symptoms with other hepatic side effects of chemotherapy.

SURGICAL TECHNIQUE

Hepatic Artery Pump Placement

The arterial anatomy of the liver varies (Table 86.6), and a normal anatomy is present in only about two thirds of patients

(Allen et al, 2002; see Chapter 1B). Before consideration of pump placement, it is imperative to carry out a careful review of the arteriogram with the radiologist and formulate a plan for the management of aberrant anatomy. In the past, direct arteriography was required, but excellent definition now can be ascertained from CT angiography. In most cases, a pump with a single catheter is adequate to provide access to the entire hepatic arterial inflow. It is best not to place the catheter directly into the hepatic artery, which risks thrombosis of the vessel; instead, it should be placed into an accessible side branch. The gastroduodenal artery (GDA) is the preferred conduit for the catheter and provides the most reliable method of catheter implantation (Allen et al, 2002). As previously mentioned, cholecystectomy should be performed to prevent chemotherapy-induced cholecystitis. Numerous incisions have been employed for this operation with success, including an upper midline incision, right subcostal incision, or limited right subcostal hockey-stick incision. Preoperative intravenous antibiotics close to the time of incision are imperative.

For patients with unresectable disease, a staging laparoscopy is advisable to rule out occult extrahepatic disease, which in our experience occurs in approximately one third of patients (Grobmyer et al, 2004). A thorough examination of the abdomen is performed at laparoscopy and at laparotomy to look for extrahepatic disease. The most common sites of extrahepatic metastases are the peritoneum and portal lymph nodes; therefore a biopsy should be done if the lymph nodes look suspicious, because their involvement generally would preclude the use of the pump. The extent of liver involvement should be assessed and documented. Any radiographically occult hepatic tumors should be noted, and the potential for future resection should be specifically addressed in the operative note.

Standard Hepatic Arterial Anatomy

A standard cholecystectomy is performed, and the hepatic artery and its branches are circumferentially dissected. The common hepatic artery and the GDA are palpable superior to the body of the pancreas and the first portion of the duodenum. The GDA runs parallel to and lies immediately to the left of the common bile duct, and it is advisable to start by dissecting the common hepatic artery to minimize the risk of injuring the bile duct. The right gastric artery is ligated and divided. The distal common hepatic artery, the entire GDA, and the proximal proper hepatic artery are dissected away from their attachments. It is important to mobilize the full length of the extrapancreatic GDA to facilitate insertion of the catheter. Suprapyloric side branches of the GDA are often encountered and must be ligated. Frequently, branches to the pancreas and duodenum arise from many of these dissected vessels, and it is essential to identify and ligate these branches to avoid perfusion of the pancreas, stomach, or duodenum. The common hepatic artery is mobilized 1 cm proximally, and the proper hepatic artery is mobilized about 2 cm distally from the origin of the GDA. Branches to the retroperitoneum from the right or left hepatic artery are common and should be ligated. Review of preoperative angiography to look specifically for these branches

Table 86.6

From Allen PJ, et al, 2002: The management of variant arterial anatomy during hepatic arterial infusion pump placement. Ann Surg Oncol 9:875-880.

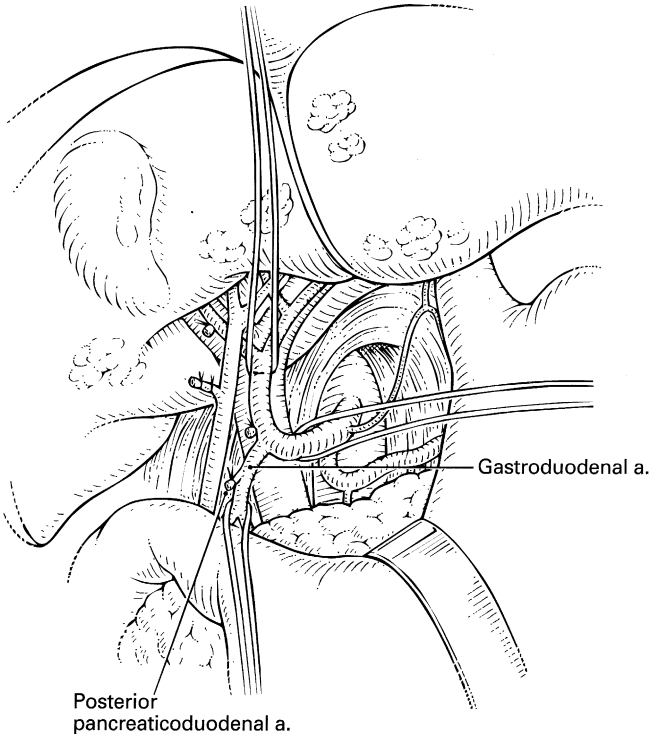

FIGURE 86.1. The common hepatic, proper hepatic, and gastroduodenal arteries are completely mobilized. All branches to the stomach, duodenum, or pancreas are identified and ligated.

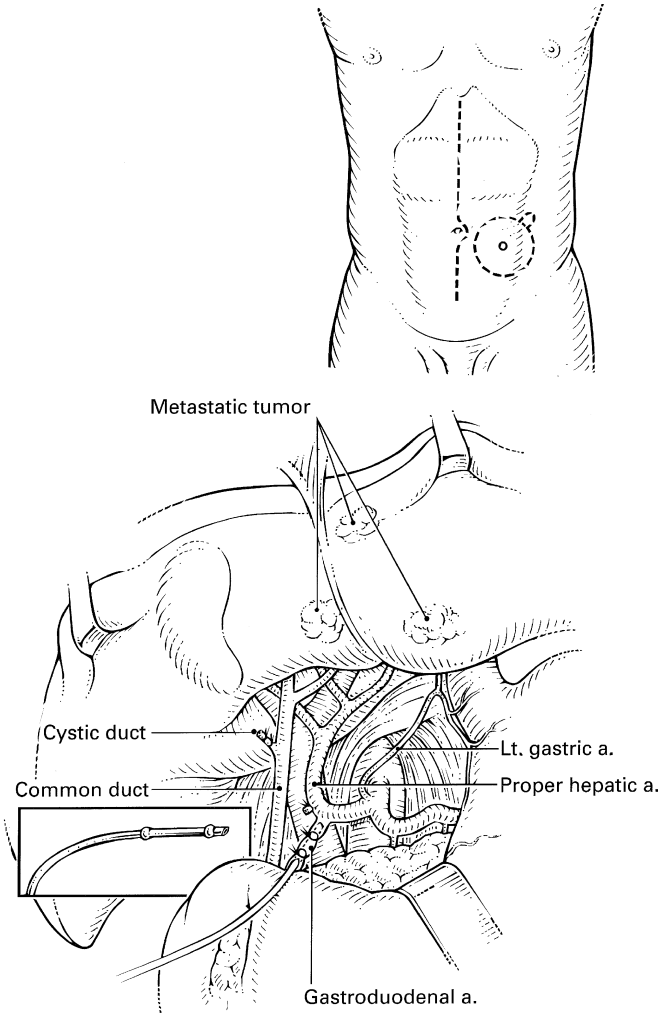

FIGURE 86.2. The infusion pump ideally is placed in the left lower quadrant, away from the liver, to avoid artifacts on subsequent computed tomographic scans. With normal anatomy, the catheter is placed in the gastroduodenal artery and secured with nonabsorbable ties, the right gastric artery is ligated, and the gallbladder is removed.

is important, because they are often found in retrospect. At this point, a complete circumferential dissection of the common hepatic artery, GDA, and proper hepatic artery should be ensured such that no vessels to the pancreas, stomach, or duodenum remain (Fig. 86.1). The GDA should be temporarily occluded with palpation of the proper hepatic artery to rule out retrograde flow to the liver through the GDA secondary to celiac stenosis. No attempt at dissection of the common bile duct is necessary, because this risks devascularization and ischemic stricturing.

The pump pocket should be created in the lower abdomen so that the pump lies below the waist and avoids contact with the iliac spine and the edge of the ribs. In obese patients, placing the pump over the ribs should be considered, because this may help in locating and accessing the pump. The pump and catheter should be handled carefully, avoiding contact with the patient's skin. The catheter is trimmed at a level just beyond the last tying ring and is tunneled into the abdominal cavity. The pump is secured to the abdominal fascia with nonabsorbable sutures; the catheter should be positioned behind the pump to prevent injury by a needle. The GDA is ligated with a nonabsorbable tie at its most distal point, and vascular control of the common and proper hepatic arteries is achieved with vascular clamps or vessel loops. Isolated vascular control of the GDA at its orifice also can be used to avoid occlusion of the hepatic artery.

An arteriotomy is made in the distal GDA, and the catheter is inserted up to, but not beyond, the junction with the hepatic artery (Fig. 86.2). If the catheter protrudes into the common hepatic artery, turbulence of blood flow can lead to thrombosis of the vessel. Failure to pass the catheter to the junction leaves a short segment of the GDA exposed to full concentrations of FUDR without the diluting effect of blood flow, potentially resulting in sclerosis, thrombosis, or late dislodgment. When positioned, the catheter should be secured two or three times with nonabsorbable ties proximal to the tying rings on the catheter. Perfusion of both lobes of the liver and lack of extrahepatic perfusion is confirmed by infusing 2 to 3 mL of half-strength fluorescein through the pump and visualizing it with a Woods lamp. Half-strength methylene blue injection is an alternative method of ensuring proper perfusion. After the perfusion test, the catheter is flushed with heparinized saline, and the wounds are closed. Antibiotic coverage should be continued for 2 to 3 days postoperatively because of the seriousness of a pump infection. Any sign of erythema indicates a wound infection postoperatively and should be treated immediately and aggressively.

Aberrant Hepatic Arterial Anatomy (See Chapter 1B)

As discussed earlier, aberrant hepatic arterial anatomy is common, and numerous variations occur. Each anatomic

situation is specifically addressed here, but first, general principles in managing variant anatomy are discussed. In analyses of our extensive experience with this operation, the factor most consistently associated with catheter-related complications and decreased durability of the catheter is cannulation of a vessel other than the GDA. The overall preferred technique is placement of the catheter in the GDA with ligation of the isolated variant vessel. This method relies on intrahepatic collateral development and cross-perfusion to the liver fed by the ligated vessel. Although concerns have been raised over incomplete hepatic perfusion with this technique, it is rare; in our published experience with this operation for variant anatomy, incomplete hepatic perfusion occurred once in 52 cases. This cross-perfusion sometimes can take 4 weeks to occur, and early perfusion scans may be abnormal initially; however, these should be rechecked in a few weeks to assess for the cross-perfusion, because most normalize (Allen et al, 2002; Curley et al, 1993). The only exception to this rule may be patients with central tumors so large that they impede cross-collateralization. Lastly, although cross-perfusion after ligation of aberrant vessels is highly reliable, it has not been proven that this results in equal blood flow for chemotherapy delivery.

Aberrant Origin of the Gastroduodenal Artery

The GDA can arise from the right or left hepatic artery, or there can be a trifurcation in which the GDA, right hepatic artery, and left hepatic artery all arise simultaneously from the common hepatic artery; this anomaly occurs 6% to 11% of the time (Allen et al, 2002). In general, it is preferable to place the catheter into the GDA and ligate vessels that are not receiving catheter-directed flow, because this is the technique associated with the lowest rate of catheter-related complications (Allen et al, 2002, 2005). In the case of a trifurcation, the catheter should be placed in the GDA, and perfusion should be tested with fluoroscein or methylene blue. If bilobar perfusion is adequate, ligation of vessels is unnecessary. If no perfusion of one lobe of the liver is seen at testing, the hepatic artery to that lobe should be ligated, most commonly the left hepatic artery, thereby relying on cross-perfusion of the left liver.

The hepatic arterial tree also may be accessed through the splenic artery just to the left of the celiac axis. The catheter is placed in the splenic artery and maneuvered across the celiac axis to lie freely in the hepatic artery, ending proximal to the bifurcation. The GDA and the right gastric artery are ligated, and the catheter is secured doubly in the splenic artery. This technique is technically difficult, as it requires extensive dissection of the celiac axis and manipulation of the catheter across the celiac artery branches; it is also associated with more complications, including thrombosis and extrahepatic perfusion, and it is therefore rarely used. Another option is retrograde cannulation of the common hepatic artery through the GDA with an attached short, stiff, small-gauge catheter; however, this technique is also associated with a higher rate of complications, including arterial dissection and thrombosis, and it should be used rarely if ever.

Accessory Left Hepatic Artery

An accessory left hepatic artery arises from the left gastric artery, crosses the gastrohepatic ligament, enters the liver at the base of the umbilical fissure, and typically supplies segments II and III. The native left hepatic artery, which arises from the proper hepatic artery, also supplies the left liver, typically segment IV in this situation. This abnormality is present in 2% to 10% of cases. The simplest, safest, and most reliable option is to ligate the accessory left hepatic artery and place the pump catheter in the GDA, because cross-perfusion is highly reliable. Another option is to use two catheters (or pumps), one in the GDA and one in the accessory left hepatic artery, although this technique is cumbersome and is generally not used.

Accessory Right Hepatic Artery

Accessory right hepatic arteries arise from the superior mesenteric artery and run in the portacaval space to supply a portion of the right lobe of the liver. This abnormality is present 1% to 7% of patients. Accessory and replaced right hepatic arteries rarely have side branches adequate for cannulation. The preferred technique in this situation is placement of the catheter in the GDA and ligation of the accessory vessel, because cross-perfusion is reliable. Placing a second catheter directly in the accessory vessel is another option but is generally unnecessary and not advised.

Replaced Left Hepatic Artery

A replaced left hepatic artery arises from the left gastric artery and supplies the left liver; no native left hepatic artery is found, an abnormality present in 4% to 16% of patients. Once again, the preferred technique is to place the catheter in the GDA and ligate the replaced left hepatic artery. Initial reports on this specific situation suggested rates of incomplete cross-perfusion of 40% (Cohen et al, 1987). More recent reports, including our experience, show that incomplete cross-perfusion is uncommon in this situation and occurred in only 1 of 10 of our patients at last analysis (Allen et al, 2002; Curley et al, 1993). Other techniques, such as placing catheters in the GDA and in a branch of the replaced left hepatic artery, can be considered in patients with bulky disease in the left liver or in those with a large central tumor that may impede cross-perfusion.

Replaced Right Hepatic Artery

A replaced right hepatic artery originates from the superior mesenteric artery, runs in the portacaval space, and supplies the whole right liver. No branches to the right liver originate from the proper hepatic artery, an anatomic situation that occurs 6% to 16% of the time. If the surgeon ligates the replaced right hepatic artery, cross-perfusion from the left hepatic artery occurs almost uniformly (Allen et al, 2002; Cohen et al, 1987; Curley et al, 1993). The catheter should be placed in the GDA, and the replaced right hepatic artery should be ligated. Other techniques have been described, such as placing a second catheter in the replaced right hepatic artery, either directly through a small arteriotomy, as there are no significant side branches from this vessel, or using a vascular graft, but these are rarely if ever indicated. This technique requires that the catheter be trimmed flush just beyond the tying ring and that it be placed such that the ring lies just inside the vessel, and the arteriotomy is closed over the ring.

PUMP PLACEMENT AFTER MAJOR HEPATECTOMY

In the event that a pump is being placed for adjuvant therapy after hepatectomy, the specific anatomy to the remnant liver must be considered. In general, the best results are obtained if the catheter is placed in the GDA. In the presence of replaced

or accessory vessels to the remnant liver, the surgeon must consider the condition of that remnant (i.e., steatosis, congestion) and the potential risk of ligating the arterial supply or risking thrombosis by directly cannulating the vessel to the remnant. One option that is often available after a hemihepatectomy is to use the stump of the artery to the resected liver as a conduit for the catheter, if the anatomy allows this. If the arterial anatomy is normal, or a trifurcation is present at the GDA, there is generally no issue, and the catheter is placed routinely in the GDA. When a variation of the origin of the GDA is present (i.e., off of the right or left hepatic artery), care must be taken to preserve the origin such that the catheter can be placed. For a remnant right lobe, an accessory right hepatic artery generally can be ligated, unless major concerns about the condition of the remnant are an issue. In the case of a remnant right lobe and a replaced right hepatic artery, it is generally not recommended to place a pump, because it would require direct cannulation of that artery, risking thrombosis, injury, and a higher rate of catheter-related complications in general. For a remnant left lobe, an accessory left artery generally can be ligated. If the remnant left lobe is fed solely by a replaced left hepatic artery, a pump can be placed, but this requires dissection of the left gastric artery and a suitable side branch for the catheter. Special care must be taken to ensure that all branches to the stomach have been properly ligated to prevent extrahepatic perfusion.

POSTOPERATIVE ASSESSMENT

After surgery and before administering chemotherapy, the distribution of arterial perfusion is assessed by a radionuclide pump flow study (see Chapter 15). A baseline technetium 99m (^{99m}Tc)-sulfur colloid scan is obtained to identify the liver contour. Pump perfusion is assessed by infusing ^{99m}Tc-labeled macroaggregated albumin (MAA) through the bolus port of the pump and into the hepatic artery. When the MAA scan produces an image that matches the sulfur colloid liver scan, the pump is perfusing the entire liver as intended. Perfusion of extrahepatic tissues produces ^{99m}Tc signals outside the liver image (Fig. 86.3). Incomplete perfusion of the liver produces an incomplete image on the MAA scan. Misperfusion is discovered in 5% to 7% of cases and often can be corrected by surgical or angiographic intervention to occlude additional hepatic vessels missed at operation (Campbell et al, 1993). If no additional vessels are seen on angiography for embolization, it is worth repeating the scan in a few weeks to allow sufficient time for intrahepatic collaterals and cross-perfusion to develop (Allen et al, 2002).

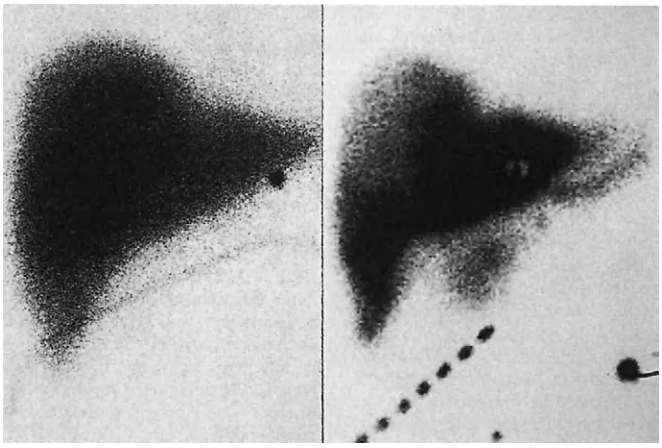

FIGURE 86.3. The liver-spleen technetium 99m–sulfur colloid scan on the left shows the normal liver. The macroaggregated albumin (MAA) scan on the right shows extrahepatic perfusion to the duodenum and head of the pancreas.

TECHNICAL COMPLICATIONS OF HEPATIC ARTERY INFUSION PUMP PLACEMENT

Surgical and technical complications of pump placement occur, and the spectrum and frequency of these complications must be understood by the surgeon, the medical oncologist, and the patient before initiating treatment. To assess the risks of insertion and the use of an implantable pump for hepatic artery chemotherapy, we reviewed the charts of all patients who underwent pump insertion for unresectable metastases over a 15-year period (1986 to 2001) at MSKCC (Allen et al, 2005). During this period, 544 infusion pumps were inserted by several different surgeons for HAI of FUDR alone or in combination with other drugs for patients with isolated unresectable colorectal hepatic metastases. Variant arterial anatomy was present in 205 patients (38%), most of which (82%) involved a single vessel. A colectomy was performed in addition to the pump placement in 136 patients (25%).

Operative mortality was low, and five patients died within 30 days of the operation (0.9% mortality rate). Early in this series, two deaths were from hepatic failure secondary to extensive metastatic disease within the liver. We now exclude patients with extensive (>70%) liver replacement from pump placement because of this risk. Generalized operative morbidity unrelated to the pump itself occurred in approximately 25% of patients in our series. The most common complications were prolonged ileus, wound complications, atelectasis, and abscesses.

Pump-related morbidity occurred in 120 patients (22%) and is summarized in Table 86.7. Most of these complications (63%) occurred more than 30 days after pump placement. The most common complications (51%) were related to the hepatic arterial system and included thrombosis, hemorrhage, or perfusion abnormalities. Early (<30 days) pump-related morbidity occurred in only 8% of cases, and all of the catheter-related complications occurred after 30 days. Overall, the pumps were salvaged from these complications 45% of the time; however, salvage was much more common with early complications (70% if <30 days) than with late complications (30% if >30 days). In a multivariate analysis, surgeon experience and the use of any vessel other than the GDA were independently associated with pump-related morbidity and pump survival. Pump failure was generally low—5% at 6 months, 9% at 1 year, 16% at 2 years, and 26% at 3 years—and HAI was discontinued for pump-related complications in only 9% of cases. The performance of a concomitant colorectal resection was not associated with a higher rate of complications.

Extrahepatic Perfusion

Small branches of the hepatic artery to the stomach, duodenum, and pancreas can be missed on preoperative angiography. If small vessels are not divided and ligated, perfusion of the bowel with FUDR produces severe pain and GI ulceration; if the pancreas is perfused, severe pancreatitis will ensue. These

complications are potentially lethal, and extrahepatic perfusion should be identified and corrected before starting chemotherapy whenever possible.

If extrahepatic perfusion is seen on the ^{99m}Tc MAA scan, the next step is to perform an angiogram by bolus injection through the pump; the angiogram usually shows the vessel responsible for the extrahepatic perfusion. This occasionally is unsuccessful, and a transfemoral celiac or superior mesenteric artery study is needed to identify the problem (Fig. 86.4). More recently, we have proceeded directly to transfemoral angiograms for assessment of patients in whom the perfusion scan shows obvious extrahepatic perfusion. This approach simplifies the process, because one procedure can diagnose the problem and potentially treat it. In our review of 544 cases, 9 patients (2%) were found to have extrahepatic perfusion on the postoperative scan. The cause was identified arteriographically, and in 7 cases, it was corrected with transarterial embolization or surgical ligation; these patients went on to receive HAI without complication (Allen et al, 2005).

FIGURE 86.4. A transfemoral celiac angiogram shows a vessel arising from the gastroduodenal artery (GDA), which had not been ligated. At operation, this vessel was found to be arising from the posterior aspect of the GDA.

Incomplete Hepatic Perfusion

In nine cases (2%), the postoperative ^{99m}Tc MAA scan showed incomplete perfusion of the liver. The causes included failure to ligate a replaced or accessory hepatic artery and failure to achieve cross-perfusion after ligation of an accessory artery (one case). In every case, the anatomic problem was identified by a side port or transfemoral angiogram. Overall, seven of the nine cases were corrected with embolization or surgical ligation of the accessory vessel, and chemotherapy was administered uneventfully. In the instance of incomplete crossover perfusion, collateral flow to the remaining liver developed over time. A repeat MAA scan in 4 weeks confirmed the development of collateral blood flow.

Gastroduodenal Ulcers

In rare instances, the ^{99m}Tc MAA scan fails to identify subtle extrahepatic perfusion. The most frequent anomaly is a small branch to the lesser curve of the stomach. Early in our experience, we treated three patients who were clinically shown to have extrahepatic perfusion that was not apparent on ^{99m}Tc MAA scan, even in retrospect. The patients developed severe epigastric pain during the first course of chemotherapy, and endoscopy showed large ulcers in the stomach or duodenum. These patients do not respond to standard antiulcer therapy, because the cause is not acid hypersecretion but loss of mucosa in the area perfused with FUDR. The diagnosis is confirmed by angiography, and treatment requires angiography or laparotomy for identification and ligation of the vessel. When the

offending vessel has been occluded, and the ulcer has healed, chemotherapy can be given safely. If a patient develops unexplained epigastric pain during infusional chemotherapy, the pump should be emptied immediately and refilled with heparinized saline until the cause of the pain can be elucidated.

Arterial or Catheter Thrombosis

Complete dissection and thrombosis of the hepatic artery intraoperatively has been described during pump insertion, but this condition is rare. In our series, 13 cases (2%) of acute postoperative arterial thrombosis were noted, but the technical problem leading to thrombosis was uncertain in most of these cases. Of these 13 cases of early thrombosis, 31% were salvaged with anticoagulation or lytic therapy. We also observed that delayed thrombosis of the hepatic artery (20 cases) was more common than acute thrombosis (13 cases). The vasculitis caused by infusional chemotherapy is thought to contribute to late arterial thrombosis. Often, arterial thrombosis manifests as extrahepatic perfusion on ^{99m}Tc MAA scan (Fig. 86.5). Catheter thrombosis was seen only as a late complication, and it occurred in 11 cases (2%) and was more likely to be related to technical errors, such as not filling the pump frequently or allowing back bleeding into the catheter during side-port manipulation.

Infectious Complications

Infectious complications associated with any major operation—including pneumonia, urinary tract infections, and wound infections—may occur after laparotomy and pump placement. Because a foreign body is inserted during this operation, particular care must be directed against wound or pump-pocket infections. Technical precautions must be taken in the operating room to limit bacterial contamination of the pump. Postoperatively, any sign of pump-pocket erythema should be treated early and aggressively with parenteral antibiotics.

We have not seen an increased incidence of complications in patients undergoing pump insertion combined with colectomy. It is preferable to place the pump first, close the pump pocket, exclude the catheter from the rest of the procedure, and then proceed with the colectomy. In this way, the instruments and

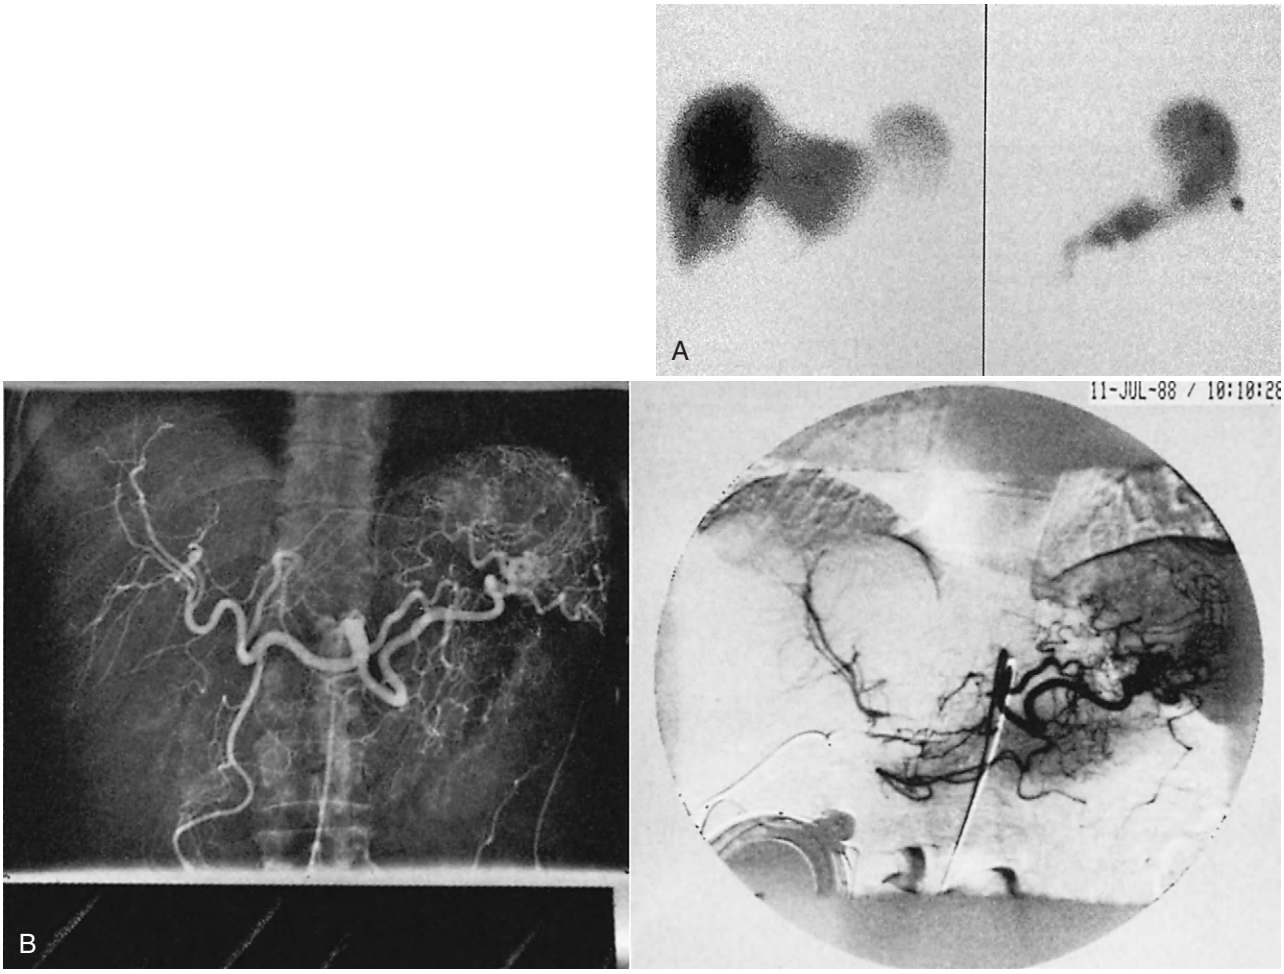

FIGURE 86.5. A, When hepatic artery thrombosis occurs, the macroaggregated albumin scan (*right*) shows an absence of perfusion of the liver together with perfusion of the spleen, stomach, and pancreas. **B,** Arteriogram before operation shows normal patent vessels (*left*), but postoperative arteriography (*right*) confirms that the artery is thrombosed. The first sign of hepatic artery thrombosis may be abdominal pain occurring with chemotherapy owing to perfusion of the stomach and pancreas. If severe pain occurs during chemotherapy, the first step should be to empty the pump and replace the chemotherapy with heparinized saline.

the wound have not been contaminated by the open bowel. Because this approach violates the principle of treating the primary problem first, the surgeon may choose to mobilize the bowel initially. In this manner, the colectomy can be performed rapidly and safely should the patient have difficulties during the procedure.

Hemorrhagic Complications

Two patients developed bleeding complications postoperatively. In one case, the patient developed severe abdominal pain when the pump was injected for the initial ^{99m}Tc MAA scan. On the flow scan, extrahepatic extravasation of ^{99m}Tc was seen. At laparotomy, bleeding from a suprapyloric branch that had been inadequately clipped during the operation was observed. A second patient developed bleeding into the pump pocket that resulted in a hematoma. Both complications were salvaged, and the pumps were used successfully.

LAPAROSCOPIC PLACEMENT OF HEPATIC ARTERIAL INFUSION PUMPS

The necessity of a laparotomy to place HAI pumps has been and remains a hurdle for pump chemotherapy. Because a major operation is mandated, many oncologists and patients have been deterred, and minimally invasive methods of pump implantation are attractive. HAI pump placement requires substantial skill, sophisticated knowledge of upper GI anatomy, and experience, making this operation technically challenging and difficult to perform laparoscopically.

The technique of laparoscopic HAI pump placement should mimic the open operation. Review of the preoperative angiogram is crucial, and management of aberrant anatomy must be planned for in advance. A right subcostal port is placed for retraction of the liver, and a three-port working triangle is created in the left upper quadrant, aiming at the porta hepatis. The dissection and isolation of the vessels is exactly the same as in the open operation. Ultrasonic dissectors are helpful to divide the often dense lymphatics and keep bleeding to a minimum. Branches to the stomach, duodenum, and pancreas can be clipped or divided with the ultrasonic dissector; because controlling torn branches can be difficult, patience is crucial.

When the anatomy is dissected, the pump pocket is made in the right abdominal wall, and the catheter is placed into the peritoneal cavity under laparoscopic visualization. The distal GDA is ligated, and ties are left long for countertraction. Laparoscopic bulldogs are used for vascular isolation; two can be placed on the common hepatic artery and proper hepatic artery each, or a single clamp can be placed just at the orifice of the GDA. A tie is left around the GDA in anticipation of tying the catheter in, and a laparoscopic No. 11 blade is used to create an arteriotomy. Using countertraction on the GDA, the catheter is placed into the GDA, up to the orifice, and tied into place. The clamps are carefully removed, and hemostasis is ensured; this is followed by intraoperative dye injection to confirm bilobar hepatic perfusion and absence of extrahepatic flow.

Published experience with laparoscopic placement of HAI pumps is largely limited to small cases series (Cheng et al, 2003, 2004; Feliciotti et al, 1996; Urbach & Hansen, 2000; Urbach et al, 2001). The largest series to date was published by Cheng and colleagues and describes their experience in 38 patients (Cheng et al, 2004), of whom 24 had additional radiofrequency ablation (RFA), 2 had a laparosopic partial hepatectomy, and 1 was converted to laparotomy. The median time in the operating room was 5.5 hours, and the overall results were excellent: only one postoperative cardiac-related mortality was reported but no pump-related morbidity, and the median hospital stay was 3 days.

When this chapter was submitted for the previous edition of this text, we had attempted laparoscopic pump placement in 13 cases over a 2-year period; of these, five were converted for minor bleeding, severe chronic cholecystitis, bowel injury, dense adhesions, and a small GDA that could not be cannulated at open operation. Eight cases were completed laparoscopically with no significant moribidy, no pump-related complications, and a median hospital stay of 3.5 days (unpublished data). With limited experience, it seems that laparoscopic HAI pump placement is feasible and safe. It is crucial, however, that these cases are attempted by surgeons experienced in laparoscopic surgery and open pump placement.

NONOPERATIVE PLACEMENT OF HEPATIC ARTERIAL INFUSION PUMPS

HAI pump placement can be done safely by laparotomy with an acceptable morbidity. Poor overall prognosis and the requirement for a laparotomy have deterred many surgeons and oncologists from using this modality, however. Robotic-assisted laparoscopic pump placement has recently been described (Hellan & Pigazzi, 2008) that carries the potential to improve on perioperative outcomes but warrants surgical expertise with new technology. Several groups have worked on alternate placement methods to eliminate the laparotomy "hurdle."

Percutaneous techniques to catheterize the hepatic artery for delivery of intrahepatic chemotherapy have been developed using a variety of peripheral arteries for access (Table 86.8). Most of these techniques have been abandoned or are used only by a few specialized groups for the following reasons:

1. The insertion is technically difficult and sometimes cumbersome. The technique described by Arai and colleagues (Arai, 1988; Arai et al, 1997; Inaba et al, 1998) requires embolization of the GDA to anchor the catheter. The tip of the catheter remains anchored in the GDA, while perfusion is achieved through a sidehole in the catheter.
2. The insertion site is in a mobile part of the body, such as the arm or the leg, resulting in risk of catheter dislocation or migration (Oberfield et al, 1979).

Table 86.8

Peripheral Arteries Used for Catheter Placement in the Hepatic Artery

Artery	References
Femoral artery	Matsumada et al, 1997
Brachial artery	Cohen et al, 1980
Axillary artery	Arai, 1988; Cohen et al, 1983
Subclavian artery	Arai, 1988; Arai et al, 1997; Inaba et al, 1998
Hypogastric artery	Arai et al, 1997, 1988; Inaba et al, 1998
Intercostal artery	Castaing et al, 1998; Saldinger & Sandhu, 2004

3. The artery used for access is "essential" for limb perfusion, and any thrombotic complication is a potentially limb-threatening complication (see Table 86.8).

Castaing and colleagues (1998) tried to address these shortfalls by using an intercostal artery as conduit. A cutdown is performed over the tenth left rib. The intercostal artery is catheterized and the catheter is advanced, under fluoroscopic control, across the aorta into the ostium of the celiac axis and ultimately into the proper hepatic artery, just beyond the takeoff of the GDA. The catheter is connected to an implantable port located in the left upper quadrant. The study included 35 patients with metastatic lesions to the liver, mainly from CRC, and 30 patients (86%) underwent a successful placement. Placement was not feasible in five patients because of an unsuitable artery. No procedure-associated deaths were reported, no thrombotic complications in either the aorta or the hepatic artery resulted, and no dislocations or migrations of the catheter occurred. Follow-up was brief because most of these patients died from their disease, although all of the patients had not responded to previous standard treatments and had advanced disease at the time of catheter placement.

This method has clear advantages because of its simplicity and the fact that the catheter is attached to an immobile part of the body, thus preventing catheter motion. Catheter patency was less than 50% at 4 months, likely as a result of a lack of continuous flow. Also, the catheter used in Castaing's study has not been approved by the FDA for prolonged indwelling use; their method is therefore not applicable in the United States.

Our group modified Castaing's method to address these points (Saldinger & Sandhu, 2004). A peripherally inserted 3-Fr central catheter was chosen as the indwelling arterial catheter (Arrow International, Reading, PA). We used a 15-mL Codman 3000 constant-flow implantable pump for access and drug delivery (Codman, Raynham, MA). The pump catheter and arterial catheter were connected via a special connector (Arrow International, Walpole, MA; Fig. 86.6). Our method uses largely the same techniques as described by Castaing, but with a few differences:

FIGURE 86.6. The indwelling arterial catheter is tunneled from the insertion site at the eleventh rib to the left upper quadrant, where it is connected to the catheter of the infusion pump via a connector. The pump is placed into a pocket in the subcutaneous tissue.

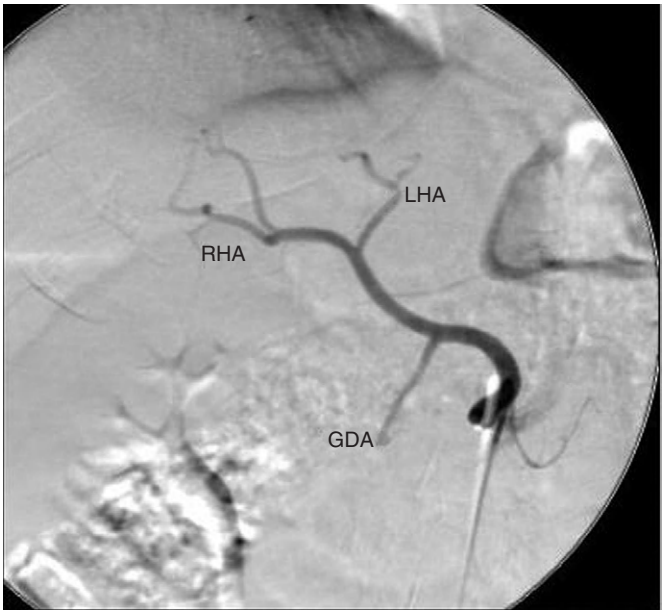

FIGURE 86.7. Transfemoral celiac arteriogram mapping the hepatic arterial anatomy. GDA, gastroduodenal artery; LHA, left hepatic artery; RHA, right hepatic artery.

1. A preoperative angiogram is obtained for mapping of the hepatic vessels (Fig. 86.7). The angiogram is saved and used during the procedure as a guide. Accessory hepatic arteries are embolized to optimize pump perfusion, and if the distance between the GDA and the hepatic bifurcation is deemed too short, the GDA is embolized; that is, if it poses a risk for nondelivery of the target drug.
2. The intercostal artery is accessed by micropuncture, followed by introduction of a sheath. This sheath allows repeated introduction of wires, should the situation require it. A guidewire is introduced and placed into the hepatic artery (Fig. 86.8). The 3-Fr catheter is advanced into the hepatic artery, the wire is withdrawn, and the catheter is secured (Fig. 86.9). An on-table angiogram is obtained through the catheter to confirm proper placement. We confirm catheter placement and exclude extrahepatic perfusion the next day with a perfusion scan. The pump is filled the same day with chemotherapy.

This procedure was performed successfully in four patients with metastatic colon cancer to the liver as part of a feasibility study. All patients had failed at least two chemotherapeutic regimens and were unresectable; no perioperative deaths or complications were reported. The catheters remained patent until the patient's death from progression of disease at 1, 3, 6, and 7 months. The nonoperative placement of HAI pumps is a safe method and has all the advantages of minimally invasive procedures. Its role in the armamentarium of therapies to treat metastatic CRC to the liver depends largely on the role of intraarterial chemotherapy for liver tumors.

APPROACHES TO DECREASE HEPATIC TOXICITY

New approaches to decrease the hepatic toxicity induced by HAI of FUDR have been studied. Because portal triad

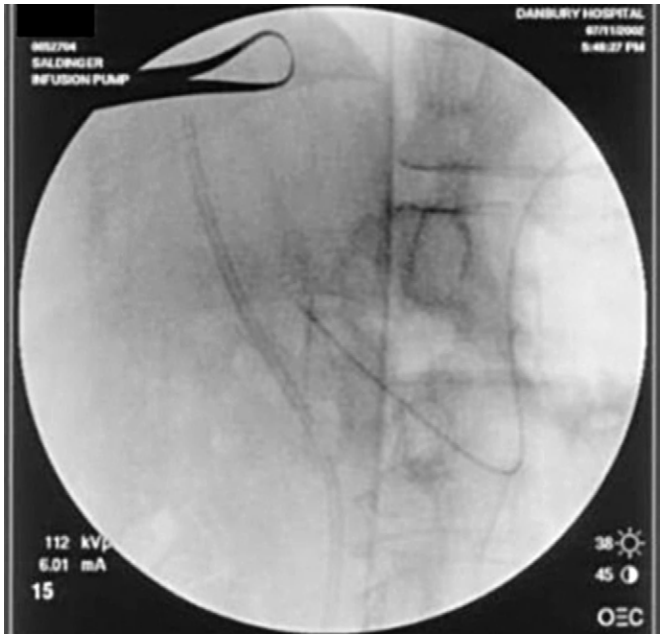

FIGURE 86.8. Fluoroscopic control of guidewire placement. Note the course of the wire: its entrance into the aorta and exit into the celiac axis, and finally the hepatic artery, is outlined.

inflammation may lead to ischemia and stricturing of the bile ducts, the hepatic arterial administration of dexamethasone decreases biliary toxicity. As previously mentioned, a prospective double-blind randomized study of intrahepatic FUDR with dexamethasone versus FUDR alone was conducted at MSKCC (Kemeny et al, 1992). The response rate in 49 evaluable patients was 71% for those who received FUDR plus dexamethasone versus 40% for those given FUDR alone ($P = .03$). Survival also favored the FUDR-dexamethasone group: 23 months versus 15 months for FUDR alone ($P = .06$). In addition, a trend was noted toward decreased bilirubin elevation in patients receiving FUDR plus dexamethasone compared with the group receiving FUDR alone (9% vs. 30%; $P = .07$).

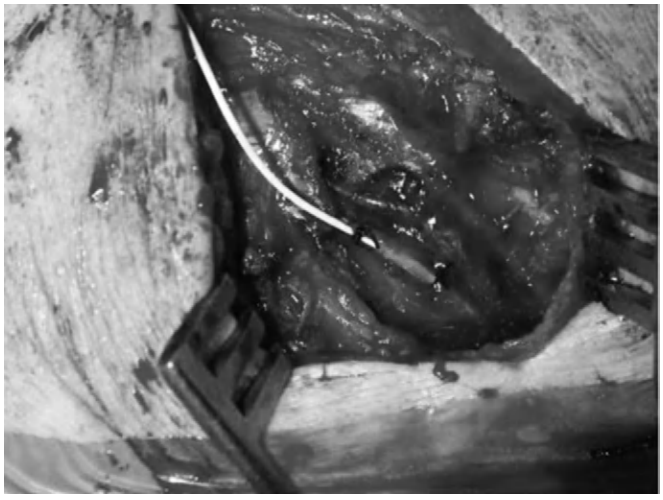

FIGURE 86.9. A 3-Fr catheter secured to the intercostal artery. The inferior border of the eleventh rib has been exposed, allowing exposure of the intercostal artery and vein.

A second method to decrease hepatic toxicity is the use of circadian modification of hepatic intraarterial FUDR infusion. In a retrospective nonrandomized study (Hrushesky et al, 1990), a comparison of constant (flat) infusion versus circadian-modified HAI of FUDR was conducted in 50 patients. Over nine courses of treatment, the patients with circadian-modified infusion tolerated almost twice the daily dose of FUDR. Circadian-modified infusion resulted in 46% of patients having no hepatic toxicity versus 16% after flat FUDR infusion. The authors did not present information on response rates achieved in both groups.

Another approach to decrease toxicity from HAI is to alternate intraarterial FUDR with intraarterial 5-FU. A weekly intraarterial bolus of 5-FU has similar activity to intraarterial FUDR and does not cause hepatobiliary toxicity; however, it frequently produces treatment-limiting systemic toxicity or arteritis with the pharmacokinetic differences previously discussed. Stagg and colleagues (1991) used an alternating regimen of HAI of FUDR and HAI of 5-FU, with a response rate of 51% and median survival of 22.4 months. In contrast to the experience with single-agent HAI of FUDR, no patient had treatment terminated because of drug toxicity. Another report described 57 CRC patients with unresectable liver metastases treated with an alternating HAI schedule of FUDR and 5-FU (Davidson et al, 1996), of which 2 patients (3.5%) developed biliary sclerosis, and 12 (21.1%) had mild transient liver function abnormalities.

METHODS TO INCREASE RESPONSE RATE

Based on the fact that systemic combination chemotherapy regimens are more effective than single agents, the potential benefit of multidrug HAI has been evaluated. In an early study using mitomycin C, bis-chloroethyl-nitrosourea, and FUDR, Cohen and associates (1985) produced a 69% partial response rate. In a randomized trial at MSKCC comparing this three-drug regimen with FUDR alone (Kemeny et al, 1993), the response rates were 45% for the three-drug regimen and 32% for FUDR alone in the 67 patients who entered this trial. The median survivals from the initiation of HAI were 18.9 months and 14.9 months. Other trials using FUDR and LV have produced response rates up to 62% (Hohn et al, 1989).

METHODS TO TREAT EXTRAHEPATIC DISEASE: COMBINED HEPATIC ARTERIAL INFUSION AND SYSTEMIC CHEMOTHERAPY

Extrahepatic disease develops in 40% to 70% of patients who undergo HAI. Such metastases can occur even when the patient's hepatic tumors are responding. In many patients, extrahepatic disease is the cause of death. Safi and colleagues (1989) studied whether concomitant SYS reduces the development of extrahepatic metastases in patients who receive HAI. Ninety-five patients were randomized to intraarterial FUDR (0.2 mg/kg/day for 14 of 28 days) or a combination of intraarterial FUDR (0.21 mg/kg/day) and intravenous FUDR (0.09 mg/kg/day) given concurrently for 14 of 28 days (intraarterial/intravenous). The response rates were 60% for both arms of the study; however, the incidence of extrahepatic disease was

Table 86.9

Results of Hepatic Arterial Infusion Combined with Systemic Chemotherapy in the Second-Line Setting

Drug	No. Patients	Response (%)	Median Survival from Pump Placement (mo)
FUDR + dexamethasone + sideport mitomycin C (Kemeny et al, 2005b)	37	70	20
FUDR + dexamethasone + SYS CPT-11 (Kemeny et al, 2001)	56	74	20
FUDR + dexamethasone + SYS oxaliplatin + CPT-11 (Kemeny et al, 2005a)	21	90	28
FUDR + dexamethasone + SYS oxaliplatin + FU/leucovorin (Kemeny et al, 2005a)	15	87	22

significantly less in patients who received the intraarterial/intravenous treatment (56%) compared with intraarterial treatment (79%; $P < .01$). No significant difference in survival was found between the two groups ($P = .08$). The results of this trial, as well as the development of improved SYS regimens, have underscored the need for further study of combined systemic/intraarterial regimens. Results of some of these studies are presented in Table 86.9, and SYS irinotecan and oxaliplatin are discussed in detail below.

Irinotecan is a topoisomerase I inhibitor with proven efficacy in first-line and second-line treatment of metastatic CRC. The activity of irinotecan is not inhibited by high thymidylate synthase activity (Saltz et al, 1998); combining systemic irinotecan with HAI therapy may therefore result in improved control of extrahepatic disease. In a Phase I study at MSKCC, 46 patients with unresectable liver metastases, 8 of whom underwent cryosurgery, received HAI of FUDR/dexamethasone and systemic irinotecan in escalating doses; all 38 patients who did not undergo cryosurgery were previously treated, and 16 had prior therapy with irinotecan. The regimen was well tolerated, with dose-limiting toxicities of diarrhea and myelosuppression. The response rate was 74%, median time to progression was 8.1 months, and 13 of 16 patients who had previously received irinotecan had partial responses (Kemeny et al, 2001).

Another nonrandomized study used HAI of FUDR with systemic irinotecan as "adjuvant" therapy after cytoreduction (therefore not "true adjuvant") of unresectable hepatic CRC metastases. The cytoreduction was defined as using cryosurgery, RFA, partial resection, or some combination to treat all identifiable sites of disease. Seventy-one patients received "adjuvant" therapy and were compared with a historic control group that received cytoreduction alone. Time to progression was 19 months versus 10 months, and median survival was 30.6 months versus 20 months, for HAI versus control groups (Bilchik et al, 2000). A Japanese group examined HAI of 5-FU and SYS irinotecan in previously treated patients and demonstrated response rates of 76.5%, with median OS of 20 months (Shiatra et al, 2006).

Oxaliplatin is a cytotoxic agent with a mechanism of action similar to that of other platinum derivatives, but it has a different spectrum of activity and toxicity. When combined with 5-FU/LV, clinical response rates have been greater than 50%, with median survival of 16.2 months in untreated patients with metastatic CRC (de Gramont et al, 2000; Tournigand et al, 2004). Preliminary studies using systemic oxaliplatin-based regimens combined with HAI of FUDR demonstrated the feasibility and safety of this approach and revealed promising early results (Pancera et al, 2002). In a two-grouped MSKCC Phase I study, 36 patients with unresectable hepatic metastases, 89% of whom were previously treated, received HAI of FUDR/dexamethasone and SYS oxaliplatin plus either SYS irinotecan or SYS 5-FU/LV. Both regimens were well tolerated, and response rates for the two groups were 90% and 88% (see Table 86.9; Kemeny et al, 2005a). This high response rate for second-line therapy with HAI plus SYS, as well as conversion to resectability, was demonstrated in a recent MSKCC pooled analysis of phase I data in 49 patients with unresectable liver metastases from CRC (Kemeny et al, 2009a). Patients received HAI of FUDR/dexamethasone, SYS irinotecan, and SYS oxaliplatin, and 98% had bilobar disease, whereas 85% had tumors bordering vasculature. A partial or complete response was reported in 92% (84% partial, 8% complete), and 47% of patients were resectable, three with pathologic complete responses. With a median follow-up of 26 months from time of pump placement, OS was 51 months for untreated patients: all 23 responded to treatment, and 57% had resection. OS was 35 months for previously treated patients: 85% responded to treatment, and 38% had resection. This revealed that even in heavily pretreated patients with significant hepatic metastasis, HAI of FUDR can increase response and resection rates when combined with modern SYS. Future randomized trials are needed to assess the impact that HAI specifically has in these outcomes.

ADJUVANT TREATMENT AFTER LIVER RESECTION OF COLORECTAL METASTASES

The rationale for the use of adjuvant chemotherapy after resection of liver metastases from CRC is based on the observation that, although some patients have long-term disease-free survival (DFS) after resection, many patients' disease recurs. Recurrence may be solely in the liver, it may be extrahepatic and intrahepatic, or it may be solely extrahepatic. An effective adjuvant treatment may have a substantial impact on recurrence and survival. The use of SYS without HAI has been formally tested in this setting, but only to a limited extent, with one randomized study (Portier et al, 2006) that met its primary end point of 5-year DFS—33.5% for the chemotherapy group and 26.7% for the control group ($P = .028$)—but failed to show a survival benefit with 6 months of adjuvant 5-FU/folinic acid. Because this trial and another Phase III study (EORTC) both closed early because of slow accrual, their results were pooled and reported together (Mitry et al, 2009), demonstrating both a lack of DFS and OS statistical significance for 5-FU adjuvant therapy in this setting. When adjusting for poor characteristics

¶Hepatic disease-free survival.
HAI, hepatic artery infusion; MSKCC, Memorial Sloan-Kettering Cancer Center; SYS, systemic chemotherapy.

Modified from Cohen AD, Kemeny NE, 2003: An update on hepatic arterial infusional chemotherapy for colorectal cancer. Oncologist 8:553-566.

in a multivariate analysis, however, an increase in DFS was reported for the group treated with chemotherapy. In EORTC 40983, reversible complications occurred in 25% of the patients receiving perioperative 5-FU plus leucovorin and oxaliplatin (FOLFOX) compared with 16% in the surgery-alone group (P =.04) (Nordlinger et al, 2008). The Japanese are conducting a multicenter randomized Phase II/III trial of adjuvant modified FOLFOX versus hepatic metastasectomy alone (Kanemitsu et al, 2009).

Because combining HAI and SYS may be useful in decreasing recurrence, four relatively large randomized trials have been conducted in this group of patients (Table 86.10). In the MSKCC study (Kemeny et al, 1999), 156 patients with resected hepatic metastases were randomized to 6 months of systemic 5-FU/LV or systemic 5-FU/LV plus HAI with FUDR. Primary end points were 2-year overall and progression-free survival. Forty percent of patients received prior adjuvant chemotherapy after resection of their primary CRC, and 15% had received prior chemotherapy as treatment for metastatic disease. Randomization was performed intraoperatively after complete resection of metastases, and patients were stratified based on number of metastases and prior treatment history. Of enrolled patients, 92% received treatment as assigned; 2-year survival was 86% in the combined therapy group versus 72% for those who received systemic therapy alone (P = .03), with median survivals of 72.2 months and 59.3 months, respectively. In an updated analysis, 10-year survival was 41% in the HAI plus SYS group, with 27% alive in the SYS-alone group still alive (Fig. 86.10; Kemeny & Gonen, 2005). Two-year hepatic progression-free survival was 90% for the combined group and 60% for the monotherapy group ($P < .001$). Updated hepatic progression-free survival at 10 years was 70% and 40%, respectively (P = .0001; Fig. 86.11), and overall progression-free survival was 40% and 20%, respectively, at 10 years (P = .001). If patients with poor clinical risk scores are considered (Fong et al, 1999), their survival is still improved with HAI compared with SYS alone (Fig. 86.12).

Toxicity was increased in the combined group, and 39% of patients required hospitalization for diarrhea, neutropenia, mucositis, or small bowel obstruction compared with 22% in the monotherapy group (P = .02). Elevated bilirubin was seen in 18% of patients in the combined group. In most patients, the bilirubin returned to normal, but 6% of patients required biliary stents. In the control group, 2% had an elevation in bilirubin, and 2% required biliary stents. No significant difference was found among the groups in therapy-related deaths (one combined, two monotherapy).

The intergroup study (Kemeny et al, 2002) randomized 109 patients to resection alone or resection followed by four cycles of HAI with FUDR and infusional systemic 5-FU, followed by eight more cycles of systemic 5-FU. Patients with more than three liver metastases or extrahepatic disease at laparotomy were taken off the study; only 80 of 109 patients were actually included in the study, which was designed to examine the effect of adjuvant therapy on DFS. When patients were analyzed as treated (n = 75), the 4-year DFS (46% vs. 25%; P = .04) and 4-year hepatic DFS (67% vs. 43%; P = .03) favored

HAI over the control groups. Based on an intention-to-treat analysis, no difference was reported in median or 4-year OS between the groups. Currently, the 5-year survival is 55% versus 37.5% favoring adjuvant therapy (Kemeny M, 2005); however, this study was not designed to look at OS.

In the German cooperative multicenter study (Lorenz et al, 1998), 226 patients were randomized to resection alone or resection plus 6 months of HAI with 5-FU/LV given as a 5-day continuous infusion every 28 days. The study was terminated early, because an interim analysis suggested a very low chance of showing a survival benefit with adjuvant therapy. The impact of HAI in this study is difficult to assess because only 74% of patients assigned to HAI received this treatment, and only 30% completed it. No difference in time to progression, time to hepatic progression, and median OS was noted in an intention-to-treat analysis. When patients were analyzed "as treated," time to hepatic progression (45 months vs. 23 months) and time to progression or death (20 months vs. 12.6 months) were improved in the HAI arm. Grade 3 or 4 toxicity—including stomatitis, nausea, and vomiting—was noted in 63% of patients who received adjuvant therapy. These findings reflect significant systemic absorption of 5-FU when given via HAI.

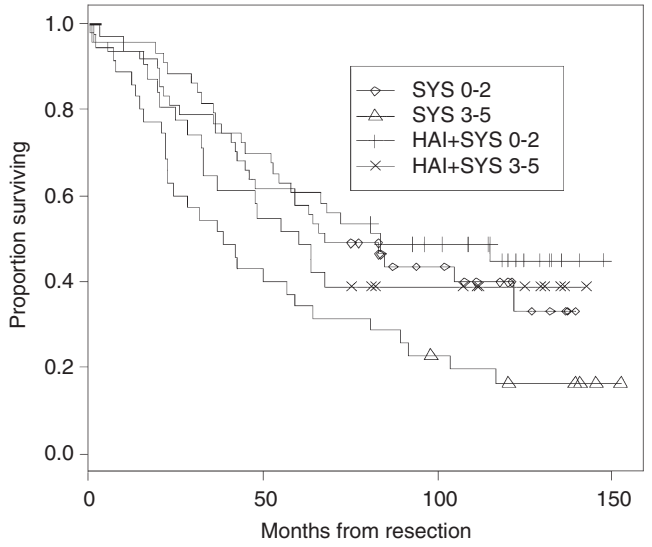

FIGURE 86.12. Survival stratified by clinical risk score. A score ranging from 0 to 5 was calculated by adding 1 point for the following clinical variables: tumor size >5 cm, tumor number >1, serum CEA >200 ng/mL, node-positive primary tumor, and disease-free interval >12 months (Fong et al, 1999). SYS, systemic therapy; HAI, hepatic arterial infusion.

A study conducted in Greece on 122 patients used mitomycin C, 5-FU, and interleukin (IL)-2 by both HAI and the intravenous (IV) route versus the IV route alone. The 2-year survival was 92% versus 75%, and 5-year survival was 73% versus 60% for the HAI plus SYS group versus the SYS-alone group, respectively. DFS was significantly longer for the HAI plus SYS group: 60% at 5 years versus 20% for the intravenous group ($P = .0012$); hepatic DFS was 85% versus 50% ($P = .0001$; Lygidakis et al, 2001).

The two American studies showed a reduction in hepatic and extrahepatic recurrence for combined HAI plus systemic therapy after surgical resection. Of the two European studies, one showed a significant increase in survival and DFS, whereas the other did not. In the MSKCC study, 2-year survival after liver resection was significantly improved with combined therapy: 86% compared with 72% with systemic therapy alone. Historic 2-year survivals (Chang et al, 1987; Fegiz et al, 1991; Jamison et al, 1997; Scheele et al, 1990) for patients treated with resection alone range from 55% to 70%.

Nonrandomized studies of modern chemotherapy regimens combined with HAI of FUDR in the post–liver metastasis resection (adjuvant) setting have been conducted and suggest improved outcomes. Phase I and II trials of adjuvant SYS irinotecan combined with FUDR/dexamethasone in 96 patients showed a 2-year survival of 89% at a median follow-up of 26 months. The dose-limiting toxicities were diarrhea and neutropenia, and all 27 patients treated at the maximum-tolerated dose were alive at publication (Kemeny et al, 2003). A phase I trial of adjuvant HAI of FUDR/dexamethasone with escalating doses of SYS oxaliplatin/5-FU/LV in 35 patients revealed 4-year survival and progression-free survival of 88% and 50%, respectively, at a median follow-up of 43 months. Dose-limiting toxicities of diarrhea and elevated bilirubin were each 8.5% (Kemeny et al, 2009b).

A multivariate analysis performed as a part of a recent review of over 1000 patients showed that post–liver metastasis resection HAI was one of the significant factors to improve survival. Median OS was 50 months in those who did not receive HAI and 68 months in those who did ($P = .0001$) (Ito et al, 2008). Another MSKCC retrospective review described 612 patients who underwent liver resection from 1985 to 1994. The 10-year OS was 38% for patients who received HAI of FUDR and 15% for those who did not ($P < .0001$) (Tomlinson et al, 2007). Finally, colleagues at our institution retrospectively compared outcomes from 125 metastatic CRC patients who received postoperative SYS (FOLFOX or 5-FU plus leucovorin and irinotecan [FOLFIRI]) with HAI to 125 similar patients who received only SYS. The 5-year hepatic progression-free survival was 75% in the HAI group and 52% in the SYS group ($P = .0005$) with

a median follow-up of 43 months; OS at 5 years was 72% and 52%, respectively (House et al, 2011). These data underscore the need for randomized studies of modern HAI plus SYS compared with modern SYS alone.

NEOADJUVANT HEPATIC ARTERIAL INFUSION

Neoadjuvant treatment is a strategy increasingly used in solid-tumor oncology, given the multifaceted rationale that it may enable downsizing and subsequent resectability of tumor burden, and more systemic treatment may be tolerated, or given at all, than in postoperative settings, where complications may limit or preclude administration of chemotherapy. In addition, neoadjuvant HAI may prevent unnecessary operations in patients who have clinically and biologically declared themselves to have inoperable metastatic disease. In the context of converting CRC patients with unresectable liver metastases to operable candidates, some neoadjuvant approaches have been discussed above. Combining SYS with HAI agents besides FUDR has been studied in the neoadjuvant setting. Numerous reports have been made that HAI of oxaliplatin, for instance, has shown benefit in response and resectability rates when combined with SYS 5-FU (Boige et al, 2008; Del Freo et al, 2006; Ducreux et al, 2005).

HEPATIC ARTERIAL INFUSION FOR NONCOLORECTAL LIVER METASTASES AND PRIMARY LIVER CANCER (SEE CHAPTERS 50A, 80, AND 81C)

Although liver metastases from noncolorectal carcinoma are less commonly treated with regional therapy, HAI chemotherapy has been used in cases of breast cancer, HCC, melanoma (Melichar et al, 2009), bronchogenic carcinoma, and pancreas cancer. Studies in breast cancer have employed numerous HAI agents including FUDR, mitomycin/FU/doxorubin, vinblastine/cisplatin, and cyclophosphamide/etoposide. One trial of 15 patients undergoing systemic chemotherapy for refractory metastatic breast cancer tested HAI of FUDR and mitomycin and demonstrated a partial response rate of 53% and OS of 18 months after HAI was begun (Maral et al, 1985). FUDR alone and in combination with various cytotoxic agents has also been evaluated in HCC (see Chapter 80), including treatment with mitomycin/interferon/FUDR (Atiq el al, 1992) and LV/doxorubicin/cisplatin/FUDR (Patt el al, 1994) in 27 patients. In the latter, response rates were 41% to 54%, and median OS was 15 months.

More recent experience with HAI for HCC and intrahepatic cholangiocarcinoma (ICC; see Chapter 50A) at MSKCC was published, and it demonstrates the correlative and predictive utility of dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) in 34 patients with unresectable disease treated with HAI of FUDR/dexamethasone. Partial responses were seen in 47%, with median OS of 30 months (Jarnagin et al, 2009). One patient in this study responded sufficiently to undergo resection and was found to have had a complete pathologic response. The median duration of response was 1 year, and median time to progression was 7 months. Median follow-up at time of publication was 35 months, and 1- and 2-year survival was 88% and 67%, respectively. Therapy was well tolerated, and DCE-MRI data showed that pretreatment and posttreatment tumor perfusion and permeability parameters correlated with median survival, therefore these may serve as a biomarker of treatment outcome.

CONCLUSION

HAI offers several advantages. From a pharmacologic standpoint, HAI is more effective than SYS, because higher drug levels are achieved at the sites of metastatic disease. Using agents with high hepatic extraction virtually eliminates the systemic toxicity observed with standard systemic therapy. The 50% to 70% response rate obtained in trials of intrahepatic FUDR therapy has not been matched by any systemic therapy to date. The addition of leucovorin or dexamethasone to FUDR has increased both response rate and survival. Most randomized HAI studies do not clearly evaluate the issue of survival, mainly because a crossover was allowed in some, whereas patients with positive portal nodes were included in the HAI-treated groups in other studies. In addition, severe toxicity may occur with HAI or SYS. Although HAI therapy may produce GI or hepatic toxicity, this is minimized with proper surgical technique during pump placement, with close monitoring of liver function tests, and with HAI of dexamethasone.

Because the liver is often the initial site of metastatic disease in patients with colorectal carcinoma, early intensive therapy with surgical resection, HAI, or both at a time when the tumor burden is small may prevent the progression of metastases to other sites. Although HAI therapy is applicable only to selected patients with hepatic metastases, it may be the best therapy available.

CHAPTER 87

Systemic chemotherapy for hepatic colorectal cancer: impact on surgical management

Peter J. Kneuertz and David A. Kooby

OVERVIEW

The liver is the most common site of metastases from colorectal cancer (CRC). Approximately half of all patients with CRC will develop liver metastases at some point during their disease (Ekberg et al, 1987; Steele & Ravikumar, 1989), and half of these will be seen with synchronous liver metastases at the time of diagnosis (Bengmark & Hafstrom, 1969). Resection remains the best treatment for patients with resectable colorectal liver metastases (CLM; see Chapter 81A). Early studies reported 5-year survival rates of 25% to 48% following complete resection of the liver metastases (Adson et al, 1984; Fong et al, 1997; Sugihara et al, 1993) in an era when the only active chemotherapeutic agent used in the United States was the antimetabolite 5-fluorouracil (5-FU). With the single-agent regimen of 5-FU, or 5-FU plus leucovorin (LV), tumor response was seen in only 10% to 20% of those treated, which provided an overall survival of approximately a year in patients who were not candidates for an operation (Meta-Analysis Group in Cancer [MAGIC], 1998; Thirion et al, 2004). Substantial improvements in both response and survival have been reported with the use of the two "modern" cytotoxic agents, irinotecan and oxaliplatin.

Newer chemotherapeutic regimens that combine continuously infused 5-FU and LV with either oxaliplatin (FOLFOX) or irinotecan (FOLFIRI) yield overall response rates over 50% and provide a doubling of survival time in patients with unresectable disease (de Gramont et al, 2000; Tournigand et al, 2004). The integration of molecularly targeted agents, such as bevacizumab (monoclonal antibody to vascular endothelial growth factor) and cetuximab (antiepidermal growth factor receptor), into treatment strategies has further increased response rates to an impressive 70% (Folprecht et al, 2010). By combining surgery with these newer chemotherapeutic agents and regimens, 5-year survival rates approaching 60% have been reported following hepatic resection of CLM (Abdalla et al, 2004; Choti et al, 2002; Fernandez et al, 2004).

As the efficacy of systemic chemotherapy is increasing, the number of patients who potentially benefit from adjuvant and neoadjuvant chemotherapy is also growing. Traditional dogma of offering hepatic resection to only those patients with four or fewer lesions confined to one side of the liver no longer applies. Planning the right therapeutic approaches for individual patients is becoming more complex, and it requires a close multidisciplinary collaboration between surgical and medical oncologists. This chapter will discuss the current data on the role of systemic chemotherapy in a multidisciplinary approach in the treatment of metastatic CRC, and it will focus on the implications of surgical management.

CHEMOTHERAPEUTIC AGENTS

Fluoropyrimidines

The fluoropyrimidine 5-FU has remained the backbone of systemic chemotherapy for metastatic CRC for decades. This drug inhibits thymidylate synthase, thereby lowering production of the pyrimidine thymidine for DNA synthesis. It has been used synergistically with leucovorin (folate) either in a daily bolus administration in repeated cycles of 5 days (Mayo Clinic regimen) or on a biweekly infusional schedule (de Gramont regimen). By meta-analysis, continuous infusional administration of 5-FU/LV provides an improved response rate (24% vs. 14% with bolus; $P = .002$) and decreased grade 3 to 4 toxicity (4% vs. 31% with bolus; $P < .001$) compared with bolus therapy (MAGIC, 1998; de Gramont et al, 1997). Capecitabine is the orally administered prodrug of 5-FU, which has lower toxicity and provides similar survival rates compared with an intravenous 5-FU/LV regimen (Hoff et al, 2001).

Irinotecan

Irinotecan (CPT-11) is a topoisomerase I inhibitor, which prevents DNA unwinding and results in failure of DNA replication, DNA strand breaks, and cell death. In a randomized trial that evaluated irinotecan in patients with unresectable metastatic CRC, survival after irinotecan alone was equivalent to that of patients treated with standard bolus 5-FU/LV, but the combination of irinotecan and 5-FU/LV improved overall survival by 2.2 months over 5-FU/LV alone (14.8 vs. 12.6 months; $P = .04$) (Saltz et al, 2000). Subsequently, the combination of irinotecan with 5-FU/LV administered in continuous infusion (FOLFIRI) was associated with further improvement in survival (17.4 vs. 14.1 months; $P = .03$) (Douillard et al, 2000).

Oxaliplatin

Oxaliplatin is a platinum compound that alkylates DNA strands, thereby inhibiting DNA transcription and replication, resulting in cell death. Although already in use in Europe, oxaliplatin received U.S. Food and Drug Administration (FDA) approval in 2002. Oxaliplatin is commonly used in combination with

continuous infusional 5-FU/LV (FOLFOX). Different drug doses and timed regimens—FOLFOX4, FOLFOX6, and FOLFOX7—have been evaluated, but no data support the superiority of any one over another in terms of patient survival. In a national effort, the intergroup N9741 trial (Goldberg et al, 2004) showed that FOLFOX treatment was associated with a 4.5-month improvement in median overall survival compared with continuous infusion of 5-FU/LV alone (19.5 vs. 15 months; $P = .001$). As no trial has found a difference in efficacy between FOLFOX and FOLFIRI regimens, both remain first-line treatment options for systemic chemotherapy treatment of unresectable metastatic CRC. FOLFOX is used primarily over FOLFIRI because of potentially debilitating diarrhea associated with the latter.

MOLECULAR TARGETED AGENTS

The monoclonal antibodies bevacizumab and cetuximab have emerged as useful adjuncts to systemic chemotherapy for metastatic CRC. Bevacizumab targets and effectively neutralizes circulating vascular endothelial growth factor (VEGF), and several mechanisms of action have been proposed. VEGF is one of the key growth factors required for development and stabilization of new blood vessels that supply tumor growth. Bevacizumab decreases microvascular density and integrity and reduces interstitial tumor pressure in vivo, potentially increasing local delivery of other concurrently administered cytotoxic drugs (Jain, 2001; Willett et al, 2004).

In 2004 Hurwitz and colleagues demonstrated a benefit of adding bevacizumab to systemic chemotherapy for metastatic CRC. In a randomized controlled double-blinded trial, they compared bolus 5-FU/LV plus irinotecan in conjunction with either bevacizumab (n = 402) or placebo (n = 411). Patients in the bevacizumab group had a near 5-month improvement in median survival compared with the placebo group (20.3 vs. 15.6 months; $P < .001$), and they had an increase in median progression-free survival (10.6 vs. 6.5 months; $P = < .001$). Although generally well tolerated, the toxicity seen in the bevacizumab group was that of increased gastrointestinal perforation (1.5% of patients) and major thrombotic events (2.5%). In addition, treatment with bevacizumab prior to surgery may be associated with increased wound infections and dehiscences, attributable to inhibition of neovascularization of the healing wound (Scappaticci et al, 2005); however, following hepatic resection for CLM, this phenomenon was not observed in a prospective Phase II trial, in which bevacizumab had been discontinued for 5 weeks (Gruenberger et al, 2008). The current recommendation is still to wait at least 28 days from cessation of bevacizumab to proceed with surgery, but many surgeons prefer to wait 6 weeks.

Cetuximab and the newer drug panitumumab are two recombinant chimeric monoclonal antibodies, which bind to the epidermal growth factor receptor (EGFR). Cetuximab is sometimes used as first-line therapy of unresectable metastatic colon cancer. By competitively blocking the transmembrane tyrosine kinase EGFR, these agents inhibit cell growth, induce apoptosis, and decrease matrix metalloproteinase and VEGF production; however, the effectiveness of both of these drugs seems to be significantly dependent on the wild-type phenotype of *KRAS*, as this protein is part of the downstream signal-transduction pathway of EGFR. Results from the CRYSTAL study showed that for patients with wild-type *KRAS*, the addition of cetuximab to FOLFIRI as first-line treatment for CLM increased the response rate to 59% compared with 43% using FOLFIRI alone ($P = .003$). A slight increase in progression-free survival was found (9.9 vs. 8.7 months; $P = .017$), a benefit not seen among patients with *KRAS* mutations (Van Cutsem et al, 2008). The OPUS study was constructed similarly and assessed the addition of cetuximab to FOLFOX, and it also showed benefits for the *KRAS* wild-type subgroup (61% vs. 37%; $P = .011$) but not for patients with *KRAS* mutations (Bokemeyer et al, 2009). Based on these results, the American Society of Clinical Oncology published a consensus statement that patients who have tumors with *KRAS* mutations in codon 12 or 13 were unaffected by EGFR inhibition, and they recommended that anti-EGFR drugs not be used as part of the treatment regimen for this patient population (Allegra et al, 2009).

The colorectal liver metastases (CELIM) study randomized patients with unresectable colorectal liver metastases to receive FOLFOX plus cetuximab or FOLFIRI plus cetuximab in a nonblinded fashion. Response rates for the 53 patients in each arm were similar (68% and 57%; P = not significant [NS]). When analyzed for *KRAS* mutation, an impressive overall response rate of 70% was found for the entire group (Folprecht et al, 2010). Following a median of eight cycles, complete resection was achieved in 41 patients (34%), suggesting that this regimen was useful for converting unresectable cases to resectable ones. In a secondary analysis, 68 patients were included in a retrospective reevaluation by seven experienced hepatobiliary surgeons. Twenty-two patients (32%) were considered to be resectable based on initial staging imaging studies, which increased to 41 patients (60%) based on restaging studies after chemotherapy ($P = .001$).

In summary, the array of chemotherapeutic and molecular targeted agents available to treat CRC and CLM is growing. As such, patients who were not typically considered candidates for liver-directed surgery for CLM are now sometimes considered for potentially curative resection. The following sections will illustrate how the availability of active medical therapy is changing the landscape of surgical therapy for CLM.

CONVERSION THERAPY

One possible use of chemotherapy for patients with initially unresectable CLM is for downsizing tumors to the point where they become amenable to a complete resection. This treatment strategy is commonly referred to as *conversion therapy,* as opposed to *neoadjuvant therapy,* which is designated to those patients with resectable disease at initial presentation.

The first retrospective reports from France (Adam et al, 2001; Bismuth et al, 1996; Giacchetti et al, 1999) were updated in 2004 with a series of 1439 patients who underwent resection of colorectal liver metastases between 1988 and 1999. Among these, 1104 patients were described who were initially considered to have unresectable disease based on large tumor size, poor tumor location, multinodularity, or presence of extrahepatic disease. After receiving an average of 10 cycles of systemic chemotherapy (5-FU and chronomodulated oxaliplatin), 138 patients (12.5%) demonstrated enough response to become anatomically resectable, but within the median follow-up time of 49 months, 111 (80%) recurred. Recurrence was limited to the liver in 29%. Five-year overall and disease-free survival were 33% and 22%, both of which were lower than for those patients

Table 87.1

Outcome Associated with Resection Following Conversion Chemotherapy of Initially Unresectable Colorectal Liver Metastases

Reference	n	Chemotherapy Agents	Metastases Confined to Liver	Resection Rate, n (%)	R0 Rate, n (%)	Median PFS (mo)	Median OS (mo)
Zelek et al, 2003	31	5-FU/LV, IRI, HAI	Yes	11 (35)	9 (82)	20.2*	NR
Baize et al, 2006	39	5-FU/LV, OX	Yes	11 (28)	—	14	60

*In patients with R0 resection

OS, overall survival; PFS, progression-free survival; NR, not reached; 5-FU, 5-fluorouracil; LV, leucovorin; OX, oxaliplatin; IRI, irinotecan; HAI, hepatic artery infusion

considered resectable prior to chemotherapy (48% and 30%, respectively; $P = .01$). The authors identified four preoperative factors independently associated with shorter survival: a rectal primary, three or more metastases, maximum tumor size greater than 10 cm, and a carbohydrate antigen (CA) 19-9 greater than 100 U/L. Mean adjusted 5-year survival rates—according to the presence of 0, 1, 2, 3, or 4 of these factors—were 59%, 30%, 7%, 0%, and 0%, respectively (Adam et al, 2004a).

Since those first retrospective reports, prospective trials have provided additional data concerning outcomes of conversion chemotherapy, but few studies report on long-term outcome after resection (Table 87.1). Resectability rates following preoperative chemotherapy for 20 patients presenting with unresectable CLM have been reported as high as 80% (Mentha et al, 2006). Subsequent reports with larger sample sizes provide more modest results with respect to conversion to resectability after chemotherapy (15% to 24%) (Masi et al, 2009; Tournigand et al, 2006). Variability in chemotherapy type, duration, and timing with respect to resection and a lack of standard definitions of resectability make comparison between studies impossible.

Two recent prospective studies compared long-term outcomes between primary resection and secondary resection following systemic therapy. Capussotti and colleagues (2006) found no statistical difference in overall survival after resection in 34 patients who were converted to resectable, compared with 116 patients who underwent immediate partial hepatectomy (median survival 41 vs. 50 months, respectively; P = NS). At a median follow-up of 35 months, a 94% recurrence rate was observed in the conversion group compared with 66% in the immediate-resection cohort ($P = .001$). Disease-free survival was 9 months in the converted group compared with 37 months in the immediate-surgery group ($P = .001$). These authors also noted that extrahepatic recurrence after resection was greater in patients who were converted from unresectable to resectable (Capussotti et al, 2006).

The second study by Nuzzo and colleagues (2007) compared the outcomes of 60 initially resectable patients to that of a cohort of 15 patients with initially unresectable CLM who underwent complete resection following conversion chemotherapy. This study also found no significant difference in overall survival between initially resectable and unresectable patients with a mean survival of 46 and 47 months, respectively (P = NS). At a median follow-up of 34 months, disease recurrence rates were higher in initially unresectable patients (53%) compared with those of the primarily resectable comparison group (28%), and 3-year disease-free survival rates were 31% and 58%, respectively ($P = .04$) (Nuzzo et al, 2007).

In summary, conversion chemotherapy is a reasonable strategy for managing CLM in motivated patients with good performance status; however, this group of patients must understand that the benefit of resection following conversion is lower than if they had presented with resectable disease at the outset. Furthermore, attempting to compare results among studies illustrates the need for standardized chemotherapy regimens and common definitions of resectability.

COMBINING SYSTEMIC THERAPY WITH SURGERY

Preoperative Versus Postoperative Chemotherapy

Although developments in systemic therapy for CRC over the past decade have resulted in objective improvements for patients with advanced, unresectable disease, less is known regarding the benefits of systemic therapy for patients with primary, resectable CLM. Few clinical trials have investigated the role of systemic chemotherapy in the preoperative and/or adjuvant setting.

The use of adjuvant chemotherapy in patients who have undergone resection of colorectal liver metastases has the theoretic benefit of decreased recurrence rates from addressing potential micrometastases before they become too large to treat medically. Early evidence of the effect of systemic chemotherapy on resected patients was published by Figueras and colleagues in 2001. They reported on a series of 235 patients who underwent partial hepatectomy with curative intent. Of 180 patients considered for adjuvant treatment with six cycles of 5-FU, only 99 were actually treated, and several patients received oxaliplatin in addition. Patients receiving adjuvant therapy had an improved 5-year survival rate of 53%, compared with 25% for those intended to receive therapy but denied

treatment, or for those who declined for other reasons ($P <$ .001). Multivariate analysis revealed adjuvant chemotherapy as an independent predictor of survival (Figueras et al, 2001). Selection bias in this report limits interpretation of the results.

The largest retrospective multicenter study from Parks and colleagues (2007) included 247 patients treated with adjuvant 5-FU–based chemotherapy following resection of CLM and 518 patients who received no adjuvant treatment. They found an increase in overall survival with the use of adjuvant chemotherapy with a 47-month median survival and a 5-year survival of 37% compared with 36 months and 31%, respectively, for patients who did not receive chemotherapy ($P = .007$). Stratifying patients according to the clinical risk scores (Fong et al, 1999), they noted that patients who received adjuvant chemotherapy had improved survival in each category (range, 1.3- to 2.0-fold) (Parks et al, 2007).

Subsequently, Portier and colleagues (2006) conducted a multicenter, randomized, controlled trial that compared surgery combined with adjuvant 5-FU/LV to surgery alone. After recruiting 173 patients who had undergone R0 resection, this trial was aborted early because of low accrual rates. Although the study was underpowered, the investigators reported their results. At a median follow-up of 87 months, they demonstrated an improved 5-year disease-free survival rate in the adjuvant chemotherapy group compared with that of the surgery-alone group (33.5% vs. 26.7%; $P = .028$); they also found a nonsignificant trend toward increased 5-year overall survival (51.1% vs. 41.9%; $P = .13$). Recently, Mitry and colleagues (2008) pooled the results of this trial with another trial reported in abstract form to overcome the lack of statistical power. By combining patients, they were able to increase the study population to 278, of which 138 (50%) received six cycles of adjuvant 5-FU/LV following complete resection. In this combined dataset, a trend toward improved median progression-free survival was noted (27.9 months vs. 18.8 months; $P = .058$) and a trend toward increased overall survival (62.2 months vs. 47 months; $P = .095$) for the adjuvant chemotherapy group. Treatment with adjuvant chemotherapy was independently associated with improved disease-free and overall survival by multivariate analysis.

Regarding newer systemic regimens, some data are available from Phase II studies. Mackay and colleagues reported a multicenter Phase II study of 29 patients treated with six 21-day cycles of irinotecan (after receiving 5-FU) following resection of metachronous CLM. This study found an estimated median relapse-free survival time of 45.2 months, with acceptable toxicity.

Although these data suggest a benefit for adjuvant systemic therapy following hepatic resection for patients with CLM, other investigators have raised the possibility of using a preoperative approach, as has been championed in the treatment of rectal cancer (Bosset et al, 2005; Sauer et al, 2004). The rationale and theoretic benefits of preoperative chemotherapy include the ability to 1) treat micrometastatic disease prior to exposing patients to the regional growth factors that attend surgery following partial hepatectomy; 2) downsize tumors; 3) ensure that patients will get some systemic therapy, as complications after partial hepatectomy may preclude this; and 4) identify those patients who have aggressive tumor biology with disease progression while on systemic therapy, who would not likely have benefited from surgical resection. On the other hand, the risks of preoperative chemotherapy include liver toxicity, increased risk of disease progression or development of new metastatic sites, and selection of more resistant cell clones (Kemeny, 2007).

The best data have been published by the European Organization for Research and Treatment of Cancer (EORTC). Their prospective randomized controlled trail enrolled 364 patients and compared a group who received perioperative FOLFOX and surgery to a group who received surgery alone. A median of six cycles were given prior to and following resection, and all patients had four or fewer lesions and were deemed resectable prior to enrollment. This trial demonstrated a 7.3% progression-free survival benefit, from 28.1% (95.66% confidence interval [CI], 21.3 to 35.5) to 35.4% (CI, 28.1 to 42.7; hazard ratio [HR], 0.79 [0.62 to 1.02]; $P = .06$) for patients receiving chemotherapy along with surgery (Nordlinger et al, 2008). Only 63% of patients (115 of 151) in the chemotherapy group actually received chemotherapy following surgery, of which only 70% (n = 80) received all six cycles. Thirty-six patients did not receive postoperative chemotherapy, mainly because of patient refusal, perioperative complications, toxic effects of preoperative chemotherapy, or disease progression. Overall, the results of this study support the hypothesis that chemotherapy is beneficial for some patients undergoing partial hepatectomy for CLM, but it does not address the question of whether treating patient with preoperative chemotherapy impacts prognosis.

The existing retrospective studies that compare survival after resection of CLM with and without preoperative chemotherapy typically include patients who also received adjuvant chemotherapy. To date none of these studies demonstrates a significant benefit from preoperative chemotherapy (Table 87.2).

In summary, the combination of systemic therapy plus hepatic resection is superior to resection alone for resectable patients with CLM; however, prospective randomized trials are needed to determine whether administering systemic therapy prior to, following, or both prior to and following hepatic resection for CLM provides superior outcomes.

IN VIVO RESPONSE TO SYSTEMIC TREATMENT

It seems clear that chemotherapy improves the results of resection, but it remains unclear whether such therapy is optimally given before or after surgery. One of the potential benefits of administering chemotherapy prior to hepatic resection for CLM is to assess in vivo response of disease. Adam and colleagues (2004b) investigated the response to chemotherapy as a predictor of long-term outcome in 131 patients after potentially curative resection of multiple liver metastases (≥4). After a median of nine courses of 5-FU/LV with either irinotecan or oxaliplatin, they observed objective tumor response in 58 patients (44%), stable disease in 39 (30%), and tumor progression in 34 (26%). Response to chemotherapy correlated with overall survival following hepatectomy at 37%, 30%, and 8%, respectively, at 5 years ($P < .001$). In another recent retrospective analysis of 88 patients treated with preoperative oxaliplatin or irinotecan-based chemotherapy regimens followed by partial hepatectomy for resectable CLM, Chiappa and colleagues (2009) also noted that response to chemotherapy on restaging was associated with a significantly improved 5-year survival compared with that of nonresponders (71% vs. 15 %; $P = .026$).

Two studies from Memorial Sloan-Kettering Cancer Center (MSKCC) addressed the question of chemoresponsiveness of

CLM and survival in patients who had staged resections. Allen and colleagues (2003) found that the 46 patients who did not progress on chemotherapy administered prior to hepatic resection saw a 5-year survival benefit over that of the 54 patients who did not receive chemotherapy (85% vs. 35%; $P = .03$). The results of this analysis suggest that a clinical response to chemotherapy can identify a subset of patients with biologically favorable tumors, and treating clinicians can select them for more aggressive therapy. In a separate study by Gallagher and colleagues (2009) of 111 patients from MSKCC who underwent hepatic resection after preoperative chemotherapy, no differences were seen in median overall survival among patients who responded, had stable disease, or showed progression of disease (58 months vs. 65 months vs. 61 months; $P = .98$); however, it should be noted that the protocol for this evaluation was to proceed with hepatectomy at the first clinical sign of progression, as opposed to proceeding with resection at the first sign of response.

It remains unclear what the optimal duration of preoperative chemotherapy should be and when to proceed with hepatic resection; however, more surgeons are advocating proceeding with hepatic resection at the first signs of tumor response to avoid extended exposure of the liver to cytotoxic chemotherapy (see Chapter 65). To address this question, White and colleagues (2008) reviewed data for 35 patients with CLM who received FOLFOX with or without bevacizumab and evaluated radiologic tumor changes at 2-month intervals after the start of treatment; they found that the mean cumulative tumor reduction among responders (n = 30) was 39% at 2 months, and it increased to 56% at 4 months ($P < .01$) after commencing therapy. Importantly, no significant incremental tumor size reduction occurred between 4 and 6 months. Although this study was constructed to assess the time of maximal response in initially unresectable patients, these data suggest that 4 months of preoperative therapy may be sufficient to achieve the maximal tumor response in potentially resectable patients.

In summary, close multidisciplinary observation and communication are essential to avoid overtreating patients during preoperative chemotherapy for CLM. Borderline resectable and higher risk patients may benefit from in vivo response testing to systemic treatment.

Complete Response

As a result of increased effectiveness of systemic chemotherapy, it is now more common for tumors to demonstrate a complete radiographic response. This creates a new set of issues for managing patients with CLM following conversion or preoperative chemotherapy. The question remains whether these lesions are undetectable but still present and therefore likely to grow back. Elias and colleagues (2004) reported on 11 patients in whom at least one liver metastasis disappeared on imaging and could not be localized at laparotomy. Local recurrence was seen in three of these patients (27%), with a median follow-up time of 31.1 months. Few conclusions can be drawn from this initial report, given the small sample size, but the result from this analysis suggests that a durable response is possible in a majority of patients following complete radiographic resolution.

Subsequently, Benoist and colleagues (2006) reported on 66 liver metastases that disappeared radiographically following chemotherapy, which represented 20% of all lesions in the cohort. At the time of exploration, 31 lesions (47%) could not be identified, even with intraoperative ultrasonography, and they were consequentially not removed. By 1 year of follow-up, 23 (74%) of these lesions recurred. Of the other 35 liver lesions (53%) identified and removed at surgery, 32 (91%) contained viable disease, suggesting that tumors are still present, even when they disappear on imaging. Thus 55 of the original 66 lesions (83%) either harbored residual viable disease or returned following complete radiographic response.

Even more compelling is the question of a complete histologic response and how it impacts patient survival. In a study from the M.D. Anderson Cancer Center (MDACC), 305 patients received a median of five cycles of oxaliplatin- and irinotecan-based chemotherapy, with or without bevacizumab, prior to hepatic resection, and they were then stratified according to histopathologic response (Blazer et al, 2008). Complete response with no residual histologic evidence of tumor was observed in 9%, a major response (1% to 49% residual cells) was seen in 36%, and a minor response (≥50% residual cancer cells) was seen in 55% of tumors in the resection specimen. The 5-year survival rates for these three groups were 75%, 56%, and 33%, respectively ($P < .05$), and pathologic response to preoperative chemotherapy was independently associated with improved survival on multivariate analysis.

Adam and colleagues (2008b) found that only 4% of patients had a complete pathologic response in a series of 767 patients who underwent liver resection after preoperative chemotherapy for CLM. This cohort involved a heterogeneous group of patients with initially resectable and unresectable disease, including some patients with extrahepatic disease. As with the Blazer study, patients with a complete pathologic response (n = 29) had an excellent 5-year survival that reached 76% compared with 45% for patients without (n = 738; $P = .004$). A complete radiographic response was reported in only two patients when reviewed by a radiologist; interestingly, neither of these patients had complete pathologic response.

A report by Chun and colleagues (2009) assessed the association of morphologic radiologic response with pathologic response. A total of 234 lesions were examined from 50 patients who underwent hepatic resection after treatment with bevacizumab. In the cohort that had an "optimal" morphologic radiologic response, the median number of residual tumor cells was 20%, and the median survival was not yet reached by the time of the study's conclusion. In contrast, patients who had an "incomplete or absent" response had 50% to 70% residual tumor cells on pathologic assessment and had a shorter median survival (31 months; $P = .03$). This report represents an early assessment of the correlation between radiographic and histologic findings and how they correlate with patient outcome.

These data suggest that all original sites of metastases should be addressed surgically or with ablative therapy if possible, even if they are no longer present on restaging imaging, as they are likely to harbor viable malignant cells that may progress at some point. Identifying hepatic metastases after a complete radiologic response remains a technical challenge that can be overcome by use of a simple coil-marking technique described by Zalinski and colleagues (2009). This is especially valuable in steatotic, chemotherapy-treated livers, given the muted contrast between the lesions and the liver background as a result of impaired perfusion (Peppercorn et al, 1998). Medical oncologists are urged to refer potential resection candidates to surgeons prior to starting chemotherapy, and surgeons are urged to review available imaging obtained prior to preoperative chemotherapy.

CHEMOTHERAPY-INDUCED LIVER DAMAGE (SEE CHAPTER 65)

With increased use of preoperative chemotherapy, treating physicians are becoming more aware of the toxic effects of chemotherapy on liver parenchyma and how these changes affect postoperative outcome (Fong & Bentrem, 2006; Zorzi et al, 2007). Investigators have shown a wide spectrum of histopathologic changes to the underlying liver parenchyma in resection specimens (see Chapter 65 for a detailed description). Prolonged use of 5-FU and irinotecan-based chemotherapy has been associated with fatty liver changes ranging from mild forms of steatosis to more severe forms of steatohepatitis with additional necroinflammatory components (Peppercorn et al, 1998; Vauthey et al, 2006). Oxaliplatin-based regimens have been associated with venoocclusive injuries, termed *sinusoidal obstruction syndrome* (SOS) (Rubbia-Brandt et al, 2004). Although the association between chemotherapy and histopathologic changes has been well documented, the impact of chemotherapy-associated hepatotoxicity on surgical management of colorectal liver metastases remains somewhat ill defined.

From the transplant literature, we know that hepatic steatosis can impair liver function and postoperative regeneration. In a study of 485 patients undergoing liver resections for neoplasms (325 steatotic livers, 160 matched controls), steatosis was found to be an independent predictor of postoperative complications on multivariate analysis ($P < .01$) (Kooby et al, 2003). Overall and infective complication rates of 62% and 43% for the marked steatosis group (n = 102) were significantly higher than in the control group, at 35% and 14%, respectively ($P < .01$). The association between steatosis and previous exposure to chemotherapy was noted. Vauthey and colleagues (2006) systematically analyzed hepatic injury in 158 patients treated with varying preoperative chemotherapy regimens for metastatic CRC and correlated them to postoperative outcomes after hepatic resection. This study distinguished steatosis and steatohepatitis as separate pathologic findings and demonstrated that steatohepatitis induced by irinotecan-based chemotherapy was associated with an increase in 90-day mortality following major hepatectomy for CLM (14.7% vs. 1.4%, no steatohepatitis; $P = .001$). Furthermore, patients with steatohepatitis have a higher risk of death from postoperative liver failure compared with all other patients (6% vs. 1%; $P = .01$).

Karoui and colleagues (2006) reported that chemotherapy was significantly associated with sinusoidal dilation ($P = .005$), present in 49% of patients in the chemotherapy group (two thirds receiving oxaliplatin) compared with 14% in controls. Furthermore, significantly greater postoperative morbidity after major hepatectomy was found in the chemotherapy group compared with the control group (38% vs. 14%; $P = .03$), which was mostly attributed to the high incidence of transient liver failure in the chemotherapy group (11% vs. 0% in controls; P = NS). The addition of bevacizumab to oxaliplatin-based chemotherapy may have a protective effect on sinusoidal injury. Ribero and colleagues (2007) found that the addition of bevacizumab to oxaliplatin-based chemotherapy reduced the incidence of sinusoidal dilation of any grade by half (27% vs. 54%) and lowered severe, grade 2 to 3 sinusoidal dilation (8% vs. 28%) to about a third of reviewed pathologic specimens.

Although multiple studies support that patients with damaged livers have higher perioperative morbidity and mortality rates compared to those with healthy livers, others that directly compare perioperative outcome with and without preoperative chemotherapy for CLM have not been able to demonstrate this phenomenon (Pawlik et al, 2007; Scoggins et al, 2009). The reason for this discrepancy likely lies in factors of timing and dose of preoperative chemotherapy treatments and extent of hepatic resection. Both prolonged chemotherapy treatments and short intervals between the cessation of chemotherapy have been found to be associated with significantly increased morbidity (Aloia et al, 2006; Welsh et al, 2007). Although the optimal regimen and duration of systemic chemotherapy are still being assessed, dialogue between treating medical and surgical oncologists regarding the timing of surgery is critical. Theoretically, a longer interval may provide the liver time to recover from any reversible hepatotoxic effect of chemotherapy. On the other hand, a longer interval prior to hepatic resection may result in progression of disease. With this in mind, most surgeons will proceed with resection between 3 and 6 weeks after the last dose of chemotherapy.

MANAGEMENT OF SYNCHRONOUS LIVER METASTASES

Synchronously diagnosed CRC liver metastases pose additional challenges regarding the timing, sequence, and method of treatment. The traditional approach would be resection of the colorectal primary followed by a course of adjuvant chemotherapy and hepatic resection in the absence of interval disease progression; however, in the era of more active chemotherapy, this approach remains most applicable for patients with unresectable liver metastases, with the hope of conversion to secondarily resectable status. Alternative treatment pathways have also been proposed for patients with initially resectable synchronous liver disease (Fig. 87.1). The first issue specific to this patient subset is the question of whether the bowel or liver should be addressed first, or if they should both be removed at the same time.

In recent years, two large studies have confirmed previous smaller reports that simultaneous colon and hepatic resections are safe and may demonstrate benefits of reduced morbidity and mortality compared with staged procedures (Martin et al, 2003; Reddy et al, 2007). In the earlier report, by Martin and colleagues (2003), simultaneous resections were more likely performed for right colon primaries and for smaller and fewer liver metastases, and they resulted in similar rates of major complications (27% vs. 25%; P = NS) and mortality (4% vs. 4%; P = NS) for patients undergoing major hepatic resections between the groups. Reddy and colleagues (2007) found similar morbidity between simultaneous and staged minor hepatectomy (overall 36% and 38%; P = NS), but a significantly higher rate of severe morbidity (36.1 vs. 17.6%; $P = .05$) and mortality (8.3 vs. 0%; $P = .007$) was reported after simultaneous major hepatic resection. Long-term outcomes are similar among simultaneous and staged hepatic resections for synchronous CLM, and more than one study has shown that timing of hepatic resection does not affect long-term outcome (Minagawa et al, 2006; Tanaka et al, 2004).

Another more recent report by de Haas and colleagues (2010) confirms the safety of simultaneous resection, but it suggests that this strategy is an independent predictor of earlier tumor recurrence compared with the delayed hepatectomy approach. The authors compared outcomes from 55 patients who had simultaneous hepatic and colorectal resections to 173 patients who had the staged approach. The morbidity rate was

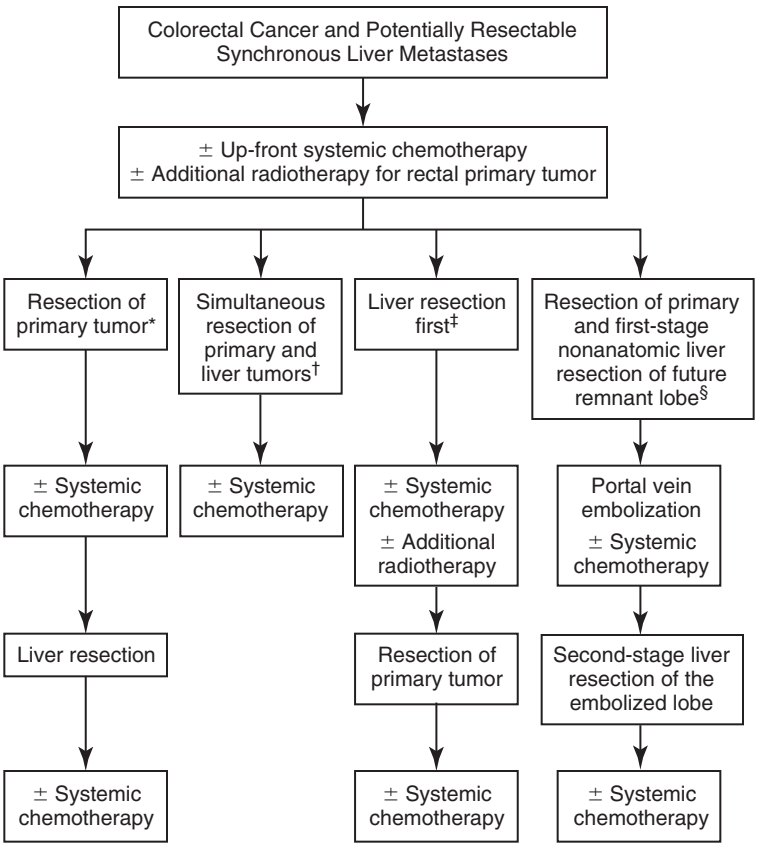

FIGURE 87.1. Treatment pathways for colorectal cancer patients with synchronous liver metastases. *Primary goal in patients with obstructing or bleeding tumors. †Preferred for cases of minor hepatectomy or for selected cases of major hepatectomy. ‡Option for advanced local disease and initially resectable liver disease. §Option for selected patients with limited bilobar disease.

actually lower in the simultaneous group (11% vs. 25%; P = .015), but more recurrences were observed in the simultaneous group at 3 years (85% vs. 64%; P = .002).

The "liver first" approach has been introduced as alternative treatment strategy for patients with advanced CRC with synchronous liver metastases. Patients receive chemotherapy before the liver resection and then undergo resection of the colorectal primary at a later date. This approach resulted from the improved efficacy of chemotherapy and focuses on delivering chemotherapy to the liver without potential delays as a result of prolonged recoveries from colon surgery. This idea is based on the belief that the liver is the component that will ultimately limit survival. Secondly, authors have raised concerns of enhanced metastatic tumor growth after removal of the primary tumor (Demicheli et al, 2008). Published reports of this approach are limited to small case series. Mentha and colleagues (2008) have recently updated their initial series and reported 35 patients, of which 30 completed the pathway. With a clinical risk score of 3 or higher, the reported 5-year survival of 31%, with a median survival of 44 months, is encouraging. Limitations of this approach include risks of secondary obstruction, disease progression, and chemotherapy-induced liver damage.

The role of preoperative chemotherapy in patients with resectable synchronous liver metastases remains a subject of debate. Despite the theoretic benefits of preoperative chemotherapy, data on the actual survival benefits are equivocal. In a study of 151 patients initially evaluated at MSKCC, Fahy and colleagues (2009) reported an overall disease-specific survival of 26.7 months after diagnosis of synchronous colon cancer. Both liver resection and preoperative chemotherapy were treatment modalities significantly associated with survival, but most patients received some sort of postresection therapy. Reddy and colleagues (2009) specifically addressed timing of chemotherapy in their large multiinstitutional study of 499 patients undergoing resection for synchronous CLM. Postoperative chemotherapy alone was independently associated with recurrence-free survival, if given for 6 months or longer (HR, 0.75; P = .04), and with overall survival, if administered for 2 months or longer (HR, 0.59; P = .001). Preoperative chemotherapy alone was not associated with improved survival, but patients with perioperative chemotherapy had similar outcomes to patients who received postoperative chemotherapy alone, thus given the lack of level 1 evidence, the available data do not support use of prehepatectomy chemotherapy uniformly in all resectable synchronous CLM.

Among selected patients prehepatectomy therapy may be useful. Tanaka and colleagues (2003) found that prehepatectomy chemotherapy was associated with improved survival (5-year survival of 39% vs. 52%; P = .04) in a group of 71 patients with bilateral multiple, mostly synchronous CLM. Interestingly, the authors also noted a lower rate of major hepatectomy in their patients who received prehepatectomy chemotherapy (81% vs. 100%; P = .027). Given the fact that patients who received preoperative chemotherapy had unresectable

extensive bilobar disease, this is one of the few studies that indicate the possibility for smaller resection after effective treatment; however, no studies directly compare extent of resection to the originally planned procedure before chemotherapy.

In rectal cancer patients, the potential need for locoregional radiotherapy further complicates the matter. Neoadjuvant chemosensitizing radiation has proven to lower local relapse rates to less than 10% (range, 6% to 8%) in locally advanced rectal cancer (T3 to T4) in several prospective randomized trials (Roh et al, 2009; Sauer et al, 2004). This outcome is extremely valuable, because surgical salvage options are slim and are generally associated with poor quality of life and poor survival (Salo et al, 1999); however, this treatment modality has not proven to be beneficial in terms of overall survival, and its role in patients with stage IV disease is unclear. Several potential approaches to integrating neoadjuvant chemoradiation exist in this stage of disease, and the question is in what sequence neoadjuvant chemotherapy, radiation, or chemoradiation should be given. This decision naturally is dictated by the toxicity of such extensive therapy and based on the needs of the individual patient. Although simultaneous resection can theoretically be achieved through one long midline incision, most surgeons recommend a staged procedure with initial resection of the rectal primary (Reddy et al, 2007). Early reports of the liver-first approach have also been published from a European Center (Verhoef et al, 2009). Of 22 patients with advanced local rectal primaries and synchronous liver metastases in this series, 16 patients (73%) completed the full treatment protocol, and all were alive after a median of 19 months. Morbidity of this approach was equivalent to that seen with the rectum-first approach and simultaneous resections in a second small case series (van der Pool et al, 2010).

EXTRAHEPATIC DISEASE

The presence of extrahepatic disease in the setting of CLM has traditionally been considered a contraindication for hepatic resection. With better systemic chemotherapy, survival has improved in all stages of disease, and surgeons have become more aggressive in considering resection in patients who were not candidates in the past. Several centers have published their experience with liver resection in patients with concomitant extrahepatic disease. Carpizo and colleagues (2009) reported the outcome of 127 patients with extrahepatic disease, which comprised 9% of all patients undergoing liver resection at MSKCC between 1997 and 2007. Overall survival of 47% and 26% at 3 and 5 years was significantly inferior to the 67% and 49% ($P < .001$) observed in patients without extrahepatic disease. Importantly, the survival observed in patients with extrahepatic disease in this study is similar to that observed for patients with only liver disease resected during the 1980s and 1990s.

It is noteworthy that recurrence was observed in 95% of patients in this group with median follow-up of 24 months. This included both local extrahepatic invasion and distant metastatic sites including lung, ovaries, peritoneum, and regional hepatic lymph nodes. Although this study found that patients with perihepatic lymph node metastases had worse survival than those with lung and ovarian metastases, with a median survival of 26, 45, and 82 months, respectively ($P < .05$). The incidence of occult microscopic lymph node involvement ranged from 2% to as high as 28% (Beckurts et al, 1997), likely because of the fact that hepatic lymph node dissection is not commonly performed. Adam and colleagues (2008a) found regional lymph node metastases in 6% of 763 patients undergoing hepatic resection for CLM and reported a predicted 5-year survival that was significantly inferior compared with that of patients without nodal involvement (18% vs. 53%; $P = .001$). The authors pointed out that all patients who survived 5 years had lymph node metastases in the hepatoduodenal ligament, and no long-term survivors were among those with celiac or retroperitoneal lymph node metastases.

Jaeck and colleagues (2002) prospectively performed systematic portal lymphadenectomy on 160 patients and examined differences in survival of different subsites; overall, metastatic lymph nodes were found in 17 patients (11%), with a 3-year survival of 19%. Similarly, this study distinguished between hepatoduodenal ligament nodes (zone 1) and celiac/common hepatic artery nodes (zone 2) and found a substantially worse survival for patients with zone 2 compared with zone 1 lymph node involvement (0% 1-year vs. 38% 3-year survival). The same group recently updated their results of 45 patients with regional lymph node involvement (Oussoultzoglou et al, 2009). After a change in multimodal treatment strategies, the vast majority received modern oxaliplatin- or irinotecan-based chemotherapy, with or without bevacizumab or cetuximab, and the surgical approach shifted toward a more aggressive lymphadenectomy. With a median follow up of 26 months, 3-year overall survival was increased to 29.7%, and 5-year survival of 17.3% was reported. Interestingly, no significant survival difference was found among patients with zone 1 and 2 nodal involvement, with a median survival of 19 and 20 months ($P = .44$), respectively. Elevated carcinoembryonic antigen (CEA) greater than 200 μg/L was found in 82% of patients and was found to be the only preoperative factor independently associated with overall survival (odds ratio [OR], 7.1; $P < .001$).

Given recent data, lymphadenectomy can provide a chance for long term-survival in selected patients with extrahepatic disease, and that may outweigh any additional associated morbidity. Data regarding resections of distant sites of extrahepatic disease are limited, and the surgical approach must be considered on a patient-by-patient basis.

PORTAL VEIN EMBOLIZATION AND CHEMOTHERAPY

Preoperative portal vein embolization (PVE) is used to promote compensatory hypertrophy in patients whose future liver remnant (FLR) may be insufficient to support them during the recovery phase following major hepatic resection. Techniques, indications, and results of PVE are outlined in Chapter 93; they will only be discussed briefly here, as they may be affected by concurrent systemic chemotherapy or underlying chemotherapy-induced liver damage.

PVE increases the safety of hepatectomy for patients with marginal hepatic reserve. The average increase of the estimated FLR is between 8% and 16% at 2 to 4 weeks after PVE, depending on the measurement technique and underlying liver disease (Covey et al, 2005; Madoff et al, 2003; Vauthey et al, 2000). Long-term survival has been found to be comparable for patients with and without PVE before major hepatic resection for CLM, at 40% and 38% at 5 years (Azoulay et al, 2000).

Given the cytotoxic nature of chemotherapeutic agents and their ability to hinder cell proliferation, the question arises whether liver regeneration and hypertrophy are altered by concurrent chemotherapy. In particular, the inhibition of vascular endothelial growth factor (VEGF), as targeted by bevacizumab, has been shown to impair liver regeneration in animal models after partial hepatectomy (Bockhorn et al, 2007). One of the first reports to address this issue was from Goéré and colleagues (2006) in France. Data from 10 patients who had no chemotherapy between static portal embolization and surgery were compared with data from another 10 patients who had continuous chemotherapy. No significant difference was observed in FLR growth between the groups, but the sample size was small. Covey and colleagues (2008) further addressed this question in a study of 100 patients undergoing PVE before resection of CLM, 43 of whom received concurrent chemotherapy of various regimens. This study found no statistically significant difference in liver growth between the patients who had concurrent chemotherapy treatment and those who did not (22% vs. 26%; P = NS). Confirming results were presented by Zorzi and colleagues (2008), who showed no difference in FLR growth after PVE in patients treated without chemotherapy, those treated with systemic chemotherapy, and those treated with chemotherapy that included bevacizumab (10.1% vs. 8.8% vs. 6.8%; P = NS). More recently, one paper suggested that a bevacizumab-containing chemotherapy regimen impairs FLR hypertrophy after PVE (Aussilhou et al, 2009). The authors found a significantly smaller increase in FLR in the bevacizumab-treated group (n = 13) compared with the group that did not receive bevacizumab (n = 27) in their regimens (561 + 171 cm^3 vs. 667 + 213 cm^3; P = .031). Based on existing data, administration of systemic therapy appears to be acceptable around the time of PVE, but it may be prudent to avoid bevacizumab in these patients.

Data regarding the impact of chemotherapy-induced liver injuries on liver regeneration after PVE are scant. A recent study showed that steatosis was associated with significantly lower hypertrophy volume and hypertrophy ratios after right PVE in 35 patients after hemihepatectomy (Tanaka et al, 2010). Based on existing data, it appears safe to consider PVE in patients who receive chemotherapy prior to hepatic resection; however, the actual benefit of PVE for this set of patients still remains unclear. Our recommendation is to limit the use of PVE to patients who will undergo major hepatic resection with an FLR less than 25%. Further data on PVE in patients with CLM are needed.

TWO-STAGE HEPATECTOMY

Two-stage hepatectomy is a relatively new strategy to expand the criteria of resectability. Using this approach, complete resection is feasible in selected patients with bilateral CLM. PVE or portal vein ligation is often required after the first resection to promote hypertrophy of the FLR and to ensure sufficient liver remnant. In the first description by Adam and colleagues (2000), the authors proposed to remove as many tumor sites as possible during the first operation, followed by a course of chemotherapy, with or without PVE, and second-stage resection to clear the remaining liver. Among 13 patients who had both resections, reported 3-year survival was 35%. This strategy was then modified by Jaeck and colleagues (2004) because of concerns of accelerated tumor growth during the regeneration period after major hepatectomy and PVE. The new strategy is to initially remove tumor in the FLR, clear one side of the liver in a usually smaller operation prior to PVE, and resect the remaining tumor-bearing liver in a second operation.

Success rates and long-term outcome of patients who have both hepatic resections largely depend on patient selection and utilization of modern chemotherapy. The literature reports success rates from 69% to 92% (Adam et al, 2000; Jaeck et al, 2004; Tanaka et al, 2007; Wicherts et al, 2008), but perioperative morbidity and mortality rates are uniformly higher after the second hepatectomy. In the largest series of 41 patients who underwent two-stage hepatectomy, the cumulative morbidity was 79%, with an overall morbidity of 20% and 59% and mortality of 0% and 7% after the first- and second-stage hepatectomy, respectively (Wicherts et al, 2008).

The best long-term results were presented in a study by Chun and colleagues (2007) from the MDACC. In this study, all patients received a course of modern oxaliplatin- or irinotecan-based chemotherapy preoperatively, and 81% received additional chemotherapy postoperatively. With a median follow-up of 25 months, they reported an astonishing 3-year overall and disease-free survival of 86% and 51%, respectively, which was favorable when compared with patients who had a one-stage hepatectomy. Although this series presents a well-selected patient population, it demonstrates that in combination with modern chemotherapy, two-stage hepatectomy offers a chance of long-term survival for patients who would otherwise not be candidates for resection.

CHAPTER 88

Advances in systemic therapy for hepatocellular carcinoma

Ghassan K. Abou-Alfa and Leonard B. Saltz

OVERVIEW

Hepatocellular carcinoma (HCC) is the fifth most common solid tumor and the third most common cause of cancer death worldwide (Abou-Alfa, 2008; see Chapter 80). Its incidence mirrors that of chronic liver injury, most commonly the result of viral infection by both hepatitis B and C (see Chapter 64). Other etiologies that lead to chronic liver injury and cirrhosis include alcohol abuse; nonalcoholic steatohepatitis, commonly associated with morbid obesity and diabetes; and other metabolic diseases, such as hemochromatosis. The highest incidence of HCC remains in Southeast Asia and sub-Saharan Africa (McGlynn et al, 2001); however, concern continues about the rising incidence of HCC in North America (El-Serag & Mason, 1999). A threefold increase in the age-adjusted rates for HCC associated with hepatitis C virus (HCV) infection has been observed, from 2.3 per 100,000 between 1993 and 1995 to 7.0 per 100,000 between 1996 and 1998; this is most likely explained by the increased incidence of HCV in North America during that period.

Many chemotherapeutic agents have been demonstrated to produce occasional responses in some patients with HCC, yet none has shown a clear impact on survival. The advent of novel therapeutics and their impact on survival in patients with HCC have changed the platform of managing advanced HCC and have opened opportunities to look into other therapeutic indications, such as adjuvant therapy.

HEPATOCELLULAR CARCINOMA AND CIRRHOSIS: TWO DISEASES IN ONE (SEE CHAPTER 70)

Both cirrhosis and the tumor itself impact the HCC patient's overall survival (OS), thus the cirrhosis status of patients with liver cancer must be evaluated. A scoring system was originally developed by Child (1964) that consisted of three parameters: jaundice (bilirubin), ascites, and encephalopathy. This scoring system was later updated by Pugh et al (1973), who added an assessment of hepatic synthetic function by evaluating serum albumin levels and prothrombin time (PT) (Table 88.1; see Chapters 2 and 70B). This combined score is known as the *Child-Turcotte-Pugh (CTP) score,* and it remains the most commonly used scoring system for liver cirrhosis. The pitfall of this classification is its lack of any parameters that relate to the cancer itself, as it was developed in patients who have cirrhosis but no cancer. As such, it is unlikely to be the best predictor of outcome in patients with HCC.

Okuda and colleagues (1985) recognized the need for an HCC staging system that incorporated factors related to both the cirrhosis and the tumor itself and developed what is known as the *Okuda staging system,* which encompasses four variables: 1) albumin, 2) bilirubin, 3) ascites, and 4) tumor size as a percentage of the size of the liver (greater or less than 50%). The Okuda staging system served as a platform for more advanced and sophisticated prospective scoring systems that used the Cox proportional hazard regression model. The Cancer of the Liver Italian Program (CLIP) developed a scoring system in patients with HCC, with mainly HCV as an etiology (CLIP, 1998, 2000), that found the independent prognostic variables for patients with HCC to be the CTP score plus three additional variables that relate to the tumor itself: tumor morphology, as assessed by the number of lesions and extent of disease in the liver; presence or absence of portal vein thrombosis; and α-fetoprotein (AFP) level (Table 88.2). Patients with a high score (4 to 6) were shown to have a median survival of only 3.2 months.

In contrast to the CLIP scoring system, the Chinese University Prognostic Index (CUPI), another scoring system based on multivariate analysis, was developed mainly in patients with hepatitis B virus (HBV)-associated HCC (Leung et al, 2002). This prognostic index identified bilirubin, alkaline phosphatase, and the presence or absence of ascites, in addition to tumor stage based on the tumor-node-metastasis (TNM) staging and AFP levels, as the most important predictors of outcome. In addition, a clinical assessment parameter of presence or absence of symptoms at presentation was incorporated (Table 88.3). An important aspect of the CUPI index is that different weights are attributed to the different parameters. The median survival of the highest risk group was close to 1 month. Other scoring systems include the Groupe d'Étude et de Traitement du Carcinome Hépatocellulaire (GETCH) staging system (Chevret et al, 1999), the Japan Integrated Staging (JIS) Score (Kudo et al, 2003), and the Barcelona Clinic Liver Cancer (BCLC) classification system (Llovet et al, 1999).

The BCLC system was developed with the aim of fine tuning the differences between patients with early stage disease, something the Okuda staging system fails to do; however, by the same token, the BCLC staging system had limited permutations for patients with advanced disease and grouped patients with unresectable disease—with Okuda stage I or II or CTP class A or B—in the same category as advanced disease.

In a retrospective analysis of patients with advanced HCC seen by medical oncologists at Memorial Sloan-Kettering Cancer Center (MSKCC) over a period of 5 years, we attempted to identify which of these eight scoring systems would be most valuable in this specific clinical setting (Huitzil-Melendez et al,

Table 88.1

α-Fetoprotein (ng/dL)	<400		≥400		
Score	0	1	2	3	4-6

2010). By using a concordance index, the GETCH, CLIP, and CUPI were found to be the most informative staging systems in predicting survival in patients with advanced HCC. The BCLC system did not score well in this exercise, which studied a specific niche of patients with advanced HCC, all of whom fell within the single basket of category C of BCLC; therefore it lacks any discriminatory value. Other groups have independently come to the same conclusion regarding the BCLC system (Collette et al, 2007).

ROLE OF CHEMOTHERAPY IN HEPATOCELLULAR CARCINOMA

Almost all classes of chemotherapy have been studied in advanced HCC (Nerenstone et al, 1988). Doxorubicin is one of the most studied drugs in this disease, partly as a result of what has thus far been an irreproducible response rate of 79%, originally reported by Olweny and colleagues (1975). It should be noted that this early report from the mid-1970s did not use modern computerized tomography (CT) or magnetic resonance imaging (MRI) methods available and used routinely today. The majority of "responses" were determined either on the basis of physical examinations of the liver or using a colloidal gold liver scan, measuring techniques that would not be acceptable as evidence of a response in clinical trials by current standards. Many subsequent attempts to try to reproduce this high response rate have been made, both with doxorubicin as a single agent (Barbare et al, 1984; Chlebowski et al, 1984; Ihde et al, 1977; Johnson et al, 1978; Sciarrino et al, 1985; Vogel, 1977; Williams & Melia, 1980) and in combination with other chemotherapeutic agents (Choi et al, 1984; Falkson et al, 1978, 1984; Melia et al, 1983; Olweny et al, 1980), but to no avail.

Other older and newer chemotherapeutic agents have also been studied in HCC, including cisplatin (Falkson et al, 1987), etoposide (Melia et al, 1983), mitoxantrone (Falkson et al, 1987), vinblastine (Damrongsak et al, 1973), capecitabine (Patt et al, 2004), gemcitabine (Kubicka et al, 2001), irinotecan (O'Reilly et al, 2001), and paclitaxel (Chao et al, 1998), all with reported dismal response rates and no impact on survival.

Although several combination chemotherapy agents have shown improved response rates, the impact on survival was not noticeable in most cases (Baker et al, 1977; Bobbio-Pallavicini et al, 1997; Porta et al, 1995). As a single agent, interferon α-2b in a trial by the Gastrointestinal Tumor Study Group (GITSG, 1990) showed a limited response rate of only 7%. This disappointingly low response, in addition to increased toxicity as a result of high doses of interferon, led to testing lower doses in combination with chemotherapy. Despite a reported high response rate of 31% in some trials (Ji et al, 1996; Patt et al, 1993), favorable results have not been reproducible (Kardinal et al, 1993; Stuart et al, 1996).

Nevertheless, the preliminary indication of some activity for interferon set the platform for a more intense combination

Table 88.3

of cisplatin, interferon, doxorubicin, and 5-fluorouracil (5-FU), which became commonly known as PIAF (Patt et al, 1999). PIAF was subsequently modified and tested in the outpatient setting (Leung et al, 1999), and a Phase II trial of 50 patients showed a response rate of 26%. More importantly, nine patients (18%) had their tumor resected after therapy, and of these resected patients, four had a pathologic complete response noted in the resected tumor. Considerable hematologic toxicity was reported in this 50-patient cohort, and two treatment-related deaths resulted from neutropenic fever. It is important to note that this study was conducted before granulocyte-stimulating factors were commonly used for similar intense chemotherapeutic regimens.

These data led to a randomized Phase III trial of doxorubicin versus a combination, PIAF (Yeo et al, 2005). This trial showed the same 21% response rate for PIAF versus 10% for single-agent doxorubicin; however, the study failed to show any survival advantage in favor of the PIAF combination (8.7 vs. 6.8 months; $P = .83$). Despite this trial having a negative outcome for the primary end point, it did provide several important and useful pieces of information: First, as noted above, it identified what can realistically be considered the true response rate—by current standards of response definition and determination—of doxorubicin in HCC, and that response rate is 10%. Furthermore, although the study failed to provide support for use of PIAF as a routine palliative therapy for advanced disease, it might be considered as a conversion therapy in very carefully selected patients with potentially resectable tumors.

Some of the generally disappointing results are explained by the genetic makeup of HCC, which comprises highly resistant clones of cancer cells (DeVita & Abou-Alfa, 2000). The HCC cells carry a high genetic mutation load, which makes them less amenable to the destructive actions of chemotherapy. HCC cells usually contain a high level of dihydropyrimidine dehydrogenase (DPD), which potentially makes them relatively resistant to 5-FU (Jiang, 1993). HCC cells also overexpress the multidrug resistance gene *MDR1* (Chenivesse, 1997) and the gene product P-glycoprotein (P-gp) (Soini et al, 1996). This may help explain the resistance of HCC to paclitaxel (Chao et al, 1998), but it would not necessarily explain the PIAF pathologic response (Leung et al, 1999), the witness to the efficacy that chemotherapy can exert onto HCC, contrary to all attestations that it cannot; this concept will be revisited as part of its evaluation in combination with biologic therapy (Abou-Alfa, 2008).

Several attempts at overcoming this resistance by developing novel cytotoxic agents have been made, although not with any appreciable success. T138067 is an antimicrotubular non–P-gp substrate (Shan et al, 1999; Venook et al, 2004) that showed a modest 9% response in chemotherapy naïve patients (Leung et al, 2002); however, a randomized Phase II/III trial of T138067 versus doxorubicin in patients with advanced HCC was prematurely closed because of lack of survival benefit (Posey et al, 2005). Nolatrexed dihydrochloride is a nonclassic lipophilic inhibitor of thymidylate synthase that is not catabolized by dihydropyrimidine dehydrogenase. It lacks a glutamate side chain and thus has reduced potential transport-associated resistance (Webber et al, 1993). Nolatrexed was studied in two different clinical trials; however, results were disappointing, with an 8% response rate in a Phase II North American study (Stuart, 1999) and no responses in a randomized Phase II study in Hong Kong (Mok et al, 1999). Despite those disappointing results, a randomized Phase III trial that evaluated nolatrexed versus doxorubicin in patients with unresectable HCC was performed. It showed a median OS of 5.6 months for nolatrexed versus 8 months for doxorubicin ($P = .0068$) (Gish et al, 2007). It is unclear whether nolatrexed conferred a negative survival effect or was simply inactive.

A novel modality of administering floxuridine (FUDR) and dexamethasone via hepatic arterial infusion (HAI) was also studied in HCC (Jarnagin et al, 2009). Among eight patients studied, the response rate was 25%, and the hepatic progression-free survival (PFS) was 9.4 months. Interestingly, patients in the same study with cholangiocarcinoma fared better, with a 53.8% response rate and 11.6 months hepatic PFS. HAI is discussed in detail in Chapter 86.

In summary, no chemotherapy agent or combination of agents has so far shown any impact on survival in patients with HCC. With the advent of novel targeted agents came a pressing need to have them evaluated in the setting of HCC; however, chemotherapy is not necessarily forgotten, as the potential of combining it with targeted therapies may carry a certain promise in HCC given the success of such a strategy in multiple other solid-tumor models.

NOVEL BIOLOGIC THERAPIES IN HEPATOCELLULAR CARCINOMA

The advent of novel targeted therapeutics and the lack of a consistent standard of care for advanced HCC has led to interest in identifying and evaluating relevant targets in HCC along the signal transduction pathways (Huitzil-Melendez et al, 2009; Fig. 88.1).

Epidermal Growth Factor Receptor, c-MET, and Insulin Growth Factor Receptor

The epidermal growth factor receptor (EGFR) is one of the most thoroughly studied therapeutic targets. Several authors have reported no difference in expression of EGFR between HCC and noncancerous diseased liver tissues (Harada et al, 1999; Kira et al, 1997), whereas others have reported overexpression in 17% of HCC cases (Kiss et al, 1997). Erlotinib, an

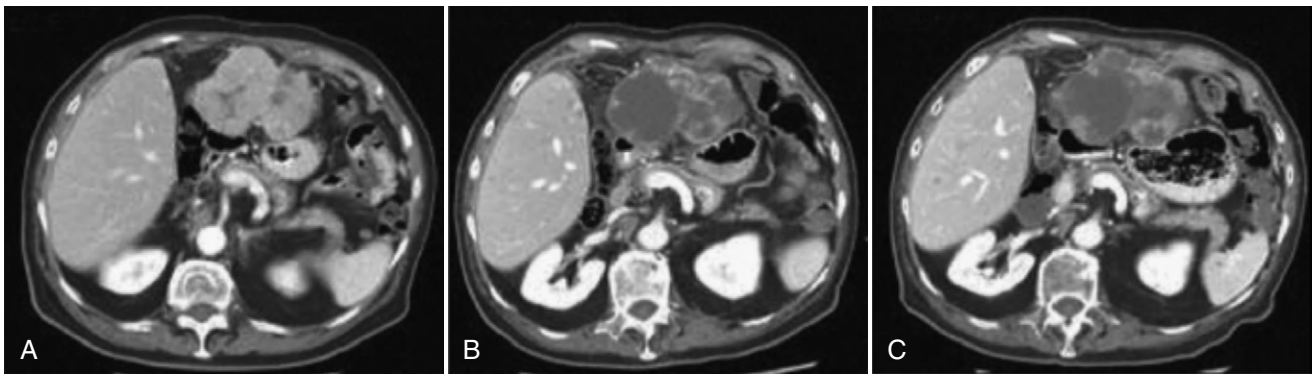
CDK, cyclin-dependent kinase; c-Met, mesenchymal epithelial transition factor; EGFR, epidermal growth factor receptor; Her2, human epidermal growth factor receptor-2; RAF, rapidly growing fibrosarcoma (serine/threonine protein kinase); RAS, rat sarcoma (guanosine triphosphate–binding protein).

EGFR-specific receptor tyrosine kinase inhibitor, was tested in HCC as part of a Phase II trial of 38 patients with advanced HCC (Philip et al, 2005). Close to half of the patients had prior therapy, and 71% of all patients had class A cirrhosis. The primary end point was PFS at 6 months, using Response Evaluation Criteria in Solid Tumors (RECIST), and this end point was reached in 12 (32%) of 38 patients, with a median PFS of 3.8 months. In addition, three partial responses (8%) were reported, and median OS was 13 months. Similar to the experience with other tumors, immunohistochemical staining of EFGR expression was not associated with outcome. The most frequent grade 3 and 4 toxicities were skin rash (13%), diarrhea (8%), and fatigue (8%).

Despite having some preclinical activity in HCC (Huether et al, 2005), cetuximab has not been tested in HCC. Lapatinib, an oral agent with dual inhibition of EGFR and tyrosine kinase 1 and 2 (Her2/Neu), has been studied in HCC (Ramanathan et al, 2009) despite the rare expression of Her2/Neu in human HCC tissues (Hsu et al, 2002) and with disappointing results. In a Phase II trial, 40 patients with advanced HCC were treated with lapatinib, and the response rate was 5%, PFS was 2.3 months (95% confidence interval [CI], 1.7 to 5.6), and median survival was 6.2 months. Both fall short of other reported data in the literature, and EGFR genotyping indicates that HCC patients with less than 20 repeats have the worst PFS.

Another potential target is the hepatocyte growth factor (HGF) and its receptor c-Met, which were found to be overexpressed in 33% and 20% of human HCC tissues, respectively (Kiss et al, 1997). In another study, c-Met was found to be overexpressed preferentially in early stage resected HCC, with no association with outcome as measured by OS (Huitzil-Melendez et al, 2009). Certain c-Met inhibitors are already being studied in HCC, such as ARQ 197, which was already evaluated in a Phase I study (Garcia et al, 2007).

Insulin growth factors (IGFs) are reported to be a strong mitogen of HCC, exerting their effect through the IGF1 receptor (Pollak, 2005). IGF1 receptor inhibitors are currently under study in HCC. In conclusion, the data shown so far do not provide enough support for the routine use of any of the single-agent EGFR, c-Met, or IGF receptor inhibitors in the management of HCC.



Sorafenib

Sorafenib is a novel molecular targeted agent that inhibits the serine/threonine kinase Raf-1 in vitro in addition to the pro-angiogenic (vascular endothelial growth factor receptor [VEGFR]-1, -2, and -3; platelet-derived growth factor receptor [PDGFR]-β); and tumorigenic receptor tyrosine kinases (RTKs; RET, Flt-3, and c-Kit) (Wilhelm et al, 2004). Sorafenib has been studied extensively in HCC and has now been approved by regulatory agencies worldwide as a standard therapy for unresectable HCC.

HCC is a highly vascular solid tumor with high expression of VEGF, which plays a major role in HCC development and potentiates its metastatic capability in preclinical models (Yoshiji et al, 2004). Proangiogenic platelet-derived growth factor receptor-β (PDGFR-β) also contributes to this increased metastatic potential (Zhang et al, 2005).

Anti–VEGFR-1, -2, and -3 and PDGFR-β sorafenib are the most studied antiangiogenic drugs in HCC so far; although an initial Phase II trial evaluating response to sorafenib in patients with advanced HCC showed no significant response rate (2%) (Abou-Alfa et al, 2006), 34% of patients had stable disease of a minimum 4 months' duration. This was commensurate with a median time to progression (TTP) of 4.2 months and median OS of 9.2 months, both of which compare favorably to historic controls (Yeo et al, 2005). The main grade 3 and 4 toxicities were fatigue (9.5%), diarrhea (8%), and hand-foot skin reaction (5.1%), known also as *hand-foot syndrome*. The high rate of stable disease was associated with an observed phenomenon of central tumor necrosis in many patients in the study whose tumors were evaluated using triphasic CT scans inclusive of an arterial phase (Fig. 88.2). This central tumor necrosis was quantified, and the volume was assessed using a computer algorithm for semiautomated delineation of tumors (Zhao et al, 2006). It was later found that the ratio of the percentage of the described tumor necrosis over the tumor volume correlated with objective response (Abou-Alfa, 2008). This phenomenon is still pending validation and is currently the subject of many prospective correlative studies of ongoing HCC clinical trials.

The suggested improved outcome noted in this Phase II study led to a large, double-blinded, randomized Phase III trial evaluating sorafenib versus placebo in patients with advanced

Volume (cm^3)	295	341	285
Necrosis (%)	2.1	53.1	51.0

FIGURE 88.2. A representative example of baseline and serial follow-up scans demonstrating tumor necrosis in a hepatocellular carcinoma patient. *(From Abou-Alfa GK, et al, 2006: A phase II study of sorafenib in patients with advanced hepatocellular carcinoma. J Clin Oncol 24[26]:4293-4300.)*

HCC and class A cirrhosis (Llovet et al, 2008) with two primary end points of OS and time to symptomatic progression (TTSP) using the FHSI8-TSP instrument. This Phase III study, known for short as the *SHARP trial* (Sorafenib HCC Assessment Randomized Protocol), demonstrated a survival of 10.7 months in the sorafenib group versus 7.9 months in the placebo group ($P < .001$, hazard ratio [HR], 0.69). The second primary end point in evaluating TTSP showed no difference between the two arms ($P = .77$). This observation is limited by the poor understanding of the validity of the FHS18-TSP instrument in this setting. Add to the fact that a large number of the patients in this study—including 17% with locally advanced tumor, BCLC B patients—had an excellent performance status and lacked any symptoms that the FHS18-TSP instrument would otherwise depend on for its measurements. The toxicity profile was similar to that noted in the Phase II study, with 8% grade 3 to 4 diarrhea and hand-foot syndrome. Rare bleeding events were observed (<1%) that would still force a word of caution considering the antiangiogenic nature of sorafenib, which is true also for other agents in its class, such as bevacizumab and sunitinib, that may cause fatal hemorrhage (Siegel et al, 2008; Faivre et al, 2009).

A second randomized Phase III study to evaluate sorafenib in patients with advanced HCC and class A cirrhosis was conducted in the Asia-Pacific geographical area (Cheng et al, 2009). The study had eligibility criteria similar to the SHARP trial but had two differences in the design: 1) the study had a 2:1 randomization, typically to help encourage accrual, and 2) it did not have a predefined primary end point but rather looked at several. Similar to the SHARP trial, the Asia-Pacific study showed an improvement in survival in favor of sorafenib (6.5 months) versus placebo (4.2 months); however, this statistically significant improvement ($P = .014$) was not of the same magnitude as that of the SHARP trial, despite similar HRs—0.68 and 0.69, respectively—in the Asia-Pacific and SHARP studies. In an attempt to explain the difference in magnitude of the OS, it was argued that in the Asia-Pacific study, patients were more ill at the time of accrual (Abou-Alfa et al, 2009) and had more extensive disease at a more advanced stage. This observation may partly explain the difference in magnitude of benefit from sorafenib between those two populations, and it may suggest, in view of the similar HRs, that the benefit for sorafenib was expressed on the survival curve at two different times in the natural history of the disease: earlier in the SHARP trial and later in the Asia-Pacific study.

In a subgroup analysis of the SHARP trial, it was noted that sorafenib-treated patients with HCV-based HCC (n = 93) had a median survival advantage of 14 months compared with the entire sorafenib-treated group, whose survival was only 10.7 months (Bolondi, 2008); this suggests a possible positive influence of HCV status on the efficacy of sorafenib. The placebo-controlled HCV group did not have any added survival advantage over the placebo population of the study, thus proving the lack of any advantage brought on by the HCV itself. Of note, in HCV infection, the virus core proteins result in high basal activity of Raf-1, which leads to a sustained response to EGFR by hepatocytes and results in an increased possibility of neoplastic transformation (Giambartolomei et al, 2001). A similar observation was noted in a retrospective analysis of the Phase II trial that evaluated sorafenib in patients with advanced HCC (Abou-Alfa et al, 2006). In this analysis, it was noted that patients who were infected with HCV but not HBV (n = 13) had a longer time to progression of 6.5 months, compared with 4 months ($P = .05$) for the patients infected with HBV (n = 33; Huitzil et al, 2008). A similar trend was noted in survival advantage ($P = .29$) for the HCV patients (12.4 months) versus HBV patients (7.3 months), with 73% of those accrued in the Asia-Pacific study found to have HBV as an underlying etiology for their HCC, versus only 18% of patients in the SHARP trial; this may offer another explanation, or at least a complementary one, for this difference in the outcome magnitude between the two studies. Of note, the outcome of the 18% of patients with HBV in the SHARP trial for unspecified reasons is still not reported; however, this observation does undermine the antiangiogenic effect of sorafenib, which continues to be indicated for all patients with unresectable HCC irrespective of the etiology of their cancer.

Patients with unresectable HCC and CTP class A cirrhosis who are eligible for sorafenib based on the SHARP trial encompass no more than half of the patients seen by medical oncologists (Huitzil, 2010). The safety and efficacy of sorafenib in patients with class B or C cirrhosis, who make up the other half, remain a subject of discussion. In the Phase II study that evaluated sorafenib in HCC (Abou-Alfa et al, 2006), 28% of patients had class B cirrhosis and pharmacokinetic profiles that included area under the curve (AUC) and maximun drug concentration (Cmax) comparable to patients with class A disease. The class B patients had more frequent worsening of liver function, including elevated total serum bilirubin, worsening ascites, and encephalopathy (Abou-Alfa, 2008). Considering the lack of a control arm, these data cannot help determine whether this deterioration in liver function is part of the expected natural history of class B disease, a result of sorafenib, or a combination of these. The elevated total bilirubin may also be due to sorafenib's inhibitory effect of uridine diphosphate-glucouronosyl-transferase-1 polypeptide-1 (UGT1A1) and decreased bilirubin glucuronidation; because the study did not collect direct bilirubin measurements, this distinction cannot be made. Median TTP for class A patients was 21 weeks (95% CI, 16 to 25 weeks), and it was 13 weeks for class B patients (95% CI, 9 to 18 weeks); median OS was 41 weeks (95% CI, 36.6 to 63.6 weeks) and 14 weeks (95% CI, 11.6 to 25.7 weeks), respectively. In a phase I study that evaluated two different doses of sorafenib in Japanese patients with advanced HCC (Furuse et al, 2008), geometric means of $AUC_{0\text{-}12}$ and Cmax were slightly lower in patients with class B cirrhosis compared with class A disease despite the lack of any substantial differences in the incidence of adverse events between the two groups.

One additional study evaluated sorafenib in 150 patients with different types of tumors in cohorts of different levels of liver dysfunction, and their results offer some guidance on the use of sorafenib in such patients (Miller et al, 2009). Among all the cohorts with higher than normal total bilirubin, the most commonly reported drug-limiting toxicity (DLT) among patients was further elevation of bilirubin. The study suggested sorafenib doses of 400 mg PO twice per day for bilirubin up to 1.5 times the upper limit of normal (ULN) and 200 mg PO twice per day, or 400 mg PO daily, for bilirubin 1.5 to 3 times the ULN; it was recommended that sorafenib be avoided for patients whose bilirubin is above three times the ULN. These recommendations may at least be used as a guideline, until more data become available regarding the safety and efficacy of sorafenib in patients with HCC and class B or C cirrhosis; this would require a randomized study that allows assessment of the natural history of the disease, and ways of evaluating worsening

cirrhosis, in noninvasive ways that are also more predictive than measuring bilirubin levels.

Bevacizumab, an anti-VEGF, has been studied extensively in patients with advanced HCC. Bevacizumab was studied as a single agent in 46 patients with advanced HCC at doses of 5 mg/kg and 10 mg/kg (Siegel et al, 2008). Median PFS was 6.9 months, and median survival was 12.4 months. Grade 3 to 5 hemorrhage occurred in 11% of patients, including one death secondary to a variceal bleed. In the initial phase of this study with 18 patients accrued, 4 had to discontinue therapy because of serious adverse events, including one transient ischemic attack and three serious esophageal bleeding events. The study was thus modified to identify and manage esophageal varices prior to enrollment (Schwartz et al, 2005). Another study that evaluated single-agent bevacizumab in HCC showed similar results (Malka et al, 2007). Among 24 patients evaluable for response, 3 had a partial response and 13 had stable disease.

Sunitinib, a multitargeted receptor tyrosine kinase inhibitor, was evaluated as a single agent in patients with advanced HCC as part of a Phase II study (Zhu, 2009). Of 34 patients treated with sunitinib at a 37.5 mg daily dose, 50% of patients had stable disease, with a median PFS of 3.9 months and an OS of 9.8 months. The most common grade 3 and 4 adverse events included hematologic toxicities, fatigue, and transaminase elevation; in addition, two deaths were reported and attributed to worsening disease and liver failure. A second well-conducted study evaluated sunitinib at a higher dose of 50 mg/day in 37 patients with advanced HCC; however, it did not move to a planned second stage because of a low response rate of 2.7% in the first stage of the study (Faivre et al, 2009). In addition, four deaths were reported that were interpreted as possibly drug related; these included events of hepatic encephalopathy, hematologic toxicities, and a variceal bleed. Despite those findings, enthusiasm continues regarding the potential therapeutic value of sunitinib, which is being studied as part of a Phase III clinical trial to evaluate sunitinib versus sorafenib in patients with advanced HCC.

Brivanib, a dual inhibitor of VEGF and fibroblast growth factor (FGF), was also studied in HCC. In a study that evaluated brivanib as first- and second-line therapy in 96 patients with advanced HCC, limited responses were reported, and OS was 10 months in the treatment-naïve cohort and was not reached in the second-line cohort (Raoul et al, 2009). Although the OS compared favorably to the historic control, PFS was only 2.7 months in the treatment-naïve group, and TTP was only 2 months in the second-line group; however, the drug was well tolerated in the second-line setting (Finn et al, 2009). Another drug recently studied in advanced HCC is ABT-869, a VEGF and PDGF inhibitor. In a recently reported Phase II study of 44 patients, of whom 38 had class A and 6 had class B liver dysfunction, the class A patient outcome was equivalent to historic controls, with a median OS of 9.7 months and TTP of 5.4 months. Despite this similarity in outcome, and with the lack of any apparent advantage over sorafenib (Llovet et al, 2008), both brivanib and ABT-869 are currently being evaluated in large randomized Phase III trials against sorafenib.

Combination Therapy Studies with Antiangiogenics

Bevacizumab is the antiangiogenic most studied in combination with various other agents. Several Phase II studies have evaluated bevacizumab in combination with chemotherapy. Gemcitabine and oxaliplatin plus bevacizumab were examined in a Phase II trial in 30 previously treated HCC patients (Zhu et al, 2006). The objective response rate was 20%, and 27% of patients had stable disease; median PFS was 5.3 months, and median OS was 9.6 months. The most common grade 3 and 4 toxicities included leucopenia and neutropenia, elevation of transaminases, hypertension, and fatigue.

Another Phase II study evaluated the combination of bevacizumab, oxaliplatin, and capecitabine in 30 patients with advanced HCC (Sun et al, 2007). Partial response was noted in 13.3% of the patients, and 76.7% had stable disease. Median PFS and median OS were 4.5 and 10.6 months, respectively. Toxicity was not trivial: 33% of the patients sustained grade 2 or 3 peripheral neuropathy, and 11% experienced grade 2 or 3 hand-foot syndrome. In addition, three bleeding events, one gastrointestinal perforation, and two variceal hemorrhages were reported. Bevacizumab plus capecitabine only was also studied in 25 patients with advanced HCC and yielded parallel results (Hsu et al, 2007), with median PFS of 4.1 months and OS of 10.7 months. The most common treatment-related grade 3 toxicity was hand-foot syndrome, and one gastric ulcer hemorrhage was reported.

Bevacizumab was also studied in combination with erlotinib in 40 patients with HCC and class A or B cirrhosis and an Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 2. Bevacizumab was administered at a dose of 10 mg/kg every 2 weeks, and erlotinib was given PO daily at 150 mg (Thomas, 2009). The primary end point at 16 weeks for PFS was 62.5%, with median PFS of 39 weeks; median OS was 68 weeks, and the response rate was 25%. The most common grade 3 or 4 drug-related toxicities were fatigue (20%), hypertension (15%), diarrhea (10%), elevated transaminase levels (10%), and gastrointestinal hemorrhage (12.5%). A randomized Phase II study of erlotinib, bevacizumab, and sorafenib was also started.

Sorafenib has also been evaluated in combination with biologic therapy and chemotherapy in two separate studies: despite the almost inexistent data (Duran et al, 2007) on the combination in HCC, one ongoing randomized Phase III study was initiated to evaluate sorafenib plus erlotinib versus sorafenib alone in patients with advanced HCC; the other study was a randomized Phase II study that evaluated doxorubicin plus sorafenib and doxorubicin plus placebo in 96 patients with advanced HCC and class A cirrhosis (Abou-Alfa, 2008). The primary end point, median TTP, was 9 months for the doxorubicin-sorafenib arm and 5 months for the doxorubicin-placebo arm. An exploratory comparison of OS between the two arms showed a significant difference of 13.7 months in favor of doxorubicin and sorafenib versus 6.5 months for doxorubicin and placebo ($P = .0049$; HR, 0.45). In both arms of this study, grade 3 and 4 toxicities included fatigue (15%) and neutropenia (50%). In the combination arm, sorafenib-related toxicities included grade 3 and 4 diarrhea (11%) and grade 3 and 4 hand-foot syndrome (9%). In addition, more left ventricular dysfunction was reported in the doxorubicin-sorafenib arm, observed in 19% of the cases (all grades), most of which were subclinical and caught solely on a Multiple Gated Acquisition test (MUGA) or echocardiography evaluation, with only 2% clinical grades 3 or 4.

A potential synergistic effect between doxorubicin and sorafenib is suggested that may explain the improved outcome as well as the increased cardiac function. Anthracyclines such as doxorubicin depend on Ask-1 to exert their apoptotic effect. In

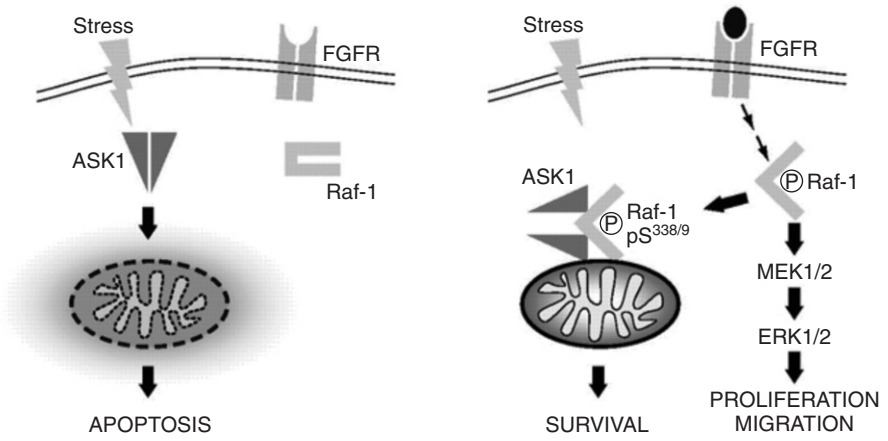


FIGURE 88.3. A model depicting the role of Raf-1 in regulation of ASK1-mediated apoptosis. At the mitochondria, bFGF-mediated activation of Raf-1 promotes a complex between Raf-1 and ASK1, leading to inhibition of ASK1 kinase activity and prevention of stress-mediated apoptosis. ASK1, apoptosis signal-regulating kinase-1; ERK, extracellular signal-regulated kinase; FGFR, fibroblast growth factor receptor; MEK, mitogen-activated protein kinase/ERK kinase; Raf-1, rapidly growing fibrosarcoma (protein). *(From Alavi AS, et al, 2007: Chemoresistance of endothelial cells induced by basic fibroblast growth factor depends on Raf-1–mediated inhibition of the proapoptotic kinase, ASK1. Cancer Res 67[6]:2766-2772.)*

cancer cells, a basal fibroblast growth factor (bFGF)-mediated activation of Raf-1, a target of sorafenib, may promote a complex between Raf-1 and ASK1 at the mitochondrial level that leads to inhibition of Ask-1 kinase activity and prevention of stress-mediated apoptosis of anthracyclines. Inhibiting RAF kinase activity with sorafenib may release Ask-1 and restore the apoptotic activity of doxorubicin (Alavi et al, 2007; Fig. 88.3). A large, randomized, Phase III trial was recently initiated to evaluate the combination of sorafenib and doxorubicin versus sorafenib alone, and it will answer the question regarding the potential synergy between sorafenib and doxorubicin.

Second-Line Therapies

With the advent of sorafenib as a first-line agent in the treatment of HCC, efforts to study second-line treatments have already been noticed. Brivanib has already been tested in the second-line setting (Finn et al, 2009; Raoul et al, 2009), and it is currently being evaluated against placebo in a large, randomized Phase III trial.

ASSESSMENT OF RADIOLOGIC RESPONSE IN HEPATOCELLULAR CARCINOMA

In contrast to early clinical trials conducted in the 1970s, in which assessment of response was mainly dependent on clinical evaluation, the advent of radiologic technologies, such as contrast-enhanced computed tomography (CT) and triphasic CT scanning (see Chapter 16) and magnetic resonance imaging (MRI; see Chapter 17), have helped improve our ability to assess disease extent and tumor response to therapy in a more objective manner. Despite these improved imaging modalities, HCC remains one of the most difficult tumors to evaluate radiologically; this is due in part to the infiltrative nature of these tumors, their poor margination, and their hypervascularity, all of which make it hard to define their exact margins. In addition, there is growing recognition that response can also be assessed through dynamic measures, such as necrosis and blood flow to the tumor.

In the Phase II trial that evaluated sorafenib in patients with advanced HCC, tumor necrosis was noted in the absence of actual tumor regression (Abou-Alfa et al, 2006). This was associated with declines in AFP in several patients and in improvement of symptoms. A subanalysis to evaluate the correlation between tumor necrosis and response followed (Abou-Alfa, 2008). Triphasic CT scans of 12 patients from the study were evaluated; 5 patients were found to have stable disease or stable disease with necrosis, and 7 progressed on therapy. Median survival was based on a landmark analysis computed from the date of the last CT scan to the date of death or last follow-up to ensure that all probability estimates and statistical tests were conditional on the response status of patients at the landmark time (Anderson et al, 1983). The landmark analysis-based median survival was 4.8 months among responders and 3.1 months among nonresponders. The ratio of tumor necrosis and volume (TN/V) was significantly associated with response, with responders having greater increases in the TN/V relative to baseline compared with nonresponders ($P = .02$). TN/V was not significantly associated with OS and surely needs to be further evaluated prospectively as part of a large clinical trial.

Dynamic contrast-enhanced MRI (DCE-MRI) has been shown to be useful in studying the pathophysiology of tumors (Taylor, 1999; Yuh, 1999) and possibly response (Morgan et al, 2003). In view of the antiangiogenic activity of drugs like sorafenib in HCC, this technology could be helpful in assessing parameters of interest, such as microvascular density, vascular permeability, and the extravascular extracellular space (Knopp et al, 1999). DCE-MRI has also been investigated as an early indicator of response or failure of an agent. Several studies have shown that successful therapies result in early changes (within 48 hours) in DCE-MRI contrast-enhancement parameters, which may prove to be a more accurate early indication of response (Barentsz et al, 1998; Brasch et al, 1997; Pham et al, 1998). In the Phase II study evaluating sunitinib in 34 patients with advanced HCC (Zhu, 2009), DCE-MRI was performed and showed a sunitinib-related rapid decrease in vessel leakiness, and this effect was more pronounced in patients with delayed progression. In the randomized Phase II study that evaluated doxorubicin plus sorafenib and doxorubicin plus placebo in patients with advanced HCC (Abou-Alfa, 2008), DCE-MRI scans obtained on six patients showed no significant association between response and changes in k_{ep}, $K^{trans,}$ and AFP, but a trend toward significant association was observed between response and AUC180 ($P = .07$; Abou-Alfa et al, 2009). DCE-MRI as a surrogate of response needs to be better evaluated as part of a large clinical study.

NEOADJUVANT AND CONVERSION THERAPY

In some instances, surgical resection of a large, localized primary HCC tumor might be feasible, if disease regression was

achieved. Conversion therapy as a concept may render some unresectable tumors surgically approachable (see Chapter 87); it may also contribute to better outcome by possibly eradicating microscopic local and systemic disease, in contrast to neoadjuvant therapy, which is potentially given to patients considered resectable a priori. Different modalities have been studied in the context of conversion therapy for HCC, but none thus far has been shown to add any survival benefit over surgery alone. Bridging to transplant may be considered under the same umbrella, in view of its goal of maintaining or reducing a tumor size to fit within the transplant (Milan) criteria (Mazzaferro, 1996).

Transarterial chemoembolization (TACE) has been evaluated in multiple randomized studies. A randomized trial of one to five TACE applications prior to surgery (n = 24) versus surgery alone (n = 28) did not offer a benefit as neoadjuvant therapy (Wu et al, 1995). TACE had no effect on 33% of the patients who had the intervention, and they either remained with stable disease or had progression. No difference was found between the two groups in operative morbidity or mortality rates and pathologic staging. The disease-free survival (DFS) rate in the two groups was similar, but the incidence of extrahepatic cancer recurrence was higher in the neoadjuvant group (57% vs. 23%; $P = .03$), and 5-year survival was also significantly worse in the TACE group (30% vs. 60%; $P = .01$).

The experience with transarterial embolization (TAE, without chemotherapy) has not been any different. In a study that randomized 97 patients to TAE plus surgery versus surgery alone, DFS did not differ between the two groups (39 vs. 31.1 months) despite an increased rate of necrosis in the TAE group (Yamasaki et al, 1996).

The experience with yttrium-90 TheraSpheres (MDS Nordion, Kanata, Canada) in the treatment of locally advanced HCC continues to expand (Salem et al, 2002; see Chapter 84A). A new study to evaluate sorafenib with or without ^{90}Y in patients awaiting transplant is underway. In addition, limited experience has been gained with immunoembolization (Lygidakis & Tsiliakos, 1996), radiation (Tang et al, 1995), and chemoradiation (Sitzmann & Abrams, 1993); however, none of these techniques have so far been shown to confer a survival advantage when administered in the neoadjuvant setting.

Chemotherapy-based clinical trials in the conversion therapy setting have lagged because of the discouraging response rates seen in the advanced disease setting. This has changed somewhat with the advent of the more intense chemoimmunotherapeutic combination of cisplatin, interferon, doxorubicin, and 5-FU, also known as PIAF (Patt et al, 1999). In the Phase II study discussed above of 50 patients with unresectable HCC, 13 (26%) had a partial response (Leung et al, 1999). Of those 13 patients, 9 (18%) underwent surgical resection, and 4 had a pathologic complete response, meaning no viable tumor was evident at surgery. Unfortunately, PIAF did not stand up to a randomized Phase III trial (Yeo et al, 2005) against doxorubicin in the advanced disease setting, and it is important to recall that the PIAF combination carries substantial treatment-related morbidity and mortality. The majority of those patients who had excellent performance status had grade 3 or higher hematologic toxicity, and two deaths occurred secondary to neutropenic sepsis. The role of PIAF may therefore be limited to those very thoroughly reviewed cases in a multidisciplinary clinic or conference, where conversion therapy may be valuable to a patient with a potentially resectable tumor.

ADJUVANT THERAPY

Regardless of surgical techniques, which have improved in the last decade, a high number of patients with resected HCC will have recurrence of their disease (Ziparo et al, 2002). In a recent series, the recurrence rate after surgical resection was 55% after 26 months' follow-up (Cha et al, 2003). The experience with liver transplantation has been better, with lower recurrence rates; however, these are nonrandomized comparisons, and transplant patients are more carefully selected and in general have a lower volume of disease (Mazzaferro, 1996). Although liver transplantation eliminates the cirrhotic fertile ground for recurrence (Nissen et al, 2004), it unfortunately cannot be the answer for every patient with HCC, not only because of the limited supply of organs but also because of its limited efficacy in anything other than small tumors; thus the question of whether adjuvant therapy reduces the risk of recurrence after surgical resection remains an important and pressing one.

With the lack of a standard, active systemic chemotherapy for advanced disease, chemotherapy has never been seriously considered in the adjuvant setting. One very small, randomized study investigated oral carmofur (1-hexylcarbamoyl-5-fluorouracil) versus no therapy (Yamamoto et al, 1996). The study randomized and stratified 67 patients based on their Liver Cancer Study Group of Japan (LCSGJ) staging (LCSGJ, 1994). The regimen was poorly tolerated and offered no survival advantage for either stage I or II disease. DFS for the stage I patients showed a tangible advantage of 60% versus 30% at 3 years and 50% versus 20% at 5 years ($P = .04$). This trial was suspended prematurely, because 56% of the treated patients had unacceptable side effects.

Hepatic arterial chemotherapy, with or without systemic chemotherapy, has also been utilized in the adjuvant setting in HCC. An underpowered randomized study that combined hepatic arterial epirubicin and systemic epirubicin and carmofur versus no further therapy (Ono et al, 1997) showed no survival or DFS benefit. Side effects again led to the discontinuation of therapy in 21% of randomized patients. In addition, a randomized trial of hepatic artery epirubicin versus the same plus oral tegafur showed no difference in survival or rate of recurrence between the two groups (Kohno, 2004), and no description of any difference in side effects between the two arms was reported.

TAE, both bland and with chemotherapy, was studied in the adjuvant setting. An improvement in DFS was reported in a randomized study of a bolus hepatic arterial infusion (HAI) of Lipiodol containing doxorubicin and mitomycin C versus no adjuvant therapy after surgical resection (32% vs. 12% at 3 years; $P = .02$) (Izumi et al, 1994); however, no survival advantage was reported. Another trial randomized patients to a hepatic artery emulsion of iodized oil and cisplatin and intravenous epirubicin (Lai et al, 1998). This trial showed a worse DFS in the treatment group at 3 years (18% vs. 48%; $P = .04$). A third study of TACE versus no further therapy after surgical resection was able to show a survival advantage in patients defined at risk for residual tumor and thus recurrence (Ren et al, 2004). These risk factors included tumor diameter more than 5 cm, multiple nodules, and vascular invasion; 5-year survival was 44.36% in the adjuvant TACE group versus 37.40% in the control group ($P = .0216$).

More promising data in the adjuvant setting comes from the use of transarterial ^{131}I-Lipiodol (Lau et al, 1999). In a randomized phase II trial evaluating transarterial ^{131}I-Lipiodol versus

no adjuvant therapy after surgical resection, an improvement was seen in DFS in the adjuvant therapy arm of 74% versus 36% in the control arm (P = .037). In addition, 3-year OS improved and was reported in 85% of the treatment group versus 46% of the control group (P = .039). A recent update showed the actuarial 5-year DFS in the treatment and control groups to be 61.9% and 31.8%, respectively (P = .0397), and the actuarial 5-year OS in the treatment and control groups was 66.7% and 36.4%, respectively (P = .0433); however, 7 years after randomization, the DFS and OS benefits lost their statistical significance (Lau et al, 2008). It should be noted that ^{131}I-Lipiodol is not available in the United States.

Immune modulators have also been tested in the adjuvant setting, including an attempt at infusing autologous lymphocytes cultured with interleukin (IL)-2 and antibodies to CD-3 versus no therapy (Takayama et al, 2000), HAI of doxorubicin and IL-2 plus an infusion of lymphokine-activated killer (LAK) cells versus HAI of doxorubicin (Kawata et al, 1995), oral acyclic retinoids versus placebo (Muto et al, 1996), and interferon-α versus no therapy (Kubo, 2001). None of those studies reported a survival advantage with the exception of the retinoid study, which did on further follow-up and 2 years after the study was originally reported (Muto et al, 1999); in addition, 6-year survival was 74% in the acyclic retinoid group versus 46% in the placebo group (P = .04).

Active immunization has also been evaluated in the adjuvant setting for HCC. An HCC vaccine consisting of autologous formalin-fixed tumor tissue fragments, biodegradable microparticles containing human granulocyte macrophage colony-stimulating factor and human IL-2, and tuberculin (autologous formalin-fixed tumor [AFTV]) was tested in a small, randomized trial (Kuang et al, 2004). Nineteen patients received three intradermal vaccinations at 2-week intervals beginning 4 to 6 weeks after hepatic resection, and 22 patients received no further therapy after surgical resection. In a median follow-up of 15 months, the risk of recurrence in the vaccinated patients was reduced by 81% (P = .003). Vaccination significantly prolonged OS by 89% (P = .01). AFTV was most effective in preventing recurrence in patients with small tumors; in addition, 12 vaccinated patients showed a positive delayed-type hypersensitivity response, and 92% of those patients were recurrence-free at the end of the trial. Adverse effects were limited to grade 1 or 2 skin toxicities, such as erythema, dry desquamation, and pruritus. Again, this is a very small trial that is intriguing, but larger confirmatory data are required before the merits of this approach can be fully assessed.

A more aggressive approach was attempted in a very small pilot study of five patients who, after undergoing orthotopic liver transplantation (OLT) for HCC, received a nonmyeloablative preparative regimen of fludarabine combined with total-body irradiation or cyclophosphamide followed byallogeneic peripheral blood stem cell transplant (PBSCT), which was performed 16 to 135 days after OLT with human leukocyte antigen-matched donors (Soderdahl et al, 2003). The aim of the study was to see whether a stable mixed-donor chimerism could be sustained, which was observed in one of two patients with HCC in the study. Chimerism analysis 36 days after PBSCT showed 100% donor T cells and 90% donor myeloid cells in peripheral blood. The patient was reportedly doing well, albeit after only 10 months follow-up after OLT. Sorafenib is also being evaluated in the adjuvant setting.

It is clear that investigators have utilized almost every therapeutic modality to attempt to reduce the risk of recurrence of HCC after surgical resection or transplantation. Although some rare positive outcomes have been reported, most were either part of very small series or lacked the statistical power to show true evidence of a survival advantage. Until these issues and many others, such as the molecular predictors of recurrence, are answered or identified, no standard adjuvant therapy can be recommended for resected HCC; therefore adjuvant treatment outside of a clinical trial cannot be supported by available data at this time.

CONCLUSION

The incidence of HCC is on the rise, especially in developed countries, mainly as a result of an increased incidence of hepatitis C. Trying to treat HCC means that both the underlying cirrhosis and the cancer must be addressed. A thorough understanding of the cirrhosis is imperative as part of understanding the status of the disease and to help identify the appropriate therapies that a physician might recommend.

In the case of advanced HCC, sorafenib has shown an improvement in survival and thus can be considered an appropriate standard treatment. Other novel therapies and combinations of biologics and chemotherapies continue to be evaluated in advanced HCC.

Finding a better therapy for advanced HCC does not mean only developing better therapeutics, it also means finding a better way to assess the disease. The infiltrative nature of HCC, poor margination, and hypervascularity limits the use and benefit of the standard radiologic techniques, such as CT and MRI. Newer modalities that evaluate the necrosis and dynamic aspects of the cancer are in development and parallel the investigation of novel biologics in the treatment of HCC.

Thus far, neoadjuvant and adjuvant therapies have failed to be proven effective in HCC. Systemic therapy is a critical component of the managing of patients with advanced HCC.

CHAPTER 89

Isolated hepatic perfusion for extensive liver cancer

James Pingpank Jr.

OVERVIEW

Each year, isolated hepatic metastases from a variety of primary malignancies pose a significant clinical dilemma for tens of thousands of patients. For a small percentage of patients, surgical resection or ablation is effective in controlling clinically apparent disease, but for many patients with colorectal, gastrointestinal, or neuroendocrine tumors or ocular melanoma, the number of tumors and volume of affected liver render resection and/or ablation incapable of meaningful disease control (see Chapter 81). In more selected circumstances, metastases arising from tumors of the breast, skin, and soft tissue can be present solely as hepatic disease, with patient quality of life and survival dictated by the ability to control liver-based disease.

Since the 1950s, strategies designed to focus chemotherapy solely upon liver metastases have been investigated by a number of researchers at a limited number of institutions around the world, with sequential improvements in safety and efficacy observed with advances in surgical and catheter-based technology. Isolated hepatic perfusion (IHP) has been developed under a series of clinical trials within institutions with experience in regional therapies to the liver, limb, and lung, approaches that share a common goal of intensifying focused treatment to the cancer-bearing region of the body, while minimizing systemic drug exposure and toxicity. Regional isolation of drug delivery allows for unaffected tissue to be spared from drug exposure, and potential associated toxicity, via complete separation of the regional and systemic circulation; thus dose escalation of therapeutic agents is limited largely by the tissue tolerance of the perfused organ or limb. For agents with a sharp dose-response curve, such as melphalan, improved efficacy manifested via increases in tumor response can be observed as the absence of bone marrow and gastrointestinal visceral exposure to the drug, allowing dose escalation into more clinically relevant dose levels.

Based on its unique vascular anatomy (see Chapter 1B), the liver is a favorable site for delivery of regional therapy (see Chapter 86), as complete control of circulatory inflow and outflow can be readily obtained. Additionally, established tumors in liver derive the majority of blood flow from the arterial tree, and the portal vein is maintained as the primary source of nutrient flow to the hepatic parenchyma, allowing intra-arterial delivery to effectively concentrate drug within tumor-bearing areas of the liver. Animal models demonstrate that nearly 100% of blood delivered to tumors arises from the arterial circulation versus 25% for normal liver (Breedis & Young, 1954; Ridge et al, 1986). The ability to obtain complete vascular isolation also permits the delivery of clinically relevant levels of hyperthermic and/or biologic agents that would otherwise be too toxic or technically impractical to deliver. For patients with multiple hepatic metastases, the likelihood of additional subclinical disease being present within the liver increases with greater tumor volume, and thus the ability to treat the entire diseased organ through regional perfusion strategies allows the targeting of micrometastatic disease within the diseased organ.

The initial report detailing the clinical use of IHP was published in 1961 by Robert Ausman from the Roswell Park Cancer Center, describing his experience with both a porcine treatment model along with five treated patients (Ausman, 1961). In this brief report, evidence of antitumor efficacy was seen in two patients after a 60-minute perfusion with melphalan. Over the ensuing 2 decades, additional small series examined the utility of prolonged hyperthermic perfusions (Skibba & Quebbeman, 1986) without drug, as well as normothermic perfusions utilizing melphalan (Hafström et al, 1990) or mitomycin-C and 5-fluorouracil (5-FU) (Aigner et al, 1988), and were described by Skibba (Medical College of Wisconsin) and multiple European groups, respectively. The absence of long-term follow-up and the presence of significant toxicity prevented widespread adoption of this approach, until interest in the field of regional therapy was reignited by Leinhard and colleagues' 1992 publication that detailed the successful delivery of a combination of melphalan, tumor necrosis factor (TNF), and interferon-α via hyperthermic isolated limb perfusion in a group of 29 patients with advanced extremity sarcoma or melanoma. Clinical results demonstrated a 90% complete response rate for patients with in-transit melanoma along with an 80% limb salvage rate for patients with advanced sarcoma. Of equal or greater significance was the demonstration that meticulous surgical technique could result in very effective vascular isolation with a resultant decrease in out-of-field drug exposure and associated toxicity. When this increased attention to circuit integrity and leak monitoring was applied to patients undergoing IHP, a similar decrease in systemic toxicity permitted more widespread investigation of this clinical approach.

Within the United States, a significant effort in the development and refinement of vascular isolation-perfusion techniques was initiated by Drs. Douglas Fraker and Richard Alexander within the Surgery Branch of the National Cancer Institute (NCI) (Alexander et al, 1998, 1999).

SURGICAL TECHNIQUE

Preoperative evaluation of patients thought suitable for IHP should include an assessment of the patients' overall cardiovascular risk factors, the extent of both intrahepatic and extrahepatic tumor malignancy, and an assessment of the liver functional status (see Chapter 2). Standard preoperative cardiac

clearance should include a treadmill stress test, as the induction of venovenous stress can lead to the induction of atrial fibrillation in patients so disposed. Hepatic reserve is important to assess, as the dose-limiting toxicity observed in Phase I trials was liver based, and it was seen in patients with more than 50% of hepatic replacement with tumor or a serum bilirubin level higher than 3 mg/dL. For patients with colorectal cancer and a significant chemotherapy history that includes either oxaliplatin and/or irinotecan, a biopsy assessment of the uninvolved hepatic parenchyma must be done to rule out extensive portal inflammation, hepatic congestion, and steatohepatitis (see Chapter 65). Patients who have had extensive portal of hepatic venous dissection associated with major hepatectomy should be approached with caution.

IHP is performed under general anesthesia via an upper midline incision, with a right flank transverse extension once extrahepatic disease is ruled out. In patients in whom the primary tumor remains in situ, a full midline incision is indicated. The presence of extrahepatic disease other than periportal lymphadenopathy or primary tumor amenable to complete resection is a contraindication to perfusion.

Preparation of the liver for perfusion includes completion of a cholecystectomy and full mobilization the liver (Alexander, 2005; Libutti et al, 2000). All lateral attachments are taken down so that the vena cava is fully visualized, and all retroperitoneal venous tributaries are taken down to ensure there will be no leak of chemotherapy from the isolated segment of the retrohepatic inferior vena cava (IVC). The duodenum is mobilized, and the IVC is mobilized from the renal veins to the hepatic veins. The right adrenal vein is suture ligated and divided, but both phrenic veins are preserved. The hepatic artery is identified, and the gastroduodenal artery (GDA) is mobilized from its origin for a length of 2 cm to serve as the arterial inflow catheterization site. Nodal tissue in the porta hepatis is dissected to allow clamping of the portal structures, with the hepatic artery clamp proximal to the takeoff of the GDA. Minor accessory right and left hepatic vessels may be ligated, but replaced or accessory arteries of a significant size are prepared for cannulation along with the GDA.

After completion of dissection, the patient is heparinized to an activated clotting time longer than 400 seconds. An external venovenous bypass circuit is established by placing a cannula into the left femoral vein and advancing it into the infrarenal IVC and then advancing a second cannula through the internal jugular vein into the superior vena cava (SVC). This allows maintenance of the systemic circulation by actively shunting IVC blood during treatment. Once the venous bypass has been established, the intrahepatic (IHP) circuit is constructed (see Fig. 89.1), and the GDA is ligated distally. The inflow perfusion cannula is positioned in the proximal GDA; once it has been secured, a cross clamp is placed across the entire porta hepatis, including the common hepatic artery, bile duct, and portal vein. The perfusion outflow cannula is inserted into the retrohepatic IVC via a percutaneous cannulation of the right femoral vein, and a tourniquet is placed around the cannula at the level of the suprarenal infrahepatic IVC. The suprahepatic IVC is then cross clamped, completing the vascular isolation of the liver, and perfusion is initiated; the perfusate consists of approximately 500 mL Ringer's lactate to which 2 U packed red blood cells are added.

Once perfusion is initiated, flow through the isolated circuit is maintained between 400 and 600 mL/min. The routine use of leak monitors has been abandoned, as detectable leak is rare in the presence of a stable circuit reservoir (Barker et al, 1995). Temperature probes are placed into the anatomic right and left lobes of the liver, and the perfusate is heated to maintain hepatic

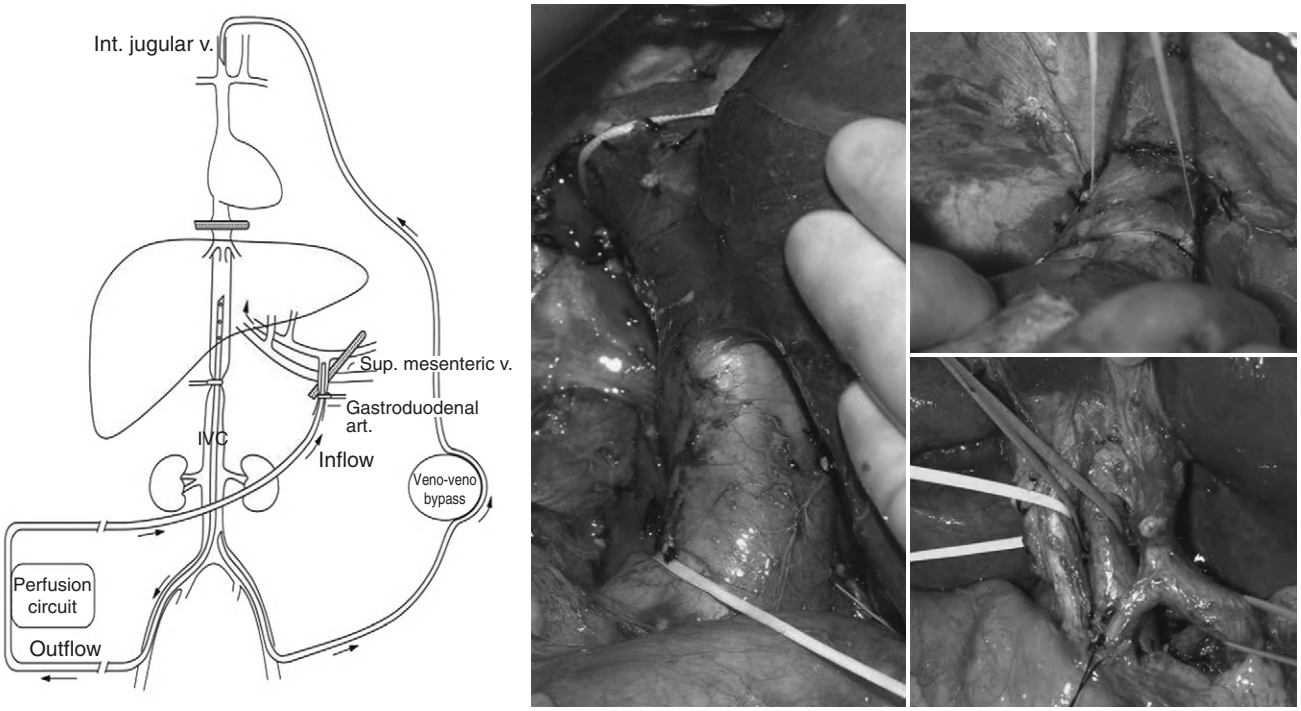

FIGURE 89.1. Schematic of the intrahepatic perfusion circuit, detailing both the hepatic perfusion circuit and the venovenous bypass circuit. The procedure is associated with an extensive dissection of the retrohepatic and suprahepatic inferior vena cava (*IVC*) and a full portal dissection. art., artery; v., vein.

hyperthermia of 40° C. Once hyperthermia is obtained, and perfusion parameters are stable, melphalan (1.5 mg/kg ideal body weight) is administered into the arterial limb of the isolated perfusion circuit over 5 minutes. The liver is perfused for 1 hour, after which time the circuit is flushed with 2000 mL saline and 500 mL colloid to flush all chemotherapy from the hepatic vasculature. The portal and suprahepatic IVC clamps are removed to allow native blood flow to be restored. The GDA is either suture ligated or a hepatic arterial infusion pump is placed. The venovenous bypass circuit is halted, and both the femoral vein and right internal jugular vein catheters are removed; anticoagulation is reversed with protamine and 2 U fresh frozen plasma.

Postoperative care focuses on the maintenance of normal coagulation profiles and standard fluid resuscitation (see Chapter 22). Heparin should be avoided, as high levels of heparin-induced antibodies are common (Masucci et al, 1999); this phenomenon is rare but can lead to devastating consequences, if heparin is administered in the early postoperative setting.

Pharmacokinetic analyses performed during early phase IHP trials have demonstrated that complete vascular isolation is routinely achieved with no detectable levels of melphalan in the systemic circulation (Lans et al, 2001). A small amount of systemic drug observed in the immediate postperfusion period has been addressed by unclamping the portal clamp for 10 seconds during the washout phase, facilitating clearing of the portal circulation. A transient significant elevation of aspartate and alanine transaminases was universally observed but was self-limited and resolved within 7 days. Biliary congestion and cholestatic jaundice is rare when proper patient selection is maintained with regard to underlying liver disease and tumor volume. Overall operative mortality rate is 4% across single-institution experiences (Alexander, 2005), and operative times and blood loss have decreased with the implementation of less invasive catheterization techniques, with operative times of less than 5 hours and mean operative blood loss less than 500 mL. An additional 500 mL of blood loss results from the removal of melphalan-contaminated hepatic circuit blood. Recent dose-escalation studies performed by Zeh and Bartlett at the University of Pittsburgh have demonstrated effective isolation and safety utilizing both 5-FU and oxaliplatin (Colville et al, 2010).

RESULTS

Colorectal Cancer (See Chapters 81A and 86)

The greatest volume of data regarding clinical effectiveness of IHP can be found for patients with metastatic colorectal cancer treated at two institutions: the Surgery Branch of the NCI in Bethesda, MD, and the Leiden Medical Center in the Netherlands. In a series of 154 patients reported by Van Iersel and colleagues (2008), 105 patients were deemed eligible for IHP at laparotomy. A 50% response rate with a median survival of 11.4 months was reported in treated patients, with improved survival associated with the delivery of adjuvant systemic chemotherapy. The primary site of progressive disease was intrahepatic, either in isolation (68%) or associated with other systemic progression (18%).

Alexander and colleagues (2005, 2009) reported a series of 120 patients treated with melphalan-based IHP over an 11-year period ending in 2005 at the NCI in Bethesda. The majority of patients received melphalan alone (n = 69) or in combination with TNF (n = 41), with an additional 10 patients receiving TNF alone. The latter small cohort of patients did not appear to show any clinically meaningful benefit from IHP. Overall, this was a heavily pretreated patient group: 74 patients had received systemic or liver-directed therapy for their metastatic disease. A median overall survival (OS) of 17.4 months was achieved, with a 2-year survival rate of 34% and an overall response rate of 61%. Five treatment-related mortalities were reported, but three of these events were associated with the Phase I dose-escalation portion of the program. A multivariate analysis of factors associated with hepatic progression-free and OS demonstrated that a preoperative carcinoembryonic antigen (CEA) level less than 30 and the ability to successfully administer postoperative hepatic arterial embolization (HAI) therapy with fluorodeoxyuridine (FUDR) (see Chapter 86) were associated with significant gains in both outcomes. Of interest, neither response rate nor duration of survival was impacted negatively with a history of previous chemotherapy, contrary to observations made in other second-line approaches.

Recently, Zeh and colleagues (2009) published a Phase I dose-escalation trial that examined the use of oxaliplatin administered via the IHP circuit, with dosing based upon ideal body weight. Dose-limiting hepatic venoocclusive disease was noted at 60 mg/m^2, establishing the maximally tolerated dose of 40 mg/m^2, at which minimal hepatic toxicity was observed (Zeh et al, 2009). Although only 10 patients were included in this report, the assessment of overall response at 6 months was 66% based on Response Evaluation Criteria in Solid Tumors (RECIST). An additional Phase I trial examining dose escalation of 5-FU paired with fixed-dose oxaliplatin is ongoing (Table 89.1).

Ocular Melanoma (See Chapter 81C)

Ocular melanoma has the unique ability to metastasize to the liver in the absence of clinically apparent extrahepatic disease, with liver failure being a significant source of mortality in this patient population. Of the approximately 4000 patients who have ocular melanoma develop on an annual basis in the United States, nearly 50% will develop metastatic disease; in 80%, the liver will be the sole or life-limiting site of spread. The group from the surgery branch at the NCI reported an overall response rate of 62%, including a 10% complete response in 29 patients treated with melphalan alone via the IHP circuit (Alexander et al, 2003). OS for all treated patients was 12 months, with a median progression-free survival (PFS) of 8 months. In those patients who achieved a response by RECIST criteria, the median duration of response was 10 months, with the majority of patients (66%) experiencing hepatic progression as the initial site of progressive disease. Transient, self-limited grade 3 or 4 toxicity was observed in noted in 19 patients, with no treatment mortalities; however, patient-selection criteria limited treatment to individuals with less than 50% hepatic replacement with tumor, and elevations in preoperative lactate dehydrogenase were observed as a strong predictor of poor outcome.

Several European groups reported similar experiences in cohorts of patients with metastatic ocular melanoma, including Noter and colleagues (2004) and Rizell and colleagues (2008); both supported the results of Alexander and others. Noter and colleagues at the Leiden University Medical Center treated 8 patients with a fixed dose of 200 mg melphalan for 60 minutes;

Tumor Characteristics	
Number of metastatic lesions, median (range)	8 (1 to 50)
Percentage of liver replaced by tumor, median (range)	20% (5% to 75%)
Preoperative CEA Level	
Normal	14
High, stable	15
High, increasing	81
Unknown	10
Type of Liver Metastases	
Synchronous	79
Metachronous	41
Prior Chemotherapy	
Chemotherapy for established liver tumors (5-FU/LV and CPT-11 or HAI)	74
Chemotherapy as adjuvant (5-FU/LV, at least 4 cycles)	20
None	26
Perfusion and Operative Data, Median (Range)	
Total melphalan (mg) dosed at 1.5 mg/kg	105 (69-160)
Tumor necrosis factor dose (mg)	1 (0.3-2.0)
Perfusion flow rate (mL/min)	800 (550-1350)
Perfusion pressure (mm Hg)	145 (70-255)
Bypass flow rate (mL/min)	1888 (1300-2520)
Central liver temperature (°C)	40 (39-40.8)
Estimated blood loss (L)	2.0 (0.5-5.0)

CEA, carcinoembryonic antigen; FU/LV, fluorouracil/leucovorin; CPT-11, irinotecan; HAI, hepatic arterial infusion

From Alexander HR Jr, et al, 2009: Analysis of factors associated with outcome in patients undergoing isolated hepatic perfusion for unresectable liver metastases from colorectal center. Ann Surg Oncol 16:1852-1859.

they reported a 50% response rate and median progression-free and OS of 6.7 and 9.9 months, respectively, and 2-year survival was 37.5%. A larger series of 27 patients, with a response rate of 71% and a median OS of 12.6 months, was reported by Rizell. Multiple series consistently report recurrent liver disease to be the greatest threat to patient survival, even after significant treatment responses.

Hepatocellular Carcinoma (See Chapters 80, 86, and 88)

Ku and colleagues (1998) from Kobe, Japan, reported long-term IHP with 60 to 150 mg/m^2 doxorubicin in 28 consecutive patients with multiple advanced HCC. In this group of stage IV patients, the main tumor diameter averaged 7.4 cm, and 17 of 28 patients had macroscopic vascular invasion to the portal vein. The overall response rate was 63% with 5 complete remissions and 12 partial responses. The OS rate was 67% and 39% at 1 and 5 years, respectively. A similar tumor response rate of 64% has been reproduced by the current updating series with 79 patients (Ku et al, 2003), which represents the largest single-institution experience with IHP. In this expanded series, with a mortality rate of 4%, the 1- and 5-year survival rates of stage IVa patients were 81% and 20%, respectively.

The Kobe group also reported results of repetitive IHP combined with reductive hepatectomy for 25 patients with multiple advanced HCCs (Ku et al, 2004) previously deemed to be unresectable. This dual-treatment strategy of surgical resection plus IHP is based on several oncologic advantages: First, a large HCC frequently accompanies feeding arteries from adjacent organs, and these collateral arteries are eliminated at the time of surgical resection. Second, reductive hepatectomy results in decreasing the vascular bed of the liver, which is theoretically beneficial to IHP, because the relative dose rate to the residual tumors is increased. Third, in HCC patients with tumor thrombi in the portal trunk, a life-threatening sequence of events, such as massive ascites, variceal hemorrhage, and eventual hepatic failure, frequently occurs. Such urgent situations could be prevented by the first-stage surgery. In a series of 35 patients with multiple advanced HCCs, the complete response rate was 46% with a partial response rate of 36%; in patients with the disease confined to the liver, the 5-year survival rate reached 51% (Ku et al, 2004).

Other Histologies

Phase II trials examining the utility of IHP for patients with advanced gastrointestinal neuroendocrine tumors (see Chapter 81B) and primary hepatobiliary tumors (see Chapter 50) were reported by the NCI group. Grover and colleagues (2004) described a group of 13 patients who were treated with melphalan (n = 10), melphalan plus TNF (n = 2), or TNF alone (n = 1). A single treatment-associated mortality was observed, along with a response of 50% and a median OS of 48 months. Nine patients with either HCC or cholangiocarcinoma were treated under the same conditions. Baseline tumor volume was significant, with a median percent hepatic replacement of 41%. Overall response rate (all positive response) was 66%, with median PFS and OS of 7.7 and 16.3 months, respectively (Feldman et al, 2004).

PERCUTANEOUS HEPATIC PERFUSION

The greatest weakness of IHP technology is the inability to repeat the procedure secondary to extensive surgical scarring around the IVC, made more acute by the observation that intrahepatic recurrence is common even after significant clinical responses. First reports of a less invasive technique of liver perfusion were published by Curley and colleagues (1993, 1994); utilizing percutaneously catheters and hepatic venous filtration, 80% of doxorubicin administered via the hepatic artery was effectively filtered from the hepatic venous circulation. Ravikumar and colleagues (1994) reported a similar series of 28 patients who underwent 58 treatments with either 5-FU or doxorubicin, but neither series established a clear utility for the technology, and further studies were not completed.

A systematic examination of a refined percutaneous hepatic perfusion (PHP) system was initiated at the Surgery Branch of the NCI in 2001 that utilized melphalan in a formal dose-escalation protocol with results published in 2005. The PHP system uses a double-balloon IVC catheter system (Delcath

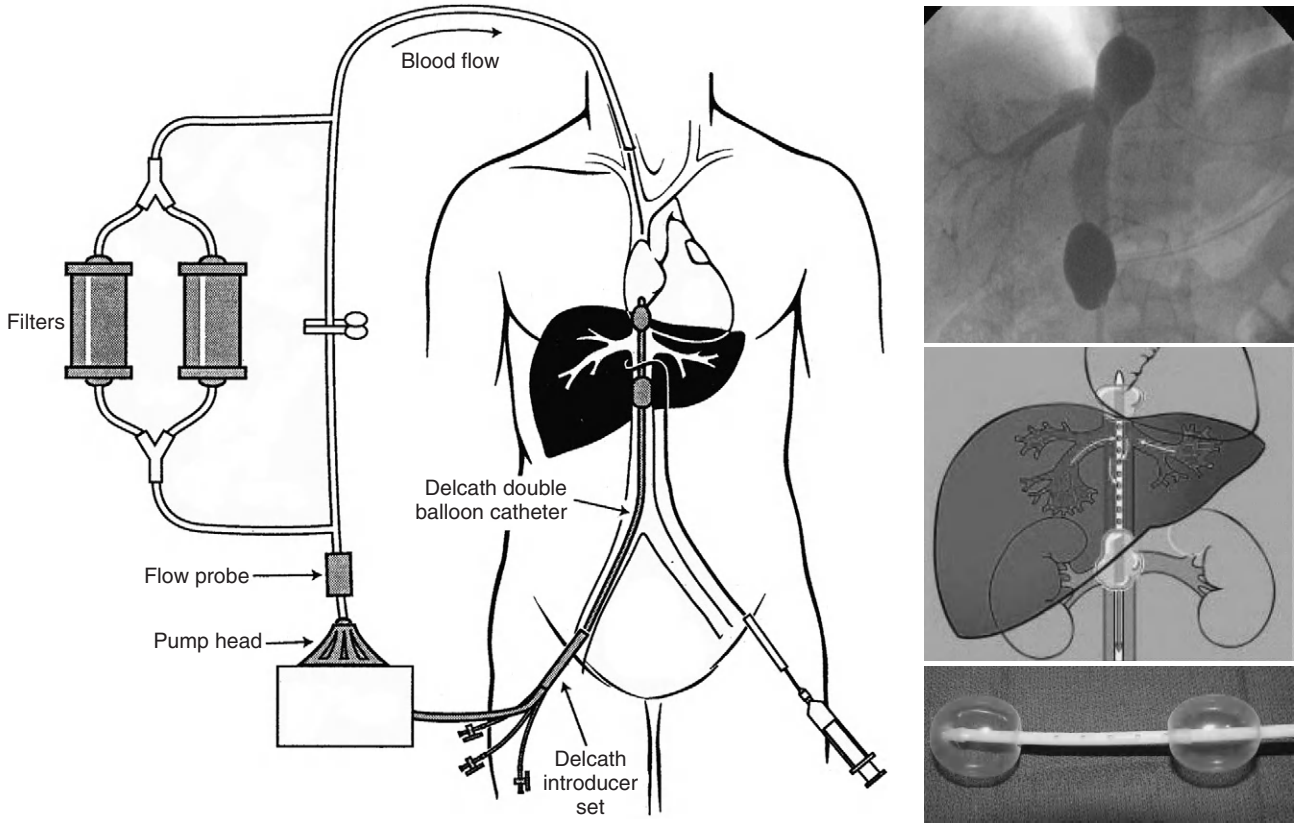

FIGURE 89.2. Schematic of the percutaneous hepatic perfusion circuit with inflow from a catheter introduced via the femoral artery. The double-balloon catheter is pictured, along with a radiograph depicting the catheter with both balloons deployed; isolation of the retrohepatic vena cava and hepatic veins is shown. *(From Pingpank JF, et al, 2005: Phase I study of hepatic arterial melphalan infusion and hepatic venous hemofiltration using percutaneously placed catheters in patients with unresectable hepatic malignancies. J Clin Oncol 23:3465-3474.)*

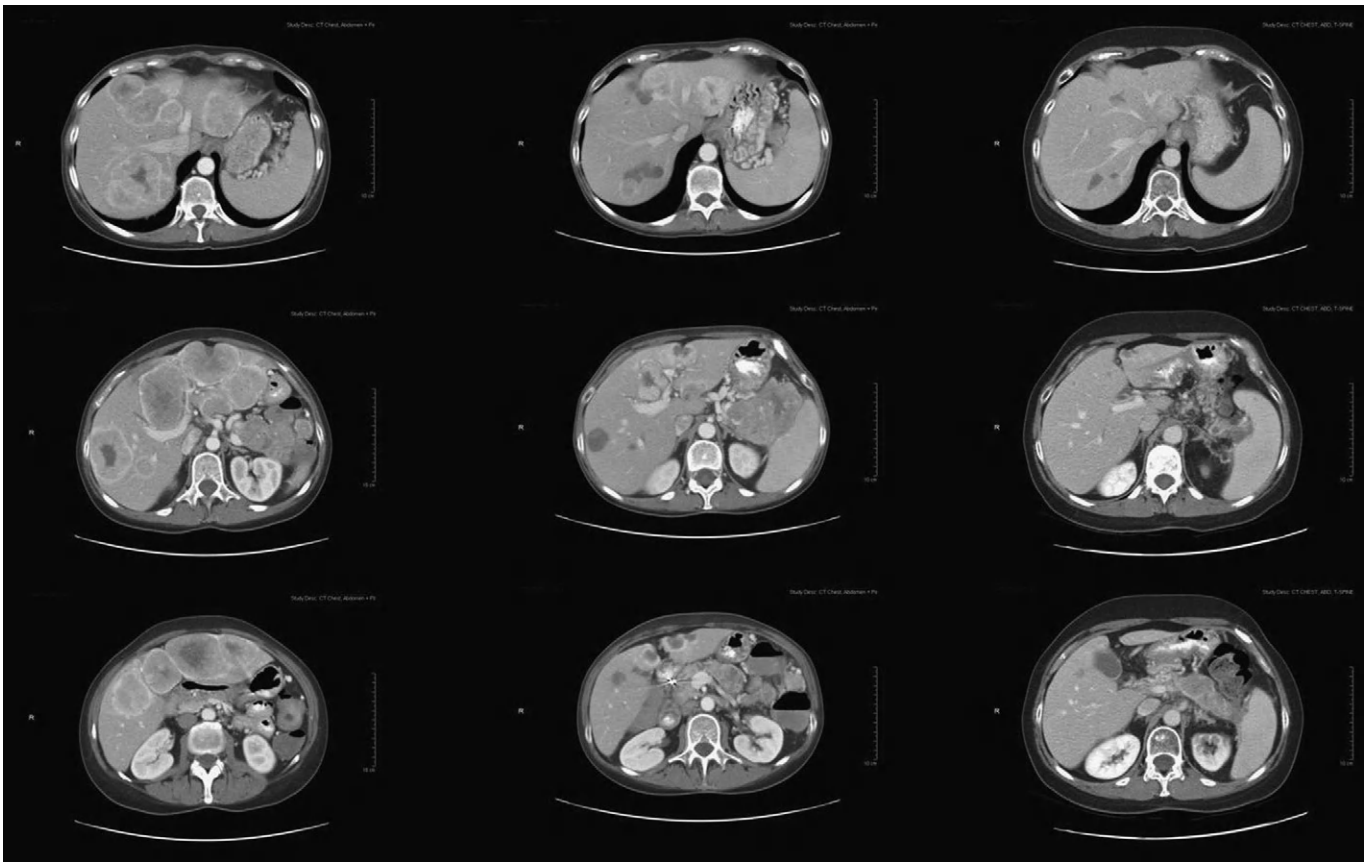
Systems, New York, NY) to isolate hepatic venous outflow and allow high-dose infusion of chemotherapy to the liver (Fig. 89.2). The main component of the system is a 16-Fr polyethylene double-balloon catheter with one large lumen and three accessory lumina. The two low-pressure occlusion balloons are inflated independently through separate lumina. The cephalic balloon blocks the IVC superior to the hepatic veins, and the caudal balloon obstructs the IVC inferior to the hepatic veins, allowing complete isolation of hepatic venous outflow. The span between the two occlusion balloons consists of a fenestrated segment that feeds into the large, central lumen, which exits the catheter from the proximal end. The additional lumen enters the catheter at a point inferior to the caudal balloon and exits at the distal tip; it serves as a channel for a guidewire and also allows some blood flow from the infrarenal IVC to the right atrium. During the procedure, melphalan is infused through a catheter percutaneously inserted into the hepatic artery. The melphalan perfuses the liver and exits the organ through the hepatic veins. Hepatic venous effluent is collected using the occlusion balloon catheter, and melphalan-dosed blood from the central lumen is pumped through an extracorporeal circuit that consists of a centrifugal pump and hemoperfusion drug-filtration cartridges. Melphalan flowing through the circuit is filtered with two activated-carbon filter cartridges arranged in parallel, and filtered blood is returned to systemic circulation via a venous return sheath inserted into the internal jugular vein. Treatments are administered with patients under general anesthesia (Figs. 89.3 and 89.4)

The completed Phase I study reported 28 patients who underwent 74 treatments (Pingpank et al, 2005). Twelve patients were treated in an initial feasibility cohort at 2.0 mg/kg prior to a 16-patient dose escalation to 3.5 mg/kg, after which dose-limiting bone marrow toxicity was observed in 2 of 6 treated patients. Maximum tolerated dose (MTD) was established at 3.0 mg/kg for a total of four planned treatments per patient. Examination of the venous filtration system revealed a consistent 78.5% melphalan extraction. At the MTD, grades 3 and 4 hepatic and hematologic complications, neutropenia and thrombocytopenia, were observed in 19% and 66% of treated patients, respectively. An overall response rate of 30% was reported across multiple tumor types and at all dose levels, with a 50% response rate noted in the 10 patients with metastatic ocular melanoma.

Two subsequent trials have been reported, including a Phase II cohort of 23 patients with metastatic gastrointestinal neuroendocrine tumors. The overall response rate was 79% in the 19 evaluable patients, with median hepatic PFS and OS of 39 and 40 months, respectively (Pingpank et al, 2008). A recently completed Phase III random-assignment trial that compared PHP with melphalan to standard of care for patients with hepatic metastatic melanoma has been reported. The primary end point of this trial was hepatic PFS, and 93 patients were randomized



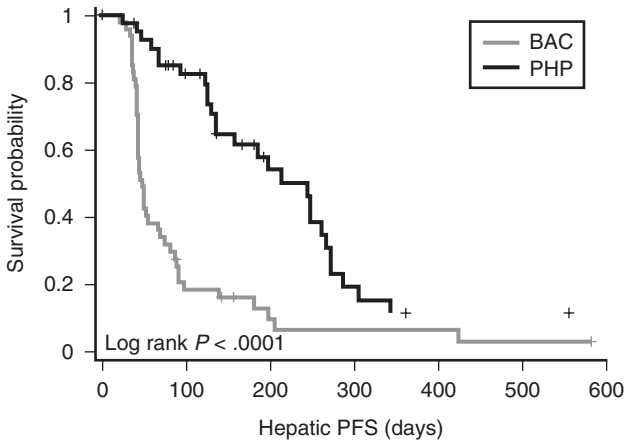


FIGURE 89.3. Response to percutaneous hepatic perfusion. Computed tomographic scans before and after treatment of a patient with multiple hypervascular hepatic metastases from a pancreatic neuroendocrine tumor. *(From Pingpank JF, et al, 2008: High-dose intra-arterial melphalan delivered via percutaneous hepatic perfusion [PHP] for patients with unresectable hepatic metastases from primary neuroendocrine tumors. Proc AHPBA, March.)*

	No. of subjects	Event	Censored	Median Survival (95% CI)
BAC	49	88% (43)	12% (6)	49.0 (43.0 68.0)
PHP	44	61% (27)	39% (17)	245.0 (136.0 267.0)

FIGURE 89.4. Kaplan-Meier assessment of hepatic progression-free survival (*PFS*). The primary end point in the phase III percutaneous hepatic infusion trial versus standard of care was hepatic PFS. BAC, best alternative care; CI, confidence interval; PHP, percutaneous hepatic perfusion. *(From Pingpank JF, et al, 2010: A phase III random assignment trial comparing percutaneous hepatic perfusion with melphalan [PHP-mel] to standard of care for patients with hepatic metastases from metastatic ocular or cutaneous melanoma. Proc ASCO [LBA #8512].)*

at 10 institutions, with 27 of 49 patients crossing over from the standard-of-care arm at hepatic progression. Median hepatic (245 days vs. 49 days; $P < .001$; hazard ratio [HR] .301) and overall (186 days vs. 46 days; $P < .001$; HR, 0.404) PFS were significantly improved on the experimental (PHP) arm of the study. OS was not significantly improved, in part because of the high crossover rate. Overall response rate was 34.1% (15 of 44) for PHP vs. 2.0 % (1 of 49) for best alternative care (BAC) ($P < .001$) (Pingpank et al, 2010).

CONCLUSION

Regional hepatic perfusion with high-dose melphalan provides an important clinical benefit for patients with diffuse hepatic metastases of ocular melanoma not amenable to surgical resection. Both IHP and PHP are well tolerated and effective. Careful patient selection and proper use of appropriate systemic chemotherapy is very important for these patients. The characteristics of the nonspecific alkylating agent melphalan make it an ideal candidate for these systems, as incremental dose-escalation provides meaningful increases in drug efficacy. The use of additional drugs with known therapeutic benefit against colorectal and primary biliary malignancies, such as 5-FU and oxalipatin, is the rational next step in the development of these treatment modalities, and this is underway at a limited number of centers.

CHAPTER 90A

Hepatic resection: general considerations

Jacques Belghiti and William R. Jarnagin

OVERVIEW

Over a comparatively short period, partial hepatectomy has been transformed from a high-risk, resource-intensive procedure to one that is now performed routinely, often removing a large amount of liver tissue and/or combined with resection of other organs, with the expectation of an uncomplicated postoperative course and recovery in most patients. Although reports of hepatic resection date back to antiquity (see the Introduction to this text), it was Lortat-Jacob's report of an elective right hepatectomy for malignancy in 1952 that ushered in the modern era of hepatobiliary surgery, suddenly creating new possibilities to treat a wide range of disorders (Lortat-Jacob & Robert, 1952); however, from that point forward, the initial experience with hepatic resection was far from promising. In 1977, James Foster and Berman published a multiinstitutional summary of hepatic resection surgery in the United States composed of 168 resections performed over the preceding 14 years. This report documented a marked and unacceptably high operative mortality rate, which was due primarily to two often related factors: inability to control hemorrhage in the operating room and postoperative liver failure (Foster & Berman, 1977).

Since that time, progressive advances in many different areas have led to the improvement in outcome required for hepatic resection to take its place as a mainstream procedure. These advances have come on several fronts, and it is therefore difficult to single out one for special mention. Perhaps the most noteworthy gain has been a greater appreciation of the segmental anatomy of the liver and the willingness and ability of surgeons to pursue resections based on anatomic principles (see Chapters 1B, 90B, and 92). This particular element has had a profound effect, not only improving the results of major resections but spurring greater use of parenchyma-sparing sublobar resections, such as posterior or anterior sectoral hepatectomy or central hepatectomy, rather than right or extended right hepatectomy, respectively. Equally important, this change fundamentally altered the approach to patients who require bilobar resections.

A number of studies have documented this trend over time, and it has been associated with, and is probably responsible for, decreases in blood loss and transfusion rates, reductions in hospital stays, and decreases in operative mortality (Fan et al, 1999; Jarnagin et al, 2002; Belghiti et al, 2000).

Practice changes in other areas, including intraoperative and perioperative management and patient selection, have clearly contributed to the overall improvement in outcomes (see Chapter 22). The use of low central venous pressure (CVP) anesthesia, now widely used, represented a notable change in the previous standard practice of fluid loading prior to resection. Despite concerns of possible risks of air embolization or disturbance of renal function, both unfounded, low-CVP anesthetic management has been shown to reduce blood loss during the resection because of decreased filling pressures and reduced distension of the hepatic veins, and it does so with no significant untoward effects (Cunningham et al, 1994; Melendez et al, 1998).

Beyond the technical aspects of partial hepatectomy, a greater understanding of the impact of resection on the natural history of many diseases, combined with a clearer delineation of perioperative risk, have allowed a much more informed patient-selection process, one that has increasingly targeted resection more effectively to those patients most likely to benefit (see Chapters 49 and 50 and 79 through 81). Additionally, the quality and quantity of the future liver remnant has assumed great importance in patient selection for operations (see Chapter 93). Both of these issues have represented particularly critical developments for patients with hepatic colorectal metastases, for whom the advent of more active chemotherapeutic agents has led to more frequent treatment prior to operation. The latter development has greatly altered the landscape of this disease by allowing many more patients, particularly those with very advanced lesions previously considered surgically

unapproachable, to undergo potentially curative surgery (Adam et al, 2000; Masi et al, 2009); however, while enhancing the results of resection, such therapy has the potential to cause significant hepatotoxicity and increase the risk of postoperative liver failure (see Chapters 65 and 87; Vauthey et al, 2006). In an effort to mitigate the risks in heavily pretreated patients and those with fibrosis or cirrhosis, preoperative portal vein embolization, first introduced 30 years ago, has been used with increasing frequency and has emerged as a powerful tool for inducing hypertrophy of the future liver remnant (see Chapter 93; Makuuchi et al, 1984).

This changing treatment paradigm in patients with hepatic colorectal metastases, with chemotherapy playing an increasingly prominent role, has yet to evolve in other malignant diseases; however, as more effective drugs emerge, it is more than likely that similar changes in practice will be seen in other tumor types. An example of note is biliary tract cancer: recent publication of the results of the ABC-02 trial holds some promise for better results with chemotherapy treatment (Valle et al, 2010).

Advances in imaging technology deserve special mention, as patient selection is continually refined. Whereas radiologic evaluation once required invasive investigations in many cases, it can now provide complete, noninvasive assessment of the liver, including the biliary tree, the arterial and venous anatomy, and the intrahepatic and extrahepatic disease extent in the case of malignant disease (see Chapters 13, 16, and 17). Indeed, for certain tumors, classic imaging findings are now considered pathognomonic and have supplanted the need for a biopsy. Specific examples in this regard include liver hemangiomata and focal nodular hyperplasia (see Chapter 17) and the guidelines for the diagnosis of hepatocellular carcinoma (Bruix & Sherman, 2005). Going forward, advances in imaging technology likely to influence the practice of hepatic resectional surgery include computer-aided reconstruction, functional imaging, and intraoperative navigation (Cherqui & Belghiti, 2009; Chopra et al, 2010).

Technical progress in other areas, particularly with devices such as vascular staplers and those used to transect the liver parenchyma (see Chapter 90B), is often hailed as a significant advance; however, although their value should not be dismissed, they cannot overcome poorly conceived or poorly executed operations, and their relative contribution, compared to the enhancements in other aspects, is modest at best.

Advances in imaging have also played a major role in postoperative management, particularly in diagnosing and treating postoperative complications. Over the past several years, the marked reduction in operative mortality after hepatic resection has seemingly occurred with little obvious change in morbidity (see Chapter 25). This observation suggests an overall improvement in the ability to salvage patients who experience significant complications. The ready availability of high-quality imaging and a heightened sense of awareness of the perioperative problems that may occur have led to earlier detection of complications. These changes, combined with the ability to manage many problems percutaneously or endoscopically, rather than operatively, have clearly had a major impact on perioperative outcome.

CONCLUSION

This chapter has detailed the contemporary approach to hepatic resection for a wide variety of diseases and indications (see Chapters 90B, 90C, and 90F), including the technical aspects of partial hepatectomy for living-donor transplantation (see Chapter 90D), and advances in minimally invasive approaches (see Chapter 90E) in particular, which represents a remarkable evolution in hepatic surgery; continued technical progress will certainly bring laparoscopic and robotic approaches to resection further into the mainstream. The descriptions herein reflect the current state of the art, built upon the collective contributions of many pioneering surgeons over the past several decades and continuing to the present. The techniques and approaches discussed include, to some degree, the biases of the authors; however, the overriding theme is always adherence to best principles of hepatic resection surgery, and alternative viewpoints must be considered where appropriate.

CHAPTER 91A

Vascular isolation

Jacques Belghiti and O. Scatton

OVERVIEW

Bleeding and subsequent blood transfusions remain important causes of death and morbidity with hepatectomies. Evidence also shows that blood transfusion may be associated with an increased risk of recurrence of malignancy through impairment of the patient's immune response (Asahara et al, 1999; Tung-Ping Poon et al, 2000). Vascular clamping, irrespective of its modality, minimizes the risk of bleeding during liver resection. Liver cell injury induced by ischemia and reperfusion is the major drawback of clamping. Overall, normal liver tolerates up to an hour of warm ischemia, but diseased liver with fibrosis, steatosis, inflammation, and vascular or biliary disease requires much shorter periods of ischemia. Indeed, the vast majority of liver resections are performed in such diseased livers, including resections of hepatocellular carcinoma (HCC) (see Chapters 70 and 81A) and of liver metastases, which are more often performed after chemotherapy and can induce parenchymal changes (chemotherapy-associated steatohepatitis, sinusoidal obstruction syndrome) (see Chapters 65 and 81A).

With technical improvements in liver surgery, patients with various underlying liver conditions—such as fibrosis, steatosis, or chemotherapy-induced injury—are undergoing complex and extensive liver resections (Belghiti et al, 2000; Poon et al, 2002). In this regard, pedicular intermittent clamping, which alternates short periods of clamping with intervals of restoration of blood flow, has been shown to be the best tolerated clamping modality, especially in patients with diseased liver parenchyma (Belghiti et al, 1999; Man et al, 1997). Although a real advantage in clinical practice was not demonstrated (Gurusamy et al, 2009), ischemic preconditioning that initiates a short period of clamping and restoration of blood flow followed by continuous clamping is an attractive concept (Clavien et al, 2000). On the other hand, better understanding of vascular anatomy, particularly of the venous tributaries; better anesthesiologic management with perioperative low filling (restrictive fluid administration); and the development of modern tools of transection and coagulation, such as the ultrasonic dissector associated with bipolar coagulation, have made possible even major liver resection without vascular clamping or transfusion. Therefore if vascular clamping must be applied, balancing its efficacy to control bleeding with the potential side effects of ischemic liver injury is vital.

This chapter describes techniques, benefits, drawbacks, and hemodynamic monitoring of vascular control of the most appropriate technique for each patient's requirements.

ANATOMIC BASIS FOR VASCULAR CONTROL

The liver receives a dual vascular inflow that provides approximately one quarter of the total cardiac output, or a blood flow of 1500 mL/min. The portal vein provides 75% of the total hepatic blood flow, and the hepatic artery provides the remaining 25%. The portal vein originates behind the neck of the pancreas at the confluence of the superior mesenteric and splenic veins, and it courses posterior to the bile duct and hepatic artery in the free edge of the lesser omentum. At the hilum of the liver, the vein divides into a shorter, more vertically oriented right branch and longer, horizontally oriented left branch. The right portal branch may be absent when the right anterior and posterior sectorial veins originate directly from the trunk of the portal vein, thus the right portal branch can be more difficult to dissect and control than the left portal branch.

The hepatic artery is highly variable, but it most commonly arises as a branch of the celiac axis and enters the hepatoduodenal ligament after providing the right gastric and gastroduodenal arteries; the right and left branches usually lie on a plane posterior to the bile ducts at the hilum of the liver. In fact, this classic branching pattern is found in only 50% of patients. The accessory or replaced arteries pertinent to vascular clamping include a left artery, which can arise from the left gastric artery (25% to 30%), and a right artery, which can arise from the superior mesenteric artery (17% to 20%).

Three large hepatic veins lie posterosuperior to the liver just below the diaphragm and form the major drainage of the liver (Fig. 91A.1). The right hepatic vein is a short, wide trunk formed by the convergence of an anterior trunk situated in the right portal fissure, which drains mainly segments V and VI, and a posterior trunk, which drains mainly segment VII. The right hepatic vein also drains part of segment VIII. The middle hepatic vein is situated in the plane of principal portal fissure; it drains the entire central sector and receives the veins from segments V and VIII at its right border and the veins of segment IV at its left border, thus forming the major drainage vein of segment IV and part of segments V and VIII. The left hepatic vein arises from the confluence of the segment II and III veins. It often receives drainage from the posterior part of segment IV, and it terminates as a short common trunk with the middle hepatic vein in the majority. In 10% to 20% of cases, a significant right inferior hepatic vein may be found (>5 mm diameter), which mainly drains segment VI. In addition to these, there are two groups of accessory hepatic veins, the right and the left. The right accessory veins drain the posterior part of the dorsal sector. On the left, they are formed by the veins of the caudate lobe. In half of the cases, a large solitary vein terminates in the inferior vena cava (IVC); in the other half, two or three veins are present, and they end in a staged fashion in the left border of the IVC. These anatomic variations are important in the context of vascular clamping, as the presence of large drainage veins can result in the inability to achieve complete vascular control during the clamping procedure (see Chapter 1B).

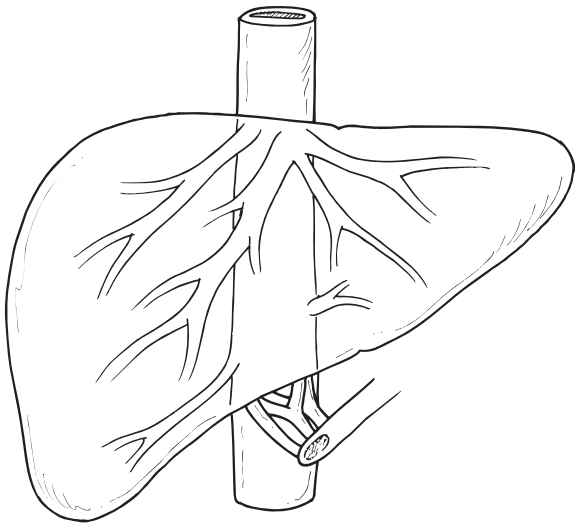

FIGURE 91A.1. Venous drainage of the liver depicting the major hepatic veins and their tributaries.

HEMODYNAMIC RESPONSE TO DIFFERENT TYPES OF CLAMPING

Hemodynamic changes are proportional to the type and extent of vascular interruption. These changes are also related to several factors, including the level of anesthesia, quantity and rapidity of bleeding, vascular filling, and spontaneous adaptation of the circulatory system to the reduction of venous return. Pedicular clamping is nearly always well tolerated, but the addition of caval clamping is more likely to be followed by major hemodynamic consequences (Table 91A.1).

Hemodynamic Response to Pedicle Clamping

The pedicular clamping, which leads to a moderate decrease in cardiac preload with a 5% decrease in pulmonary artery pressure and a 10% decrease in cardiac index, is paradoxically associated with a 10% increase in mean arterial pressure because of a sympathetic reflex after arterial clamping that induces a significant increase in systemic vascular resistance (Delva et al, 1987). Therefore isolated pedicle clamping is usually well tolerated and does not require specific anesthetic management. During the period of declamping, blood pressure is restored to normal or even shows an increase from the baseline; however, it is a frequently observed phenomenon that, as the cycle of clamping and declamping progresses, declamping causes more significant hypotension. This phenomenon, which can be observed when the cumulative period of clamping lasts 1 hour, may be attributed to a reperfusion-like syndrome as a result of the long-term ischemia of liver parenchyma and splanchnic release of toxic vasodilators; therefore it is recommended to increase the duration of declamping during each cycle, if the cumulative duration is prolonged more than 1 hour, especially in patients with diseased liver (Imamura et al, 2003).

Hemodynamic Consequences and Limitations of Hepatic Vascular Exclusion

The hemodynamic consequences of the addition of total caval clamping to pedicular clamping is more profound (see Table 91A.1). Hepatic vascular exclusion (HVE), which leads to a severe decrease in cardiac preload with 25% decrease in pulmonary artery pressure and 40% to 50% decrease in cardiac index, is associated with a 10% decrease in mean arterial blood pressure despite a 50% increase in heart rate and a very significant increase in systemic vascular resistance. Reduced venous return produces a marked reduction in left ventricular and diastolic volume that could be precisely monitored by transesophageal echocardiography (Eyraud et al, 2002). The sequence of HVE includes initial inflow occlusion followed by infrahepatic caval clamping and then suprahepatic caval clamping. The compensatory cardiac response to maintain blood pressure requires approximately 5 minutes and is facilitated by "preloading" the patient with intravenous fluids. A fall in mean arterial pressure less than 80 mm Hg suggests intolerance to HVE and should lead to consideration of caval declamping. Ventricular dimensions could be monitored by transesophageal echocardiography (Eyraud et al, 2002).

Causes of hemodynamic intolerance to HVE include 1) inadequate fluid loading, 2) hepatic congestion as a result of persistent inflow (see below), and 3) inadequate cardiovascular response. Insufficient fluid loading is likely to occur in case of fluid restriction and unexpected need for caval occlusion without adequate preparation of the patient. In addition, the 10% of patients who cannot increase their cardiac output are difficult to identify preoperatively.

ANESTHETIC CONSIDERATIONS (SEE CHAPTER 22)

Liver surgery requires continuous collaboration and communication among experienced surgeons and anesthesiologists. Historically, liver resections were associated with significant hemorrhage; hence, anesthesiologists tend to overload patients with intravenous fluids to minimize the hemodynamic consequences of blood loss. This approach has paradoxically

Table 91A.1

Hemodynamic Changes Observed During Various Methods of Clamping

Clamping Technique	Portal Pressure	Caval Artery Pressure	Pulmonary Index	Cardiac Resistance	Vascular Pressure	Arterial Procedure
Pedicle clamping	Severe increase	No change	Slight decrease	Slight decrease	Moderate increase	Slight increase
HVE	Severe increase	Moderate increase	Moderate decrease	Moderate decrease	Severe increase	Slight decrease
HVE with preservation of caval flow	Severe increase	No change	Moderate decrease	Slight decrease	Moderate increase	No change

HVE, hepatic vascular exclusion

aggravated operative blood loss even during pedicular clamping as a consequence of backflow bleeding from the hepatic veins, and this is increased by increased filling. One of the main advances in the past decade was the ability of anesthesiologists to maintain a low central venous pressure (CVP) during hepatectomy.

Low Central Venous Pressure Anesthesia and Limited Filling

The CVP directly influences the occurrence of back bleeding during liver inflow occlusion. In a retrospective study, Smyrniotis and colleagues (2004) showed that the Pringle maneuver at a CVP of 6 mm Hg or more is associated with greater blood loss than the maneuver performed at a CVP of 5 mm Hg or less. Thus the concept of low CVP anesthesia during hepatectomy has emerged. Maintaining a low CVP during hepatic transection reduces the distension of hepatic veins and thus significantly decreases bleeding (Jones et al, 1998). It also avoids vena caval distension and thus facilitates safe dissection of the retrohepatic vena cava and major hepatic veins. As the blood loss resulting from a vascular injury is proportional to the pressure gradient across the vessel wall and to the fourth power of the radius of the injury, lowering the CVP to one fifth will decrease the blood loss by a factor greater than 5 (Melendez et al, 1998).

Low CVP during liver transection is consistently associated with reduced blood loss (Chen et al, 2000; Cunningham et al, 1994; Eid et al, 2005; Jones et al, 1998; Melendez et al, 1998; Wang et al, 2006). Moreover, in retrospective studies, low CVP tends to be associated with lower postoperative morbidity and reduction of hospital stay (Chen et al, 2000; Smyrniotis et al, 2004).

The potential drawbacks of low CVP anesthesia include perioperative occurrence of air embolism, requirement for pressor agents, and postoperative renal dysfunction. The incidence of gas embolism varies according to the approach and the surgical technique used for parenchymal transection. During a laparoscopic approach, transesophageal echocardiography detects, in nearly all cases, small volumes of air embolism (Schmandra et al, 2002, 2004). During liver resection using ultrasonic devices, air embolism was detected in all the patients who underwent liver resection with an ultrasonic surgical dissector (Koo et al, 2005). Although in the previous study, nearly half of the patients had air embolism filling more than half the right heart diameter, the incidence of clinically relevant accidents is rarely defined. Zhou and colleagues (2008) found an incidence of three cases in 110 liver resections performed with inflow occlusion, and liver surgery complicated by gas embolism accounted for 4% of the patients treated in a referral center for hyperbaric treatment (Bessereau et al, 2010).

Gas embolism usually originates in the venous system from hepatic vein injury through the parenchymal resection stump. Venous gas embolism can lead to arterial paradoxical embolism favored by a patent foramen ovale or intrapulmonary arteriovenous pulmonary shunting (Lee et al, 2002). During hepatic surgery, gas embolism is usually recognized by a sudden drop in end-tidal expiratory carbon dioxide, followed by a subsequent drop in arterial blood pressure or sudden cardiac arrest (Adachi et al, 2006). Arterial systemic embolism can cause arterial ischemia in cerebral, myocardial, spinal, or limb circulation (Lee et al, 2002). Gas embolism is considered a medical emergency, and treatment includes interruption of the embolic procedure, an attempt to extract intravascular gas, external cardiac massage, and immediate oxygenation. Despite an absence of high-level evidence, hyperbaric oxygen therapy is recommended in case of cardiac arrest or in any patient with an unexpected neurologic abnormality following a risky procedure (Blanc et al, 2002; Trytko & Bennett, 2008). But it should be kept in mind that hyperbaric therapy can be limited by the location of hyperbaric chambers, necessitating the transfer of critically ill patients; the ability of those chambers to be used to care for critically ill patients during the therapy; and the risk of hyperoxic seizures and barotrauma (Bessereau et al, 2010; Edsell & Kirk-Bayley, 2009).

The risk of postoperative renal failure linked to low-CVP anesthesia has been suggested in the setting of liver transplantation (Schroeder & Kuo, 2008). During liver resection, the incidence of postoperative renal dysfunction related to low intraoperative volemia has not been clearly established (Melendez et al, 1998). The ability of patients to tolerate fluid restriction in terms of renal function with improved recovery has led some authors to use a restrictive fluid policy in liver surgery. It has been shown in living donor resection that CVP monitoring did not reduce blood loss when a low-infusion policy was routinely applied (Niemann et al, 2007).

Maintaining Low Venous Backflow (See Chapter 22)

The anesthesiologist can maintain a low venous backflow by several methods. Fluid restriction during induction and liver transection is the most commonly used method. Intravenous fluids are given at a rate of 0.5 to 1 mL/kg/h, until the hepatic resection is complete. The patient is brought back to normovolemia at the end of surgery, and hemostasis is ensured. Other methods commonly used are the use of anesthetic gases such as isoflurane, which has systemic vasodilatory properties and results in minimal cardiac depression (Gatecel et al, 2003), and the use of certain drugs that produce vasodilatory effects. Although low tidal volume ventilation was considered to reduce the backflow bleeding, no evidence is available to support that this maneuver reduces the quantity of blood lost during the hepatic transection phase (Hasegawa et al, 2002). The surgeon can decrease the backflow bleeding by partially or totally clamping the infrahepatic IVC. This technique, which decreases venous return, has been shown to have no deleterious effect on renal function, even with a clamping time of up to an hour (Otsubo et al, 2004). The ideal tool for hemodynamic monitoring under these circumstances remains to be determined, although transesophageal echocardiography and pulmonary artery catheterization can be used (Eyraud et al, 2002). Intraoperative monitoring of fluid responsiveness could also be implemented noninvasively, using respiratory variations in arterial pulse pressure or monitoring of peripheral venous pressure (Choi et al, 2007; Solus-Biguenet et al, 2006). In experienced centers, CVP monitoring did not show any significant advantage (Niemann et al, 2007).

Special Considerations During Hepatic Vascular Exclusion

Application of vascular isolation techniques mandates a high level of anesthetic expertise. Intraoperative management of patients undergoing vascular exclusion should include the use

of pulmonary artery catheterization and occasionally of transesophageal echocardiography. When a major hepatectomy performed under HVE is planned, anesthetic management is adjusted to anticipate the reduction in venous return, sudden decrease in cardiac output, and increase in afterload. Volume expansion is usually required for patients undergoing HVE. This is achieved by rapid infusion of 500 mL of colloids before cross clamping of the vena cava. In patients who do not tolerate caval cross clamping, even after volume expansion, vasopressor agents such as noradrenaline are added (Redai et al, 2004). Persistent hypotension and/or low cardiac index, which can occur in 10% to 20% of patients, should be considered intolerance to HVE and is an indication to unclamp the vena cava or to consider the use of venovenous bypass (Redai et al, 2004).

SURGICAL ASPECTS OF VASCULAR CLAMPING

The easiest procedure to reduce bleeding during liver resection is inflow control. Pedicular clamping, which controls the inflow, has little hemodynamic consequence and offers the greatest efficiency in association with low filling. Continuous clamping, which increases ischemic injury of the liver parenchyma, induces splanchnic congestion as well. Intermittent clamping has supplanted the use of continuous pedicular clamping to overcome these two drawbacks; however, patients with large tumors involving the caval-hepatic confluence may require additional outflow vascular control.

Inflow Vascular Clamping

The hepatic pedicle clamping (Pringle maneuver), which interrupts the arterial and portal venous inflow to the liver, is a standard in hepatic surgery. According to the Cochrane database, in elective resection, intermittent portal triad clamping seems better than continuous clamping, especially in patients with diseased parenchyma; therefore intermittent triad clamping could be recommended as the gold standard method of clamping (Gurusamy et al, 2007).

Total Inflow Control

Inflow control implies an encircling of the hepatic pedicle (Fig. 91A.2). Adhesions to the gallbladder are freed, and the lesser omentum is opened at the level of the pars flacida, taking care to avoid injury to the right gastric pedicle. A finger or a blunt dissector may thereafter be easily passed through the foramen of Winslow, and the hepatoduodenal ligament is encircled with tape. Clamping is easily achieved by a vascular clamp or tourniquet, which should be closed until the pulse in the hepatic artery distal to the clamp is stopped; excessive closure should be avoided, as it may otherwise result in arterial or biliary injury. Care should be taken to avoid lymph nodes of the hepatoduodenal ligament, as these may be large in cirrhotic patients or in patients with a long-standing cholestasis. A search for a left hepatic artery originating from the left gastric artery is mandatory to prevent persistent bleeding during parenchymal transection. When a left hepatic artery exists, simultaneous occlusion of this vessel should be performed to complete the vascular inflow control.

In patients who have undergone previous abdominal surgery, dense adhesions may lie between the right lateral and posterior aspects of the hepatoduodenal ligament, and the portal vein in particular, and the anterior surface of the IVC and segment I. Adhesions may form between the duodenum, greater omentum, and the anterior aspect of the hepatoduodenal ligament. All these adhesions should be lysed prior to pedicular clamping to avoid accidental injury to the vena cava or the duodenum. A safe approach is to expose the IVC in its retropancreatic portion by a Kocher maneuver and to progress cranially.

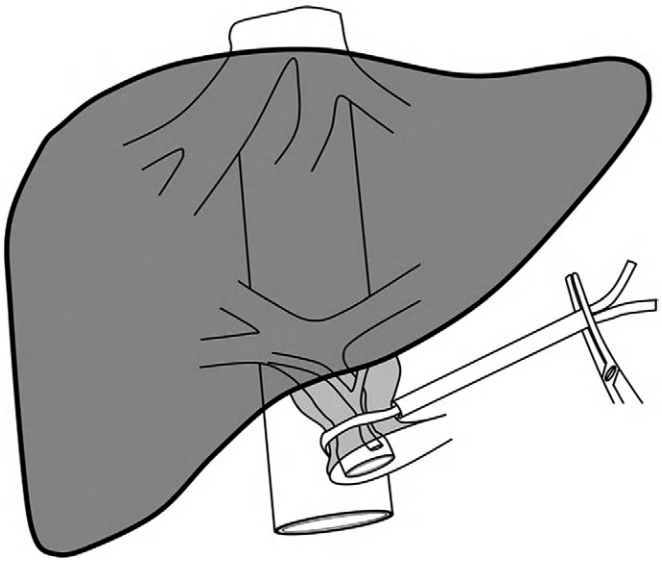

FIGURE 91A.2. Hepatic pedicle clamping (Pringle maneuver) occludes the arterial and portal inflow of the liver.

Continuous Clamping

Continuous clamping implies interruption of inflow continuously during the hepatic transection phase without intermittent release to allow reperfusion. Although conceptually very efficient to control bleeding, it is used less frequently, as it is not universally effective and has several disadvantages (Table 91A.2). The efficacy is limited by its inability to control the backflow bleeding, which is increased if the CVP is high or the patient has large hepatic tumors that compress hepatic veins associated with multiple venous collaterals.

Disadvantages of continuous clamping include splanchnic congestion and prolonged parenchymal ischemia. The splanchnic congestion and fluid sequestration in the visceral compartment cause bowel edema, which takes a long time to subside, leading to difficulties in the closure of the abdominal cavity at the end of the operation and to prolonged postoperative ileus. A difficult closure of the abdomen can lead to abdominal compartment syndrome with subsequent effects on the intraabdominal organs (Moore et al, 2004). Development of edema will be detrimental to bowel anastomoses, especially in the context of synchronous hepatic resections for colorectal malignancies (Elias et al, 1995). Continuous clamping has been shown to induce hyperamylasemia, and it can lead to clinically significant pancreatitis in some patients (Miyagawa et al, 1994, 1996). Interruption of splenic venous return without arterial interruption poses a risk for spontaneous splenic rupture during prolonged continuous clamping (Emree et al, 1993). Continuous clamping causes prolonged ischemia to the liver. Normal liver can tolerate inflow occlusion under normothermic conditions

Table 91A.2

Comparison of Relative Technical Difficulty, Control of Blood Loss, and Physiologic Tolerance for Various Clamping Techniques

Clamping Technique	Technical Difficulty	Hemodynamic Tolerance	Hepatic Tolerance	Prevention of Bleeding	Contraindications	Complications
No clamping	—	Most	Most	Least	—	Bleeding requiring transfusion
Intermittent hepatic pedicle clamping	Least	Most	Intermediate	Intermeidate	—	—
Continuous hepatic pedicle clamping	Least	Most	Least	Intermediate	Diseased liver	Splanchnic congestion
Hepatic pedicle and infrahepatic IVC clamping	Least	Intermediate	Intermediate*	Intermediate	Low CVP	—
Partial pedicle clamping	Intermediate	Most	Most	Most	Pedicular involvement	—
HVE (classic)	Intermediate	Least	Least	Least	Diseased liver; cardiac disease	Splanchnic congestion; renal dysfunction
Intermittent HVE with preservation of caval flow	Most	Intermediate	Intermediate	Most	Juxtacaval tumors	—

for up to 60 minutes (Delva et al, 1989; Huguet et al, 1992), but diseased livers are much less tolerant of extended ischemia, so continuous clamping cannot be applied to diseased livers for very long. Moreover, restoration of blood flow after prolonged clamping can cause reperfusion syndrome characterized by hemodynamic disturbances as a result of the release of toxic metabolites and vasodilators from the liver and the splanchnic bed (Kim, 2003; Kim et al, 2002). Intermittent clamping has been introduced to overcome these drawbacks of continuous clamping.

Intermittent Clamping

Intermittent inflow occlusion with intervals of reperfusion reduces the consequences of splanchnic congestion and decreases the ischemic injury to the liver parenchyma. After a short period of pedicular clamping, ranging from 10 to 20 minutes, the inflow is restored for 5 to 10 minutes, according to the duration of the transection, underlying liver status, and surgeon preference (Imamura et al, 2003). Classically, each cycle comprises 15 minutes of clamping followed by 5 minutes of reperfusion (Belghiti et al, 1999; Capussotti et al, 2003; Hardy et al, 1995; Man et al, 1997; Takayama et al, 1998). Although a randomized, controlled trial (RCT) that compared the short-term outcome of hepatectomy using intermittent clamping with an ischemic interval of 15 minutes instead of 30 minutes, with 5 minutes of reperfusion, showed no significant difference (Esaki et al, 2006), most authors favor 10 to 15 minutes of clamping.

Genuine intermittent clamping requires a true period of unclamping, which implies that the surgeon should not continue transection during the period of unclamping. This interval, during which the surgeon applies gentle compression to the transected surface, can be used to reexamine the adequacy of the transection line with respect to the vascularization and the oncologic margin. The period of revascularization gives the surgeon an opportunity to visualize the healthy color of the remnant liver. Intraoperative ultrasonography (US) can be performed to confirm the adequacy of inflow and outflow of the remnant liver and to examine the progress and direction of transection in relation to tumor margin.

Intermittent pedicle clamping, the most commonly used vascular clamping modality, has gained wide acceptance, as it is technically simple, effective in control of hemorrhage, and is well tolerated, above all, by diseased liver. Intermittent clamping of a diseased liver has no significant deleterious effects, even if the cumulative clamping time is up to 1 hour (Takayama et al, 1998). Two randomized, controlled studies compared continuous versus intermittent portal triad clamping and found that, although significantly more bleeding was noted in the intermittent group during parenchymal transection, no statistical difference was reported in the total operative blood loss (Belghiti et al, 1999; Capussoti et al, 2003). The most important result, however, was the better tolerance of diseased liver to intermittent clamping (Belghiti et al, 1999); thus the application of intermittent clamping in normal livers has prolonged the total clamping duration by up to 3 hours, which allows surgeons to perform even complex hepatic resections with minimal blood loss (Sakamoto et al, 1999).

The wide safety margin of intermittent pedicle clamping has served to promote its safe use in donor hepatectomy in living donor liver transplantation (LDLT). This has not jeopardized donor safety, nor has it compromised graft function (Imamura et al, 2002, 2004). The use of intermittent clamping enables a bloodless resection, thus it adds to donor safety, suggesting that surgeons should not hesitate to use this technique during surgery for live donation (Imamura et al, 2002, 2004). The better tolerance of intermittent ischemia has stimulated investigators to further explore the possible benefits of preconditioning.

Preconditioning

A newer perspective on inflow vascular clamping has emerged from study of the biologic response to ischemia and reperfusion (Clavien et al, 2000; Hardy et al, 1996). A period of ischemia followed by reperfusion of the liver not only protects the liver from the negative effects of any subsequent period of ischemia, but it may also protect distant organs from the systemic effects of organ ischemia; recognition of this phenomenon led to a study of this technique in humans. Clavien and colleagues (2000) revealed that an initial period of ischemia (10 minutes) followed by reperfusion (10 minutes) protects the liver against subsequent prolonged ischemia, and the authors postulated that some of the benefits of intermittent clamping may actually result from the impact of the first clamp-unclamp sequence as a preconditioning treatment.

In addition, preconditioning followed by continuous clamping may have the advantage of avoidance of blood loss during the unclamped period, although no major differences have been shown in terms of blood loss between the continuous versus intermittent clamping approaches. In a prospective randomized study, the authors showed that this protective strategy against hepatic ischemia was shown to be efficient, especially in the presence of steatosis (Clavien et al, 2003); however, the beneficial effect of preconditioning was shown only for 30 minutes of continuous clamping and only for a small volume of liver resection.

Although the theoretic advantage of a hepatoprotective effect of preconditioning is definitely attractive, in practice this procedure has not been shown to have significant advantages over intermittent clamping. An RCT that compared ischemic preconditioning versus continuous clamping (Chouker et al, 2004) showed improved cardiovascular stability by lowering the need for catecholamines after liver reperfusion. In contrast, a third RCT (Azoulay et al, 2006) did not confirm a beneficial effect of ischemic preconditioning. Furthermore, the application of ischemic preconditioning in the setting of liver transplantation has not been shown to be beneficial compared with conventional liver-harvesting methods for deceased or living donors (Azoulay et al, 2005; Koneru et al, 2005). In addition, a recent Cochrane analysis found no statistically significant difference in mortality rate, liver failure, blood loss, or hemodynamic changes (Gurusamy et al, 2007).

Pharmacologic preconditioning is a promising field, as a variety of substances have been proven effective in animal experiments, although very few concepts have made the transition to being applied to humans. In one RCT (Beck-Schimmer et al, 2008), 64 patients undergoing liver surgery with inflow occlusion were randomized to 30 minutes of intraoperative preconditioning with sevoflurane or anesthesia with propofol. Thirty minutes before inflow occlusion, propofol was replaced by sevoflurane in the preconditioning group, and it was found that preconditioning with sevoflurane significantly reduced postoperative aspartate aminotransferase and alanine transaminase levels. Furthermore, the overall incidence of postoperative complications and the number of major events was reduced, and this beneficial effect was stronger in patients with hepatic steatosis.

Topical Hypothermia

As hepatic inflow occlusion carries a serious risk of ischemic injury to the remnant liver, induction of hypothermia was proposed to reduce the injury, particularly in patients with underlying liver disease (Kim et al, 1994, 2004). The adverse hemodynamic effects of systemic hypothermia has led some authors to use topical cooling by placing ice packs or ice slush on the liver surface (Imakita et al, 2000; Yamanaka et al, 1998); using such techniques, ischemic time could be prolonged for more than an hour in diseased livers, especially if the hepatic core temperature fell below 30° C (Kim et al, 2004).

Selective Inflow Control

Selective inflow control selectively interrupts the arterial and portal venous inflow to the hemiliver to be resected. The advantages of this procedure include 1) clear demarcation of the limits of resection, 2) absence of ischemic injury of the remnant liver, 3) absence of splanchnic congestion, and 4) hemodynamic disturbances. Selective inflow control was specifically devised for segmental and subsegmental resections for small hepatocellular carcinomas in diseased liver (Shimamura et al, 1986; Castaing et al, 1989). Additional clamping of the ipsilateral hepatic vein can also be performed along with this procedure for better vascular control (Makuuchi et al, 1987; Fig. 91A.3) With the wider use of intermittent clamping, selective clamping techniques have not gained wide acceptance, as this is more technically demanding and has no obvious beneficial effects compared with genuine intermittent clamping. In a prospective controlled study that included patients who underwent minor resection, both techniques were associated with similar blood loss and postoperative complications (Figueras et al, 2005); however, induction of lesser cytolysis was observed in those in the cirrhotic group who underwent selective clamping.

TECHNICAL ASPECTS. After encircling the pedicle and performing cholecystectomy, the portal vein is approached

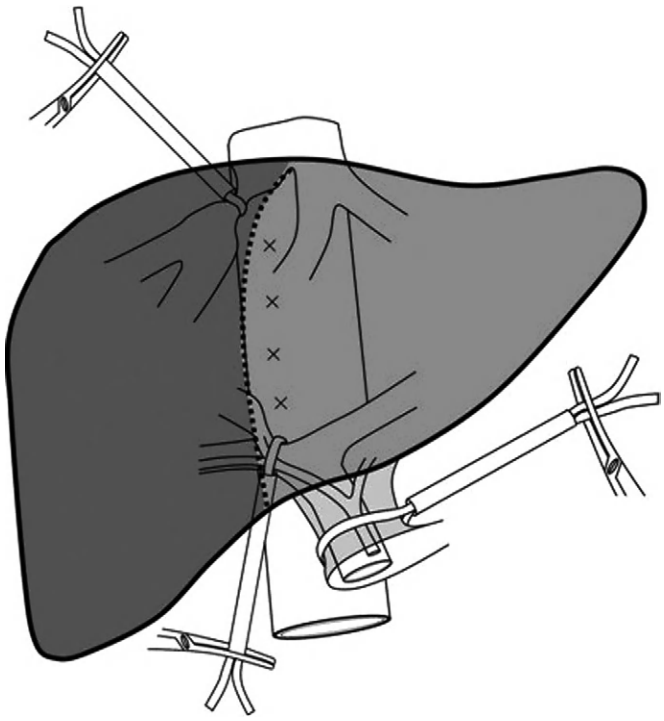

FIGURE 91A.3. Hemihepatic vascular clamping interrupts the inflow and outflow of the hemiliver to be resected.

posterolaterally from the right to avoid devascularization of the common bile duct. Care must be taken to avoid inadvertent injury to a right hepatic artery arising from the superior mesenteric artery. The main portal vein is dissected caudally to cranially on its anterior surface up to the bifurcation. During the dissection of its posterior surface, the consistent branch from the right posterior face of the right portal vein to the paracaval portion of the caudate lobe is ligated. After isolation and retraction of the right branch of the hepatic artery, the portal bifurcation is identified. The posterior passage of the curved dissector in the bifurcation is facilitated by a slight caudal traction of the main portal trunk. The bifurcation of the portal vein is usually accessed from the right side; however, when the caudate lobe is preserved, the dissection of the left branch of the portal vein should be accessed from the left side of the portal pedicle, with attention to one or two small portal branches to the left part of the caudate lobe. The right or left branch of the hepatic artery is identified and encircled. We do not advocate extrahepatic biliary dissection before parenchymal transection because of the risk for biliary injury. The branches of the portal vein and hepatic artery supplying the liver to be resected can be cross-clamped or ligated.

Segmental selective clamping can be useful for delineating the territory of some tumors, but this requires difficult segmental or subsegmental resection. Sectoral territories can be delineated by extraparenchymal pedicular control of the respective sectors. Isolated control of single segments is more difficult and requires balloon occlusion of the portal flow. Under US guidance, the portal branch is punctured, followed by introduction of a balloon catheter. Inflation of the balloon, along with pedicular arterial clamping, can delineate the portal territory; the injection of methylene blue into the portal catheter can allow more precise identification of the territory of interest.

Inflow and Outflow Vascular Control

Hepatic Vascular Exclusion

HVE combines total inflow and outflow vascular occlusion of the liver. Total isolation of the liver from the systemic circulation is intended during resection of large tumors adjacent to or involving the major hepatic veins and/or the IVC. This procedure can also be considered when significant backflow bleeding occurs as a result of persistently elevated CVP despite efficient hepatic pedicle clamping (e.g., in a patient with tricuspid insufficiency). This procedure, which requires prolonged continuous clamping, cannot be tolerated in patients with diseased liver and can cause significant hemodynamic disturbance in some patients (see Table 91A.2).

Effective HVE requires complete mobilization of the liver from its ligamentous attachments and from all surrounding adhesions. The IVC is completely freed from the retroperitoneum, which requires the ligation of the right adrenal vein. The IVC is mobilized above and below the liver and is encircled. The hepatoduodenal ligament is encircled as described above, and a careful search is made for accessory or replaced hepatic arteries (Fig. 91A.4). Clamps are applied in the following order: 1) hepatoduodenal ligament, 2) infrahepatic IVC, and 3) suprahepatic IVC. Once the surgeon and the anesthesiologist agree that clamping will be tolerated, clamps are reapplied for up to 60 minutes in patients with a normal liver. After completion of the parenchymal transection, prior to removing the clamps, the clamp on the infrahepatic vena cava can be partially released to flush air that might have been trapped and to test for caval integrity. The clamps are then removed in reverse order of placement.

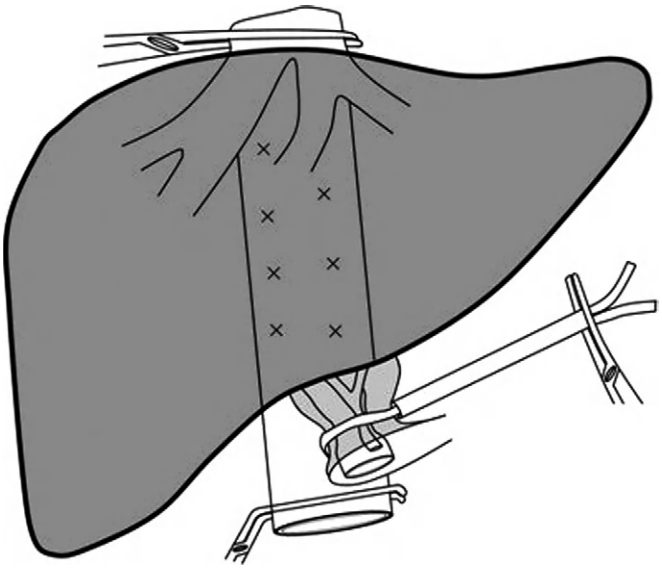

FIGURE 91A.4. Hepatic vascular exclusion.

Inadequate HVE technique will result in progressive congestion of the liver as a result of 1) inadequate clamping of the portal pedicle or the IVC, 2) persistent arterial inflow through an unrecognized left hepatic artery or through hypervascular perihepatic adhesions, 3) persistent entry of venous blood into the excluded retrohepatic IVC via anatomic (right adrenal) or pathologic veins (tumor adhesions). Patients with huge tumors with diaphragmatic and peritoneal adhesions, the best candidates for HVE, can experience hepatic congestion after suprahepatic caval clamping. This congestion reveals itself by an increase in liver size and a change in color and consistency of the liver, which is always associated with hemodynamic intolerance that immediately reverses after release of the suprahepatic clamp; this is because flow through retrocaval veins may fill the liver, when every connection from the cava to the liver is not controlled.

Supracaval declamping provides the path of least resistance for blood from the liver to flow toward the heart rather than backward into the surgical field. Although concomitant supraceliac aortic clamping has been proposed in this situation, the technique has not been widely adopted. Three randomized studies (Belghiti et al, 1996; Chen et al, 2006; Smyrniotis et al, 2002) compared total vascular exclusion (TVE) with portal pedicle clamping or selective vascular exclusion and showed that both techniques were effective in bleeding control. No statistically significant difference was reported in the operative blood loss, number of patients transfused, or number of units transfused (Gurusamy et al, 2007), and no difference in mortality was found between the two groups; however, TVE was associated with significant decrease in mean arterial pressure and mean pulmonary arterial pressure. Postoperative serum creatinine level and length of hospital stay were significantly greater in the TVE group (Gurusamy et al, 2007). Finally, TVE requires prolonged continuous clamping that can be poorly tolerated in patients with diseased liver.

Two refinements have been proposed to overcome these drawbacks: 1) HVE with preservation of caval flow to minimize the hemodynamic impact and 2) hypothermic perfusion to decrease parenchymal injury related to prolonged warm ischemia.

Hepatic Vascular Exclusion with Caval Flow Preservation

Better understanding of intrahepatic anatomy and advances in surgical techniques allow many liver surgeons to safely expose and control the three main hepatic veins. In the absence of tumor involvement of the hepatocaval junction, HVE with caval flow preservation can be considered. The association of inflow occlusion (hepatic pedicle clamping) and outflow occlusion by extraparenchymal clamping of the three main hepatic veins (Fig. 91A.5) enables complete vascular isolation without interruption of the IVC flow (Cherqui et al, 1999; Elias et al, 1995); however, this attractive procedure is restricted to patients without tumor involvement of the hepatocaval junction. In addition, the presence of large veins draining the caudate lobe may render this procedure ineffective. Caudate lobe veins are not isolated in this technique and can communicate intraparenchymally with other major veins, causing persistent backflow bleeding. The technical sequence of HVE with preserved caval flow includes total pedicular clamping with subsequent clamping of the three major hepatic veins at their confluence with the IVC. This clamping procedure can be applied either continuously or intermittently.

Extrahepatic control of the right hepatic vein (RHV) requires a complete mobilization of the right liver. Division of the falciform ligament is extended cranially to the upper peritoneal folds of the right and left triangular ligaments. The gutter between the liver, the RHV, and the middle hepatic vein (MHV) is dissected free to the anterior surface of the IVC. At this stage, dissection of a major hepatic vein from above is considered very hazardous and should not be attempted.

After mobilization of the right lobe, and upon complete exposure of the right and anterior side of the IVC, the liver is retracted medially and upward. The right half of the IVC is dissected caudally to cranially with ligation of short and small retrohepatic veins. When a significant right inferior hepatic vein is present, it is either encircled or ligated and then divided according to the type of resection. Before reaching the RHV level, the IVC ligament is encountered, which is dissected and divided between clamps; because it contains small veins, it should be closed with a running suture. Only after this has been completed should the RHV be encircled and taped, which is achieved easily by placement of a clamp that passes on the anterior surface of the IVC toward the space between the RHV and MHV. To facilitate the subsequent parenchymal dissection, a tape is inserted behind the RHV and is passed along the anterior surface of the IVC (Fig. 91A.6), and the right liver is released to lie in its anatomic position. The tape that elevates the precaval space, the so-called hanging maneuver, facilitates subsequent division and hemostasis of the parenchyma (Belghiti et al, 2001).

Extrahepatic control of the middle and left hepatic veins requires exposure of left border of the IVC. The left upper aspect of the IVC is exposed by division of the peritoneal reflection above the caudate lobe, and the ligamentum venosum is ligated and divided to expose the junction of left hepatic vein (LHV) and the IVC (Majno et al, 2002). When the left phrenic vein drains directly into the LHV, the former is ligated and divided. A dissector is inserted from above in the previously dissected gutter between the right and middle hepatic veins and is passed in close contact with the anterior surface of the IVC beneath the MHV. The common trunk is then encircled with a tape. When the confluence of the middle and left hepatic veins

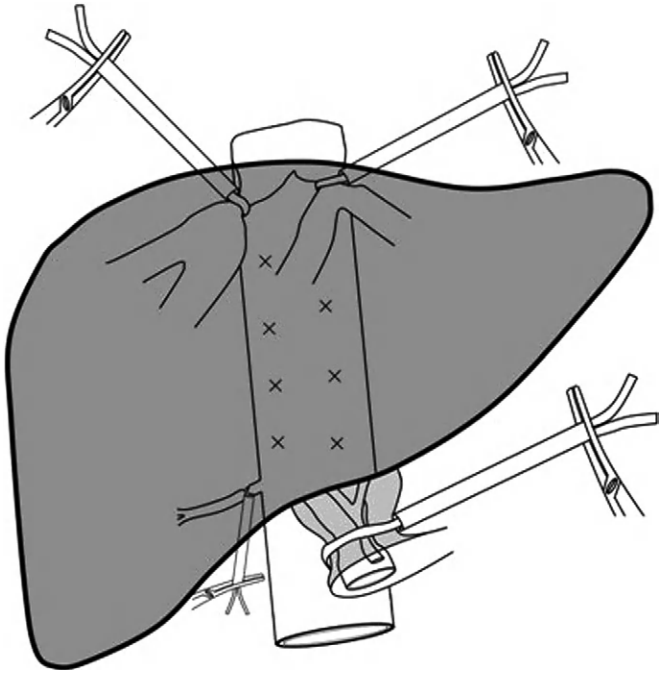

FIGURE 91A.5. Hepatic vascular exclusion (HVE) with preservation of caval flow enables isolation of the liver from the systemic circulation, thereby avoiding the hemodynamic disturbances of HVE as the vena caval flow is maintained.

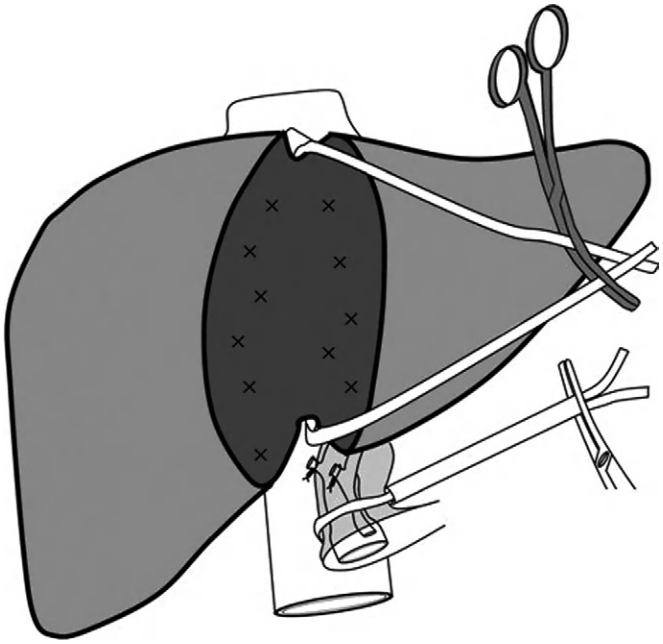

FIGURE 91A.6. Liver-hanging maneuver helps to guide the direction of transection.

is extrahepatic, it is possible to separately encircle these two vessels; otherwise the common trunk of the middle and left hepatic veins can be encircled as a unit.

Hepatic Vascular Exclusion with Hypothermia

Initially described by Fortner and colleagues (1974), this technique has been reevaluated by Azoulay and others, especially when HVE was longer than 60 minutes in duration (Azoulay et al, 2005). Compared with standard HVE, this group showed that hypothermic perfusion of the liver was associated with better postoperative liver and renal functions and less morbidity, especially in patients who required more than 60 minutes of HVE, although the technique requires systematic venovenous bypass for all patients. In the study, cooling was performed using 4 to 8 L of University of Wisconsin solution chilled to 4° C, perfused through the PV, and let out through an incision above the inferior caval clamp. To expedite the process, surface cooling using cold packs, ice, or cold water may be used. Intraparenchymal temperature should ideally be monitored using a fine needle, and the objective is to range between 14° C and 18° C. This renewed attractive procedure is applicable in difficult and complex liver resection in patients with diseased liver, and it should be added to the armamentarium of modern surgery.

Isolated Caval Clamping

Infrahepatic Caval Clamping

The major impact of caval pressure on blood loss during liver resection has led some surgeons to propose isolated IVC clamping to decrease the CVP (Fig. 91A.7; Abdalla et al, 2004; Otsubo et al, 2004). This technique is simple and is usually hemodynamically well tolerated, and it can decrease the CVP by approximately 4 cm of H_2O and can be used alone, when the liver resection is performed without pedicular clamping or along with pedicular clamping. When it is used in fluid-loaded patients, the hemodynamic impact on arterial pressure and postoperative renal function is minimal (Otsubo et al, 2004); therefore surgeons should consider this method, especially when the anesthesiologist cannot maintain a low CVP.

Isolated Total Caval Clamping

Clamping of the infrahepatic vena cava before liver transection can be considered in patients with a persistently high CVP (Otsubo et al, 2004). When a suprahepatic venous trunk is not involved by a tumor that otherwise involves the vena cava, total caval clamping below the hepatic veins associated with clamping of the vena cava but above renal veins maintains hemodynamic stability (Varma et al, 2007). This technique of caval clamping is indicated in patients with tumors in contact with the vena cava or near the cavohepatic junction, which necessitates en bloc resection of the IVC or cavohepatic junction. In this maneuver, the vena cava alone is clamped, leaving the inflow and outflow of the remnant liver intact; this procedure requires the control of the infrahepatic vena cava and of the uninvolved venous trunk.

The initial phase of the procedure consists of parenchymal transection by an anterior approach, usually under intermittent clamping after ligation of the hepatic pedicle to the tumor-bearing hemiliver. When the parenchymal transection reaches the anterior surface of the vena cava, the tape that encircled the uninvolved venous trunk is passed behind the suprahepatic IVC. The IVC is clamped at the site of this caval tape after clamping the infrahepatic vena cava. Thus the vena cava is isolated while hepatic flow is maintained through the remnant liver (Fig. 91A.8). The maintenance of the flow to the suprahepatic vein through the "liver shunt" avoids splanchnic congestion, hemodynamic disturbances, and liver ischemia. Total caval clamping without liver ischemia allows comfortable caval resection and reconstruction. This procedure, which is especially indicated, is efficient when the caudate lobe is involved and resected, which further reduces the indication of HVE to exceptional patients.

Nonclamping Technique

The ideal alternative to clamping would be to perform hepatectomy without clamping and without significant blood loss.

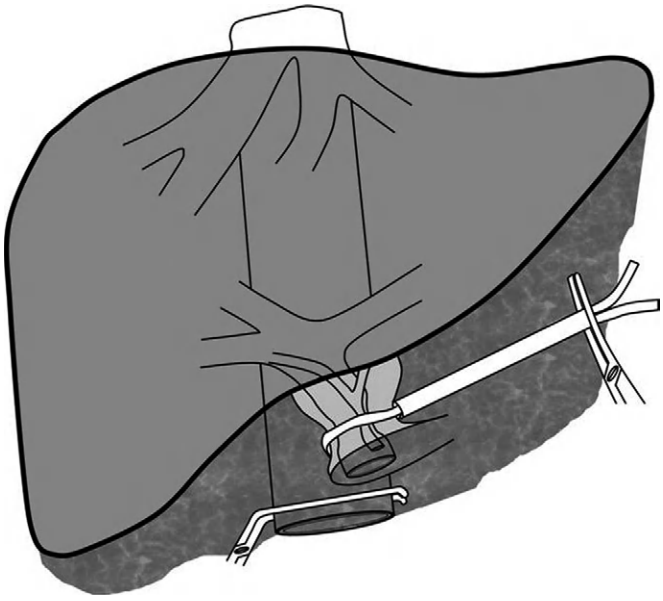

FIGURE 91A.7. Isolated infrahepatic vena caval clamping is performed to reduce a persistently elevated central venous pressure.

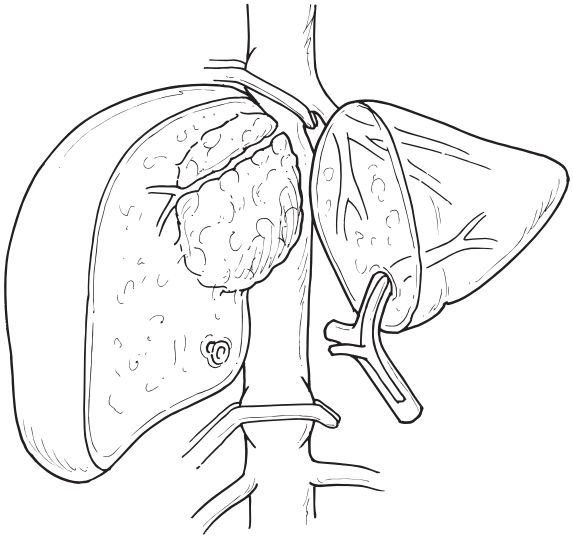

FIGURE 91A.8. The vena cava is isolated while the hepatic flow is maintained through the remnant liver.

This ideal approach is considered by many surgeons faced with major resection on underlying diseased parenchyma, living donor harvesting, and combined digestive operation to avoid splanchnic congestion on bowel anastomoses.

Several conditions should be satisfied to perform a hepatectomy without clamping: 1) fluid must be restricted, 2) completely preserved remnant liver venous drainage should be assessed preoperatively with CT scan and intraoperatively by Doppler US, and 3) the surgeon should possess modern tools of parenchymal transection. Bleeding from the transection surface is minimized when the remnant liver has a patent venous drainage; therefore a nonclamping technique should be considered essentially in major anatomic resections that preserve complete venous drainage of the remnant liver. Nonclamping increases liver transection time, which can be reduced by the use of several technical refinements that include use of an ultrasonic dissector, bipolar scissors, or water-irrigated bipolar forceps. As minimizing blood loss remains the major objective, the pedicle should be controlled and clamped if the blood loss approaches 20 mL/kg (Scatton et al, 2004). A recent randomized trial has shown that major liver resection can be performed without clamping (Capussotti et al, 2006).

CONCLUSIONS

Living donor liver resection is the best illustration that major hepatectomy can be performed without clamping and without transfusion. This reflects the progress and improvements in technique that have been achieved during the past decade. Minimizing blood loss, however, is not well tolerated in patients with diseased liver and requires the use of vascular clamping, especially in complex liver resections. Each vascular occlusion technique, which should be defined with the anesthesiologist, has a place in major and minor hepatic resection surgery, based on the tumor location, presence of associated underlying liver disease, patient cardiovascular status, and experience of the operating surgeon; however, intermittent pedicle clamping remains the procedure of choice.

CHAPTER 92

Segment-oriented anatomic liver resections

Charbel Sandroussi and Paul D. Greig

OVERVIEW

Decreased intraoperative blood loss and preservation of parenchyma are key contributors in recent advances in liver surgery that have resulted in reduced morbidity and mortality in liver resection. The understanding of the segmental anatomy of the liver has been pivotal in the evolution of a safe liver surgery (Scheele et al, 1995). Segmental liver resection offers maximum preservation of liver parenchyma with minimal blood loss and without compromising oncologic safety (Agrawal & Belghiti, 2011; Billingsley et al, 1998; Bismuth et al, 1988; Machado et al, 2003; Polk et al, 1995). The ability to resect one or more segments, rather than the entire lobe, allows parenchymal preservation in patients with diseased parenchyma or in re-resection patients with limited residual volume. Segmental vascular inflow control facilitates the resection by precisely mapping the transection plane. In addition, anatomic resections that involve the removal of a hepatic segment confined by tumor-bearing portal tributaries for the eradication of intrahepatic metastases in the vicinity of the primary tumor represent an oncologic approach to liver resection for some malignant tumors (Agrawal & Belghiti, 2011; Liau et al, 2004).

ANATOMY AND TERMINOLOGY

The current understanding of the segmental anatomy of the liver has come from the original 1952 descriptions of Claude Couinaud (1952a, 1952b, 1956). Based on his analysis of vascular and biliary casts of the liver, Couinaud determined that the human liver consists of eight segments, each with its own portal triad—vein, hepatic artery, and hepatic duct—and hepatic venous outflow. Subsequently it has been shown that each segment can be resected independently (Bismuth et al, 1982). These segments have evolved to become the standard for hepatic nomenclature. This so-called Brisbane terminology (Pang, 2002) eliminates confusing lobes and sectors used in the American, European, and Japanese descriptions of liver anatomy. The terms *hemiliver* (first-order division), *section* (second-order division), and *segment* (third-order division) are not interchangeable; these provide universal terminology for better communication among liver surgeons.

The first-order divisions are *right liver* (segments V through VIII) and *left liver* (segments I through IV), or *hemiliver,* the boundary of which lies along the Cantlie line marked by the path of the middle hepatic vein (MHV), from the middle of the gallbladder fossa to its termination in the inferior vena cava (IVC) (Fig. 92.1). The second-order division into liver sections is based upon hepatic arterial supply and biliary drainage. The sections are derived from the primary divisions of the major right and left portal triads. The right hemiliver is divided into sections known as the *right anterior* (segments V and VIII) and *right posterior* (segments VI and VII), separated by the right hepatic vein (RHV). The left hemiliver is divided into *left lateral* (segments II and III) and *left medial* (segments IVa and IVb) sections by the umbilical fissure and falciform ligament. Together segments II and III are often erroneously referred to as the *left lateral segment.*

The third-order division, segments I through VIII, is defined by hepatic arterial supply and biliary drainage. The axial plane is at the level of the intersection of the hepatic veins and the axial plane of the bifurcation of the portal vein (Table 92.1 and Fig. 92.2). When considering a segmental resection, it is important to identify the common anomalies that may determine resectability. The biliary and arterial anomalies are the most common: about 30% of patients have a major arterial anomaly, and up to 50% have nonstandard biliary anatomy.

PATIENT SELECTION

A liver resection based on the segmental anatomy should be the first consideration for any liver resection. Excluding the fenestration of liver cysts or small "wedge excisions" of superficial lesions, an understanding of the patient's segmental liver anatomy is essential to a safe, controlled resection. This technique is applicable for all types of livers and indications for resection (Hasegawa et al, 2005).

Achieving balance between parenchymal sparing and radical oncologic clearance is of the utmost importance in hepatocellular carcinoma (HCC) patients with cirrhosis. Segmental liver resection forms a bridge between major hepatectomy and nonanatomic resection to preserve maximum liver volume and prevent postoperative liver failure (Agrawal & Belghiti, 2011; Wakai et al, 2007). Replacement with nonanatomic resection should be done only when the anatomy is unsuitable, or when the residual liver would be at high risk for complications. Segmental liver resection is preferred in patients who have colorectal metastasis with multifocal lesions and are undergoing preoperative chemotherapy, which is frequently associated with steatosis and hepatic cirrhosis (DeMatteo et al, 2000).

PREOPERATIVE PLANNING

Variable anatomy from patient to patient confounds the preoperative planning of liver resection. Seldom does any patient have the classic vascular anatomy as depicted by the idealized diagrams. The planning of a segment-based resection must be individualized for the specific anomalies, and their relationship to the plane of transection is particularly important. The assessment of suitability of the operation requires a precise mapping with attention to vascular and biliary anomalies. Resection has been facilitated by the precision digital imaging provided by

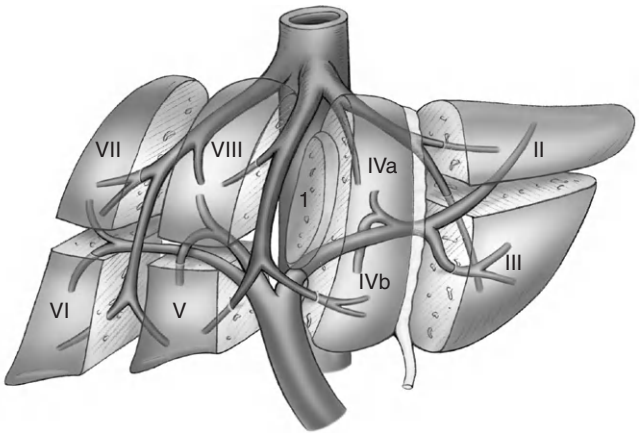

FIGURE 92.1. Diagram depicting the relationships of the eight liver segments with the major hepatic veins and portal veins of the idealized liver.

Table 92.1

Description of the Anatomic Boundaries of Each Segment

Segment	Vertical Boundary	Horizontal Boundary	Other
I	Middle of the IVC		Posterior to PV
II	Left of the left PV (falciform)	Cephalad to the left HV	
III	Left of the left PV (falciform)	Caudate to the left HV	
IVa	Right of the left PV (falciform) Left of the middle HV	Cephalad to the bifurcation of the PV	
IVb	Right of the left PV (falciform) Left of the middle HV	Caudate to the bifurcation of the PV	
V	Right of the middle HV Anterior to the right HV	Caudate to the bifurcation of the PV	
VI	Posterior to the right HV	Caudate to the bifurcation of the PV	
VII	Posterior to the right HV	Cephalad to the bifurcation of the PV	
VIII	Right of the middle HV Anterior to the right HV	Cephalad to the bifurcation of the PV

computerized tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US), allowing the surgeon an interpretation of intrahepatic vascular and biliary anatomy, facilitated by the ability to manipulate the images using widely available software. With the appropriate protocol for arterial and venous enhancement, the third- and fourth-level vascular structures can be accurately defined. Furthermore, the ability to easily scroll through reconstructions in the axial, coronal, or sagittal planes allows the surgeon to analyze and define the anatomy. More advanced, three-dimensional reconstructions of the liver allow the surgeon to dynamically view the anatomy by rotating the liver along a vertical axis, centered on the IVC, or along a horizontal axis, through the bifurcation of the porta. Based on the segments involved by the disease process, their relationship with the segmental hepatic venous outflow and portal venous inflow, which is representative of the arterial and biliary triad structures, can be determined. One technique for planning is to first determine which hepatic veins require resection or

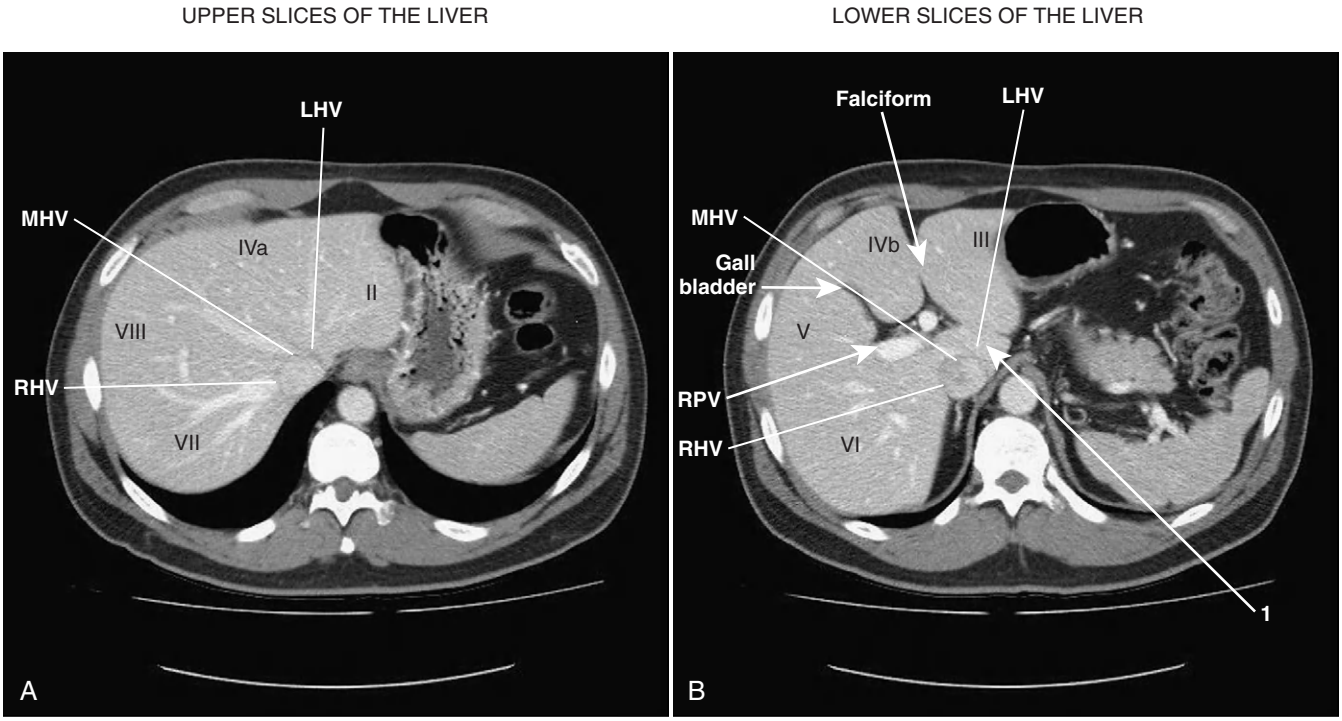

FIGURE 92.2. A, Axial computed tomographic (CT) scan image through the upper liver, demonstrating the anatomic boundaries of segments I, II, IVa, VIII, and VII. **B,** Axial CT scan image through the lower liver, demonstrating the anatomic boundaries of segments I, III, IVb, V, and VI. LHV, left hepatic vein; MHV, middle hepatic vein; RHV, right hepatic vein; RPV, right portal vein.

preservation, and at what level for an adequate margin, and then to consider the portal triads that need to be included as a basis for the segmental resection.

For a donor right hepatectomy, the presence of single or multiple right portal veins, hepatic arteries, and hepatic ducts impacts the suitability of the donor graft. For example, the presence of the segment V and VIII portal pedicle, arising from the left portal pedicle, and the size of the hepatic veins of segments V and VIII could influence the decision to include the MHV with the graft.

Other technology is being developed, and more sophisticated software is available, that will facilitate the preoperative planning of liver resection. These easily manipulated, three-dimensional reconstructions create a virtual reproduction of the liver that can be used to determine the proposed plane of transection, taking into account the minimum resection margin and residual liver volume. Some facilities that use such technology include the University of Toronto and the University of Illinois at Chicago. The MeVIS imaging system (MeVisLab, Bremen, Germany) is widely used. Some of these systems have been extended to facilitate real-time, image-guided resection by coupling the preoperative images of the virtual liver to a real-time liver and instrument tracking system. Systems being investigated include those under development by Pathfinder Therapeutics (Nashville, TN) and the Medical University of Graz, Austria. These advances offer significant potential for increased precision of preoperative planning for segment-oriented liver resections and intraoperative application to facilitate image-guided surgery.

GENERAL OPERATIVE PRINCIPLES

Preoperative Assessment and Anesthesia

The preoperative assessment and preparation of the patient for a liver resection have been described in Chapter 2. Comorbidities should be identified and optimized. Careful assessment of liver function is important, particularly in those with intrinsic liver disease. Preoperative decompression of an obstructed biliary tree should be considered for improving postoperative liver function (Belghiti & Ogata, 2005). Volumetric analysis should be performed in patients with potentially marginal residual liver size and function. Preoperative portal vein embolization (PVE) may facilitate the safety of a complex or extended liver resection by inducing regeneration of the potential contralateral remnant liver segments (Abulkhir et al, 2008). Particular attention should be paid to the reduction of the central venous pressure during transection to reduce blood loss, and measures to prevent hypothermia are also important. The appropriate prophylaxis of infections and venous thromboembolism is required.

Exposure and Mobilization

For a segment-oriented liver resection, open operative exposure can be achieved through a variety of incisions. The most common incisions include the right subcostal with midline extension cephalad (hockey stick) or its modification (J-shaped), or a bilateral subcostal incision with midline extension cephalad ("Mercedes" incision) or without (chevron incision). For access to the infrahepatic IVC, right kidney, duodenum, and retroperitoneum, a midabdominal transverse incision to the umbilicus with midline extension offers generous exposure. A long midline incision may be used for selected liver resections; a right thoracoabdominal incision is seldom required.

One principle to consider in selecting the appropriate incision is whether exposure of the suprahepatic IVC and the origin of any of the hepatic veins is needed. If so, an incision that extends cephalad to the right of the xiphoid process to the junction with the costal margin is valuable. This can usually be achieved without resection of the xiphoid process. Adequate exposure of the liver, including the porta and suprahepatic structures, is facilitated by a retractor fixed to the operating table, which provides for substantial cephalad and somewhat anterior retraction of the costal margins, especially the right. Suitable retractors are the Omni-Tract (Omni-Tract Surgical, St. Paul, MN), the Iron Intern (Automated Medical Products, Edison, NJ), and similar retractors made by various other manufacturers, such as the Bookwalter (Codman, Raynham, MA) and Thompson retractors (Thompson Surgical Instruments, Traverse City, MI).

After the laparotomy and general inspection, the liver is mobilized by transection of the obliterated umbilical vein and division of the falciform ligament, as it triangulates onto the IVC, to identify the origins of the hepatic veins and, in particular, the right middle groove and the left middle groove, if it is extrahepatic. Mobilization of the left and/or right lobes may be performed either before or after pedicular dissection. Left liver mobilization requires division of the left triangular ligament, and a laparotomy pad or sponge placed posterior to segment II can be valuable in protecting the cardia of the stomach and spleen, especially in a patient with a very long left lateral section that wraps over the spleen.

During the division of the lesser omentum (gastrohepatic ligament), attention should be given to the presence of an anomalous left hepatic artery, arising from the left gastric artery. Right liver mobilization requires division of the right triangular ("rookie") ligament; division of the anterior layer of the coronary ligament, as it reflects from the diaphragm onto segment VIII; and the posterior layer of the coronary ligament that reflects onto segment VI. The liver is mobilized off the right hemidiaphragm, thereby exposing the bare area of segments VI and VII. The right adrenal gland is separated from segment VI (a densely adherent adrenal gland may be divided and oversewn), and the retrohepatic IVC is identified.

Intraoperative Assessment

Intraoperative assessment of the liver requires correlation of the findings of inspection and palpation of the mobilized liver with those of the preoperative imaging. Intraoperative US has been advocated to localize the lesion and further stage the proposed remnant liver (Makuuchi et al, 1991); however, with the increased precision of preoperative imaging, intraoperative ultrasound (IOUS) seldom alters the procedure (Jarnagin et al, 2001). IOUS of the liver may be valuable to identify venous tumor thrombus and to assess the proposed plane of transection and its relationship with major hepatic veins and portal triads.

Recently, systematic segmentectomy and subsegmentectomy by IOUS-guided finger compression has been described (Torzilli et al, 2010). This technique can be applied in each segment of liver, as long as the thickness of the parenchyma and the anatomy of liver are suitable. IOUS-guided finger compression of the vascular pedicle feeding the tumor at the level

closest to it results in a demarcation area, allowing oncologic resection.

Transection Techniques

There are at least two distinct philosophies of liver transection, which result in distinct surgical techniques and surgical styles. The first is that blood loss from the transected liver is minimized by speed, external compression, vascular occlusion (outflow and/or inflow) (Bismuth et al, 1989; Stephen et al, 1996), and the use of surgical interventions to stop bleeding using cautery, sutures, and tissue glues. The second is that blood loss is best minimized by prevention of injury to vascular structures, using transection techniques that dissect out structures from the surrounding parenchyma as understood and anticipated by preoperative imaging and planning. Use of the Cavitron Ultrasonic Surgical Aspirator (CUSA; Valleylab, Boulder, CO), which reduces blood loss better than the clamp-crushing technique (Fan et al, 1996), has become the standard technique of liver transection even in cirrhotic liver (Takayama et al, 2001).

More recently, a third technique has been described that reflects a philosophy of prevention of bleeding that uses destructive hemostatic control of the parenchyma before transection (Ayav et al, 2007; Curro et al, 2008). We prefer the second approach, although clamp crushing, the conventional method of liver transection, is still used in some centers (Imamura et al, 2003; Jarnagin et al, 2002; Lin, 1974). Surgical techniques that facilitate a precise, controlled transection of liver parenchyma and allow the dissection of intrahepatic structures are the Helix Hydro-Jet dissector (ERBE USA, Marietta, GA) (Baer et al, 1991) and the CUSA dissector (Little & Hollands, 1991). Each provides selective destruction of liver parenchyma with relative sparing of denser fibrotic tissue, such as hepatic veins and portal triads. Inflow and outflow vascular occlusion may be added to these techniques for better hemostasis. Because no evidence clearly supports the superiority of any one technique (Clavien et al, 2003), the transection method for any particular operation should be dependent on local expertise.

Techniques that achieve destructive control of the parenchyma and any crossing structures before division include linear cutting staplers, in-line radiofrequency ablation (Habib; Angiodynamics, Latham, NY), and bipolar cautery (Gyrus, Gyrus ACMI, Southborough, MA; and LigaSure, Covidien, Boulder, CO). In-line radiofrequency ablation (RFA) allows surgeons to perform minor and major hepatectomies with minimal blood loss, low blood transfusion requirement, and reduced mortality and morbidity (Ayav et al, 2008); however, this device is seldom used in tertiary reference centers because of concerns about the preservation of venous drainage of the remnant liver and the risk of postoperative bile leak and necrosis (Kim et al, 2003; Lupo et al, 2007). The role of this technology is probably limited to segmental or wedge excision because of the potential risk of bile duct injury, when using this instrument near the liver hilum, and its inability to control bleeding from large venous branches.

Pretransection vascular control is used by many surgeons with oncologic, anatomic delimitation and hemostasis (Bismuth et al, 1989; Stephen et al, 1996). Early occlusion of the hepatic venous outflow of any resected segments may reduce the risk of venous tumor emboli. Occlusion of the hepatic artery (HA) and portal vein (PV) to those segments being resected facilitates the procedure by defining the line of division between ischemic segments to be removed and the well-perfused remnant liver for reduction of blood loss. Pretransection occlusion of the inflow of the segments to be resected before outflow results in better hemostasis. Occlusion of the inflow to sectors of the right hemiliver (VI and VII and V and VIII) or to the segments of the left lobe (II, III, IVa, and IVb) can be performed either by dissection and division of the artery and vein outside the liver, leaving the transection of the hepatic duct and remaining hilar plate for later in the procedure (Figueras et al, 2003), or by the glissonian technique (Launois & Jamieson, 1992), in which the sectoral or segmental pedicle is encircled, using either an anterior or posterior intrahepatic approach; this is done by incising the reflection of the Glisson capsule onto the portal structures to drop the hilar plate off the liver parenchyma, thereby encircling the pedicle. The duct, artery, and vein can be transected en masse either by suture or with a linear stapler.

PROCEDURES

Monosegment and Bisegment Resections

Segment I Resection

Segment I lies behind the posterior aspect of the portal bifurcation and receives inflow predominantly from the left PV and HA. The biliary drainage of segment I is variable, and the segment I bile duct runs in the hilar plate and enters the posterior aspect of either the left or right hepatic duct. Posteriorly, segment I rests on the IVC, and most of its outflow is directly into the IVC via a series of fragile veins. Tumors arising in the caudate lobe are closely related to the posterior aspect of the left and middle hepatic veins. This "critical oncologic margin" is a decisive factor in the choice between an isolated caudate resection or a left hepatectomy, with or without the MHV, including the caudate lobe.

DIRECT APPROACH. The falciform ligament is dissected in a cephalad direction, until the anterior and left surface of the suprahepatic vena cava has been isolated. The left hepatic vein (LHV) is identified, and the left triangular ligament is divided from left to right; as the dissection is carried medially, care should be taken to avoid injury to any low-entering phrenic veins and the LHV. The fissure for the ligamentum venosum, the *caudate groove,* is identified by retracting segments II and III to the right, and the hepatogastric ligament is incised.

For large tumors the right lobe should be mobilized to fully expose the caudate lobe from the right side as well. The resection can usually be performed from the left, although some large tumors may require an anterior approach. Peritoneal reflection onto the IVC in the lesser sac is incised, which allows some retraction of segment I, and occasionally the left side of the IVC is exposed through some or all of its length. The small bridge of liver between segments I and VI is also divided. To obtain further mobility and reduce the chances of a traction injury to the hepatic veins, the ligamentum venosum is ligated and divided in the superior aspect of its fissure, as it enters the posterior aspect of the left or middle vein. The inflow is then ligated as it emerges from the posterior aspect of the PV and HA. Often two distinct, paired PV branches enter segment I.

The dissection of segment I from the IVC then continues in a cephalad direction, dividing several thin-walled veins that drain segment I into the IVC. It must be noted that a large

predominant vein of segment I is often present 1 to 2 cm below the MHV and LHV confluence. Some of the venous branches between segments VI and VII and the IVC may be divided to provide adequate mobilization of the caudate off the IVC. Once segment I is mobilized, the thin parenchymal bridge between the caudate groove and the posterior transection line is divided. Usually, very few vascular structures are found in this plane, although the segment I duct and hilar plate tissue should be anticipated anteriorly. During parenchymal transection, the fissure for the ligamentum venosum is sometimes encountered and may need to be divided again. Dissection continues to its completion at the apex of segment I beneath the confluence of the hepatic veins.

ANTERIOR APPROACH. For very large tumors in segment I, an anterior approach may be used. A full mobilization of the liver off the IVC up to the inferior aspects of the left, middle, and right hepatic veins is performed by dividing the branches that drain segments I, VI, and VII directly into the IVC. Following division of the HAs and PVs to the caudate lobe, a vertical parenchymal transection plane through the Cantlie line to the left of the MHV partitions the right and left livers. The second parenchymal transection plane is made from the fissure of the ligamentum venosum, posterior to the plane of the left and middle hepatic veins and horizontally toward the vertical cut edge of the liver. The caudate duct is divided as it enters either the left or right hepatic ducts. At the conclusion of the resection, the remaining segments II and III should be resuspended by reapproximating the falciform ligament.

Segment III or III Resection

Given the discrepancy between portal venous supply and biliary drainage, and also given the difficulty of preserving left hepatic venous drainage, the combined segment II and III resection (left lateral sectionectomy; Fig. 92.3) is safer and more feasible than isolated resection of segments II or III. When either of these segmentectomies is being planned, the plane of resection is by either side of the LHV (left and posterior for segment II resection, right and anterior for segment III). The inflow is approached on the left side of the falciform ligament by incising the peritoneal reflection onto the liver and identifying either the

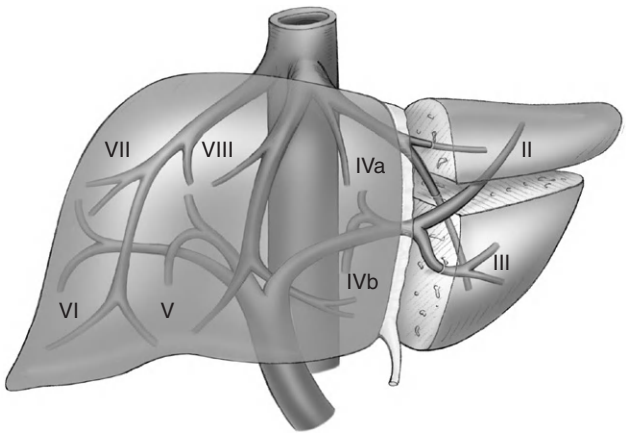

FIGURE 92.3. Diagram of the planes of transection for resection of segments II and III or segments IV, V, VI, VII, VIII (extended right hepatectomy).

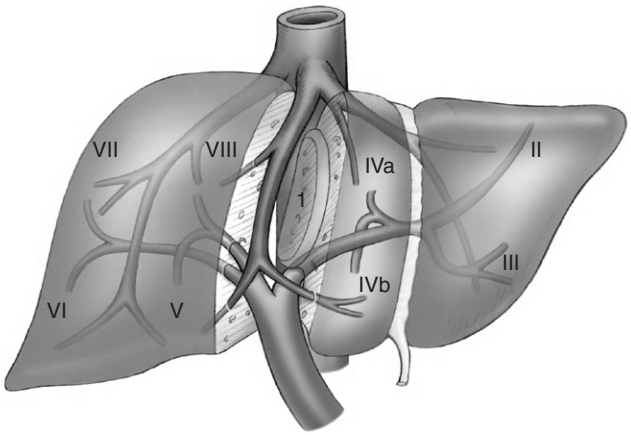

FIGURE 92.4. Diagram of the planes of transection for a right or left hepatectomy (hemihepatectomy).

segment II or III portal pedicles. Once the inflow is divided, the line of parenchymal transection becomes prominent between the ischemic segment to be resected and the normally perfused residual segment.

Combined Resection of Segments II and III: Left Lateral Sectionectomy

The left lateral section is mobilized by division of the falciform ligament and the left triangular ligament (Fig. 92.4). The extrahepatic portion of the left hepatic vein can be lengthened by dividing the fibrous tissue to the left of the IVC down to the level of the fissure for the ligamentum venosum, which is then ligated and divided as it enters the posterior aspect of the LHV; this allows encircling of this vein if the joining with the MHV is not intraparenchymal. Otherwise, the isolation of the LHV is delayed until completion of the parenchymal transection.

The inflow to segments II and III is usually isolated during transection of the parenchyma to the left of the falciform ligament. Occasionally, pedicles to segments II and III could be identified and encircled outside the liver in the left side of the portoumbilical fissure. The plane of parenchymal transection follows the falciform ligament. As the liver is divided, the portal structures to segments II and III will become apparent, and these can be electively ligated and divided. Once this is done, and the parenchyma surrounding the LHV has been dissected, the vein can also be ligated and divided.

The transection is completed by dividing the parenchyma anterior to the caudate lobe, in the fissure for the ligamentum venosum. The blood supply to the caudate emerges from the PV and left HA at the level of the portoumbilical fissure, and these should be identified and preserved before the parenchymal transection.

Segment IV Resection

Isolated resection of segment IV or IVa alone is very uncommon. This segment is limited posteriorly by the hilar plate and IVC, on the right by the falciform ligament and the left PV, and on the left by the MHV. Inflow and biliary drainage to segment IV comes from left to right from the left-sided portal structures in the base of the falciform ligament (the "comeback" branches from the left portal vein). Sometimes, aberrant right anterior and posterior sectoral ducts cross in this position; these should

be avoided during resection. Outflow from segment IV is predominantly to the MHV, but occasionally a separate draining vein (scissural vein) goes directly to the suprahepatic IVC or to the terminal part of the LHV or MHV.

Once the falciform ligament has been divided, with identification of the termination of the HVs, the arterial and venous inflow can be divided. By incising the peritoneal reflection on the right of the falciform ligament, the segment IVa and IVb pedicles can be isolated, encircled, and divided; the lines of transection become demarcated on the surface of the liver along the Cantlie line.

The resection continues at the base of segment IV off the anterior surface of the hilar plate. Care must be taken to avoid excessive use of cautery in the hilar plate, as the bile duct bifurcation and left hepatic duct lie immediately behind this area. Parenchymal transection commences on the right side of the falciform ligament with identification of portal pedicles to segments IVa and IVb. These may arise from a common trunk, and occasionally there are more than two, which is usually appreciable on preoperative imaging.

Transection continues superiorly to the level of the suprahepatic IVC to the junction of the LHV and MHV. The LHV and MHV commonly join within the liver at this point prior to insertion into the IVC, and in this case, the dissection terminates inferior to this point. Care should be taken to identify significant venous tributaries from segment IV into the left hepatic vein, which may not be appreciated on preoperative imaging. The dissection of the right side is along the Cantlie line to the left of the MHV. Several tributaries to the middle hepatic vein, the IVa and IVb veins, will need to be identified and ligated. Once the medial border of the hilar dissection has been reached, the parenchymal transection is done in a transverse plane to complete the separation of segment IV.

Segment V or VIII Resection

These two segments compose the right anterior sector. The bifurcation of the right portal pedicle into anterior and posterior pedicles is intrahepatic, and primary ligation of these pedicles is difficult, especially for segment VIII; therefore some parenchymal transection along the Cantlie line toward the pedicle is required before its division to allow demarcation of either segment V or VIII. The segment V pedicle emerges anteriorly and runs anteroinferiorly, and the segment VIII pedicle emerges posteriorly and runs superiorly. The horizontal plane of transection for an isolated segment V or VIII resection runs through the liver at the level of the bifurcation of the portal vein, with segment V below and segment VIII above this line. The medial and lateral limits of the resection are the middle and right hepatic veins, respectively.

Segment V Resection

Isolated segment V resection begins with division of the liver on the undersurface up the center of the gallbladder fossa and anteriorly along the Cantlie line halfway up toward the IVC. Then the parenchyma is divided in a plane to the left of the RHV, which extends on the undersurface of the liver along the incisura dextra to the free edge and anteriorly halfway toward the IVC. This posterior plane is quite coronal and usually results in a large exposed area of parenchyma. The resection is completed by connecting the two vertical transection lines by division of the parenchyma horizontally from anterior to posterior immediately below the level of division of the portal vein.

Segment VIII Resection

Isolated segment VIII resection is a very challenging procedure, because no external demarcation of this segment is apparent. The initial landmark is the Cantlie line with a parenchymal transection in the right side of the MHV. The segment VIII pedicle, which corresponds to the ascending division of the right anterior sectoral pedicle, can be isolated either at this point, after division of the liver, or by dividing the liver between segments IV and V in the horizontal plane along the level of the portal bifurcation. This latter maneuver is useful, as it allows for demarcation of the right-sided resection margin, which is on the left side of the RHV. This horizontal transection should follow the coronal plane of the RHV, which requires IOUS guidance.

The parenchymal division of the right-sided resection margin continues superiorly; using the termination of the RHV as a landmark, there is often only 1 to 2 cm of liver at the upper margin of the transection between the RHV and MHV. Care must be taken during the right-sided parenchymal division to adhere to the correct transection plane, as this plane takes about a 45-degree angle from the vertical. This allows resection of all the liver in segment VIII, while avoiding injury to the RHV. The segment VIII resection is completed by separating the remaining parenchyma off the deep attachment to the IVC, although this should have been mostly completed during mobilization.

Combined Resection of Segments V and VIII

The combined resection of segments V and VIII requires the division of the right anterior sectoral portal triad with left-sided parenchymal division along the Cantlie line along the right side of the MHV; the right-sided parenchymal division is in the coronal plane of the left side of the RHV. The anterior sectoral pedicle may be encircled from outside the liver, either anteriorly or posteriorly, and it is divided en masse with a linear cutting stapler, or it may be identified during the parenchymal transection along the Cantlie line at the base. Early division of the inflow provides demarcation of the ischemic parenchyma, which facilitates identification of the planes of parenchymal transection.

Segment VI or VII Resection

The right posterior sectoral pedicle can be identified in the incisura dextra of Ganz, which corresponds to the horizontal fissure lateral to the gallbladder fossa. The segment VI/VII branch of the right HA can usually be isolated extraparenchymally; however, the segment VI/VII portal branch, which corresponds to the posterior division of the right portal branch, is more difficult to isolate. Therefore the pedicle for an isolated resection of segment VI or VII is usually approached within the liver during parenchymal transection (Fig. 92.5). A resection of segment VI or VII requires complete mobilization of the right lobe of the liver with division of the segment VI and VII hepatic veins, when present, to the IVC.

Segment VI Resection

Isolated segment VI resection (Figs. 92.5 and 92.6) commences with an oblique transection line along the incisura dextra in the inferior surface of the liver and anteriorly halfway toward the IVC, following the posterior side of the RHV. The horizontal plane of resection is at the level of the PV bifurcation. The descending branches of the right posterior sectoral portal triad are encountered about two thirds of the way through the dissection. The resection is completed by taking a horizontal

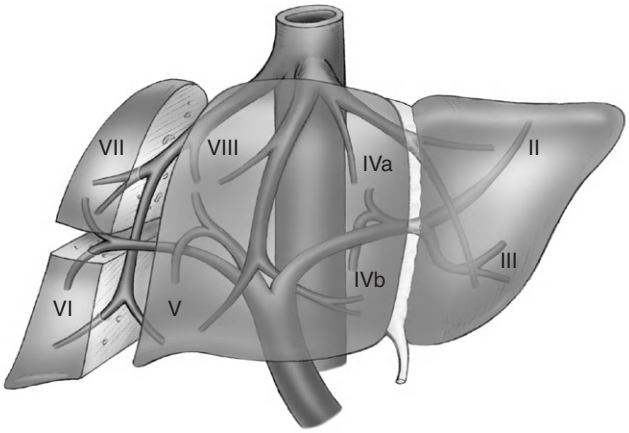

FIGURE 92.5. Diagram of the planes of transection for resection of segments VI and VII or segments II, III, IV, V, and VIII (extended left hepatectomy).

transection plane through the posterior surface of the liver lateral to the right hepatic vein.

Segment VII Resection

An isolated segment VII resection (see Fig. 92.5) commences with the horizontal transection line just above the bifurcation of the portal vein; this line is congruous with the horizontal resection line for a segment VI resection. The resection continues medially to the lateral margin of the RHV. During the horizontal resection, the ascending right posterior sectoral branches can be isolated and divided, which will allow for demarcation of the medial aspect of the resection. The vertical transection line runs obliquely through the liver lateral and posterior to the RHV.

Combined Resection of Segments VI and VII

This right posterior sectorectomy (see Fig. 92.5) is a procedure often considered as an alternative to a right hepatectomy, especially in patients with diseased parenchyma. Identification of the right posterior sectoral pedicle may be possible from outside the liver. Early division of the inflow facilitates the identification of the transection margins. Otherwise, the segment VI and VII HA and PV may be divided separately, leaving the transection of the VI and VII duct and plate for later, during the parenchymal transection. The plane of transection posterior to the RHV is coronal and results in a relatively large surface area of cut parenchyma, which requires specific attention for hemostasis and biliostasis.

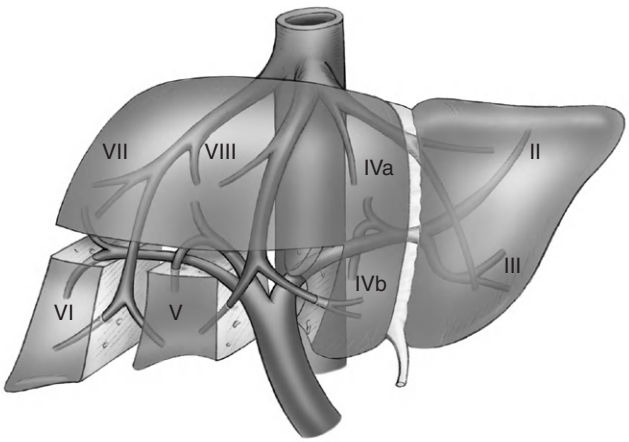

FIGURE 92.6. Diagram of the planes of transection for resection of segments V and VI.

Combined Resection of Segments V and VI

Resection of these two segments is very commonly performed. The vertical plane of transection is along the Cantlie line on the right side of the MHV from the edge of the liver to halfway up toward the IVC (see Fig. 92.6). The horizontal plane of transection is at the level of the PV. The portal pedicles to segments V and VI are usually divided during the parenchymal transection, which requires full mobilization of the right lobe of the liver from the diaphragm with division of segment VI and most, if not all, of the segment VII hepatic veins on the anterior surface of the IVC. The transection starts in the middle of the gallbladder fossa and extends along the Cantlie line up to the level of the right portal pedicle. Then with a dissection to the left, the horizontal plane of transection is developed from the top of the vertical plane. The segment V portal pedicle may be identified at the base and divided, followed by division of the segment VI pedicle posteriorly. From right to left, the horizontal dissection plane reaches the RHV.

Three or More Segmental Resections

Resection of Segments V Through VIII: Right Hepatectomy

Right hepatectomy is a very well-standardized procedure, consisting of resection of liver parenchyma on the right side of the Cantlie line in the right side of the MHV (see Fig. 92.4). The inclusion of the MHV corresponds to an extended right hepatectomy. Inflow and outflow control prior to transection may be appropriate and can be accomplished in many ways, and parenchymal resection can be performed with or without an intermittent Pringle maneuver. Mobilization commences by dividing the falciform ligament as it triangulates onto the IVC. The right middle groove, between the right hepatic and middle hepatic veins, is developed taking care not to injure a small tributary that may empty directly into the IVC from segment VIII.

Dissection of the porta hepatis commences with a cholecystectomy. A glissonian approach to the right portal pedicle may be performed by dividing the capsule that reflects onto the porta anteriorly and posteriorly, hugging the sheath as it is dropped off the parenchyma. Once encircled, the pedicle may be divided en masse with an Endo GIA (Covidien) stapler. Alternately, the inflow HA and PV may be dissected and divided individually. The peritoneum posterior and lateral to the portal structures is incised, and the RHA or its branches can be identified and divided. The peritoneum along the PV is incised, and the PV is mobilized off the back of the bile duct to clearly identify the bifurcation and origin of the left PV. The dissection continues cephalad along the anterior surface of the right PV. A small branch off the posterolateral aspect of the right PV to segment VI should be identified and divided to provide sufficient length for transection. The right PV is then encircled, taking care to divide any small branches that arise from the bifurcation, and it is divided with a vascular stapler. The liver should demarcate along the Cantlie line.

The right liver is mobilized by dividing the coronary ligament then exposing the bare area of the liver by dissecting the diaphragm and adrenal off the liver to expose the IVC. Rotation of the liver along the axis of the IVC facilitates this dissection.

Division of the left triangular ligament may make this rotation easier, especially when the liver is large, or when the patient is obese. Once the IVC has been identified, the segment VI and VII hepatic veins are ligated and divided. The retrocaval fibrous bridge between segments VII and I is divided, taking care to control any significant veins that may run through it. The RHV identified is encircled by passing a Kelly hemostat up the right middle groove between it and the MHV. The RHV is then divided with a vascular stapler, and an umbilical tape is placed in the groove of the IVC behind the liver to perform the hanging maneuver.

The parenchymal transection commences at the gallbladder fossa along the line of demarcation. The first major structure to be expected is the segment V hepatic vein, as it becomes the MHV. After division of this vein, the parenchymal transection continues along a broad front, either staying to the right side of the MHV or leaving a small amount of liver parenchyma on the surface of the vein. The hilar plate containing the right hepatic duct is approached at the base of the resection plane and may be divided prior to completion of the superior aspect of the parenchymal transection. Division of the bile duct and the hilar plate allows the parenchyma of the superior aspect of the liver to be separated and consequently reduces the risk of hepatic vein injury. Uppermost parenchymal transection is facilitated by placing some upward traction on the umbilical tape, the so-called hanging maneuver, dividing any segment VIII veins that cross over to the MHV. The dissection is completed posteriorly by dividing the glissonian capsule in the caval groove.

The right hepatectomy can be extended to include the middle hepatic vein and part of segment IV. To include the MHV, the transection begins to the left of the gallbladder fossa, and the first major structure expected is the segment IVb vein as it forms the MHV. Transection is then carried out to the left of the MHV, dividing any IVa veins that cross over to it. The MHV is encircled and divided before its junction with the LHV. Alternatively, the MHV may be identified and divided outside the liver, early after division of the RHV, by mobilizing a part of the caudate lobe off the IVC and encircling the MHV. In order to include segment IV in the resection specimen, the plane of transection is 1 cm to the right of the falciform ligament. The recurrent branches of the left portal triad to segments IVa and IVb need to be divided within the liver.

Resection of Segments II to IV: Left Hepatectomy

A left hepatectomy consists of resection of segments II, III, IVa, and IVb along the the Cantlie line to the left of the MHV (see Fig. 92.4). An extended left hepatectomy includes the MHV and/or segment I (caudate lobe). Inflow and outflow control prior to transection may be appropriate and can be accomplished in many ways, and parenchymal resection can be performed with or without an intermittent Pringle maneuver. Mobilization commences by dividing the falciform ligament as it triangulates onto the IVC. The plane between the LHV and MHV may be developed anterior to the IVC; however, the LHV and MHVs may join within the substance of the liver, and the left vein may not be able to be encircled outside the liver. To encircle the LHV, the ligamentum venosum is divided within its fissure to allow access to the posterior aspect of the LHV. Alternatively, the LHV may be divided at the end of the parenchymal transection, and control of vascular inflow may be appropriate. Using the glissonian approach, the left portal pedicle is encircled, and the pedicle may be transected en masse using an Endo GIA stapler. Alternatively, the branches of the left HA and the left PV may be divided outside the liver, leaving the left hepatic duct and plate to be divided late during the parenchymal transection.

The base of segment IV is dissected off the anterior surface of the bile duct bifurcation to allow for the transection line to be defined. The branches of the left HA are identified on the left side of the porta hepatis and are ligated. An early segment IV branch is often present, and this also should be ligated. The anterior surface of the PV can be identified and mobilized to clearly identify the origin of the right PV, and the left PV is encircled after dividing one or two of the branches to the caudate lobe. The left PV can then be ligated and divided. The parenchymal transection commences along the Cantlie line beginning to the left of the gallbladder fossa. The first major vascular structure encountered is the segment IVa vein, as it becomes the MHV. When the MHV is identified, the dissection is carried in a cephalad direction on its left side.

At the base of segment IV, the parenchymal transection should be carried to the left to minimize injury to any aberrant right hepatic ducts draining into the left hepatic duct. If the plane of transection is close to the falciform ligament, leaving the medial portion of segments IVa and IVb, the segment IVa and IVb portal pedicles that return from the left portal structures are identified and divided. The hilar plate is transected using a stapler, or it is ligated and divided. As the parenchymal transection continues cephalad, the LHV will become apparent, and it should be divided proximal to its junction with the MHV, if it was not divided outside the liver. The resection is completed by separating the parenchyma of segments II and III off the caudate lobe, ending by dividing the capsule along the caudate groove.

The left hepatectomy can be extended to include the MHV and variable amounts of segments V and VIII. Left hepatectomy extended to the right parenchyma with part or all of segments V and VIII could include parenchymal transection up to the left side of the RHV. In this procedure, also called *anterior hepatectomy,* the plane of transection is almost parallel to the operating table. The right anterior sectoral pedicle is usually ligated within the liver during the parenchymal transection. The right anterior and posterior pedicles can be orientated in many different ways, and it is important to ensure that the correct pedicle has been isolated, before anything irreversible has been done. This can be achieved by temporary pedicle clamping with a bulldog vascular clamp, assessing the delimitation of devascularized parenchyma. The anterior surface of the RHV should be cautiously dissected.

These major resections can be combined with caudate lobe and extrahepatic biliary tree resection in some cases of hilar cholangiocarcinoma. En bloc resection requires prior mobilization of the caudate off the IVC.

Resection of Segments IV, V, and VIII: Mesohepatectomy

This resection is very uncommonly performed, and it is indicated primarily for large central tumors where a formal extended right or left hepatectomy will not leave enough residual liver. The left-side plane of transection is to the right of the falciform ligament and the umbilical fissure, and the right-side plane is to the left side of the RHV (Fig. 92.7). The coronal transection plane is above the hilum and anterior to the right posterior sectoral portal pedicle.

Once the liver is mobilized completely, the RHV, MHV, and LHV are identified as they enter the IVC. After cholecystectomy, the hilar plate is dissected away from the base of

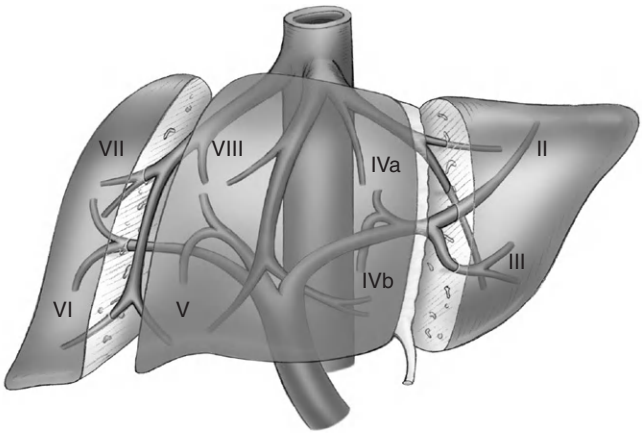

FIGURE 92.7. Diagram of the planes of transection for resection of segments IV, V, and VIII (mesohepatectomy).

segment IV by dividing the areolar tissue between the bifurcation of the common hepatic duct and the liver. Early isolation and division of the right anterior pedicle demarcates the liver and identifies the lines of transection. The inflow pedicle to IVb may be controlled outside the liver, but more commonly the IVa and IVb pedicles are taken during the parenchymal transection. The right anterior sectoral pedicle may be controlled using the glissonian extrahepatic approach, or the segment V and VIII pedicles may be ligated during the transection.

The parenchymal transection begins to the right of the falciform ligament. The portal pedicles to segments IVa and IVb are ligated and divided as they come back from the left-sided portal structures. This transection plane is carried cephalad toward the junction of the middle and left hepatic veins. Care must be taken to ensure that the LHV is not injured or inadvertently divided. The deeper portions of the left-sided dissection plane are best left until the right-sided parenchymal transection is complete. The right-sided transection plane is to the left of the RHV, angled approximately 45 degrees from the horizontal and vertical planes.

Transection begins to the right of the gallbladder fossa and is directed anteriorly toward the right middle groove and posteriorly toward the incisura dextra. Care must be taken to remain anterior to the right posterior portal pedicle and also not to injure the RHV. At the base of this transection plane, the right anterior sectoral portal pedicle or the individual segment V and VIII pedicles are divided, if they were not controlled earlier; prior to division a test clamping is valuable to ensure that the right posterior portal pedicle is not accidentally encircled. The dissection continues until the upper aspect of the left and right transection margins meet, and then the MHV is divided to complete the resection. Because of the large surface of cut liver and the proximity to the hilar plate, these resections are more prone to bleeding and bile leak.

CHAPTER 93A

Preoperative portal vein embolization: rationale, indications, and results

Taku Aoki, Hiroshi Imamura, Norihiro Kokudo, and Masatoshi Makuuchi

OVERVIEW

Although recent advances in surgical techniques and perioperative care have significantly improved both short- and long-term outcomes after hepatic resection (Belghiti et al, 2000; Fan et al, 1999; Grazi et al, 2001; Imamura et al, 2003; Jarnagin et al, 2002), postoperative liver volume insufficiency is still a major concern after an extensive liver resection. Both the small size of the remnant liver parenchyma after an extensive liver resection and sinusoidal injury caused by an abrupt increase in portal venous flow/pressure may be implicated in an increased rate of postoperative morbidity associated with cholestasis, ascites, and impaired synthetic function (Panis et al, 1997). These conditions all may lead to a protracted recovery and extended hospital stay and may eventually result in fatal liver failure, although rarely. This concern is even more relevant in patients with obstructive jaundice or underlying liver disease; that is, in those who not only have liver fibrosis or cirrhosis but also liver injury induced by chemotherapy, originally in patients with normal liver (see Chapters 50B, 65, 87, and 90F).

In 1982, we first carried out a preoperative portal vein embolization (PVE) for a patient with hilar bile duct carcinoma with the intention of increasing the operative safety under these circumstances (Makuuchi et al, 1984, 1990). The approach was based on the concept of the hepatic atrophy-hypertrophy complex (see Chapter 5). We attempted to initiate hypertrophy of the future liver remnant (FLR) before resection to induce atrophy in the embolized part of the liver to be resected with compensatory hypertrophy of the nonembolized FLR. Satisfactory initial outcomes led us to extend the indications for PVE to patients with metastatic liver tumors of colorectal origin (Kawasaki et al, 1994a) and for patients undergoing hepatopancreatoduodenectomy (Kawasaki et al, 1994b). Because of its technical simplicity and the consistent attainment of liver hypertrophy after the procedure, PVE has become a standard preoperative intervention worldwide, and its indications have been expanded to patients with hepatocellular carcinoma (HCC) (Aoki et al, 2004; Azoulay et al, 2000a; Lee et al, 1993; Ogata et al, 2006; Tanaka et al, 2000; Yamakado et al, 1997).

HISTORIC BACKGROUND

The concept of the hepatic atrophy-hypertrophy complex dates back to 1920, when Rous and Larimore (1920) showed that ligation of a major branch of rabbit portal vein resulted in atrophy of the ipsilateral hepatic lobe and hypertrophy of the contralateral lobe. The same phenomenon was observed in experiments involving long-term bile duct obstruction (McMaster & Rous, 1921); however, in contrast to the predictable response to portal venous occlusion, the magnitude of response to bile duct obstruction differs substantially among species (Braasch et al, 1972; Schalm et al, 1956; Steiner & Martinez Batiz, 1962; Stewart et al, 1937).

In 1975, Honjo and colleagues ligated the ipsilateral portal venous branch in patients with HCC in an effort to suppress tumor growth. Although this approach did not succeed in preventing tumor growth, it did produce marked atrophy of the occluded hemiliver. Likewise, our patients experienced an uneventful postoperative clinical course after extensive hepatectomy for hilar bile duct carcinoma involving a branch of the portal vein, causing hemiliver atrophy with corresponding hypertrophy of the contralateral hemiliver (Takayasu et al, 1986). These clinical observations led one of us (M.M.) to attempt PVE application as an adjunct procedure for major hepatectomy.

HEMODYNAMIC CONSEQUENCES

Total portal venous flow volume was thought to remain unchanged before and after PVE, because liver does not have an intrinsic ability to modulate portal flow, which is a function of extrahepatic (i.e., splanchnic and systemic) factors. This principle was confirmed in a study using a rat model of hemihepatic portal vein ligation and radioactive microsphere technique (Rocheleau et al, 1999) and in a human PVE study using Doppler ultrasound (Denys et al, 2000), proving that the same volume of portal venous flow as that prior to PVE would enter nonembolized liver segments after PVE. Portal pressure in the nonembolized hemiliver is elevated immediately after PVE by 4.9 ± 2.7 cm H_2O (Takayama et al, 1997). A similar increment was observed in patients with cirrhosis, who had higher baseline portal pressure (Aoki et al, 2004). Information on chronologic alterations in portal pressure after PVE is unavailable, but the elevation is believed to be transient, with pressure gradually returning to the baseline value in 2 to 3 weeks, as indicated by the portal flow velocity (cm/sec) changes measured by transcutaneous Doppler ultrasound (Goto et al, 1998).

Our concern that an abrupt increase in portal venous pressure after major hepatectomy may result in liver damage is one of the two reasons why we had attempted PVE. This concern seems to have been given little attention compared with a concern that a diminished liver may not meet metabolic demands after resection. We believe that incremental increases in portal venous flow/pressure observed after PVE may increase

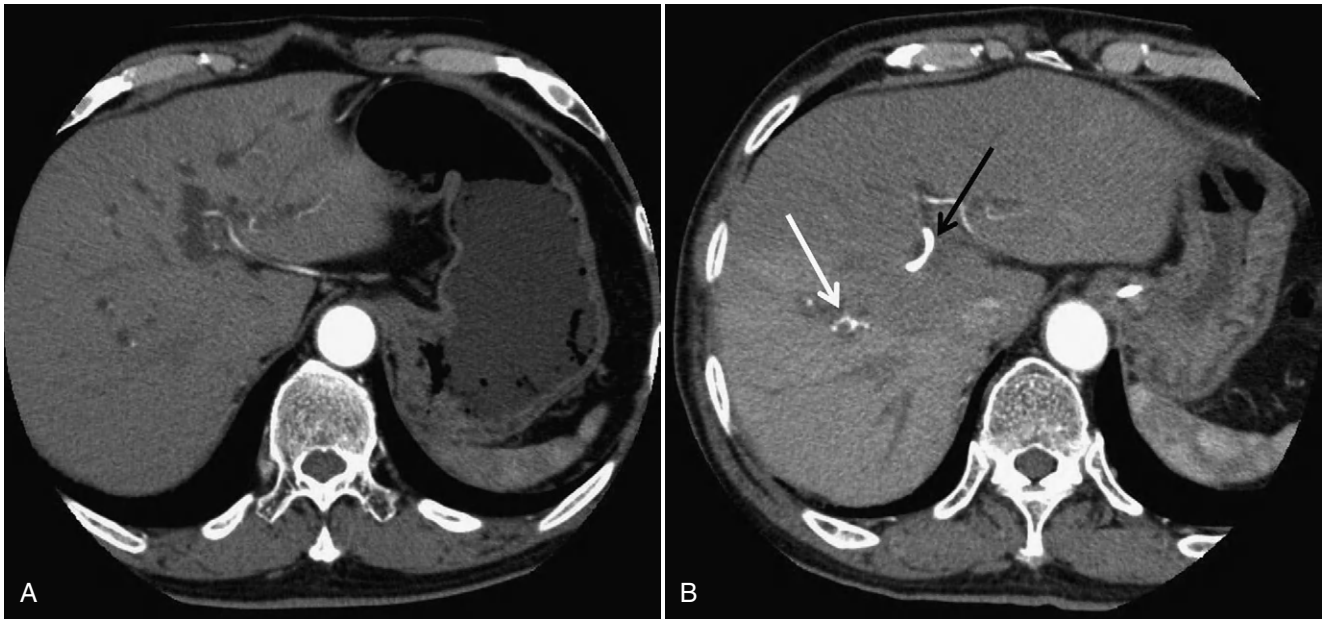

FIGURE 93A.1. Computed tomographic images of a 76-year-old man with hilar bile duct carcinoma. **A,** Before portal vein embolization (PVE). **B,** The same patient 2 weeks after PVE at the right hemiliver using gelatin sponge, thrombin, and coils (*white arrow*). The *black arrow* indicates the biliary drainage tube. Note the cessation of portal flow and attenuation difference by hepatic arterial buffer response in the right hemiliver.

tolerance in patients to high portal venous flow/pressure after extensive hepatic resection, resulting in an attenuation of liver damage after the subsequent resection (Makuuchi et al, 1991). Other recent studies on living donor liver transplantation (LDLT) have focused on portal pressure and small-for-size syndrome, and high portal pressure immediately after LDLT was reported to be associated with daily volume of ascites (Konishi et al, 2008). Attempts were made to attenuate this problem by splenic arterial ligation or portacaval shunt by some groups (Boillot et al, 2002; Man et al, 2003; Takada et al, 2004; Troisi et al, 2003, 2005).

In contrast to portal venous flow, liver is known to have an intrinsic regulatory mechanism to compensate even partially for alteration in portal flow, which is referred to as *hepatic arterial buffer response* (Lautt, 1985). In the case of PVE with hemihepatic portal vein occlusion or thrombosis of a portal branch, hepatic arterial buffer response is thought to still operate in embolized liver based on studies using dynamic computed tomography (CT) (Fig. 93A.1; Nagino et al, 1998; Wakabayashi et al, 2001), Doppler ultrasound (Denys et al, 2000; Kito et al, 2001), and three-dimensional magnetic resonance angiography (Gülberg et al, 2004), and their findings are in line with the report of a study using a rat model (Rocheleau et al, 1999); however, controversy surrounds the maintenance of hepatic arterial buffer response in nonembolized hemiliver (Denys et al, 2000; Kito et al, 2001; Rocheleau et al, 1999; Wakabayashi et al, 2001). Total liver blood flow, as estimated by a pharmacologic method, remained unchanged throughout the post-PVE period in our previous study (Shimada et al, 2002).

In summary, arterial flow in an embolized hemiliver is increased after PVE, in part to compensate for the cessation of portal flow. It is unclear whether arterial flow in the nonembolized hemiliver remains stable or decreases in response to the increment in portal flow. These factors may be a major concern when considering tumor growth in these hemilivers after PVE.

Because hepatic arterial buffer response is a partial compensation, hyperperfusion in a nonembolized hemiliver occurs after PVE, in contrast to hypoperfusion in an embolized hemiliver as expressed per gram of liver tissue. Corresponding hepatocyte regeneration in the nonembolized hemiliver occurs immediately after PVE proportional to the magnitude of the stimulus; however, little is known about when and how the atrophy-hypertrophy complex is terminated. Rocheleau and colleagues (1999) reported that, in a rat model of hemihepatic portal vein ligation, the hepatic atrophy-hypertrophy complex process (i.e., liver weight changes in the ligated and nonligated lobes) continues until total lobar flow per gram of liver tissue is restored. In Western series, planned hepatectomy after PVE had been scheduled when hypertrophy of the nonembolized liver segments seemed to reach their plateau, and full hypertrophy of the nonembolized segments was obtained 7 to 9 weeks after PVE (Azoulay et al, 2000a).

CLINICAL COURSE AFTER PORTAL VEIN CHEMOEMBOLIZATION

In contrast to transcatheter arterial chemoembolization (TACE), signs and symptoms of postembolization syndrome—such as pain, nausea, and vomiting—are minimal. Most patients experience mild fever after PVE, which subsides within 2 to 3 days. Changes in liver function, as reflected by an increased total bilirubin value and prolonged prothrombin time, are mild and transient, returning to their baseline values 2 to 3 days after PVE. Serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) values are found to be stable in half of the patients, and in those remaining, values are mildly elevated (1.5 to 3 times the pre-PVE values) on day 1, returning to baseline values in 4 to 7 days after PVE, regardless of the embolization materials used. These findings suggest that inflammatory and necrotic reactions after PVE are minimal, if they

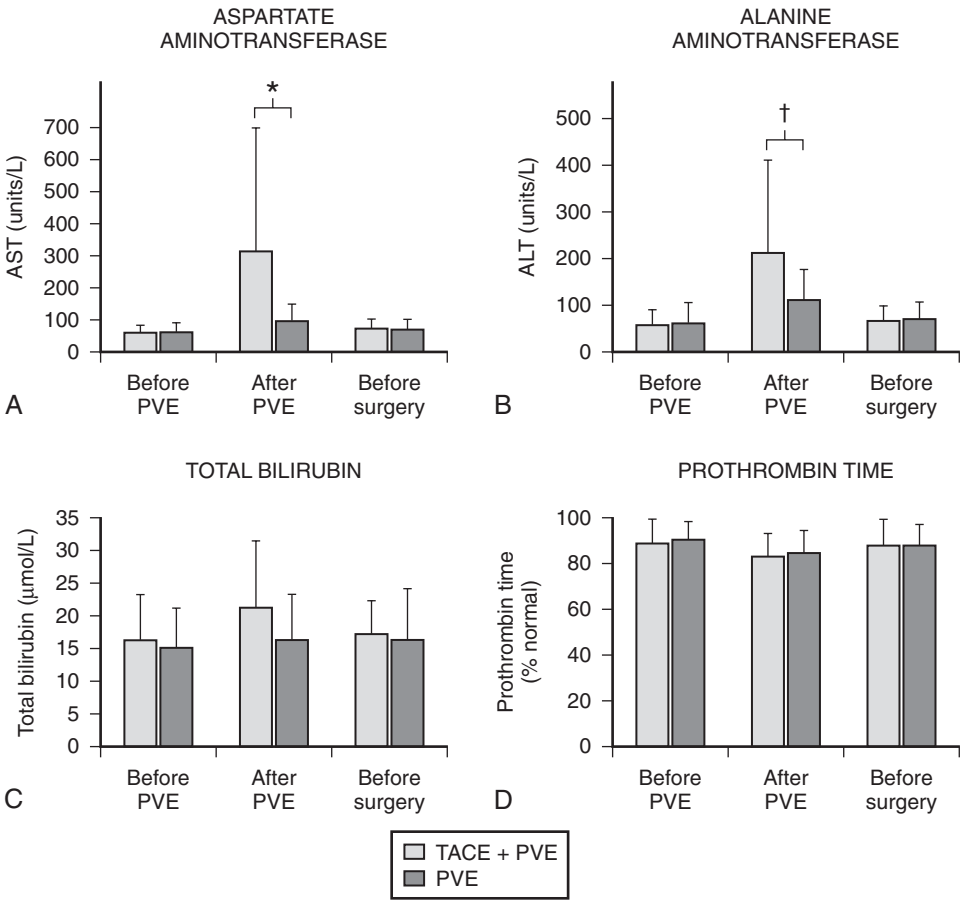

FIGURE 93A.2. Results of liver function tests before portal vein embolization (*PVE*), after PVE, and before surgery for patients who had transarterial chemoembolization (*TACE*) plus PVE and PVE alone. Values are mean (standard deviation). Peak values of (**A**) aspartate aminotransferase, (**B**) alanine aminotransferase, and (**C**) total bilirubin and (**D**) minimum value of prothrombin time were assessed before PVE, within 5 days after PVE, and within 5 days before surgery (*P = .026, †P = .031; student t test). *(From Ogata S, et al, 2006: Sequential arterial and portal vein embolizations before right hepatectomy in patients with cirrhosis and hepatocellular carcinoma. Br J Surg 93:1091-1098.)*

are present at all (Imamura et al, 1999a). The exceptions are when absolute ethanol is used for embolization (Shimamura et al, 1997), and when PVE is carried out after TACE (Aoki et al, 2004; Ogata et al, 2006). In both situations, PVE is followed by marked AST and ALT elevations, although both returned to baseline values by the time of scheduled hepatectomy (Fig. 93A.2).

Some have reported on adverse events (complications) or on morbidity rates associated with PVE (Table 93A.1). A multicenter European study of 188 patients who underwent contralateral PVE reported 24 adverse events (12.8%) (Di Stefano et al, 2005). Most adverse events were associated with the PVE technique, including complete portal thrombosis (n = 1), migration of embolic material in the main left portal vein feeding the FLR (n = 2), hemoperitoneum (n = 1), hemobilia (n = 1), rupture of a metastasis into the gallbladder (n = 1), and transient liver failure (n = 6). A recent meta-analysis documented overall morbidity rate for PVE to be 2.2% (Abulkhir et al, 2008). A summary of 37 publications involving 1088 patients showed a total of 497 minor complications and 11 major complications (see Table 93A.1).

VOLUMETRIC CONSEQUENCES OF PORTAL VEIN EMBOLIZATION

CT scan with contrast enhancement is the most commonly used method for calculating total liver volume (TLV) and FLR volume (FLRV). The nontumorous FLRV/(TLV– Tumor volume), or FLRV/TLV ratio, is a widely used parameter to determine whether PVE is necessary before hepatic resection and to assess the degree of FLR hypertrophy. Vauthey and associates (2002) proposed the use of standard liver volume (SLV), a concept first applied to clinical situations by us in 1995 (Urata et al, 1995). SLV is an alternative method for estimating TLV from a linear regression formula, correlating body surface area or body weight and TLV in healthy subjects (Urata et al, 1995; Vauthey et al, 2002). This formula is based

Table 93A.1

Complications Following Portal Vein Embolization

Portal hypertension	1
Septic necrosis from hepatic artery injury	1

From Abulkhir A, et al, 2008: Preoperative portal vein embolization for major liver resection: a meta-analysis. Ann Surg 247:49-57.

on a concept that optimal liver/body mass ratio in healthy subjects is constant. We first referred to this optimal liver volume as SLV and proposed the application of SLV for recipients of LDLT and also for patients with end-stage liver disease, whose actual liver volumes are either extremely large or small in terms of ideal liver volume to be grafted, such as in cases of primary biliary cirrhosis or fulminant hepatic failure (Urata et al, 1995).

Vauthey and associates (2002) emphasized the importance of SLV as determining indications for PVE, because it may be applied to patients with pathologic liver or obstructive jaundice with dilated bile ducts and may even be calculated in patients with multiple liver metastases. Nevertheless, we adhere to the use of actual TLV for several reasons. First, SLV is a virtual volume estimated by using a formula, and different formulas are used among investigators; r^2 in the equation of Vauthey and associates (2002) is 0.49, indicating that their formula explains only half of the interindividual variations for TLV even in healthy subjects. Second, patients with extremely large or small livers in terms of SLV because of underlying liver diseases may not be candidates for liver resection even after PVE. Finally, up-to-date devices such as multislice helical CT with contrast administration allow accurate volumetric measurement by subtracting small tumor volumes and vasculobiliary structures, even to Couinaud's segment level.

PVE leads to an increment of segmental volume in nonembolized hemiliver and a decrement of segmental volume in embolized hemiliver, homogeneously maintaining a constant TLV (in most studies, TLV remained unchanged after PVE). In case of right hemiliver PVE, regeneration rate of the noncirrhotic liver was 12 cm^2/day 2 weeks after PVE (Lee et al, 1993; Nagino et al, 1995), decreasing to 11 cm^2/day at 4 weeks (Nagino et al, 1995) and then 6 cm^2/day at 32 days (De Baere et al, 1996). In cirrhotic patients, regeneration is reportedly slower, at a rate of 9 cm^2/day at 2 weeks (De Baere et al, 1996; Lee et al, 1993). In noncirrhotic and cirrhotic livers, regeneration processes are thought to be blunted by approximately 50% compared with that after hepatectomy (Yamanaka et al, 1993). Results of hypertrophy of nonembolized liver segments after PVE are summarized in Table 93A.2. In most series, hypertrophy of nonembolized liver segments in normal liver was 10% to 15%, expressed in volumetric ratio of nonembolized liver segments to TLV. The figure was smaller (5% to 10%) in diseased liver.

Various factors have been reported to affect the regeneration rate after PVE. Regeneration rate depends on embolized hemiliver volume (Imamura et al, 1999a; Yamakado et al, 1997). In other words, the greater the FLRV before PVE, the smaller the volume increase after PVE. Materials used for embolization affect the results in magnitudes of hypertrophy. Hypertrophy seemed to be modest when biologic materials such as Gelfoam and fibrin glue were used, most probably as a result of the progressive recanalization they induced. Absolute ethanol was reported to achieve the highest degree of regeneration but at the expense of marked increases in AST and ALT levels secondary to liver necrosis (Shimamura et al, 1997). Among the disorders related to background patient characteristics, diabetes, obstructive jaundice, active hepatitis, and cirrhosis have been reported to hamper the regeneration process (Imamura et al, 1999a; Nagino et al, 1995; Tanaka et al, 2000).

HISTOLOGIC CONSEQUENCES OF PORTAL VEIN EMBOLIZATION

Human liver tissue obtained 3 weeks after PVE showed almost normal microscopic structures in the embolized and the nonembolized lobes. In the embolized lobe, dilation of sinusoids with decreased hepatocyte density and hepatocyte apoptosis were observed, especially in the pericentral area (Harada et al, 1997). Nevertheless, no signs of necrosis or inflammation were apparent, except when the embolizing material used was absolute ethanol, with tissue showing clear evidence of necrosis (Shimamura et al, 1997), or cyanoacrylate, which causes peribiliary fibrosis (De Baere et al, 1996). In contrast, microscopic findings in the nonembolized hemiliver showed hepatocyte replication as evidenced by the increased mitotic figures and other parameters of cell proliferation, such as proliferative cell nuclear antigen and Ki-67 (Harada et al, 1997; Kusaka et al, 2006), these hepatocytes were histologically characterized by basophilic cytoplasm and abundant binuclear cells, and they were small. These observations are indirect evidence of hepatocyte proliferation (Harada et al, 1997).

Concluding from the above described laboratory and volumetric data, embolized hemiliver seemed to atrophy (Fig. 93A.3) through apoptosis and subsequent cell deletion, as already suggested by Kerr and associates (1972), who coined the term *shrinkage necrosis.* Meanwhile, the volume increase in nonembolized hemiliver is explained by hyperplasia; that is, a net increase is seen in cell numbers, rather than cellular hypertrophy, such as in the case of *foie gras de canard.*

FUNCTIONAL CONSEQUENCES OF PORTAL VEIN EMBOLIZATION

Cellular hyperplasia and resulting hemiliver hypertrophy do not signify functional gain in the corresponding hemiliver, because proliferating isolated hepatocytes lose their differentiated hepatocyte-specific functions. Most previous reports that investigated liver function after PVE assessed whole liver function, including the embolized and the nonembolized lobe. Overall, functional hepatocyte number—estimated by the clearance of antipyrine, a prototype of low-extractable drug—showed similar values before and 2 weeks after PVE (Shimada et al, 2002). The adenosine triphosphate concentrations and hepatic energy reserves per gram of liver tissue assessed in the nonembolized lobe 3 weeks after PVE were similar to those of control tissue (Chijiiwa et al, 2000). Likewise, the nonembolized lobe uptake of technetium 99m-galactosyl human serum albumin (^{99m}Tc-GSA), a ligand bound to asialoglycoprotein receptors on the hepatocyte cell membrane, showed a rapid increase 1 to 2 weeks after PVE (Hirai et al, 2003; Nishiguchi et al, 2000). These findings showed the volume increase in the nonembolized lobe accompanied by a parallel increment in liver function in the corresponding lobe. Improvement in FLR function was also apparent from an increase in bilary excretion (Ijichi et al, 2001; Uesaka et al, 1996).

In a human PVE study, Uesaka and associates (1996) reported that patients with obstructive jaundice showed biliary indocyanine green (ICG) excretion from the nonembolized lobe increasing from the baseline value 10 to 16 days after PVE, and that this increment was more significant than the volume increase. Taking into account that the ICG extraction ratio in noncirrhotic liver is 0.7 to 0.8, ICG transport from hepatocyte to bile canaliculi is extremely fast, and accordingly, its biliary excretion is highly flow dependent; this result in human studies is thought to be an equivalent to that of the rat study reported by Rocheleau and colleagues (1999), and it suggests that the hepatic atrophy-hypertrophy complex process is still underway 2 weeks after PVE. Although this study is often considered to suggest that the gain in function is faster than the gain of volume after PVE, the results should appropriately be interpreted as relating to hemodynamic changes after PVE, considering the pharmacokinetic properties of ICG.

FIGURE 93A.3. Liver of a 75-year-old man with hepatitis C–related chronic hepatitis and hepatocellular carcinoma after right portal vein embolization. Left hemiliver was hypertrophied; right hemiliver was atrophied with darkened color and a wrinkled surface.

INDICATIONS

Cholangiocarcinoma

PVE is indicated most frequently for cholangiocarcinoma, because extended right hepatectomy together with caudate lobe resection is often necessary for curative resection (Kawasaki et al, 2003; Makuuchi et al, 1984, 1990; Nagino et al, 2001; Seyama et al, 2003; see Chapter 50B). Most patients have obstructive jaundice and cholestasis-induced impairment of liver function. Associated pancreatoduodenectomy is necessary in cases with widespread bile duct carcinoma of the main bile duct, as a scheduled procedure or as a result of intraoperative frozen section pathology, to obtain a negative surgical margin. These factors favor the application of PVE to achieve safe hepatic resection.

Unilateral biliary decompression of the FLR lobe is recommended before PVE to improve function in the portion of the liver to remain after hepatectomy. We favor a unilateral approach, even when the communication between the right and left bile ducts is interrupted by tumor progression, in view of the enhanced atrophy-hypertrophy process and the volume gain in the FLR lobe (Braasch et al, 1972; Kawasaki et al, 2003; Kyokane et al, 2003; Seyama et al, 2003). Our recent results also demonstrated that both hypertrophy and bilirubin clearance of the FLR were much improved by selective biliary drainage when compared with total biliary drainage (Ishizawa et al, 2007). The rate of catheter-related infection was also reported

to have increased with the number of stents (Neuhaus et al, 1999), and it is important not to carry out unnecessary cholangiography after biliary drainage until hepatectomy. When PVE by a transhepatic contralateral approach is scheduled, biliary decompression before PVE decreases the risk of portobiliary fistula, although not all agree with this approach.

Liver Metastases

Liver resection offers the only chance for cure with possible long-term survival for patients with liver metastases of colorectal origin, including bilateral metastases (Weber et al, 2000; see Chapter 81A). In patients with massive liver tumors that occupy the right liver, extended right hepatectomy does not result in a marked decrease in normally functioning hepatic mass. When similar extensive surgical procedures are indicated for small multiple metastases in the right hemiliver, for a solitary tumor located adjacent to the hilum of the liver, or for bilateral tumors, a large amount of functional hepatic mass must be removed. PVE may be performed under these circumstances to expand the operative indications to patients whose tumors would otherwise be unresectable, owing to their small FLRV, or to increase operative safety (Azoulay et al, 2000b; Elias et al, 2002; Kawasaki et al, 1994a). PVE is also recommended when major hepatectomy is planned with a simultaneous major gastrointestinal procedure, such as when hepatic metastases are removed synchronously with the primary colorectal lesion, or when liver injury is suspected from the preceding systemic or locoregional chemotherapy (Farges et al, 2003).

One major concern is whether PVE enhances tumor growth, especially in the nonembolized lobe (Elias et al, 1999; Kokudo et al, 2001). Increasing evidence suggests that PVE itself stimulates tumor growth, both in embolized and nonembolized segments of the liver, by altering the blood supply and/or inducing a network of cytokines and growth factors, although the precise mechanism and network have not been fully clarified (Fig. 93A.4; see Chapter 10). In embolized segments of the liver, the increased hepatic arterial flow induced by the occluded portal venous flow, the *hepatic arterial buffer response*, may also promote tumor growth.

In addition, various cytokines and growth factors associated with liver regeneration and hypertrophy may also have stimulatory effects on tumors in the nonembolized segments. Hepatocyte growth factor, epidermal growth factor, transforming growth factor–α, tumor necrosis factor–α, and interleukin-6 are all positive regulators of regeneration and hypertrophy, and all are candidates for tumor growth–inducing factors after PVE (Christophi et al, 2008). On the other hand, a recent animal study suggests that cytokines and growth factors associated with atrophy-hypertrophy after PVE are different from those associated with liver regeneration after a partial hepatectomy (Heinrich et al, 2006).

Clinically, long-term results were reported to be similar regardless of whether PVE was conducted (Azoulay et al, 2000b; Elias et al, 2002). However, Kokudo and colleagues (2001) reported that the disease-free survival period was significantly poorer in the PVE group than in the control group, suggesting that PVE may enhance the aggressiveness of metastatic tumors.

With this possible shortcoming in mind, several authors have proposed two-stage procedures to avoid possible tumor growth in the nonembolized FLR lobe for patients with bilobar metastases: first, the primary tumor is resected, if necessary; next, left liver limited metastasectomies are performed; then right portal vein ligation or PVE are carried out. After an interval of several weeks, (extended) right hepatectomy is performed (Jaeck et al, 2004; Kianmanesh et al, 2003a).

Currently, an increasing number of patients with colorectal liver metastases receive neoadjuvant chemotherapy; however, the liver parenchyma after neoadjuvant chemotherapy using irinotecan is often steatotic, fibrotic, and sometimes cirrhotic. Similarly, sinusoidal obstruction syndrome associated with oxaliplatin has been reported. Such hepatotoxicity is assumed to have an inhibitory effect on the hypertrophy of the nonembolized FLR. Several groups have evaluated the effect of periprocedural chemotherapy, both on tumor growth and FLR hypertrophy, with conflicting results (Aussilhou et al, 2009; Beal et al, 2006; Covey et al, 2008; Goere et al, 2006; Zorzi et al, 2008). Further investigation is necessary to draw an exclusive conclusion.

Hepatocellular Carcinoma

Hepatectomy remains the sole treatment for large HCC, and major hepatic resection is often required (see Chapter 80). Likewise, segment-oriented anatomic resection is recommended even for small HCCs to prevent postoperative recurrence (Hasegawa et al, 2005; Imamura et al, 1999b; Makuuchi et al, 1985; Regimbeau et al, 2002; see Chapter 92); however, 90% of HCC patients have impaired hepatic functional reserve because of hepatitis B or C virus–associated liver fibrosis and cirrhosis, which is the main obstacle to performing hepatic resection. Shirabe and associates (1999) reported a rise in the rate of postoperative liver failure with a smaller FLRV in HCC patients, and PVE triggered liver regeneration in 80% to 90% of HCC patients with chronic liver disease; however, the process was hampered compared with that in patients with normal livers (Aoki et al, 2004; Azoulay et al, 2000a; Farges et al, 2003; Wakabayashi et al, 2002).

We combine selective TACE with PVE before performing major hepatic resections for patients with HCC (Aoki et al, 2004; Kubota et al, 1997). This double preparation aims at 1) using TACE to prevent tumor progression during the interval between PVE and the planned hepatectomy, in view of the fact that most HCCs are hypervascular tumors fed exclusively by arterial blood flow (Fig. 93A.5); and 2) enhancing the effect of PVE by first using TACE to embolize the possible arterioportal shunt, which is frequently found in cirrhotic livers and HCC tumors. Others also advocate this double preparation (Azoulay et al, 2000a; Ogata et al, 2006; Wakabayashi et al, 2002; Yamakado et al, 1997).

In most cases, we perform PVE when liver function test results stabilize, usually 7 to 10 days after TACE. Compared with cases with PVE alone, PVE performed after TACE resulted in marked elevations of AST and ALT values, reflecting necrotic and inflammatory reactions after embolization (see Fig. 93A.2). These values returned to their baseline by the time of the planned hepatectomy. Bilirubin level remained essentially stable after PVE (Aoki et al, 2004); however, 10% to 20% of patients did not show FLR hypertrophy after PVE, and hepatectomy was abandoned. Despite a technically successful PVE, lack of hypertrophy is most likely explained as failure to increase portal flow to the FLR because of the presence or development of collateral vessels to the systemic circulation.

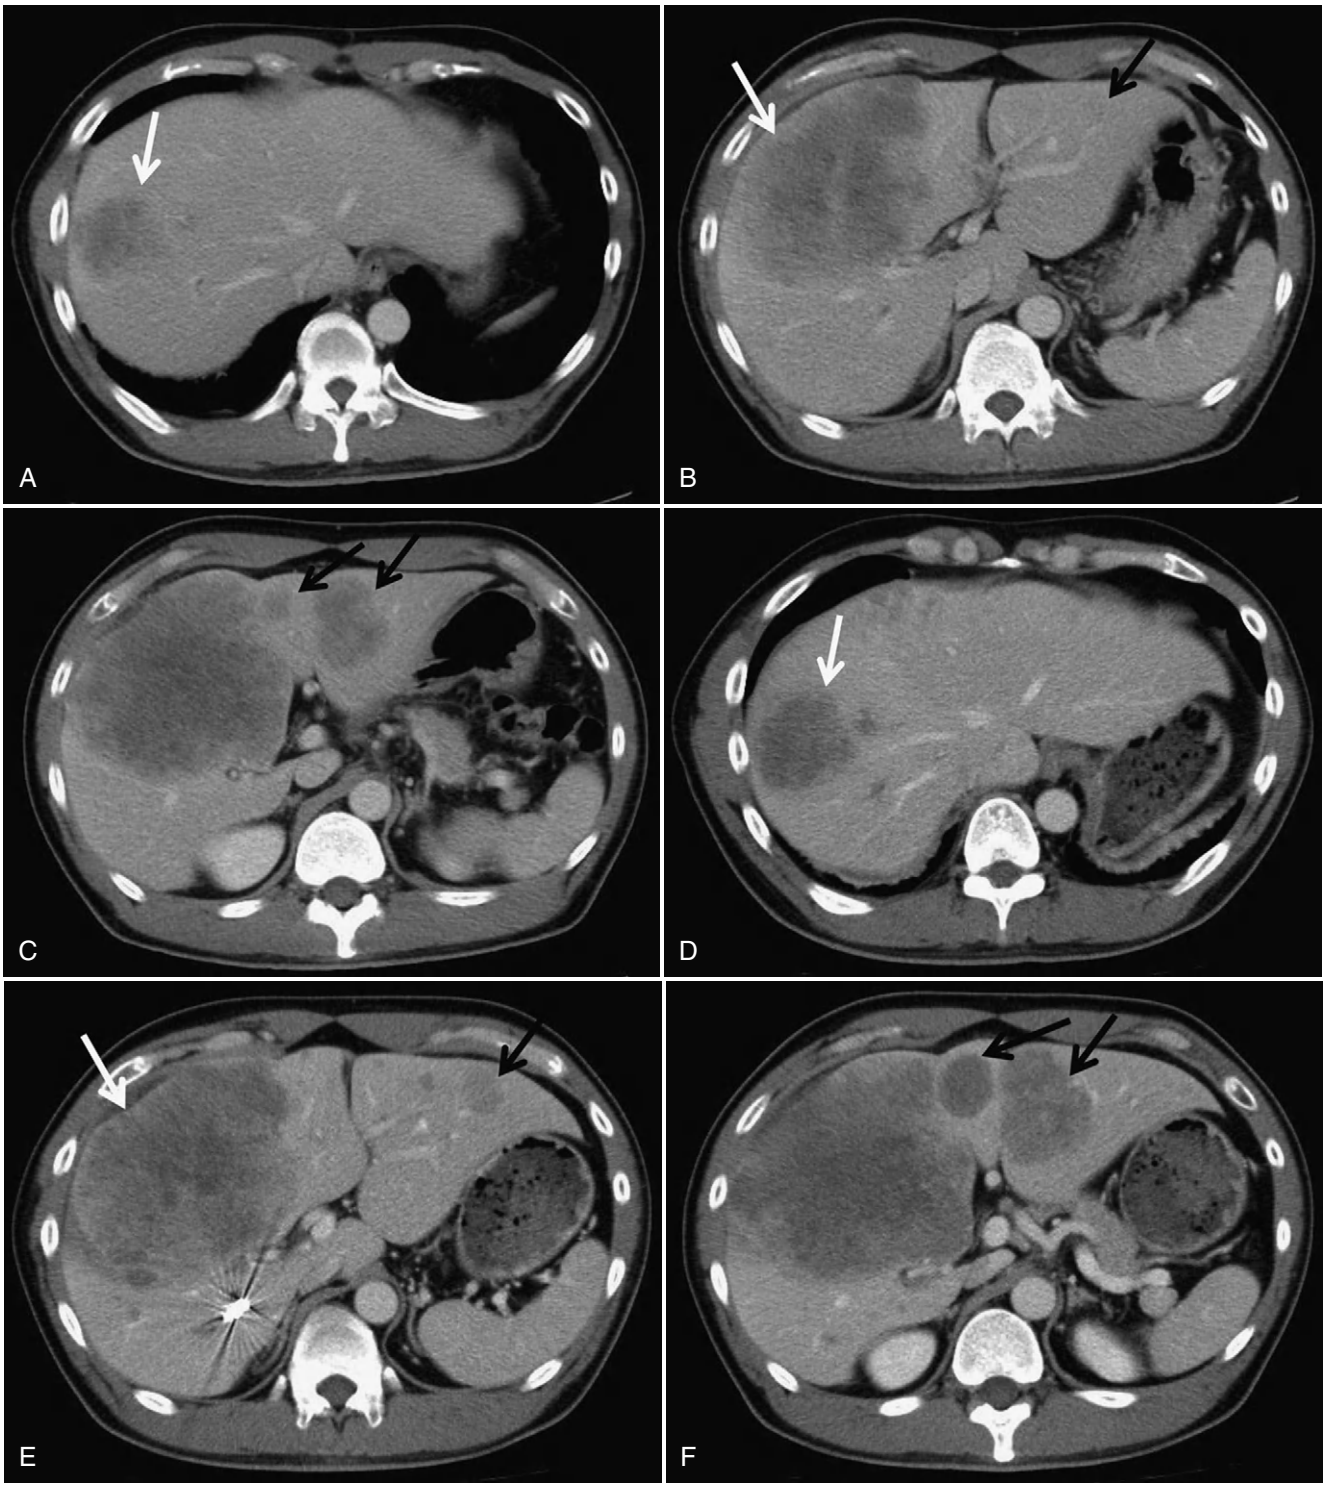

FIGURE 93A.4. Tumor growth after portal vein embolization (PVE) is shown on computed tomographic imaging of a 47-year-old man with multiple colorectal liver metastases before (**A** to **C**) and 2 weeks after (**D** to **F**) right PVE. Tumors both in the embolized segments (*white arrows*) and nonembolized segments (*black arrows*) show increases in size.

Our group and others have reported similar phenomena after embolization in patients with portal hypertension (Hasegawa et al, 2004; Nagino et al, 2002). Based on these observations, Kianmanesh and associates (2003b) used it in Child-Turcotte-Pugh class A patients. PVE preoperatively tests the capacity of injured liver to regenerate, and the absence of hypertrophy after PVE is a contraindication for major hepatic resection for these patients. Wakabayashi and associates (2002) also recognized the close relationship between the result of hypertrophy and short-term outcome. Based on their results, Farges and associates (2003) claim that, contrary to the views of Azoulay and colleagues (2000a), in most patients showing

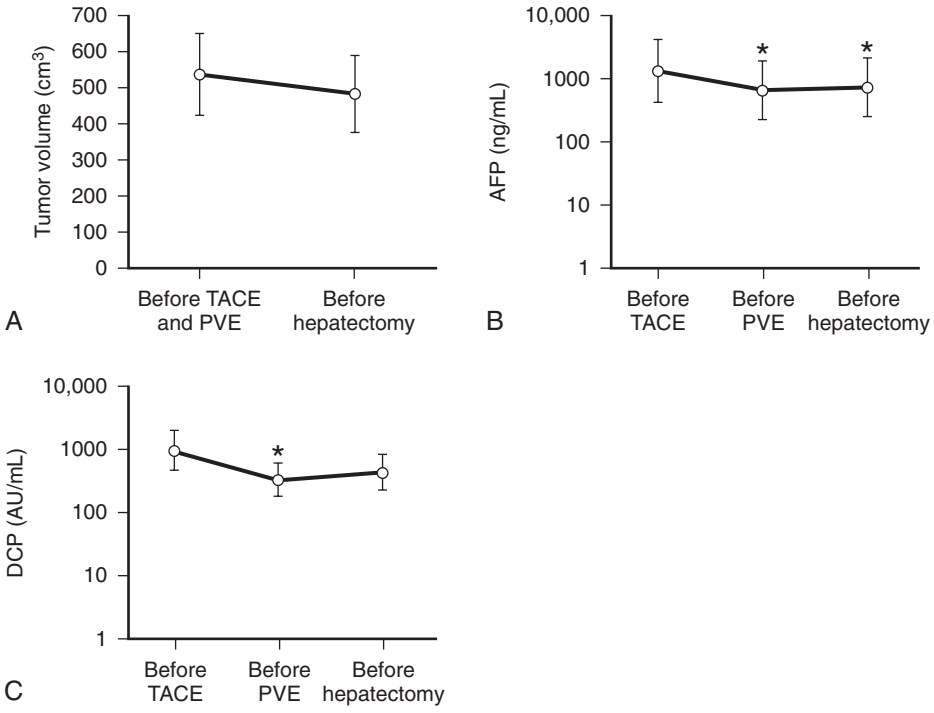

FIGURE 93A.5. Changes in (**A**) tumor volume before transarterial chemoembolization (*TACE*) and portal vein embolization (*PVE*) and before hepatectomy, and changes in (**B**) serum α-fetoprotein (*AFP*) and (**C**) plasma des-γ-carboxy prothrombin (*DCP*) before TACE, before PVE (after TACE), and before hepatectomy (after PVE), all in patients with hepatocellular carcinoma. Data are expressed as mean ± standard error of the mean, and the levels of AFP and DCP were compared after logarithmic transformation (*$P = .02$ by analysis of variance). *(From Aoki T, et al, 2004: Sequential preoperative arterial and portal venous embolizations in patients with hepatocellular carcinoma. Arch Surg 139:766-774.)*

adequate hypertrophy, the actual interval between PVE and resection can be less than 4 weeks. Our opinion is in line with Farges and colleagues (2003) because one of the aims of conducting PVE is to avoid the sudden increase of portal venous pressure after major hepatectomy, and because portal pressure is elevated immediately after PVE, it decreases gradually in 1 to 2 weeks.

In contrast to the observation that PVE may affect disease-free survival of patients with colorectal liver metastases with its stimulatory effect on the tumor (Kokudo et al, 2001), it was suggested that long-term results after right hepatectomy following PVE for HCC may be superior to right hepatectomy without PVE, although tumor-free survival was comparable between the two groups. Tanaka and associates (2000) speculated that preoperative PVE may preserve hepatic function and allow treatment of tumor recurrence, which in turn leads to better overall survival. In addition, Ogata and associates (2006) reported that, compared with PVE alone, the combination of TACE and PVE resulted in superior FLR hypertrophy and better long-term survival.

General Indications

Under what circumstances does PVE become necessary? In other words, to what extent can liver be safely resected without PVE? General indications for PVE are based on the size of the FLR, the underlying liver disease, and the extent or complexity of the hepatectomy. Intuitively, patients with liver pathology—such as fibrosis or cirrhosis, cholestasis, steatosis, and side effects of prior chemotherapy—require a larger FLRV than patients whose liver is normal. The same holds true for patients who require synchronous additional surgery, such as pancreatoduodenectomy or low anterior resection for rectal carcinoma; however, few data exist regarding the hepatic volume required to support life and prevent complications. In LDLT, the lower limit of residual liver volume or TLV that allows a patient to be a donor candidate is thought to be 30% (Fan et al, 2000; Kokudo et al, 2005). The FLRV/TLV ratio indicated for PVE is determined arbitrarily by each institution, and it ranges from 20% to 40% (Azoulay et al, 2000a, 2000b; Elias et al, 2002; Hemming et al, 2003; Imamura et al, 1999a; Kishi et al, 2009).

We advocate PVE in two situations: first, in patients with normal liver (ICG retention rate at 15 minutes [ICG R15] < 10%) if FLRV/TLV is less than 40% and, second, in patients with an injured liver (10% < ICG R15 < 20%), if FLRV/TLV is less than 50%. If ICG R15 exceeds 20%, major hepatectomy is contraindicated even after PVE (Kubota et al, 1997). Again, we think that actual TLV is more suitable for required volume estimation than the estimated TLV calculated from a formula correlating to body size, whereas Vauthey and colleagues advocate a standardized FLRV (percentage of FLRV to estimated TLV) of 20% or less (Abdalla et al, 2002).

Farges and associates (2003) reported that induction by PVE resulted in an increase of the FLRV/TLV ratio from 31% to 47% in patients with normal liver parenchyma (n = 13); however, these patients showed similar postoperative courses to those of patients who underwent hepatectomy without PVE (n = 14; FLRV/TLV = 30%) in terms of total bilirubin, prothrombin time, and hospital stay. Meanwhile, the authors obtained data to improve these parameters by conducting PVE in patients with chronic liver disease (n = 14 each; FLRV/TLV ratio increased by 9% in the PVE group) (Farges et al, 2003). Based on these findings, they recommended routine application of PVE for patients with diseased livers. On the other hand, this procedure was considered unnecessary for patients with normal liver, except in patients undergoing an extensive resection, a major synchronous surgical procedure, or for minor hepatectomies involving the FLR lobe (Belghiti, 2004; Farges et al, 2003).

Indications for PVE should be discussed, with special emphasis on its medical cost and associated complications.

Complication rates depend heavily on technical expertise; however, if these factors are considered negligible, we would favor our criteria, discussed earlier. Although fatal complications such as liver insufficiency are rare, hepatic dysfunction as assessed by prothrombin time prolongation and bilirubin elevation, overall complication rate, and mean hospital stay correlated closely with FLRV/TLV ratio (Abdalla et al, 2002; Belghiti, 2004; Shoup et al, 2003). At the same time, in LDLT, although the clinically significant complication rate did not differ among the various types of grafts, residual liver volume fraction showed a close correlation with peak prothrombin international normalized ratio and total bilirubin levels (Kokudo et al, 2005; Salamé et al, 2002).

CONCLUSION

In 2 to 4 weeks, PVE induces atrophy in the embolized hemiliver to be resected, with compensatory hypertrophy of the hemiliver to be preserved. By decreasing the risk of liver failure, complication rate, and hospital stay, PVE increases the safety of resection and expands the indication for liver resection to patients who are otherwise poor candidates for hepatectomy, owing to inadequate estimated liver size and function. PVE is of particular value for patients with chronic liver disease, including obstructive jaundice and steatosis; for patients undergoing concomitant resection of major organs; or those with bilateral liver tumors. Some variables are known to effect the atrophy-hypertrophy complex after PVE, including extent of embolization, the embolizing material used, and comorbidities such as diabetes, obstructive jaundice, active hepatitis, and cirrhosis.

Meanwhile, the effect of periprocedural chemotherapy on hypertrophy of the FLR remains to be clarified. According to published reports, the cutoff residual liver volume indicated for PVE ranges from 20% to 40%. The range is inevitable, because a randomized trial to verify which patients might be candidates for liver resection, with the lowest residual liver volume but without PVE, would be unethical. Continued prospective examination of PVE with defined end points—such as postoperative liver function, operative complications, and length of hospital stay—should in the future clarify the benefits attained by PVE.

CHAPTER 94

Ex vivo and in situ hypothermic hepatic resection

Ian D. McGilvray and Alan W. Hemming

OVERVIEW

The limits of liver surgery are constantly evolving, propelled by advances in surgical technique and imaging. Extended right and left hepatectomies, previously considered to be pushing the boundaries of resection, have become relatively standard procedures for experienced liver surgeons. Strategies such as preoperative portal vein embolization (PVE) (see Chapter 93) to allow growth of the planned liver remnant allows even more aggressive resections to be performed with a morbidity similar to that of less extensive resections. Advances in surgical technique have been paralleled by advances in hepatic imaging, giving the liver surgeon greater ability to assess tumor position in relation to the intrahepatic vascular and biliary structures. Over the same period, liver transplantation has thrived and proliferated, and more recently the development of living donor liver transplantation (LDLT) has led to a variety of techniques that also can be applied in nontransplant liver surgery. Standard components of LDLT include resection and reconstruction of portal venous, hepatic arterial, biliary, and hepatic venous structures (see Chapters 90D and 98B). These same techniques are now more frequently being considered for the resection of hepatic tumors by surgeons experienced with liver resection and transplantation techniques.

The principal difficulty of vascular reconstruction during hepatic resection is the resulting period of hepatic ischemia. The liver can tolerate short periods of ischemia surprisingly well. During standard liver resections, the use of hepatic inflow occlusion is often used during the parenchymal transection to control excessive blood loss. The use of a combination of inflow occlusion with maintenance of low central venous pressure (CVP) allows relatively bloodless transection of the liver. Intermittent hepatic inflow occlusion for 15 minutes with 5 minutes of reperfusion at the end of each 15-minute interval can reduce the degree of liver injury (Man et al, 1997) and may be particularly useful in more complex resections.

Ischemic preconditioning seems to protect the liver from subsequent ischemic injury (Clavien et al, 2003) and is performed by applying a Pringle maneuver for 10 minutes, then reperfusing the liver for at least 10 minutes before reapplying inflow occlusion. The mechanisms by which ischemic preconditioning protects the liver from subsequent ischemia have not been fully elucidated, but even longer periods of ischemia are relatively well tolerated. The normal liver can tolerate 60 minutes or more of continuous inflow occlusion and warm ischemia (Huguet et al, 1994; Azoulay et al, 2005), but patients with cirrhosis or altered liver function from biliary obstruction or prolonged chemotherapy may tolerate significantly less ischemic insult before sustaining irreversible injury (Hannoun et al, 1996); the same may be true of older patients (Selzner et al, 2009). Even with normal liver function, the risk of irreversible liver damage following prolonged periods of continuous ischemia is significant.

Beyond inflow occlusion, tumors that involve the retrohepatic inferior vena cava (IVC) or that involve the hepatic veins at their junction with the vena cava may require total vascular isolation (see Chapter 91A). Total vascular isolation may increase the degree of ischemic injury to the liver more than inflow occlusion alone, as there is some evidence that backward diffusion of hepatic venous blood into the liver attenuates ischemic injury (Smyrniotis et al, 2003). In most cases, however, the procedure can be planned such that most of the hepatic parenchymal division is performed without total vascular exclusion, and caval clamping is reserved for the relatively short time that is required to deal with the IVC or hepatic veins.

In fact, most resections involving hepatic vascular structures can be dealt with using techniques that do not involve protective strategies, such as hypothermic perfusion of the liver. Tumors that involve hilar vessels usually can be dealt with by temporary occlusion of the hepatic artery or portal vein with relatively short ischemic times. Blood flow to the liver is maintained by the artery, if the portal vein is reconstructed, or the portal vein, if the artery is reconstructed. In the rare case that the hepatic artery *and* the portal vein require reconstruction, the reconstructions can be performed sequentially, maintaining flow through one vessel or the other.

Based on the previous information, it would seem that standard liver resection techniques can be applied to almost every liver resection, without the need to consider the use of techniques that require hypothermic perfusion; however, a minority of patients will have lesions that seem truly unresectable by any conventional technique. Lesions that are centrally placed and involve all three main hepatic veins, with or without involvement of the retrohepatic IVC, are essentially unresectable using standard liver resection techniques. These few patients who require complex reconstruction of venous outflow may benefit from ex vivo or in situ hypothermic perfusion of the liver with hepatic resection and vascular reconstruction.

History of Hypothermic Perfusion and Ex Vivo Techniques

Fortner and colleagues (1974) first described the use of hypothermic perfusion during liver resection to protect the liver from ischemic injury in a series of 29 patients. Technical improvements in liver surgery over the next 2 decades, along with the growing understanding of the liver's ability to tolerate normothermic ischemia, made the use of hypothermic perfusion

unnecessary in most cases. During the same period, liver transplantation had been applied to technically unresectable primary and secondary liver malignancy with dismal results (see Chapter 97A). Although the procedure was technically feasible, transplantation for large, unresectable primary liver tumors, and especially for metastatic lesions, resulted in the rapid recurrence of malignancy, either in the new liver or elsewhere shortly after transplantation.

In response to patients with unresectable tumors who were considered inappropriate for liver transplantation, Pichlmayr and associates (1988) developed hypothermic perfusion with ex vivo liver resection. During ex vivo liver resection, the liver is removed completely from the body and perfused with cold preservation solution on the back table. The liver resection is performed on the back table in a completely bloodless field such that reconstruction of hepatic venous outflow is performed under ideal conditions; however, the morbidity and mortality rates from this procedure are relatively high; as a result, in situ and ante situm hypothermic perfusion techniques have been explored.

In situ hypothermic perfusion is performed using standard liver resection mobilization techniques, but the liver is placed in total vascular isolation (see Chapter 91A) and cold perfused via the portal vein. In the ante situm procedure, the liver is cold-perfused via the portal vein, with the hilar structures left otherwise intact; but the suprahepatic IVC is divided, and the liver is rotated forward, allowing improved access to the area of the liver and IVC centered around the hepatic vein confluence. To a great extent, the three techniques—in situ hypothermic liver perfusion, ante situm hypothermic liver perfusion, and ex vivo liver resection—overlap, and all three mirror aspects of LDLT. The procedure and role for each technique are described below.

IN SITU HYPOTHERMIC PERFUSION

In situ hypothermic perfusion is the least technically demanding of the three techniques. In situ perfusion has been recommended (Hannoun et al, 1996) for liver resections that require total vascular isolation for periods exceeding 1 hour. More recently Azoulay and colleagues (2005) demonstrated that hypothermic perfusion of the liver is associated with better tolerance to ischemia in the setting of total vascular isolation of any duration.

The need for total vascular isolation arises when patients have tumors in close proximity to or involving the hepatic veins, retrohepatic IVC, or both. In initial descriptions, the entire hepatic parenchymal transection was performed after cold perfusion of the liver, allowing a precise dissection of the hepatic veins and IVC to occur under bloodless conditions. If caval or hepatic vein resection was required during resection of the tumor, hepatic hypothermia safely allowed the additional ischemic time to perform reconstruction of the vascular structures.

To perform in situ cold perfusion as originally described, the liver is mobilized as for total vascular isolation (see Chapter 91A) with control of the suprahepatic and infrahepatic IVC and the portal structures. The main portal vein is dissected out for insertion of a perfusion catheter. Although the portal vein can be dissected from the right of the bile duct, for in situ perfusion, it is usually easier to dissect it from the left of the bile duct after dissecting out the hepatic artery; the hepatic artery eventually requires control in any event. A sufficient length of portal vein (3 to 4 cm) is exposed to place a perfusion catheter and the portal venous cannula of venovenous bypass, if this is to be used. Most patients tolerate total vascular isolation without venovenous bypass; however, the standard use of bypass reduces the time pressures involved in these cases and reduces the gut edema associated with prolonged portal clamping. Prior to clamping, the patient is bolused with at least 5000 U of heparin intravenously. The infrahepatic cava is clamped, and the patient is placed on the caval portion of venovenous bypass.

It is generally advisable, although not absolutely necessary, to ligate and divide the right adrenal vein before clamping the infrahepatic IVC, because it otherwise has a tendency to become avulsed during some particularly inconvenient portion of the procedure. A portal clamp is placed relatively superiorly on the portal vein with bypass instituted below. The portal cannula can be inserted down toward the superior mesenteric vein after complete division of the portal vein or by dividing just the anterior wall of the portal vein and sliding the cannula down the back wall. Full venovenous bypass is started. The liver side of the portal vein is cannulated with the perfusion solution tubing, and the hepatic artery is clamped. The suprahepatic cava is clamped, and a transverse venotomy is created in the infrahepatic IVC just above the clamp. Cold perfusion of the liver is begun with preservation solution, and the effluent is suctioned from the venotomy in the infrahepatic cava (Fig. 94.1).

Preservation solution is either histidine-tryptophan-ketoglutarate (HTK) (Gubernatis et al, 1990) or University of Wisconsin (UW) solution (Kalayoglu et al, 1988). The liver resection proceeds in a bloodless field with excellent visualization of intrahepatic structures. The liver can be cooled continuously throughout the parenchymal transection by slow infusion of cooling solution (see below), or it can be cooled intermittently

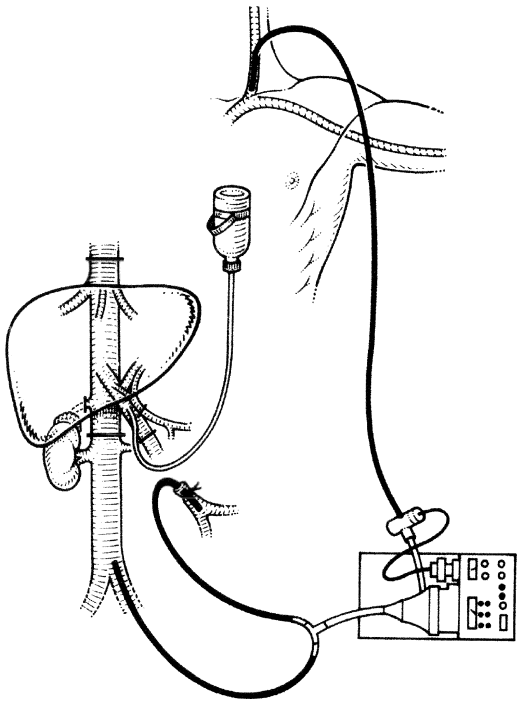

FIGURE 94.1. In situ cold perfusion. The patient is placed on venovenous bypass, and a cold perfusion solution is infused through the portal vein and vented through a venotomy in the infrahepatic inferior vena cava.

every 30 minutes by bolus infusion; at completion of the liver resection, the liver should be flushed of cold preservation solution, which can be done by flushing the portal vein with cold 5% albumin before restoring flow to the liver, or by allowing the initial 300 to 500 mL of venous effluent from the reperfused liver to be vented out the infrahepatic cava venotomy after reperfusion but before removing the suprahepatic cava clamp. Next, the portal bypass cannula is removed, and the portal vein is repaired or reanastomosed if divided. If the liver has been flushed with 5% albumin, the infrahepatic venotomy is closed, and the suprahepatic cava clamp is removed to assess hepatic venous bleeding, which should be controlled if present. Portal and hepatic arterial inflow is reestablished.

If the liver is warm-flushed with the initial blood flow through the liver, the sequence is altered slightly to prevent flushing of cold, high-potassium solution into the cardiac return. If a warm-flush technique is used, the portal vein is repaired, and the infrahepatic venotomy is closed with a running suture left loose and untied. Portal flow is established with the suprahepatic cava clamp in place. The initial 300 to 500 mL of blood is suctioned from the infrahepatic cava venotomy, the suture is secured, and the suprahepatic cava clamp is removed. We often cold flush the liver with 5% albumin, because it can be done in an unhurried fashion, and it allows sequential removal of clamps with separate assessment of hepatic venous and portal bleeding on reperfusion. The patient is decannulated from caval bypass if bypass has been used.

We rarely use in situ perfusion as just described. The advent of LDLT (see Chapters 90D and 98B) and the more frequent use of the anterior approach to liver resection (Liu et al, 2000) have improved the ability to divide the liver parenchyma and dissect along the hepatic veins without the need for extensive periods of inflow occlusion. In patients in whom a single hepatic vein or the vena cava requires reconstruction, most of the parenchymal transection can be performed without inflow occlusion under low CVP conditions. As the parenchymal transection is near completion, total vascular isolation is applied to divide and reconstruct the vascular structures only. This practice results in substantially shorter periods of hepatic ischemia and allows a different method of applying in situ cold perfusion that is simpler and generally does not require bypass.

In this technique, the liver is mobilized as for total vascular isolation. The portal vein is dissected to the right and left branches, and perfusion tubing is placed into the portal vein branch on the side of the liver to be removed (Fig. 94.2). The branch is divided, maintaining portal flow to the side of the liver to be left in but allowing access for cold perfusion. Alternatively, the anterior wall of the main portal vein can be used as a site of cannula insertion (Fig. 94.3). As much of the hepatic parenchyma as possible is divided under low CVP, maintaining hepatic perfusion until it becomes necessary to divide the hepatic veins or IVC that requires reconstruction.

At this point, the patient is volume loaded, and clamps are placed sequentially on the infrahepatic cava, the portal vein, hepatic artery, and the suprahepatic IVC. If only the hepatic vein requires reconstruction, caval flow can be maintained by controlling the offending hepatic vein by placing a clamp tangentially down onto the IVC, across the hepatic vein orifice, but only partially occluding the IVC (Fig. 94.4). The anterior wall of the IVC or hepatic vein is incised, and cold perfusion of the liver is instituted through the portal cannula. Only the side of the liver remaining in place is perfused. The vessels are transected, and the specimen is removed. The vessels, hepatic veins, or IVC can be reconstructed in a bloodless field without time pressures (Fig. 94.5). Before completing the anastomoses, the liver can be flushed with cold 5% albumin. Alternatively, the liver can be flushed with 300 to 400 mL of portal vein blood with the caval clamps still in place, whereupon the portal vein clamp is reapplied, the caval venotomy is closed, and all clamps are removed. With the shorter ischemic periods involved, we have not had to use venovenous bypass with this technique (Dubay et al, 2009; Hemming et al, 2002, 2004, 2008); even longer periods of total vascular isolation do not necessarily require venovenous bypass.

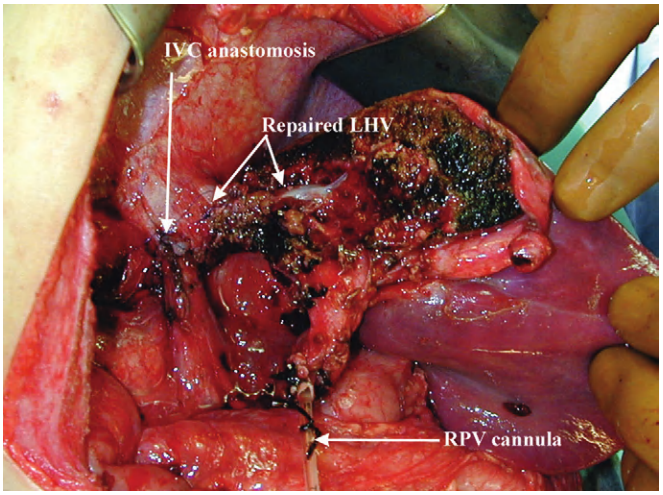

FIGURE 94.2. A portal cannula is inserted in the right portal vein (RPV) branch to allow in situ perfusion of the remaining segments II and III in an infant undergoing resection for hepatoblastoma. Cold perfusion allows resection of the inferior vena cava (IVC) and resection and repair of the medial aspect of the left hepatic vein (LHV) to be done in a controlled fashion.

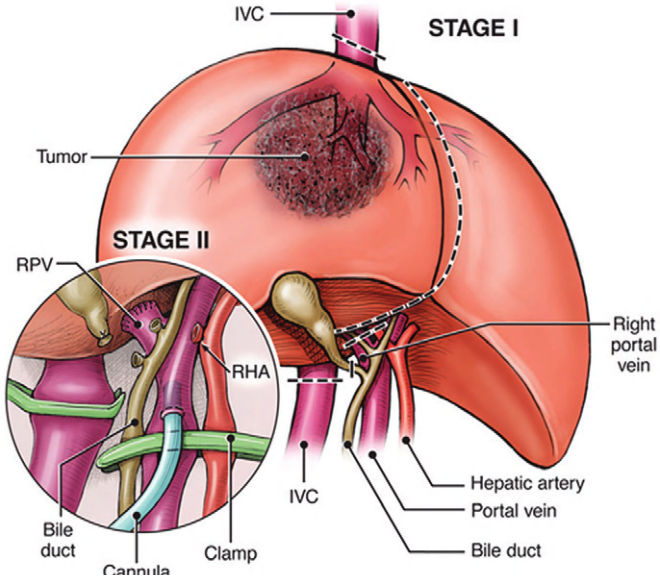

FIGURE 94.3. The anterior wall of the portal vein above the portal clamp can also be used for cannulation ad cold pefusion. IVC, inferior vena cava; RHA, right hepatic artery; RPV, right portal vein.

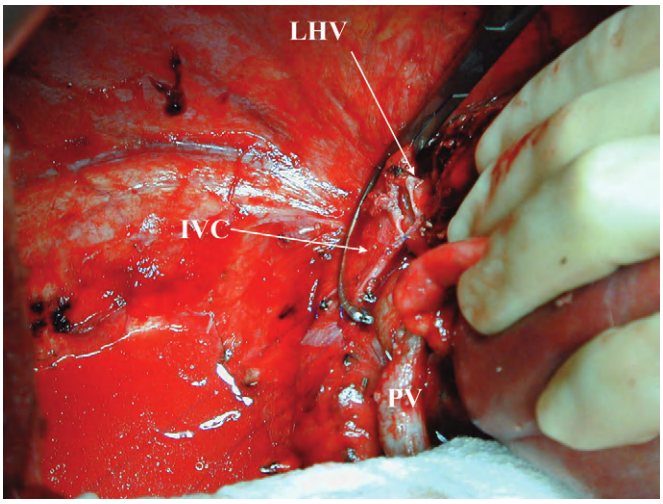

FIGURE 94.4. A vascular clamp can be placed tangentially on the inferior vena cava, occluding the implantation site of the hepatic vein but allowing maintenance of cava flow. This maneuver may allow in situ perfusion to be performed without the need for venovenous bypass. LHV, left hepatic vein.

ANTE SITUM PROCEDURE

The ante situm technique of liver resection can be used when resection of the IVC and hepatic veins is expected to be difficult, and when improved access to the hepatic veins and IVC is required. We have used this technique when combined cava and hepatic vein reconstruction is required (Azoulay et al, 2006).

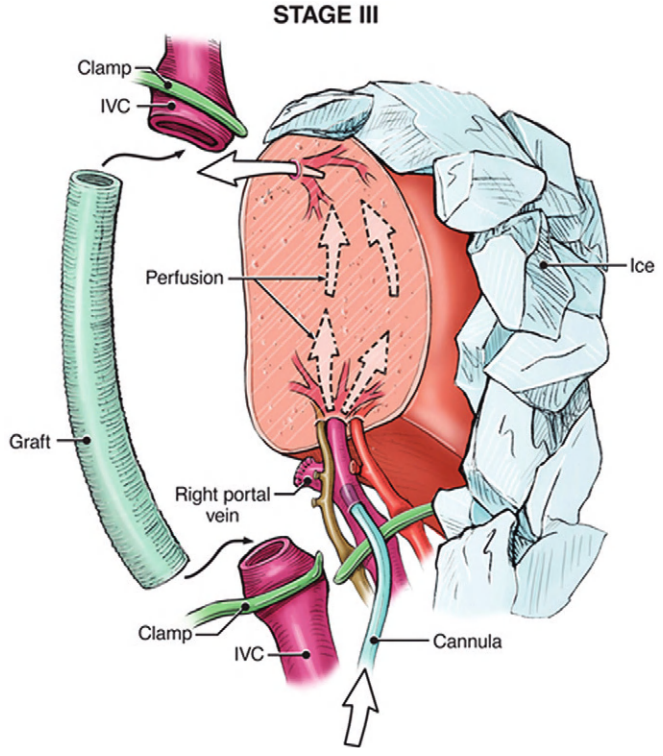

FIGURE 94.5. Continuous cold flushing of the remnant liver allows resection and reconstruction of the hepatic vasculature without time pressure. IVC, inferior vena cava.

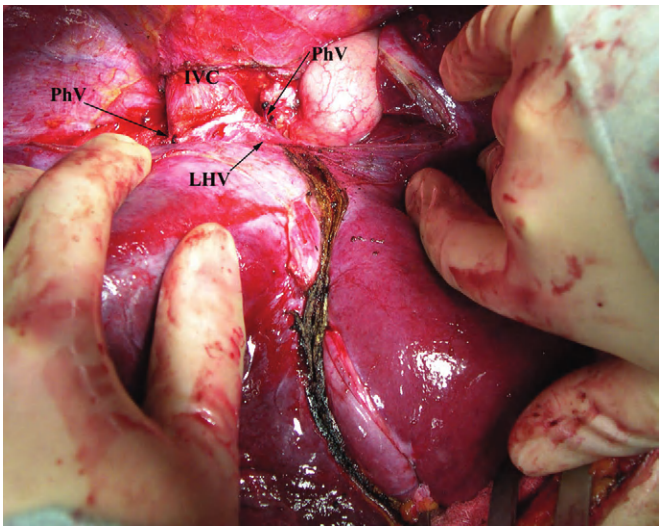

FIGURE 94.6. The phrenic veins (*Phvs*) are divided, and the suprahepatic inferior vena cava (*IVC*) is dissected away from the diaphragm to allow adequate length for placement of a suprahepatic cava clamp. This allows division of the suprahepatic vena cava with enough length to allow reanastomosis. LHV, left hepatic vein.

The ante situm technique uses the same technique as in situ cold perfusion with several caveats. The suprahepatic IVC requires more extensive dissection to achieve enough length to place a clamp on, divide, and subsequently reanastomose. Greater exposure of the suprahepatic cava can be obtained by dividing the phrenic veins and gently dissecting the IVC away from the diaphragm (Fig. 94.6). We frequently also open the pericardium directly anterior to the IVC and loop the intrapericardial vena cava; alternatively, a sternotomy provides superb exposure of the entire area (Fig. 94.7).

Control of the intrapericardial cava allows placement of the clamp on the vena cava or caudal right atrium within the pericardium as a primary option or as a secondary option in case technical difficulties arise with placement of the original suprahepatic cava clamp. We perform as much of the liver transection

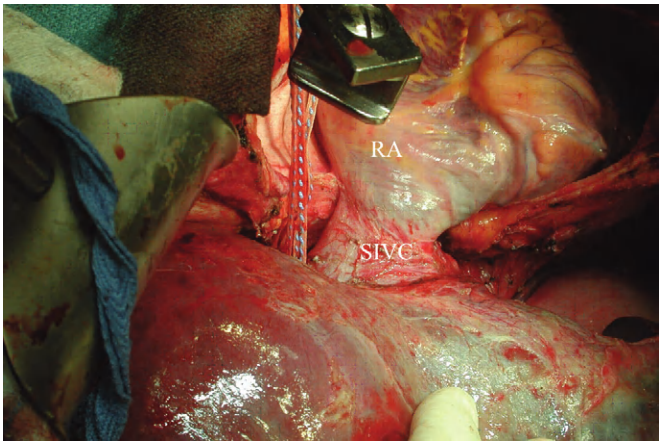

FIGURE 94.7. The addition of a median sternotomy provides excellent exposure to the suprahepatic inferior vena cava and confluence of the hepatic veins. RA, right atrium; SIVC, suprahepatic inferior vena cava.

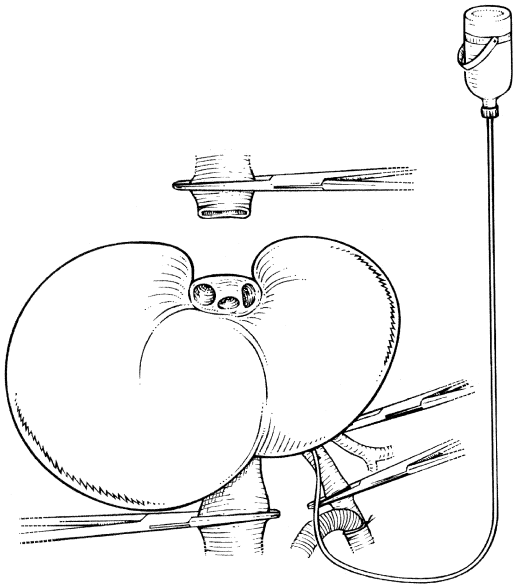

FIGURE 94.8. Ante situm cold perfusion. The suprahepatic inferior vena cava (IVC) is divided, allowing the liver to be rotated forward so the region of the hepatic vein–IVC confluence can be better visualized.

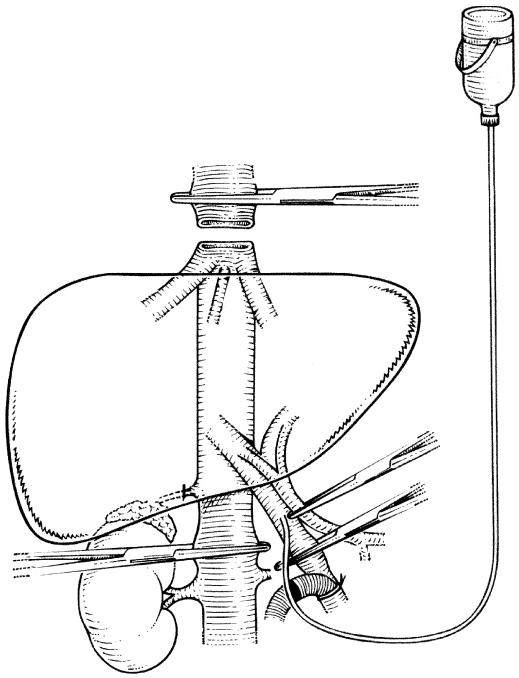

FIGURE 94.9. Venovenous bypass can be used during ante situm perfusion. If more exposure is required to the retrohepatic inferior vena cava (IVC) than is provided by dividing the suprahepatic IVC alone, the infrahepatic IVC also can be divided, allowing the liver to be rotated completely up onto the abdominal wall.

as possible without inflow occlusion before cold perfusing the liver. Venovenous bypass is generally recommended for this procedure; however, many patients tolerate caval clamping without difficulty. Institution of cold perfusion is as originally described for in situ perfusion; however, the perfusate is vented via the suprahepatic IVC as the suprahepatic cava is divided. Dividing the suprahepatic IVC allows the liver to be rotated forward and upward toward the abdominal wall, enabling greater access to the area immediately around the IVC–hepatic vein junction (the hepatocaval confluence) (Figs. 94.8 and 94.9).

If further access is required, the infrahepatic vena cava can be divided, allowing the liver to be rotated completely up onto the abdominal wall. With this technique, we have found that continuous, slow cold perfusion is required after the initial flush to prevent excessive warming of the liver. As a rule, the liver is first flushed with 1 L or so of ice-cold preservation solution wide open, with the bag suspended at shoulder height. After the initial bolus, the infusion rate is slowed to about a third of the original rate. Care is taken to suction the vented perfusate to avoid its systemic absorption.

The liver transection is completed, dividing the hepatic vein within the liver and resecting the origin of the junction of the IVC and hepatic vein en bloc with the tumor. If extension grafts are required, vascular reconstruction can be performed; the hepatic vein anastomoses, which are the most tenuous, are performed while the liver is rotated onto the abdominal wall. The liver is replaced, and the caval anastomosis is performed. The liver can be flushed with 5% albumin before reperfusion, or it can be flushed with warm portal blood, as described above.

The ante situm approach gives better access to the cava–hepatic vein junction than does simple in situ cold perfusion. The exposure is not as good as with a complete ex vivo approach. The advantage to the ante situm approach is that biliary and hepatic arterial anastomoses are not required, reducing the ischemic time to the liver and reducing the potential for complications resulting from these additional anastomoses. Currently, we use the ante situm approach when a combination of cava resection and hepatic vein reconstruction is required, and we expect to implant only a single hepatic vein orifice, whether from a single vein or one or more veins plastied together, into the cava (Figs. 94.10 through 94.12. In the few cases where the reconstruction is expected to be significantly more complex, we use a complete ex vivo approach.

FIGURE 94.10. Computed tomographic scan showing a cholangiocarcinoma centered on all three hepatic veins at the junction of the inferior vena cava. Right portal structures also were involved. A right trisegmentectomy with reconstruction of the left hepatic vein was planned.

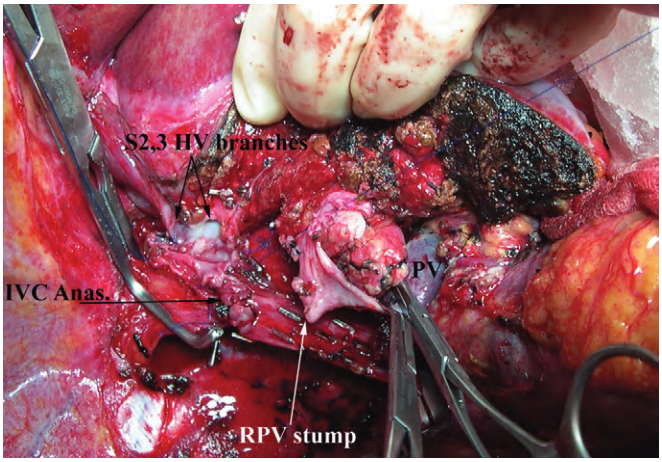

FIGURE 94.11. Parenchymal division along a right trisegmentectomy plane was performed, crossing into segments II and III superiorly. A cannula was placed in the stump of the right portal vein (*RPV*) for cold perfusion with University of Wisconsin solution. A short segment of the inferior vena cava (*IVC*) at the level of the hepatic veins and the first 3 cm of the left hepatic vein origin were resected, and the liver was rotated anteriorly. The IVC was reconstructed end to end with the left hepatic vein reimplanted above the cava anastomosis. IVC anas, IVC anastomosis; S2,3 HV, segments II and III hepatic vein branches.

EX VIVO LIVER RESECTION

Although the techniques described above can be applied to the majority of patients with difficult hepatic vein or caval reconstructions, patients who have tumors that involve the IVC and hepatic veins that require complex venous repair or patients with combined hepatic vein and hilar involvement may be candidates for ex vivo resection. During ex vivo resection, the liver is removed from the patient completely and perfused with cold preservation solution on the back table. The hepatic resection is performed in a bloodless field, and vascular reconstructions are performed before reimplanting the remnant liver into the patient.

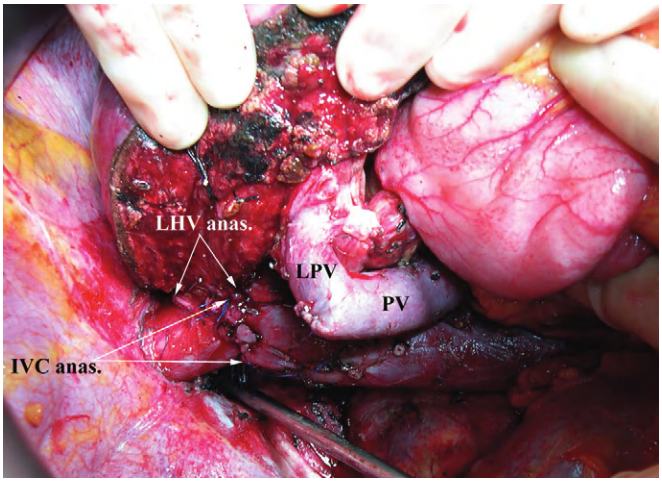

FIGURE 94.12. Reimplanted segments II and III from Figure 94.11. The left hepatic duct was reconstructed later using a Roux-en-Y limb. IVC anas., IVC anastomosis; LHV anas., left hepatic vein anastomosis; LPV, left portal vein; PV, portal vein.

Patient Selection and Preoperative Workup

In principle, any patient with liver malignancy that is unresectable by other means can be assessed for ex vivo liver surgery. In practice, almost all liver resections can be performed without the need for an ex vivo approach, whether hypothermic perfusion of the liver is required or not. Patients with tumors that involve the junction of the IVC and hepatic veins, such that complex, prolonged vascular reconstruction is required, or patients with combined vascular involvement of the hepatic veins and hilar structures, may benefit from a planned ex vivo approach.

One of the benefits of planning the ex vivo approach—or for that matter, planning any of the hypothermic perfusion techniques—is that frequently at operation, what initially was thought to be unresectable by any method short of complete removal of the liver is found to be resectable with a less complex procedure. General assessment of the patient is similar to that for liver transplantation, with particular assessment of cardiac risk factors. In patients older than 50 years of age or those with any cardiac abnormalities, a functional stress test, such as dobutamine stress echocardiogram, is performed. Any significant cardiac abnormality is a contraindication. Even mild renal dysfunction has been shown to increase the risk of standard extended hepatectomy (Melendez et al, 2001), and a creatinine level greater than 1.3 mg/dL should be considered a contraindication. Ex vivo liver resection should be attempted only in otherwise healthy, well-selected patients.

Preoperative imaging is crucial to stage the tumor and to assess its position in relation to hepatic vascular anatomy. Our current standard is triphasic spiral computed tomography (CT) with three-dimensional (3D) reconstructions, to assess the liver anatomy and tumor position, and CT of the chest and pelvis (see Chapter 16). In some instances, magnetic resonance imaging (MRI) is required, including MR angiography and MR venography, particularly when all three hepatic veins are involved, and some degree of hepatic venous obstruction is present that prevents adequate flow of contrast material into the hepatic veins during CT (see Chapter 17). With the combination of CT and MRI and the present availability of 3D reconstruction, invasive angiography is usually unnecessary. Contrast ultrasound provides a dynamic view of the relationship of the tumor to the hepatic veins and cava, and it is particularly useful for gauging extent of invasion of vascular structures by the tumor.

Remnant liver volume assessment can be performed as for extended hepatectomy. In a standard liver resection, assuming normal liver function, 25% of total liver volume (TLV) after resection is considered adequate for resection without the need for preoperative PVE (see Chapter 93A). One caveat is that patients who have undergone or are undergoing prolonged and aggressive preoperative chemotherapy may require more liver volume because of chemotherapy-induced steatohepatitis. With cold preservation and reperfusion, additional ischemic injury occurs over and above what happens during standard liver resection. We have arbitrarily chosen a projected liver remnant of 40% of TLV as a cutoff for consideration for preoperative PVE in patients who require extended hepatectomy who may need complex vascular reconstruction and cold-perfusion techniques (Hemming et al, 2003, 2008). A positron-emission tomography (PET) scan should also be considered for all patients to assess for the possibility of otherwise undetected extrahepatic disease (see Chapter 15).

Accurate imaging of the intrahepatic architecture is paramount to assess the possibilities for reconstruction. Three-dimensional imaging techniques occasionally may reveal unusual anatomy that makes vascular reconstruction unnecessary, such as the presence of a large inferior hepatic vein that makes reconstruction of the main right hepatic vein unnecessary. Alternatively, anatomy may be discovered that requires additional reconstruction, such as a large segment VI vein that drains into the middle hepatic vein (Lang et al, 2004).

Anesthesia

Anesthetic management for ex vivo liver resections is similar to that for liver transplantation (see Chapter 97B). Maintaining patient temperature is a key component of anesthesia management and includes the use of forced-air warming blankets and warming of all fluids. In addition to standard monitoring for liver resection, a Swan-Ganz catheter is inserted for hemodynamic monitoring and assessment of blood temperature in the pulmonary artery. Access for venovenous bypass, which originally was achieved by cutdowns, has been simplified by percutaneous insertion techniques.

Most cases begin with maintenance of low CVP, as would be standard for most liver resections, because most cases do not proceed to ex vivo techniques. Percutaneous catheters are placed in the internal jugular vein or subclavian vein and the femoral vein for the cava portion of the bypass circuit, when an ex vivo procedure is decided on. At that time, the patient can subsequently be volume loaded. The portal limb of the circuit is placed directly into the portal vein by the surgeon, although an alternative approach is to insert the portal cannula through the inferior mesenteric vein; this vein can then be ligated at the time of cannula removal.

In an ex vivo procedure, the anhepatic phase generally lasts from 2 to 4 hours, and attention must be paid to coagulation during this period. As for liver transplantation, we give fresh frozen plasma to meet volume requirements during this time and minimize the use of crystalloid. Glucose levels are monitored, and constant glucose infusion is required.

As with LDLT, on reperfusion of the cold autograft, the temperature of the blood in the pulmonary artery can drop precipitously. For liver transplantation and ex vivo liver resection, we continuously monitor the pulmonary artery blood temperature and manually compress the portal inflow temporarily, when the temperature decreases to less than 35° C. Portal occlusion for 10 seconds or so allows the pulmonary artery blood temperature to increase to 36° C, after which portal compression is released. The maneuver is repeated as many times as may be required over the course of reperfusion. Pulmonary artery blood temperature commonly decreases to 32° C to 33° C without portal compression on reperfusion. In our experience, avoiding this precipitous drop in pulmonary artery blood temperature seems to reduce the cardiac dysfunction that occurs on reperfusion of the liver.

Surgical Procedure

Pichlmayr and Hauss (1994) described the procedure of ex vivo liver resection in the second edition of this textbook; they appropriately described the procedure in terms similar to liver transplantation. The following description of technique is taken largely from Pichlmayr's original description in this textbook with some minor modifications by the current authors. The procedure comprises three phases: 1) assessment of resectability and removal of the liver, 2) liver resection and vascular reconstruction on the back table, and 3) reimplantation of the liver autograft. As with the preceding discussion, many of the recommendations found below are applicable to any of the three hypothermic perfusion techniques described in this chapter.

Assessment of Resectability and Removal of the Liver

An initial assessment of resectability is undertaken via laparoscopy or a limited abdominal incision to assess the presence of peritoneal disease that would preclude proceeding with resection. Even after a negative laparoscopy, we perform a limited abdominal incision and assess the abdominal cavity. It is common to have a negative laparoscopy only to find additional small lesions in the liver or elsewhere that would be a contraindication to proceeding. The incision is lengthened to some variation of a bilateral subcostal incision, with or without a midline extension. Alternatively, a midline laparotomy with a horizontal right extension can be used, and either approach can be combined with a midline sternotomy for the sake of exposure of the hepatocaval confluence.

The liver is assessed for resectability. Because the indication for ex vivo resection is generally involvement of the hepatic veins with or without cava involvement, the liver may be quite congested as a result of obstructed venous outflow. Therefore care must be taken not to injure the liver during mobilization: any small breach of the liver capsule becomes an outflow route for the obstructed venous flow, and bleeding can be torrential. Venous congestion of the liver is not a contraindication to resection, as the planned resection should relieve the venous outflow obstruction. Large tumors may restrict the ability to rotate the liver without undue tension, and in these cases, it is prudent to make an early decision regarding ex vivo resection before attempting elevation of the liver off of the IVC. A midline sternotomy can also be of use in these cases. Intraoperative ultrasound is used to assess the level of vascular involvement and to confirm vascular anatomy originally identified on preoperative imaging. If a decision is made to proceed with an ex vivo approach, the following steps are performed:

1. The hilar structures are prepared. The arterial anatomy is dissected, and an appropriate site is chosen for planned division. This usually is at the level of the common hepatic artery–gastroduodenal artery junction. If aberrant arterial anatomy is evident, an alternative site may be required, depending on the particular anatomy and the portion of the liver that remains after the resection. In most cases, to preserve small arterial communications to the biliary plate and tree, the artery is not dissected high into the hilum. If the tumor involves the hilar structures, the artery must be dissected far enough to determine that there is a usable, tumor-free portion of the respective hepatic artery branch to reconstruct. The portal vein is identified, and the common bile duct is encircled without skeletonization. A cholecystectomy is performed, and the bile duct is reflected off the portal vein, taking care to preserve its blood supply, and the neural and lymphatic tissue around the portal vein is cleared.
2. The infrahepatic IVC is dissected out down to the level of the renal veins and encircled. Planned vascular clamp placement is immediately above the renal veins, although division of the vena cava may be substantially more cephalad. The

right adrenal vein should be ligated and divided, and small caudate veins should be divided if accessible. The large size of the tumor may make access to the caudate veins difficult, in which case they can be dealt with on the back table.

3. The liver is freed from surrounding attachments. If the tumor is infiltrating the diaphragm, the portion of the diaphragm involved is resected en bloc with the tumor.
4. The suprahepatic IVC is prepared. The phrenic veins are divided bilaterally, allowing the diaphragm to be dissected away from the IVC, providing an increased length of intraabdominal IVC for subsequent clamping and reconstruction. We currently also open the pericardium directly anterior to the IVC and loop the intrapericardial IVC, or we use a midline sternotomy for the same reason. Control of the intrapericardial IVC allows placement of the clamp on the vena cava within the pericardium as a primary option for tumors that are very large, or as a secondary option in case technical difficulties arise with placement of the original suprahepatic cava clamp.
5. Clamp placement and subsequent transection lines are assessed, along with the need for vascular conduits for reconstruction, and alternatives for reconstruction are contemplated before removing the liver. Hepatic venous branches may be reconstructed using hepatic vein or portal vein segments from the side of the liver resected or from autologous vein grafts, such as superficial femoral vein, proximal left renal vein, gonadal vein, or saphenous vein panel grafts. Cryopreserved femoral vein grafts can be used for reconstruction of long segments of hepatic veins or IVC, although long-term patency is currently unclear. The IVC alternatively can be replaced with a 20-mm ringed polytetrafluoroethylene (Gore-Tex) tube graft. Planning for these eventualities should occur before placement of clamps and removal of the liver.
6. Percutaneous access of the internal jugular vein and femoral vein is achieved, the IVC is clamped, and the cava portion of the bypass is started. The portal vein is clamped just below the bifurcation, and the portal cannula is inserted down toward the superior mesenteric vein and secured. The portal vein is completely transected approximately 1.5 to 2 cm below the bifurcation, and the portal flow is added to the bypass circuit, while the liver continues to be perfused by arterial blood.
7. The liver is removed, and the bile duct is transected sharply approximately 1 to 1.5 cm below the bifurcation. To permit a duct-to-duct anastomosis on reimplantation, we do not ligate either end. The gastroduodenal artery is ligated and divided, the common hepatic artery is clamped, and the hepatic artery is transected at the takeoff of the gastroduodenal artery such that a branch patch is formed on either side of the arterial transection if possible. The suprahepatic IVC is clamped either below the diaphragm or within the pericardium, and the suprahepatic vena cava is transected, far enough away from tumor to provide an adequate oncologic margin but close enough to leave room to perform the suprahepatic cava anastomosis at the time of reimplantation. If the vena cava has been freed of its posterior attachments before clamp placement, the infrahepatic IVC is divided as cephalad as possible, and the liver is removed and placed in an ice bath. Cold perfusion through the portal vein and hepatic artery is initiated on the back table. As with any hypothermic perfusion technique, cold perfusion can be with either HTK or UW solution. If the retrohepatic IVC has not been freed up previously because of the large tumor size and difficulty with access, the liver can be cold perfused via the portal vein after the suprahepatic IVC is divided. The liver is rotated forward, as in the ante situm approach, and the retrohepatic IVC is freed of attachments. The infrahepatic IVC is divided, and the liver is removed and placed in the ice bath.
8. Bleeding is controlled, and the bypass circuit is assessed. Flows of 3 to 6 L/min would be expected on total bypass (see Fig. 94.1). The abdomen is loosely packed and covered, and attention is turned to the back table.

An alternative method can be performed in patients with complex hepatic vein involvement without IVC involvement with tumor. If access allows, the liver can be mobilized completely off of the retrohepatic IVC, until it is suspended only by the hepatic veins. The hilar structures are divided as for standard ex vivo resection, but the patient is not placed on bypass. A vascular clamp is placed partially across the IVC, occluding the hepatic vein orifices but allowing cava flow to remain uninterrupted. The hepatic veins are transected, and the liver is removed and cold flushed on the back table. A temporary portacaval shunt is constructed (Fig. 94.13) to decompressing the enteric circulation; this option avoids bypass, but it can be used only when there is no IVC involvement, and when the IVC can be preserved in situ. It is worth assessing whether the tumor can be dissected away from the IVC in most patients, because preoperative imaging can be inaccurate in determining true IVC involvement (Okada et al, 2003).

Ex Situ Liver Resection

After it is removed from the patient, the liver is placed immediately in an ice bath and perfused with preservation solution through the portal vein. We use UW solution, because it is also the preservation solution we use for LDLT; HTK solution also is a reasonable choice. After the initial 500 to 1000 mL of solution has been flushed through the liver, the effluent from the

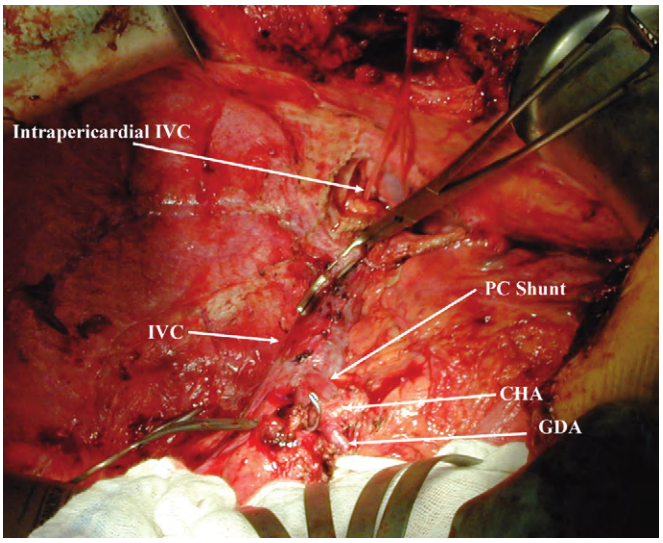

FIGURE 94.13. A temporary portacaval (*PC*) shunt is constructed, allowing a prolonged anhepatic phase without the need for venovenous bypass. The intrapericardial inferior vena cava (*IVC*) has been encircled. CHA, common hepatic artery; GDA, gastroduodenal artery.

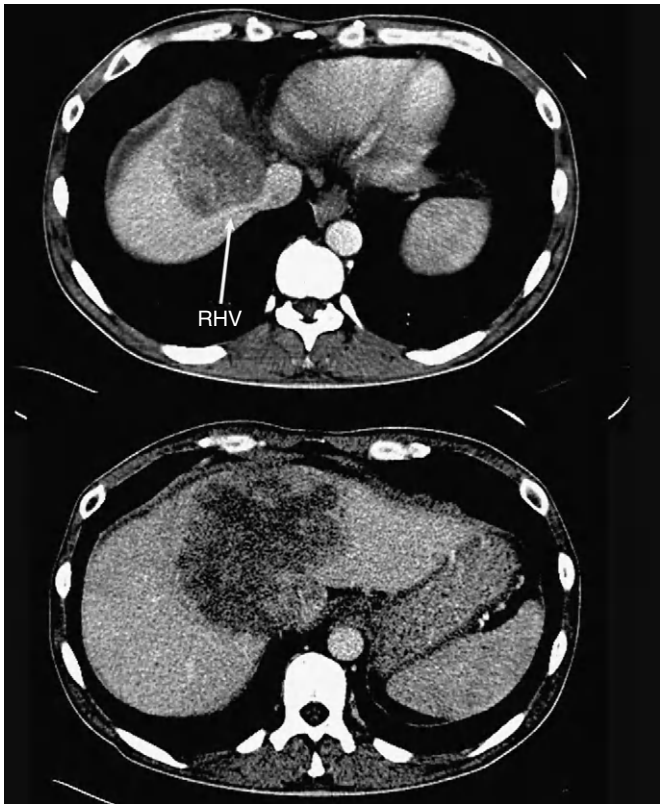

FIGURE 94.14. A single colorectal metastasis (*arrow*) involving all three hepatic veins. RHV, right hepatic vein.

IVC should be clear. The hepatic artery and biliary tree also are flushed with another 200 to 300 mL of preservation solution, the liver is immersed in cold UW solution, and the resection is performed.

Hilar structures are dissected out and divided. Great care must be taken not to divide segmental arteries that supply portions of the liver that are to remain, as their caliber is too small to reconstruct with confidence. Main segmental divisions of the portal vein usually can be repaired and reconstructed. Parenchymal transection can be performed using a variety of techniques, including ultrasonic and water-jet dissection or even sharp division with a knife. Small bile ducts and vessels are ligated or oversewn, and large hepatic veins are cut sharply and are assessed later for reconstruction (Figs. 94.14 to 94.17). The surgical tumor margin should not be compromised in order to minimize the subsequent complexity of vascular reconstruction.

A key advantage to the ex vivo approach is the ability to extend the resection to obtain negative margins, while providing the necessary time and exposure for complex reconstructions. At completion of the resection, it is helpful to flush the portal vein, hepatic artery, and bile duct with UW solution to identify leaks from the cut surface of the liver, which can be repaired before reimplantation. Fibrin glue may be sprayed on the cut surface of the liver to minimize bleeding.

Hepatic Vein and Inferior Vena Cava Reconstruction

Complex hepatic vein reconstruction, with or without IVC reconstruction, is the raison d'être for ex vivo liver resection. The hepatic veins are relatively thick-walled and straightforward to reconstruct within 2 to 3 cm of their merging with the IVC. For reconstructions of hepatic veins transected relatively close

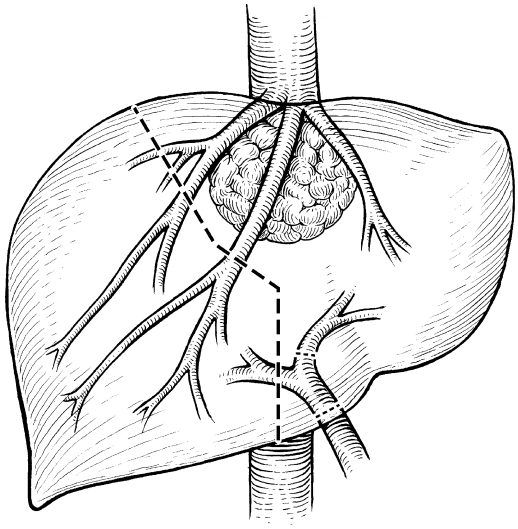

FIGURE 94.15. The planned hepatic transection line for the tumor shown in Figure 94.14. Multiple hepatic vein branches require reconstruction.

to the IVC, the liver parenchyma can be trimmed back such that direct reimplantation of the hepatic vein into the IVC or the IVC replacement can be performed.

Multiple orifices of hepatic veins can be plastied together or implanted into venous conduits (Figs. 94.18 to 94.20). The farther away from the IVC that the hepatic vein is transected, the thinner the wall of the hepatic vein, and the more difficult it is to reimplant the vein directly into the IVC. We have harvested the portal vein bifurcation, reversed it, and used it to reconstruct multiple hepatic vein branches into a single outflow vessel on several occasions (Figs. 94.21 to 94.23; Hemming & Cattral, 1999). Grafts of saphenous, superficial femoral, internal jugular, and cryopreserved vein all have been used to reconstruct hepatic veins (Dong et al, 2004; Kaneoka et al, 2000; Kishi et al, 2004;

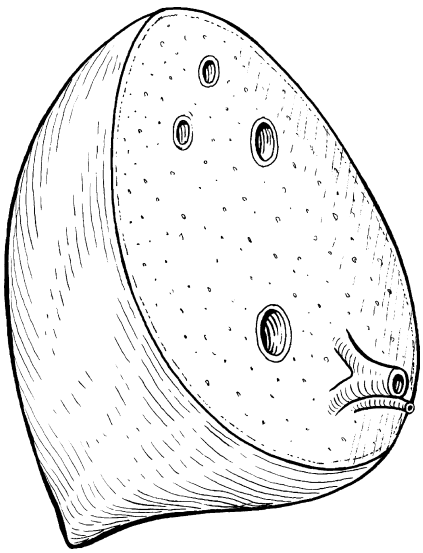

FIGURE 94.16. Back-table transection of the liver results in multiple branches of the right hepatic vein requiring reconstruction. A large segment VI branch that enters the middle hepatic vein also requires reimplantation.

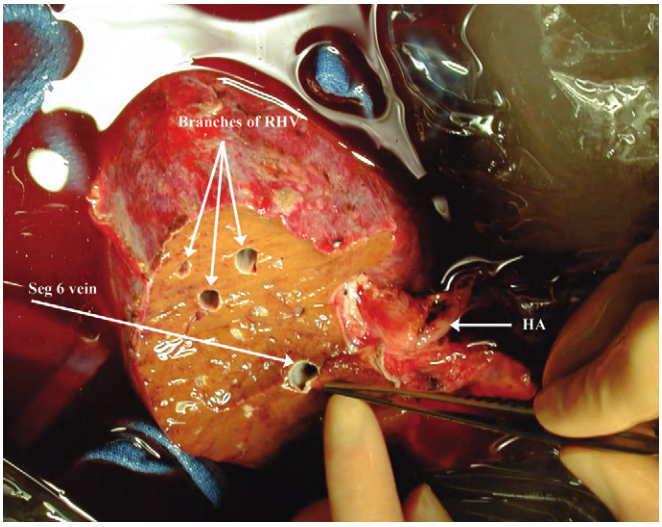

FIGURE 94.17. Completed transection on the back table. HA, hepatic artery; RHV, right hepatic vein; Seg 6, segment VI.

Kubota et al, 1997, 1998). In addition, segments of uninvolved hepatic vein from the side of the liver resected can be salvaged and used for grafts or patches.

Venous grafts should be kept as short as possible, and great care must be taken to place the grafts such that they do not kink. For extension grafts, the hepatic vein–graft anastomosis is performed first with subsequent reimplantation of the graft into the IVC. One alternative to consider prior to choosing an extension graft is whether the liver remnant can be rotated on its inflow pedicle such that the hepatic vein orifice is brought to lie directly against the caval graft; this avoids the issue of kinking of a venous extension graft.

An important issue is how to reconstruct the vena cava. If possible, it is best to reimplant the hepatic veins into native vena cava. Frequently, a large portion of the vena cava that was

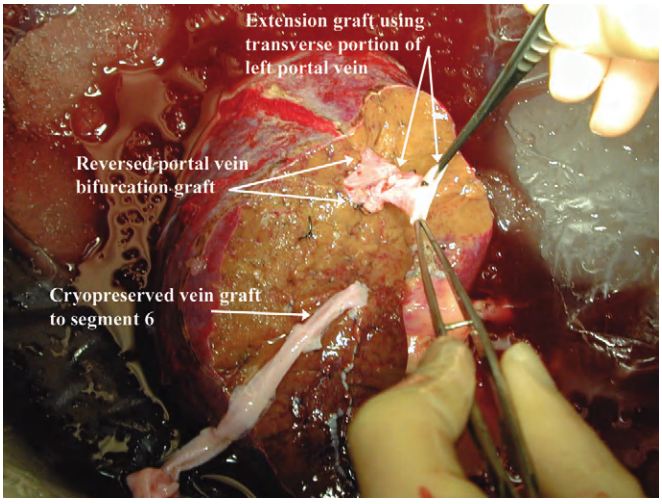

FIGURE 94.18. Joining two of the three right hepatic vein branches together and implanting the resulting two orifices into the reversed portal vein bifurcation taken from the patient's hilum allows reconstruction of the right hepatic vein branches. The transverse portion of the left portal vein is added to allow the graft to reach the inferior vena cava (IVC) without tension. A cryopreserved femoral vein graft is used to extend the segment VI vein to the IVC.

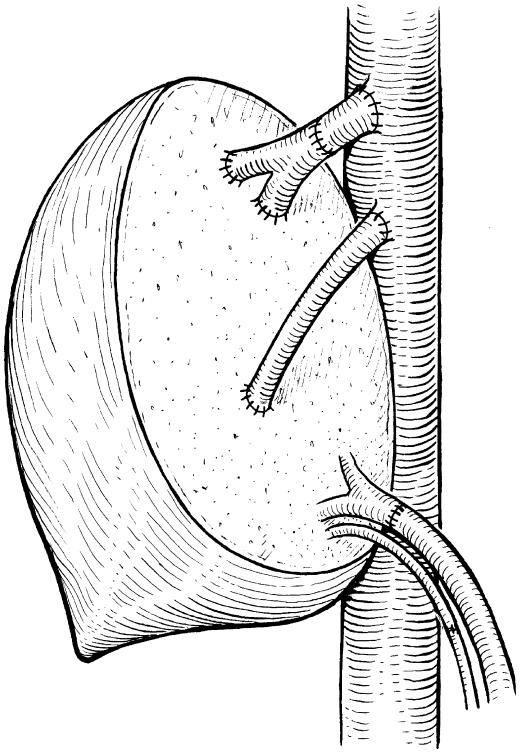

FIGURE 94.19. The prepared autograft is reimplanted into the patient as diagrammed. Reimplantation is done in similar fashion as for living donor right lobe transplantation.

removed initially with the liver can be salvaged and moved superiorly, with the hepatic veins reimplanted into this newly situated portion of IVC. A ringed 20-mm Gore-Tex tube graft can be used to make a composite cava graft with the Gore-Tex graft placed inferiorly. Alternatively, a section of the IVC remaining in the patient immediately above the renal veins can be harvested and used as the segment of IVC into which the hepatic veins are reimplanted. A ringed 20-mm Gore-Tex tube graft is used to replace the segment of IVC immediately above the renal veins. In some circumstances, it is necessary to

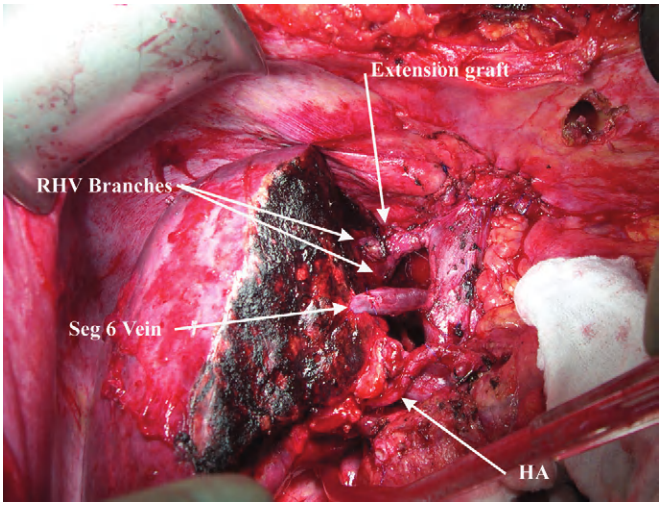

FIGURE 94.20. The reimplanted liver as in Figure 94.19. HA, hepatic artery; RHV, right hepatic vein; Seg 6, segment VI vein.

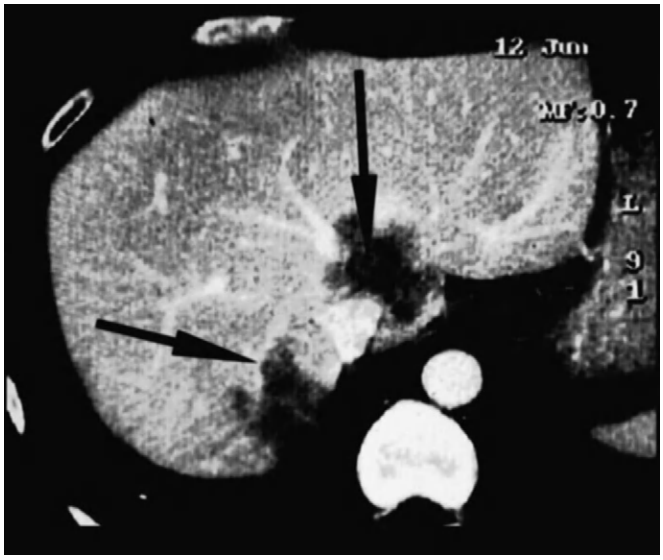

FIGURE 94.21. Computed tomographic scan showing colorectal metastases involving all three hepatic veins. *Arrows* indicate tumor.

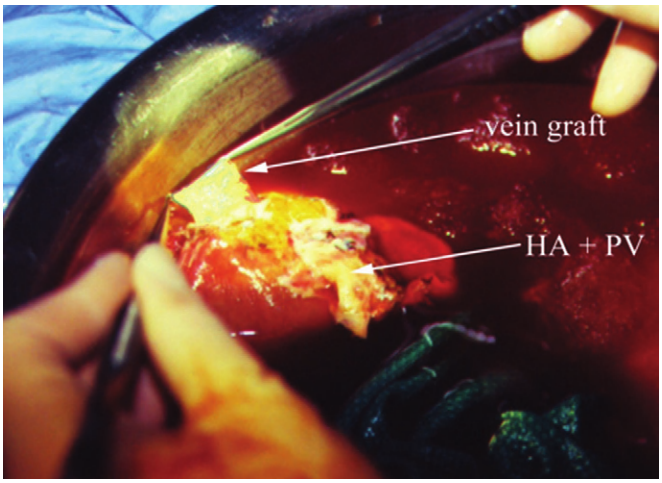

FIGURE 94.23. A reversed portal vein bifurcation (vein graft) graft taken from the patient's hilum is used to reconstruct the left hepatic vein outflow. HA, hepatic artery; PV, portal vein.

reimplant the hepatic veins directly into a relatively stiff artificial graft that is replacing the IVC (Figs. 94.24 and 94.25). In this situation, it is important to make a larger opening in the Gore-Tex than one might expect and to triangulate the anastomosis to prevent anastomotic stricturing (Lodge et al, 2000).

At completion of the back-table reconstruction, an autograft results that is similar to that of a reduced-size or split-liver allograft (Figs. 94.26 through 94.28). Total cold ischemic time is usually 2 to 4 hours, which is well within acceptable limits, when comparing cold ischemic times for split-liver or reduced-size liver transplantation.

Reimplantation

Reimplantation is similar to reduced-size liver transplantation or LDLT. The suprahepatic IVC anastomosis is performed first. If an artificial venous graft has been used to reconstruct the IVC, it is shortened such that it does not kink on implantation. When the back wall of the infrahepatic vena cava anastomosis has been completed, the portal vein is flushed with 500 mL of cold 5% albumin, which is vented through the infrahepatic cava anastomosis. The infrahepatic vena cava anastomosis is then completed. The cold rinse washes the UW solution out of the liver before reperfusion, as this solution contains high levels of potassium and adenosine, which can cause dramatic cardiac dysfunction or arrest if allowed into the circulation on reperfusion. As previously described, an alternative to cold flushing the liver before reperfusion is to leave the lower cava anastomosis open until after portal reperfusion, venting the initial 300 mL of blood before removing the suprahepatic cava clamp. Although little solid evidence supports the use of one technique over the other, we prefer the cold-flush technique only because it reduces the number of possible bleeding sites at the time of reperfusion.

After the infrahepatic cava anastomosis is performed, the portal limb of the bypass circuit is clamped and removed from the portal vein, and the portal venous anastomosis is performed. Next, the suprahepatic cava clamp is removed, and the liver is allowed to back-perfuse through the hepatic veins. Any major bleeding is controlled before reestablishing the portal flow. The portal venous clamp is removed, and the liver is reperfused. Any bleeding from the cut surface of the liver is controlled, and the patient is taken off venovenous bypass.

Finally, the arterial anastomosis is performed, and the liver is reperfused with arterial blood; total warm ischemic time ranges from 20 to 40 minutes. After hemostasis has been achieved, the biliary anastomosis is performed. In the first few ex vivo liver resections that we did, our preference was to perform a Roux-en-Y choledochojejunostomy, but our more recent cases have involved duct-to-duct anastomoses over an internal stent. This experience mirrors our larger experience with living donor right lobe transplantation.

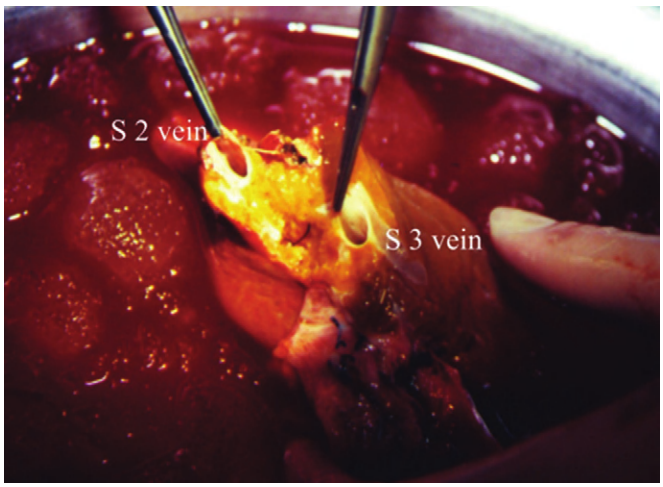

FIGURE 94.22. Remnant liver after ex vivo resection of tumor seen in Figure 94.21. S2 and S3 veins are segments II and III hepatic vein branches.

Postoperative Course

Postoperative care is similar to any major liver resection or liver transplantation. Ultrasound with Doppler assessment is performed on postoperative day 1 to assess liver blood flow. Day 1

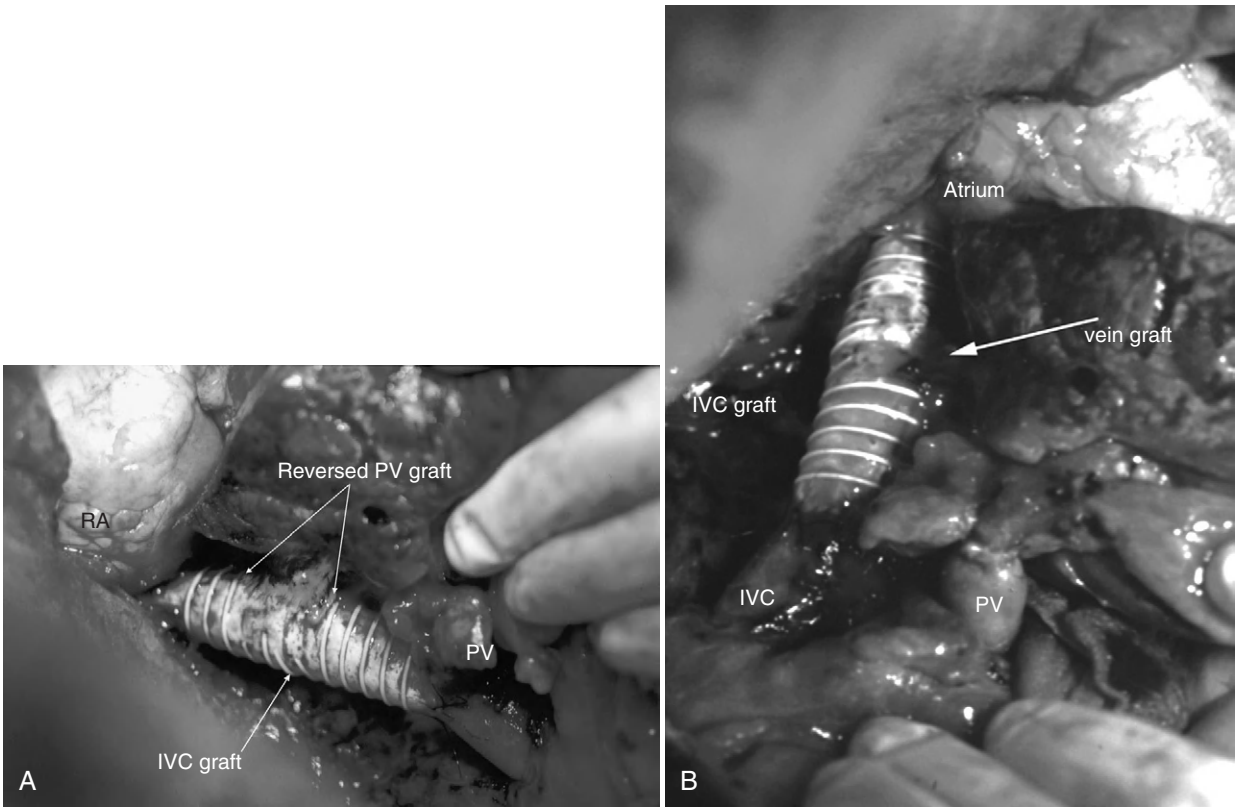

FIGURE 94.24. The reversed portal vein (*PV*) bifurcation graft has been reimplanted directly into a segment of ringed 20-mm polytetrafluoroethylene (Gore-Tex) that replaces the IVC. RA, right atrium.

transaminase levels in the 200 to 1000 IU/L range are standard but return to near normal in 1 week. Hyperbilirubinemia is common, and as might be expected, it seems to vary inversely with the size of the liver remnant. Hyperbilirubinemia by itself is not concerning, if other markers of liver function are improving.

An early sign that the autograft is functioning is the return of lactate levels to baseline in the first 12 to 24 hours after surgery. Maintenance of coagulation parameters, in particular prothrombin time or international normalized ratio (INR), suggests recovery of liver function. It is frequently necessary, however, to give fresh frozen plasma for the first few days to maintain an INR target less than 2 (Martin et al, 2003). Hypophosphatemia can occur between postoperative days 1 and 3 as the liver regenerates, and it may be so profound as to require constant intravenous replacement. Without much evidence as to its effectiveness, we have used low-dose intravenous heparin (500 U/h) perioperatively, and we attempt to maintain the hematocrit between 30% and 35%. Patients who have artificial venous caval grafts are started on low-dose aspirin before discharge. This is maintained for life, although no data confirm the need for long-term anticoagulation.

Current Role of Ex Vivo Liver Resection

The role of such an extensive procedure in advanced malignancies is open for discussion. Although 2 decades have passed since Pichlmayr and colleagues (1988) described the first ex vivo liver resection, relatively few surgeons have attempted the

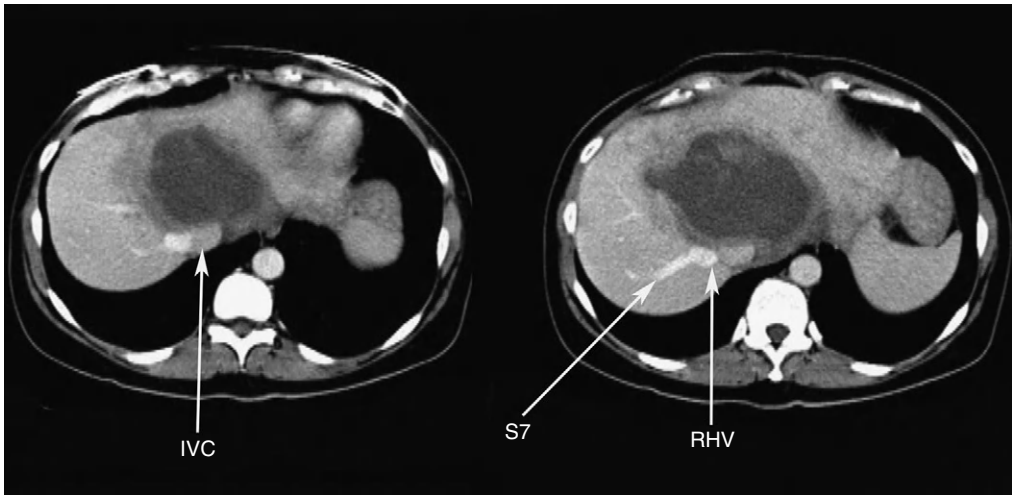

FIGURE 94.26. CT scan showing a large, centrally placed tumor. IVC, inferior vena cava; RHV, right hepatic vein; S7, segment VII hepatic vein branch.

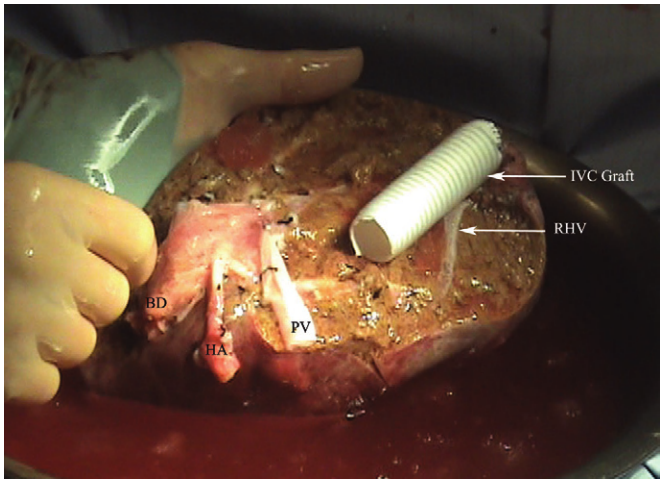

FIGURE 94.27. Ringed Gore-Tex graft has been used to reconstruct the inferior vena cava on the back table for the case in Figure 94.26. BD, bile duct; HA, hepatic artery; IVC, inferior vena cava; PV, portal vein; RHV, right hepatic vein branch.

procedure. The largest reported series from Pichlmayr's own group consists of only 22 patients (Oldhafer et al, 2000). There are several reasons behind the lack of adoption of this technique, not least the fact that the two other hypothermic perfusion techniques described in this chapter, in situ and ante situm hepatic hypothermic perfusion, can be applied to the great majority of difficult vascular reconstructions with the important exception of tumors involving both hilar structures and the hepatic vein and/or the cava. The ex vivo technique requires a surgeon familiar with advanced techniques in liver resection and liver transplantation, which restricts the procedure to relatively few individuals. Many patients who may be candidates for ex vivo resection are deemed unresectable by competent hepatic surgeons and are not referred on. Perhaps the most compelling reason for the lack of adoption of this technique is the relatively high risk-to-benefit ratio that the procedure offers. Most of the literature on ex vivo liver resections has been case reports that describe aspects of technique, and long-term follow-up is not available. Even in well-selected patients, perioperative mortality is between 10% and 30%. By contrast, the perioperative mortality for patients undergoing in situ or ante situm hepatic hypothermic perfusion with vascular reconstruction is around 10% or less (Azoulay et al, 2005; Dubay et al, 2009; Hemming et al, 2008). Long-term survival after ex vivo liver resection is also poor: at best, the 5-year survival for ex vivo resections performed for malignancy is 15% to 30%. In Oldhafer's series (2000), the six patients who underwent ex vivo resection for colorectal metastases had a median survival of 21 months, although it might be expected that the general improvement in survival following resection for colorectal metastases seen over the last decade would apply to ex vivo liver resections as well.

Notwithstanding the considerations above, there is no doubt that the occasional patient is cured by this aggressive procedure. One patient with resection for cholangiocarcinoma in Oldhafer's series was alive and disease free at 3.5 years after resection, whereas one of our own patients who underwent ex vivo resection for HCC was alive and disease free more than 5 years after the operation (Hemming et al, 2000). It is worth noting that many patients may benefit by being considered for ex vivo liver resection, simply because a surgeon prepared to perform ex vivo resection realizes that the resection can be

done using a less aggressive technique, such as in situ cold perfusion or standard vascular reconstruction.

It is also true that liver surgery is constantly evolving, and what is considered questionable today may become a mainstream technique in the future. Even standard liver resection for malignancy was considered of dubious worth several decades ago. Improvements in surgical technique and perioperative care transformed liver resection for malignancy from a technique that many thought bordered on lunacy into an accepted therapy. Further advances in surgical technique, along with advances in adjuvant oncologic therapies, may do the same for ex vivo liver resection. Currently, it seems reasonable to consider highly selected patients for ex vivo liver resection on a case-by-case basis in centers with expertise in both hepatic resection and liver transplantation, particularly live donor liver transplantation.

CHAPTER 95

Adjuncts to hepatic resection: ultrasound and emerging guidance systems

Guido Torzilli

OVERVIEW

Hepatic surgery performed without a parenchyma-sparing policy carries relevant risks for patient survival because of postoperative liver failure; for this reason, the application of hepatic surgery is limited (Vauthey et al, 2004). In particular, the coexistence of liver cirrhosis in most patients with hepatocellular carcinoma (HCC) has a considerable adverse effect on the surgical results (see Chapter 80), and recent series are still associated with mortality rates higher than 5% (Liu et al, 2004) and with resectability rates of 30% to 35%, which is relatively low (Sotiropoulos et al, 2006). For this reason, and for the broadening of ultrasound (US)-guided percutaneous therapies (N'Kontchou et al, 2009), the surgical treatment of HCC has surrendered its role as first choice treatment for all patients and is now reserved only for those patients with a normal bilirubin level, no signs of portal hypertension, and a single, small HCC (Bruix & Llovet, 2009).

Conversely, for colorectal cancer liver metastases (CLM), surgical treatment remains the gold standard (see Chapter 81A). The definition of *resectability* has shifted from a focus on tumor characteristics, such as tumor number and size, to determination of whether both intrahepatic and extrahepatic disease can be completely resected, and whether such an approach is appropriate from an oncologic standpoint. Therefore limiting surgery in the case of CLM has increasingly focused on the technical feasibility, although not entirely (Minagawa et al, 2000; Torzilli et al, 2009b). In this sense, progress with chemotherapeutic regimens has improved the resectability rate (Wicherts et al, 2008), although it remains generally around 15% to 25% of patients (Garcea et al, 2008). A major limit of resectability is the need for major hepatectomies, which still represents a significant factor impacting the risk of perioperative mortality and morbidity (Schroeder et al, 2006; Cucchetti et al, 2006). Portal vein embolization (PVE) was devised with the double aim of increasing the safety of major liver resection and allowing more patients to benefit from the surgical treatment (Jaeck et al, 2004; see Chapter 93). However, liver failure occurs in 33% of patients who did not undergo PVE, and it still happens in 10% of those who did (Hemming et al, 2003). As with HCC, alternative therapies have been devised for treating CLM, such as percutaneous interstitial treatment (Siperstein et al, 2007). Although these new therapies initially enabled patients otherwise excluded from the surgical program to be treated, the apparently good results obtained have generated confusion in the scientific community as to which treatment modalities should be chosen to manage these patients.

Imaging techniques have been introduced as aids for surgeons in performing liver resection. In fact, since the early 1980s, intraoperative ultrasonography (IOUS) has been used in hepatic surgery, initially in patients with liver cirrhosis (Makuuchi et al, 1980; see Chapter 21). Now liver resections can be carried out with very low mortality, even if cirrhosis is present (Imamura et al, 2003; Torzilli et al, 1999a). There are many reasons for this improvement, but a large part can be attributed to better operative technique, including IOUS. Indeed, US guidance allowing the so-called radical but conservative policy (Torzilli et al, 2005a, 2006b) makes feasible an alternative to major hepatectomies, having the aim of reducing the need for major parenchymal removal while keeping an acceptable oncologic radicality. This policy has allowed resectability rates from outpatient evaluation to hepatectomy of 68% and 69% for HCC and CLM, respectively (Torzilli et al, 2008b, 2009b). Recently, the demonstration of feasibility and efficacy of contrast-enhanced US performed intraoperatively (CE-IOUS) has furthermore stressed the relevance of IOUS guidance during liver surgery (Torzilli et al, 2007b, 2008a).

In this chapter, technical aspects of IOUS, its impact, and future perspectives of this tool during liver surgery both for staging and resection guidance are discussed.

TECHNICAL ASPECTS

Probe Selection

High-frequency (7.5 to 10 MHz) echoprobes are commonly recommended to perform IOUS, because they allow a higher spatial resolution than those that operate at lower frequencies (3.5 to 5 MHz); however, the latter are also useful, at least along the initial exploration, providing a better panoramicity that helps compensate for the lower spatial resolution (Fig. 95.1). On the other hand, it should be pointed out that often higher spatial resolution at the superficial portion of the liver is less important than the overall visibility of the deeper structures, because the most superficial portions are also those appreciable with palpation. In the latter condition, once a nodule is slightly visible at IOUS but is not palpable, especially in a cirrhotic liver, a surgical glove filled with deaerated sterile water can be positioned between the probe and the liver surface for making the lesion more visible (Fig. 95.2). Lower frequency echoprobes are also useful for allowing CE-IOUS; therefore, having both low- and high-frequency probes would be the optimal solution, and new probes with wider ranges of frequencies (3.5 to 10 MHz) are expected.

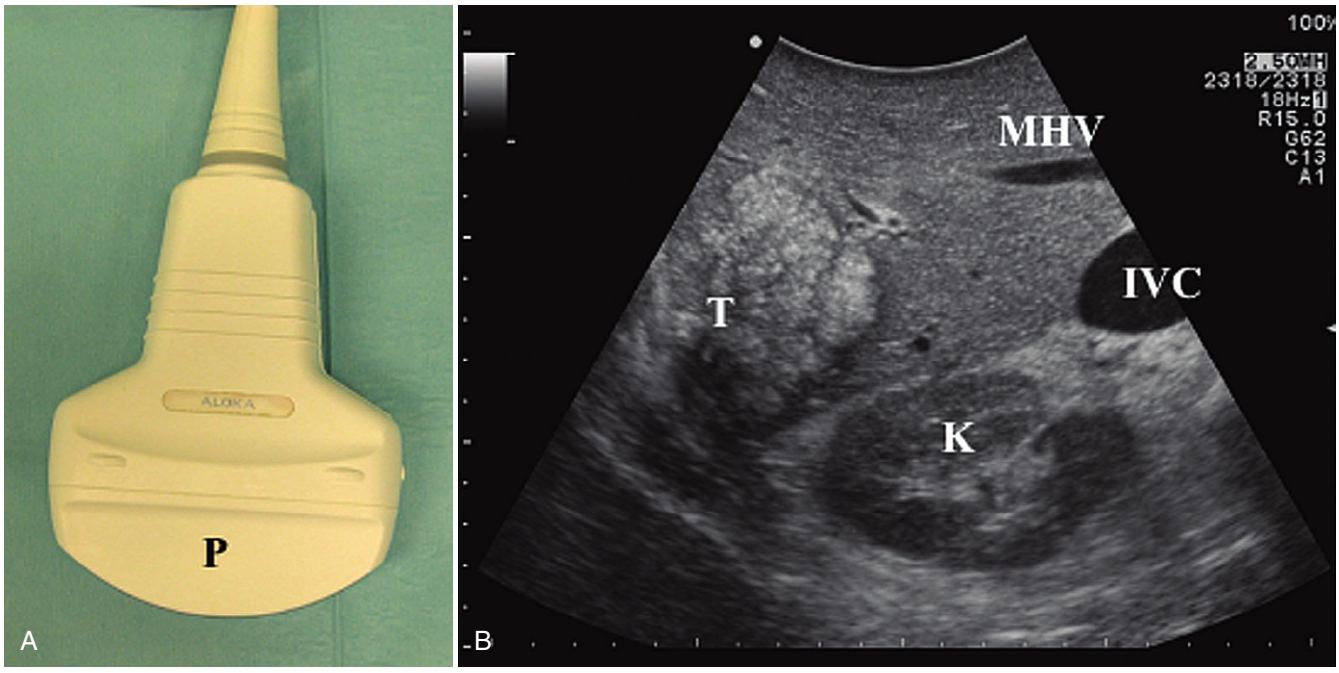

FIGURE 95.1. A, Convex probe for percutaneous exploration used intraoperatively for an initial overview. The relatively low frequency allows visualization of deep structures, although it offers some degree of spatial resolution. **B,** Appearance of a convex probe scan. In one scan, it is possible to visualize the liver with a tumor (*T*) and to recognize the middle hepatic vein (*MHV*), the retrohepatic inferior vena cava (*IVC*), and the right kidney (*K*).

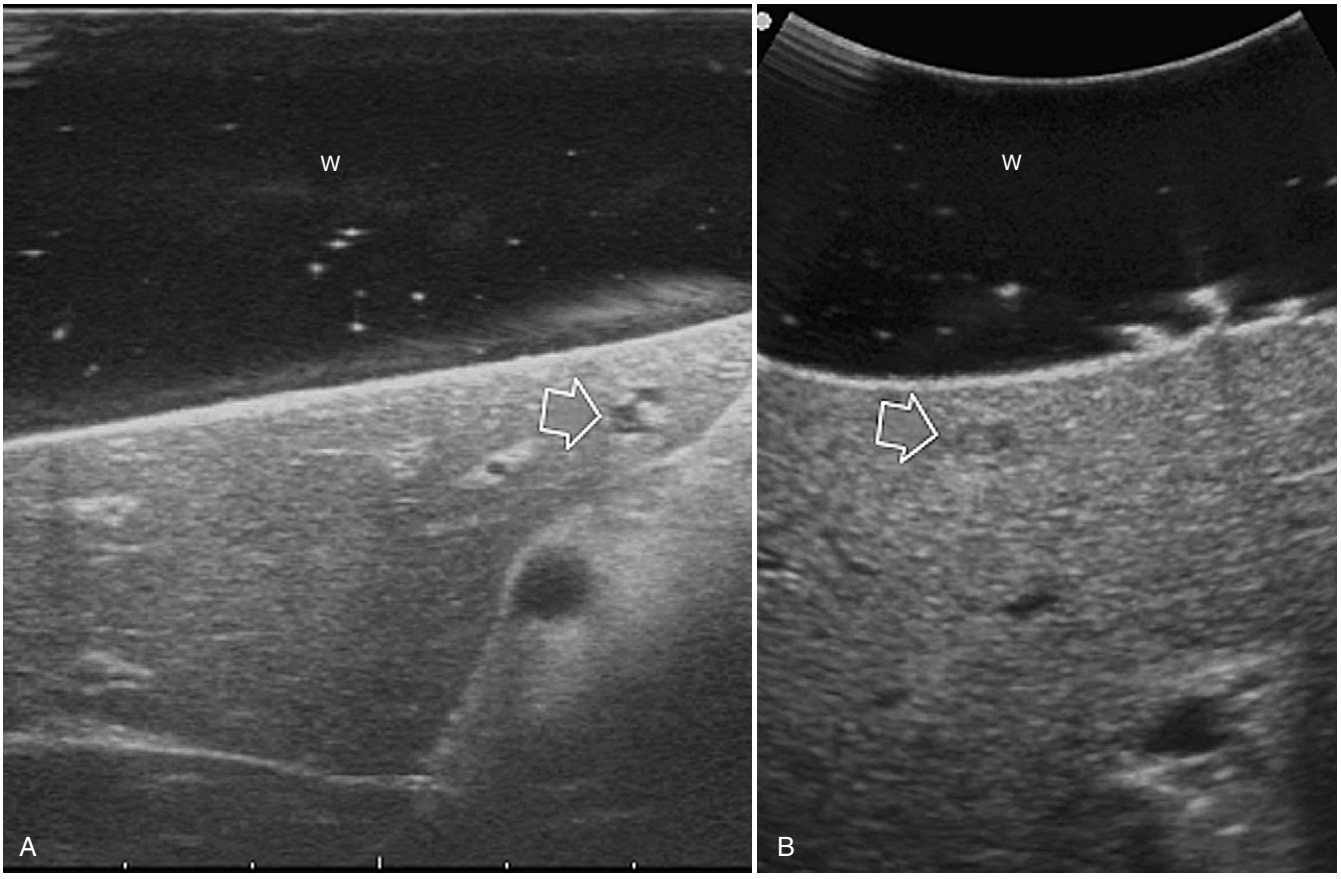

FIGURE 95.2. For better exploration of the superficial structures, a glove filled with deaerated water (*W*) is positioned in between the probe and the targeted surface. The *arrows* indicate two 1-mm lesions superficially located, a simple cyst (**A**), and a small colorectal liver metastasis (**B**).

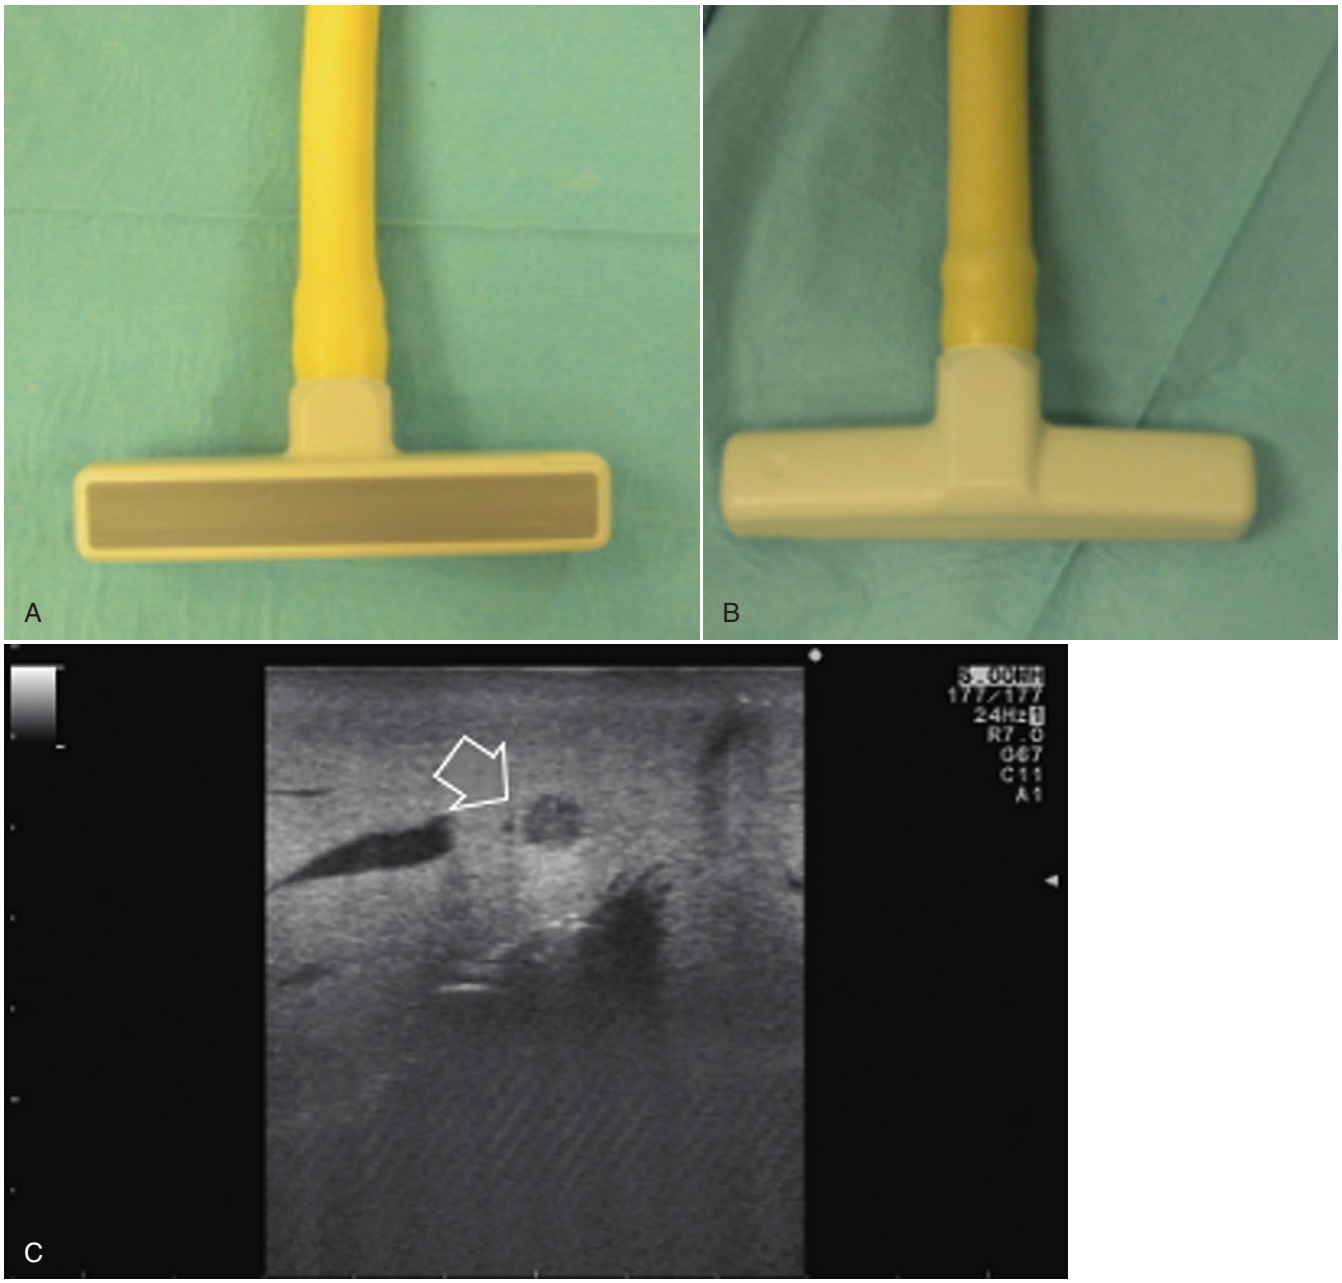

FIGURE 95.3. **A,** The scanning side of a T-shaped echoprobe. **B,** Reverse side. The scanning area is also disclosed (**C**), and a small metastatic lesion is shown (*arrow*). This high-frequency echoprobe (7.5 to 10 MHz) features high resolution but low ultrasound penetration.

Crucial points to be evaluated when selecting a probe are its shape and volume. Indeed, an optimal probe should represent the best compromise between the size, which should be smaller to facilitate handling in deep and narrow spaces; the ultrasonographic scanning window, which should be larger to enable the widest area of exploration at once; and the adherence with the surface of the target organ, which should be higher to enable adequate stability during handling and for avoiding gas interposition and artifacts that may compromise organ exploration.

The most frequently used probes are the T-shaped (Fig. 95.3), interdigital, and microconvex probes (Fig. 95.4). The microconvex probe represents the best compromise among all the aforementioned requirements. Indeed, the T-shaped probe, although it remains more stable and is associated with higher image resolution, has a lower ratio between lateral length and US scanning window than the microconvex probe. Linear transducers with enlarged scanning windows are under development that combine the stability of the linear probes and their higher image resolution with larger scanning windows and a limited volume (Fig. 95.5). When evaluating probes, another aspect that should be considered is the possibility of using them for surgical maneuvers, as described below; newer probes are being designed from this perspective (see Fig. 95.5).

Color Doppler imaging, and particularly new, more sensitive color-flow modes, are progressively assuming greater relevance in hepatic surgery. For example, e-flow intraoperative US (EF-IOUS) is useful for studying the inflow and outflow of the liver intraoperatively (Fig. 95.6), and it shows the flow modifications

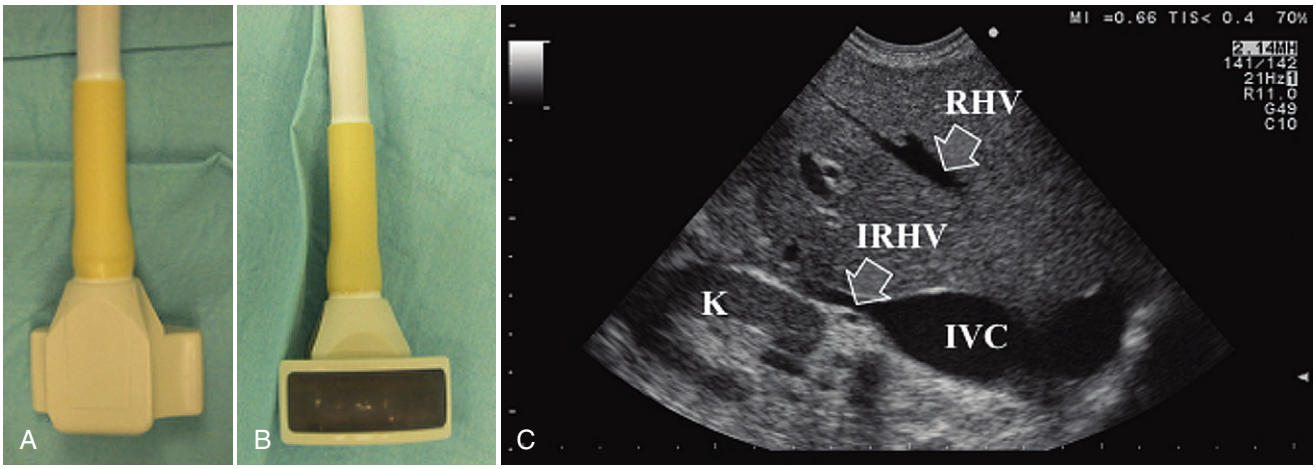

FIGURE 95.4. A, Microconvex echoprobe. **B,** Scanning side of the probe. **C,** The scanning area is shown. This wide-range frequency echoprobe (2 to 7 MHz) makes it possible in one scan to visualize the liver with a tumor, in which the right hepatic vein (*RHV*), an inferior right hepatic vein (*IRHV*), and the right kidney (*K*) are recognizable.

during surgical maneuvers; this represents crucial data for allowing surgical strategies that would not be feasible otherwise. These promising new technologies will be discussed in this chapter.

CE-IOUS is one of the latest advancements in intraoperative application of US, but dedicated probes built to carry out this diagnostic modality in direct contact with the targeted organ are few; furthermore, CE-IOUS requires high-quality digital US machines. We use the Alpha 10 (Aloka, Tokyo; Fig. 95.7), which is equipped with a convex probe working at 3- to 6-MHz frequency and at 1.88- to 3.76-MHz harmonic frequency (see Fig. 95.1). The contrast agent used, SonoVue (Bracco Imaging, Milan, Italy), consists of sulfur hexafluoride microbubbles stabilized by a phospholipid shell; the anesthesiologist injects 4.8 mL of SonoVue intravenously for exploration through a peripheral vein. The purpose of the contrast enhancement is to evaluate the lesion's vascularity, aid in the characterization of those eventually found at IOUS, and to detect new ones, taking advantage of the enhanced brightness of the liver parenchyma, especially along the delayed phases (Fig. 95.8). New liver-specific contrast agents, such as those containing perfluorobutane (Sonazoid, Daiichi Sankyo, Tokyo), will soon become commercially available for clinical use; however, initially, these are being used clinically and only in Japan. This contrast agent, which has properties similar to liver-specific contrast medium used in magnetic resonance imaging (MRI), could improve nodule differentiation (Kudo, 2007) and detection (Nakano et al, 2008).

Preparation for Liver Exploration

First of all, it must be stressed that the surgeon in charge of the surgical procedure should carry out the IOUS, rather than assistants, radiologists, or technicians. This is because obtaining and interpreting the information requires skills and a background in US imaging. But for their most profitable impact to the surgical strategy, and for allowing maneuvers guided and carried out with the echoprobe, such information must be fully comprehended by the surgeon; for that, the optimal condition would be that the US and the operation are performed by the same person.

The US machine should be positioned opposite the first operator, who should be able to simultaneously view both the screen and the operative field (Fig. 95.9). The screen must be large enough to allow optimal visibility at that distance, and lights should be positioned with caution so as not to interfere with the visibility of the US screen. An assistant familiar with the US keyboard should stay beside it, or a transparent and sterile covering pad should be available that allows the lead member of the surgical team to handle the keyboard directly (see Figs. 95.7 and 95.9).

After entering the abdominal cavity, liver mobilization, division of the round and falciform ligaments, and division of adhesions to free the anterosuperior and inferior surfaces of the liver are the steps that should precede liver exploration with IOUS (Fig. 95.10). Of course, adhesions from the tumor to other organs or structures should not be approached, as they may represent areas of tumor infiltration; in this situation, IOUS can help exclude or confirm tumor invasion, which could change the surgical strategy.

Pulling on the round ligament for traction, the liver surface is widely exposed, and following the portal branches and the hepatic veins, the liver can be entirely studied. The probe should be managed using enough pressure to ensure good contact with the liver surface but not so much as to compress the intrahepatic vascular structures and the hepatic vein in particular.

Ultrasound Liver Anatomy

Solid knowledge of the liver anatomy is required to perform IOUS properly (see Chapter 1B). For surgical anatomy, the Brisbane terminology is considered here (Pang, 2002). The three main hepatic veins are readily identified at their junction with the inferior vena cava (IVC), positioning the probe at this level and tilting it upward once the confluence of the hepatic veins into the IVC is recognized. Then, gently withdrawing the probe, the hepatic vein paths can be traced into the liver. Hepatic veins appear as echo-free zones in the liver parenchyma, and the vessel wall is invisible or appears as a thin, hyperechogenic line (Fig. 95.11A); the walls of hepatic veins can be thicker in the cirrhotic liver, and their lumens thinner, as a result of the stiffness of the diseased liver (Fig. 95.11B).

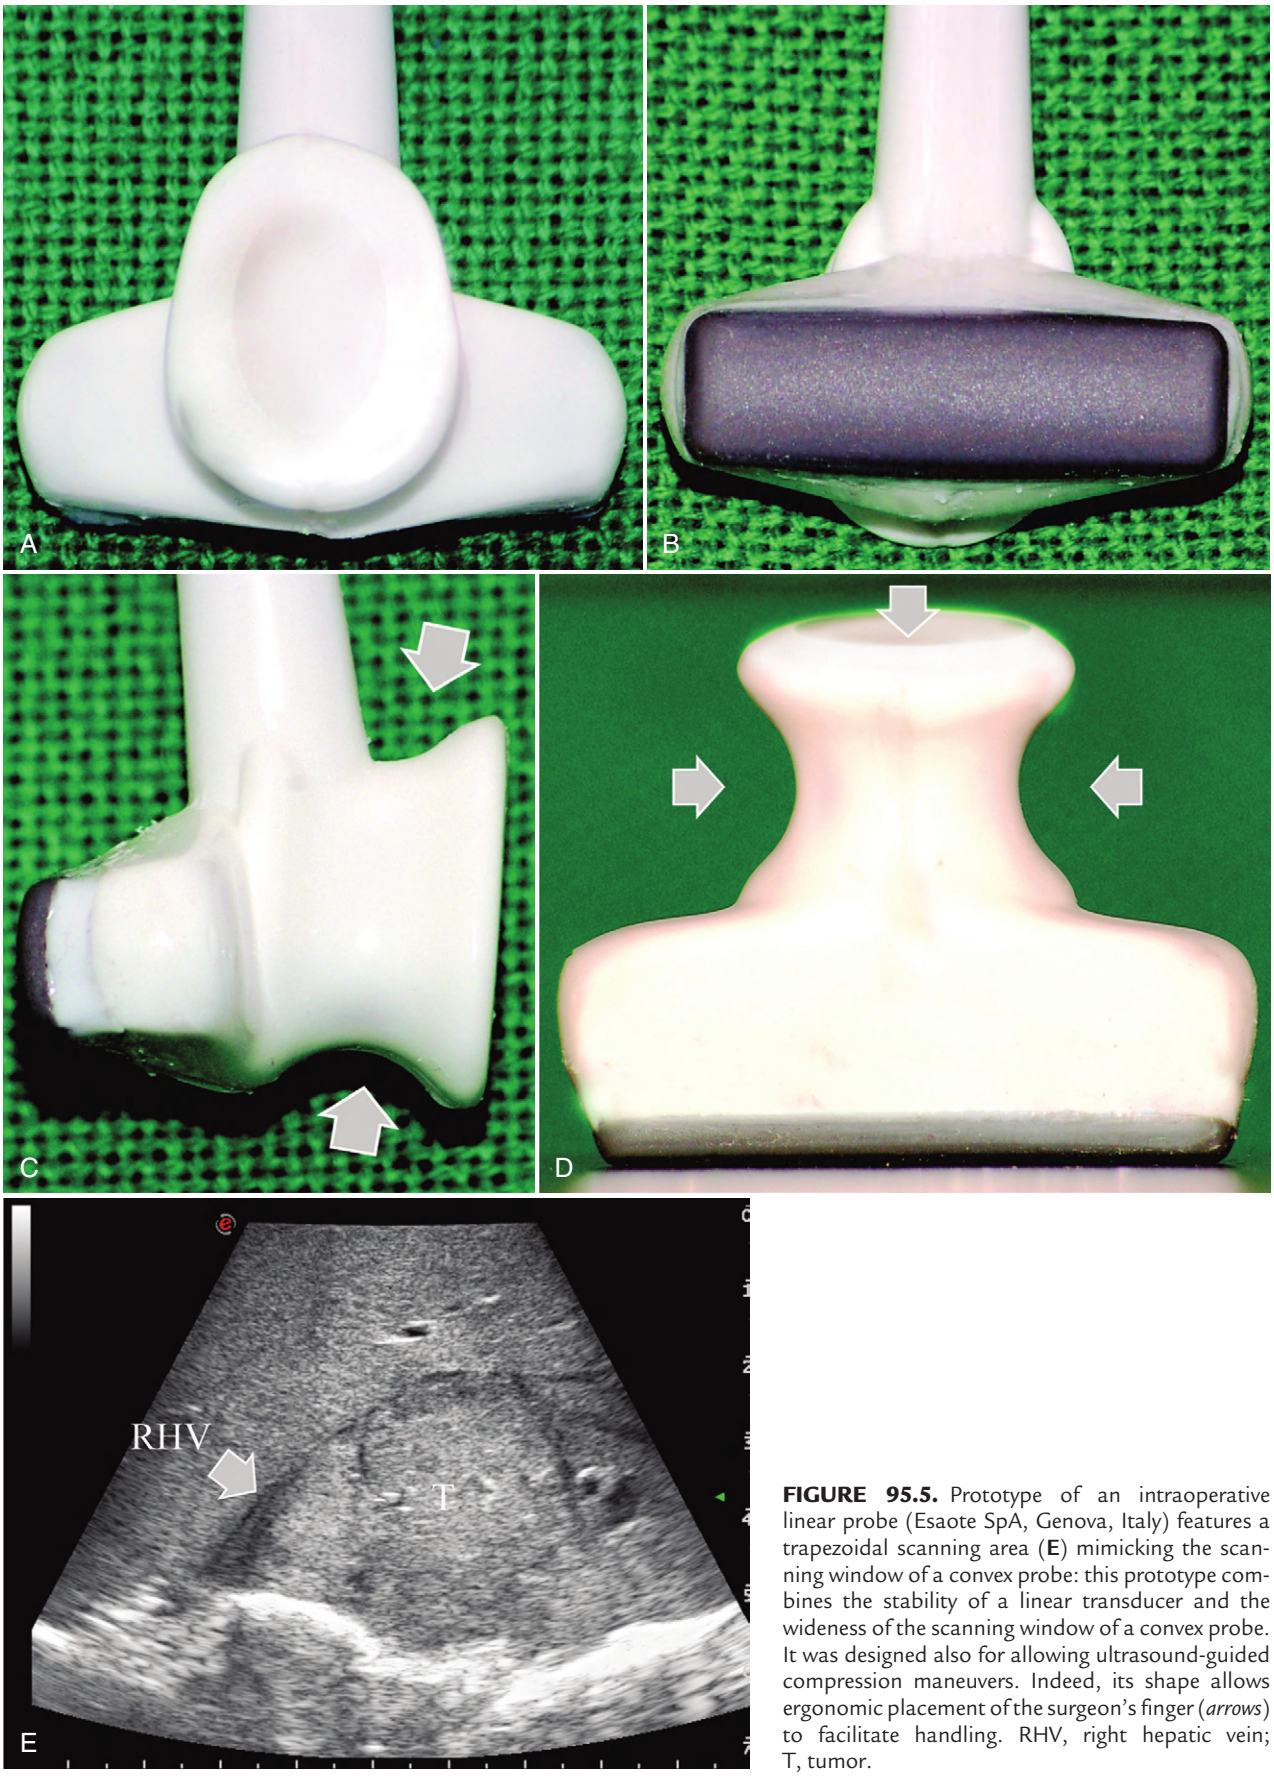

FIGURE 95.5. Prototype of an intraoperative linear probe (Esaote SpA, Genova, Italy) features a trapezoidal scanning area (**E**) mimicking the scanning window of a convex probe: this prototype combines the stability of a linear transducer and the wideness of the scanning window of a convex probe. It was designed also for allowing ultrasound-guided compression maneuvers. Indeed, its shape allows ergonomic placement of the surgeon's finger (*arrows*) to facilitate handling. RHV, right hepatic vein; T, tumor.

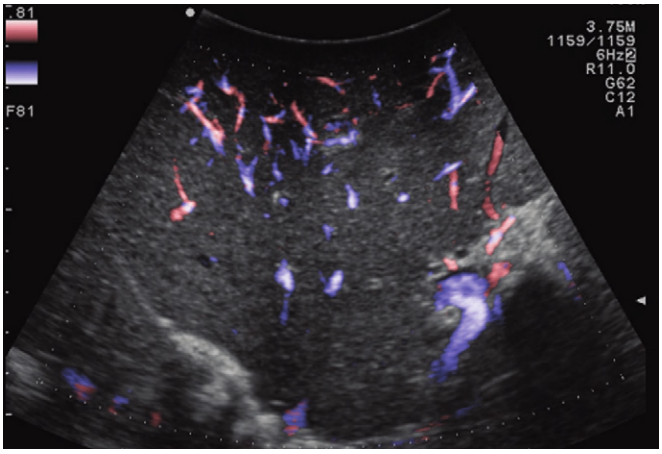

FIGURE 95.6. The appearance of the liver, once the exploration is carried out under the e-flow mode, a more sensitive modality compared with color Doppler for analyzing the blood flow. This increases the sensitivity and allows precise mapping of the slow-motion flow as shown in this picture; tiny vessels are clearly depicted.

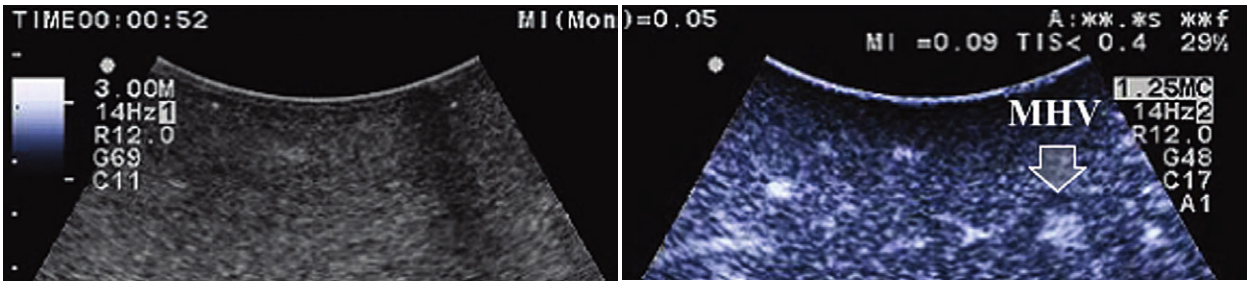

FIGURE 95.8. The appearance of the liver using contrast enhancement. **A,** B-mode conventional modality is shown on the US machine screen simultaneously with the contrast-enhanced image shown in **B. B,** Liver is shown at 52 seconds after injection of contrast (time appears in the left upper corner in **A**). The vessel and parenchymal enhancement are shown; both portal branches and hepatic veins are filled with contrast. On the upper right corner of the image, *MI* refers to the mechanical index, which should be <0.1 so as not to break the microbubbles and to allow the contrast effect of real-time enhancement at ultrasound. IVC, inferior vena cava; MHV, middle hepatic vein; P8d, portal branch to segment VIII dorsal; RHV, right hepatic vein.

FIGURE 95.9. The ultrasound machine positioned in the operative theater: the operator is facing the screen while the keyboard is managed by the first or second assistant.

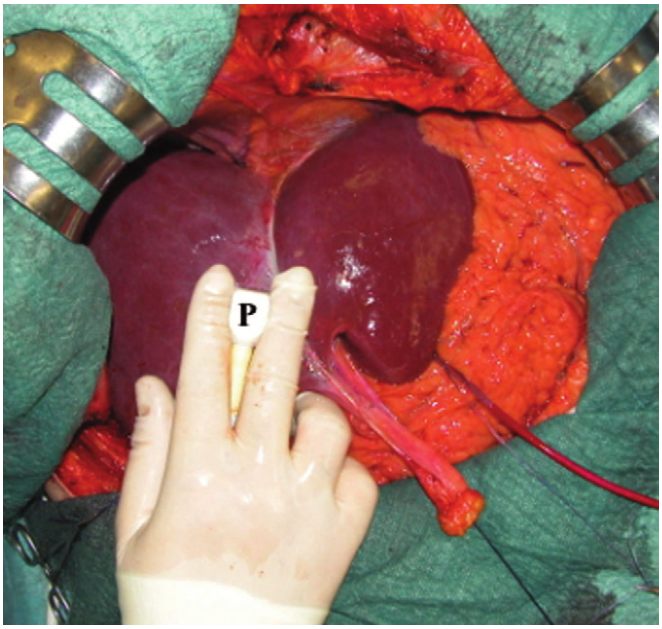

FIGURE 95.10. Liver exposed for initial exploration, once the falciform ligament has been cut; the surgeon is handling a microconvex probe (*P*).

FIGURE 95.11. A, The glissonian sheath (*GS*) and the middle hepatic vein (*MHV*) in a normal liver have a different wall thickness on intraoperative ultrasound. The GS is represented by at least two hypoechoic (black) structures, representing the artery and the portal vein; the bile duct is always seen in the case of the first- and second-order branches, which are often disclosed, particularly when dilated in the case of a more peripheral GS. **B,** In the cirrhotic liver, HVs have a thickened wall that mimics the wall of a glissonian vessel: the anatomic landmarks and the inclusion of various structures together allow their proper differentiation. Shown is an inferior right hepatic vein (*IRHV*) with a thickened wall but typically running behind the right portal branches as the right portal vein (*RPV*). IVC, inferior vena cava; LPV, left portal vein.

The portal vein branches can be followed by initially positioning the probe horizontally above the inferior portion of segment IV (see Fig. 95.10) to visualize the first-order bifurcation (Fig. 95.12), then the first-, second-, and third-order portal branches can be followed. Because of the existence of the Glisson capsule, the portal pedicles—which include portal vein branches, arteries, and bile ducts—have thicker vessel walls compared with the hepatic veins, and for this reason, they appear at IOUS as echo-free zones surrounded by a thicker hyperechogenic layer (see Fig. 95.11); furthermore, other parallel, thinner vascular structure are visible, which are the arteries (Fig. 95.13), and the bile ducts of the glissonian triad are also visible (Fig. 95.14). The newer, more sensitive color-flow modalities, such as EF-IOUS, help in this differentiation by allowing the recognition of arterial and portal elements that also lie within thin glissonian sheaths (Fig. 95.15); however, in principle, distinction between hepatic veins and portal branches should be based not only on their appearance but mainly on their anatomy. Indeed, in the cirrhotic liver, as already mentioned, the vessel wall of the hepatic vein could be thicker and not easily differentiated from a peripheral portal branch. Following the portal pedicles at the sectional, segmental, and subsegmental level, and positioning them in relation to the hepatic veins, it is possible to precisely define the location of the IOUS target in terms of sections and segments (Fig. 95.16).

The appearance of the bile ducts on IOUS is worth mentioning because of their peculiarity. Whereas normally they result as thin echo-free zones in the glissonian triad (see Fig. 95.14), once dilated, they appear as more evident echo-free zones with a serpiginous path (Fig. 95.17). The element that is difficult to recognize in the IOUS study of the bile ducts is their segmental anatomy; bifurcation of sectional and segmental ducts is closer to the hilum, compared with the portal branches

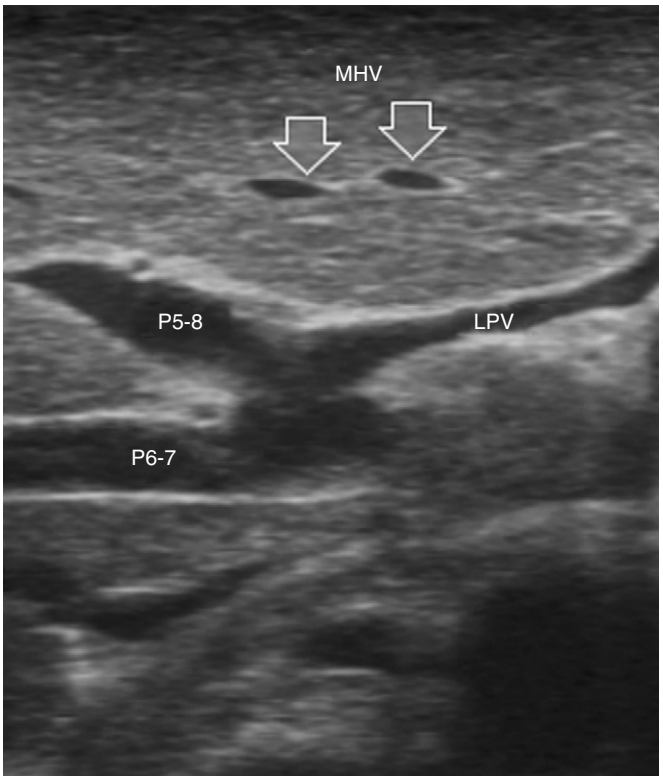

FIGURE 95.12. An atypical branching pattern of the portal branches with the portal branch to right anterior section (*P5-8*) and to the right posterior section (*P6-7*) originating separately and lacking a formal right portal vein. MHV, middle hepatic vein; LPV, left portal vein.

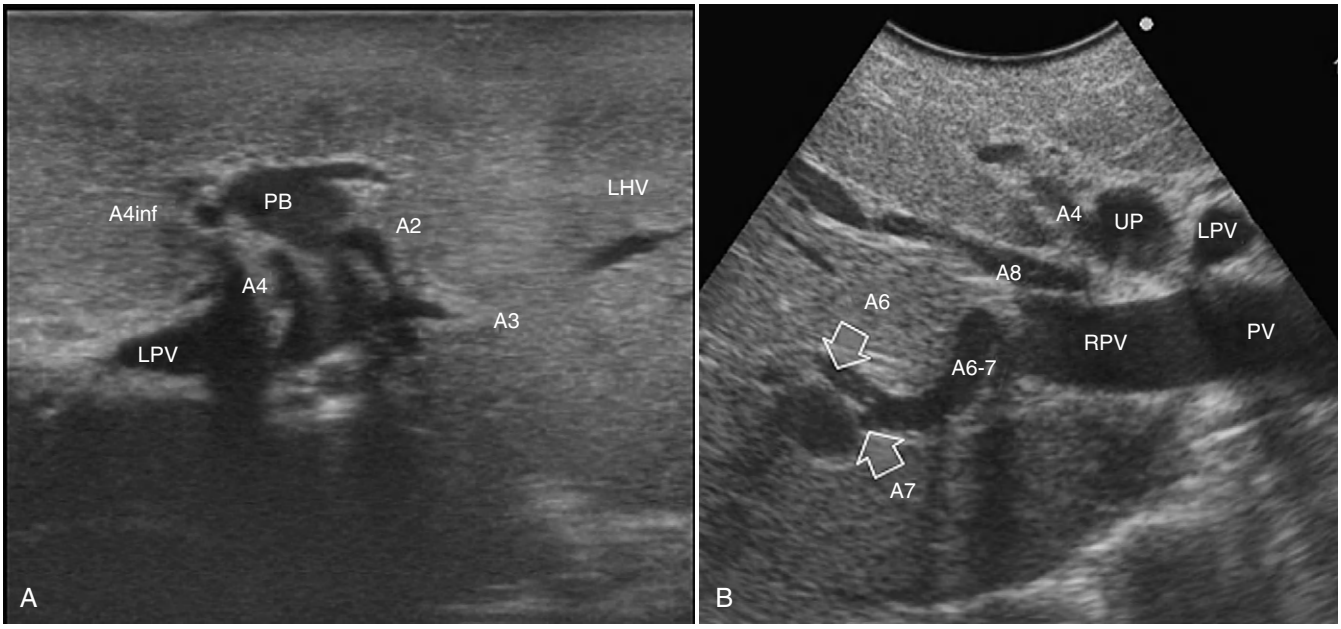

FIGURE 95.13. Arterial branching pattern in the left (**A**) and right (**B**) hemiliver. A2, arterial branch to segment II; A3, arterial branch to segment III; A4, arterial branch to segment IV; A4inf, arterial branch to segment IV inferior; A6, arterial branch to segment VI; A7, arterial branch to segment VII; A6-7, arterial branch to the right posterior section; A8, arterial branch to segment VIII; LHV, left hepatic vein; LPV, left portal vein; PB, portal branch; PV, portal vein; RPV, right portal vein; UP, umbilical portion.

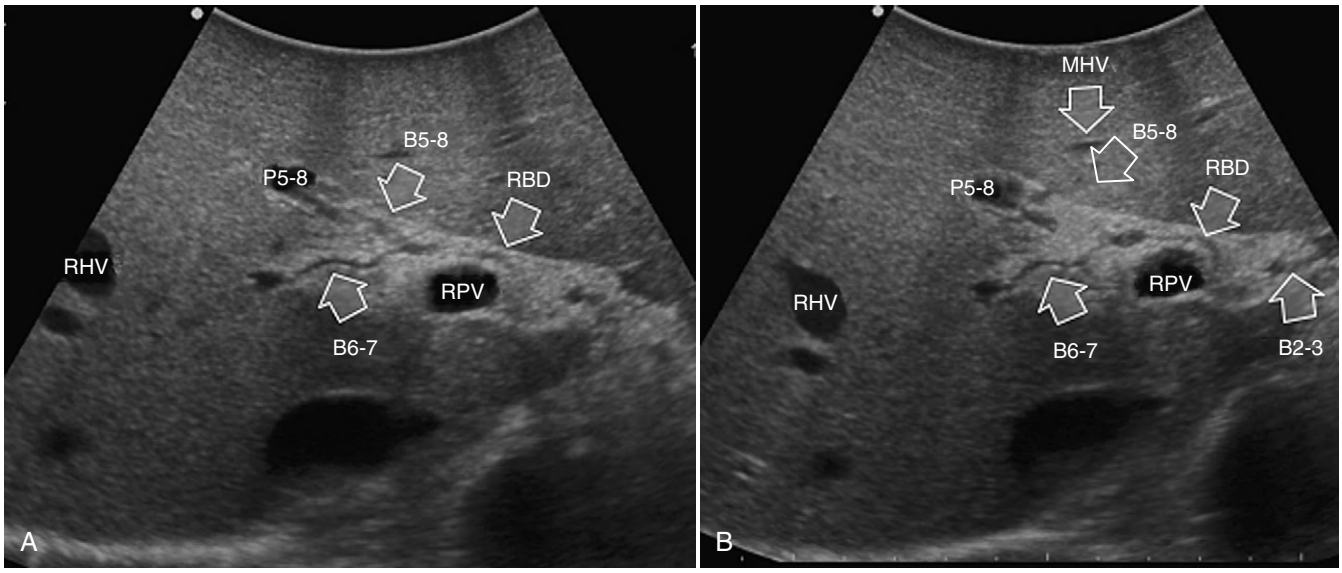

FIGURE 95.14. The biliary branching pattern in the right hemiliver and partially the left. B2-3, bile duct to segments II and III; B5-8, bile duct to right anterior section; B6-7, bile duct to right posterior section; LPV, left portal vein; MHV, middle hepatic vein; P5-8, portal branch to right anterior section; RBD, right bile duct; RHV, right hepatic vein; RPV, right portal vein.

(Fig. 95.18), and because of that, it is possible to visualize more than one segmental bile duct with one scan; however, with enough US background, IOUS can allow exact definition of the bile duct anatomy, not only in pathologic conditions but also in the normal state. This possibility also allows assessment of variations in the normal anatomy, such as confluence of the right posterior sectional bile duct into the left hepatic duct (Fig. 95.19), which is clearly critical information, particularly if a left hepatectomy is planned.

INDICATIONS

The use of IOUS in liver resections can be schematically divided into three principal phases: 1) liver exploration for staging of the disease, 2) planning of the surgical strategy, and 3) guidance of surgical maneuvers.

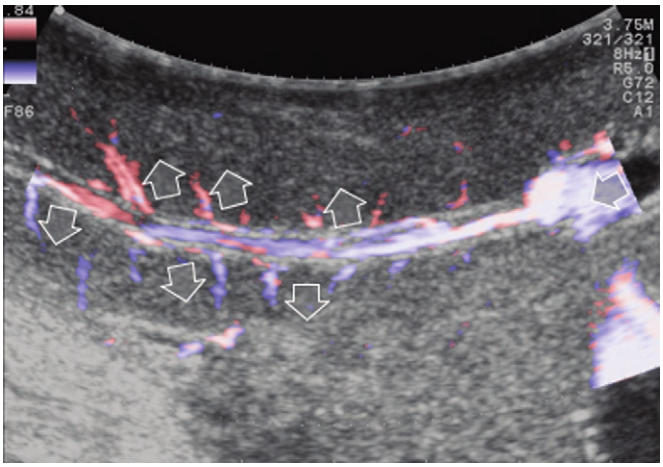

FIGURE 95.15. This image shows the capability of e-flow intraoperative ultrasound to disclose flow and its direction (*arrows*), not only in the third-order portal branches but even more peripherally.

Liver Exploration

Detection and differentiation are the two main targets of IOUS exploration of the liver. The hard and irregular surface of cirrhotic livers makes difficult the detection of small nodules by palpation; conversely, IOUS allows the detection of new lesions in around 30% of cases (Kokudo et al, 1996), although most of the nodules detected by IOUS in the cirrhotic liver are not tumors but more often are regenerative nodules. In this way, IOUS introduces the risk of overestimating tumor stage (Fig. 95.20). Indeed, except for those nodules with a mosaic pattern

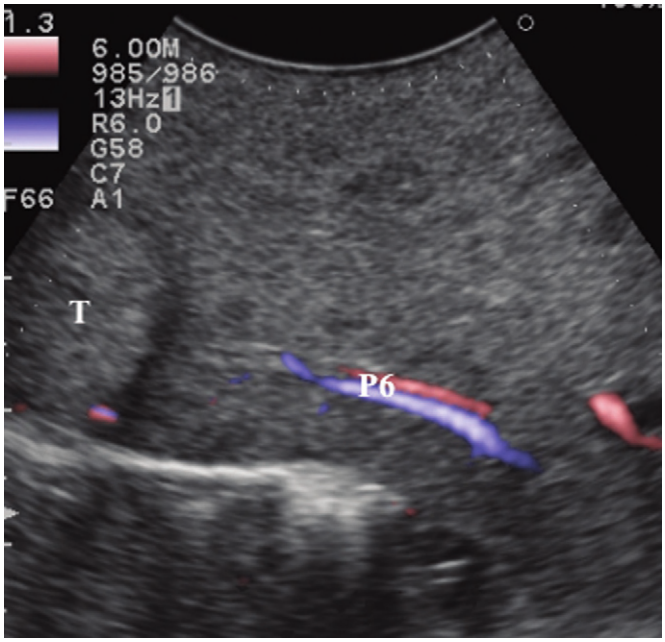

FIGURE 95.16. Tumor (*T*) fed by the portal pedicle of segment VI (*P6*).

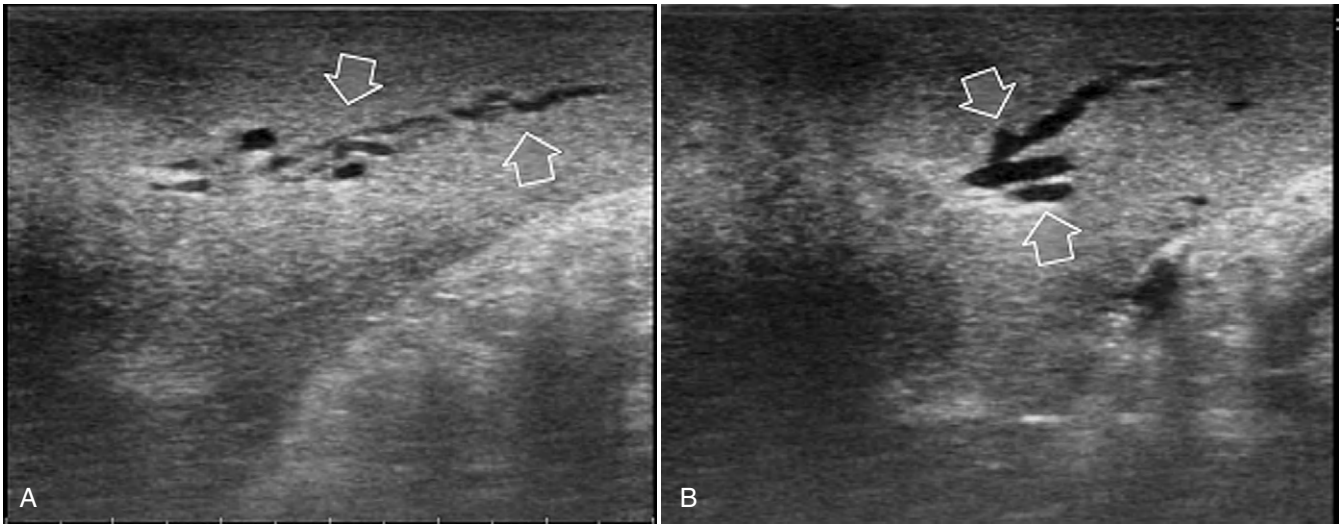

FIGURE 95.17. **A** and **B** show the dilation of segmental bile ducts, which assume a serpiginous path (*arrows*).

IRHV, inferior right hepatic vein; IVC, inferior vena cava; P5-8, portal branch for right anterior section; P6-7, portal branch to right posterior section.

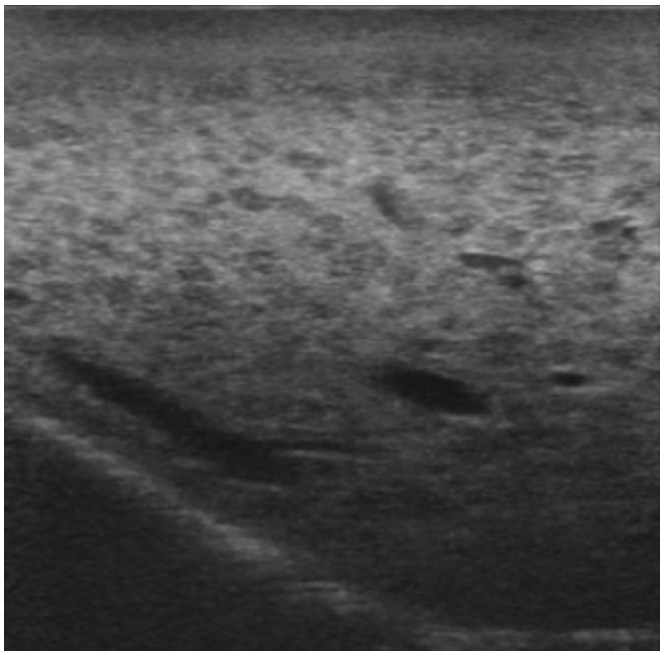

FIGURE 95.20. Cirrhotic liver with an inhomogeneous pattern as a result of the presence of an uncountable number of hypoechoic (dark) nodules.

evident on US (Fig. 95.21A), which are malignant in 84% of cases, only 24% to 30% of hypoechogenic (dark) nodules (Fig. 95.21B) and 0% to 18% of those hyperechogenic (bright) nodules (Fig. 95.21C) are neoplasms (Kokudo et al, 1996; Takigawa et al, 2001).

To overcome this problem, even biopsy seems to be inadequate. The only nodule that can be easily differentiated intraoperatively from HCC or liver metastases is the small hemangioma, often discovered primarily at IOUS (see Chapter 79); it displays a typical ultrasonographic pattern, and when compressed, it changes in size and appearance (Fig. 95.22; see Chapter 13). The problem of differentiating benign from malignant lesions on IOUS exploration becomes crucial. Some attempts are now ongoing using elastography, which should allow lesion differentiation based on tissue stiffness expressed on the IOUS screen and indicated by different colors (Fig. 95.23); however, to date, limited data are available to describe its use in this application. In the next section, it will be shown how CE-IOUS will play an increasingly important role in this context and will be even more relevant in the near future.

Rather than differentiation, in the case of CLM, their clue is their accurate detection, particularly in the event of multinodular hepatic involvement. Indeed, in patients with CLM, the detection of any tiny nodule undiscovered preoperatively becomes crucial for attempting a reduction of the still high postoperative early recurrence rate (Yoshidome et al, 2008). From 10% to 40% of patients with colon cancer have nonpalpable CLM (Agrawal et al, 2006; Machi et al, 1991); as a consequence, IOUS exploration of the liver remains crucial, and CE-IOUS seems able to enhance its role in this context.

Contrast-Enhanced Intraoperative Ultrasonography

Hepatocellular Carcinoma

CE-IOUS is now used for characterizing the new lesions of HCC eventually detected at IOUS (Torzilli et al, 2007b). The rationale is to check the vascular pattern during contrast enhancement of each new lesion. Because it is very important to identify the arterial vascularization in HCC, which can take 20 to 30 seconds, each nodule must be carefully evaluated, and this necessity demands multiple injections in the presence of multiple nodules. This requirement may be obviated by the new liver-specific contrast agents. Using these, the contrast enhancement remains visible from several minutes to even hours after injection, and CE-IOUS should become easier to use and will likely be more effective for detection of HCC.

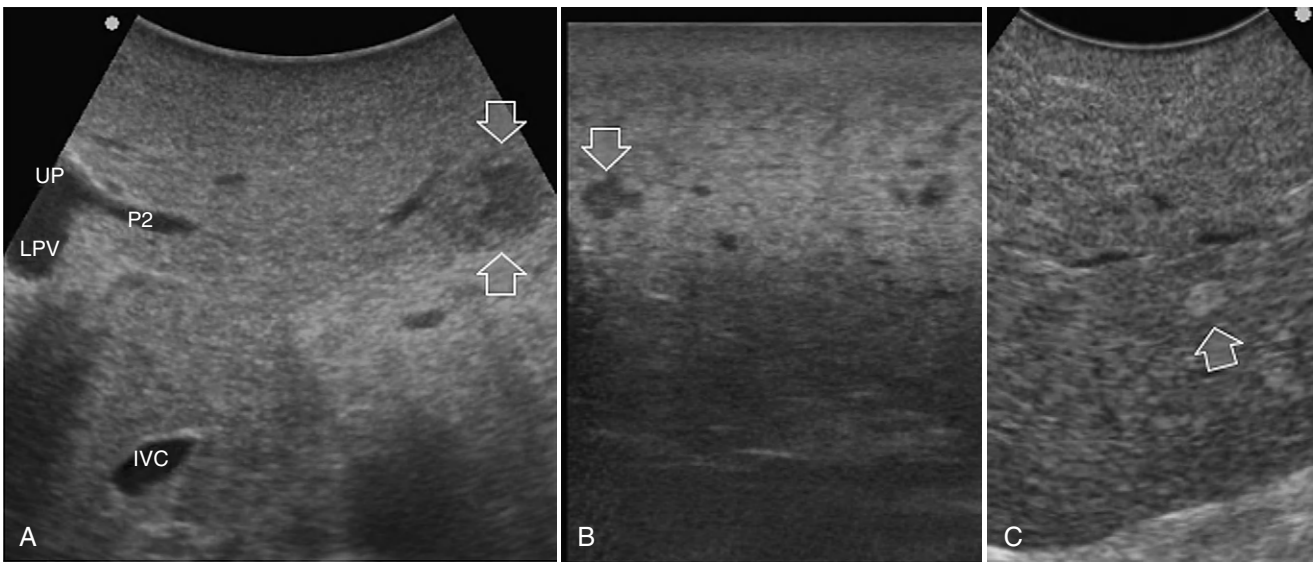

FIGURE 95.21. A, Nodule (*arrows*) with a mosaic pattern on intraoperative ultrasound (IOUS). **B,** Nodule (*arrow*) with a hypoechoic dark pattern at IOUS. **C,** Nodule (*arrow*) with a hyperechoic bright pattern at IOUS. IVC, inferior vena cava; LPV, left portal vein; UP, umbilical portion; P2, portal branch to segment II.

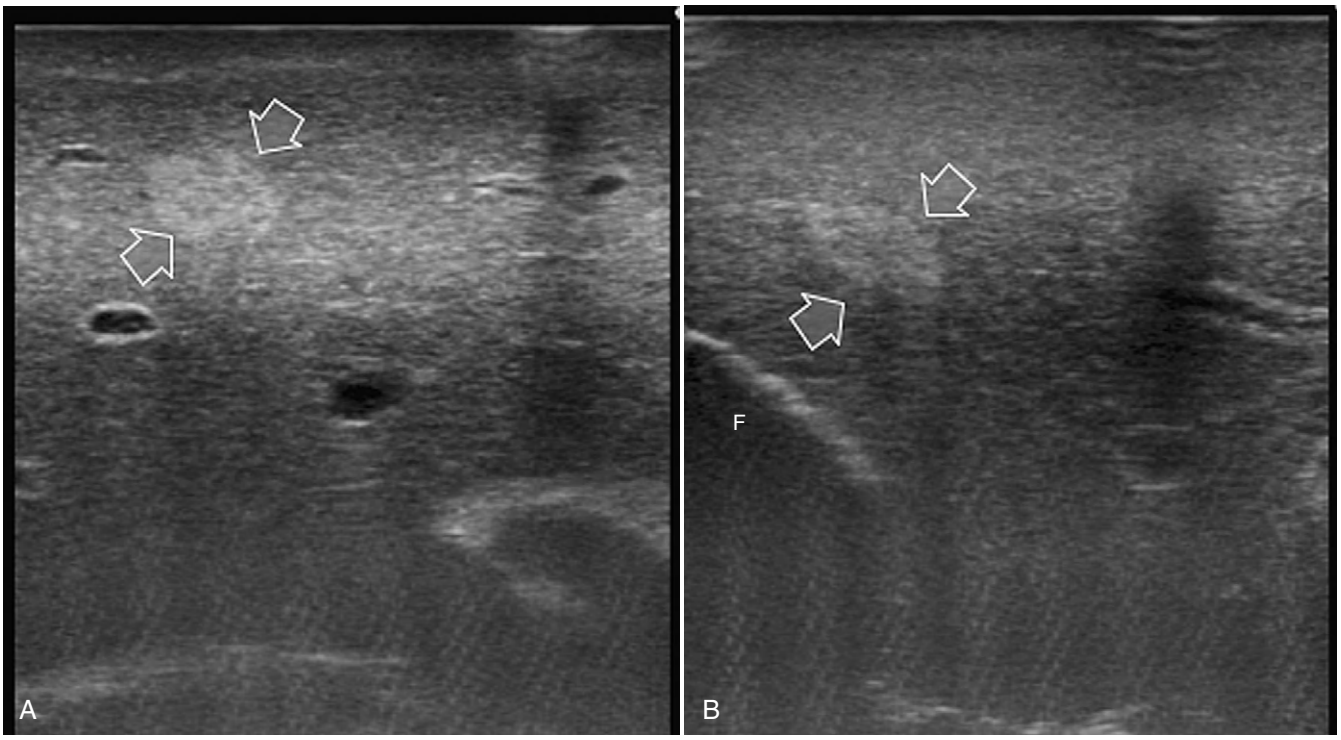

FIGURE 95.22. Test for diagnosing a hemangioma. **A,** Hemangioma (*arrows*) with hyperechoic (bright) pattern compatible with this type of lesion, although not specific enough. **B,** Once compressed under IOUS guidance, the lesion modifies its shape (*arrow*); this finding together with its echogenicity leads to the diagnosis of hemangioma. F, finger.

Tumor vascularity as a criterion for differentiating regenerative or dysplastic nodules from HCC correlates with the histologic evidence of a progressive increase in unpaired arteries from dysplastic to neoplastic nodules in a cirrhotic liver (Roncalli et al, 1999). Certainly, the pattern of vascular enhancement by itself is not sufficient for differentiating malignant from nonmalignant nodules with 100% specificity. Indeed, although percutaneous contrast-enhanced US (CE-US) provides differential diagnosis of hepatic nodules based on their vascular pattern with 95% specificity (Quaia et al, 2004), intraoperatively there is the need to differentiate lesions smaller than 1 cm. For these nodules, the vascularity as a criterion for differential diagnosis is less specific, although some improvements compared with conventional IOUS could be expected. Therefore, in the early 1990s, attempts were made to apply CE-IOUS using carbon dioxide as a contrast material, but the need for arterial catheterization made this technique too invasive (Takada et al, 1990). In my preliminary experience, CE-IOUS has provided remarkable findings, either by adding information on nodular vascularity in patients with HCC, or by detecting nodules that were not visible at IOUS, in patients with CLM (Torzilli et al, 2004).

For patients undergoing operation for HCC, my colleagues and I have introduced a classification of the enhancement pattern of lesions seen at CE-IOUS, upon which the surgical decision making is established (Fig. 95.24; Torzilli et al, 2007b). In brief, any pathologic lesion should appear as hypoechogenic at the late phases, with or without inner vessels and with or without an arterial phase, in which it is enhanced prior to the remnant liver parenchyma. Lesions with this type of appearance

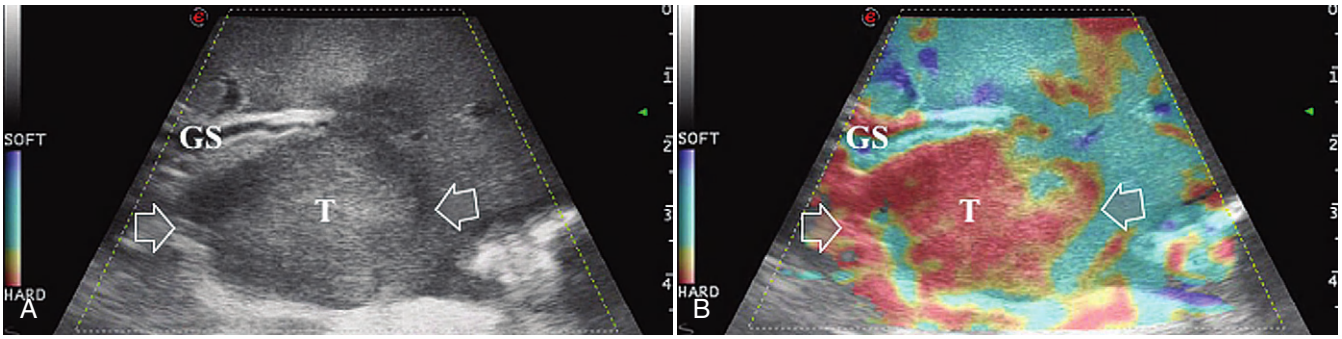

FIGURE 95.23. Potential value of elastography in estimating the tissue stiffness, relating it to a color scale disclosed on the left of each image. **A,** Tumor (*T*) as it appears at the B-mode (*arrows*). **B,** Once elastography is activated, the tumor appears brownish (*arrows*), according to its higher stiffness compared with the surrounding liver parenchyma. GS, glissonian sheath.

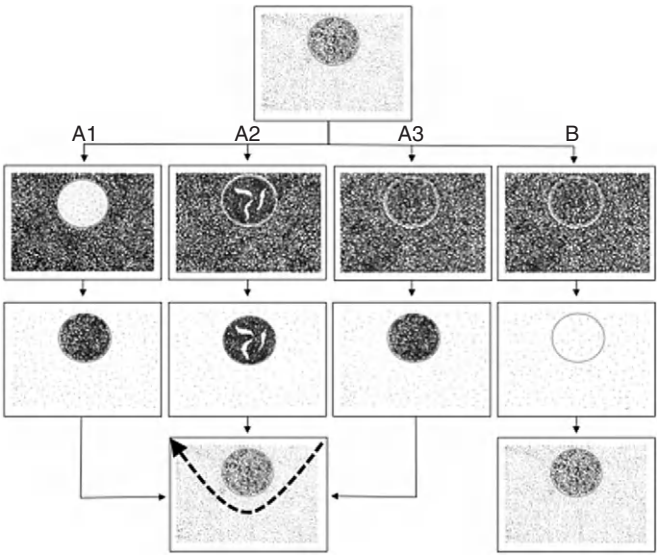

FIGURE 95.24. Classification of pattern of enhancement with contrast-enhanced intraoperative ultrasound (IOUS) of those lesions detected at IOUS and during surgery for hepatocellular carcinoma. Lesions with a class A pattern of hypervascular enhancement in early phase (*A1-A2*) or a hypoechoic pattern in the delayed phases (*A1, A3*) must be resected; inversely, lesions showing a class B pattern of enhancement (disappearance during contrast phases) are not removed.

should be removed (Fig. 95.25). Those lesions that disappear once the contrast enhances the liver are not considered neoplastic and are not removed (Fig. 95.26). With these criteria, we obtained with CE-IOUS a specificity of 69% (Torzilli et al, 2007b). This value is probably not that high, especially when compared with that reported for CE-US (Quaia et al, 2004); however, as mentioned before, the small size of the lesions targeted for CE-IOUS study could explain this discrepancy. For these tiny nodules, the neovascularity as a criterion for differentiation between malignant and benign lesions has limits that are independent from the method we use; therefore CE-IOUS can be helpful in a certain percentage of nodules but not in all, although the rate of 69% specificity is encouraging, as it means that we can provide proper information with this new technique in 7 of 10 lesions we detect at laparotomy. For those lesions remaining, even histology may be lacking, as we know no common agreement exists among Western and Eastern pathologists on the definition of early HCC and dysplastic lesions (International Consensus Group for Hepatocellular Carcinoma, 2009). New perspective may be provided by a more extensive use of the new contrast agent, for now clinically available only in Japan (Kudo, 2007). This agent (Sonozoid) has a Kupffer phase, and it adds further criteria for differentiating those nodules detected at IOUS.

Colorectal Liver Metastases

Improving detection is the main target of CE-IOUS in the case of CLM. In the 1990s, half of the patients who underwent surgery for CLM had a surgical strategy modified by IOUS findings (Kane et al, 1994). More recently, progress in preoperative imaging has reduced this rate; in fact, some authors have reported that just 4% of the operative decision making is modified by IOUS (Sahani et al, 2004). Conversely, adding CE-IOUS to IOUS exploration modified operative decision making in 38% of patients with CLM (Torzilli et al, 2008a). If this discrepancy in the rates of modified surgical strategy among series is partially the result of different surgical approaches, particularly more parenchyma-sparing procedures, then probably CE-IOUS is playing a role, too. Indeed, with CE-US, the CLM shows the so-called "black hole" effect (Fig. 95.27). The

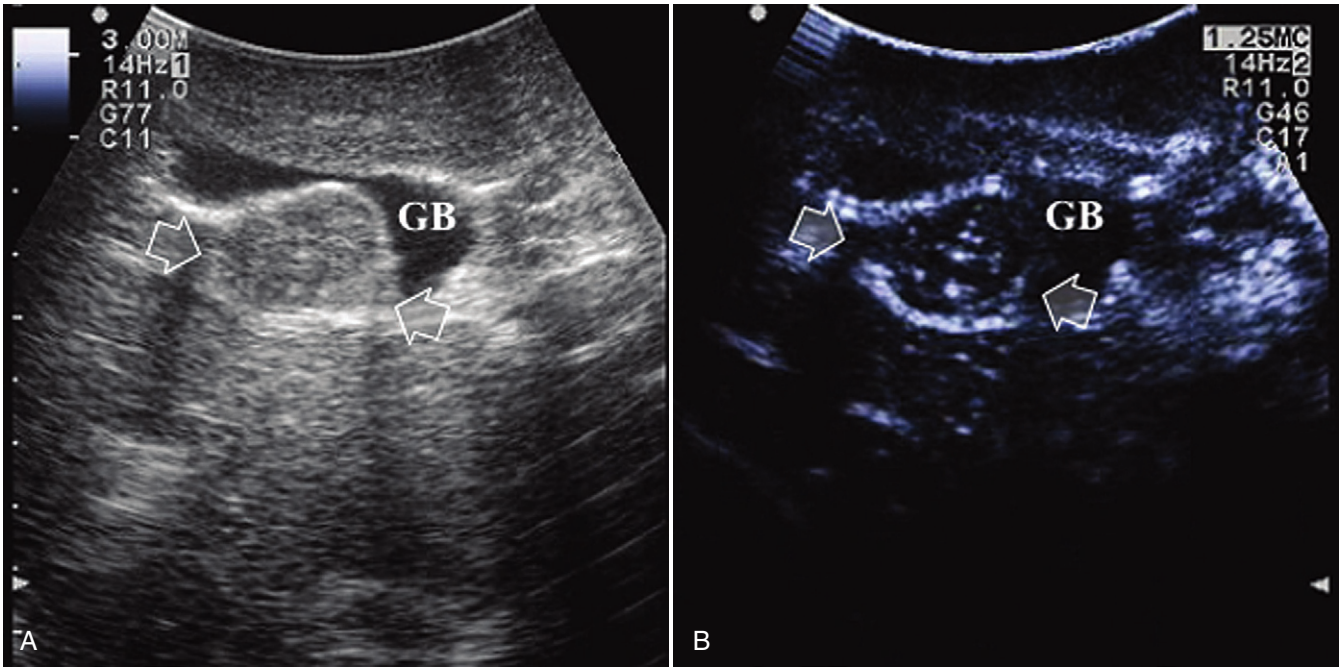

FIGURE 95.25. A, *Arrows* indicate a lesion at the level of the gallbladder (*GB*) fossa. **B,** At early enhancement, the same lesions (*arrows*) shows intranodular, hyperechoic (bright) spots, which allow its classification as an A2 nodule.

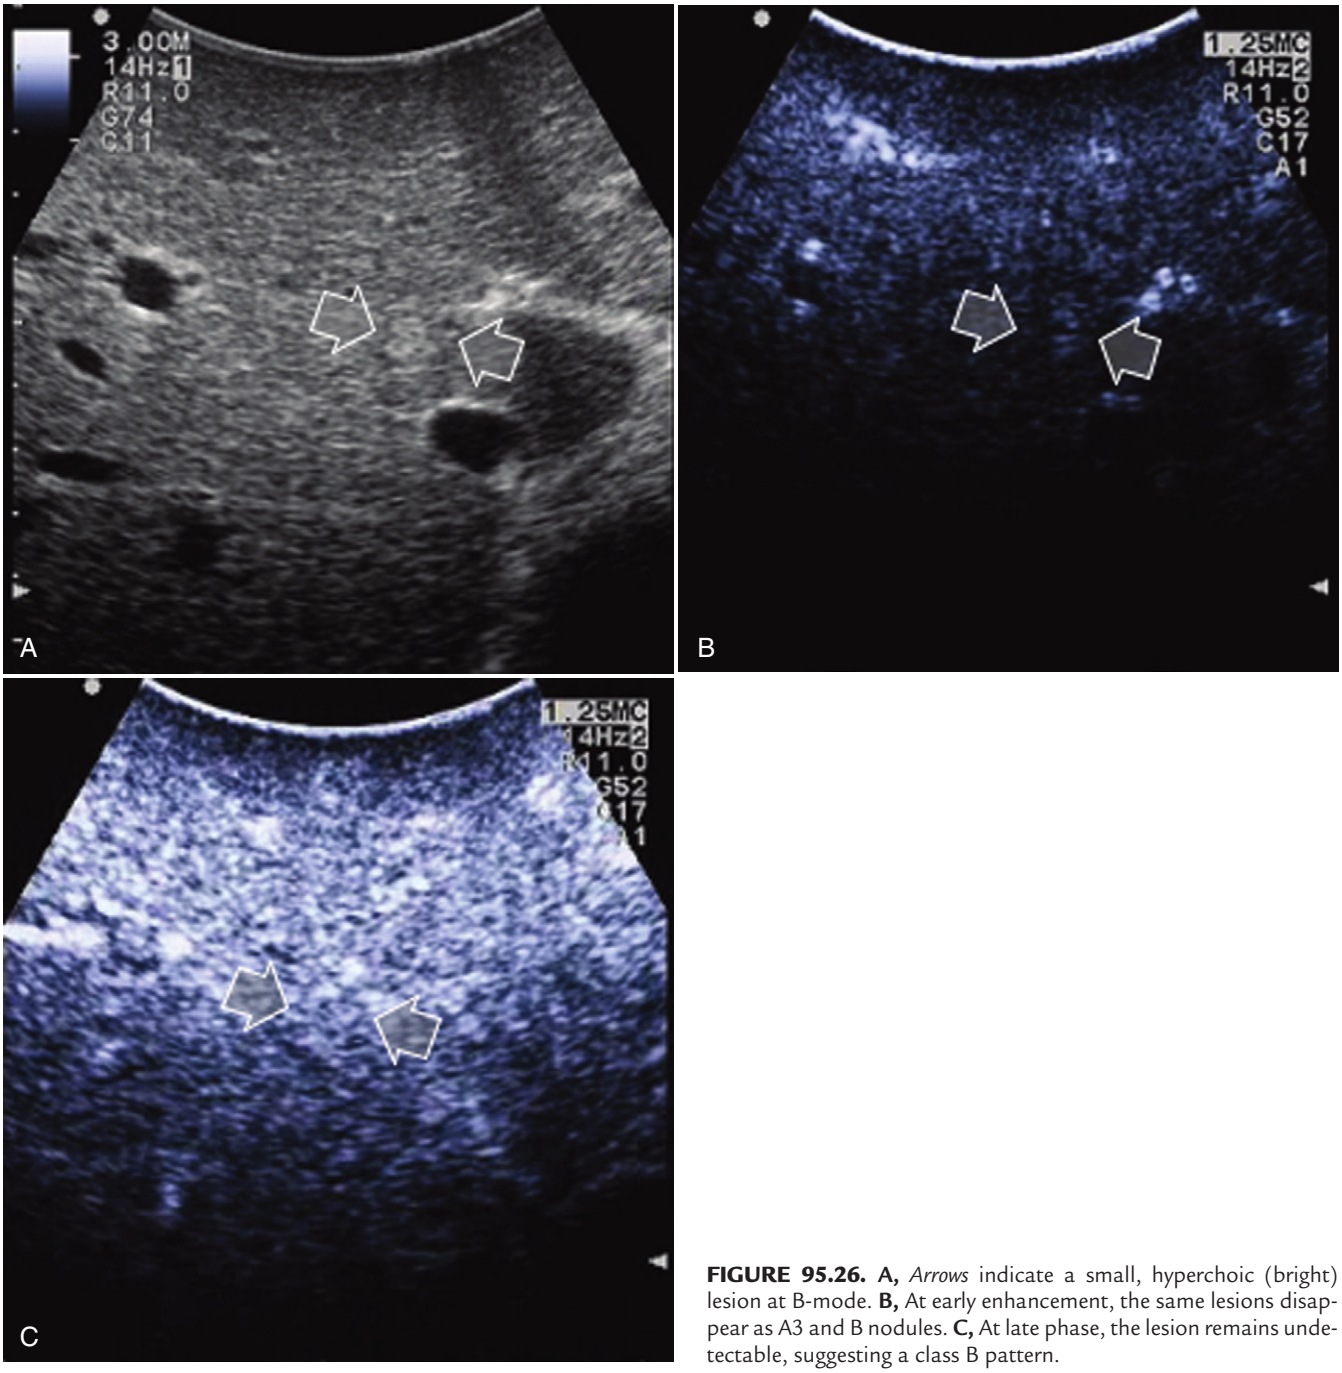

FIGURE 95.26. A, *Arrows* indicate a small, hyperchoic (bright) lesion at B-mode. **B,** At early enhancement, the same lesions disappear as A3 and B nodules. **C,** At late phase, the lesion remains undetectable, suggesting a class B pattern.

metastastic nodule in the late phase, which lasts from 2 to 5 minutes after injection, remains unenhanced and black in comparison with the surrounding enhanced liver parenchyma (Fig. 95.28). This is particularly useful in those patients who undergo surgery after chemotherapy, in whom some nodules may not be well visualized by IOUS because of the histologic rearrangements induced by the chemotherapeutic agents. CE-IOUS allows better nodule visibility and has allowed my colleagues and me to detect 9% of adjunctive nodules (Torzilli et al, 2008a); therefore CE-IOUS application resulted in an increased sensitivity, and in patients with CLM, it appears to have an important role. The only condition under which it may not help is in the event of a bright liver at IOUS (Chen et al, 2008), which correlates with the degree of fatty change and accounts for 10% of our patients (Torzilli et al, 2008a). Indeed, in these circumstances, the visibility of CLM, generally hypoechogenic, is enhanced by the brightness of the surrounding liver parenchyma, mimicking the effect of the contrast enhancement (Fig. 95.29). As a confirmation of this, we never found new sites of disease at CE-IOUS in those patients having a bright liver at IOUS.

For CLM, new perspectives could be obtained by using liver-specific contrast agents, which allow prolonged exploration. A preliminary experience of eight patients showed new lesions in two detected only at CE-IOUS (Nakano et al, 2008).

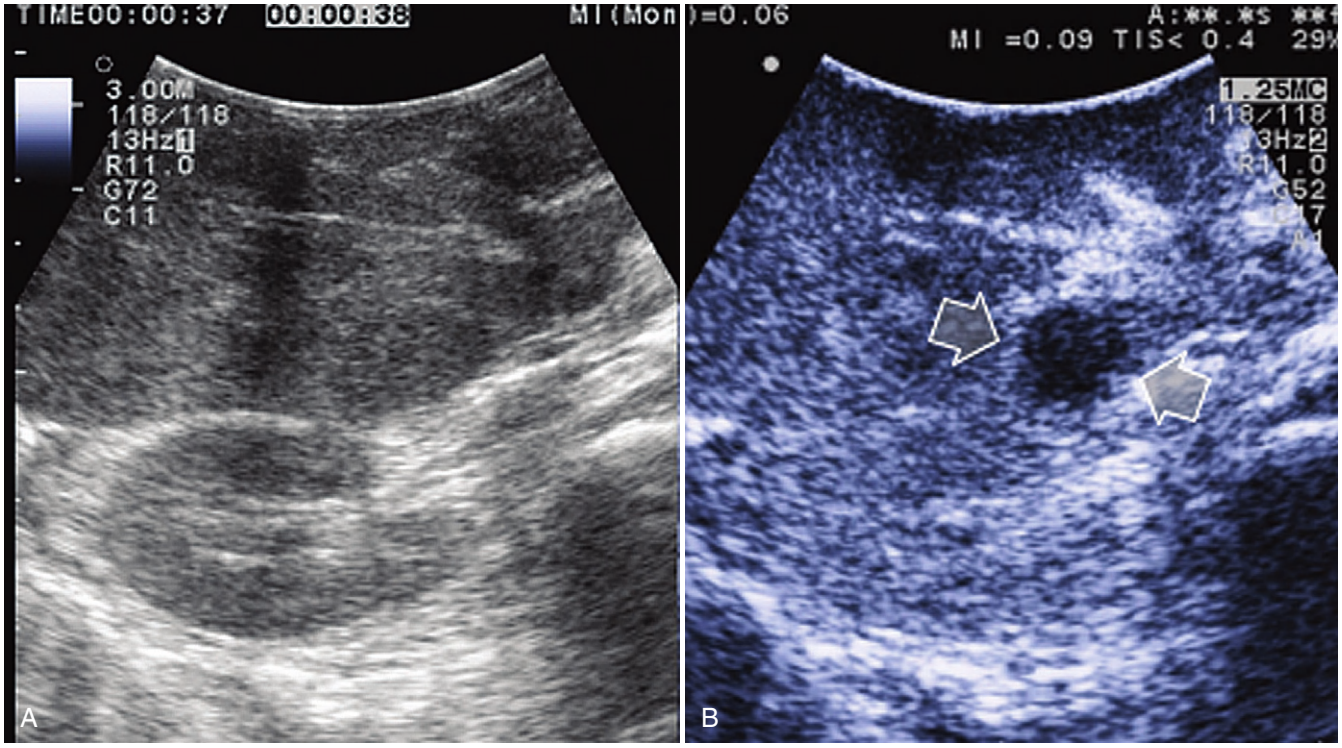

FIGURE 95.27. A, This relatively large metastatic lesion is substantially hypoechoic compared with the surrounding liver parenchyma. **B,** At 37 seconds after injection of the contrast agent (time is shown in the upper right corner), the lesion is clearly visible (*arrows*), showing the so-called "black hole" effect.

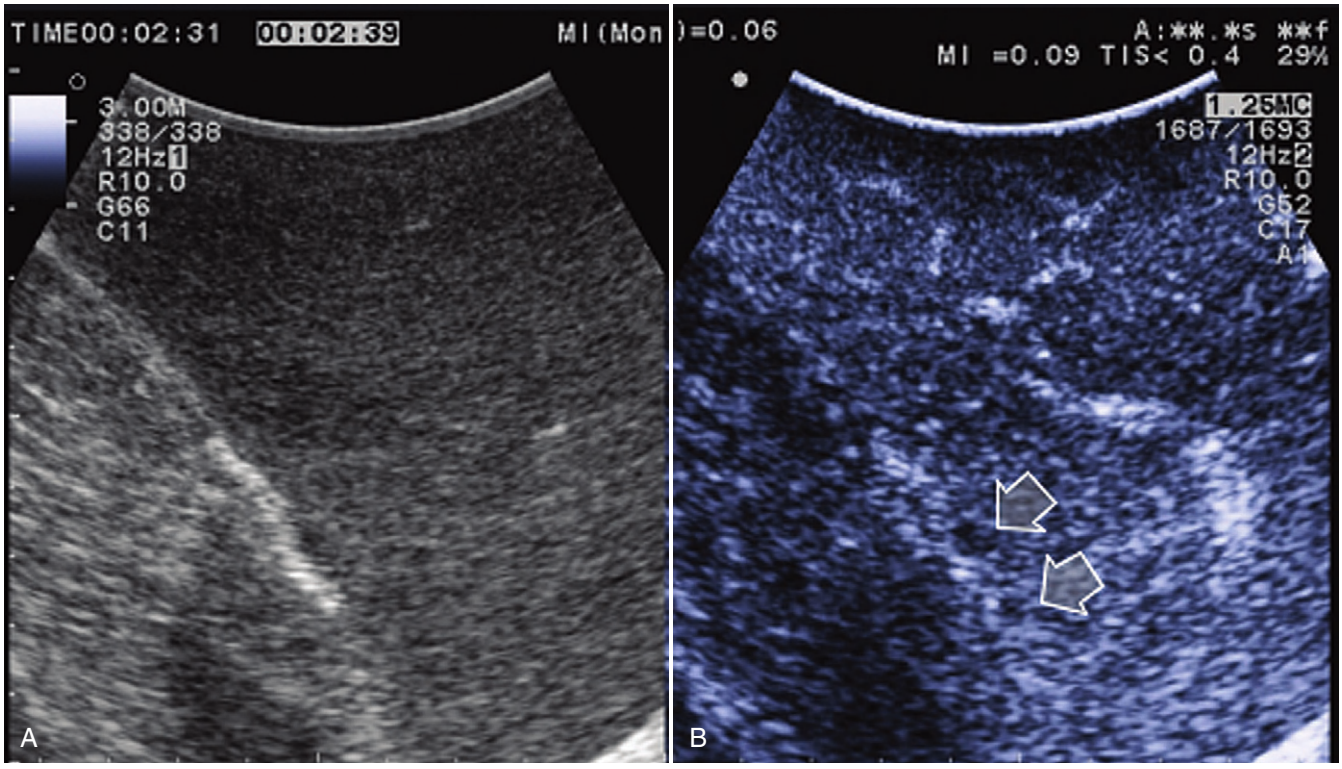

FIGURE 95.28. A, Two small metastatic lesions cannot really be visualized in intraoperative ultrasound. **B,** At 2 minutes and 39 seconds after injection of the contrast agent (time is shown in the upper right corner), the lesions (*arrows*) are clearly visible, showing the so-called "black hole" effect.

FIGURE 95.29. Clear visibility of two hypoechoic masses (*arrows*) in a so-called bright (fatty) liver.

Care should be used in CLM patients who also have coexisting liver cysts, which may appear similar to the CLM along the delayed phases of contrast enhancement; however, the cysts should have been already mapped based on the preoperative imaging and should have been identified at exploration with conventional IOUS. Therefore, any new "black hole" detected in the liver in locations other than where cysts were eventually detected should be considered suspicious for malignancy. Liver cyst features at unenhanced IOUS have an anechoic content and a posterior enhanced echo (Fig. 95.30; see Chapter 13), and it must be taken into account that the anechoic pattern could be mimicked by tiny CLM (Fig. 95.31).

Other Intraoperative Techniques

Recently, imaging using indocyanine green (ICG) as a fluorescent source has been proposed (Ishizawa et al, 2009; Gotoh et al, 2009). Used in many centers to assess liver function, ICG is injected intravenously approximately 3 days before surgery and during laparotomy, and the liver is explored to detect any sign of fluorescence on its surface by means of a fluorescent imaging system that comprises a control unit and a camera. Once removed, the specimen is explored to detect undisclosed fluorescent areas. With this device, Ishizawa and colleagues (2009) disclosed 13 of 91 lesions with only an ICG fluorescent-imaging technique, obtaining a sensitivity of 100% for HCC and 93% for CLM. Although in a smaller series that included only patients with HCC, Gotoh and colleagues (2009) similarly showed that all the new lesions detected in the examined patients were visible only because of the ICG fluorescent-imaging technique.

These promising results should certainly stimulate further investigation. Furthermore, it is noteworthy that the ICG staining pattern is different compared with the histology and tumor differentiation. Indeed, CLM and poorly differentiated HCC retain ICG at the periphery, but well-differentiated HCC is fully and diffusely stained. Certainly, the main limitation of this technique is that it can be applied only to those lesions superficially located, both on the liver surgery and on the cut surface once the specimen has been removed. Indeed, the near infrared light penetrates human tissue at a depth of 5 to 10 mm.

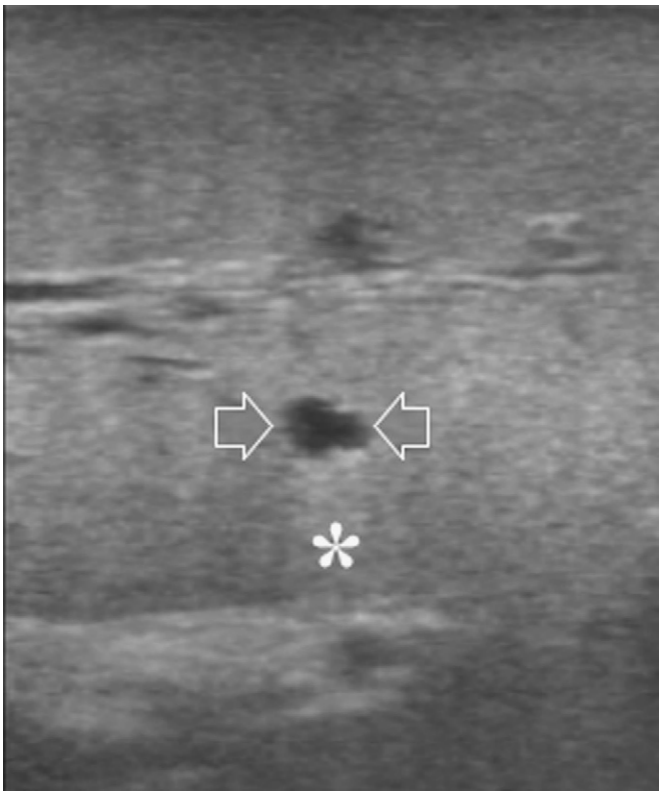

FIGURE 95.30. A small, simple hepatic cyst (*arrows*) with its typical posterior echo (*asterisk*) and the echo-free (*black*) content.

Planning of the Surgical Strategy

IOUS exploration of the liver could have a significant impact on the surgical strategy. More recently, impact of IOUS on the operative decision making, when compared with that of preoperative imaging techniques, is reported to be around 4% to 7% (Cerwenka et al, 2003; Jarnagin et al, 2001). The problem of

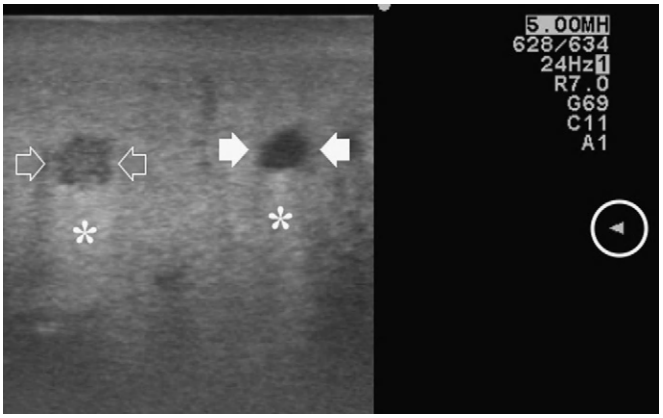

FIGURE 95.31. A small, simple hepatic cyst (*white arrows*) and a small metastasis (*transparent arrows*); both have a typical posterior echo (*asterisk*), but while the cyst is echo free (*black*), the metastasis is not. Once the focus of the ultrasound probe (*circled*) is not properly regulated (much deeper than at the level of the two lesions), the cyst may mimic the hypoechogenicity of the metastases; this represents a known artifact that should be avoided.

the impact of IOUS on the operative decision making depends on two main factors: the surgical policy of each specific team and the type of tumor. Indeed, the relatively low rates reported (Cerwenka et al, 2003; Jarnagin et al, 2001) are also influenced by the surgeon's resection policy; when a considerable number of patients undergo major hepatectomies, new nodules detected by IOUS in the same hemiliver would still be resected, and the surgical strategy would not be modified.

Recently, it was shown that major hepatectomies are carried out in a minority of patients, even in extremely complex presentations (Torzilli et al, 2009b), simply because of the extensive use of IOUS guidance for achieving parenchyma-sparing resections; from this perspective, detection of new nodules is more likely to change the surgical strategy.

IOUS allows an accurate three-dimensional reconstruction of the relationship between the tumor, the portal branches, and the hepatic veins, which is a fundamental step in defining the proper surgical strategy. Definition of tumor-vessel relationships is relevant for planning the type of resection (Torzilli et al, 2008c, 2010a). IOUS allows the surgeon to easily recognize whether an HCC is separated by some normal parenchyma from the vessel, or if it is in contact with the vessel without invading its wall, or conversely whether the HCC is invading the vessel wall or is determining the proximal bile duct dilation, or if it is associated with a tumor thrombus. Similarly, definition of the relationship between a CLM and intrahepatic vascular structures is precisely defined by IOUS; once the vessel wall is found to be intact, the circumferential extent of the contact is relevant for planning a resection that spares the vessel in contact with the CLM (Torzilli et al, 2009b). Based on these features, the decision whether the vessel should be resected is considered, and a precise surgical strategy can be pursued.

Tumor in Contact with a Glissonian Pedicle

The glissonian pedicle may be spared when in contact with an encapsulated HCC with integrity of the vessel wall appreciable at IOUS without any sign of bile duct dilation (Fig. 95.32). Similarly, the pedicle can be spared when it is in contact with a CLM, the integrity of the vessel wall is confirmed, bile duct dilation is ruled out, and the contact extent is less than one third of the pedicle circumference (Fig. 95.33). In the presence of bile duct dilation, tumor thrombus, invasion of the vessel wall, and for CLM, contact wider than one third of pedicle circumference, the pedicle must be divided (Fig. 95.34). In these conditions, extension of the hepatectomy is required for complete tumor clearance.

Tumor in Contact with a Hepatic Vein

The hepatic vein may be spared when in contact with an encapsulated HCC with integrity of the vessel wall appreciable at IOUS (Fig. 95.35). Initially for the CLM, its contact was considered an indication for hepatic vein resection; however, the vein may be spared when it is in contact with a CLM, but at IOUS, the integrity of the vessel wall is confirmed, and the contact extension is less than two thirds of the vein circumference (Figs. 95.36 and 95.37). In the presence of tumor thrombus, invasion of the vessel wall, and contact wider than two thirds of the vein circumference in CLM, the hepatic vein must

Detachment of the tumor from the glissonian pedicle (*GP*) and the hepatic vein (*HV*) would be suitable, therefore the drawn dissection line (*DL*) should be feasible. **C,** Cut surface at the end of the resection, which consisted of a segment IV partial resection with exposure of the left portal vein (*LPV*), the MHV, and the UP. P2, portal branch to segment II; P3, portal branch to segment III.

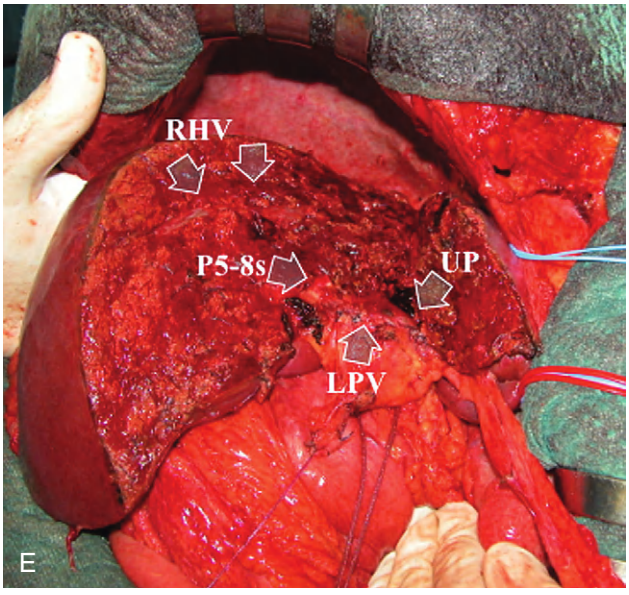

FIGURE 95.34. A, Appearance on intraoperative ultrasound of a colorectal liver metastasis (*T*) located in segment VIII, invading the portal branch of the right anterior section (*P5-8*) and causing dilation of the segmental portal branches of segment VIII (*B8*). **B,** Detachment of the tumor from the glissonian pedicle (*GP*) would not be suitable because of bile duct (*BD*) dilation. A suitable dissection line (*DL*) should include the GP. **C,** Relationship of the other lesion (*T*), which is located posterosuperiorly to the umbilical portion (*UP*) and in contact with it. **D,** Schematically, this lesion could be classified as shown, and as a consequence, a detachment of the tumor from the GP would be feasible, planning the drawn DL. **E,** Cut surface at the end of the resection, which consisted of a right anterior sectionectomy extended to segment IV, with the exposure of the right hepatic vein (*RHV*), left portal vein (*LPV*), and the UP. IVC, inferior vena cava; MHV, middle hepatic vein; P2, portal branch to segment II; P3, portal branch to segment III; P4, portal branch to segment IV; P6-7, portal branch to segments VI and VII.

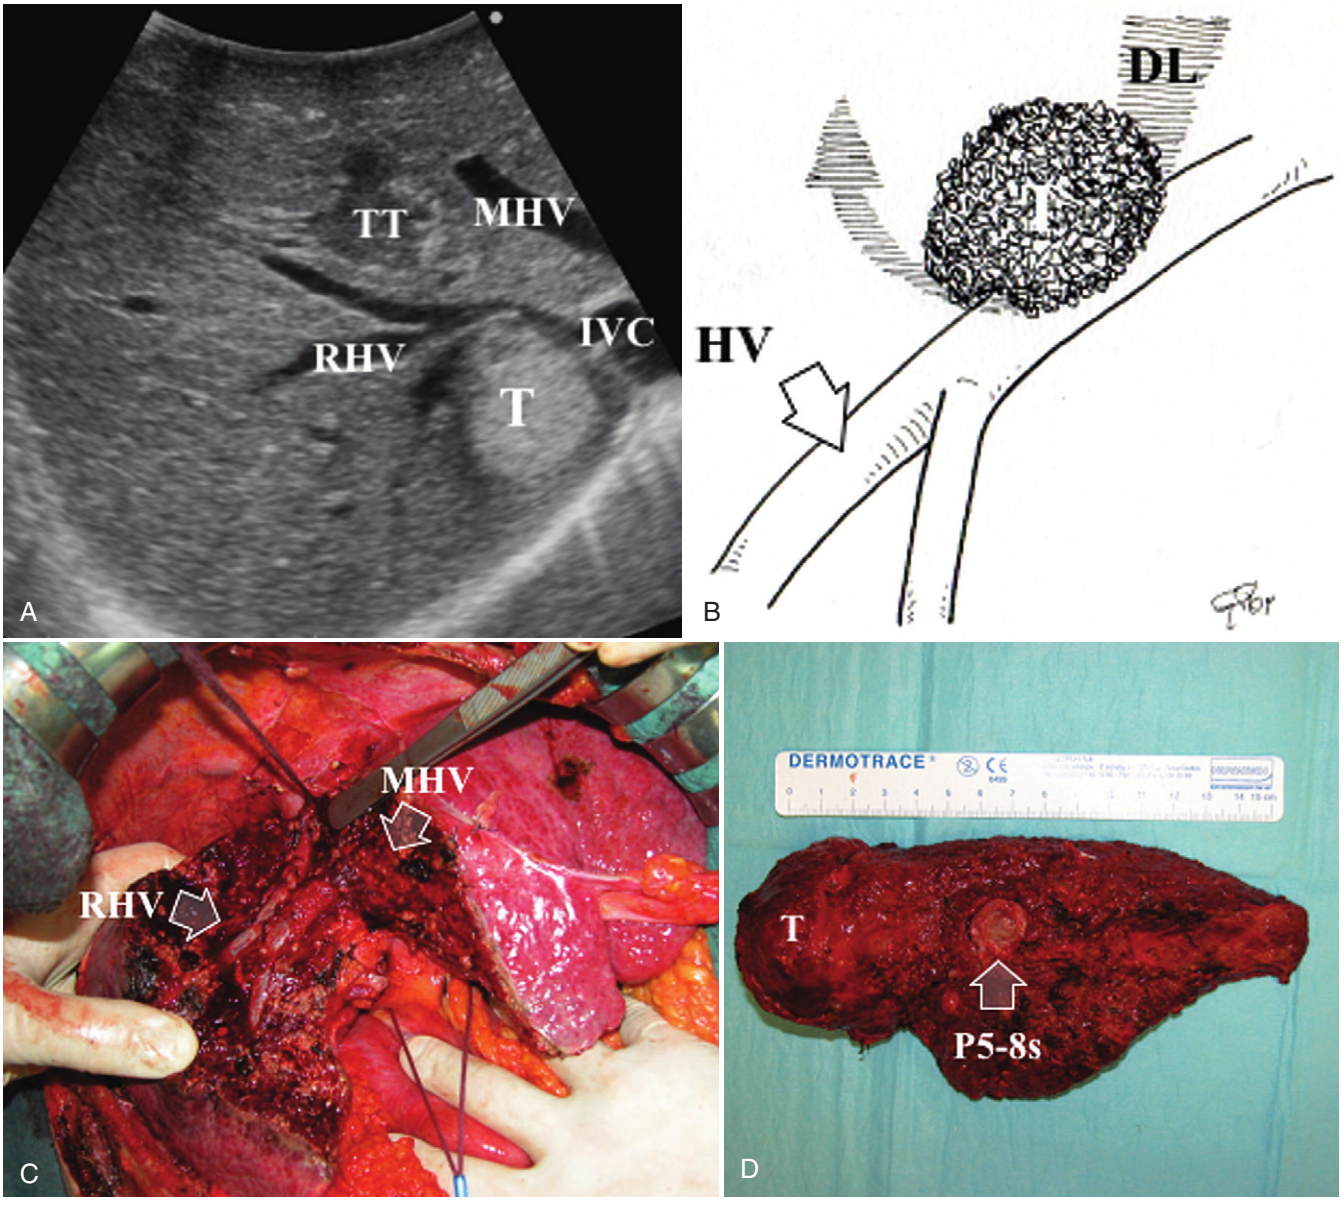

FIGURE 95.35. A, Intraoperative ultrasound appearance of a hepatocellular carcinoma (HCC) is located in the dorsal portion of segment VIII, in extensive contact with the right hepatic vein (*RHV*) and causing a tumor thrombus (*TT*) in the portal branch feeding the right anterior section. **B,** Detachment of the tumor from the hepatic vein (*HV*) would be feasible with the drawn dissection line (*DL*). **C,** Cut surface at the end of the resection, which consisted of a right anterior sectionectomy with complete exposure of the right hepatic vein (*RHV*). **D,** Specimen showing an encapsulated HCC (*T*) exposed on the cut surface and the stump of the sectional portal branch (*P5-8s*) occupied by the tumor thrombus. IVC, inferior vena cava; MHV, middle hepatic vein.

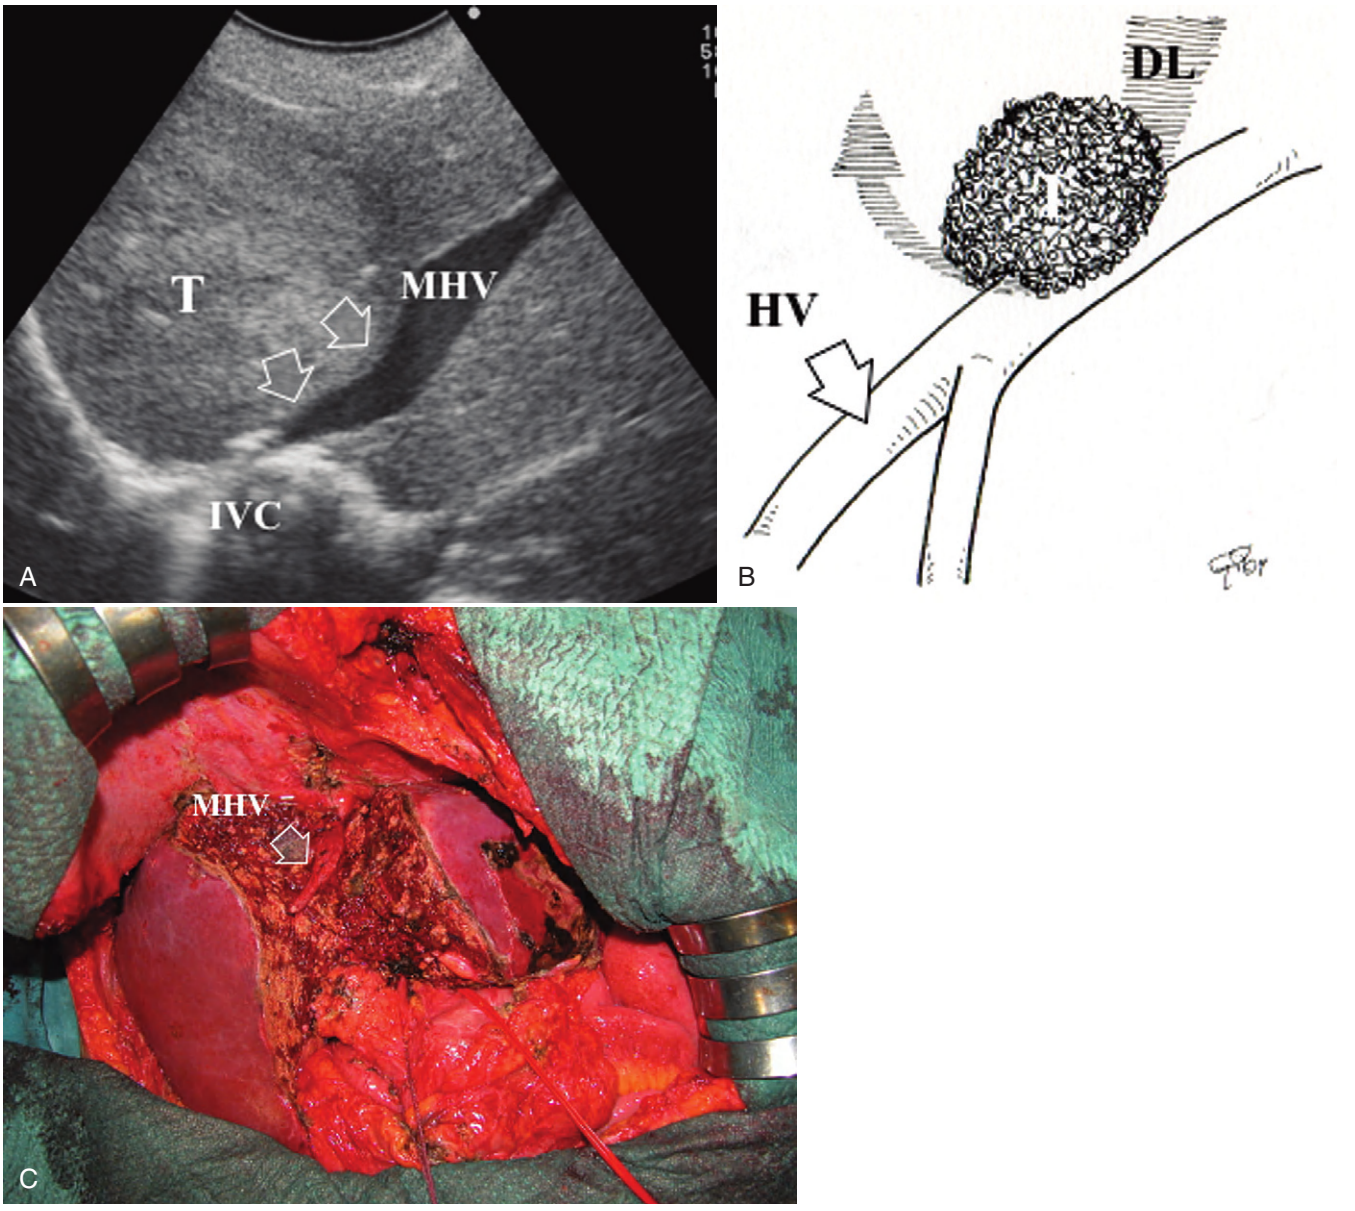

FIGURE 95.36. **A,** Intraoperative ultrasound appearance of a colorectal liver metastasis (*T*) located in segments IV (superior) and VIII ventral in extensive contact (*arrows*) with the middle hepatic vein (*MHV*). **B,** Schematically this lesion could be classified as shown, and detachment of the tumor from the hepatic vein (*HV*) would be feasible with the drawn dissection line (*DL*). **C,** Cut surface at the end of the resection; another lesion was present in segment IV inferior and necessitated a segment IV full segmentectomy extended to segment VIII ventral with complete exposure of the MHV. IVC, inferior vena cava.

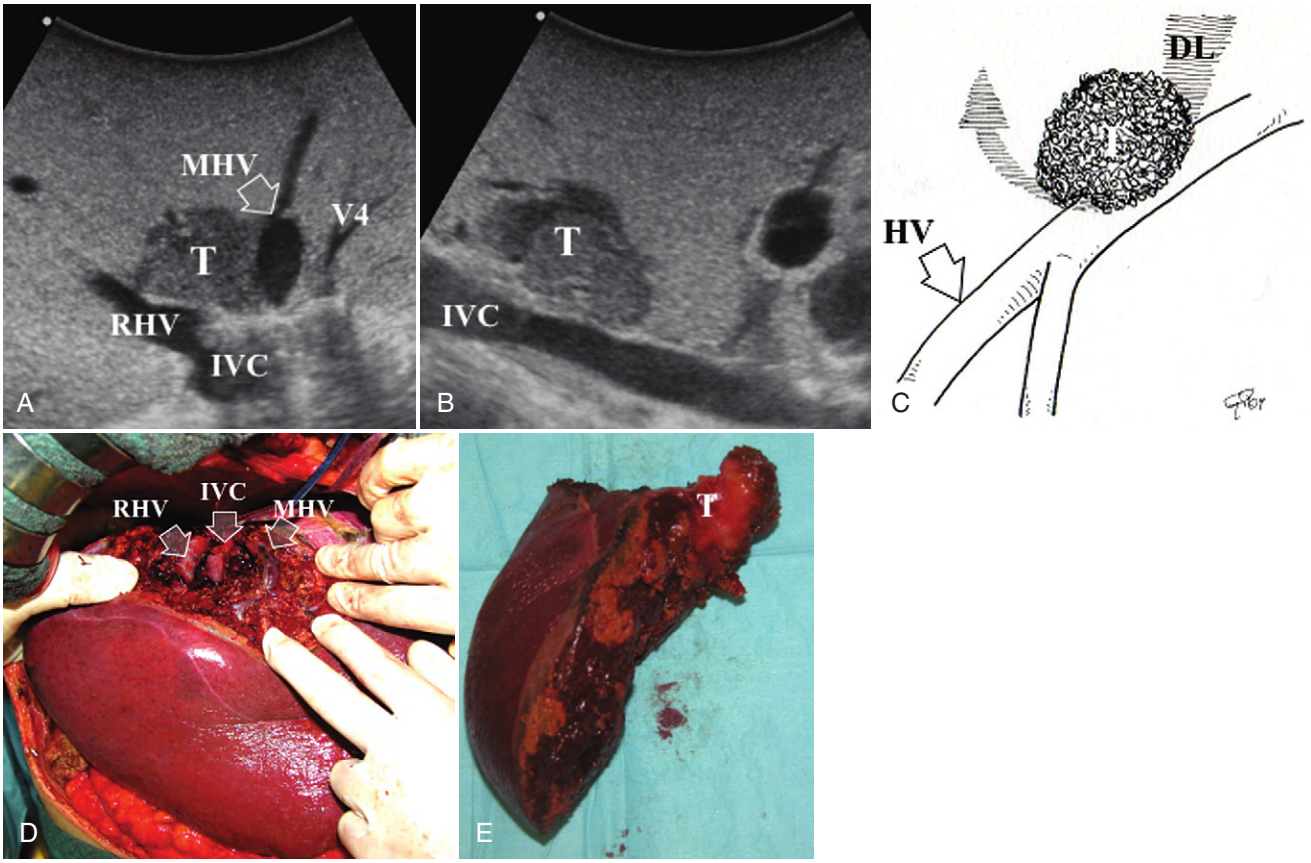

FIGURE 95.37. A, Intraoperative ultrasound appearance of a colorectal liver metastasis (*T*) located in segment VIII, segment I (paracaval), and in extensive contact with the right hepatic vein (*RHV*), the middle hepatic vein (*MHV*), and the inferior vena cava (*IVC*). **B,** Relationship of the tumor with the IVC is shown. **C,** Schematically this lesion could be classified as shown, and as a consequence, a detachment of the tumor from the hepatic vein (*HV*) would be feasible, planning the drawn dissection line (*DL*). **D,** Cut surface at the end of the resection, which consisted of a segment VIII partial resection extended to segment I (paracaval) with complete exposure of the IVC, MHV, and RHV. **E,** Specimen showing a metastases (*T*) exposed on the cut surface. V4, scissural vein.

be divided (Fig. 95.38). In this condition, extension of the hepatectomy is not compulsorily considered, even if the hepatic vein is invaded at its caval confluence (the last 4 cm). Indeed, in this condition, an extension of the resection to the liver parenchyma theoretically drained by the hepatic vein to be resected is considered only if one of the following US signs is missing:

- Presence of accessory hepatic veins at IOUS as an inferior right hepatic vein in the presence of an invasion at the caval confluence of the right hepatic vein (Fig. 95.39)
- EF-IOUS showing hepatopetal blood flow in the feeding portal branch (Fig. 95.40), once the hepatic vein to be resected is clamped (Torzilli et al, 2006b) by means of encirclement, or more simply by vein compression at its extrahepatic route using a fingertip (Torzilli et al, 2007a)
- Communicating veins connecting adjacent hepatic veins (Fig. 95.41), these being more easily detectable using EF-IOUS to disclose their presence (Torzilli et al, 2010c).

Adopting these criteria, we have been able to minimize the rate of major hepatectomy and to devise new procedures.

Systematic Extended Right Posterior Sectionectomy

Systematic extended right posterior sectionectomy (SERPS) is a surgical technique that allows the systematic sparing of part of the right anterior section (see Fig. 95.38, C and D) in the presence of tumors with the presentation shown in Figure 95.42 (Torzilli et al, 2008c).

Eligibility Criteria

Patients suitable for SERPS are those with tumors showing one of three conditions:

1. Invasion of the right hepatic vein (RHV) is evident within 4 cm of the hepatocaval confluence, with other lesions involving segment VI and eventually segment VII (Fig. 95.42A).
2. Invasion of the RHV within 4 cm of the hepatocaval confluence is evident, without other lesions involving segment VI, without an inferior RHV (IRHV), and with hepatofugal portal blood flow at color-flow IOUS in the portal branch to segment VI (P6) when the RHV is clamped if not already

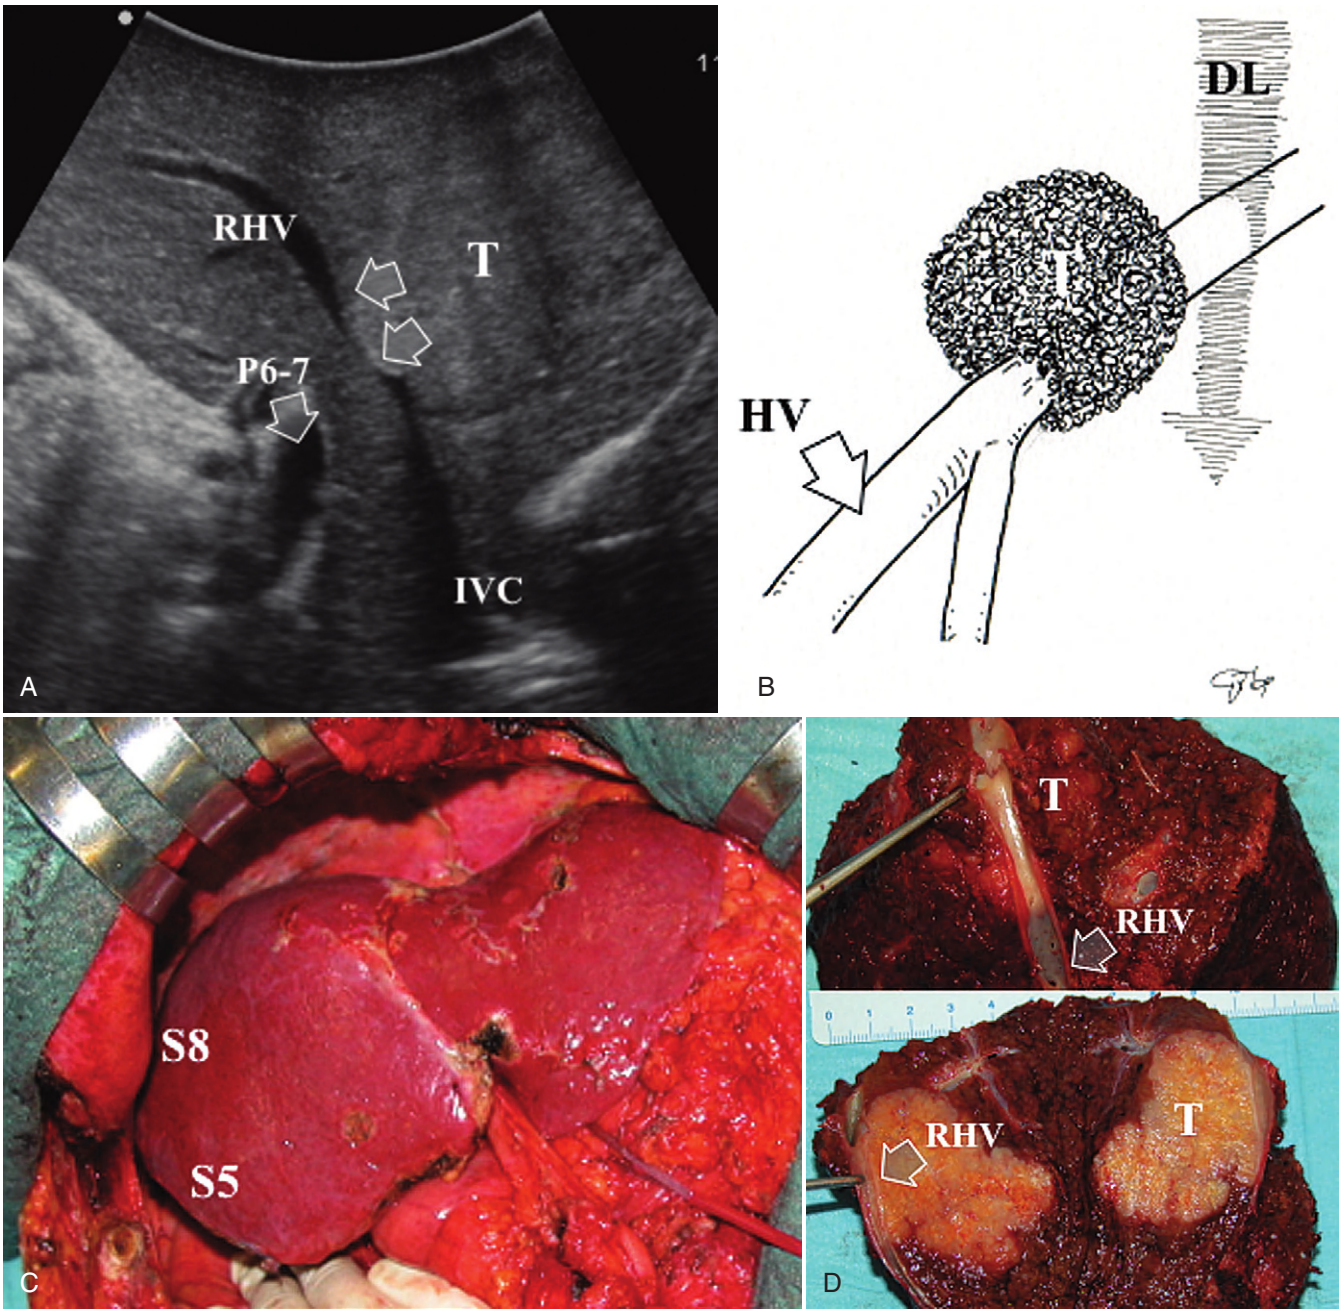

FIGURE 95.38. **A,** Intraoperative ultrasound appearance of a colorectal liver metastasis (*T*) located in segments VII and VIII and invading the wall of the right hepatic vein (*RHV*). **B,** Detachment of the tumor from the hepatic vein (*HV*) would not be feasible; the drawn dissection line (*DL*) is shown. **C,** Remnant liver at the end of the resection, a systematic extended right posterior sectionectomy sacrificing the RHV but almost completely sparing segments V (*S5*) and VIII (*S8*). **D,** Specimen showing a metastasis (*T*), not detachable from the RHV, which it contacts for more than two thirds of its circumference. IVC, inferior vena cava; P6-7, portal branch for right posterior section.

occluded (Fig. 95.42B). In the event an IRHV is present, or, if not, when the flow direction in P6 remains hepatopetal, resection of segments VII and VIII together with the RHV is carried out (Makuuchi et al, 1987) rather than SERPS; therefore SERPS is applied as an alternative to resection of segments VII and VIII in those patients who do not have proper outflow for segment VI once the RHV is divided.

3. Contact with the right anterior glissonian sheath and a relationship with the right posterior section is evident, with at least one of the following features: contact with the right posterior section determining proximal bile duct dilation, vessel wall invasion, or, for CLM, contact wider than one third of the pedicle circumference (Fig. 95.42C).

Procedure

In the first two conditions, extension to the right anterior section is tailored to guarantee the complete removal of the tumor, and a dissection line is drawn on the left side of the RHV, which is also resected (see Fig. 95.42, A and B); flow direction in the right anterior portal branch at EF-IOUS is estimated as previously described, once the RHV is clamped, if it is not occluded (Fig. 95.43). The right anterior pedicle is not necessarily

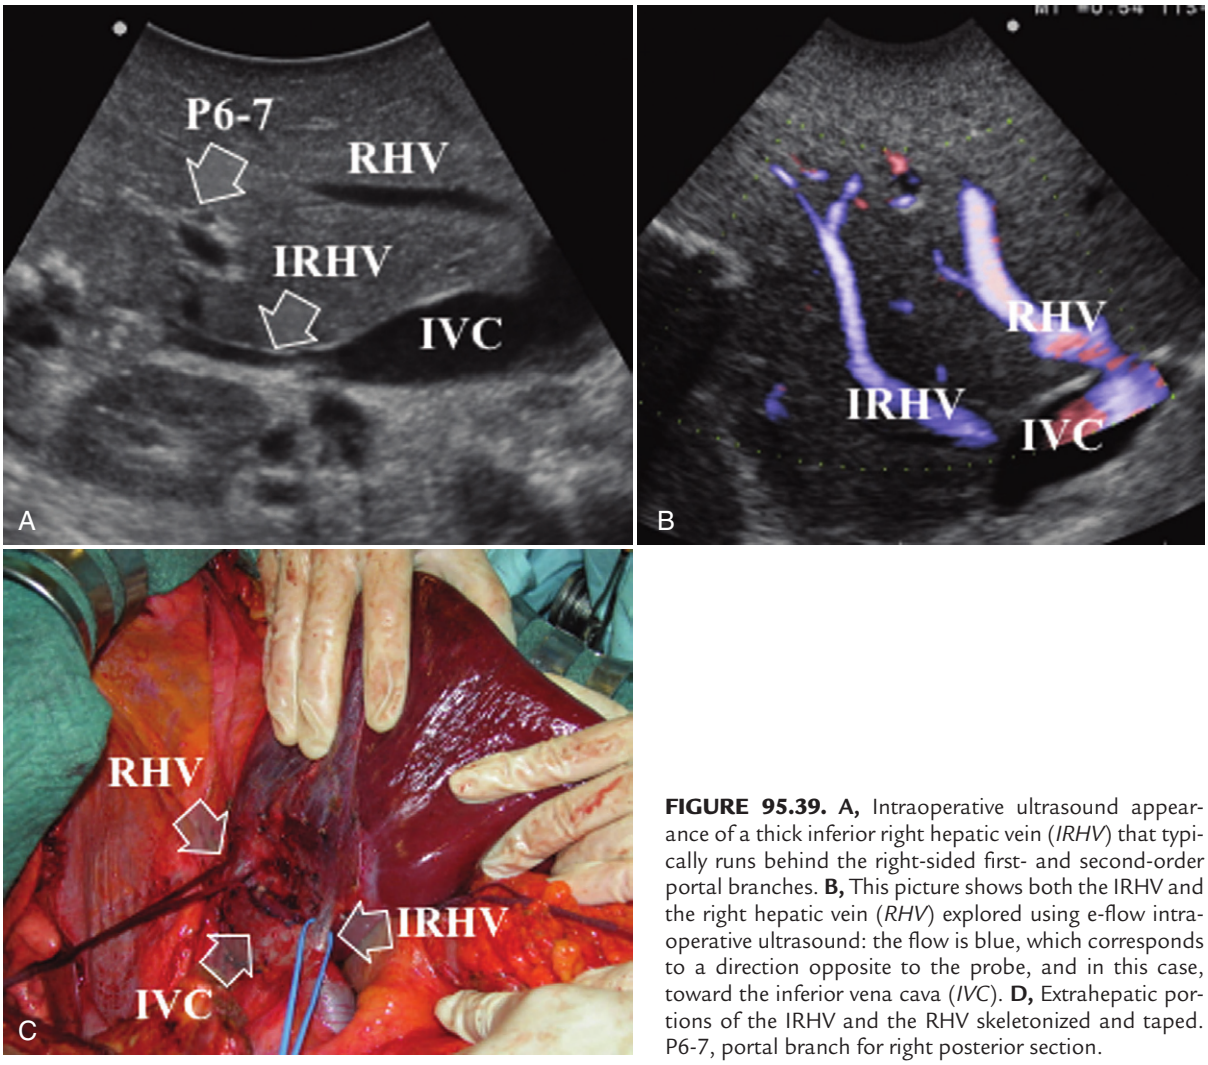

FIGURE 95.39. A, Intraoperative ultrasound appearance of a thick inferior right hepatic vein (*IRHV*) that typically runs behind the right-sided first- and second-order portal branches. **B,** This picture shows both the IRHV and the right hepatic vein (*RHV*) explored using e-flow intraoperative ultrasound: the flow is blue, which corresponds to a direction opposite to the probe, and in this case, toward the inferior vena cava (*IVC*). **D,** Extrahepatic portions of the IRHV and the RHV skeletonized and taped. P6-7, portal branch for right posterior section.

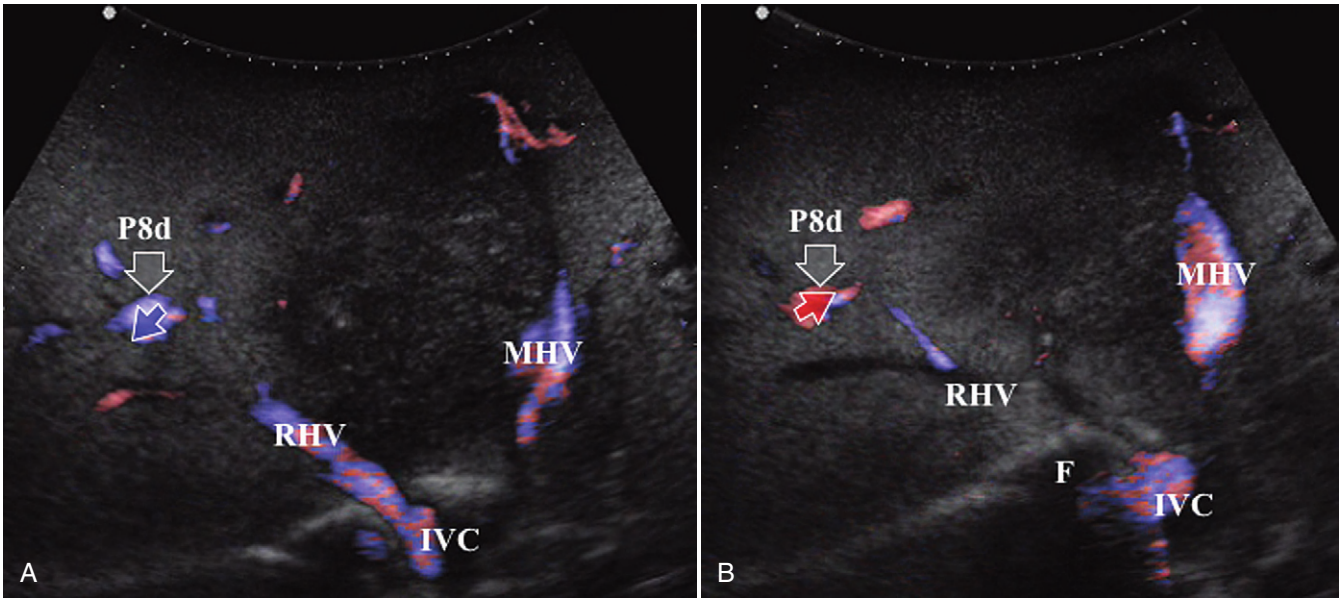

FIGURE 95.40. A, Hepatopetal flow direction (*arrow*) at e-flow intraoperative ultrasound of the portal branch to the dorsal portion of segment VIII (*P8d*). **B,** When finger compression (*F*) is applied to the right hepatic vein (*RHV*) at its caval confluence, the flow direction in P8d becomes hepatofugal (*arrow*). MHV, middle hepatic vein; IVC, inferior vena cava; T, tumor.

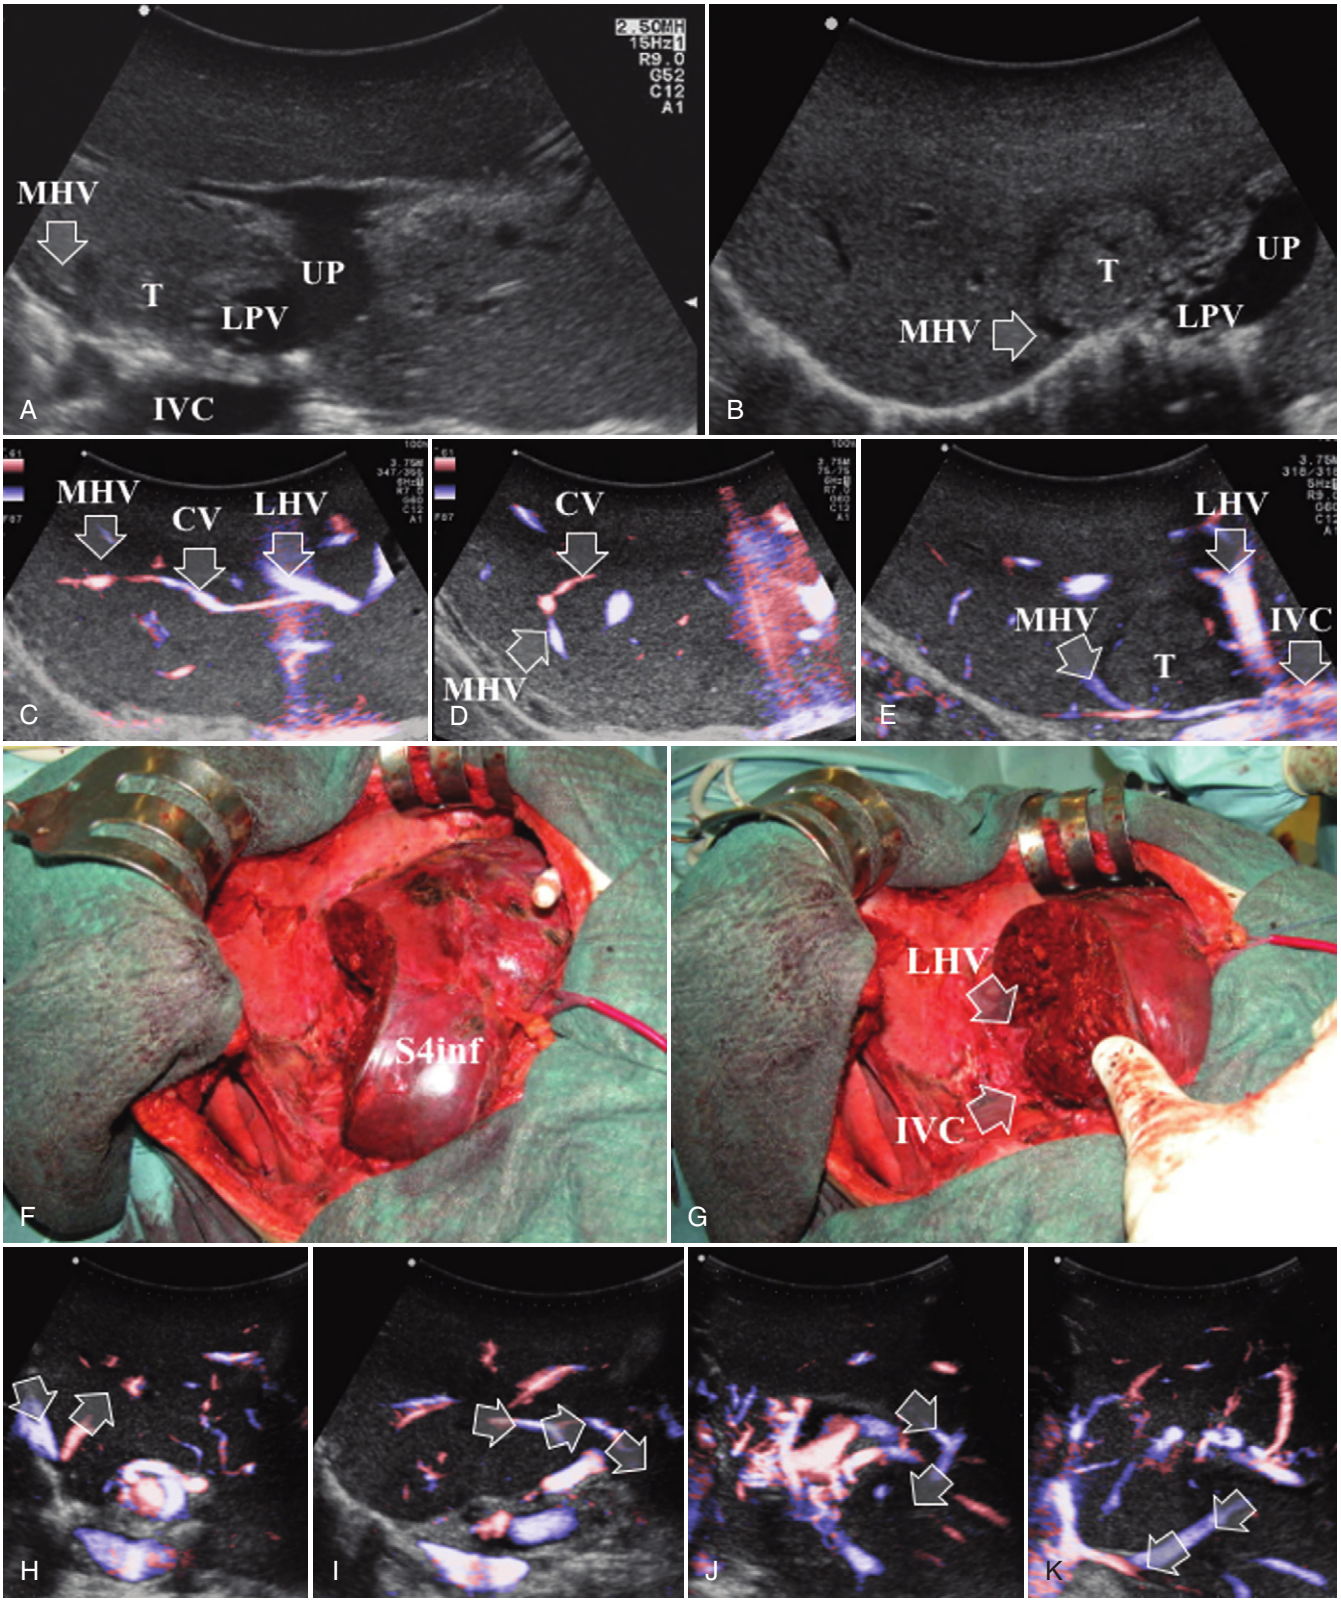

FIGURE 95.41. **A,** Intraoperative ultrasound (IOUS) appearance of a colorectal liver metastasis (*T*) located in segment IV superior in a patient who had previously had a right hepatectomy. The lesion is invading the middle hepatic vein (*MHV, arrow*) at its caval confluence and is in contact with, staying beside and above, the left portal branch (*LPV*). **B,** Another IOUS scan showing the saggital view of the same lesion with further disclosure of its relationship with the umbilical portion (*UP*), LPV, and MHV. **C,** In the same patient, EF-IOUS discloses a communicating vein (*CV*) between the left hepatic vein (*LHV*) and the MHV. **D,** The confluence of the CV into the MHV. **E,** The LHV and MHV are shown at e-flow IOUS, flowing into the inferior vena cava (*IVC*). **F,** Preserved segment IV inferior (*S4inf*). **G,** LHV flowing into the IVC after resection. **H** to **K,** Hepatic vein drainage of the S4inf at EF-IOUS (*arrows*), passing through the MHV stump and the CV (**H**), the CV (**I**), the CV and the LHV (**J**), and the LHV (**K**).

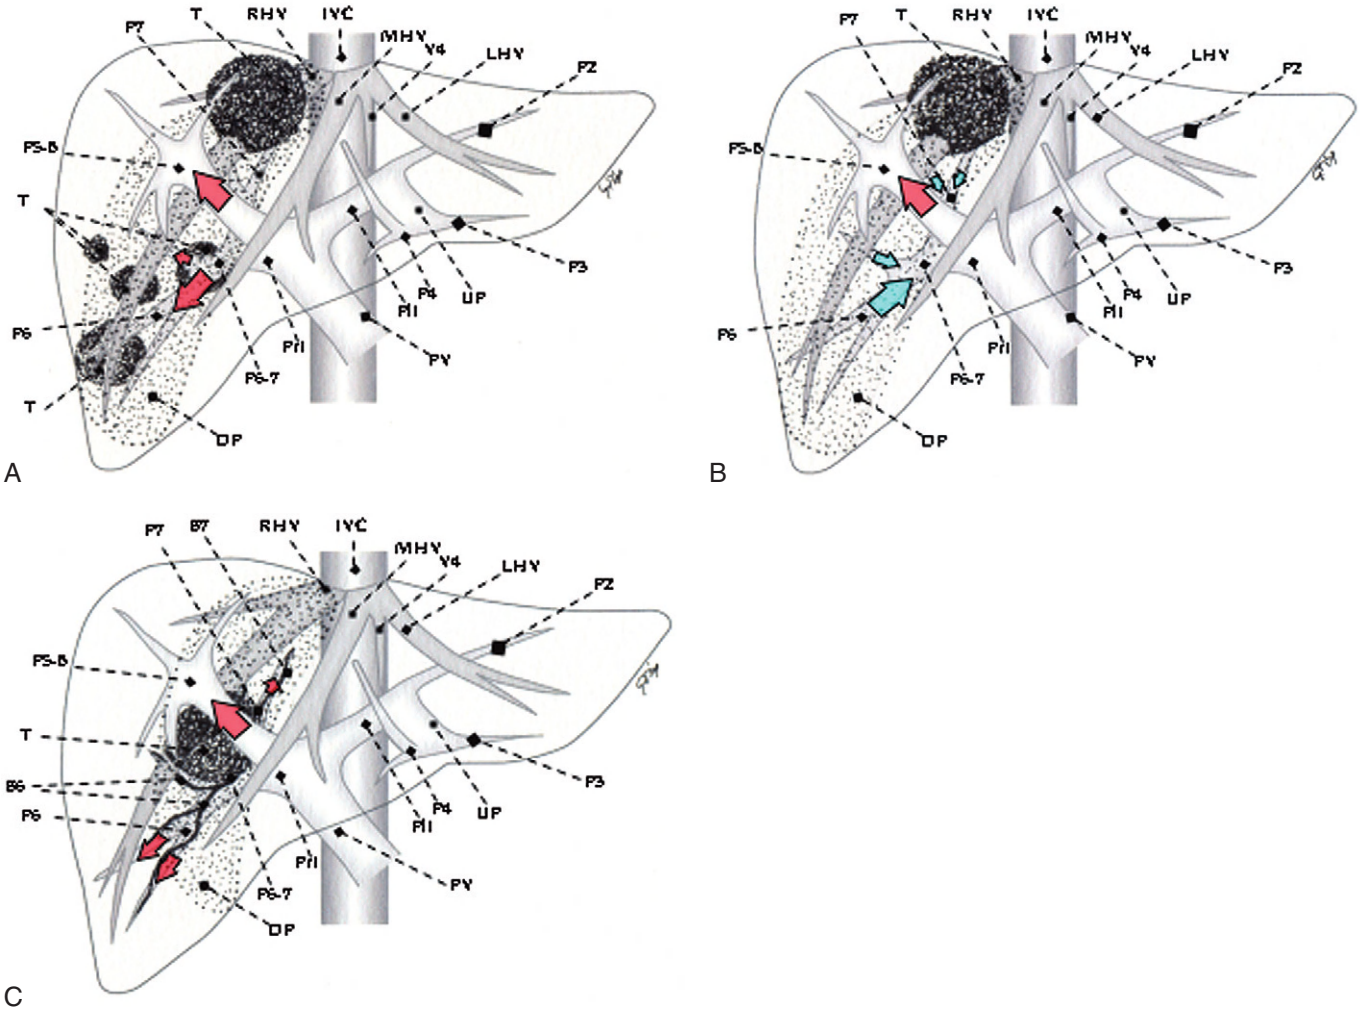

FIGURE 95.42. Eligibility criteria for systematic extended right posterior sectionectomy (SERPS). In all circumstances, at e-flow intraoperative ultrasound hepatopetal portal blood flow (*arrows*) has to be evident in the main portal branch to the right anterior section (*P5-8*), once the right hepatic vein (*RHV*) is clamped, if not already occluded. **A,** Presence of vascular invasion of the RHV at the hepatocaval confluence (within 4 cm) with tumor (*T*) in segment VI. **B,** Presence of vascular invasion of the RHV at the hepatocaval confluence (within 4 cm) without tumor in segment VI and without accessory veins and/or with hepatofugal portal blood flow (*arrow*) in the portal branch to segment VI (*P6*), once the RHV is clamped, if not already occluded. **C,** Presence of vascular invasion of the right posterior portal branch (*P6-7*) or biliary dilation of sectional branches (*B6 and B7*), with tumor (*T*) in contact with the P5-8 without signs of biliary dilation in the right anterior section. DP, dissection plane; IVC, inferior vena cava; UP, umbilical portion; P2, P3, P4, P5, P6, and P7 are portal pedicles to their respective segments. Prt, right portal vein; Plt, left portal vein; LHV, left hepatic vein; MHV, middle hepatic vein; V4, scissural vein.

exposed on the liver cut surface. In the third condition, the extension of the resection into the right anterior section is tailored to preserve most of the parenchyma of segment VIII, the tract of the RHV at the hepatocaval confluence, and the left portion of segment V without division of the right anterior pedicle, which is exposed on the cut surface (see Fig. 95.42C).

Minimesohepatectomy

This procedure represents an alternative to the conventional mesohepatectomy in patients with tumors invading the middle hepatic vein (MHV) at its caval confluence; it consists of a limited resection, including the tract of the invaded vein without its reconstruction, sparing part of segment IV, and/or of the right anterior section as shown in Figure 95.44 and as described in the next section (Torzilli et al, 2010a).

Eligibility Criteria

Patients suitable for minimesohepatectomy (MMH) are those with tumors having macroscopic signs of vascular invasion on preoperative imaging and IOUS, showing the MHV within 4 cm of the hepatocaval confluence.

Procedure

Once the anterior surface of the hepatocaval confluence is exposed, a space between the RHV and MHV extrahepatic tracts, just before their caval confluence, is obtained by dissection to accommodate the surgeon's fingertip. If not already occluded, finger compression is then applied to the MHV at its caval confluence, verifying at EF-IOUS the disappearance of blood flow in the MHV or its inversion. For planning an MMH, at least one of these three findings should be confirmed during

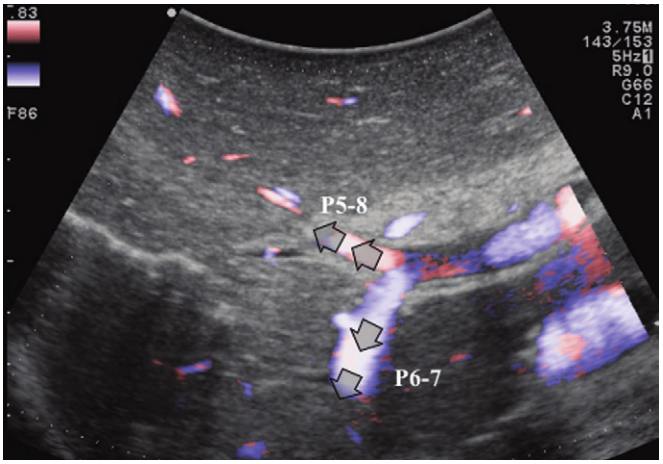

FIGURE 95.43. Direction of hepatopetal blood flow (*arrows*) into the right-sided sectional portal branches (*P5-8* and *P6-7*), as it appears at e-flow intraoperative ultrasound.

a finger compression clamping test of MHV or in the event of its occlusion:

1. Reversal flow on EF-IOUS in the peripheral portion of the MHV, which suggests drainage through collateral circulation in the RHV/left hepatic vein (LHV), depending on the side of the MHV branch with reversal flow (Fig. 95.45)
2. Detectable communicating veins on EF-IOUS between the MHV and RHV and/or LHV and/or IVC (Fig. 95.46; as mentioned, this last feature could be also visible without compressing the vein)

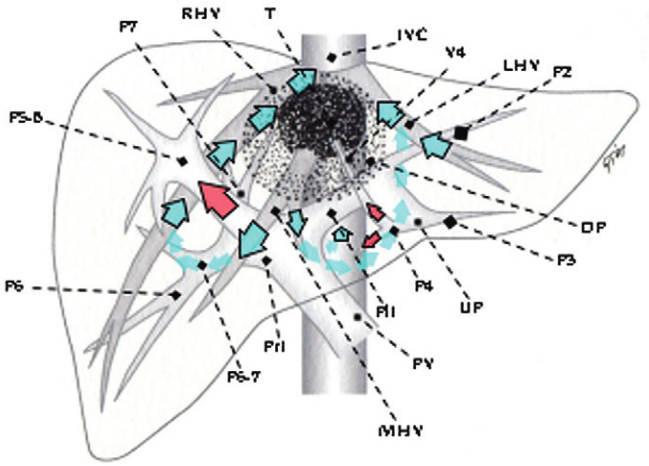

FIGURE 95.44. Eligibility criteria for minimesohepatectomy (MMH). At least one of the three signs should be present: 1) reversal of blood flow into the middle hepatic vein (*MHV*) once it is clamped at its caval confluence if not already occluded; 2) hepatopetal blood flow into portal branches to right anterior section (*P5-8*) and to segment IV (P4; if subsegmental branches show hepatofugal blood flow, that area should be included in the resection area); 3) evidence of communicating veins between the MHV and the left hepatic vein (*LHV*) and/or right hepatic vein (*RHV*). DS, dissection plane; IVC, inferior vena cava; UP, umbilical portion; P2, P3, P4, P5, P6, and P7, portal pedicles to their respective segments; P6-7, portal branch to right posterior section; Prt, right portal vein; Plt, left portal vein; V4, scissural vein.

3. Hepatopetal flow in segments V through VIII and/or the segment IV inferior portal branches (Fig. 95.47A)

If none of these findings is confirmed, and especially if hepatofugal flow direction in portal branches to segments V and/or VII and/or IV inferior is detected (Fig. 95.47B), hepatectomy should be extended to the area fed by those portal branches.

The posterior wall of the MHV, or of the tumor involving the paracaval portion, is used as a deep landmark for delimiting the resection area (Fig. 95.48). A crucial point for proper performance of the MMH in the presence of a communicating vein is to delineate a dissection plane that does not interrupt the communicating vein (see Fig. 95.48I).

RESECTION GUIDANCE

Mobilization of the Liver (See Chapter 90)

Although for liver exploration with IOUS, any approach would be suitable to allow most of the IOUS-guided parenchyma-sparing procedures described here, adequate preparation of the surgical field is essential, which implies adequate incision and liver mobilization. A J-shaped laparotomy is usually performed, and a J-shaped thoracophrenolaparotomy is carried out when the tumor is located in the paracaval portion or at the hepatocaval confluence; control of the hepatic veins at this level could prove difficult with an abdominal incision only.

For right-sided segmentectomies, subsegmentectomies, or sectionectomies, the bare area is dissected, and the right hemiliver is mobilized, until the surgeon's nondominant hand is positioned behind the hemiliver to sustain it and is passing over the resection area established by means of IOUS (Fig. 95.49). A slight mobilization of the right hemiliver, just dividing the triangular ligament and partially or completely dividing the bare area, will be accomplished for lesions located in segments V, VI, and the inferior portion of section VII (Fig. 95.50). Conversely, the right side of the retrohepatic IVC is reached for lesions located in the dorsal portions of segments VII and VIII (Fig. 95.51). If the lesion is located in the superior portion of segment VII or the dorsal portion of section VIII—that is, close to the hepatocaval confluence, in the last 4 cm—but it is not in contact with the hepatic veins and an anatomic segmental approach is not required, the hepatocaval ligament is not divided, and only the space between the RHV and the MHV is dissected to allow fingertip insertion. The caval confluence of the RHV is recognized, following the trajectory of the right inferior phrenic vein, which flows near the RHV at this level and which is a constant landmark (Fig. 95.52; Torzilli et al, 2006a).

If the lesion is still right-sided but makes contact with an HV at its caval confluence, or if it involves the paracaval portion of segment I or an anatomic segmental approach with hepatic vein exposure is not required, liver mobilization includes division of the retrohepatic caval ligament and exposure of the retrohepatic IVC; this proceeds until the area to be resected is under control of the surgeon's nondominant hand, with the surgeon's fingertip reaching over the most distal portion of the planned dissection plane, including the complete detachment (Figs. 95.52 and 95.53).

For segment II and III segmentectomies or subsegmentectomies, the left triangular ligament and the left coronary ligament are divided, and with the surgeon's nondominant hand, the left lobe is handled. For lesions located in the superior portion of

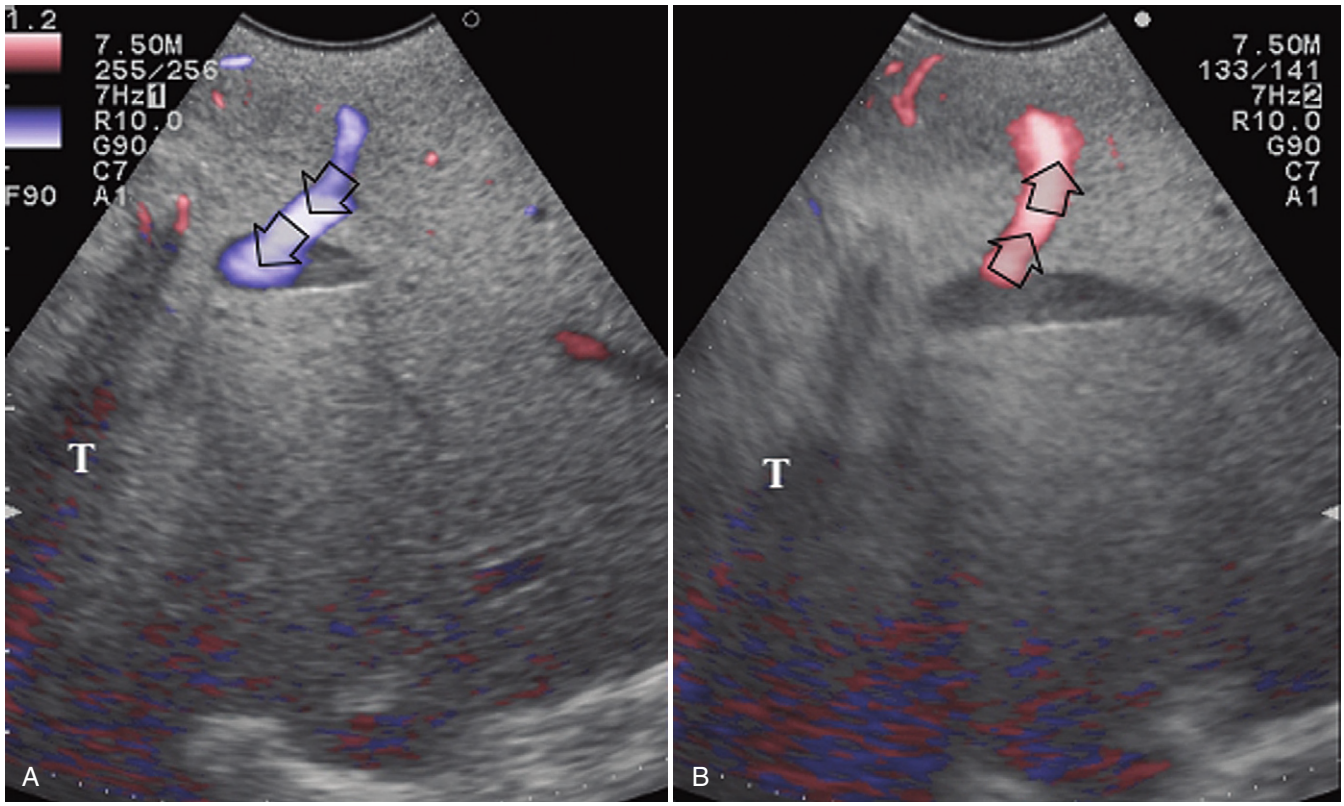

FIGURE 95.45. E-flow IOUS appearance of direction of blood flow into the middle hepatic vein (MHV) toward the inferior vena cava (*arrows*), before clamping of the MHV (**A**), and reversed after MHV clamping (**B**). T, tumor.

segment IV at the hepatocaval junction without contact with the LHV and/or MHV, the mobilization combines those described for lesions at segments VII (inferior) and those in the left lobe. In case of contact with hepatic veins, their selective encirclement at the caval confluence and eventually the exposure of the retrohepatic IVC are carried out.

Anatomic Resections (See Chapters 90 and 92)

Selection of an anatomic resection for CLM may not be relevant for long-term prognosis (Sarpel et al, 2009), and its use for HCC is still controversial (Cho et al, 2007; Eguchi et al, 2008; Kaibori et al, 2006; Regimbeau et al, 2002; Tanaka et al, 2008; Wakai et al, 2007); indeed, for the latter, no studies have been done that compare anatomic and nonanatomic resections in a truly randomized fashion; however, many reports show the long-term benefits of the anatomic approach (Cho et al, 2007; Eguchi et al, 2008; Kaibori et al, 2006; Regimbeau et al, 2002; Ueno et al, 2008; Wakai et al, 2007), and significant selection bias likely influences the reliability of the results (Hasegawa et al, 2005). The rationale for anatomic resection for HCC is based on its pattern of intrahepatic dissemination from the main lesion through the portal branches. As a consequence, the resected specimen should include at least the portal area perfusing the area of the liver that includes the lesion. Indeed, the superiority of the anatomic resection seems more evident in those subgroups with a single HCC larger than 2 cm in diameter (Eguchi et al, 2008) or with extranodular growth (Ueno et al, 2008), which should be those with higher risk of satellites and microvascular invasion.

Whether technical requirements for accomplishing truly anatomic sectionectomies and formal major hepatectomies are more uniformly accepted, the agreement on the requirements for defining a subsegmental resection as a genuine anatomic one is still unclear. Indeed, the recognition and demarcation of the segmental area to be removed in a fully anatomic fashion is still subject to debate. The only certainty is that the portal area feeding the tumor cannot be recognized visually on the liver surface if it is not associated with an interventional procedure for its precise disclosure. Almost all the proposed techniques require US guidance, especially in a cirrhotic liver, where there are generally wide variations and abnormalities in the extension of the segmental areas. The first procedure described in this was the systematic segmentectomy devised in early 1980s (Makuuchi et al, 1980), which consists of puncture of the portal branch feeding the tumor and subsequent injection of dye (Fig. 95.54); more recently, alternatives to this approach have been devised. In the following paragraphs, details concerning US-guided techniques and others for segmental and sectional resection will be provided.

Segmentectomies (See Chapter 92)

Puncture of the Portal Branch

The portal branch feeding the tumor to be resected is punctured under IOUS guidance, using a freehand technique or with a proper device, and 3 to 5 mL of indigo-carmine dye is injected into the vessel (see Fig. 95.54A). The stained area becomes evident on the liver surface, it is marked with

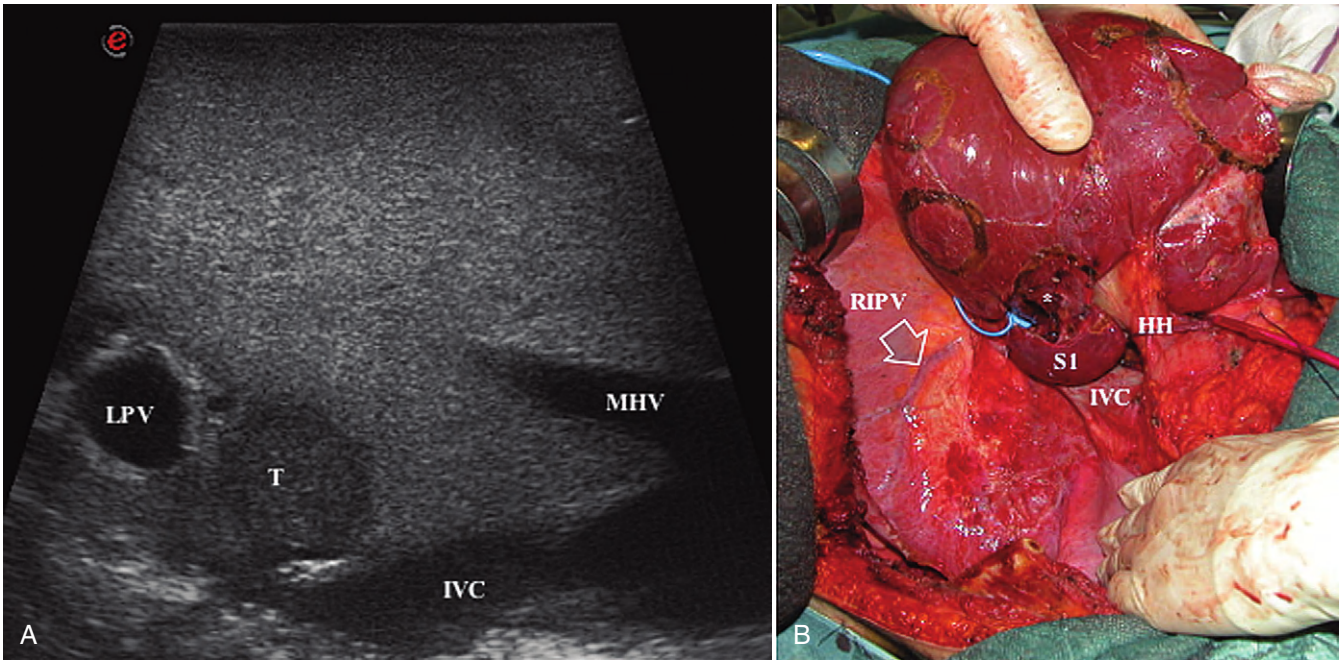

FIGURE 95.53. A, Intraoperative ultrasound image of a lesion (*T*) located in the paracaval portion of segment I. **B,** For its removal by means of a limited resection (*asterisk*), full mobilization of the liver from the retrohepatic inferior vena cava (*IVC*) is carried out. LPV, left portal vein; HH, hepatic hilum; MHV, middle hepatic vein; RIPV, right inferior phrenic vein; S1, segment I.

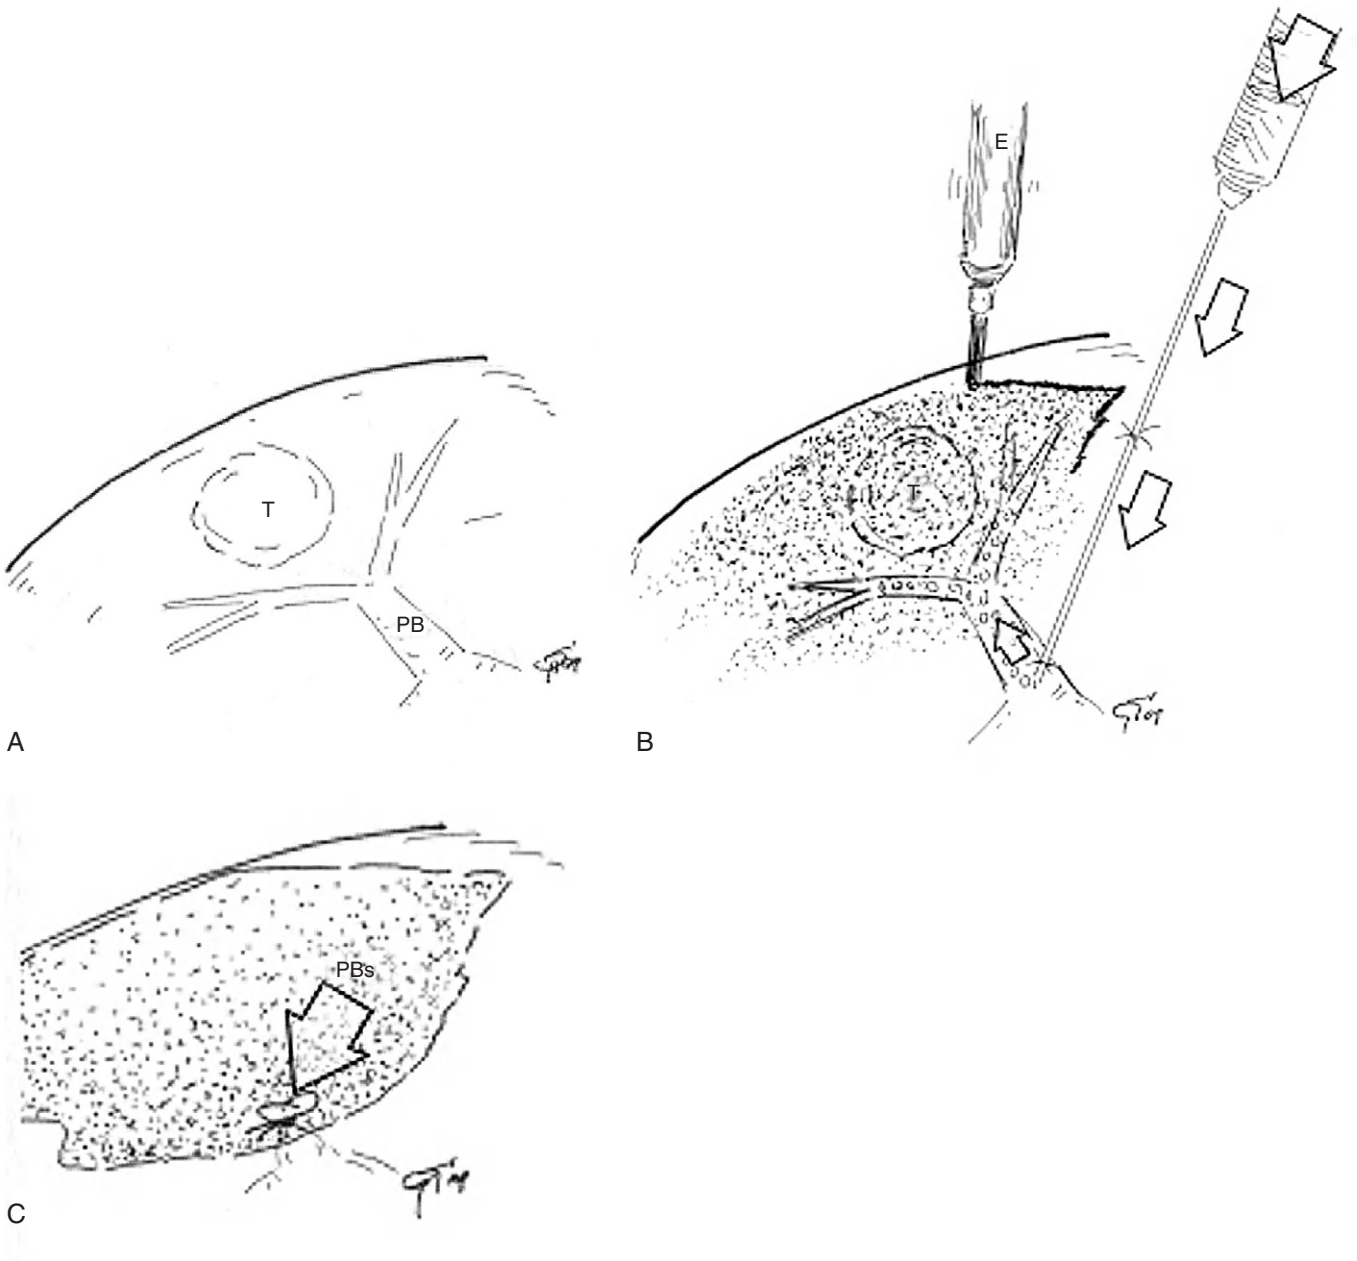

FIGURE 95.54. **A,** For a systematic subsegmentectomy, the feeding portal branch (*PB*) is identified and punctured for injecting dye, resulting in coloring of the subsegmental area. **B,** This is marked with electrocautery (*E*). **C,** Resection is carried out with the PB stump (*PBs*) visible at the end on the cut surface.

electrocautery (see Fig. 95.54B), and the resection can be accomplished fully anatomically (see Fig. 95.54C). If the nodule is located between two adjacent segments, the two portal branches afferent to the area must be punctured and injected. In this case, the deepest and most dorsal vessel must be punctured first to prevent the air bubbles contained in the dye from disturbing the US detection and puncture of the other branch. The portal branch is punctured 1 to 2 cm distally from its origin to avoid dye reflux; the direction and velocity of the infusion are controlled by IOUS. To prolong the staining, the hepatic artery at the hilum is clamped before portal branch puncture. When there are numerous and thin vessels that should be punctured, or in the case of tumor thrombus in the segmental portal branch of the segment that should be removed, the dye is injected in the portal branches afferent to the adjacent segment; this is the so-called counterstaining technique (Takayama et al, 1991).

This technique remains the most precise method for segmental and subsegmental anatomic demarcation. Its main drawback, other than the level of skill required for puncturing very small vessels, is the fact that if the ink regurgitates or is injected into the wrong portal branch, it could be difficult to identify the proper area to be removed.

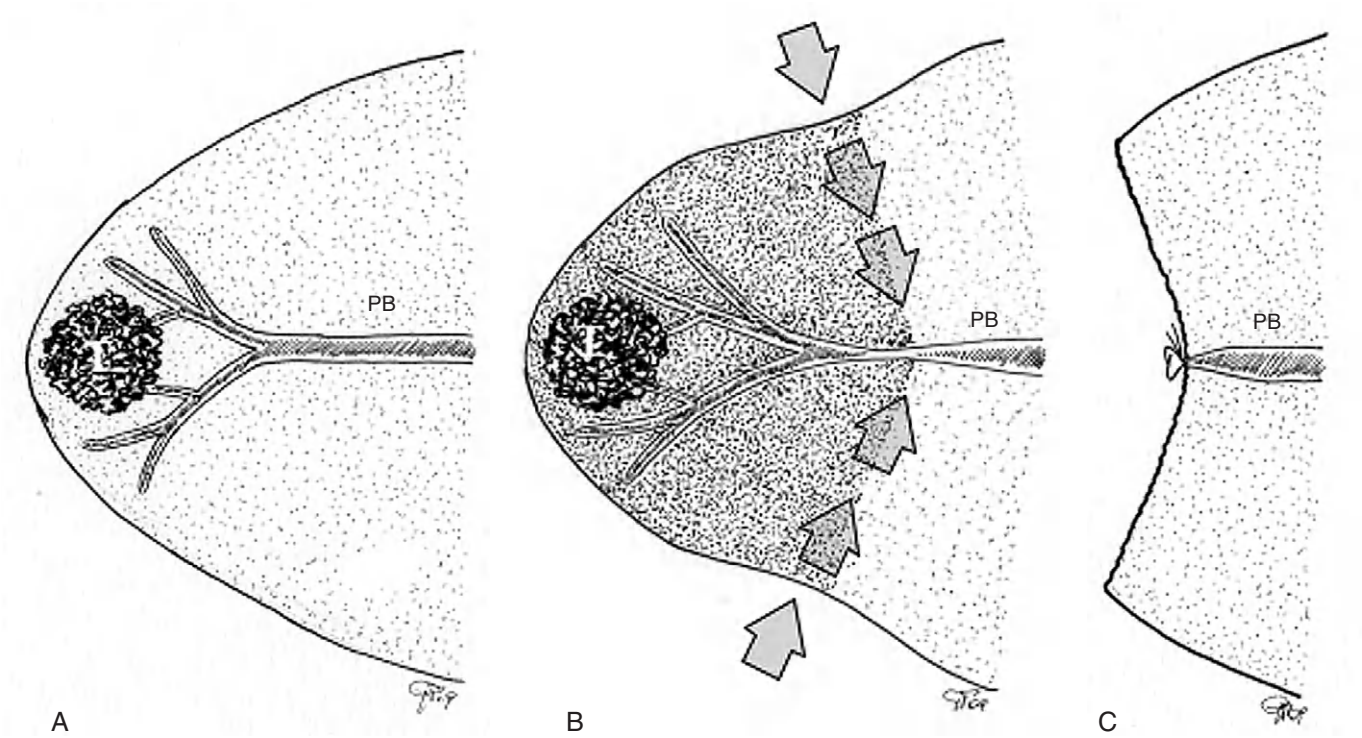

FIGURE 95.55. For subsegmentectomy by means of compression, the feeding portal branch (*PB*) is identified (**A**) and compressed at the point targeted by intraoperative ultrasound, resulting in discoloring of the subsegmental area, which is marked with electrocautery (**B**) and selectively removed (**C**).

Compression of the Portal Branch

Initially used for tumors located in the left hemiliver (Torzilli & Makuuchi, 2004), more recently it has been successfully extended in its application to any segmental location (Torzilli et al, 2010b, 2011a) and even to a sectional portion of the liver (Torzilli et al, 2009a). Conceptually, the procedure could be summarized as shown in Figure 95.55. In practice, once the feeding portal branch is identified at IOUS (Figs. 95.56A and 95.57A), it is compressed using the IOUS probe on one side of the liver and the finger on the opposite side (Figs. 95.56B and 95.57B), confirming the proper compression by IOUS real-time control (Figs. 95.56C and 95.57C); in this way, it is possible to induce a transient ischemia of the portion of the liver distally to the compression site. This portion can be marked with electrocautery, the compression is released (Figs. 95.56D and 95.57D), and the resection is carried out (Figs. 95.56E and 95.57E). This technique is simple, fast, noninvasive, and reversible, with the possibility of modifying the site of compression if necessary.

Furthermore, the compression can be used in a countercompression perspective, borrowing from the technique proposed by Takayama and colleagues (1991) of defining the adjacent segmental margins. Indeed for segments such as segment I and the superior portion of segment IV, for which direct compression of the feeding portal branch is difficult, compressing the adjacent segmental branch allows the definition of their segmental margins (Torzilli et al, 2010b; Fig. 95.58). Similarly, as is described later, this technique can be applied to disclose the margin of the right anterior section of the liver by compressing the glissonian pedicles to the right posterior section and to the left hemiliver, respectively (Torzilli et al, 2009a).

More recently, for segment VIII as a whole—and selectively for its subsegmental dorsal and ventral branches—contrary to what had appeared at the first experiences with right-sided compression of the portal branches (Torzilli et al, 2010b), direct compression of their respective feeding portal branches has been demonstrated as feasible (Torzilli et al, 2011a).

Hooking of the Portal Branch

The segmental portal branches to segment IV are generally divided into two groups: those for the superior and those for the inferior portion, but the commonest branching pattern can be recognized in only half of the patients (Onishi et al, 2000). Instead of puncture under IOUS guidance, these branches can be approached by dissecting the umbilical portion. Once exposed the vessel can be encircled with a suture and pulled, under IOUS control, to verify that it is the branch to the inferior portion of segment IV. The proper portal branch can then be ligated and divided, and the discolored area that appears on the liver surface should correspond to the inferior portion of segment IV, which can be marked with electrocautery; this is a peculiar application of the so-called hooking technique (Torzilli & Makuuchi, 2001). Furthermore, the superior portion of subsegment IV could be resected by clamping the portal branch to the inferior portion, as it is identified with the hooking

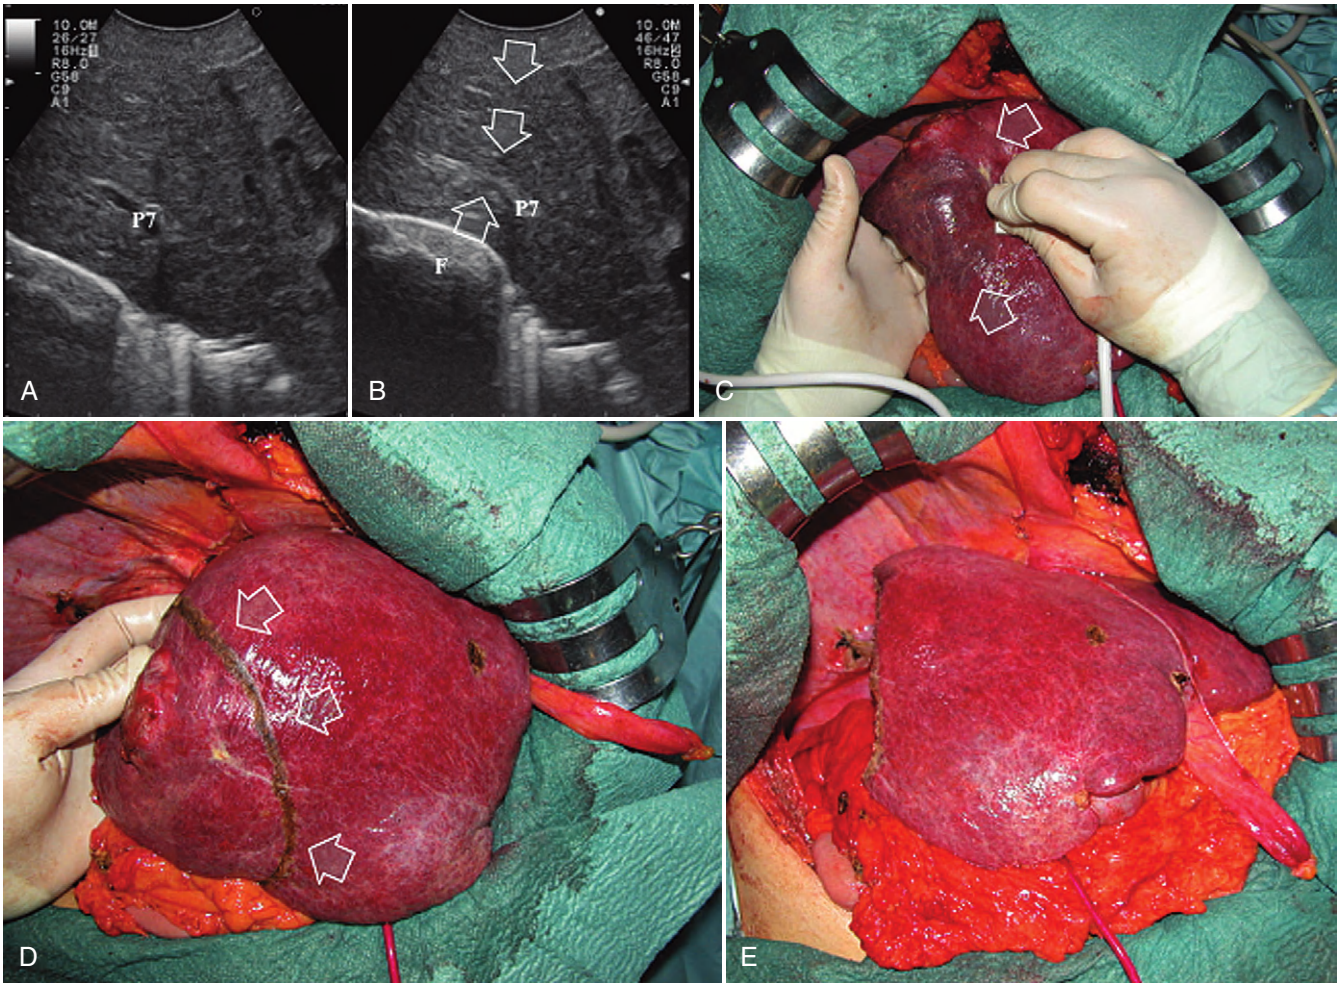

FIGURE 95.56. **A,** This intraoperative ultrasound (IOUS) scan shows the portal branch (*P7*) feeding the tumor in segment VII. **B,** Once identified under IOUS guidance, P7 compression is carried out (*arrows*) by means of the probe and the surgeon's finger (*F*) positioned on the opposite side. **C,** Compression results in discoloration of the subsegmental portion to be removed (*arrows*). **D,** The area is marked with electrocautery (*arrows*). **E,** The liver after subsegmental resection.

technique; the discolored inferior subsegment IV caudally, the plane that includes the MHV laterally, as seen on IOUS, and that marked by the falciform ligament medially delimit the area to be resected.

Other Techniques

Other methods have been proposed, such as a balloon catheter inserted transhepatically to occlude the feeding portal branch (Shimamura et al, 1986), or, more recently, the portal branch is accessed through the mesenteric vein (Ou et al, 2007). For segment VIII resection, Mazziotti and colleagues (2000) proposed the division of the liver along the main portal fissure and a subsequent intraparenchymal approach to the segment VIII glissonian pedicle. Other authors have recently suggested ablation of the feeding portal and arterial branches (Curro et al, 2009; Lupo et al, 2003; Santambrogio et al, 2008). All these alternative techniques are made less attractive by their invasive nature, and in some circumstances (Curro et al, 2009; Lupo et al, 2003; Santambrogio et al, 2008), for their irreversible damage to the target, which could imply compulsory extension of the resection area, should the first targeted vessel be incorrectly identified. This extension of the resection area, although accidental, is exactly what anatomic segmental resection seeks to avoid.

Sectionectomies (See Chapter 92)

Right Posterior Sectionectomy

As for segmentectomies, the demarcation of the sectional area to be removed is advocated. Among methods proposed for obtaining this demarcation, extrahepatic isolation of the right-sided sectional pedicles consists of careful and meticulous skeletonization of each sectional arterial and portal branch (Makuuchi et al, 1993). Alternatively, the three glissonian pedicles in their surrounding fibrous sheath could be encircled as a whole with or without the use of a hepatotomy incision (Takasaki et al, 1990). As an alternative to these established techniques, the compression technique could be applied (Torzilli et al, 2011b). The hepatic pedicle is encircled with a tourniquet but not dissected.

At IOUS, the portal pedicle for the right posterior section (segments VI and VII) is identified as well as the branches for segments VI and VII (Fig. 95.59A); the level targeted for

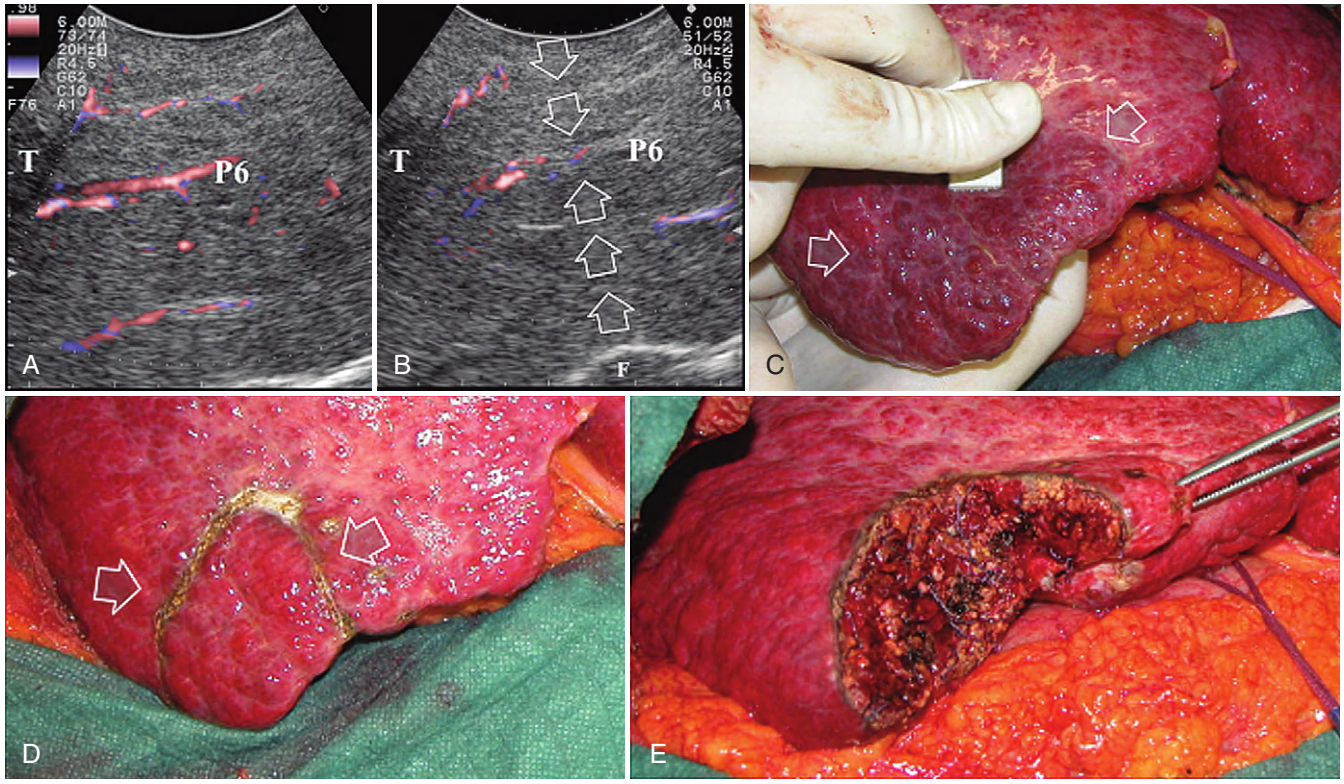

FIGURE 95.57. **A,** This intraoperative ultrasound (IOUS) scan shows the portal branch (*P6*) feeding the tumor in segment VII. **B,** Once identified under IOUS guidance, P6 compression is carried out (*arrows*) with the probe and the surgeon's finger (*F*) positioned on the opposite side. **C,** Compression results in discoloration of the subsegmental portion to be removed (*arrows*). **D,** The area is marked with electrocautery (*arrows*). **E,** The liver after subsegmental resection, which is particularly limited but anatomic.

compression is then identified (Fig. 95.59B). The surgeon's nondominant hand is put behind the right hemiliver, and the probe is positioned with the dominant hand to show the sectional portal branch at the level of interest, which corresponds to the most distal portion of the vessel in relation to its origin but proximal to the tumor to be removed.

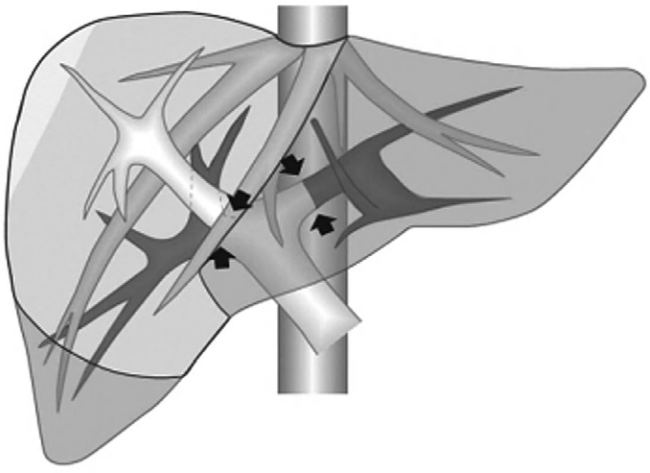

FIGURE 95.58. Countercompression sites for disclosing the right anterior section. Once marked, a right anterior sectionectomy is performed. *Dark gray areas* are those discolored by finger compression at the sites shown by the arrows. The *light gray area* is the right anterior section to be removed.

The surgeon next uses the fingertips of the nondominant hand and the IOUS probe as instruments to compress the liver bilaterally at the targeted position, resulting in compression of the sectional portal branch in the previously identified tract. When there is not a common sectional pedicle to segments VI and VII, compression is applied to the respective segmental portal pedicle as previously described. This maneuver is constantly monitored in real time by IOUS by means of the probe used for compression, and compression is maintained until the surface of the right posterior section lateral to the compression site starts to discolor (Fig. 95.59C); at this time the assistant marks the discolored area with the electrocautery device, and the compression is released (Fig. 95.59D). In this way, a three-dimensional plane has been drawn on the liver surface that passes through portal branch at the level of compression; liver resection is now carried out following that plane (Fig. 95.59E).

Right Anterior Sectionectomy

Similarly, as for the right posterior section, the hilar dissection and the encirclement of the sectional glissonian pedicles are the most commonly adopted techniques for defining the resection area in a fully anatomic manner. More recently, the countercompression technique has been applied for this purpose (Torzilli et al, 2009a). The portal pedicle feeding the right posterior section (segments VI and VII) is identified at IOUS, and the level targeted for compression is then detected just after its origin from the right portal branch (Fig. 95.60A). Demarcation of the right posterior section is carried out as described in

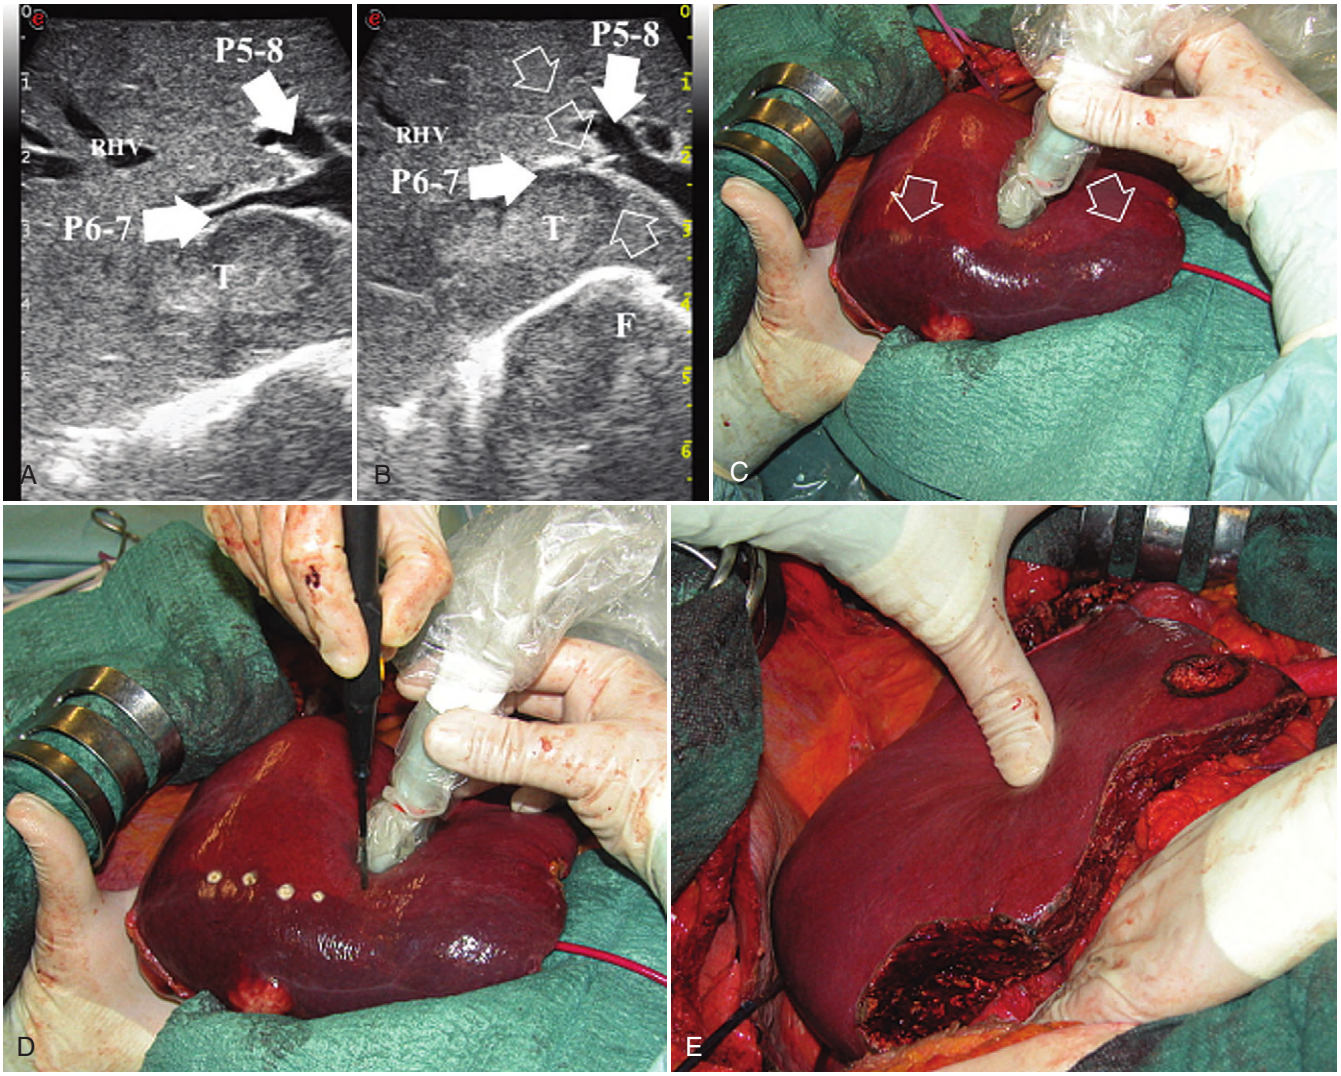

FIGURE 95.59. **A,** This intraoperative ultrasound (IOUS) scan shows the sectional portal branches for the anterior (*P5-8*) and posterior (*P6-7*) sections. **B,** To disclose the margins of the right posterior section in the eventuality of a right posterior sectionectomy, under IOUS guidance, P6-7 compression is carried out (*arrows*) with the probe and the surgeon's finger (*F*) positioned on the opposite side. **C,** Compression results in discoloration of the right posterior section to be removed (*arrows*). **D,** The area is marked with electrocautery. **E,** The liver at the end of the right posterior sectionectomy.

the previous paragraph (Fig. 95.60, B and C). Similarly, the left portal vein (LPV) is identified at IOUS, and the level targeted for compression is then identified just past its origin from the main portal vein (Fig. 95.61A); the LPV compression is carried out and is released once the Cantlie line becomes evident by left hemiliver discoloration (Fig. 95.61, B and C), and it is demarcated with the electrocautery. Once the right anterior section is defined, resection can be carried out.

Limited Resections

Selection of an anatomic or nonanatomic resection for HCC, although a controversial issue (Cho et al, 2007; Eguchi et al, 2008; Kaibori et al, 2006; Regimbeau et al, 2002; Tanaka et al, 2008; Wakai et al, 2007), is leaning in favor of the anatomic approach (Eguchi et al, 2008; Hasegawa et al, 2005; Ueno et al, 2008). Conversely, limited resection is commonly accepted as an oncologically proper approach for CLM (Sarpel et al, 2009). For limited resections, IOUS guidance plays a fundamental role; indeed, although there is no need for identifying the area of the liver fed by the portal branch to be ligated, once the tumor is identified, the surgeon can mark the border of the lesion and that of the area to be removed on the surface of the liver with the electrocautery under IOUS control. To carry out this maneuver, the flat and thin tip of the electrocautery device is positioned between the probe and the liver surface. This results in a shadow on the IOUS image that runs deeply just below the electrocautery (Fig. 95.62, A to D). In this way, it is possible to define the position of the electrocautery device with the tumor edge and consequently to mark the nodule profile on the liver surface with electrocautery and to select the safer edge for the incision. The adequacy of the marked edge can be further checked with IOUS, as the air trapped between the probe and the irregular surface of the demarcation line

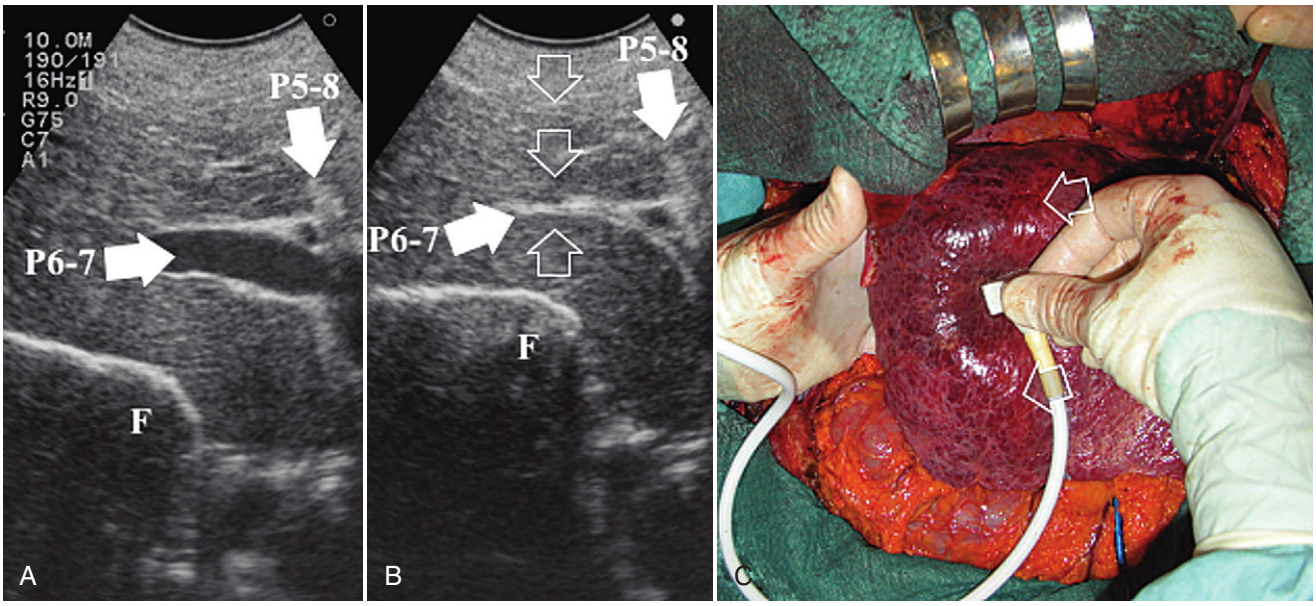

FIGURE 95.60. A, This intraoperative ultrasound (IOUS) scan shows the sectional portal branches for the anterior (*P5-8*) and posterior (*P6-7*) sections. **B,** To disclose the margins between the right posterior and right anterior sections, P6-7 compression is carried out (*open arrows*) under IOUS guidance using the probe and the surgeon's finger (*F*) positioned on the opposite side. **C,** Compression results in discoloration of the right posterior section (*arrows*).

drawn with the electrocautery on the liver surface can be visualized at IOUS, having a similar aspect compared with the images that result with the electrocautery (Fig. 95.63).

Additionally, with the probe positioned on the liver surface at the site of the resection margin previously drawn, the surgeon uses a fingertip to push at the opposite edge of the resection area (see Fig. 95.62A), and the profile of the resection area is visualized at IOUS. As a consequence, structures between the fingertip and the tumor edge can be precisely estimated, the resection area can be marked on the liver surface, and the dissection plane is visualized (see Fig. 95.62B). The main target to be obtained once the resection area is drawn on the liver surface is that of achieving at the end of the dissection the flattest and most regular cut surface (see Fig. 95.62E).

Liver Parenchyma Dissection

The main advantage provided by the resection guidance accomplished with the aid of IOUS is the modification of the traditional way to dissect the liver tissue, which was done on vertical planes to avoid the tumor exposure on the cut surface. IOUS allows the surgeon to follow the dissection plane in real time, to see it constantly in relation to the tumor edge, and then to modify its direction when needed: this is because it is possible to visualize the dissection plane on the IOUS image, which appears as an echogenic line as a result of the entrapment of air bubbles and clots between facing cut surfaces (Fig. 95.64). If the dissection plane is not clearly visible, it can be better visualized by inserting plain gauze (Fig. 95.65) or a specifically devised silicone gauze between facing surfaces. These techniques allow the surgeon to keep the proper dissection plane, and early recognition of an improper dissection plane permits its modification and avoids a possible tumor seeding. In this way, it is possible to carry out a rounded trajectory of the dissection plane around the tumor, avoiding its seeding and allowing the surgeon to spare important vascular structures; this results in more conservative but radical treatments and in a lower rate of major hepatectomies.

The artifacts that may show up on IOUS sometimes mask structures critical to the dissection plan, such as portal branches, which should be ligated or conversely respected. For this reason, to better visualize the targeted point where the portal branch should be divided, the so-called hooking technique has been devised (Torzilli et al, 1999b). When the glissonian sheath is exposed and skeletonized, it is encircled with a stitch. Under US control, the stitch hooking the exposed vessel is then gently pulled up, which stretches the portal branch slightly; this traction point is demonstrated clearly by IOUS (Fig. 95.66, A and B). If the exposed portal branch is not clearly visible because it has collapsed, the portal triad is unclamped. If the target site is correct, the portal branch is ligated and divided, and resection is completed under IOUS guidance; conversely, if the exposed vessel was not the targeted one, it is spared, and useless sacrifice of further liver parenchyma is avoided.

A practical example in which the hooking technique is used is during ventral or dorsal subsegmentectomy of segment VIII. The portal trunk to this segment may show bifurcation in its dorsal branch and ventral trunk near the origin of the portal vessel to segment V. In this situation, there is the risk of ligating and dividing the portal branch of segment V, instead of the planned subsegmental branch of segment VIII, and necrosis of segment V may occur. Under IOUS control, the hooking technique enables the identification of the branch, which was encircled, and then the surgeon can decide with certainty whether to ligate it.

This technique is also useful in case of tumor thrombus in major portal branches (Torzilli et al, 2005b). In this situation, once the portal branch is skeletonized, it is encircled with a stitch; then the stitch is gently pulled up under IOUS control, and this traction stretches the portal branch slightly, and the traction point is demonstrated clearly by IOUS (Fig. 95.67). If

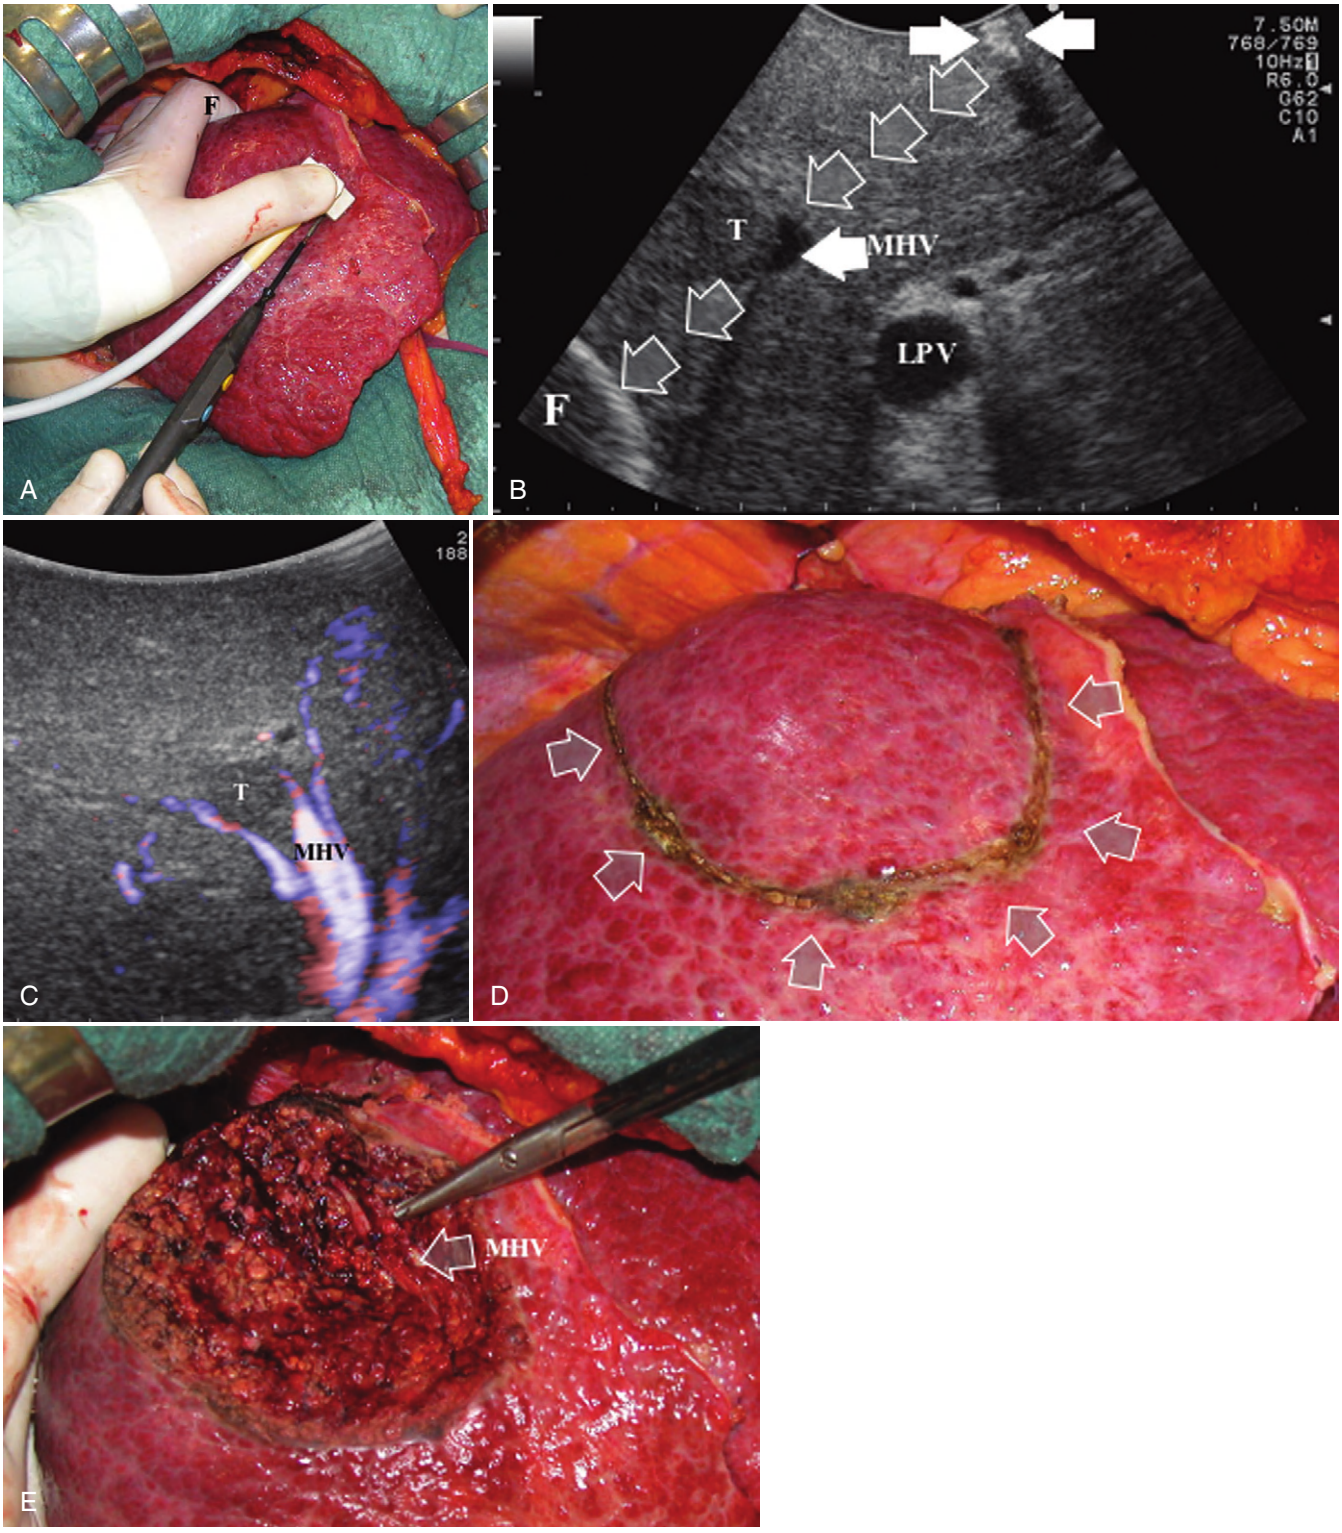

FIGURE 95.62. **A,** The electrocautery positioned between the probe, liver surface, and surgeon's finger (*F*) at the opposite edge of the resective area. **B,** Both the shadow generated by the electrocautery (*white arrows*) and the profile of the surgeon's finger (*F*) are visualized, and the surgeon can draw an ideal dissection plane (*transparent arrows*) that can be followed once the resection area is marked using these landmarks. **C,** This e-flow intraoperative ultrasound image confirms that the lesion (*T*) is in contact with the middle hepatic vein (*MHV*). **D,** The resected area is marked on the liver surface (*arrows*). **E,** Cut surface of the limited resection with exposure of the tract of the MHV, which was in contact with the lesion.

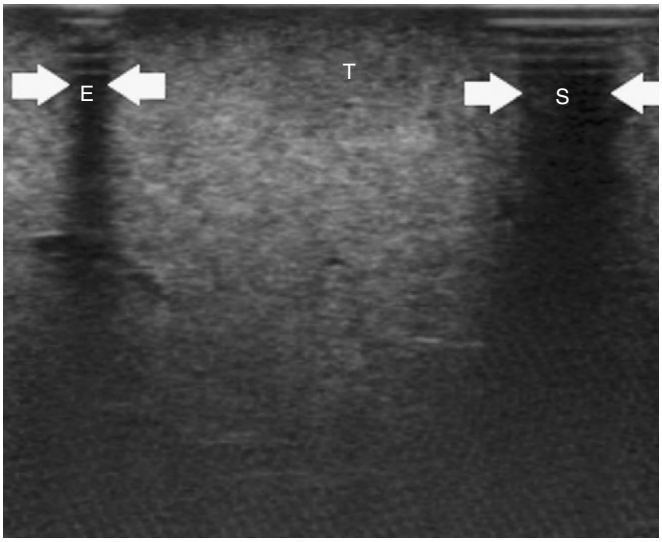

FIGURE 95.63. Intraoperative ultrasound shows both the electrocautery (*E*) and the scar (*S*). A vertical shadow is generated that allows verification of the proper margins of resection in relation to the tumor (*T*) location.

the traction point is not at the level of the tumor thrombus, it is possible to ligate the portal branch and proceed with the liver resection, being sure that thrombus will not migrate because of surgical manipulation.

During liver dissection, the backflow bleeding from the hepatic veins is an important source of blood loss, and it is one of the most important factors in determining the short- and long-term outcome; therefore limiting the backflow bleeding from the hepatic veins is a priority in liver resections. A US-guided technique has been recently described for backflow bleeding control from the RHV during right-sided liver resection (Torzilli et al, 2007a). The technique is very simple and is now applied to every hepatic vein. Once the hepatocaval confluence is exposed anteriorly (Fig. 95.68, A to C), dissection proceeds until the surgeon's fingertip is able to compress the targeted hepatic vein at its caval confluence; the effectiveness of this maneuver is checked by EF-IOUS (Fig. 95.68D to E).

Alternative Methods for Liver Dissection Guidance

In recent years, tracking systems that combine the position of the dissecting instruments and the three-dimensional (3D) liver reconstruction, based on software elaboration of the preoperative CT or MRI or the 3D US images themselves, have been proposed for dissection guidance (Chopra et al, 2008). This approach is mainly used to offer real-time and continuous guidance of the liver dissection, rather than the one warranted by IOUS guidance, which can be done repeatedly but is not providing information anyway, if dissection is not interrupted for the US check; however, up to now, data provided by a few groups are not consistent enough to disclose a real advantage of an approach that on the other hand seems rather complex. A free line between the tracking system and the trackers allocated on the US probe and the dissecting instrument used must be maintained; otherwise, data registration for navigation is interrupted. In this context, tracking systems may be optical, for which a free line of sight must be maintained between the instruments, or they may be electromagnetic, which makes them sensitive to disturbances originated by the surgical instruments.

In one of the few experiences reported, the lack of communication between elements connected via an infrared-based optical line was responsible for the failure of the navigation in 4% of those treated (Beller et al, 2007). Another problem concerning the use of these navigation systems is in the reduction of precision, once the dissection gets deeper into the liver, as a result of organ shifting and deformation that make data less reliable. This represents the major limitation of this approach, because it seems to fail to provide information exactly when more data may be needed. Indeed, with neurologic or head and neck surgery, for example, the targets are fixed, and results seem more consistent with the objectives (Hamada et al, 2005; Hohlweg-Majert et al, 2005); whereas in abdominal surgery, the mobility of the viscera do not facilitate the fixing of targets. More recently, a further modification has been introduced in the original setting in which an electromagnetic sensor is inserted into the liver under US guidance, close to the tumor to be removed (Beller et al, 2009), with the purpose of overcoming the problem of decreased navigating precision as the instrument gets deeper into the liver; however, some concerns may be raised by the further complexity of the method proposed.

Some authors are trying to overcome the problem of organ shifting and deformation during surgical maneuvers with a framework that makes feasible the updating of the 3D preoperative models with the new intraoperative data (Dagon et al, 2008). This allows us to foresee that, in the future, improvements in technology may be able to overcome the difficulties brought about by organ deformation and shifting; however, the need for adjunctive instruments in the surgical theatre—and the use and related costs of 3D US, which is somewhat more complex to interpret than two-dimensional US, even if the technical drawbacks are resolved—make unclear the advantages of the implementation of these technologies compared with the use of US guidance as it has been described here. Indeed, in expert hands, US guidance provides suitable results in terms of enhanced conservation of parenchyma in the various hepatectomies, while at the same time maintaining and somewhat improving the oncologic radicality; therefore US guidance should be considered the gold standard in terms of "navigated" liver surgery.

Postresectional Control

After nodule removal, two possibilities for specimen handling are offered by IOUS: one is the "water bath" technique, which consists of real-time control of the proper resection of the targeted nodule, verifying its complete inclusion in the specimen removed from the liver (Makuuchi, 1987; Fig. 95.69); the second is done checking the cut surface, which is refilled with saline to avoid the artifacts generated by the residual air bubbles and clots (Fig. 95.70).

In those patients in whom major resections are needed, color Doppler IOUS allows the proper positioning of the remnant liver, until the inflow and outflow are proper in terms of velocity and waveform on color Doppler US (Ogata et al, 2005; Fig. 95.71).

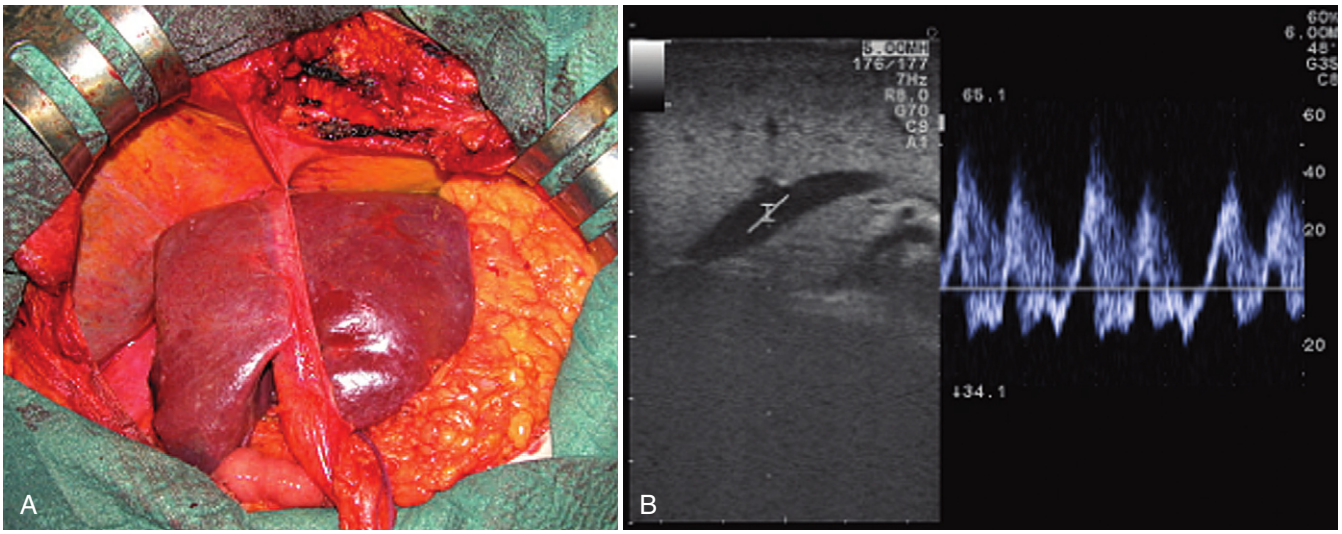

FIGURE 95.71. If a right hepatectomy is carried out (**A**), the proper repositioning of the remnant liver is performed using color Doppler to see whether the proper outflow is obtained with a triphasic wave pattern as shown (**B**).

CONCLUSIONS

IOUS is still the best method for staging the involvement of liver by tumor. The role played by CE-IOUS in this context seems relevant to enhancing sensitivity and specificity of IOUS, although this to be better evaluated. IOUS is certainly the best method for the surgeon to use to understand the liver anatomy and the relationships between tumors and intrahepatic vessels. This information is crucial for planning the resection, and in this sense, IOUS probably has the most important role in guiding the surgeon's hand in real time during the liver parenchyma dissection.

The aforementioned methods for performing an IOUS-guided resection guarantee, whenever possible, both anatomic and limited resection with a radical intent; this has consequences for both the effectiveness of the surgical treatment and for its safety. Procedures that are not guided by IOUS lead to dangerous and somewhat useless major resection or, inversely, to incomplete operations. IOUS tumor vessel classification and the related surgical policy has proven that in selected patients, it is possible to get close to the tumor burden without increasing the risk of incomplete removal and, as a consequence, of local recurrence or tumor seeding (Torzilli et al, 2005a); therefore new oncologic concepts are introduced.

For HCC, tumor exposure of the cut surface is not in contradiction with a fully anatomic resection, if it respects the oncologic requirements for this kind of tumor (see Figs. 95.32 and 95.35), and descriptions of several experiences are confirming this (Torzilli et al, 2008b; Matsui et al, 2007; Ochiai et al, 1999). Similarly, in the case of CLM, getting closer to the tumor burden under IOUS guidance, even exposing the tumor, is not only not in contradiction to the concept of radical surgery, at least in conditions otherwise not suitable to any other approach, but also does not increase the risk of local recurrence and allows survivals similar to those obtained by more conventional procedures (de Haas et al, 2008; Kokudo et al, 2002; Minagawa et al, 2000; Pawlik et al, 2005; Torzilli et al, 2009b).

In practice, this evidence suggests that with IOUS guidance, it is possible to perform conservative but radical hepatectomies, even in complex presentations, and then to enlarge the surgical indications. With this approach, the rate of major hepatectomies has been limited to about 8% in patients with tumors involving one or more hepatic veins close to their caval confluence, without performing any vascular reconstruction (Torzilli et al, 2006b); it has been limited to 4% in patients with multiple bilobar CLM, with removal of up to 49 lesions at once (Torzilli et al, 2009b).

Limitation of major hepatectomy allows resection of advanced HCC, with a less than 1% mortality rate and improved long-term outcome (Torzilli et al, 2008b). New US-guided operations have contributed to achieving these results, thus allowing technical solutions otherwise not feasible (Torzilli et al, 2008c, 2010a). Just because this approach reduces the rate of major hepatectomies, the real need could be debated for interventions such as preoperative PVE, which are adopted to prevent liver failure after removal of significant amounts of liver parenchyma (Torzilli et al, 2009c); however, this approach to liver resection, which allows the combination of widened indications and a high standard of safety, demands large incisions with extensive mobilization and complex dissection planes. These requirements run counter to the trend to use smaller incisions, such as with the anterior approach, with or without the hanging maneuver (Liu et al, 2006; Ogata et al, 2007), and in laparoscopic hepatic surgery, in which the complex IOUS-guided maneuvers described herein, and the required complex dissection planes, would be difficult to realize, at least with the same level of safety.

In spite of this, IOUS-guided liver surgery should be considered a minimally invasive procedure whose main target is the sparing of liver parenchyma, and its absolute safety is paradigmatic of what has been just affirmed. Mostly because of that, surgery can still be considered the treatment of choice for most liver tumors, in spite of the development and progresses in other local treatments, such as ablation therapies and intravascular procedures. Furthermore, this use of US

intraoperatively for expanding the indications for tumor removal is paradoxically in opposition to the trend of introducing US for guiding intraoperative tumor ablation. As a matter of fact, stressing the use of IOUS for guidance, it is possible to expand indications for HCC and CLM without risking the recurrence rates observed after ablation, even when performed intraoperatively (Abdalla et al, 2004; N'Kontchou et al, 2009; Torzilli et al, 2008b, 2009b).

From this standpoint, having IOUS in the surgeon's technical background, every effort should be focused on maximizing the capability of enhancing the hepatic surgeon's resective power, rather than for allowing ablation technique, which from the perspective of a simple alternative is undoubtedly an oncologically suboptimal shortcut. This use of US will probably improve with further improvements in contrast agents and new color-flow modalities, which up to now have shown more potential. Conversely, such potentials can be anticipated and will no doubt be consolidated by the technical evolution and consequent diffusion of the navigation systems, which for now have proven too costly and are limited in number to those centers involved in relevant clinical trials.

For all these reasons, IOUS should be in the armamentarium of every hepatic surgeon, and in this sense, the present and future challenge should be to train young surgeons in the use of US-guided technique in the course of their educational process. Only with this perspective can an effective diffusion of US technologies in the practice of hepatic surgery be definitely and fully established.

CHAPTER 96

Liver and pancreas transplantation immunobiology

David A. Bruno, Kiran K. Dhanireddy, and Allan D. Kirk

MAINTENANCE MINIMIZATION, IMMUNOSUPPRESSANT WITHDRAWAL, AND TOLERANCE

Allotransplantation, the transfer of tissues between genetically nonidentical individuals, has been shown to provide relief from incurable liver diseases and type 1 diabetes; however, unless some modification of the recipient immune system is made, transplanted organs are invariably destroyed through a process broadly known as *rejection*.

Over the past 5 decades, the ability to manipulate the immune response has become increasingly selective and less morbid. Through a general understanding of alloimmunity and the unique properties of the liver and pancreas, transplantation results have steadily improved (U.S. Organ Procurement and Transplantation Network, 2009). This chapter provides an overview of the principles governing immune management of liver and pancreatic transplant recipients, highlighting agents and strategies generally available for clinical use.

GENERAL CONSIDERATIONS: SPECIFICITY AND CONTEXT

Allograft rejection is mediated by the elements of physiologic immunity but stems from a nonphysiologic practice: transplantation. As with most immune responses, rejection requires a specific recognition event and a context that signifies that this recognition warrants a response.

Immune recognition is mediated through one of two types of lymphocyte receptors, the T-cell receptor and/or immunoglobulin. Immune specificity is dictated by the ability of these receptors to bind a suitably complementary epitope. A cluster of highly polymorphic genes on chromosome 6, known as the *major histocompatibility complex* (MHC; or human leukocyte antigen [HLA] in humans), governs the recognition of cell-based antigens. Proteins produced from polymorphic genes have the same basic structure but differ in detail. The role of these molecules differs between physiologic and transplant immunity, as will be described below.

The context of an immune response is governed through another set of receptors known as *costimulation receptors*. Broadly speaking, these receptors provide signals that determine whether antigen recognition should evoke an immune response and whether that response should be aggressive or attenuating; these receptors are also involved in the mechanisms of response termination, ensuring that immune responses are contained within physiologic parameters. By separating the signals for specificity and appropriateness, the immune response to pathogens and allografts can be tightly regulated and finely manipulated.

Typically, the ligands for costimulation receptors are most prominently expressed on professional antigen-presenting cells (APCs), the role of which is to initiate and sustain an immune response. The interactions between APCs and lymphocytes usually take place in lymphoid organs, such as the spleen or lymph nodes. The requirement for APCs and the necessity for secondary lymphoid organs provide additional opportunity for regulation and lessen the chance for autoimmune responses.

PHYSIOLOGIC IMMUNITY

The immune system developed to protect the body from pathogens, not to mediate transplant rejection. Although alloimmunity and physiologic immunity differ, it is critical to understand the components of alloimmunity in their physiologic roles.

The immune system is typically divided into two complementary arms, *innate* and *acquired*. The innate immune system recognizes general motifs that universally represent pathologic states, such as ischemia, necrosis, trauma, and nonhuman cell surfaces (Dempsey et al, 1996; Fearon & Locksley, 1996; Matzinger, 1994, 2001). The acquired immune system distinguishes specific pathogens through antigen presentation and recognition. Both systems interact to maintain overall

homeostasis. Typically, innate responses localize acquired responses to sites of pathologic processes and are less overtly regulated. In contrast, acquired immune responses lead to carefully regulated destruction of antigen-expressing tissue. The regulatory checks on acquired immunity prevent autoimmunity and uncontrolled lymphocyte proliferation. It is important to recognize that the acquired immune system is tailored for the individual based on each person's unique MHC makeup. Evolutionarily, this diversity reduces the chance that any single pathogen can evade all individuals within a population; however, this also means that one person's acquired immune response may not respond appropriately when placed in the context of another person's MHC.

Innate Immunity

Receptors of innate immunity are cell bound on macrophages, neutrophils, and natural killer cells, and they circulate freely in the form of complement (Dempsey et al, 1996; Fearon & Locksley, 1996; Wright et al, 1990). Innate immunity is limited in specificity, and it retains broad reactivity to lipopolysaccharide (LPS) and components of pathogenic organisms. Importantly, the receptors of innate immunity are conserved between individuals and, in general, function similarly in physiologic and transplant situations. Once activated, the innate immune system initiates cytolytic pathways and recruits the acquired immune response.

The complement cascade is the primary mediator of cytolysis, and the byproducts of complement, along with phagocytic cells, signal initiation of acquired immunity (Baldwin et al, 2010; Wasowska et al, 2007). Platelets also have been increasingly recognized as serving an innate immune role through the release of chemotactic proteins and other immunostimulatory molecules (Kirk et al, 2009). Professional APCs not only engulf cells coated with complement but also those bearing foreign carbohydrate moieties (Hart, 1997).

Toll-like receptors (TLRs) have also been recognized as important for innate APC activation. This highly conserved family of receptors binds to pathogen-associated molecular pattern motifs commonly expressed on invading pathogenic organisms (Akira & Takeda, 2004). Engulfed cells are processed by the APC into protein fragments and are expressed on the cell surface bound to MHC molecules. Subsequently, T cells that are specific for these peptides can recognize their cognate antigens and become activated. Interestingly, the TLRs expressed in the liver differ from those expressed in the periphery and tend to be less responsive to ambient LPS (Hart, 1997). This is likely an adaptation to portal bacteremia and is thought to make the liver more tolerant of minor perturbations that would evoke an innate response in other organs.

Acquired Immunity

Specific recognition is the hallmark of the acquired immune system. The lymphocyte receptors (T-cell receptor and antibody) have evolved to distinguish an extremely diverse group of antigens. Furthermore, antigen recognition induces physiologic changes in the recognizing cell that lowers its threshold for subsequent encounters and leads to the phenomenon of *immunologic memory,* the more rapid response to subsequent antigen encounters (Ahmed & Gray, 1996). T-cell receptors (TCRs) bind peptide antigens that have been processed and presented in combination with MHC, and B-cell immunoglobulins bind antigens in their native conformation at a site remote from the B cell.

Cellular Immunity

Formation of the TCR is fundamental to understanding its function (Cooper, 1987; Davis & Bjorkman, 1988). T cells are formed in the bone marrow and fetal liver and migrate to the thymus during development. After entering the thymus, T cells undergo rearrangement of the DNA that encodes the TCR (Gill & Gulley, 1994). Each gene rearrangement results in generation of a TCR with specificity restricted to one epitope or structurally similar epitopes. The sum of all random TCR gene rearrangements generates TCRs with approximately 10^9 specificities, essentially all possible combinations of MHC and peptide antigen; if these T cells were released into the periphery, they would mediate fatal autoimmunity. Accordingly, thymic selection eliminates those cells likely to evoke autoimmunity (Bevan, 1997; Kappler et al, 1987).

The initial phase of thymic selection is the interaction of developing T cells with the MHC that expresses cortical thymic epithelium. These T cells express the accessory cell surface markers CD4 and CD8, which allow for stronger binding of TCR to MHC. If binding does not occur to the self MHC available on the thymic epithelium, the cells are eliminated, as they would be unable to interact with self cells and thus would be nonfunctional in the periphery. This process is known as *positive selection.*

Thus all surviving T cells bind to self MHC. The developing T cells then move into the thymic medulla, where either CD4 or CD8 expression is lost. If binding to the self MHC in the medulla results in a high-affinity interaction, these T cells are also eliminated, a process known as *negative selection.* Therefore, the majority of cells released from the thymus bind to self MHC without becoming activated; however, autoreactive cells occasionally escape thymic selection and serve as the etiology of diseases such as sclerosing cholangitis (see Chapter 41), autoimmune hepatitis (see Chapter 97A), and type 1 diabetes (see Chapter 101); thus additional regulation is required to prevent autoimmunity. In fact, a single interaction of TCR and antigen-bearing MHC is inadequate to trigger T-cell activation; rather, approximately 8000 TCR-MHC interactions over a period of several hours are needed to initiate activation (Kumagai et al, 1987; Rothenberg, 1996; Viola & Lanzavecchia, 1996), which further limits the likelihood of autoimmunity. Costimulatory molecules markedly alter this need for redundancy, and we discuss this below.

Immune responses are also regulated by accessory cell surface molecules that limit the types of cells with which a T cell can interact (Leahy et al, 1992; Saizawa et al, 1987). Parenchymal cells of the body express class I MHC and display internal cellular peptides within the binding groove of this molecule. T cells charged with destruction of diseased or infected parenchymal cells express CD8 that stabilizes TCR ligation with class I MHC. These cells are termed *cytotoxic T cells.* CD8+ T-cell killing can occur through either Ca^{2+}-dependent secretory mechanisms or Ca^{2+}-independent direct cell-contact mechanisms (Berke, 1995).

Hematopoietic cells express class I and class II MHC. Class II MHC displays peptide fragments that have been phagocytized from the extracellular space (Germain, 1994; Monaco,

1993). CD4 stabilizes the TCR–class II MHC interaction. CD4+ cells interact with dendritic cells, macrophages, and in some cases activated endothelial cells that display antigen. In addition, the resting sinusoidal endothelial cells of the liver have the ability to present antigen to T cells, making the liver an organ with considerable ability to evoke or suppress an immune response (Knolle & Gerken, 2000). The interaction between CD4+ T cells and APCs produces APCs that have the ability to martial CD8+ T cells (Lanzavecchia, 1998; Ridge et al, 1998). This process is mediated through upregulation of APC cell surface molecules known as *costimulation receptors,* thus APCs initiate an immune response but require CD4+ T cells to activate the primary effector arm of the acquired immune system—the CD8+ T cells.

An additional subset of T cells, regulatory T cells (T_{reg}), further control promiscuous immune responses. Regulatory T cells have the ability to suppress cytokine secretion, adhesion molecule expression, and costimulatory signaling. The most extensively studied population of T_{reg} cells express CD4 and CD25, the high-affinity α-chain of the interleukin (IL)-2 receptor (Wood & Sakaguchi, 2003). Animal models have suggested that these cells play a critical role in controlling immune activation (Baecher-Allan et al, 2001; Wood & Sakaguchi, 2003). The prevailing evidence suggests that T_{reg} is responsive to established inflammation, rather than serving a prophylactic role in preventing inflammation; however, harnessing the power of T_{reg} to quell counteradaptive immune responses such as rejection is an ongoing area of research in autoimmunity and alloimmunity.

Humoral Immunity

B cells recognize antigen in its native, unprocessed form (Cambier et al, 1994). When antigen binds to two cell surface antibodies, the antibodies are brought together in a process known as *cross-linking,* which stimulates B-cell proliferation and differentiation into an antibody-secreting plasma cell. The activation threshold for a resting B cell is relatively high, as it is for T cells. As with TCR recognition, costimulation can lower this threshold substantially (Tedder et al, 1994). B cells also have the ability to internalize antigen bound to surface immunoglobulins and process them for presentation to T cells along with costimulation molecules (Lederman et al, 1992).

Antibody structure is determined in the bone marrow through mechanisms similar to those that govern the generation of TCR diversity in the thymus (Gill & Gulley, 1994; Hozumi & Tanegawa, 1976). Five different heavy-chain loci (μ, γ, α, ε, and δ) on chromosome 14 and two different light-chain loci (κ and λ) on chromosome 2—each with V, D and/or J, and C regions—are brought together randomly by the RAG-1 and RAG-2 apparatus to form a functional antigen receptor (Kim et al, 2000). The basic antibody structure consists of two identical heavy chains and two identical light chains. The type of heavy chain used dictates the immunoglobulin (Ig) type: IgM, IgG, IgA, IgE, or IgD. The overall structure of the antibody results in two identical antigen-binding sites and a common region, the Fc portion. Bound antibody triggers activation of the complement cascade (Baldwin et al, 1995). In addition, most phagocytic cells have receptors for the Fc portion of IgG, allowing them to actively engulf antibody-coated cells.

Unlike the TCR, B-cell immunoglobulin loci undergo alteration after B-cell stimulation to improve the functionality of the secreted antibody. *Isotype switching* is the process of shifting from the initial heavy-chain IgM to one of four types to improve function and specialization. IgG is the most significant soluble mediator of opsonization and is the dominant antibody produced in response to alloantigen. IgA is important in mucosal immunity, IgE is involved in mast cell–mediated immunity, and IgD is primarily cell bound. After a B cell is activated, the specific D and J regions of the used heavy- and light-chain genes undergo random alterations of the antigen binding site. The resultant B cell clones have altered antigen affinity, hence the term *affinity maturation* (Griffiths et al, 1984); those clones that have higher affinity for the target antigen have a selective survival advantage and form the basis for a more vigorous response on reexposure to the antigen.

Mediators of Context: Costimulation and Cytokines

Isolated TCR binding with an MHC-peptide complex or antibody ligation with an antigen is not usually sufficient for lymphocyte activation. Receptor-ligand pairs on T and B cells and APCs, known as *costimulation receptors,* determine the character of the T-cell response (Fig. 96.1; Allison & Krummel, 1995; Chambers & Allison, 1997; Crawford et al, 2006). The type of costimulatory signal received by the lymphocyte determines whether the cell will become activated, remain quiescent, die, or become resistant to subsequent immune stimulation.

The biology of T-cell costimulation is substantially more developed than that of B cell costimulation. Examples of T-cell costimulation receptors include CD28 and CTLA4 (CD152). CD28 promotes T-cell activation and leads to the expression of CTLA4 that then promotes downregulation of the T-cell response; thus activation typically begets deactivation. The B7 molecules, CD80 and CD86, are the ligands for CD28 and CTLA-4 on professional APCs. Although B7 can bind to either receptor, their affinity for CTLA-4 is much greater; when B7 is in limited supply, the higher affinity interaction with CTLA-4 predominates. Because B7 molecules are not expressed by normal tissues, CD8+ T-cell interaction with class I self MHC does not elicit a proliferative response, rather it reinforces quiescence of autoreactive T-cell clones; thus in the absence of activated APCs, presenting antigen in the context of high concentrations of costimulatory molecules on the cell surface, T-cell activity is typically suppressed.

Although the mechanisms of costimulation have not been completely elucidated, it is known that binding of CD28 allows more efficient T-cell signal transduction. Through CD28-B7 interactions, the number of binding events required to trigger activation of a T-cell decrease from 8000 to 1500 (Rothenberg, 1996; Viola & Lanzavecchia, 1996). In contrast, when CTLA-4 binds B7, the T cell becomes incapable of producing IL-2 during the encounter and even in subsequent interactions (Blair et al, 1998). The CD19-CD21 complex provides comparable control of antigen receptor binding for B cells (Tedder et al, 1994).

Additionally, costimulation is mediated through another pair of receptors: CD40 found on dendritic cells, endothelium, B cells and other APCs, and CD154 on T cells and platelets (Armitage et al, 1992a, 1992b; Clark & Ledbetter, 1986; Noelle et al, 1992; Henn et al, 1998). The ability of APCs to stimulate a cytotoxic T-cell response is markedly augmented by the effects of CD40 binding. Following CD40 ligation, activating cytokines are released, and B7 molecules are upregulated (Bennett

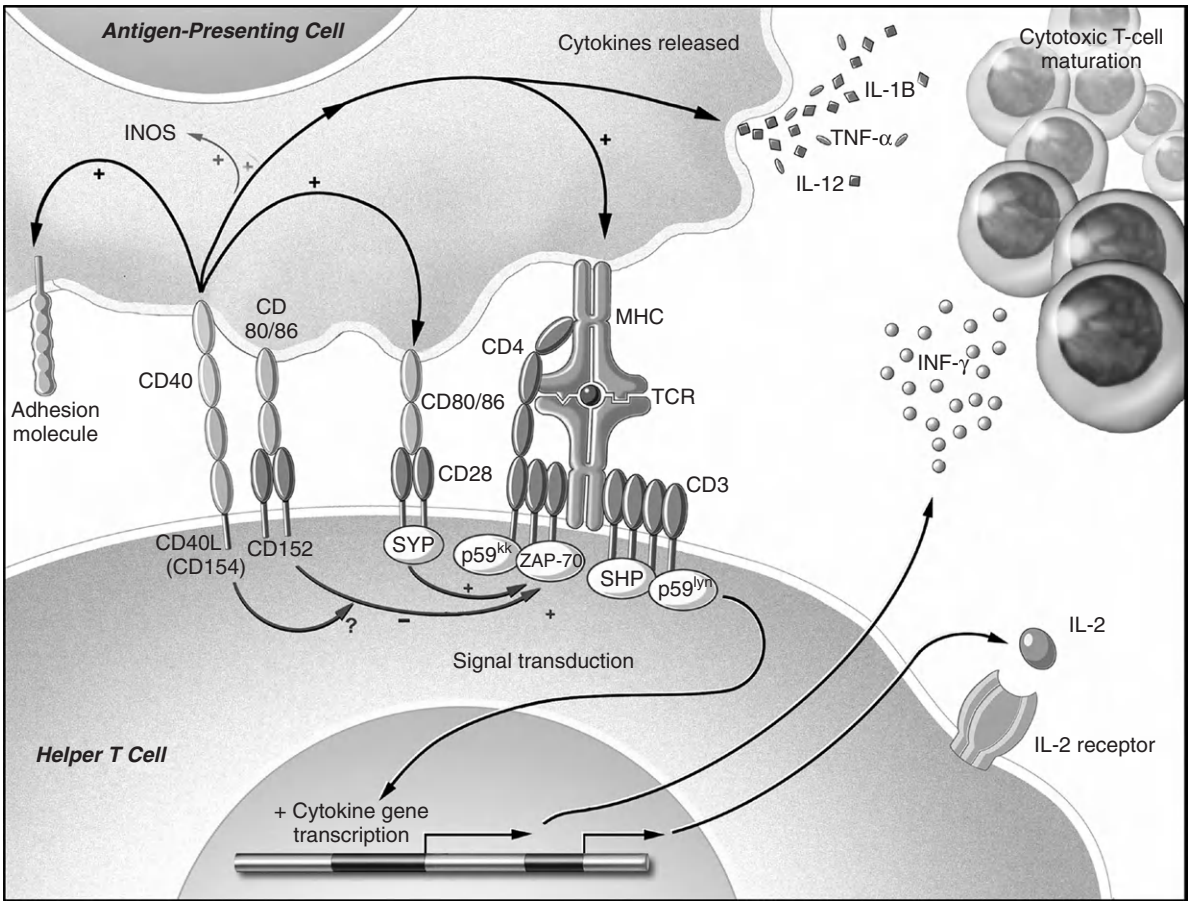

FIGURE 96.1. T-cell interactions with an antigen-presenting cell (*APC*). The T-cell receptor (*TCR*) is bound to class II major histocompatability complex (*MHC*) with the CD4 accessory molecule stabilizing the interaction. Depicted are selected costimulatory molecule interactions and the resultant effects on cytokine secretion and signal transduction. For example, CD40 ligation on the APC results in the induction of many critical APC functions, including increased MHC and B7 expression and cytokine secretion. Increased B7 expression allows CD28-positive regulation to override the negative regulation of CD152 (CTLA-4). This potentiates TCR signal transduction through CD3 and results in interferon (*IFN*)-γ and interleukin (*IL*)-2 synthesis. IFN-γ, along with APC-secreted cytokines, promotes cytotoxic T-cell maturation. IL-2 promotes T-cell proliferation in an autocrine fashion. INOS, inducible nitric oxide synthetase; TNF, tumor necrosis factor.

et al, 1998; Schoenberger et al, 1998). CD154 is upregulated after TCR ligation and provides positive feedback to the APC. In addition, CD154 is found in and released by activated platelets at sites of endothelial injury (Henn et al, 1998); therefore sites of trauma that recruit platelets create an environment of activating costimulatory molecules, thereby bridging the innate and acquired immune systems (Czapiga et al, 2004).

Direct cell-cell contact is not the only means by which immune cells communicate. Soluble mediators of communication known as *cytokines,* or *interleukins,* are polypeptides that are released from many cells; they can either activate or suppress adjacent cells (Arai et al, 1990), and the pattern of cytokine expression is thought to influence the resultant type of T-cell response (Mosmann et al, 1986; Mosmann, 1991). Once activated, T cells have been described by one of two cytokine-secretion phenotypes (see Chapter 10): cytotoxic T-cell responses are characterized by expression of interleukin (IL)-2, IL-12, IL-15, and interferon (IFN)-γ and are known as *Th1 cells;* T cells that promote humoral or eosinophilic responses are characterized by secretion of IL-4, IL-5, IL-10, and IL-13 and are known as *Th2 cells.*

In addition to cytokines, other soluble mediators of inflammation are capable of promoting increased blood flow and improved exposure of an area of injury to innate and acquired immune elements. It has been recently suggested that the APCs of the liver are more efficient in generating Th2 responses and that this may be a mechanism by which liver allografts avoid late cellular rejection.

TRANSPLANT IMMUNITY

T-cell responses to allogeneic organs are largely the result of nonphysiologic TCR-MHC interactions. T cells are initially selected to bind to self MHC and are then eliminated, if that binding event leads to activation; however, this sequence of events does not preclude the survival of cells that, through chance, bind to the MHC molecules of another individual, one with inappropriate affinity. The discrepancies between self TCR selection and allo-MHC interactions are the basis for most transplant recognition. This nonphysiologic recognition provides the opportunity for a detrimental immune response but does not mandate it in the absence of additional contextual

requirements for immunity-like costimulation; thus alloimmunity is more likely than autoimmunity but is not mandated in the absence of costimulation, innate immunity, and other factors that elicit a physiologic immune response.

Most of the significant sequence polymorphism of MHC is located in the areas of the molecule that interact with the TCR, and individual variation in the sequence at the MHC-TCR interface defines alloreactivity. The lack of recipient T-cell thymic education with donor MHC leads to a nonphysiologically high frequency of alloreactive peripheral T cells. Many of these cells are crossreactive with antigen encountered during prior viral exposures, or even with autoantigens, as in the case of autoimmune disease. This is known as *heterologous immunity,* and it results in a situation whereby recipients have allospecific memory without having been exposed to the alloantigen (Adams et al, 2003). Thus a person's immune response to a donor is the product of the individual's MHC makeup and past immune exposures. This can lead to vigorous early rejection in apparently nonsensitized recipients.

T cells recognize alloantigen via their TCR in two distinct ways: either directly, by binding to donor MHC on transplanted tissues in the presence of donor costimulation, or indirectly, through self APC that has phagocytized and processed alloantigens to be presented, bound to self MHC and costimulation (Rogers & Lechler, 2001). In the case of transplanted organs, surgical trauma and ischemia exacerbate the potential for T-cell activation by causing class I and class II MHC upregulation (Gerritsen & Bloor, 1993). In addition, adhesion molecules and costimulation molecules are upregulated perioperatively (Takada et al, 1997; Hoffmann et al, 2002).

Initial T-cell binding to donor cells is nonspecific, mediated by adhesion molecules upregulated during donor cell activation (Fuggle & Koo, 1998). CD40 on donor APCs and endothelial cells is important in mediating cell activation in this setting via CD154 on T cells and activated platelets (Henn et al, 1998). Following nonspecific adhesion, MHC recognition occurs in the relatively high costimulation environment induced by surgical trauma and ischemia (Takada et al, 1997). Once alloreactive T cells are activated, they secrete cytokines, including IL-2 and IFN-γ, and they stimulate APCs to secrete IL-12 (Arai et al, 1990; Kirk et al, 1995; Krams et al, 1992). The resultant cytokine milieu recruits more T cells to the site of injury and potentiates clonal expansion. Secretory and cell contact–dependent mechanisms, perforin/granzyme and Fas mechanisms, respectively, are involved in T-cell cytotoxicity within the graft, resulting in graft destruction (Strehlau et al, 1997). Although acute rejection is the result of T-cell activation, antibody responses accompany many episodes. Cellular and soluble components of immunity mediate multiple distinct clinical rejection syndromes through cytokine mediated toxicity, cellular cytotoxicity, and direct effects of antibody and complement.

Clinical Rejection Syndromes

Hyperacute Rejection

Hyperacute rejection (HAR) is caused by donor-specific antibody that exists at the time of transplantation as a result of prior exposure to donor antigens or to antigens with crossreactivity. It develops precipitously within minutes to hours after graft reperfusion. Typically, HAR is avoided by confirming ABO compatibility and performing a crossmatch using techniques that detect donor-specific antibodies. When clinically relevant donor-specific antibodies are detected, graft survival is significantly decreased for most organ types (Noreen et al, 2003); however, the liver has long been regarded as relatively resistant to HAR, and crossmatching is often done only retrospectively (Neumann et al, 2001). Actually, the rates of acute rejection and long-term liver survival are similar among groups with a positive or negative crossmatch; this does not hold true for ABO-incompatible liver allografts (Egawa et al, 2004).

The role of antibody in liver transplantation remains an area of investigation at present. Unfortunately, the pancreas does not have similar resistance to HAR, and a positive crossmatch represents an absolute contraindication to pancreas transplantation. Although high titer antibodies mediate rapid graft injury, chronic exposure to lower titer antibody results in indolent graft damage, particularly in the case of the pancreas. The role of chronic alloantibody in liver transplantation remains controversial but likely mediates some degree of graft injury over time. Autoantibody directed against nonpolymorphic determinants of a graft is increasingly being recognized as detrimental in pancreas transplantation with recurrent β cell–specific autoimmunity responsible for at least some late graft loss after pancreas transplantation (Vendrame et al, 2010). Recurrent autoimmunity is also relevant in autoimmune hepatitis (Hytiroglou et al, 2009).

Acute Rejection

Acute rejection is most common between 4 days and 6 months after transplantation, and rejection that occurs during this time is considered *early acute rejection;* acute rejection after 6 months is considered *late acute rejection.* Liver allografts undergo acute rejection at a rate of approximately 24% to 47% (Fisher et al, 2004; Neuhaus et al, 2002; Wiesner et al, 2001), whereas pancreas allografts in the modern era (post 1995) undergo acute rejection at a rate of approximately 15% to 30%. These differences reflect a tendency toward less immunosuppression in liver patients, because the liver tolerates rejection better, perhaps because damaged parenchyma can regenerate. Also, liver rejection is more easily diagnosed than pancreas rejection through biopsy and serum enzyme measurements.

In both organs, acute rejection evolves over a period of days to weeks. After activation by either direct or indirect allorecognition, T cells infiltrate the allograft and initiate organ destruction through cytolysis and endothelial and ductular damage. Much of the acute graft dysfunction is likely mediated through the effects of macrophage-derived inflammatory cytokines that hinder parenchymal function without necessarily causing cell death (Girlanda et al, 2008), thus prompt treatment has the potential to quell the rejection prior to direct T-cell–mediated cytotoxicity. Usually acute liver allograft rejection is also accompanied by graft and peripheral eosinophilia (Barnes et al, 2003).

Early detection of acute rejection is critical to facilitate intervention prior to permanent T-cell–mediated parenchymal damage; therefore unexplained hepatic dysfunction should prompt a graft biopsy. In the case of pancreas allografts, usually no direct biochemical evidence of rejection is present. If the transplantation was performed with a kidney, rejection of the kidney precedes or signals concomitant pancreas rejection in approximately 80% of patients. In transplantations of pancreas alone, fever, abdominal pain, allograft tenderness, and elevations in serum amylase or lipase may be signs of rejection; however, many rejections occur without early symptoms (Stratta

et al, 1996). Hyperglycemia is a late complication in pancreas rejection, because acinar cells reject prior to β cells.

Prompt recognition of acute rejection is imperative, because prolonged rejection allows for recruitment of multiple arms of the immune system and consequently results in decreased efficacy of antirejection therapies directed against T-cell responses. T-cell–specific therapies can resolve acute rejection episodes in most cases, and steroids are the first-line agent in most centers. Typically, early acute rejection episodes have a negative impact on the long-term survival of an allograft, although the liver is relatively resistant to this effect (Dousset et al, 1998). In fact, even late acute rejection in liver transplantation has not been shown to influence long-term graft function (Junge et al, 2005). This greatly contrasts both early and late acute rejection episodes in pancreas transplantation, which have repeatedly been shown to be deleterious to long-term graft survival (Reddy et al, 2001; Tesi et al, 1994).

Chronic Graft Loss

The causes of chronic graft loss remain poorly characterized (Libby & Pober, 2001). Although called *chronic rejection*, it likely has nonimmune components and immune origins. Evolving over the course of months to years, chronic graft dysfunction remains resistant to conventional immunosuppressive therapies; regardless of the transplanted organ, it develops as fibrosis with modest lymphocytic infiltration. Monocytic and dendritic cell infiltrates predominate, and destruction of epithelial and endothelial structures is progressive.

Many aspects of chronic graft loss relate to the events surrounding transplantation, such as ischemic injury. In the liver, chronic graft loss manifests as *ductopenia*, or *vanishing bile duct syndrome* (Inomata & Tanaka, 2001), typically defined as a condition wherein less than 50% of portal triads contain bile ducts (Demetris et al, 1998). The rate of chronic graft loss is far slower for liver grafts than for other organs, likely because of the ability of the liver to regenerate following subtle injury. As the technical challenges of pancreas transplantation have been corralled, more grafts are being lost to chronic rejection (Humar et al, 2003), a significant portion of which may be related to recurrent autoimmune diabetes.

IMMUNOSUPPRESSION

To date, no single agent has been discovered that effectively prevents allograft rejection, although liver transplant recipients can often be weaned over time to a single-drug regimen. Similarly, all manipulations that limit rejection also increase susceptibility to infection and malignancy. No immunosuppressant is allograft specific; therefore the rational selection of immunosuppressants involves using multiple synergistic agents to prevent rejection without simultaneously crippling the recipient's defenses. Characteristically, liver allografts typically require less immunosuppression than other organs (Ramos et al, 1995). This has been proposed to be a function of the APCs in the liver, the sheer size and antigenic load of the liver, and its regenerative capacity. Indeed, recent evidence indicates that 10% to 20% of liver transplant recipients can eventually be withdrawn from all immunosuppressive drugs over a period of years (Martinez-Llordella et al, 2008). Importantly, no immunosuppressive regimen has clearly established itself as superior, and the therapies chosen remain variable from one center to another.

The immune system is most prone to reject an allograft perioperatively because of the surgical and ischemic injury associated with transplantation; therefore the most intense immunosuppression is given during the weeks that follow transplantation. A period of rigorous immunosuppression at the time of transplant is known as *induction therapy* (Kirk, 2006), which typically consists of T-cell–depleting strategies that, while effective, are too toxic to be administered long term. Maintenance immunosuppression is less potent but can be given chronically to prevent acute rejection for the life of the transplant recipient. Finally, agents used to halt ongoing rejection are known as *rescue agents*. The sites of action of various immunosuppressive agents are illustrated in Figure 96.2.

Corticosteroids

Corticosteroids have been a mainstay of transplant immunosuppression for over 40 years (Starzl et al, 1963). At low doses, glucocorticosteroids, typically prednisone or methylprednisolone, are used as maintenance immunosuppression; at higher doses, they can be used as rescue therapy. Although steroids are ineffective as monotherapy to prevent rejection, they have been effectively combined with other agents to improve graft survival. Unfortunately, the desirable immunosuppressive effects of steroids are counterbalanced by their contribution to transplant morbidity; therefore many ongoing efforts have sought to minimize or eliminate glucocorticosteroid use for maintenance immunosuppression. Many centers now rapidly wean liver allograft recipients off steroids, whereas most pancreas programs rely on low-dose steroids indefinitely, although steroid-free regimens are increasingly being used (Singh & Stratta, 2008; Tanchanco et al, 2008; Vessal et al, 2007).

The immunosuppressive mechanism of glucocorticosteroids was elucidated long after its clinical introduction (Auphan et al, 1995; Scheinman et al, 1995). After nonspecific cytoplasmic uptake, steroids bind to an intracellular receptor, enter the nucleus as a receptor-ligand pair, and increase the transcription of several genes, notably *IκBα*. This protein binds to and inactivates NFκB, an important transcription factor of T-cell and APC activation and cytokine production.

The NFκB pathway is an important amplification step in the T-cell and APC response, and blockade of this pathway results in diverse effects. Steroids decrease IL-1, tumor necrosis factor (TNF)-α, and IFN-γ transcription and also decrease MHC upregulation. Inhibition of phospholipase A_2 results in blockade of the entire arachidonic acid cascade, and steroids mute the entire inflammatory process and decrease the costimulatory environment; steroids also promote apoptosis of activated T cells and limit the signal transduction of many innate immune receptors, such as the TLRs.

Antiproliferative Agents

Azathioprine

The antimetabolite azathioprine (AZA) was the first immunosuppressant used in organ transplantation (Calne & Murray, 1961; Hitchings et al, 1950). AZA undergoes hepatic conversion to 6-mercaptopurine (6-MP) and then to 6-thio-inosine-monophosphate (6-tIMP). These derivatives alkylate DNA precursors and inhibit DNA synthesis. In addition, they can introduce chromosomal breaks and interfere with DNA repair mechanisms, and the ultimate effect is to deplete the cell of

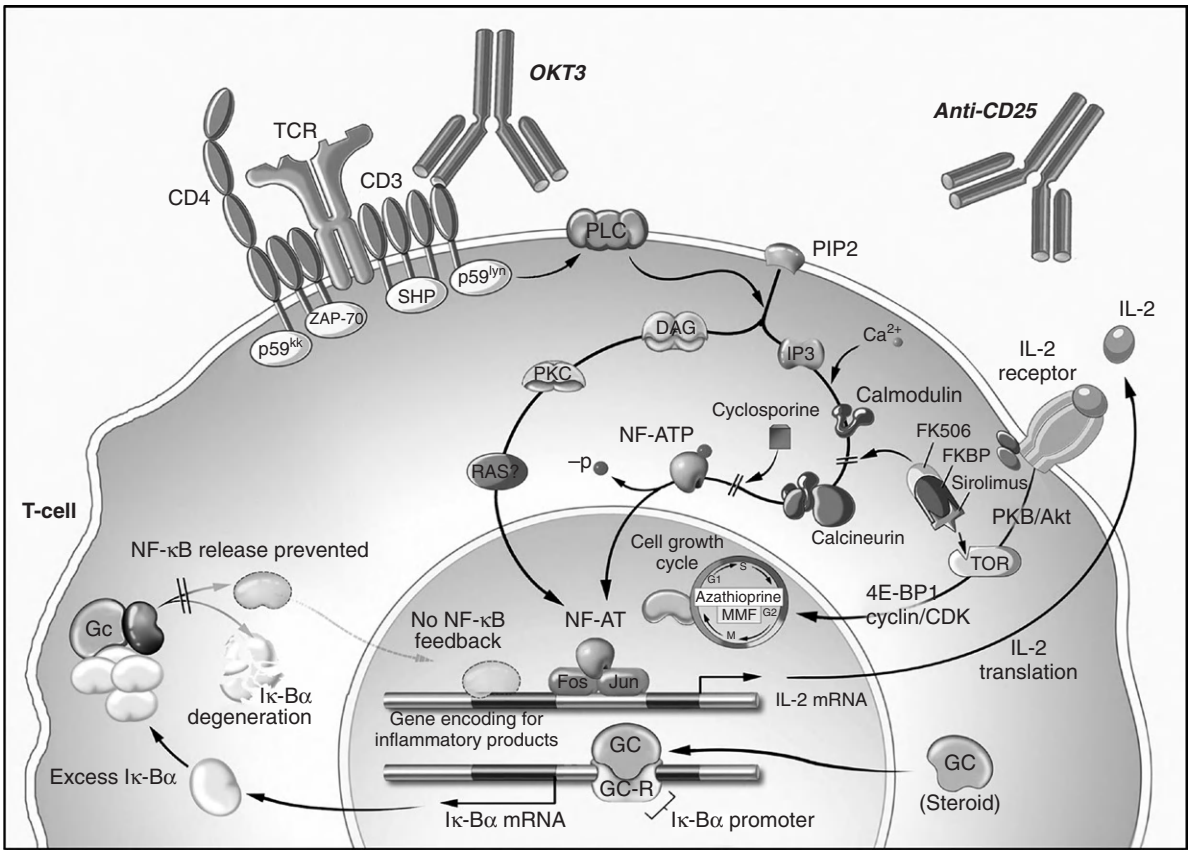

FIGURE 96.2. T-cell receptor (*TCR*) signal transduction and the sites of action of various immunosuppressants. TCR signal transduction proceeds through Ca^{2+}-dependent dephosphorylation of the nuclear factor of activated T cells (NF-*AT*), which enters the nucleus and, in conjunction nuclear factor (*NF*) κB, facilitates cytokine gene expression. Cyclosporine and tacrolimus (*FK506*) both inhibit signal transduction by blocking the ability of the calcineurin-calmodulin complex to potentiate NF of activated T cells (*AT*) dephosphorylation. The autocrine activity of interleukin (*IL*)-2 facilitates entry into the cell cycle and cell division. Sirolimus inhibits IL-2 receptor signal transduction by blocking the interactions of macrolide binding protein (*FKBP*). Mycophenolate (*MMF*) and azathioprine prevent cell cycling by altering nucleic acid metabolism. Steroids upregulate IκBα synthesis and inhibit the ability of NFκB to enter the nucleus. Monoclonal antibodies bind T-cell surface molecules and alter key interactions necessary for T-cell function. CD, Cluster of differentiation; CDK, cyclin-dependent kinase; 4E-BP1, 4E binding protein 1; IκBα, inhibitor of kappa light polypeptide gene enhancer in B cells, kinase alpha; OKT3, muromonab CD3; PIP_2, phosphatidylinositol diphosphate; PKC, protein kinase C; PKB/AKT, protein kinase B/AKT; PLC, phospholipase C; TOR, target of rapamycin.

adenosine. AZA works on all rapidly dividing cells, not only on lymphocytes; consequently, bone marrow, hepatic, and gastrointestinal toxicity are limiting factors. As monotherapy, AZA is ineffective and is rarely found in modern immunosuppressive regimens.

Mycophenolate Mofetil

Since 1995, mycophenolate mofetil (MMF) has been an approved immunosuppressant for use in adults (Platz et al, 1991). MMF is a morpholinoethyl ester of mycophenolic acid (MPA), a noncompetitive, reversible inhibitor of inosine monophosphate (IMP) dehydrogenase with improved bioavailability. MMF prevents a critical step in RNA and DNA synthesis by blocking guanosine monophosphate (GMP) formation from IMP by IMP dehydrogenase. In all cells except lymphocytes, there exists a "salvage pathway" for GMP formation. This crucial difference is exploited by MMF to produce a relatively lymphocyte-specific immunosuppressant. MMF blocks the proliferation of T and B cells and inhibits the formation of donor-specific antibody. Its introduction dramatically improved the success of pancreas transplantation; therefore it is used as an adjuvant immunosuppressive agent in most pancreas centers.

In liver transplantation, the use of MMF has continued to gain favor, because it allows a reduction in calcineurin inhibitors, the cornerstone of most immunosuppressive regimens. Presumably, this reduction mitigates the deleterious effects on renal function of calcineurin inhibitors in hepatic and pancreatic transplant recipients (Biselli et al, 2009). MMF combined with low-dose calcineurin inhibitors and corticosteroids have also been proven useful in decreasing episodes of acute rejection (Farkas et al, 2009). Its chronic use is typical in pancreas transplantation, and it plays at least a temporary role in most liver transplant regimens.

Calcineurin Inhibitors

Cyclosporine

Cyclosporine A (CyA) is a cyclic endecapeptide isolated from the fungus *Tolypocladium inflatum gams* (Borel et al, 1976; Kahan, 1994). Its introduction revolutionized transplantation and made extrarenal transplantation a viable reality. The mechanism of action of this T-cell–specific immunosuppressant is mediated through cyclophilin (Cn) binding. The CyA-Cn complex binds to the calcineurin-calmodulin complex and

prevents phosphorylation and activation of NF-AT, a transcription regulating factor. Blockade of NF-AT prevents IL-2 gene transcription. In addition, transforming growth factor (TGF)-α transcription is unregulated, and other genes critical for T-cell activation are altered (Khanna et al, 1996; Kirk et al, 1997). These and other effects may be responsible for the toxicity of CyA. Primarily, CyA blocks TCR signal transduction but does not inhibit costimulatory signaling (June et al, 1987). The effects of CyA can be overcome with high levels of IL-2, therefore once IL-2 is present in the graft, as in the case of ongoing rejection, CyA is rendered ineffective. Consequently, CyA is a maintenance immunosuppressant that has no role in rescue therapy.

CyA nephrotoxicity is a constant consideration in its use. Through a TGF-α mediated mechanism, CyA decreases renal blood flow by up to 30% (Khanna et al, 1996; Kirk et al, 1997). Increased transcription of endothelin also activates the renin-angiotensin pathway, leading to hypertension; the vascular effects of CyA may also delay resolution of hepatorenal syndrome; and CyA may lead to neurologic side effects, hypertrichosis, and malignancy (Hojo et al, 1999). In addition, metabolism of CyA through cytochrome P450 enzymes leads to multiple drug interactions.

Tacrolimus

Kino and colleagues (1987) first demonstrated the immunosuppressant effects of tacrolimus in 1987, and it has become the mainstay of most liver and pancreas transplant regimens. Tacrolimus is a macrolide antibiotic produced by *Streptomyces tsukubaensis*. Like CyA, tacrolimus blocks NF-AT activation and its downstream effects (Fruman et al, 1992). The intracellular target of tacrolimus is known as *FK-binding protein* (FK-BP). Similar to CyA, tacrolimus increases TGF-α transcription and therefore carries with it the benefits and toxicities of this cytokine (Khanna et al, 1996; Kirk et al, 1997). Although it is 100 times more potent than CyA in preventing IL-2 and IFN-γ transcription, its toxicities limit the dose to approximately 1% of CyA. In addition to its use as a maintenance agent, tacrolimus has been shown to have efficacy at high doses in reversing liver rejection episodes (Starzl et al, 1989).

As compared to CyA, tacrolimus has more pronounced neurologic side effects, such as mental status changes and tremors. Tacrolimus use also results in a higher rate of posttransplant type 2 diabetes, although it has fewer cosmetic side effects. Tacrolimus has been shown to be superior to CyA in preventing acute episodes of rejection, reducing the number of steroid-resistant acute rejections, and improving long-term graft and patient survival. For these reasons it has replaced cyclosporine as the first-line calcineurin inhibitor used in both liver and pancreas transplantation in most centers (Haddad et al, 2006). Because tacrolimus is metabolized by cytochrome P450 enzymes, drug interaction concerns are similar to those with CyA. In recent years, many liver transplant recipients have been successfully weaned to monotherapy tacrolimus, but this trend has not been seen in pancreas transplantation.

There is no doubt that calcineurin inhibitor therapy represents the current standard of care in solid-organ transplantation. Nevertheless, the improved outcomes have come at a considerable cost. The powerful immunosuppressive properties of these drugs have certainly revolutionized and improved both allograft and patient survival, and they have made liver and pancreas transplantation viable, long-term therapeutic options. They have also brought with them a host of side effects that have necessitated an entire field dedicated to their minimization or elimination.

mTOR Inhibitors

Sirolimus and Everolimus

Sirolimus and everolimus are macrolide antibiotics developed from *Streptomyces hygroscopicus* (Baker et al, 1978; Martel et al, 1977; Sehgal et al, 1975). Similar to tacrolimus, these agents bind to immunophilin FKBP12, also known as the *mammalian target of rapamycin* (mTOR). Unlike tacrolimus, these agents do not affect calcineurin activity (Dumont et al, 1990a, 1990b; Molnar-Kimber 1996). The primary effect of mTOR inhibitors is to inhibit IL-2 receptor signal transduction and not to block NF-AT nuclear translocation; therefore T cells are rendered incompetent against the proliferative effects of exogenous IL-2 (Kuo et al, 1992) but are still capable of IL-2 gene transcription.

The primary toxicities of mTOR inhibitors are hypercholesterolemia, hypertriglyceridemia, poor wound healing, thrombocytopenia, and oral ulcers. Currently, sirolimus carries an FDA black-box warning against its use in liver transplantation in the first 28 days postoperatively because of increased risk of hepatic artery thrombosis, thus its use in liver transplantation is limited to conversion regimens. In addition, sirolimus may have a direct hepatotoxic effect (Neff et al, 2004).

The principal manner in which mTOR inhibitors are being used is as an adjunct or alternative to calcineurin inhibitors, and mTOR inhibitors have been developed in recent years as antiproliferative agents for use in oncologic indications. As such, its use in patients transplanted for the treatment of hepatic malignancies is being investigated (Schnitzbauer et al, 2010; Toso et al, 2010; Vivarelli et al, 2010).

Antilymphocyte Agents

Antilymphocyte agents are commonly used in pancreas transplantation during the induction phase of immunosuppression (Niemeyer et al, 2002; Stratta et al, 2003). Their use in liver transplantation is sparse owing to the reduced immunogenic phenotype typical of liver grafts.

Antilymphocyte/Antithymocyte Globulin

A polyclonal antilymphocyte globulin (ALG) is produced by inoculating an animal, such as a horse or rabbit, with human lymphocytes and then collecting the serum and purifying the resultant IgG. This preparation contains antibodies of multiple epitope specificities directed against lymphocyte and other cell antigens (Gaber et al, 1998; Merion et al, 1998). In the United States, the common immunogen is thymocytes, and the resultant polyclonal antibody is rabbit antithymocyte globulin (RATG). These agents promote T-cell depletion through opsonization and complement-mediated lysis (Merion et al, 1998). They also have multiple nondepletional effects that inhibit T-cell activation and function, such as crosslinking costimulation and adhesion molecules and blocking TCR signal transduction through internalization of other cell surface receptors.

ALG and RATG can be used as induction and rescue agents. The primary function of these agents is to reduce the number of primary effector cells below the threshold required for acute rejection and to allow for slow repopulation after the immediate posttransplant period. Although RATG is generally

well tolerated, side effects include thrombocytopenia, increased viral disease, and transient cytokine release.

OKT3

Unlike polyclonal antibody preparations, monoclonal antibodies have single-target epitope specificity. Muromonab-CD3, better known as OKT3 (Orthoclone OKT3; Ortho Pharmaceuticals, Raritan, NJ), is a murine antibody directed against the CD3 signal transduction subunit of the TCR; it was the first monoclonal antibody approved for any use (Ortho Multicenter Transplant Study Group, 1985; Wilde & Goa, 1996). OKT3 mediates its effects by binding to CD3 and causing internalization of the TCR complex, thereby preventing antigen recognition (Marano et al, 1989; Wilde & Goa, 1996). Additionally, OKT3 opsonizes T cells, causing their activation and degranulation. This exhausts the cell, making it ineffective as an effector, but it also leads to OKT3's primary side effect: cytokine release syndrome (Chatenoud et al, 1990). Cytokine release can result in profound hypotension, pulmonary edema, and cardiac depression. Because of the relatively toxic side effect profile and the availability of other agents that accomplish the same purpose, OKT3 is no longer manufactured.

Anti–IL-2 Receptor α-Chain Monoclonal Antibodies

The high affinity α-subunit of the IL-2 receptor (CD25) has been the target of two monoclonal antibodies, daclizumab and basiliximab. CD25 is required for clonal naïve T-cell expansion and is therefore an attractive target for specific elimination of activated T cells (Goebel et al, 2000). Unlike OKT3, binding of the target epitope does not result in cytokine release, thus administration is generally well tolerated, although the antirejection effect is similarly modest. Daclizumab has recently been discontinued for use in the United States and Europe, and simulect is used in approximately a third of all pancreas and liver transplant centers.

Costimulation Blockade

As detailed earlier in this chapter, T cells not only require presentation of peptides in the context of self MHC, they require a second signal or costimulatory interaction to produce an effective and appropriate immune response. This is particularly true of naïve T cells that have never encountered antigen before. Both the CD154-CD40 and the CD28-CD80/86 pathways have been targeted in solid-organ transplantation with agents specifically designed to prevent these potentiating signals. Although promising in nonhuman primate trials, a drug targeting the CD154-CD40 pathway was abandoned after thromboembolic complications were reported. Although intense research continues pursuant to this pathway, the development of CD28-CD80/86 specific agents has advanced to the clinic.

Recently the development of belatacept, a high-affinity fusion protein specific for the B7 molecules CD80 and CD86, has been shown to be a viable costimulatory antagonist for use in renal transplant (Durrbach et al, 2010; Vincenti et al, 2010). It has also been shown to be an effective replacement for calcineurin inhibitors in selected patients and thus may find a role in liver and pancreas transplantation. Currently, trials are underway to investigate belatacept in liver and pancreas transplantation in combination with, and compared with, calcineurin inhibitor–based immunosuppression.

MAINTENANCE MINIMIZATION, IMMUNOSUPPRESSANT WITHDRAWAL, AND TOLERANCE

The benefit of organ replacement with transplantation carries with it the burden of chronic maintenance immunosuppression. Recently, numerous efforts have been made to decrease the amount of immunosuppression given to transplant recipients. The basic strategies being pursued in clinical and preclinical trials include minimization of maintenance immunosuppression through aggressive induction protocols, withdrawal of immunosuppression after the initial posttransplant period, and experimental strategies to facilitate immunologic tolerance.

The strategy of using depletional agents such as RATG to reduce the requirement for maintenance immunosuppression is gaining traction. Recently, another monoclonal depleting antibody has been investigated in liver transplantation. Alemtuzumab, a CD52-specific antibody, rapidly depletes T cells and, to a lesser degree, B cells and monocytes from the circulation and from secondary lymphoid organs. It is approved for the treatment of lymphoid malignancies and has been investigated off label in transplantation. Recently, it has been used with low-dose tacrolimus to prevent rejection in liver transplant recipients (Marcos et al, 2004; Tzakis et al, 2004). Similar efforts have been made using antithymocyte globulin induction therapy (Tchervenkov et al, 2004). Alemtuzumab depletion has also been used in pancreas (Kaufman et al, 2006), and this strategy has been used effectively in kidney transplantation (Calne et al, 1998; Kirk et al, 2003; Knechtle et al, 2003).

Steroid withdrawal is the goal for many transplant clinicians wishing to spare their patients from the numerous side effects associated with glucocorticosteroid dependence. Steroid withdrawal can be achieved in approximately 85% of liver transplant recipients at 3 months without a significant increase in acute rejection rates (Reding, 2000). Although attempts to withdraw steroids in patients receiving pancreas transplants have been less successful, with appropriate patient selection, up to 70% of pancreas transplant patients may be amenable to steroid withdrawal (Humar et al, 2000).

A modest percentage of liver transplant recipients can be completely withdrawn from all immunosuppressive agents (Benitez et al, 2009; Lee et al, 2009; Martinez-Llordella et al, 2007; Mazariegos et al, 1997). Although the periods of follow-up among withdrawal reports are highly variable, and the long-term incidence of chronic rejection and graft loss has not been defined, some recipients clearly are capable of spontaneously accepting liver allografts. The challenge remains to establish criteria for appropriate withdrawal from immunosuppression and to identify those individuals in whom drug withdrawal is a safe strategy. At present, the best predictor of successful drug withdrawal is long-term rejection-free survival on low-dose immunosuppression. Liver transplant recipients on single-drug therapy for more than 10 years are 10 times more likely to be withdrawn successfully compared with patients in the first 3 years after transplantation.

It is possible that signatures of recipient gene expression or other biologic parameters can identify a protolerant signature in liver transplantation patients (Martinez-Llordella et al, 2007). The majority of these targets are associated with NK and $\gamma\delta TCR^+$ T cells, which could be used to predict which liver

transplant patients might be successfully withdrawn from immune-modulating medications; however, no evidence suggests that pancreas transplant recipients can be withdrawn from immunosuppression.

The "holy grail" of transplantation is tolerance. From its conception (Billingham et al, 1953), *acquired allospecific tolerance* has been defined as the ability to maintain a functional allograft and an intact immune response without the need for any therapeutic drugs. Numerous strategies have been attempted in reaching this goal, but to date, all prospective attempts to create broadly applicable, reliable, and durable tolerance in humans have failed. Although the reasons are numerous and still in the process of being elucidated, the pursuit of tolerance will bring all the benefits of organ replacement therapy and eliminate its toxicity, namely chronic immunosuppression. Ongoing strategies include the manipulation of costimulation signals, depletional approaches, and techniques designed to induce mixed chimerism, a state in which elements of both the donor and recipient immune systems persist in one individual (Cosimi & Sachs, 2004; Harlan & Kirk 1999; Kirk, 2003).

Many have speculated that liver recipients are more likely to be rendered tolerant than other allograft recipients, and indeed the emerging results from immunosuppressive withdrawal trials suggest this to be the case. Reasons cited include the unique APCs in the liver (see Chapter 9), the liver's regenerative capacity, its shear antigenic bulk, and it tendency to seed the recipient's body with donor hematopoietic cells, perhaps overwhelming the recipient immune system into a state of clonal exhaustion (Starzl, 1998). Tolerance attempts in liver transplantation are likely to proceed in the coming years, and their results will be anticipated. In contrast, the pancreas has been considered an immunogenic organ with little capacity to regenerate or deal with immune insults. As such, pancreas allograft tolerance will be much less likely to be achieved in the near future with the current strategies available.

SECTION II Indications

CHAPTER 97A

Liver transplantation: indications and general considerations

Ramakrishnan Arulraj and James Neuberger

OVERVIEW

The first human orthotopic liver transplantation was carried out by Starzl in 1963. In the subsequent 2 decades, only a relatively small number of grafts were placed, usually in moribund patients with end-stage disease, and survival results were disappointing; however, with increasing experience and confidence, results began to improve, and more patients were grafted. A major increase has been seen in both the number of transplant centers and the number of patients grafted. In both Europe and the United States, more than 6000 procedures are performed annually. Results are such that many centers are currently reporting 1-year survival rates in excess of 90% in elective cases.

It is difficult to identify any one cause for the increase in success. The contribution of better surgical and anesthetic techniques, improved postoperative care, and availability of better immunosuppressive agents have all contributed to the improvements in survival (see Chapter 97B). In addition, understanding of both indications and contraindications for the procedure have improved such that major surgery is not carried out in patients with virtually no chance of surviving, and patients are referred for transplantation at a stage when they are likely to have the greatest chance of success.

Increasing success of liver transplantation and the reduction in contraindications has meant that the number of potential recipients is increasing, while the number of donors in many countries is either remaining static or else actually falling. The increasing discrepancy between supply and demand means that the mortality of patients awaiting transplantation is increasing; patients who wait longer are sicker, and their chances of survival decreases, while resource utilization increases. Attempts to increase the donor pool by use of split livers, organs from selected non–heart-beating donors, and from living donors combined with a better understanding of the contraindications to grafts have had a significant impact but have not been sufficient to meet the need.

In North America and in some European countries, the method of allocation has been changed to one based on the patient's prognosis, such as the Model for End-Stage Liver Disease (MELD), with livers allocated to individuals based primarily on the likelihood of the recipient dying while awaiting transplantation. Use of this system has resulted in a major reduction in the mortality of patients awaiting liver transplantation without an appreciable effect on outcome after transplantation.

GENERAL INDICATIONS

In general, the indications for transplantation are relatively easy to define, although the application of these principles is often far more difficult. The two broad indications for grafting are a less than 1-year estimated survival of liver disease and a quality of life deemed unacceptable by the patient. The main contraindications to liver transplantation are numerous, and although some are relative, some are absolute.

Absolute Contraindications to Transplantation

- The patient is not fit enough to withstand surgery, for example, because of advanced cardiac or pulmonary disease.
- The patient is unlikely to survive the procedure, such as with active sepsis.
- Survival after transplantation may be too short to justify the risks of transplantation, as in the case of metastatic disease.
- Active alcoholism and substance misuse is present, evident by noncompliance with medical advice ascertained on psychiatrist or psychologist evaluation.
- The postoperative quality of life may be unacceptable to the patient, for example, as with severe, intractable depression.
- Surgery is technically impossible, as in patients with extensive venous thromboses.
- The patient does not wish to undergo the operation.

Relative Contraindications to Transplantation

- Age may be an issue, and age restrictions vary at transplant centers; biologic age, rather than chronologic, is more important.
- Cholangiocarcinoma is sometimes a contraindication; transplant may still be considered, but only in highly selected patients because of the high risk of early recurrence.
- Chronic or refractory infections may preclude transplantation, depending on the nature of the infection and whether it is amenable to cure with available therapy.
- Poor social support may be a contraindication, particularly in biologically older patients with prolonged recovery anticipated after transplantation.

The last decade has shown a changing pattern of indications for transplantation. The total number of patients grafted each year in North America has risen from 1713 in 1988 to 6319 in 2008. Similar observations have been reported in Europe. Over the decades, the practice of transplantation has undergone many changes: the proportion of patients grafted for alcoholic liver disease and viral hepatitis, especially hepatitis C virus (HCV), is rising; whereas the proportion of patients grafted for malignancy and cholestatic diseases is falling.

The use of living donors has not made a significant impact on the number of transplantations. According to United Network for Organ Sharing (UNOS), of the 6319 liver transplantations done in 2008, only 249 (3.9%) were from living donors, and in fact the proportion of living-donor grafts decreased from 10% in 2001 to 3.9% in 2008. In contrast to living donors, use of non–heart-beating donor livers from those who donate after cardiac death has been increasing (0.5% in 1998 vs. 5% in 2007). In addition, new indications for liver transplantation include those with replicative hepatitis B virus (HBV) and for those with human immunodeficiency virus (HIV) infection.

GENERAL ASPECTS

Nutrition

Malnutrition is a common finding in end-stage cirrhosis, with a prevalence of 81% (Caregaro et al, 1996). Malnutrition in these patients has many causes: the disease depletes the patient, and the situation is compounded by poor intake, malabsorption, and dietary restrictions that are often inappropriate. Malnutrition is associated with increased susceptibility to infection and poor healing. Although in liver disease, the degree of malnutrition may be difficult to quantify, malnourished patients fare poorly, with reported mortality of 15% (Campillo et al, 2003). Although no convincing evidence proves that improvement in nutrition alters the outcome, it seems prudent to optimize nutrition (Figueiredo et al, 2000), and it is sensible to correct vitamin and other nutrition deficiencies.

Psychologic Assessment

Transplantation is associated with major psychologic stress, both for the patient and the family. More than half of those in the liver transplant candidate population have a wide range of psychologic health problems (Day et al, 2009). Initially, many centers arranged for full psychologic and psychiatric assessment of all potential transplant candidates, but this is rarely undertaken. Chronic ill health, possible subclinical encephalopathy, and future uncertainties all combine to make it difficult to accurately predict a patient's outcome. In addition, when a history of psychiatric illness is present, expert assessment is required. Some patients with psychiatric illness that is unresponsive to therapy and those with a history of recurrent episodes of self-harm may not be suitable candidates for transplantation.

Age

There is no agreed upper age limit, but advanced age is associated independently with mortality after transplant (Burroughs et al, 2006). The concept of biologic age has superseded that of chronologic age, although the former cannot readily be defined or quantified.

Previous Abdominal Surgery

The presence of adhesions, especially in the presence of portal hypertension, adds considerably to the difficulties of surgery and may affect outcome, especially when this involves surgery to the biliary tree (Neuberger et al, 1999).

Infection

Active bacterial, fungal, or protozoal sepsis is an absolute contraindication to transplantation, but once appropriate therapy has been instituted, the patient may become a suitable candidate for the procedure.

Human Immunodeficiency Virus

Although early studies showed patients with HIV infection fared poorly (Rubin et al, 1987; Tzakis et al, 1990), with the introduction of highly active antiretroviral therapy (HAART), the natural history of HIV infection has been greatly altered (Roland & Stock, 2006), although patients with hepatitis C virus (HCV) coinfection are at high risk for developing end-stage liver disease (Graham et al, 2001). Short-term outcomes in patients with HIV are encouraging (Fung et al, 2004), but the procedure remains limited to a few centers. Indications are becoming better defined (Samuel et al, 2003) and include 1) end-stage liver disease, 2) low or undetectable levels of HIV RNA, 3) no autoimmune deficiency syndrome (AIDS)-defining complication, and 4) a CD4 count greater than 200/mL.

Cardiovascular Disease

As with other diseases, the prognosis of patients with cardiovascular diseases will dictate whether liver replacement is an appropriate therapy. Multivessel, moderate to severe coronary artery disease is present in 15% of patients with end-stage liver disease (Tiukinhoy-Laing et al, 2006). Preoperative assessment of cardiovascular status is, at best, imprecise, as no clear guidelines exist to define limits below which grafting is unsafe. When it is possible to correct coronary artery disease, this should be undertaken prior to transplantation.

Respiratory Function

Arterial hypoxemia, an oxygen saturation less than 92% or arterial oxygen pressure less than 70 mm Hg, may be found in

up to 70% of patients with liver disease. Several possible causes for this hypoxemia include ventilation-perfusion mismatch, diffusion limitation, alveolar hypoventilation, shunt, and diffusion-perfusion abnormality (Krowka & Cortese, 1990). Furthermore, pulmonary dysfunction is present in up to 2% of patients with advanced liver disease. The presence of significant pulmonary disease is usually apparent on history and examination, but significant pulmonary disease may be cryptic. The many possible causes for these abnormalities include 1) diseases unrelated to the liver, such as those caused by smoking; 2) organic liver disease, such as α_1-antitrypsin deficiency; 3) respiratory conditions associated with certain liver disease, such as fibrosing alveolitis associated with primary biliary cirrhosis; 4) the effects of the liver disease on respiratory function, such as ascites that causes a pleural effusion or simple lung compression; 5) hepatopulmonary syndrome, and 6) portopulmonary hypertension.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome is characterized by abnormal intrapulmonary vascular dilation (Hoeper et al, 2004). Clinically, it encompasses a triad of arterial deoxygenation, intrapulmonary vascular dilation, and liver disorder. The diagnosis is suggested by showing orthodeoxia, a fall in arterial blood oxygen when standing, and the presence of intrapulmonary shunting, demonstrated by either bubble echocardiography or nuclear medicine scanning.

Portopulmonary Hypertension

Portopulmonary hypertension results from pulmonary vasoconstriction and leads to vascular remodeling, which results in pulmonary hypertension (Hoeper et al, 2004). Diagnostic criteria include presence of liver disease that results in portal hypertension; mean pulmonary arterial pressure of more than 25 mm Hg at rest or 30 mm Hg during exercise; mean pulmonary artery occlusion pressure of less than 15 mm Hg; and pulmonary vascular resistance more than 240 dyn/sec/cm^{-5} (Krowka, 2003).

Routine screening of patients with chest radiograph, electrocardiogram (ECG), lung function tests, and measurement of peripheral oxygen saturation will usually identify those with pulmonary problems. Additional investigations include assessment of arterial blood gases—both lying and standing, to detect hepatopulmonary syndrome—and on 100% oxygen, to detect shunting; imaging with high-resolution computed tomography (CT) scanning, contrast-enhanced echocardiography, and isotope-labeled macroaggregated albumin lung scan are also helpful. Pulmonary angiography and right-heart catheterization may also be indicated as suggested by the clinical and simple investigations.

No clear guidelines are available that establish when liver transplantation is contraindicated because of pulmonary disease (Krowka et al, 2004). A preoperative partial pressure of oxygen of less than 50 mm Hg and a lung scan with brain uptake of more than 20% (Arguedas et al, 2003) strongly predict mortality, although these patients may be candidates for a triple transplant of heart, lung, and liver. Similar considerations apply to those with cystic fibrosis, cystic lung disease, and liver disease. Long-term oxygen therapy is the most frequently recommended therapy for symptomatic hypoxemic patients, but the use of drugs and transjugular intrahepatic shunt (TIPS) requires validation in this setting.

COEXISTING DISEASE

The presence of coexisting disease may affect the decision to offer the patient a liver graft, either because the prospects of recovery are adversely affected, or because long-term survival may be reduced (Volk et al, 2007). Diabetes mellitus (DM) is commonly found in patients with chronic liver disease, especially in those with HCV infection. DM may occur as a consequence of the insulin intolerance associated with advanced liver disease; if so, it will resolve after successful transplantation. Concerns for those with diabetes center upon the possible microvascular complications. Evidence of a proliferative retinopathy, diabetic nephropathy, or autonomic neuropathy—evidenced by simple tests, such as abnormal beat-to-beat variation on Valsalva maneuver or postural hypotension—may be relative contraindications for transplantation. The presence of advanced microvascular disease puts the patient at risk of major autonomic disruption during the procedure, and the survival of such patients is relatively poor (Haydon & Neuberger, 2001).

Hyponatremia is a common finding in patients with advanced chronic liver disease, and it usually occurs either as a consequence of injudicious diuretic therapy or because of the reduced free-water clearance. Grafting patients with severe hyponatremia (serum sodium <120 mmol/L) has shown an increased risk of central pontine myelinolysis (Yun et al, 2009). Significant hyponatremia should be corrected prior to transplantation, either by simple water restriction and, if appropriate, cessation of diuretic therapy or, if more rapid correction is required, by use of renal support (Elias & McMaster, 1987). The role of aquaretics may also be helpful in this situation (O'Leary & Davis, 2009).

Vascular thromboses are not uncommon in patients with chronic liver disease. These may occur as a consequence of the cirrhosis itself or as part of an associated underlying thrombotic tendency; for example, the myeloproliferative disease associated with Budd-Chiari syndrome, the presence of lupus anticoagulant, deficiency of proteins C or S, or impaired fibrinolysis. In early series, portal vein thrombosis was considered to be a contraindication to transplantation, but it is now appreciated that this is no longer the case, and portal venous inflow to the graft can be provided by the superior mesenteric vein or even by a splenic vein. It is only in those rare patients in whom venous thrombosis is extensive, and where it is impossible to provide a suitable portal supply to the graft, that transplantation is actually contraindicated.

Renal disease may occur either as a consequence of the hepatorenal syndrome or as a result of intrinsic kidney damage. In the hepatorenal syndrome, the kidney is not structurally damaged, and once good liver function is reestablished, the kidney will function normally; so although the prognosis may be poorer in the presence of advanced renal insufficiency (Rimola et al, 1987), the hepatorenal syndrome is not an absolute contraindication to transplantation. When coexisting advanced renal disease is evident, it may be advisable to consider combined liver and kidney transplantation, as renal function remains a major predictive factor for the outcome after transplantation (Nair et al, 2002). It is uncertain whether pretransplant correction of renal parameters—for example, by dialysis—is associated with an improvement in survival.

Past history of malignancy is a relative contraindication to transplantation, because the effect of surgery and the consequent immunosuppression may predispose the patient to early recurrence of tumor (Penn, 1993; Saigal et al, 2001). In 1993,

Box 97A.1

Effect of Immunosuppression on Tumor Recurrence

Low Recurrence Rates (0%-10%)

Incidentally discovered renal tumors
Lymphoma
Testicular carcinoma
Uterine carcinoma
Cervical carcinoma
Thyroid carcinoma

Intermediate Recurrence Rates (11%-25%)

Uterine body carcinoma
Wilms tumor
Colon carcinoma
Breast carcinoma
Prostate carcinoma

High Recurrence Rate (>26%)

Bladder carcinoma
Sarcomas
Melanoma
Symptomatic renal carcinomas
Myelomas
Nonmelanoma skin cancers

This list is derived from patients undergoing renal transplantation and should be used only as a guide when applied to those patients.

From Penn I, 1993: The effect of immunosuppression on pre-existing cancers. Transplantation 55:742-747.

Penn identified those tumors that have a high risk of recurrence after transplantation (Box 97A.1). Most centers will offer transplantation when the risk of recurrence is below 10% at 5 years; however, recurrence rates with other kinds of malignancies—colorectal cancer (18.8%), nonmelanoma skin cancers (23.5%), thyroid carcinoma (25%), oral squamous carcionoma (33%), vulvovaginal cancers (33%), and breast carcinoma (33%)—are associated with a higher risk following liver transplantion (Benten et al, 2008). In only exceptional cases should patients with any of the above extrahepatic malignancies be considered suitable candidates for transplantation.

Bone Disease

Many patients with chronic liver disease will have bone disease. The occurrence of osteomalacia as a consequence of vitamin D malabsorption is low and can readily be corrected by parenteral administration of vitamin D; however, osteoporosis is a far greater problem and is particularly seen in female patients with chronic cholestatic disease. In many cases, successful transplantation will halt or retard the progression and may even improve bone mineralization (Guichelaar et al, 2007). The presence of severe osteoporosis may result in additional complications in the presence of significant thoracic or lumbar vertebral collapse or fractures. The development of severe osteoporosis may well be an indication for transplantation in itself.

SPECIFIC DISEASES

Fulminant Hepatic Failure (See Chapter 97C)

In recent years it has been realized that liver transplantation is an effective form of therapy for patients with fulminant hepatic failure (FHF), that is, the presence of encephalopathy occurring within 8 weeks of the onset of symptoms in a patient with previously normal liver (Peleman et al, 1987; Chapter 97C). FHF requiring transplantation accounts for less than 5% of liver transplantations. In those with severe FHF and grade 4 hepatic encephalopathy, the mortality approaches 80%. Common causes of FHF include paracetamol (acetaminophen) overdose; viral infections, such as hepatitis A, B, E, and rarely C; drug and xenobiotic toxicity, including those caused by herbal remedies; Wilson disease; and liver diseases of pregnancy.

Patients with FHF develop early multiorgan failure and require intensive supportive therapy. The common causes of death are cerebral edema, multiorgan failure, sepsis (bacterial or fungal), cardiac arrhythmia or arrest, and respiratory failure (Ostapowicz et al, 2002). Indeed, FHF poses a difficult problem, because the window is very narrow between the time when it is apparent that the patient's survival is likely to be poor in the absence of transplantation and the onset of irreversible complications that preclude a successful outcome.

Several groups have now published prognostic factors, and based on those, criteria for super-urgent transplantation in the United Kingdom have been published; these are listed in Table 97A.1 (Bismuth et al, 1987; Neuberger et al, 2008; O'Grady et al, 1989). The King's College model has been validated in other centers and was found to be robust, although it is likely that with advances in the medical management of patients with FHF, these prognostic factors will require modification. The inclusion of serum lactate in the King's College prognostic criteria provides greater accuracy (Riordan & Williams, 2002).

Contraindications to transplantation in FHF include the onset of irreversible complications; thus the development of irreversible cerebral edema—characterized either by prolonged, documented elevations of intracranial pressure (ICP) or the presence of fixed dilated pupils for more than 6 hours—precludes transplantation. Active sepsis is also a contraindication.

One of the best guides to progression is given by serial estimation of the prothrombin time (Harrison et al, 1990) or factor V levels (Bernuau et al, 1986), because in the absence of extraneous blood products, these best represent the synthetic function of the liver. Initial improvement in the prothrombin time followed by deterioration suggests the presence of sepsis; therefore such patients should no longer be considered potential candidates. In addition, the patient remains at risk of developing complications related to raised ICP for up to 48 hours after successful transplantation (Dabos et al, 2004; Keays et al, 1991).

Because of the prognostic importance of clotting parameters, patients with FHF should not be given clotting factors until the decision for transplantation has been made; unless, of course, pressing clinical reasons are apparent. Once the decision for transplantation has been made, clotting should be normalized as much as possible within the constraints of volume replacement and avoidance of the complications of intracerebral edema. The ability to give large volumes of fluid may be limited by impaired renal function, but the presence of renal support will allow fluids to be taken off more rapidly.

Because many of the extrahepatic manifestations of FHF may be a consequence of the presence of large amounts of necrotic tissue, some centers have advocated the use of a two-stage procedure, whereby the failed liver is removed, and the patient remains anhepatic until a suitable graft can become available (Ringe et al, 1993). Although there is little doubt that

Table 97A.1

Current Transplant Criteria in the United Kingdom for Registration as a Super-Urgent Transplantation for Fulminant Hepatic Failure

Category	Etiology
1	Acetaminophen poisoning with pH <7.25 >24 h after overdose and after fluid resuscitation
2	Acetaminophen poisoning with PT >100 sec, or INR >6.5 and serum creatinine >300 mmol/L, or anuria and grade 3 to 4 encephalopathy
3	Acetaminophen poisoning with serum lactate level >24 h after overdose >3.5 mmol/L on admission or >3.0 mmol/L after fluid resuscitation
4	Acetaminophen poisoning with 2 of the 3 criteria from category 2 with clinical evidence of deterioration (e.g., increased ICP, FiO_2 >50%, increasing inotrope requirements) in the absence of clinical sepsis
5	Seronegative hepatitis, hepatitis A, hepatitis B, or an idiosyncratic drug reaction with PT >100 sec or INR >6.5 and any grade of encephalopathy
6	Seronegative hepatitis, hepatitis A, hepatitis B, or an idiosyncratic drug reaction; any grade of encephalopathy; and any three from the following: unfavorable etiology (idiosyncratic drug reaction, seronegative hepatitis), age >40 years, jaundice to encephalopathy time >7 days, serum bilirubin >300 mmol/L, PT >50 sec or INR >3.5
7	Acute presentation of Wilson disease or Budd-Chiari syndrome, a combination of coagulopathy, and any grade of encephalopathy
8	Hepatic artery thrombosis on days 0 to 21 after liver transplantation
9	Early graft dysfunction on days 0 to 7 after liver transplantation with at least two of the following: AST >10,000 IU/L, INR >3.0, serum lactate >3 mmol/L, absence of bile production
10	Severe liver failure in any liver donor within 4 weeks of a donor operation

AST, aspartate aminotransferase; FiO_2, inspired oxygen concentration; ICP, intracranial pressure; INR, international normalized ratio; PT, prothrombin time

Modified from Neuberger et al, 2008: Selection of patients for liver transplantation and allocation of donated livers in the UK. Gut 57(2):252-257.

following hepatectomy, the patient's condition may well improve, few convincing data are available at present to suggest that this approach improves outcome; however, such a procedure may be indicated in a patient who is rapidly deteriorating for whom a graft has been found, but logistic conditions may enforce some delay before the graft can be successfully performed.

One of the dilemmas in considering liver transplantation in patients with acute liver failure is that if the liver does recover, a complete return to normal structure and function is likely. The use of auxiliary transplantations, such as auxiliary partial orthotopic liver transplantation, or partial transplantations may allow the earlier use of liver grafting as a safety net; because if the patient's liver does recover, the donor liver can be removed or allowed to atrophy, and the patient can return to a life of good liver function free of immunosuppression. The use of artificial liver support devices (Chapter 72) remains uncertain, but systems such as the molecular absorbent recirculation system (MARS; Gambro AB, Sweden) may offer a bridge to transplantation (Mitzner et al, 2002).

Table 97A.2

Inborn Errors of Metabolism that Have Been Treated by Liver Transplantation

Liver Affected	Other Organs Also Affected
α_1-Antitrypsin deficiency	Primary hyperoxaluria
Wilson disease	Crigler-Najjar syndrome
Protoporphyria	Primary hypercholesterolemia
Tyrosinosis	Niemann-Pick disease
Tyrosinemia	Sea-blue histiocyte disease*
Galactosemia	Hemophilia A and B
Glycogen storage disease types I and IV	Protein C deficiency
Byler disease	Protein S deficiency
Hemochromatosis*	
Cystic fibrosis	
Gaucher disease*	
Urea cycle enzyme deficiencies	

*May recur after transplantation

Patients who develop FHF as a consequence of paracetamol overdose pose a special problem. Those with a long history of psychiatric disease that has been unresponsive to full intervention and support and those with a history of recurrent overdose are not usually appropriate candidates. Many patients who are seen for acetaminophen overdose have taken the drug often on an impulse because of a relatively trivial problem. In such cases, it is appropriate to offer these patients transplantation. In contrast, if the overdose is taken as a consequence of long-term social or domestic problems, it is possible that even after successful grafting, the patient will return to identical problems with the additional burden of a liver transplantation and its consequences; in this setting, grafting may not be appropriate.

Metabolic Diseases

A number of metabolic diseases account for less than 5% of liver transplantations in adults, and these may be corrected by liver transplantation (Table 97A.2). In some cases, where the metabolic defect arises in the liver, transplantation will correct that defect. This is seen, for example, with Wilson disease or hemophilia. In other conditions, such as some types of hypercholesterolemia, the metabolic defect occurs within the liver, but the heart is the organ affected. Some centers have advocated the use of liver transplantation to prevent the onset of severe coronary artery disease, although when cardiac disease is already present, combined heart and liver transplantations may also be performed. Similar considerations apply to hyperoxaluria that requires liver and kidney replacement. In other conditions, such as hemophilia, with alternative therapies such as replacement with factor VIII, transplantation should only be considered if liver disease is extensive, such as may occur with HCV infection transmitted via blood products.

The possibility of recurrence of the metabolic disease should not necessarily be considered a contraindication to transplantation; although the consequences of genetic hemochromatosis are likely to recur following transplantation, organ damage can be prevented by early recognition and treatment. Equally, in

erythropoietic protoporphyria, the disease is likely to recur following transplantation, but the morbidity of disease may be delayed by appropriate treatment with cholestyramine. In these instances, the decision to offer transplantation must be made with a view to the benefits obtained, and the indications remain similar to those in patients with other liver diseases.

Budd-Chiari Syndrome

The role of liver transplantation in patients with Budd-Chiari syndrome remains uncertain (Chapter 77). There may be underlying thrombotic disorders, such as deficiencies in proteins C or S, Factor V Leiden mutation, lupus anticoagulant, polycythemia, or myeloproliferative disorders; some of these will be corrected by transplantation, whereas others will carry the risk of complications, such as malignant transformation (Menon et al, 2004). The early use of anticoagulants and interventional radiology has changed the management of these patients (Darwish Murad et al, 2009). In general, transplantation should be considered when portal decompression has failed, when it is not feasible, or in the presence of established cirrhosis.

Chronic Liver Disease

In many ways, patients with chronic liver disease pose the most difficult problems with respect to transplantation. The main concern lies not with whether the patient is a suitable candidate for transplantation but in deciding on the *appropriate time* to offer the patient the procedure. On the one hand, the fitter the patient, the greater the probability of surviving the procedure; on the other, the patient's life will have been shortened if the procedure is unsuccessful. In addition, if transplantation is offered too late, the chances of success are reduced.

Broadly speaking, two major indications exist for transplantation in patients with chronic liver disease: poor quality of life and poor estimated length of life. Assessment of quality of life is often difficult, because the quality of life that is unacceptable to one person may be acceptable to another. Furthermore, it is often very difficult to disentangle the effects of borderline encephalopathy and depression associated with the knowledge of chronic liver disease from the effects of the tiredness and lethargy that result from the liver disease itself. Some patients do adopt the "sick role," and even after successful transplantation, either the patient or the family is reluctant for that role to be abandoned.

Although intractable pruritus is a valid indication for transplantation, if all other measures for treatment are unsuccessful, lethargy often fails to improve and so is not, in itself, an indication; it is important to exclude extrahepatic disorders, such as coexistent myxedema or therapy that may cause lethargy. Recent evidence (Piche et al, 2005) suggests that ondansetron may be effective in improving the fatigue associated with chronic liver disease.

Most centers consider transplantation appropriate when the estimated length of life in the absence of transplantation is limited to 1 year; however, in practice, this is very difficult to assess for most patients (Box 97A.2). Mostly, chronic liver disease runs a fairly predictable course, although the patient's life may be threatened by unpredictable events, such as sepsis or variceal hemorrhage. It is for this reason that timing of transplantation remains an inexact science. A further feature to be considered is that many of the factors predicting a poor survival in patients with cirrhosis are different from those that predict outcome after transplantation.

The use of prognostic models have helped define those variables that predict outcome, but such models do have disadvantages. First, most prognostic models are defined from retrospective studies that use patient data either at referral or at a certain point in the course of the illness, and it may be inappropriate to reapply these models sequentially, unless time-dependent models are used. Second, models provide data for populations, and their application to an individual is limited by relatively wide confidence intervals. Nonetheless, the Child-Turcotte-Pugh (CTP) classification does provide a useful guide, although it may not be sufficiently detailed for estimation of short-term survival. The MELD score is also a useful marker of short-term prognosis and may be more accurate than the CTP score (Freeman et al, 2004; Olthoff et al, 2004). The onset of hepatic decompensation is often a useful clinical marker of a poor prognosis. Indications for consideration of transplantation are shown in Figure 97A.1 and Box 97A.2.

The development of complications may often precipitate referral for transplantation. Thus the development of severe ascites, spontaneous bacterial peritonitis, recurrent variceal hemorrhage, and intractable encephalopathy are all indications that hepatic reserve is limited (Gines et al, 1988; see Chapters 70, 72, 73, and 74). Both the CTP classification and the MELD score are relatively poor prognostic guides to survival after grafting; however, data suggest that transplantation of a patient with a MELD score less than 12 in those without malignancy is associated with a reduction in survival at 1 year (Neuberger, 2004).

Other centers have concentrated on functional tests of the liver (Chapter 2), and although tests such as the aminopyrine breath test, the monoethyl glycine xylidide (MEGX) test, and the galactosamine elimination clearance have their advocates, none has added greatly to clinical and serologic assessment, and none has been applied widely (Burdelski et al, 1991; Mericel et al, 1992).

Primary Biliary Cirrhosis

The prognostic criteria for transplantation in primary biliary cirrhosis (PBC) are well defined; it accounts for less than 5% of liver transplantations, and a decreasing trend has been observed. Since the early paper by Schaffner and coworkers (Shapiro et al, 1979), it has become clear that the serum bilirubin is the best guide to prognosis. Once the serum bilirubin exceeds 150 μmol/L, median survival in the absence of transplantation is approximately 18 months.

A number of prognostic models have been developed, including both static and time-dependent models (Neuberger, 1989), and these are helpful in defining those variables that predict survival, both in the absence of transplantation and following transplantation (Box 97A.3). From these models, an estimate of survival can be made; however, these models must be used with some care, because the confidence intervals are relatively wide, and any information derived from such models must be made in conjunction with clinical judgment. Ursodeoxycholic acid (UDCA) is now licensed for use in patients with PBC and is associated with a significant delay in transplantation. In most patients, there is a fall in serum bilirubin, but the prognostic models remain valid when applied 6 months after introduction of treatment.

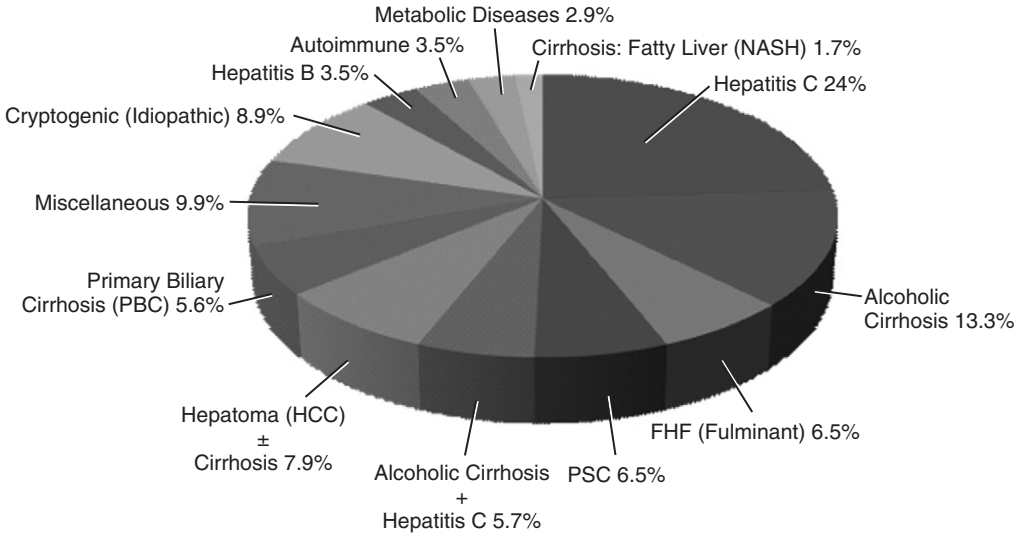

FIGURE 97A.1. Indications for liver transplantation. Based on the Organ Procurement and Transplantation Network cumulative 20-year data, from 1988 through 2008. FHF, fulminant hepatic failure; HCC, hepatocellular carcinoma; NASH, nonalcoholic steatohepatitis; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

Box 97A.2

Indications for Transplantation in Patients with Cirrhosis

Symptoms

Hepatic decompensation
Hepatic encephalopathy
Increasing ascites
Recurrent variceal bleeding
Spontaneous bacterial peritonitis

Side Effects of Liver Disease

Increasing osteopenia
Hepatopulmonary syndrome
Intractable symptoms (itching or lethargy)
Development of hepatocellular carcinoma
Muscle wasting

Biochemical Markers

Serum albumin <30 g/dL
Serum bilirubin >50 µmol/L for parenchymal disease
Serum bilirubin >100 µmol/L for cholestatic disease
MELD score >17

MELD, Model for End-Stage Liver Disease

Box 97A.3

Prognostic Models for Estimating Survival in Patients with Primary Biliary Cirrhosis

European Model

2.52 × Log serum bilirubin (µmol/L)
+ 0.069 × (Age [yr] – 20)/10
– 0.05 × Serum albumin (g/L)
+ 0.88 (if cirrhosis present)
+ 0.68 (if central cholestasis present)
+ 0.52 (if not treated with azathioprine)

Mayo Model

0.871 × Log serum bilirubin (mg/dL)
– 2.53 × Log serum albumin (g/dL)
+ 0.039 × Age (yr)
+ 2.38 × Log prothrombin time (sec)
+ 0.859 × Edema score*

*0 for no edema, 0.5 for diuretic-controlled edema, 1 for diuretic-resistant edema

Transplantation in patients with PBC may also be indicated for intolerable and intractable pruritus; however, it is important that all therapies for pruritus be considered before transplantation is decided upon. The therapeutic options are increasing: cholestyramine is the mainstay, but trials of rifampicin, naltrexone, and either plasmaphoresis or MARS should be considered before transplantation is offered to those with good liver function.

The causes for lethargy in patients with PBC are numerous: depression is common and often responds to antidepressant medication. Celiac disease is found in 3% of patients with PBC (Kingham & Parker, 1998) and may cause lethargy if unrecognized and untreated. Low levels of antibodies to gliadin are common in patients with liver disease, so celiac disease should be tested for by measuring antiendomysial antitransglutaminase antibodies; in addition, a small bowel biopsy should be taken when these antibodies are present. Coexisting myxedema should be excluded by measuring serum thyroid-stimulating hormone (TSH), and the patient should be tested for Addison disease if appropriate.

Appropriate treatment of pruritis is important, because sometimes lethargy is caused by inappropriate use of antihistamines to control itching, sometimes it is caused by sleeping tablets. Cholestyramine is effective for the treatment of pruritus, if enough is taken for long enough; for those unable to tolerate the nausea or diarrhea associated with cholestyramine, a formulation without sorbitol, such as Questran Light, or colestid is effective. Other drugs that may be effective include rifampicin and naltrexone, and other remedies that may be beneficial include extraheptic biliary diversion, plasmapheresis, and MARS (extracorporeal albumin perfusion). In the cases of intractable pruritus, after other modalities have been tried and have failed, transplantation offers an extremely effective therapy: pruritus usually disappears within 2 to 3 days after surgery. In contrast, lethargy resolves more slowly and often incompletely.

Box 97A.4

Mayo Prognostic Model for Estimating Survival in Patients with Primary Sclerosing Cholangitis

0.535 × Log serum bilirubin (mg/dL)
+ 0.468 × Histologic stage*
+ 0.041 × Age (yr)
+ 0.705 × Splenomegaly†

*1 for stages 1 and 2; 2 for stages 3 and 4
†0 for absence, 1 for presence

In addition, PBC may recur in the allograft, but this is likely to be at a slow rate, and it should not preclude transplantation. Other extrahepatic manifestations of PBC will not be affected.

Primary Sclerosing Cholangitis (See Chapter 41)

In contrast to PBC, the natural history of primary sclerosing cholangitis (PSC) is far less clear and predictable (Ludwig et al, 1990) and accounts for about 6% of all transplantations. For many patients, the disease runs a fluctuating course with exacerbations and remissions that may be due to episodes of spontaneously occurring bacterial cholangitis. Underlying these fluctuations in liver function is a persistent and relentless progression toward liver failure.

As with other chronic liver diseases, serum bilirubin and serum albumin remain useful markers of progression, and prognostic models will help in timing the procedure (see Box 97A.4). The CTP classification and MELD score are as reliable as the Mayo model (Shetty et al, 1997; see Chapter 70B).

Most cases of PSC are associated with inflammatory bowel disease, usually ulcerative colitis. Patients with PSC and colitis are at increased risk of colonic cancer, compared with those with colitis alone; because the cancers tend to be in the ascending colon, a full colonoscopy is recommended in all potential transplant candidates to exclude colonic neoplasia and to assess the degree of colitis. Quiescent colitis is not a contraindication to transplantation, but active colitis should be treated before transplantation. When surgical treatment is required to control the colitis, this can safely be done at the time of the transplant procedure. Colectomy either before or during transplantation confers a protective effect against recurrent PSC in subsequent grafts (Alabraba et al, 2009).

PSC is a premalignant condition with the patient at increased risk of developing cholangiocarcinoma in any part of the biliary tree (Rosen & Nagorney 1991), and up to 20% of patients with PSC may develop a cancer, especially smokers (see Chapter 50A). Bile duct dysplasia may identify a group of patients at special risk, but this is still controversial. It is often difficult to be certain whether a sudden deterioration in the patient is due to the development of cholangitis, the natural history of the disease, or the development of cholangiocarcinoma (Bergquist et al, 1998).

Methods of detection of cholangiocarcinoma are often unrewarding: serum markers such as carcinoembryonic antigen (CEA) are relatively nonspecific and insensitive; elevated levels of carbohydrate antigen (CA) 19-9 may be more helpful but are not specific (Qin et al, 2004). Imaging techniques including CT, magnetic resonance imaging (MRI), ultrasound, and angiography are often unreliable and miss even quite large tumors. Although the presence of dilated intrahepatic bile ducts is often a useful sign of cholangiocarcinoma, it also is too insensitive and nonspecific for routine use.

The biliary tree can usually be well visualized by magnetic resonance cholangiopancreatography (MRCP), which gives images almost as good as those obtained at endoscopic retrograde cholangiopancreatography (ERCP); however, MRCP does not allow tissue to be taken for histology or cytology (see Chapters 17 and 18). ERCP may be helpful if brushing for bile cytology is combined with biopsy of structures. Although the specificity is high, the sensitivity is relatively low, and the procedure is not without risk of precipitating severe cholangitis. Directed percutaneous biopsy or aspiration cytology again may give a positive diagnosis, but negative findings do not exclude the possibility of cholangiocarcinoma.

It must be emphasized that ERCP in the presence of advanced PSC may lead to sudden deterioration, presumably as a result of the introduction of biliary sepsis. If cholangiocarcinoma is known to be present prior to transplantation, survival is poor; thus clinicians at most centers believe the patient who is known to have cholangiocarcinoma should not be considered for transplantation, although a very small proportion of patients with cholangiocarcinoma may benefit from an aggressive approach with brachytherapy and chemotherapy (Heimbach et al, 2004).

No effective medical treatment is currently available for PSC, although encouraging claims have been made for the use of UCDA at high doses (>20 mg/kg body weight/day), but this has been challenged (Lindor et al, 2009). Surgical intervention may be helpful, although endoscopic dilation or stenting should usually be considered only in the presence of a single, dominant extrahepatic stricture. The use of biliary diversion and reconstruction is associated with a poorer result following transplantation. In our experience in Birmingham, United Kingdom, the 1-year survival of patients with PSC without prior biliary surgery was significantly better (Ismail et al, 1991). Analysis of the Mayo Clinic database suggests that the prognostic markers for patients with PSC after transplantation include disease severity, previous biliary or shunt surgery, concurrent bile duct cancer, and the presence of inflammatory disease (Wiesner et al, 1996; Chapter 42A). Our own analysis confirms these observations, but we did find that although ulcerative colitis was associated with a better outcome, Crohn disease was associated with an adverse outcome (Neuberger et al, 1999).

It is clear, therefore, that as PSC is a premalignant disease, and because cholangiocarcinoma is usually very difficult to detect, patients with PSC should be considered earlier for transplantation and, during the course of their illness, biliary surgery should be avoided if possible.

Alcoholic Liver Disease

Selected patients with alcoholic liver disease are excellent candidates for transplantation, accounting for 13% as a single indication and 19% with HCV. Initial concerns were that these patients would continue to drink alcohol to excess, comply poorly with follow-up, and be unreliable about taking immunosuppression medications. Furthermore, the ravages of alcohol include not only damage to the liver, other organs—including heart, brain, pancreas, and bone marrow—may be affected. Finally, patients with alcoholic liver disease are often more likely to have associated psychiatric problems; however, in 1988, Starzl and colleagues reported an estimated survival of more than 70% in 41 patients transplanted for alcoholic liver disease.

Of these patients, only 2 returned to alcohol abuse and subsequently died. The survival rates of these patients were similar to other patients with cirrhosis. Following these encouraging results, other centers started to consider patients with alcoholic liver disease for transplantation, and most centers now do consider such patients as candidates for the procedure (Kumar et al, 1990). Nonetheless, there remains a decreasing body of opinion that takes the view that, because alcoholic liver disease is a self-induced injury, and in view of the expense of the procedure and the limited supply of donor organs, such candidates should not be considered. In the view of most transplant units, however, this is not considered appropriate, because patients with alcoholic liver disease are not necessarily alcohol dependent; there exists a large number of self-induced diseases, and it would be no more appropriate to deny a patient with alcohol-induced liver disease transplantation for the reason it is self-induced than to deny treatment for a broken limb in a rugby player or mountain climber.

In addition to the usual criteria for transplantation and contraindications to the procedure, other specific factors need to be considered for patients with alcoholic liver disease: the first is the effect of alcohol abstinence, which undoubtedly improves survival in patients who are seen initially without compensated or decompensated cirrhosis. Although those who come to medical attention with variceal hemorrhage or severe ascites often only have limited benefit after abstinence from alcohol, those with mild ascites or other complications may have a significant improvement in both quality and quantity of life once they abstain from drinking (Suterakis et al, 1973). Furthermore, because it is now becoming apparent that those who do not abstain from alcohol are more likely to return to drinking excessively following transplantation and are less likely to comply with follow-up (Beresford et al, 1990), some centers insist on an abstinent period of 6 months. No robust justification exists for this period of abstinence, and the duration of abstinence correlates poorly with posttransplant abstinence. Furthermore, the disease may progress before the stipulated period of abstinence is over. In particular, patients with liver failure are unlikely to survive if they do not recover within the first 3 months of abstinence (Veldt et al, 2002). A period of abstinence is helpful in part to ensure that the native liver will not recover to such an extent that transplantation is no longer required, but also to identify why the person has drunk excessively and to put in place appropriate measures so that there will be a lower risk of recurrence after transplantation. So the period of abstinence must be considered in the light of the patient's condition, and transplantation is offered to the patient who has remained abstinent after being so advised (Neuberger et al, 2002).

It is recommended that the candidate with alcoholic liver disease be carefully evaluated by clinicians expert in substance abuse. Factors that suggest a poor compliance after transplantation include abuse of multiple substances, failure to recognize the nature of the addiction, lack of social support, and failure to find an alternative activity.

The role of transplantation is more difficult to define in patients with alcoholic hepatitis, severe hepatitis characterized by high serum bilirubin and prolonged clotting. Encephalopathy and renal failure have a dismal prognosis: time is usually insufficient to evaluate the patient's background, and the outcome after transplantation is usually poor. Few centers undertake to graft these patients, yet outcomes can be good in those carefully selected; thus in these patients, a multidisciplinary approach to evaluation assumes an even greater importance.

On the physical side, in addition to the routine workup, the extrahepatic effects of alcohol must be assessed, and those with advanced alcoholic cardiomyopathy or pancreatitis may not be suitable on such grounds. Psychiatric assessment is used extensively in some centers (Beresford et al, 1990), and these centers have suggested that patients who are not alcohol dependent, who have found alternative substitutes for alcohol, who have a job, who have taken part in rehabilitation programs, and who have an understanding of their problems often do very well following transplantation. Thus, patients with alcoholic liver disease are certainly potential candidates, and as such they do require appropriate referral for consideration.

Hepatitis A Viral Infection

Rarely, acute hepatitis A virus (HAV) infection is an indication for liver transplantation, and the indications are listed in the section above on FHF. In a few cases, recurrent infection in the graft occurs, but this is of little clinical significance.

Hepatitis B Viral Infection

Patients with hepatitis B virus (HBV) infection can be considered for transplantation either because of FHF or because of chronic liver disease, accounting for less than 5% of transplantations (see Chapter 64). Of those with FHF, the conventional criteria apply as indicated above. Because it is thought that the liver failure in these patients is due to the rapid clearance of virus-infected hepatocytes, most patients at the time of transplantation are HBV DNA negative and, as such, the disease recurs less commonly than in those with chronic HBV infection.

However, different considerations apply to those with chronic liver disease. Those who are HBV DNA positive at the time of transplantation are much more likely, if untreated, to have recurrence of disease following transplantation, and this is associated with a significantly poorer outcome (Freeman et al, 1991; O'Grady et al, 1992; Rizetto et al, 1991); thus patients with high HBV DNA positivity prior to transplantation are not suitable candidates. The management of these patients has been revolutionized by the introduction of effective antiviral therapy (Kim et al, 2004) that has significantly reduced the need for liver transplantation; patients with active viral disease should be treated with antivirals. At present, there are seven approved treatments for chronic HBV, and choice of treatment is based on the e-antigen status, resistance pattern, adverse events, and cost (Lok & McMahon, 2009). Treatment with HBV immunoglobulin (HBIg) and lamivudine or other antiviral agent must be continued after transplantation.

Hepatitis C Viral Infection

The indications for transplantation of patients with HCV infection are increasing, similar to those with cryptogenic cirrhosis (see Chapter 64). After 20 years of infection, up to 20% of HCV-infected patients progress to cirrhosis (Freeman et al, 2001). The optimal time to treat is before onset of advanced fibrosis or liver failure, because 5-year survival is only 50% after the onset of hepatic failure (Fattovich et al, 1997). Patients with detectable HCV at the time of transplant will almost invariably develop recurrent disease, although the extent of

graft damage is variable. Many factors—host, donor, and immunosuppressive—are associated with the extent and rate of graft damage.

Because of the effect of recurrence in the graft, some have tried antiviral therapy with pegylated interferon and ribavirin prior to transplant (Everson, 2004). When this can be done safely, a sustained viral response (SVR) is associated with a much lower risk of graft infection and damage, and 5-year survival after transplantation is similar to patients grafted for other causes of cirrhosis, although concerns remain whether survival in the longer term will be adversely affected by recurrent disease. Treatment with interferon and ribavirin may be effective in selected groups, but SVR is often hard to achieve, and treatment is poorly tolerated.

Patients with hemophilia and HCV infection pose a special problem. Although liver transplantation will correct the defect in hemophilia, this itself is not an indication for liver transplantation. Many patients will have contracted HCV through contaminated blood products. Provided the patient is supported with adequate amounts of the appropriate blood products, liver transplantation poses no major problem, and many patients will not need support beyond 72 hours (McCarthy et al, 1996).

Hepatocellular Carcinoma (Chapters 80 and 97D)

Hepatocellular carcinoma (HCC) may occur in a noncirrhotic liver, but in the Western population, it more commonly arises in the context of cirrhosis and accounts for 8% of transplants, 5.6% in those with cirrhosis. A number of approaches to the treatment of HCC have been adopted and include chemotherapy, resection, embolization, transarterial chemoembolization (TACE), injection with ethanol, cryotherapy, radiofrequency ablation (RFA), and transplantation (see Chapters 83 through 86 and 88). In those with HCC, some have argued that resection should be considered first with salvage liver transplantation used where there is tumor recurrence (Belghiti et al, 2003; Sala et al, 2004). Indications include a normal serum bilirubin and absence of portal hypertension. Such an approach remains controversial. Very few well-conducted prospective randomized trials of treatment have been conducted, and most reports are based on selected patients and compared with historic controls. It must also be remembered that in those with HCC arising in a cirrhotic liver, the optimal treatment will depend not only on the natural history of the HCC but also on the severity and extent of the liver disease.

It has been suggested that patients with the fibrolamellar variant of HCC have a better prognosis, but this is by no means universally agreed. For all those with HCC, transplantation offers the only prospect of long-term survival; given the current shortage of donor organs, guidelines must be agreed upon to determine the indications and contraindications for liver replacement.

Transplantation for patients with HCC raises a number of questions, and at the present time, few hard data are available upon which to base a logical strategy. Most centers currently adopt the Milan criteria for accepting a patient for transplantation (Mazzaferro et al, 1996). These criteria are a single tumor of less than 5 cm in diameter or, in those with multiple tumors, no more than three tumors, all less than 3 cm in diameter. The analysis was based on a small number of patients, but the results have been confirmed in larger series. Extrapolation for these observations to current practice must be done with caution, as imaging techniques have improved, so more lesions are being detected. Thus, it may be inappropriate to extrapolate conclusions based on studies done in the late 1990s.

It is clearly not the size of the tumor per se that is important, but that the size reflects the likelihood of tumor microinvasion and spread and thereby reflects the chance of recurrence after transplant; of course, this is not strictly recurrence but *persistence*. Indeed, other groups have suggested that these criteria are too strict and should be expanded. Thus, the University of California—San Francisco group (Yao et al, 2002) has suggested that the indications should be expanded to include either a solitary tumor at or less than 6.5 cm diameter or three or fewer nodules, with the largest lesion at or less than 4.5 cm and a total tumor diameter at or less than 8 cm; vascular invasion would preclude transplantation. Whether indications for transplant with cadaveric donor livers should be the same as for living donated livers is controversial.

Klintmalm (1998) published the outcome of the findings of the International Registry of Hepatic Tumors in Liver Transplantation that included the outcome of 410 patients with HCC and 12 with the fibrolamellar variant. Of these patients, 40% had incidental tumors—that is, tumors detected on explantation—and 60% had a transplant for known HCC. Overall, after transplantation, 190 patients had died during follow-up, 99 (23.5%) were free of tumor, and in 91 (21.6%), tumor was the cause of death, although many who died early were presumed to be tumor free after transplantation. The 1-year survival was 72%, and 5-year survival was 44%. Univariate analysis identified four factors that predicted patient survival and poor outcome: 1) tumor size greater than 5 cm, 2) vascular invasion, 3) positive lymph nodes, and 4) histologic grade with poor differentiation.

Incidental tumors, fibrolamellar variants, and bilobar tumors were not found to correlate with outcome. When multivariate analysis was used, only histologic grade and known tumors were significantly related to survival. For incidental tumors, survival was negatively influenced by multifocality and age greater than 60 years; tumor histologic grade and size greater than 5 cm were negatively linked to tumor-free survival. Although this report gives invaluable data in selecting patients for transplantation, these findings must be interpreted with some caution, because the data come from 53 units in 21 countries, where there are differences in the etiology of the cirrhosis, in detection, and in management of patients. Many of these factors are interrelated, so a poorly differentiated HCC may be more likely to grow rapidly and metastasize early. Not all single-center experience will confirm the registry report (Rose et al, 1998), however: for example, Achkar et al (1998) found that routine screening of cirrhotic patients will detect small, early stage tumors and that such patients do well after transplantation.

Transplantation is indicated for unresectable HCCs in noncirrhotic livers with no evidence of extrahepatic spread. Although most HCC arises in cirrhotic livers, occasionally HCC may occur in the absence of underlying hepatic parenchymal cirrhosis. In such cases, transplantation is one option usually reserved for those patients in whom other forms of treatment—such as resection, chemotherapy, chemoembolization, RFA, or TACE—are not indicated, and where the characteristics of the HCC fulfill the current indications for transplantation. In those patients with cirrhosis, the decision to resect (if possible) or transplant is more uncertain, because most HCCs in this situation are usually multifocal.

Transplantation may offer a survival benefit (Sarasin et al, 1998) that is also cost-effective, provided the delay from diagnosis to transplantation is less than 6 to 10 months.

The role of pretransplant therapy remains uncertain (see Chapter 83). Some centers are undertaking interventions with either RFA or TACE, but no controlled trials show that such interventions offer a survival benefit; indeed, it is not clear whether any reported benefit is derived from the intervention itself, or whether the delay will help identify those with rapidly growing tumors, those likely to be already outside the liver at the time of transplantation. As RFA and TACE will induce necrosis of the tumor, these and similar interventions may be of help when the waiting time is greater than 6 months in patients with stable liver functions (Bruix & Sherman, 2005). Evaluation involves ultrasound to look for evidence of extrahepatic spread together with CT and/or MRI scan of both the chest and the abdomen along with bone scans to exclude extrahepatic metastasis. Laparoscopy may reveal the presence of nodules ulcerating through the capsule, but it is not usually done. Tumor infiltrating the portal vein, in our view, contraindicates transplantation.

The role of liver biopsy to establish the diagnosis of HCC or assess the biologic characteristics must be considered. Because the risk of tumor seeding may be 2% to 4% along the needle biopsy tract (Navarro et al, 1998), biopsy should be considered only when there is uncertainty as to the diagnosis. This might occur, for example, in the presence of a hepatoma arising in the noncirrhotic liver. It is not usually possible to be sure whether the tumor is malignant or if it is indeed a liver primary. The clear-cell variant of HCC is often difficult to distinguish from pancreatic and renal neoplasm. In contrast, in a patient with known cirrhosis, a primary space-occupying lesion, and rapidly elevating serum α-fetoprotein (AFP) level, there can be little doubt as to the diagnosis; because percutaneous biopsy would only increase the risk of metastasis, it should be avoided.

Cholangiocarcinoma

As indicated above, cholangiocarcinoma (see Chapters 50A, 50B, and 97E) is not usually considered to be an indication for transplantation, because the recurrence rates are high; thus in a literature review, Jeyarajah and Klintmalm (1998) reported a 1-year patient survival of 53% but a 3-year disease-free survival of only 13%. Only in the incidental tumor found at laparotomy is transplantation to be considered, although cures are sometimes possible (Iwatsuki et al, 1998). Some centers have achieved excellent survival after transplantation in highly selected patients treated with an aggressive protocol of radiotherapy and chemotherapy (Hassoun et al, 2002).

Secondary Liver Cancers

With few exceptions, we feel transplantation is not indicated for metastatic liver because of the high rate of recurrence (see Chapter 97E). The major exception is carcinoid and other neuroendocrine tumors, as long-term results are good, and symptomatic relief is rapid (Makowka et al, 1989; see Chapters 81B and 97E). Of 103 patients with unresectable neuroendocrine tumors, the 5-year survival rate was 47%, although the disease-free recurrence rate was only 24% (Lehnert, 1998). In this analysis, multivariate factors that identified a better prognosis included age less than 50 years, primary location in lung or bowel, and pretransplant somatostatin therapy. Multivariate analysis showed that age greater than 50 years, upper abdominal exenteration, and Whipple procedure at the time of transplantation were all associated with a poor outcome.

PEDIATRIC TRANSPLANTATION

The medical indications for liver transplantation in children are similar to those in adults (see Chapters 40, 71, 82, and 98C), although additional indications include growth retardation and the development of metabolic bone disease. The commonest indication for transplantation in children remains disorders of the biliary system, of which biliary atresia (Chapters 40 and 98C) is the commonest. The procedure of portoenterostomy may be effective in some children if performed early, but if performed after 2 months, the chance of a successful outcome is limited; thus if bile drainage is not established soon after surgery, the child should be considered for transplantation rather than have the surgeon make further attempts to reconstruct the bile duct system in an attempt to establish bile flow. Other disorders of the biliary tree that may require transplantation include Alagille syndrome, Byler disease, and nonsyndromatic intrahepatic biliary hypoplasia. Disorders of metabolism are the next commonest indication for transplantation, and these include Wilson disease, tyrosinemia, glycogen storage disease, galactosemia, and Gaucher syndrome.

ASSESSMENT OF PATIENTS FOR LIVER TRANSPLANTATION

When the patient is referred for liver transplantation, it is important to confirm the diagnosis of the liver disease, to assess the indications for liver transplantation and any conditions that may either preclude transplantation or add to the risk of the procedure, and to counsel the patient and family about the benefits and risks of surgery. Although the decision for transplantation rests with the patient, it is important to include the family in discussions, because their cooperation and understanding is essential for successful rehabilitation following transplantation.

Apart from a thorough history, examination, and review of histology, it is clear that investigations required will be dependent on the patient's medical condition. Some chronic liver diseases are associated with extrahepatic diseases, thus primary biliary and autoimmune chronic active hepatitis are associated with thyroid disease, celiac disease, and Addison disease. These should be excluded, because untreated myxedema, for example, may lead to lethargy, and if corrected, this may obviate the need for transplantation.

In patients with chronic liver disease—apart from full blood count, assessment of clotting, renal function tests, and liver function tests—it is important to check viral status for HAV, HBV, HCV, HIV, and cytomegalovirus (CMV). In those who are not immune to HAV and HBV, it is worthwhile to offer immunization prior to transplantation, as there have been occasional reports of HBV being acquired during the transplant procedure, from either infected organ or blood.

In patients with established cirrhosis, HCC should be sought by imaging of the liver and measurements of serum AFP; in addition, bacterial, viral, and fungal cultures should be obtained for a baseline. In patients with a possible history of tuberculosis, tests should be directed to determine the presence of previous infection; in such cases, it is our practice to give isoniazid and

pyridoxine for the first 6 months following transplantation. Additional blood tests will be determined by the nature of the disease and may include autoantibodies, immunoglobulins, copper studies, α_1-antitrypsin phenotypes as appropriate, and crossmatching.

Cardiopulmonary function is difficult to assess. ECG, echocardiography, and simple lung function tests may be adequate to recognize pathology that requires further investigation. For example, in a patient with possible ischemic heart disease, if appropriate, we will proceed with an echocardiogram, an exercise ECG test prior to thallium scanning, and coronary angiography or other imaging as indicated. Measurement of arterial blood gases is important; if the arterial oxygen is low, these tests must be repeated after exercise and after giving 100% oxygen to gain guidance as to the extent of intrapulmonary shunting (Krowka & Cortese 1990).

Radiologic investigations consist primarily of a chest radiograph and an ultrasound of the liver, biliary tree, pancreas, spleen, and vessels. If there is any uncertainty as to the patency of the portal vein, angiography—direct, CT, or MR—can help assess patency of the portal and splenic superior mesenteric veins. Many centers do not routinely perform CT or MRI scans unless malignancy is suggested, but many believe they should be routinely performed prior to initial listing and at least annually thereafter until the time of transplant.

In patients with PSC, as discussed above, investigation of the biliary tree may be indicated. Although this may pick up undiagnosed cholangiocarcinoma, this procedure could result in an episode of cholangitis. Many patients with PSC have colitis, and although it is usually mild and often clinically inapparent, it is important to screen such patients prior to surgery to exclude a coexisting colon cancer. In particular, those with a long history of pancolitis require full investigation by colonoscopy; however, this procedure is not without risk, especially in those with ascites. In the presence of dysplasia, it may be sensible to consider early colectomy, because the additional effect of immunosuppression may further increase the risk of colonic cancer.

Routine psychiatric evaluation is not indicated, unless the history suggests the possibility of psychiatric disease that may preclude successful rehabilitation. A dental examination is required prior to transplantation, and any carious teeth are usually removed. Patients are also routinely assessed by the anesthetist prior to receiving a transplant.

MANAGEMENT OF PATIENTS AWAITING TRANSPLANTATION

In general, patients should be maintained as fit as possible while awaiting transplantation. Any vitamin deficiency should be corrected, and the patient should be asked to consume a high-protein, high-calorie diet. The presence of encephalopathy should not bar a high-protein diet, although other methods should be used to control hepatic encephalopathy, such as use of lactulose and, if necessary, metronidazole or neomycin. It is reasonable to offer nonimmune patients immunization with HAV and HBV vaccines, and any infection should be rigorously sought and actively treated.

The presence of ascites may be an indication for treatment; not only do ascitic patients remain catabolic, but the risk of spontaneous bacterial peritonitis is also present. In the presence of ascites, patients should be treated with prophylactic antibiotics, such as ciprofloxacin or co-amoxiclav, which have been shown to be not only efficacious and cost-effective but also without major risk of developing bacterial resistance. In patients with severe ascites that is resistant to therapy with diet and diuretics, requiring repeated episodes of paracentesis, a TIPS may be considered (see Chapter 76E). The role of such shunts prior to transplantation remains uncertain; they have been shown to reduce portal hypertension and thereby improve ascites and the risk of variceal hemorrhage, but insertion is not without risk, not only of sepsis but also of perforation and portal vein thrombosis.

Patients with recurrent variceal hemorrhage pose a particular problem (see Chapter 75). Injection sclerotherapy in the 2 weeks prior to transplantation is associated with a risk of paraesophageal abscesses following transplantation. Variceal banding is preferable for the treatment of bleeding esophageal varices, and again, the role of TIPS is valuable in selected patients. If successful, TIPS procedure will reduce portal hypertension, but it is not free of risks, which include perforation and portal vein thrombosis; however, current evidence suggests that the benefits outweigh the risks. Patients with portal hypertension and varices should be considered for β-blocker therapy with propranolol or carvedilol, because this will reduce the risk of both primary and secondary hemorrhage and does not impair response to anesthesia.

Finally, it is important to avoid therapy that will exacerbate the liver disease. In particular, nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided because of the risks of gastric hemorrhage, renal failure, and fluid retention. Drugs that result in constipation, such as opiates, and sedative drugs should also be avoided because of the risk of precipitating encephalopathy. Diuretics must be used with care, and renal function must be carefully monitored; renal failure is associated with poor outcome after transplantation, and hyponatremia is associated with the development of central pontine myelinolysis.

Transplant clinicians need to remain in close contact with the patient so that problems can be detected and treated early. As the waiting time for transplantation increases, patients will deteriorate, and it may be that the patient will either develop complications precluding a successful outcome or that the probability of survival will become too small for transplantation to proceed. With the increasing shortage of donor organs, transplant clinicians must consider those criteria that suggest a patient should be removed from the transplant list.

PART 8: Liver and Pancreas Transplantation

SECTION III Techniques

CHAPTER 98A

Orthotopic liver transplantation

Kendra D. Conzen, M.B. Majella Doyle, and William C. Chapman

OVERVIEW

Since the initial descriptions of orthotopic liver transplantation (OLT) in the 1960s, both the number of patients receiving transplants and the indications for the procedure have increased significantly. OLT represents the only treatment modality for many patients with a diverse spectrum of disease, with the predominant common factor being end-stage liver failure. It also has become an excellent option as curative therapy for early stage hepatocellular carcinoma (HCC). Advances in perioperative care of both donor and recipient, organ preservation methods, and surgical techniques have resulted in a 1-year overall survival of 88% for all recipients (Wolfe et al, 2010).

Although gains over the last 40 years in the field of hepatic transplantation are notable, many limitations remain, not the least of which is the relatively fixed pool of cadaveric organ donors. Techniques such as living donor liver transplantation (LDLT), use of non–heart-beating donors, and splitting cadaveric grafts may extend the benefit of OLT to more patients awaiting transplantation.

This chapter presents a broad overview of liver transplantation, including common criteria for recipient and donor selection (see Chapter 97A), standard operative approaches for donors and recipients (see Chapter 99), common postsurgical complications (see Chapter 100), and outcomes related to the underlying etiology of end-stage liver disease (ESLD). Specialized transplant techniques, such as split-liver and living-related donor liver transplantation, are described in Chapters 98B and 98C.

PATIENT SELECTION

OLT represents the only curative treatment option for most patients with irreversible acute and chronic liver disease and cirrhosis, regardless of cause. Over the past 4 decades, 5-year patient survival after liver transplantation has increased from less than 50% to greater than 70% or more (Busuttil et al, 2005; Jain et al, 2000). The improvement in patient outcome has led to an expansion in the indications for transplantation and a concomitant increase in the number of patients referred to transplant centers (see Chapter 97A). The downside to this success is the persistent disparity between the number of recipients vying for a transplant and the number of donor organs available, a relatively constant supply (Fig. 98A.1).

The number of patients listed for OLT has increased sixfold since 1993, whereas the number of transplantations performed increased by only 45% during the same time. In 2008 in the United States, 15,807 patients were on the waiting list for a liver transplant, a decline from a peak of nearly 17,000 in 2002 (Wolfe et al, 2010); however, only 5817 of the patients on the waiting list received a liver allograft, and 90% of these recipients had a Model for End-Stage Liver Disease (MELD) score above 15 at transplantation (U.S. Scientific Registry of Transplant Recipients [USRTR], 2008).

Historically, the donor-to-recipient disparity leads to longer waiting times and worsening medical status with a peak waiting-list attrition rate of 187 per 1000 patient-years at risk in 1999. This rate declined by 15% and has remained steady over the last few years at 160 per 1000 patient-years at risk (Thuluvath et al, 2010). Because of the limited supply of donor organs, appropriate recipient and donor selection is paramount to improve resource use and long-term outcome.

Recipient Selection

Common indications for OLT (see Chapter 97A) include portal hypertension as manifested by variceal bleeding, ascites, encephalopathy, hyperbilirubinemia, hepatic synthetic dysfunction, and lifestyle limitations. More than 70% of liver transplantations are for noncholestatic liver disease, of which the most common etiologies are viral hepatitis (30%) and alcoholic cirrhosis (16%) (USRTR, 2008). Biliary atresia is the most common indication for liver transplantation in patients younger than 18 years of age (Busuttil et al, 2005; Goss et al, 1998). Nonalcholic steatohepatitis (NASH) is becoming an increasingly common cause of liver cirrhosis, as the prevalence of

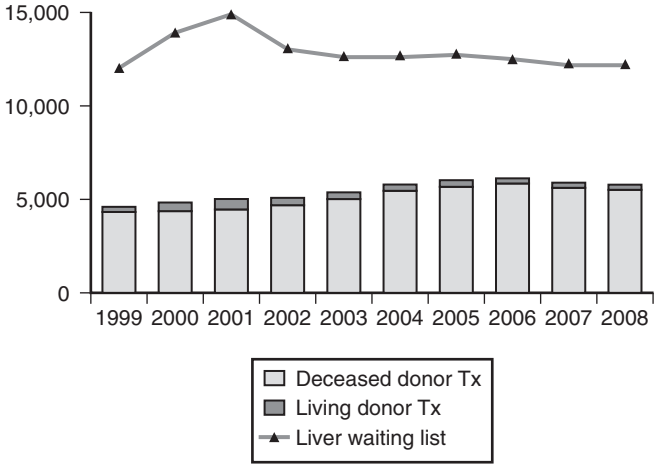

FIGURE 98A.1. Data from the Scientific Registry of Transplant Recipients (SRTR), 2009 *OPTN/SRTR Annual Report*, demonstrates the persistent disparity between patients on the waiting list and recipients of deceased-donor and living-donor allografts. The number of patients awaiting a liver transplant at year's end decreased after the introduction of the Model for End-Stage Liver Disease (MELD) and the pediatric MELD allocation system. Tx, treatment.

nonalcoholic fatty liver disease (NAFLD) increases; NAFLD now affects an estimated 10% of children (Schwimmer et al, 2006).

Few true, absolute contraindications to OLT exist that uniformly portend a poor patient outcome (Box 98A.1). Advanced cardiopulmonary disease, known extrahepatic malignancy, uncontrolled systemic sepsis from a source originating outside the liver, acquired immunodeficiency syndrome (AIDS), and ongoing or recent substance abuse are absolute contraindications. Many of the relative contraindications are conditions that are expected to improve after successful OLT. Examples include severe hemodynamic instability (e.g., shock) requiring multiple pharmacologic agents to maintain perfusion and severe hypoxia uncorrected by conventional intensive care measures in the context of hepatopulmonary syndrome. Other relative contraindications to OLT are extensive mesenteric venous thrombosis, morbid obesity, psychiatric disorders uncontrolled by conventional means, absence of a suitable social support network, and extremes of age (Jain et al, 2000; Loinaz et al, 2002; Rustgi et al, 2004).

Box 98A.1

Contraindications to Orthotopic Liver Transplantation

Absolute

Advanced cardiopulmonary disease
Extrahepatic malignancy
Uncontrolled sepsis
Active substance abuse
ABO incompatibility

Relative

Hemodynamic instability
Severe hypoxia (except with hepatopulmonary syndrome)
Human immunodeficiency virus infection
Refractory psychiatric disorders
Absence of adequate social support

Increasingly, advances in surgical technique and medical supportive care are overcoming obstacles and comorbid conditions formerly considered absolute contraindications to transplantation, including portal vein thrombosis (PVT), human immunodeficiency virus (HIV) infection, and advanced age. Patients who receive liver transplants now have higher rates of diabetes mellitus (DM), renal insufficiency, and morbid obesity (Thuluvath et al, 2010). Although pretransplantation insulin-dependent DM is not a contraindication to transplantation, evidence suggests that better risk stratification of these patients is warranted (Thuluvath, 2005). Likewise, patients with extreme body mass indexes (<18.5 or >40) might be at higher risk for posttransplantation complications (Dick et al, 2009). Morbid obesity is also associated with an increased risk of infectious complications and posttransplantation malignancy.

Although HIV infection has historically been considered a contraindication to OLT, the advent of highly active antiretroviral therapy (HAART) has turned HIV into a chronic condition, and patients are now living long enough to suffer the morbidity and mortality of other diseases, including ESLD. Therefore some patients with HIV may be considered for liver transplantation, if their CD4 T-cell count is greater than 200 and their HIV RNA viral load is less than 50 copies/μL within 12 months prior to transplantation (Di Benedetto et al, 2008). It should be noted that hepatitis C virus (HCV) coinfection with HIV predicts worse outcomes after OLT, with faster and higher rates of HCV recurrence (Di Benedetto et al, 2008).

The etiology of liver failure may be predictive of outcome after OLT, although the correlation between preoperative risk and graft survival sometimes varies. Jain and colleagues (2000) examined outcomes after OLT in 4000 consecutive patients treated at the University of Pittsburgh. Patients with metabolic or autoimmune liver disease experienced 10-year survival rates greater than 60%, whereas the survival rates for viral hepatitis or alcohol-induced cirrhosis were 40% to 50%, and patients transplanted for advanced hepatic malignancy had only a 22% survival at 10 years. Results for all patients were better in the most recent era. Earlier contradictory reports notwithstanding, recipient age probably does not influence transplantation results significantly (Gayowski et al, 1998; Ploeg et al, 1993; Totsuka et al, 2004). Thorough screening for medical comorbidities commonly found in older populations—such as lifestyle-limiting cardiopulmonary disease, systemic vascular disease, and chronic renal insufficiency—is crucial to successful OLT in patients older than 60 years.

The recipient selection process has undergone extensive revisions to ensure equitable allocation of a scarce resource (cadaveric donor livers) while attempting to avoid futile transplantation. Before February 2002, recipients awaiting OLT were prioritized based on the Child-Turcotte-Pugh (CTP) scoring system (Table 98A.1), time on the waiting list, and patient location (e.g., intensive care unit). Waiting lists grew under this system, and it became increasingly clear that these parameters were not good measures of disease severity.

In 2000, the Department of Health and Human Services issued a guideline stating that the allocation of livers for transplantation should be based primarily on medical urgency (Freeman et al, 2002). The United Network of Organ Sharing (UNOS), which administers the Organ Procurement and Transplantation Network, commissioned several subcommittees to examine new methods for allocation. The result was the universal adoption of the MELD criteria (Table 98A.2) as a

Table 98A.1

Child-Turcotte-Pugh Classification

	POINTS		
	1	2	3
Encephalopathy	None	1 or 2	3 or 4
Ascites	Absent	Slight	Moderate
Bilirubin (mg/dL)	1 to 2	2 to 3	>3
Albumin	>3.5	2.8 to 3.5	<2.8
Prothrombin time (seconds prolonged)	1 to 4	4 to 6	>6

measure of the potential recipient's necessity for OLT. Concurrent revision of the pediatric liver allocation process produced the Pediatric End-Stage Liver Disease (PELD) model, which is discussed further in Chapter 98C. Per a policy change in 2005, PELD is applied to potential transplant recipients younger than 12 years. Adolescents aged 12 to 17 years are stratified using the MELD system.

In contrast to its predecessor, the CTP score, MELD has been validated extensively as a predictor for 3-month mortality from chronic liver disease (Malinchoc et al, 2000; Wiesner et al, 2003a). It incorporates serum creatinine, bilirubin, and international normalized ratio (INR) as markers for risk of death; relies on objective and readily available blood tests; and practically eliminates time on the waiting list from consideration. Using MELD criteria, rates of death while awaiting OLT and removal from the waiting list for being too sick have decreased (Thuluvath et al, 2010). Median time to transplant in 2007 was 361 days.

As shown in Figure 98A.2, the use of MELD criteria for predicting mortality from ESLD results in an appropriate correlation between severity score and actuarial survival at 3 months. Survival benefit analysis of liver transplant recipients stratified by MELD score demonstrates that the risks involved in transplantation are equivalent or less than the risks associated with remaining a transplant candidate on the waiting list with a MELD score over 15 (Merion et al, 2005). The MELD-based allocation process is dynamic and amenable to subtle changes to reflect an evolving understanding of the diverse pathology and physiology seen in patients treated with OLT.

Table 98A.2

Predicted Mortality According to the Model for End-Stage Liver Disease Score*

Score	No. Patients	Mortality Rate (%)	Death or Removal from List Because of Illness (%)
<9	124	1.9	2.9
10-19	1800	6	7,7
20-29	1098	19.6	23.5
30-39	295	52.6	60.2
≥40	120	71.3	79.3

*$R = (0.957 \times \text{Log}_e[\text{creatinine } \{\text{mg/dL}\}] + 0.378 \times \text{Log}_e[\text{total bilirubin mg/dL}] + 1.120 \times \text{Log}_e[\text{INR}] + 0.643) \times 10$

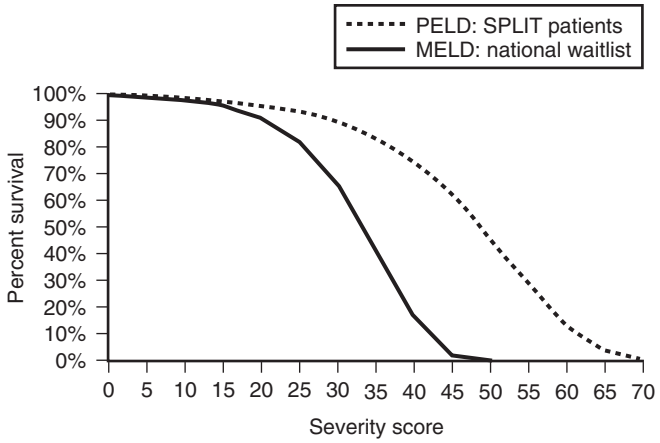

FIGURE 98A.2. Correlation between Model for End-Stage Liver Disease (*MELD*) and the pediatric MELD (*PELD*) score and patient mortality. SPLIT, Studies of Pediatric Liver Transplantation. *(Adapted from Freeman RB Jr, et al, 2002: The new liver allocation system: moving toward evidence-based transplantation policy. Liver Transpl 8:851-858.)*

Special considerations for certain subsets of patients with liver disease are ongoing. Early in the initial evaluation of the MELD criteria, it was recognized that patients with HCC and early cirrhosis should be prioritized lower on the waiting list, when they could potentially benefit most from transplantation (e.g., HCC at an early tumor stage; see Chapter 97D). Conceivably, patients with HCC but low MELD scores could develop progressive disease, which would eliminate OLT as a treatment option. Since the most recent revisions to MELD, patients with stage II HCC currently are allocated 22 MELD priority points. Criteria for selecting HCC patients for transplantation are discussed further in this chapter, including those with more advanced stage disease. Guidelines also exist for awarding priority points for other conditions, such as hepatopulmonary syndrome, portopulmonary hypertension, hepatic artery thrombosis after liver transplant, pediatric hepatoblastoma, inborn errors of metabolism, familial amyloidosis, and primary oxaluria; however, the process is highly variable by region (USRTR, 2008).

Since 2002, the number of patients on the waiting list with exception points for any condition has more than doubled, with close to 900 on the list in 2008 (Thuluvath et al, 2010). Increasingly, stage I and II hilar cholangiocarcinoma is becoming an acceptable indication for OLT, and uniform criteria for obtaining MELD exception points have been proposed (Gores et al, 2006; see Chapter 97E). Eligible patients must be treated according to a specific protocol that requires neoadjuvant chemoradiation, followed by a staging laparotomy to confirm absence of N1 disease (Rea et al, 2005).

Donor Selection

Increased demand for donor organs, as depicted in Figure 98A.1, has resulted in the concomitant increase in the use of less than ideal donors. The theoretic ideal donor is an otherwise healthy, hemodynamically stable young person who suffers an irreversible cerebral insult that results in brain death; this situation is rarely realized. Although marginal donors are being used more frequently, absolute contraindications remain, including

known extracranial malignancy (except for basal or squamous cell cancer of the skin), overwhelming sepsis, hepatic cirrhosis, hepatic macrosteatosis greater than 60%, and HIV infection. Generally, hepatitis B virus (HBV) surface antigen and core antibody positivity in the donor also constitute absolute contraindications (Wachs et al, 1995), although many centers consider transplantation of core antibody-positive livers for HBV-positive recipients, if the graft seems otherwise suitable, and even into non-HBV recipients in selected circumstances. Advanced donor age may adversely affect graft survival, and in practice, donors older than 80 years usually are excluded from consideration.

Data that demonstrate differential effects on specific recipient groups, such as HCV-positive recipients, remain inconclusive (Doyle et al, 2008; Lake et al, 2005; Russo et al, 2004). Although liver allografts with 30% to 60% steatosis are utilized in select groups of recipients, it should be recognized that greater than 60% steatosis significantly increases the risk of primary nonfunction (Urena et al, 1999). A donor risk index (DRI) has been developed to help quantify and stratify allografts by predicted failure risk (Feng et al, 2006).

As a result of the shortage of cadaveric donors, the use of living donors has increased in the United States, from 1996 with a peak in 2001; it has since declined steadily, and LDLTs now represent only 4% of liver transplantations performed (see Chapter 98B). A shift in demographics has also been seen in recipients of LDLT: patients age 50 to 64 years represent the largest group (USRTR, 2008). LDLT is appealing, because it allows elective transplantation after optimizing the health of the recipient, reduces cold ischemic times, and potentially shortens waiting times. The disadvantages include morbidity and rare mortality in the donor population (Brown et al, 2003). The most common practice in adults is transplantation of the right hepatic lobe. Despite initial data indicating worse outcomes in LDLT, a trend has been seen toward improved graft survival and overall survival in the United States in the last 10 years (Thuluvath et al, 2010). Although LDLT from an adult to a child has become well accepted and standardized, adult-adult LDLT continues to evolve, and the place of this approach as part of the overall picture of liver transplant options is not fully defined.

Early reports regarding the successful use of kidneys from non–heart-beating donors and donation-after-cardiac-death (DCD) donors encouraged a similar practice in OLT. Most commonly, DCD donors are patients with severe neurologic injury, such as anoxia and intracranial hemorrhage, and no chance for meaningful recovery, yet they do not meet brain-death criteria; family members and treating physicians must elect to withdraw support. Donor criteria are similar to cadaveric (brain dead) donors.

DCD livers are increasingly being used and now represent 5% of all liver-only transplants (USRTR, 2008). Compared with historic results with brain-dead donors, outcomes using DCD allografts are less optimal, with 1- and 3-year graft survivals of 70% and 60%, 10-year graft survival of 44% for all patients, and a primary nonfunction rate of almost 12% (Abt et al, 2004; Bernat et al, 2006; D'Alessandro et al, 2000; de Vera et al, 2009; Mateo et al, 2006; Thuluvath et al, 2010). The graft survival rate improves when donor warm ischemia time is less than 30 minutes and cold ischemia time is less than 10 hours (Mateo et al, 2006); however, DCD grafts are associated with an increased risk of nonanastomotic intrahepatic biliary strictures (ischemic cholangiopathy) and posttransplantation hepatic artery stenosis (Chan et al, 2008; Pine et al, 2009). Given the risks inherent in DCD allografts, they should be used cautiously in select groups of recipients.

OPERATIVE TECHNIQUES

The first published description of human liver transplantation was by Starzl and colleagues in 1963 at the University of Colorado. In this seminal paper, the dismal outcomes of three OLT recipients were described, including one intraoperative death from uncorrectable coagulopathy and two survivors of 7 and 22 days. In addition to the pioneering conceptual framework and implementation of liver transplantation, several advanced techniques are presented in this reference, including the use of grafts from non–heart-beating donors, venovenous bypass in the recipients, choledochocholedochostomy, and coagulation monitoring using thromboelastography (TEG). Many of these concepts remain or have reentered the realm of liver transplantation more than 40 years after their initial description. Based largely on the initial body of work by Starzl and colleagues, this section describes the surgical procedures commonly used at Washington University in St. Louis during OLT (see Chapter 99).

Donor Hepatectomy

Management of a cadaveric organ donor begins preoperatively, immediately after identification of a candidate and after evaluation by trained transplant coordinators. After brain death, severe physiologic derangements can occur, and physiologic instability increases in proportion to the length of time between declaration of death and organ procurement (Nygaard et al, 1990). The progression from brain death to somatic death results in the loss of 10% to 20% of potential donors (Wood et al, 2004).

Complications that commonly occur in a brain-dead donor include hypotension, the requirement for multiple transfusions, disseminated intravascular coagulopathy (DIC), diabetes insipidus (DI), pulmonary edema and hypoxia, acidosis, and arrhythmias and cardiac arrest. Intravascular volume repletion to normovolemia is the cornerstone of management; however, vasopressors or inotropic agents often are necessary to achieve an adequate perfusion pressure. The use of low-dose arginine vasopressin allows a reduction in the dosing of α-adrenergic agents, which may impair end-organ perfusion (Pennefather et al, 1995). Directed therapy using a pulmonary artery catheter can improve outcome in patients with brain death–induced or traumatic cardiac dysfunction (Wheeldon et al, 1995). A thorough review of the medical management of potential organ donors can be found elsewhere (Wood et al, 2004).

Surgical techniques for procuring abdominal organs from brain-dead, heart-beating donors have been described previously (Farmer et al, 2000; Merkel et al, 1972; Starzl et al, 1984, 1987). A midline incision from the suprasternal notch to the pubis is performed, followed by sternotomy and entry into the peritoneum. The abdomen is inspected for any evidence of malignancy or gross gastrointestinal ischemia, which would preclude transplantation. Procurement proceeds in several phases: warm dissection and cannulation, exsanguination with cold perfusion and organ removal, and back-table dissection and organ preparation.

In the warm dissection phase, the liver is mobilized by dividing the umbilical, falciform, and left triangular ligaments.

Hepatic arterial anatomy is delineated by inspection of the gastrohepatic ligament and porta hepatis to identify aberrant arterial anatomy. A right medial visceral rotation, or Cattel-Brasch maneuver, is performed, by which the right colon and mesentery of the small intestine are mobilized and reflected toward the donor left upper quadrant. The infrarenal aorta is exposed at the bifurcation, and proximal and distal control is obtained. The inferior mesenteric vein is identified, controlled, and cannulated for subsequent portal perfusion.

Next, the intestinal contents are returned to the lower abdomen with attention turned again to the porta hepatis. The distal common bile duct is circumferentially dissected, distally ligated, and transected. The gallbladder is flushed out through a choledochotomy to clear bile from the gallbladder and biliary tree to potentially limit injury to the bile duct epithelium. The common hepatic artery is identified, and the gastroduodenal artery (GDA) is encircled. After reflection of the left lobe of the liver medially, control of the supraceliac aorta is obtained, facilitated by dividing the diaphragmatic crura.

The entire warm dissection phase usually takes 30 minutes or less. At this stage, the donor is ready for heparinization (400 U/kg IV) and for cannulation of the distal aorta, which occurs in coordination with the other procurement teams. When the thoracic and abdominal teams are ready, the donor is exsanguinated via the suprahepatic vena cava. Suction catheters are placed in the chest to remove warm blood, the aorta is cross-clamped in the supraceliac location, and the arterial and portal circulations are flushed—usually with University of Wisconsin (UW) solution or histidine-tryptophan-ketoglutarate—via the previously placed cannulae. Infusion continues until the caval drainage is clear, which typically requires 4 to 5 L via the aorta and another 1 to 2 L via the portal vein. The donor abdomen is packed with ice slush for topical cooling during the flushing phase.

After satisfactory cooling and flushing with preservation solution, the portal dissection is initiated. The general goals of this dissection are to delineate the arterial anatomy and dissect the arterial inflow back to the aorta. This is accomplished by dividing the GDA, dissecting the common hepatic artery down to the celiac trunk, dividing the splenic and left gastric arteries, and dissecting the celiac trunk down to the aorta. This technique is modified in the presence of a replaced or accessory left hepatic artery, in which case preservation of the left gastric artery is mandatory. A search for a replaced or accessory right hepatic artery also is undertaken through identification of the superior mesenteric artery and its proximal branches. Preservation of this artery, if present, is essential.

Next, the portal vein is dissected and divided near the pancreas, although a modification is necessary if pancreas procurement is being performed simultaneously. Excision of the celiac trunk with a Carrel patch of aorta is performed; this common patch, including the superior mesenteric artery origin, is used if an accessory or replaced right hepatic artery is present. Attention is then turned to the infrahepatic inferior vena cava (IVC), which is divided above the level of the renal veins. As a final step, the diaphragm is dissected around the suprahepatic IVC. The diaphragm and all tissues between the right kidney and liver are divided, and the hepatic graft is removed from the donor and packed in ice.

The final preparation of the donor graft usually occurs at the recipient hospital and is a cold, back-table preparation of the arterial and venous cuffs. This work consists of removal of the diaphragm and preparation of the suprahepatic IVC. The adrenal gland is removed, the adrenal vein is ligated, and the infrarenal IVC is prepared. The portal vein is dissected free from surrounding tissue up to the bifurcation and is cannulated for purposes of flushing preservation solution just prior to graft reperfusion. The celiac trunk is dissected up to the GDA with all unnecessary branches ligated. During this phase, arterial reconstruction—that is, donor accessory right hepatic artery to donor GDA—or conduit creation is performed as indicated. At this point, the graft is ready for recipient implantation.

Procurement in a DCD donor requires a slight modification (Bernat et al, 2006; D'Alessandro et al, 2000). In the controlled setting, the donor is brought to the operating room, and support is withdrawn. Heparin is administered to reduce risk of thrombus formation in the graft (Bernat et al, 2006). Apnea and cessation of circulation ensue after a variable amount of time, at which point of death is declared. It is important to note that 10% of potential donors do not die within 2 hours of withdrawal of support; these patients are not candidates for subsequent organ donation and are transferred back to the intensive care unit (ICU) and are allowed to die (Cooper et al, 2004). Circulation is unlikely to resume after 2 minutes of complete cessation; a minimum waiting period of 2 minutes is required, and a 5-minute interval between asystole; pronunciation of death prior to further intervention is strongly encouraged (Bernat et al, 2006).

The goal now becomes rapid reperfusion of the organs for procurement with cold preservation solution; this usually is accomplished via a quick midline laparotomy and cannulation of the aorta. Alternatively, some centers use cannulae placed before death in the femoral artery and vein. Less than 30 minutes of donor warm ischemia time is generally considered acceptable (Bernat et al, 2006). Hepatectomy is performed as in a standard brain-dead donor, commonly followed by a back-table flush. Cadaveric split-liver and living-related liver transplantation techniques are addressed in Chapters 98B and 98C.

Recipient Hepatectomy

Removal of the diseased liver from the recipient can be a challenging technical aspect of liver transplantation. Hepatectomy often is complicated by marked portal hypertension, coagulopathy, extensive collateralization of venous drainage, a friable liver that is prone to hemorrhage, portal venous thrombosis, and possible prior abdominal surgical interventions that may have included portal venous shunting or biliary tract surgery. Preoperative preparation of the recipient includes establishment of central venous monitoring and intravascular access, ensuring availability of at least 10 U crossmatched blood, and timely administration of a second-generation cephalosporin.

Optimal recipient operative exposure is accomplished using a bilateral subcostal incision with an upper midline extension. The umbilical, falciform, and left triangular ligaments are taken down for maximum exposure. The left and right hepatic arteries are ligated in the hilum as the first step in the portal dissection. The cystic duct is divided, if needed for exposure, and circumferential dissection of the common hepatic duct is performed, which is divided in the mid-extrahepatic portion. Sufficient distal bile duct length in the recipient is preserved for the implantation phase, which usually includes choledochocholedochostomy.

Next, the portal vein is skeletonized proximally to just above the confluence of the splenic and superior mesenteric vein. At this point, further dissection is influenced by the use of temporary portocaval shunting or venovenous bypass; both techniques allow decompression of the splanchnic circulation, which reduces bowel edema during the anhepatic phase. When venovenous bypass is used, the portal vein is cannulated, and bypass is instituted as previously described (Shaw et al, 1984). A potential disadvantage of venovenous bypass is the added complexity and potential complications associated with the bypass process (e.g., thrombosis of the bypass circuit). We prefer portocaval shunting with an end-to-side anastomosis between the divided portal vein and infrahepatic IVC. The shunt is kept in place until the suprahepatic caval anastomosis is completed.

Temporary portocaval shunting in conjunction with the piggyback technique may improve intraoperative hemodynamic stability and renal function and may reduce the transfusion requirement (Arzu et al, 2008; Davila et al, 2008; Figueras et al, 2001). If neither venovenous bypass nor temporary portocaval shunting is used, the portal vein simply can be clamped proximally, ligated in the hilum, and divided; however, this method may be associated with a severe reduction in venous return, up to a 50% decrease in arterial blood pressure, mesenteric venous hypertension and associated organ failure, and potential increased hemodynamic instability resulting in intraoperative mortality (Hoffmann et al, 2009).

With the portal vein bypassed or clamped, exposure for the infrahepatic dissection and vascular control of the IVC is easily obtained. The piggyback technique leaves the recipient retrohepatic IVC intact and requires ligation and division of all retrohepatic caval branches (Tzakis et al, 1989). The advantage of this approach is that native caval flow is maintained, and venovenous bypass is not required; the disadvantage is that division of retrohepatic caval branches can be tedious and time consuming. The donor suprahepatic IVC is anastomosed to the confluence of the right, middle, and left hepatic veins, which are joined in a common cuff. Vascular control is achieved by clamping the hepatic veins at their point of entry into the vena cava.

Alternatively, if a bicaval technique is used, the recipient's native retrohepatic IVC is removed with the native liver. The retrohepatic IVC is mobilized out of the retroperitoneum from the left side. The right triangular ligament is taken down, and the retrohepatic IVC is dissected from the right side. The adrenal vein is ligated in the traditional bicaval approach; this dissection frees up the retrohepatic IVC above the hepatic veins to allow application of infrahepatic and suprahepatic IVC clamps. The recipient liver is sharply excised with care taken to leave cuffs of IVC above and below the liver. This technique allows for true orthotopic placement of the donor graft. Retrospective analysis of the bicaval and piggyback techniques suggest that safety and outcomes are comparable (Nishida et al, 2006).

Recipient Implantation

OLT requires three or four vascular anastomoses in the following order: 1) suprahepatic IVC; 2) infrahepatic IVC, if a bicaval technique is used; 3) portal vein; and 4) hepatic artery. Alternatively, the use of the piggyback technique allows just a single caval (end-to-side) anastomosis, with simple ligation of the donor infrahepatic IVC; this results in a reduction in the duration of the anhepatic phase (Hosein Shokouh-Amiri et al, 2000). When the liver is fully reperfused, reconstruction of the biliary tract begins.

Adequate cuffs of suprahepatic and infrahepatic IVC are essential for reconstruction (Starzl et al, 1979). Anastomoses of these cuffs require reconstruction of the posterior walls from within the lumen using a running 3-0 polypropylene suture. The anterior layer is sutured externally using either an interrupted or a continuous technique. Another advantage of the piggyback technique is the use of a side-biting vascular clamp on the IVC at the level of ostia of the hepatic veins. Although this clamp may impair venous return to the heart to some degree during a clamp time of 15 to 30 minutes, it generally produces greater hemodynamic stability during the anhepatic phase than does complete caval occlusion, which requires a bicaval procedure (Moreno-Gonzalez et al, 2003). After the hepatic donor vena cava has been anastomosed to the recipient IVC, the side-biting clamp can be moved to the graft side of the anastomosis, restoring complete venous return, while the remaining vascular connections are performed.

After restoration of caval flow, the portal anastomosis is undertaken. If venovenous bypass is used, interruption of the portal circuit is followed by removal of the portal cannula. In this manner, the donor and recipient main portal veins are exposed for an end-to-end anastomosis using an everting-cuff technique. The use of a fine monofilament suture (6-0 or 7-0) is mandatory. We typically tie this suture with an "air knot" or "growth factor" of approximately half the diameter of the portal vein to reduce the likelihood of portal stricture.

The final vascular anastomosis is arterial. The key principle of hepatic arterialization is to ensure pulsatile inflow through a large caliber vessel over a short length (Farmer et al, 2000). The technique involves the use of a fine (7-0) monofilament suture in a running or interrupted fashion. The vessel ends are frequently spatulated and are sewn from the outside and rotated to achieve the most precise anastomosis. The presence of aberrant hepatic arterial anatomy is encountered in 10% to 30% of grafts, and preservation of these vessels is essential for successful engraftment. Reconstruction of the aberrant vessels to obtain a single inflow vessel is imperative and takes place during the back table preparation of the graft as described earlier.

Recipient inflow is obtained from a branch off the celiac trunk, usually the proper or common hepatic artery. When adequate arterial inflow cannot be obtained by this artery, the use of an arterial conduit is recommended. Inflow originating from the infrarenal and supraceliac aorta has been described; both methods provide excellent inflow, and the choice is based on technical considerations and surgeon preference. The best choice of conduit is usually the donor iliac vessels. When donor vessels are unavailable or inadequate, prosthetic conduits can be used, typically polytetrafluoroethylene (PTFE). In the perioperative period, aortic conduits are associated with increased operating time, greater transfusion requirements, and respiratory and renal failure (Nikitin et al, 2008). In addition, several cases of internal hernias with small bowel volvulus around the intraperitoneal conduit have been reported (Nishida et al, 2002).

Completion of the vascular anastomoses is followed by establishment of biliary continuity. The most common methods used are the choledochocholedochostomy or choledochojejunostomy. The technical goals in biliary reconstruction are to achieve a tension-free anastomosis between viable ducts or intestine. The method used depends on many factors, including

the size match of the donor and recipient common bile duct and the presence of preexisting biliary pathology. Choledochocholedochostomy is preferable, because after OLT, access to the biliary tree is easier and safer with ERCP than with percutaneous transhepatic cholangiography. Choledochojejunostomy is used when the above-mentioned technical goals cannot be realized. Most pediatric recipients require choledochojejunostomy because of small duct size and a history of biliary atresia.

Prior to anastomosis, both the donor and recipient bile ducts should be trimmed sharply to remove devitalized tissues, and brisk bleeding should be evident from the cut ends. The recipient bile duct should be cleared of sludge and stones. Accommodation for size mismatch with ductoplasty of the larger duct or spatulation of both ducts has been described (Buczkowski et al, 2007; Nissen & Klein, 2009). The choledochocholedochostomy and choledochojejunostomy anastomoses are accomplished with the use of fine absorbable monofilament suture in a single-layer closure.

Whether to stent the biliary anastomosis during OLT is subject to debate (Barkun et al, 2003; Bawa et al, 1998; Johnson et al, 2000). Proponents believe that decompression of the biliary tree reduces the rate of clinically significant leaks, whereas others point to data that suggest a higher rate of biliary stricture from internal stents. At our institution, biliary stenting is performed selectively based on individual case circumstances and surgeon preferences.

COMPLICATIONS

Complications resulting from OLT can be divided broadly into technical complications, those arising as a consequence of immunosuppressive medications, and recurrence or recrudescence of the patient's original disease. The risk of surgeon-dependent technical complications increases when more complex surgical techniques, such as split-liver donation, are used. Examples of factors generally attributed to technical error include early thrombosis of the hepatic artery or portal vein, biliary complications such as leak or stricture, and, to a lesser extent, primary graft nonfunction. Invasive infection and certain metabolic complications are side effects of the immunosuppressive regimens currently in use. Finally, subacute and chronic graft rejection and recurrence of certain causes of initial liver failure eventually result in graft loss. Each of these complications is discussed.

Primary Nonfunction

Primary nonfunction is defined as early graft failure after OLT in the absence of identified technical complications. Clinical presentation varies, but patients typically are seen with alterations in mental status, diminished bile production, coagulopathy, markedly elevated transaminases, and metabolic acidosis. Multiorgan failure ensues, with oliguria and hypoxia occurring frequently. The reported rate of primary nonfunction varies between 1% to 7% of all OLTs (Jain et al, 2000; Johnson et al, 2007; Kamath et al, 1991; Kemmer et al, 2007; Taner et al, 2008; Totsuka et al, 2004). Retransplantation is the treatment of choice and typically is required within 72 hours. Some authors also report the distinctly separate category of initial poor function, in which allografts might have a chance for functional recovery; however, no consensus for a clear definition exists.

The etiology of primary nonfunction is unclear but is likely multifactorial. Factors commonly reported to be associated with nonfunction include prolonged cold and warm ischemic times, donation after cardiac death, intraoperative systemic hypotension (mean arterial pressure <40 mm Hg), severity of donor steatosis, advanced donor age, and recipient factors such as portal vein thrombosis (PVT), renal failure, dependence on life support, and status 1 listing (de Vera et al, 2009; Fernandez-Merino et al, 2003; Johnson et al, 2007; Marsman et al, 1996; Nair et al, 2002; Ploeg et al, 1993; Reich et al, 2003; Sharma et al, 2010; Strasberg et al, 1994). Although it has been proven that severe macrosteatosis (>60%) increases risk of graft failure, the influence of moderate steatosis (30% to 60%) remains unclear (Yoo et al, 2003a), and such allografts can be used with careful selection (Doyle et al, 2010).

Donor liver biopsy to quantify graft steatosis should be performed before implantation of any graft that appears marginal (D'Alessandro et al, 1991). As would be expected, the likelihood of primary nonfunction is increased in the presence of multiple risk factors (e.g., steatotic graft with extended total ischemic time) and in allografts with several marginal donor criteria (Pokorny et al, 2005; Salizzoni et al, 2003).

Hepatic Artery Thrombosis

Hepatic artery thrombosis (HAT) can be broadly divided into *early* (acute) and *late* (delayed) clinical presentation, with different etiologies, patient manifestations, and treatments. Although there is no formal consensus, *early HAT* is typically defined as occurring within the first 1 to 2 months after OLT and has a mean incidence of 2.9% in adult OLT patients, with a significantly higher incidence of 8% to 10% in the pediatric population (Bekker et al, 2009; Farmer et al, 2007). Early HAT carries a high risk of graft loss and death—53% and 33%, respectively (Bekker et al, 2009).

Technical, donor, and recipient factors contribute to an increased risk of HAT (Bekker et al, 2009; Del Gaudio et al, 2005; Duffy et al, 2009; Jurim et al, 1995; Soin et al, 1996; Vivarelli et al, 2004). Donor factors may include small-caliber vessels, aberrant anatomy that requires complex arterial reconstruction, use of aortic conduits, or cytomegalovirus (CMV) seropositivity donor-recipient mismatch. Variable recipient anatomy (e.g., replaced hepatic artery from superior mesenteric artery [SMA]) also influences risk of HAT.

Although early HAT may be asymptomatic, it frequently results in massive hepatocellular injury evidenced by increased transaminase levels and impaired hepatic synthetic function. The hepatic artery is the sole blood supply to the donor bile duct; therefore early HAT often presents with bile leak, cholangitis, or sepsis. Duplex ultrasound (US) is diagnostic in virtually all cases of HAT in adults, although visceral angiography remains the gold standard. If diagnosis is prompt, emergency exploration with attempted thrombectomy and revascularization may salvage the graft, although this is usually not possible.

Some reports suggest that endovascular procedures—intraarterial thrombolysis, percutaneous transluminal angioplasty, and endoluminal stenting—can be successful in hepatic arterial revascularization (Singhal et al, 2010); however, a majority of patients eventually require retransplantation (Bekker et al, 2009; Duffy et al, 2009). Because of the severity of this complication, some authors advocate the routine use of postoperative duplex US.

Late HAT is typically more indolent, frequently because a previously undiagnosed stricture allows collateral circulation to develop. Clinical presentation may include fever secondary to perihepatic abscess or biliary leak, biliary strictures, or cholangitis, although in some cases patients may be asymptomatic with no clinical consequences (Gunsar et al, 2003). Contributing factors are active tobacco abuse; coagulation abnormalities, such as factor V Leiden; cerebrovascular accident as donor cause of death; donor death at an age greater than 50 years; recipient CMV positivity; and use of donor iliac interposition graft (Del Gaudio et al, 2005; Gunsar et al, 2003; Pascual et al, 1997; Pungpapong et al, 2002; Stewart et al, 2009; Vivarelli et al, 2004).

Treatment may be attempted with endoscopic or percutaneous biliary decompression, stenting, or even systemic anticoagulation. Retransplantation is required less for late HAT than for early HAT. Because postoperative antiplatelet therapy may reduce the rate of late HAT in high-risk patients (Vivarelli et al, 2007), it is our practice to prescribe daily aspirin (81 mg) for all patients.

Hepatic Artery Stenosis

Hepatic artery stenosis (HAS) without thrombosis is also a recognized complication of liver transplantation, with an incidence of 4% to 11% (da Silva et al, 2008). DCD allografts have been implicated as a risk factor (Pine et al, 2009). Initial presentation typically includes a mild increase in aminotransferase levels with or without associated graft dysfunction or biliary complications. Doppler US demonstrates increased resistance in hepatic arterial flow and is often diagnostic, but confirmation by arteriography is the gold standard. Therapeutic options include angioplasty with or without stenting. Restenosis can occur in up to one third of patients within 1 year after stenting (Ueno et al, 2006).

Portal Vein Thrombosis

PVT occurs less frequently than HAT after OLT, with an incidence less than 2% in adult recipients and 10% in pediatric recipients (Duffy et al, 2009; Lerut et al, 1987; Millis et al, 1996), although PVT adversely affects overall survival after OLT (Duffy et al, 2009). Low portal flow, small-diameter veins (<5 mm), preexisting PVT in the recipient, donor-recipient vessel size mismatch, and the use of vascular grafts for reconstruction are known risk factors for developing PVT (Cheng et al, 2004).

PVT is typically symptomatic, and patients can present with acute hepatic failure, as with HAT, or with the sequelae of portal hypertension, such as increasing ascites, splenomegaly, and variceal hemorrhage (Duffy et al, 2009). Diagnosis is made using duplex US or contrast-enhanced CT portal venography.

Depending on the timeliness of diagnosis and the acuity of the patient, several treatment options exist. In patients with fulminant hepatic failure from PVT, reexploration and attempted portal revascularization are performed. These patients sometimes require retransplantation, particularly in the rare setting of combined PVT and HAT (total absence of hepatic inflow). The use of a portocaval shunt to augment flow through the reconstructed portal vein has been described (Bakthavatsalam et al, 2001), as has the use of transjugular intrahepatic portocaval shunt (TIPS) in conjunction with thrombolytics (Ciccarelli et al, 2001). Systemic anticoagulation may be sufficient in patients with preserved graft function (Duffy et al, 2009). Symptoms of portal hypertension but preserved graft function often can be managed medically with standard therapies for ascites in combination with variceal banding or sclerotherapy; however, the graft salvage rate with these alternative strategies is typically much less than 50% (Duffy et al, 2009).

Portal Vein Stenosis

Portal vein stenosis, in contrast to PVT, is frequently diagnosed on routine screening US in asymptomatic patients. The most common area of stenosis is the extrahepatic portal venous anastomotic site. Narrowing of the main portal vein diameter by more than 50%, presence of a poststenotic jet, or lack of visualized flow on Doppler imaging are diagnostic. Many stenoses can now be managed with percutaneous transhepatic balloon angioplasty and stenting (Woo et al, 2007).

Biliary Complications

Biliary complications are the most common type of posttransplantation complication, and they arise in 7% to 29% of liver recipients. Patients with HAT, living-donor allografts, and DCD livers are at higher risk for biliary complications (Maluf et al, 2005; Pine et al, 2009; Zajko et al, 1988). Historically, Roux-en-Y choledochojejunostomy was associated with higher complication rates than choledochocholedochostomy (O'Connor et al, 1995); however, this remains a controversial topic in transplantation techniques. All patients found to have a biliary complication should undergo US to evaluate HAT as a contributing factor.

Biliary strictures occur twice as frequently as anastomotic biliary leaks and can be classified as *anastomotic* or *nonanastomotic* (ischemic cholangiopathy) (Balsells et al, 1995; Qian et al, 2004). Most anastomotic strictures are managed endoscopically with balloon dilation and stenting. Ischemic cholangiopathy more commonly results from bile duct ischemia or an immune response, appears later and affects multiple sites, tends to be more difficult to manage, and is rarely amenable to endoscopic treatment. Nonanastomotic strictures are associated with a higher rate of graft failure requiring retransplantation (Chan et al, 2008; de Vera et al, 2009; Pine et al, 2009). A multidisciplinary approach to diagnosis and management of biliary complications is necessary and can result in higher patient and graft survival rates (Verran et al, 1997).

In an asymptomatic patient with stable liver function, biliary complications can often be managed nonoperatively. Bile collections should be drained percutaneously under US or CT guidance, and most leaks are controlled with endoscopic stent placement across the anastomosis (Shah et al, 2004). Major leaks or total disruption usually requires operative conversion to a choledochojejunostomy or hepaticojejunostomy, an option that can result in long-term biliary patency (Langer et al, 2009).

Numerous studies have evaluated the use of T-tubes and internal stents for prophylactic biliary decompression. Several have identified T-tube use as an independent risk factor for increased postoperative biliary complications (e.g., biliary-cutaneous fistulae and cholangitis), and their use has not been shown to reduce the need for posttransplantation interventional procedures (Qian et al, 2004; Scatton et al, 2001; Sotiropoulos et al, 2009). Consequently, T-tubes are much less commonly

used in standard adult OLT in the United States; however, a recent prospective European trial did not find evidence of increased biliary complications with T-tubes (Weiss et al, 2009). The effectiveness of internal stenting in reducing biliary complications also remains inconclusive (Welling et al, 2008).

Infection

Infection is the most common cause of death after OLT at all time points (Jain et al, 2000), directly causing 28% of all deaths in liver transplant patients. An autopsy series of OLT patients showed an even higher infection-related mortality rate of 64% (Torbenson et al, 1998). Two thirds of OLT recipients experience at least one serious infectious episode (Winston et al, 1995), despite ever-improving prophylactic regimens. Intraabdominal infections occur in 40% of recipients with a higher incidence in patients with other noninfectious surgical complications (Reid et al, 2009).

Liver transplant patients are immunocompromised as a result of antirejection medications, they are also malnourished, chronically ill, have received multiple blood-product transfusions, and have undergone lengthy and complex surgical procedures—all of which are risk factors for infectious complications. Additionally, the risk of posttransplantation infection is further increased by the prevalence of morbid obesity in the recipient population (Dick et al, 2009).

Diagnosis of infection can be complicated by a relative absence of symptoms, as infection frequently manifests only as a leukocytosis (Reid et al, 2009). As part of the pretransplantation evaluation, recipients should undergo an infectious disease workup and should receive appropriate vaccines. Appropriate antimicrobial prophylaxis can reduce the postoperative infection rate by more than half, depending on the pathogen. The current prophylactic regimen used at Washington University in St. Louis is shown in Box 98A.2.

Box 98A.2

Antimicrobial Prophylaxis for Liver Transplantation Patients at Washington University in St. Louis

Bacterial

Routine use of broad-spectrum antibiotics on-call to operating room, continued for 24 h postoperatively

Fungal

Fluconazole (Diflucan, once weekly) for 3 mo postoperatively in high-risk patients

Pneumocystis Carinii

Trimethoprim-sulfamethoxasole (Bactrim/Septra SS) for 1 yr postoperatively
Pentamidine (Pentam) or dapsone for patients with sulfa sensitivity

Viral

High Risk

Donor CMV+/recipient CMV−: valganciclovir 900 mg daily for 3 mo, then 450 mg daily for 9 mo

Intermediate Risk

(D+/R+ or D−/R+): Valganciclovir 450 mg daily for 6 mo
Low risk (D−/R−): acyclovir 200 mg bid for 3 mo

CMV, cytomegalovirus

Bacterial pathogens are the most common infectious agent in the early postoperative period, and the proportion of posttransplantation infection as a result of bacteremia has increased significantly (Singh et al, 2004). DM and serum albumin less than 3 mg/dL are independent risk factors for bacteremia. Although gram-negative bacilli remain frequent causes of postoperative infection after OLT, gram-positive cocci, such as methicillin-resistant *Staphylcoccus aureus* (MRSA) and vancomycin-resistant enterococci (VRE), have become increasingly prevalent at many transplant centers (Papanicolaou et al, 1996; Reid et al, 2009; Singh et al, 2004). Colonization with MRSA and VRE before transplantation increases the risk of developing infection after OLT with the same organism and, in the case of VRE colonization, is associated with an increased mortality risk (Russell et al, 2008).

Typically presenting in the first 2 to 3 weeks after transplantation, 25% of OLT patients are reported to develop MRSA bacteremia, with colonization of indwelling vascular catheters accounting for about half of the cases (Singh et al, 2000a). Vascular catheters account for one quarter of bacteremia for all pathogens combined. Other sources of post-OLT bacteremia include—in decreasing order of frequency—pneumonia, biliary infections, abdominal sources, and surgical wound infections (Singh et al, 2000b, 2004). The emergence of drug-resistant organisms resulting from overuse of common antibiotics has made the treatment of infected liver transplant recipients increasingly difficult.

CMV is the most common viral pathogen encountered by OLT recipients, although incidence of CMV infection has declined as a result of improved prophylaxis (Singh et al, 2004). Intraoperative hypothermia is a known risk factor for developing CMV infection regardless of prophylaxis (Paterson et al, 1999). Without appropriate prophylaxis, the overall incidence in this population is commonly 50% to 60%, with clinically apparent infections usually occurring 3 to 12 weeks after transplant (Farmer et al, 2000).

The routine use of ganciclovir (Cytovene) has been shown to dramatically reduce CMV infection after OLT in several randomized, controlled trials (Gane et al, 1997; Winston, 1995; Winston & Busuttil, 2003, 2004). The standard regimen includes an induction with intravenous ganciclovir followed by prophylaxis with oral ganciclovir for 3 to 6 months. Some studies suggest that valganciclovir, which can be administered with once-daily dosing because of improved bioavailability, might be as efficacious and safe as ganciclovir in the prevention of CMV infection in low-risk, but not high-risk, liver recipients (Jain et al, 2005; Park et al, 2006; Shiley et al, 2009); prolonged treatment (≥100 days) can be costly and might be unnecessary in low-risk patients (e.g., seronegative donor and recipient). Ganciclovir-resistant CMV has been observed in 20% of solid-organ transplant recipients treated with ganciclovir, with presentation typically observed late in the first year (Limaye et al, 2000). Our current strategy is to reserve prolonged treatment with ganciclovir for seronegative patients receiving a seropositive graft or in patients with evidence of active CMV infection.

Invasive fungal infections usually are caused by *Candida* or *Aspergillus* species, *Cryptococcus,* and non-*Aspergillus* mycelial fungi, with an incidence of 5% to 9% in OLT patients (Pappas et al, 2010; Singh, 2000). Invasive candidiasis and aspergillosis tend to occur relatively early in the postoperative period, whereas *Cryptococcus* infection becomes apparent several

months to years after OLT (Pappas et al, 2010). Traditionally, *Candida albicans* has been the most common fungal pathogen.

Risk factors for developing fungemia include use of broad-spectrum antibiotics or immunosuppressant medications, retransplantation or other reoperative intervention, CMV infection, renal failure, and overall severity of medical illness (Cruciani et al, 2006). Routine prophylaxis with antifungal agents—such as fluconazole, itraconazole, and amphotericin B—significantly reduces fungal infection and infection-related mortality after liver transplantation; however, it does not improve overall mortality (Cruciani et al, 2006). Historically, fluconazole was almost universally included in antimicrobial prophylaxis, but this subsequently led to an increase in reported *Aspergillus* infections, because *Aspergillus* is not susceptible to fluconazole.

Currently, a majority of transplant centers provide antifungal prophylaxis only to high-risk patients, including those requiring retransplantation or reexploration, dialysis, mechanical ventilation, or a prolonged ICU stay and those subject to and graft failure or colonization with *Candida* (Singh et al, 2008). Although prophylaxis against *Aspergillus* is not supported by the literature (Braun et al, 1998; Singh 2000), voriconazole, amphotericin B, and caspofungin may be used alone or in combination for treatment of invasive aspergillosis (Singh et al, 2008), which is associated with a 40% 1 year mortality rate after infection (Pappas et al, 2010).

Infection with the protozoan *Pneumocystis carinii* occurs in 3% to 11% of liver transplant patients in the absence of prophylaxis (Singh, 2000). Because T-cell immunity is the primary defense against this organism, prolonged use of corticosteroids or muromonab-CD3 monoclonal antibodies and active CMV infection increase the risk of infection. Trimethoprim-sulfamethoxazole (single strength, once daily) offers highly effective prophylaxis at a low cost and with minimal side effects. Because the risk of *P. carinii* infection is eightfold higher in the first year after OLT than in subsequent years, prophylaxis generally is continued only during these initial 12 months (Gordon et al, 1999).

Rejection

Rejection can sometimes be a major hurdle to long-term survival after OLT. Previously reported to occur in 40% to 70% of OLT patients (Klintmalm, 1991), the development of novel immunosuppressive regimens has reduced the lifetime rejection rate to less than 20% (McAlister et al, 2001). It is becoming increasingly clear that certain subpopulations of patients receiving OLT can be weaned completely from all immunosuppressive agents without experiencing rejection (Devlin et al, 1998; Mazariegos et al, 1997). The University of Pittsburgh experience shows that immunosuppression can be withdrawn successfully in almost one third of patients, although it is unknown exactly what traits allow such weaning.

Hyperacute rejection is rarely seen today. It typically occurs in the setting of ABO incompatibility, with a reported graft failure rate of 46% observed in 51 patients transplanted across ABO type (Demetris et al, 1988). Hyperacute rejection is mediated by preformed antibodies in the recipient and is directed against the graft endothelium. These antibodies produce activation of the innate immune system via the complement cascade, ultimately leading to rapid graft destruction. Retransplantation is the only treatment option.

Although acute liver rejection usually occurs within the first 4 weeks after transplantation, it can occur later. Patients with acute liver rejection are seen with signs of fever, malaise, right upper quadrant abdominal pain, and elevated liver transaminases. Elevation in liver enzymes is often detected before physical symptoms or signs occur. Percutaneous liver biopsy reveals portal inflammation with predominantly mononuclear cells, bile duct inflammation and injury, centrilobular necrosis, and lobular inflammation. Differentiation from other pathologic processes can be difficult. In contrast to other solid-organ transplants, such as kidney and heart, the occurrence of an acute rejection episode does not seem to reduce the overall graft survival, if treatment is initiated promptly (Wiesner et al, 1998).

The treatment for acute rejection is usually bolus corticosteroids: 1000 mg methylprednisolone (Solu-Medrol), followed by a 5-day taper. Patients who do not respond to bolus steroids may require additional strategies, including the use of monoclonal anti–T-cell antibody therapy (e.g., OKT3); however, this is rarely needed in the current era because fewer than 5% of patients experience rejection. When patients fail to respond to bolus steroid therapy, it is important to be certain of the diagnosis and to consider other potential causes of abnormal liver tests, including biliary or vascular causes. Repeat biopsies can be helpful to confirm the diagnosis and assess the response to therapy.

Today, only about 2% of patients experience chronic rejection after liver transplantation, although the incidence is higher in patients with autoimmune disease (Wiesner et al, 2003). The etiology of chronic rejection is multifactorial, characterized by progressive loss of bile ducts, obliteration of medium-sized and large hepatic arterioles, and cellular portal infiltration (Farmer et al, 2000). Standardized histopathologic evaluation of acute and chronic rejection using the Banff schema (Tables 98A.3 and 98A.4) allows objective decision making and facilitates comparisons of natural histories among patients (Banff Consensus, 1997; Demetris et al, 2000; Racusen et al, 2003).

Metabolic and Systemic Complications

With the increase in overall survival after OLT, a growing recognition has emerged of associated long-term medical sequelae and their impact on patient health. Prolonged use of corticosteroids can produce hyperlipidemia, obesity, DM, arterial hypertension, and mineral-deficient bone disease; commonly used antirejection drugs induce similar derangements. Cardiovascular disease then becomes a leading cause of death in patients who survive more than 3 years after liver transplantation, accounting for more than half of the reported mortality in some series (Asfar et al, 1996; Pruthi et al, 2001). Predictors of perioperative cardiac events include pre-OLT history of stroke, and perioperative mortality was increased with a history of coronary artery disease (CAD) and postoperative sepsis (Safadi et al, 2009).

Renal Dysfunction

Liver transplant recipients have a high risk of developing post-transplant chronic renal failure, with an incidence of 18% at 5 years (Ojo et al, 2003). The average functional decline in renal function is a 38% decrease in glomerular filtration rate, and it is correlated with time elapsed since transplantation (decline by 36 mL/min/1.73m^2) (Bucuvalas et al, 2006; Karie-Guigues

Table 98A.3

Rejection Activity Index from the Banff Schema for Acute Hepatic Rejection

Category	Criteria	Score
Portal inflammation	Mostly lymphatic inflammation involving a minority of the triads	1
	Expansion of most triads by a mixed infiltrate containing lymphocytes, neutrophils, and eosinophils	2
	Marked expansion of most or all triads by a mixed infiltrate containing numerous blasts, with spillover into periportal parenchyma	3
Bile duct damage	Minority of ducts infiltrated by inflammatory cells, with only mild reactive changes in epithelial cells	1
	Most or all ducts infiltrated by inflammatory cells, with occasional degenerative duct changes, such as nuclear pleomorphism, disorder polarity, and vacuolization	2
	As above, with most or all ducts showing degenerative changes	3
Venous endothelial inflammation	Subendothelial lymphocytic infiltration of some portal or hepatic venules	1
	Subendothelial infiltration involving most or all portal or hepatic venules	2
	As above, with perivenular inflammation extending into surrounding parenchyma and associated hepatocyte necrosis	3

This index has a range from 0 to 9, classified as follows: 0 to 3, minimal acute rejection; 4 to 6, mild acute rejection; 7 to 9, moderate to severe acute rejection.

Modified from the Banff Consensus, 1997: schema for grading liver allograft rejection: an international consensus document. Hepatology 25:658-663.

et al, 2009). The use of calcineurin inhibitors (CNIs) is associated with increased risk of renal failure in patients after OLT, although this decline may be partially attenuated with concomitant administration of mycophenolate mofetil and calcineurin dose reduction (Karie-Guigues et al, 2009). Other risk factors for the onset of post-OLT renal dysfunction include age and gender of the recipient, history of HCV infection, DM, and pretransplantation renal insufficiency, CAD, and primary nonfunction (Ojo et al, 2003; Pawarode et al, 2003). Mortality following OLT is four times greater in recipients who develop posttransplantation renal failure (Ojo et al, 2003).

Posttransplantation Metabolic Syndrome

Posttransplantation metabolic syndrome (PTMS) is becoming recognized as an important entity in liver transplant recipients. Prevalence in the post-OLT population is twice that of the estimated 24% prevalence in the general population (Bianchi et al, 2008; Hanouneh et al, 2008; Laryea et al, 2007; Pagadala et al, 2009). Posttransplantation obesity develops in 60% of patients, with most excess weight gain occurring in the first year (Muñoz et al, 1991). The cause of weight gain is multifactorial: corticosteroids and cyclosporine, and to a lesser extent tacrolimus, are known to correlate significantly with the incidence of obesity (Canzanello et al, 1997). Development of PTMS does not seem to be influenced by the etiology of the recipient's ESLD (Bianchi et al, 2008); however, liver transplant recipients who develop PTMS appear to be at higher risk for vascular events (Laryea et al, 2007) and are at higher risk for development of allograft steatosis (Dumortier et al, 2010).

Diabetes Mellitus

De novo DM occurs in up to one third of previously nondiabetic liver transplant recipients (Navasa et al, 1996; Sheiner et al, 2000). Corticosteroids are known to induce insulin resistance, and the occurrence of graft rejection necessitating increased steroid dosing is a risk factor for developing diabetes.

Table 98A.4

Banff Schema for Chronic Hepatic Rejection

Structure	Early Chronic Rejection	Late Chronic Rejection
Small bile ducts (<60 μm)	Degenerative changes involving most ducts: increased nuclear-to-cytoplasmic ratio, nuclear hyperchromasia, uneven nuclear spacing, ducts partially lined with epithelium	Degenerative changes in remaining bile ducts
	Bile duct loss in <50% of portal tracts	Bile duct loss in >50% of portal tracts
Terminal hepatic venules	Intimal/luminal inflammation	Focal obliteration
	Lytic zone 3 necrosis and inflammation	Variable inflammation
	Mild perivenular fibrosis	Severe (bridging) fibrosis
Portal tract hepatic arterioles	Occasional loss involving <25% of portal tracts	Loss involving >25% of portal tracts
Large perihilar hepatic artery branches	Intimal inflammation, focal foam-cell deposition	Luminal narrowing by subintimal foam cells and fibrointimal proliferation
Large perihilar bile ducts	Inflammation damage, focal foam-cell deposition	Mural fibrosis
Other	"Transition" hepatitis with spotty necrosis of hepatocytes	Sinusoidal foam cell accumulation, marked cholestasis

Modified from Demetris A, et al, 2000: Update of the International Banff Schema for Liver Allograft Rejection: working recommendations for the histopathologic staging and reporting of chronic rejection: an international panel. Hepatology 31:792-799.

Tacrolimus and other immunosuppressants also increase insulin resistance. Diabetes in most patients is transient and generally resolves within the first year, as immunosuppressive medications are tapered.

Infection with HCV is another known risk factor for the development of posttransplantation diabetes, and this risk is correlated with increased HCV viral load (Delgado-Borrego et al, 2008). Although the mechanisms underlying the relationship between HCV and diabetes are not fully understood, altered insulin sensitivity is likely to play a role. Pretransplantation glucose intolerance, as determined by formal glucose challenge testing, is present in 53% of candidates awaiting liver transplantation (Blanco et al, 2001). Although some degree of glucose intolerance may improve with OLT, insulin-dependent diabetes almost never resolves after transplantation (Shields et al, 1999; Stegall et al, 1995). Additionally, insulin-dependent DM is a known risk factor for lower survival following transplantation, and CAD is an independent predictor of worse outcomes (Yoo & Thuluvath, 2002).

Neurologic Complications

Neurologic complications occur with greater frequency in recipients of liver allografts than in other solid-organ recipients (Senzolo et al, 2009). The aggregate prevalence of neurologic sequelae is 25%, although such have occurred in more than 60% of patients in some series (Amodio et al, 2007; Bronster et al, 2000; Emiroglu et al, 2006; Ghaus et al, 2001; Lewis & Howdle, 2003; Saner et al, 2006).

Posttransplantation encephalopathy is the most common neurologic complication, followed by seizures (Bronster et al, 2000; Lewis & Howdle, 2003; Saner et al, 2006; Senzolo et al, 2009). Encephalopathy can be caused by anoxia, sepsis, medications (especially CNIs), primary graft nonfunction, renal failure, rejection, and central pontine myelinolysis (CPM) (Erol et al, 2007). Infection, stroke, and CPM are also common causes of seizures (Senzolo et al, 2009). Other neurologic complications include posterior leukoencephalopathy, cerebellar syndrome, focal deficits, headache, tremor, sleep disorders, and peripheral neuropathy. Risk factors for neurologic complications include an operative time longer than 10 hours, high CTP score, and a history of hepatic encephalopathy (Dhar et al, 2008). Older age and higher MELD scores pretransplantation are associated with increased risk of tacrolimus-related neurotoxicity (DiMartini et al, 2008). In cases of CNI-related neurotoxicity, patients can frequently be switched to a different drug within the same class with successful resolution of symptoms (Emiroglu et al, 2006; Erol et al, 2007). Most central nervous system (CNS) complications (80%) occur within 1 month after OLT but may be seen up to several years after transplantation (Bronster et al, 2000). The incidence of neurologic complications in LDLT recipients (17%) approximates that of cadaveric allograft recipients, and outcomes from these complications appear to be similar (Saner et al, 2010).

Immunosuppressant Toxicity

CNIs can cause significant renal and neurotoxicity. Use of sirolimus as an alternative immunosuppressant in patients with these adverse effects may allow patients to recover from CNI toxicity without significant risk of rejection (Di Benedetto et al, 2008; Morard et al, 2007).

OUTCOMES

Survival after OLT has improved markedly as a result of continuing refinements in organ procurement and preservation, recipient selection, surgical and anesthetic techniques, perioperative care, and long-term immunosuppression. Overall patient survival at 10 years is 60% in the United States, with an unadjusted 10-year graft survival of 54% (Thuluvath et al, 2010). In select patient populations, some institutions have achieved near zero short-term mortality (Broering et al, 2004; Sugawara et al, 2002).

Recipient factors associated with reduced survival include recipient age over 65 years, preexisting CAD, insulin-dependent DM, renal insufficiency, and extreme body mass index (BMI) (Busuttil et al, 2005; Dick et al, 2009; Nair et al, 2002; Thuluvath et al, 2010; Yoo & Thuluvath, 2002). Other factors that adversely affect survival include conditions that require urgent transplantation, such as hepatic malignancy as the indication for transplantation, donor hospitalization longer than 6 days, cerebrovascular accident as donor cause of death, prolonged warm (>45 minutes) and cold (>10 hours) ischemic time, and retransplantation (Busuttil et al, 2005).

Deceased-donor split allografts have not been shown to adversely affect outcomes in large series (Busuttil et al, 2005), and LDLT over the last decade has had better long-term outcomes than deceased-donor transplantation (Thuluvath et al, 2010). The overall rate of retransplantation for recipients of DDLT was 7.8% in 2007, representing the lowest level in the last decade (USRTR, 2008). Outcomes after liver transplantation for certain disease processes are discussed below.

Biliary Atresia

The long-term primary hepatic salvage rate after portoenterostomy in infants with biliary atresia ranges from 20% to 45% (Davenport et al, 2004; Otte et al, 1994; Schreiber et al, 2007; see Chapter 40). The remaining infants develop progressive biliary cirrhosis and ultimately require liver transplantation. Biliary atresia is the most common indication for OLT in children younger than 18 years, and the best results are obtained in patients referred for transplantation early, after only a single attempted portoenterostomy. Approximately 80% of children transplanted for biliary atresia have had a prior biliary drainage procedure (Utterson et al, 2005; Visser et al, 2004). Despite this high rate of transplantation, portoenterostomy remains a viable bridge to definitive therapy, allowing infants to grow.

Transplantation is a durable solution for biliary atresia, and this recipient population obtains the best survival rates, with 10-year patient survival greater than 80% and graft survival greater than 67% (Barshes et al, 2005; D'Alessandro et al, 2007; Diem et al, 2003; Farmer et al, 2007; Schreiber et al, 2007; Visser et al, 2004). The use of split-liver cadaveric grafts and living related transplantation has expanded the potential donor pool, extending OLT to an increased number of children with biliary atresia, without a significant increase in post-OLT mortality (Barshes et al, 2005; Chen et al, 2006; Yersiz et al, 2003).

Additionally, use of living-donor liver allografts significantly shortens time on the waiting list (Visser et al, 2004); however, technical variant grafts may increase the risk of graft failure (Utterson et al, 2005). Graft failure and vascular complications

account for the majority of early post-OLT deaths, whereas rejection remains the leading cause of late death in these patients (Barshes et al, 2005).

Primary Sclerosing Cholangitis and Primary Biliary Cirrhosis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease of unknown origin that is frequently associated (70% to 80%) with inflammatory bowel disease, usually ulcerative colitis (UC; see Chapter 41). Patients with PSC also are at risk for the development of cholangiocarcinoma. Although medical palliation exists, the only cure for PSC is liver transplantation. Outcomes after OLT for PSC are excellent, with 5-year patient survival rates ranging from 80% to 85% (Goss et al, 1997; Ricci et al, 1997; Solano et al, 2003) and 10-year survival at 70% (Busuttil et al, 2005). Whether the incidental discovery of cholangiocarcinoma in the explanted liver affects patient survival is controversial (Goss et al, 1997; Solano et al, 2003). Approximately 9% to 11% of patients develop recurrent PSC after transplantation.

Primary biliary cirrhosis (PBC) is an autoimmune disease typically characterized by the development of circulating antimitochondrial antibodies (AMAs). Patients with PBC generally have better long-term survival (>7 years) than patients transplanted for PSC (Maheshwari et al, 2004). They are more prone to chronic rejection, however, and are less likely to be weaned from immunosuppression (MacQuillan et al, 2003). PBC likely recurs in a few patients after OLT, although long-term follow-up data are lacking, and this rate appears to be much less common than for PSC recurrence. Posttransplantation AMA titers are not predictive of disease recurrence; a liver biopsy specimen showing granulomatous destructive cholangitis remains the gold standard (Faust, 2001).

Alcoholic Cirrhosis

Although often producing ESLD in conjunction with viral hepatitis, alcoholic cirrhosis is one of the leading indications for OLT in the United States (Amersi et al, 1998; Thuluvath et al, 2010). Early reports showing equivalent outcomes in patients with alcoholic cirrhosis compared with patients with nonalcoholic cirrhosis resulted in widespread application of OLT for this indication (Bird et al, 1990; Starzl et al, 1988). Medical outcomes in this group continue to be good (Busuttil et al, 2005; DiMartini et al, 1998; Lim & Keeffe, 2004).

Recidivism occurs in roughly 20% to 30% of patients transplanted for alcoholic cirrhosis (Biselli et al, 2010; Pageaux et al, 2003; Rowley et al, 2010). Although there is little convincing evidence that resumption of drinking adversely affects graft or patient survival after OLT, there are ethical concerns over possibly misallocating donor organs to active substance abusers (Lim & Keeffe, 2004). Relapse might also serve as a proxy marker for patients who are likely to have poor nutrition and overall health as well as poor compliance with their immunosuppressive regimen and, therefore, increased risk of rejection (Pageaux et al, 2003). Most transplant centers require potential transplant candidates to participate in a support program, undergo psychologic evaluation, and remain abstinent from substance abuse, with documented random drug and alcohol testing for at least 6 months before placement on the waiting list. Multivariate analysis of alcoholic patients with cirrhosis who have undergone OLT showed that abstinence for 6 months or more before OLT is the strongest predictor for nonrelapse after transplantation (Miguet et al, 2004).

Hepatitis B Virus

Since the standardization of HBV treatment with hepatitis B immunoglobulin (HBIG) and antiviral agents, the rate of recurrent HBV infection in liver transplant recipients has declined from 80% in untreated patients to less than 10% of treated patients at 2 years (Roche & Samuel, 2004; Saab et al, 2009; Todo et al, 1991; see Chapter 64). Current treatment strategies include reducing or eliminating active viral replication before transplantation through the administration of lamivudine or adefovir, in combination with other agents, then combining one of these with HBIG after OLT indefinitely. This approach has resulted in similar outcomes for patients without recurrence compared with patients undergoing OLT for other reasons (Kim et al, 2004; Roche et al, 2003; Steinmuller et al, 2002); however, HBIG administration can be costly and cumbersome, and resistance to lamivudine is reported in 20% of patients after treatment for 1 year.

Although combination prophylaxis with lamivudine and HBIG is highly effective, other methods to combat HBV recurrence are being investigated. Alternative regimens include combination antiviral agents (e.g., lamivudine and adefovir) without routine use of HBIG (Nath et al, 2006). HBV recurrence portends a poor outcome, with a 5-year survival rate of 47% (Saab et al, 2009). For patients with HCC at transplantation, recurrent HBV infection is also significantly associated with a recurrence of HCC after transplantation (Saab et al, 2009).

Hepatitis C Virus

Since its definitive identification in 1989, HCV has been determined to be a major cause of chronic liver disease and cirrhosis, accounting for 37% to 41% of OLT performed in the United States (Thuluvath et al, 2010). Approximately 2% of the general population carries the virus, and 50% to 60% of these individuals develop chronic liver disease (Farmer et al, 2000; see Chapter 64).

Short-term and intermediate-term patient survival after OLT for HCV is not significantly different from HCV-negative patients who receive transplants for other nonmalignant reasons, although graft survival is significantly reduced compared with allografts for alcoholic liver disease (Biselli et al, 2010; Boker et al, 1997; Ghobrial et al, 2001). Unadjusted 10-year survival rates are lower for HCV-positive recipients in the United States (Thuluvath et al, 2010). Recurrent infection is nearly universal, and chronic hepatitis develops in most patients after OLT (Gordon et al, 2009). The clinical course is similar to nontransplanted HCV-positive patients, with only 13% developing hepatic fibrosis (Saab et al, 2009). In these patients with recurrent hepatitis C cirrhosis, 5-year survival decreases to 30% (Saab et al, 2005). Recipients coinfected with HIV tend to experience faster and more aggressive recurrence of HCV (Di Benedetto et al, 2008).

In contrast to HBV, no approved therapies are currently available for prevention of recurrent HCV infection after liver transplantation. Outcomes for transplantation of HCV recipients with extended-criteria livers are significantly worse, and donor age has been reported to affect graft survival adversely

(Lake et al, 2005; Machicao et al, 2004; Russo et al, 2004; Thuluvath et al, 2010); however, older donors can be safely used, with similar results in HCV-positive recipients with short cold and warm ischemia times and careful donor selection (Doyle et al, 2008).

Hepatocellular Carcinoma (See Chapters 80 and 97D)

HCC was one of the first documented indications for OLT (Starzl et al, 1968). The decision to utilize transplantation for this disease is based on the oncologic premise of performing a complete resection (total hepatectomy) with wide surgical margins to effect a cure and to remove potential future sites of tumor formation in the diseased remnant liver. Improved selection of appropriate candidates with HCC for OLT has led to improved outcomes and consequently has more than doubled the number of patients with HCC on the waiting list (Thuluvath et al, 2010).

Liver transplantation in the setting of extrahepatic malignancy is contraindicated. Conversely, the finding of incidental HCC in the explanted specimen after transplantation for a nonmalignant indication does not alter patient or graft outcome significantly (Cillo et al, 2004). The difficulty has been the selection of patients for OLT with malignant disease confined to the liver but at an advanced stage.

In their series examining liver transplantation for HCC, Mazzaferro and colleagues (1996) obtained a 75% 4-year actuarial survival using specific guidelines in highly selected patients. Subsequently termed the *Milan criteria* for OLT, patients under this protocol were offered transplantation if they had a solitary tumor less than 5 cm in diameter or no more than three nodules, each less than 3 cm in diameter (stage II). Largely as a result of this report, UNOS adopted these criteria for placing potential recipients on the waiting list, limiting transplantation to patients with stage I (single tumor up to 2 cm in diameter) or stage II disease.

Currently, MELD exception points (22 points) are awarded only on a routine basis to patients with stage II HCC, who account for 8% to 9% of all deceased-donor liver recipients today (USRTR, 2008). Patients with more advanced HCC can only receive additional MELD priority points through special appeal to regional review boards of transplant surgeons and physicians. Although not equaling the excellent results of Mazzaferro and colleagues (1996), reported 5-year survival after OLT for HCC generally ranges from 60% to 75% in several large, more recent series (Goodman et al, 2005; Yao et al, 2001; Yoo et al, 2003).

Several centers have attempted to expand liver transplantation to patients with tumors exceeding the Milan criteria and have met with varying degrees of success. The University of California–San Francisco (UCSF) criteria permit transplantation for patients with solitary tumors smaller than 6.5 cm diameter, fewer than three tumors, and a maximum diameter less than 4.5 cm or total cumulative diameter less than 8 cm (Yao et al, 2001).

Prospective trials currently are examining multimodal treatment for HCC, whereby patients undergo chemoembolization or other ablative techniques to downstage the tumor clinically, followed by transplantation. We require patients with stage III or IV HCC to undergo tumor downstaging, usually with TACE, to meet Milan criteria and with a minimum period of 3 months of observation without evidence of extrahepatic tumor on restaging. Our results using this strategy in highly selected patients are equivalent to patients initially meeting Milan criteria without the need for downstaging (Chapman et al, 2008). Currently, 58% of patients receiving MELD exception points for HCC have undergone TACE or radiofrequency ablation while on the waiting list, with the majority receiving TACE (Thuluvath et al, 2010). Although no prospective trials demonstrate a long-term oncologic benefit to pretransplantation TACE, retrospective data strongly suggest that this may be beneficial, and we consider this a routine practice in our HCC transplant candidates (Bharat et al, 2006).

Cholangiocarcinoma (See Chapters 50C and 97E)

No effective medical treatment has been found for cholangiocarcinoma. Surgical extirpation is feasible in less than 30% of all patients and produces 5-year survival rates less than 30%, even with complete resection (Jarnagin et al, 2001; Rea et al, 2004). Additionally, patients with PSC, a known risk factor for cholangiocarcinoma, are often poor candidates for resection because of concurrent cirrhosis. Historically, the use of OLT for treatment of cholangiocarcinoma has been associated with 5-year survival rates of 30% and even lower rates in patients with incidentally discovered cholangiocarcinoma at transplantation (Becker et al, 2008). Surgeons at the Mayo Clinic reported successful results using strict treatment protocols for performing OLT in patients with localized, node-negative hilar cholangiocarcinoma, which included the use of neoadjuvant chemoradiation, staging laparotomy, resection to negative margins, and OLT (see Chapter 97E). Using these or similar protocols, 5-year survival rates of 72% have been achieved in a highly selected group of patients, many of whom had PSC (Heimbach et al, 2004; Rea et al, 2009; Sudan et al, 2002). Retrospective analysis revealed improved outcomes for patients enrolled in the Mayo protocol compared with those of patients undergoing major hepatic resection (Rea et al, 2005); however, these outcomes have been difficult to achieve at other institutions, and neoadjuvant therapy is associated with higher rates of arterial and venous complications after transplantation (Mantel et al, 2007).

Fulminant Hepatic Failure (See Chapters 72 and 97C)

The cohort that undergoes OLT for fulminant hepatic failure comprises a diverse group of patients and disease etiologies. By definition, these patients have no previous demonstrable liver disease, yet they present acutely with encephalopathy; synthetic dysfunction, such as coagulopathy; and jaundice. Most commonly, the etiology is never determined, but fulminant hepatic failure (FHF) can be caused by drugs, viruses, toxins, or other liver injuries (Hoofnagle et al, 1995). Although artificial liver support systems are under development, the only widely available cure for acute liver failure is OLT. Limited donor organ availability leads to the relatively high waiting-list mortality rate of 377 deaths per 1000 patient-years at risk. MELD scores tend not to predict outcome accurately in patients with FHF (Kremers et al, 2004); in this setting, outcome after OLT is below average, with approximately 67% of patients surviving to 5 years (Farmer et al, 2003).

Nonalcoholic Steatohepatitis (See Chapter 65)

Cirrhosis secondary to nonalcoholic steatohepatitis (NASH) is a rapidly increasing indication for liver transplantation, accounting for approximately 5% of transplantations performed in 2007 (USRTR, 2008). NASH, a stepwise progression in the natural history of nonalcoholic fatty liver disease (NAFLD), is associated with obesity. Data gathered to study the effects of BMI on outcomes of OLT are inconclusive. Although it has been shown that morbidly obese recipients are at higher risk for PTMS and infectious complications, it has not been definitively shown to affect long-term outcomes (Leonard et al, 2008; Malik et al, 2009). Independent risk factors for development of graft steatosis after OTL include pretransplantation graft steatosis, post-OLT obesity, hypertension, DM, hyperlipidemia, use of tacrolimus, and alcoholic cirrhosis as the primary indication for liver transplantation (Dumortier et al, 2010).

RETRANSPLANTATION

The rate of retransplantation has been gradually declining, reaching a low of 7.8% in 2007 (USRTR, 2008). In particular, the rate of retransplantation for HCV dropped to 5% in 2008 (Thuluvath et al, 2010). The most common indications for retransplantation include primary nonfunction (46% of retransplants), HAT (29%), acute and chronic rejection (7%), and recurrent disease (Busuttil et al, 2005; Jain et al, 2000; Lang et al, 2008; Marti et al, 2008; Thuluvath et al, 2010). Use of DCD allografts is associated with a 13% retransplantation rate, which has remained stable over the last decade (Thuluvath et al, 2010).

Outcome after retransplantation is generally worse than after initial OLT but is slowly improving, with a 10-year graft survival up to 69% in some centers (Marti et al, 2008); however, this varies significantly by primary indication (Adam & Hoti, 2009; Thuluvath et al, 2010). Patients requiring retransplantation are at increased risk for infection, HAT, and acute renal failure (Uemura et al, 2007). Retransplantation for primary nonfunction yields 54% to 60% patient survival at 5 years (Kemmer et al, 2007; Uemura et al, 2007). Recurrent HCV is associated with worse outcomes following retransplantation overall, and most centers avoid retransplantation for this indication; however, a recent multicenter analysis demonstrated similar 3-year survival rates in a highly select group of patients with recurrent HCV compared with non-HCV retransplant recipients (McCashland et al, 2007). Factors portending a poor prognosis include preoperative mechanical ventilation, HCV infection, elevated creatinine and bilirubin, and prolonged donor cold ischemia (Markmann et al, 1999; Yoo et al, 2003).

CONCLUSION

Results after OLT have improved over the past 3 decades, although outcomes may be expected to plateau as further improvements add only a marginal survival benefit to an already refined surgical procedure. The reasons for the successful development of hepatic transplantation are as follows:

1. Organized regional and national networks designed for the early identification of potential organ donors and rapid procurement in select candidates
2. Improved surgical and anesthetic techniques, allowing previous obstacles to OLT to be overcome (e.g., PVT, severe coagulopathy)
3. Novel antirejection and antimicrobial agents, with increasing emphasis on achieving minimal immunosuppression in the shortest time possible
4. Increased vigilance for the occurrence of acute complications after OLT, with the development of rapid screening tests for HAT, PVT, and primary nonfunction

As the only treatment option for thousands of patients, and with the added benefit of being curative for most candidate recipients, OLT will continue to be offered for the foreseeable future. Methods for expanding the donor pool and the more recent revisions to the allocation process may help to ease the shortage of suitable hepatic grafts. Newer immunosuppressive agents and further understanding of the role, or even the necessity, of immunosuppression in some patients may decrease the morbidity for patients after OLT.

CHAPTER 99

Techniques of liver replacement

J. Wallis Marsh and Thomas E. Starzl

HISTORICAL OVERVIEW

The steps by which liver replacement became the treatment of choice for numerous end-stage liver diseases (Starzl et al, 1989) were summarized in 2002 (Starzl). The basic operation was developed in dogs during the years 1958 through 1960 and was attempted clinically in 1963 under azathioprine-prednisone immunosuppression. The first humans to have liver replacement with prolonged survivals were reported by Starzl in 1969; however, not until the availability of cyclosporine in the 1980s did orthotopic liver transplantation became accepted worldwide as effective therapy. The results improved again with the advent of tacrolimus in the 1990s (see Chapter 96).

Elements other than immunosuppression have contributed to the success of liver replacement, including improved patient selection and pretransplantation management, noninvasive diagnostic techniques, new antibiotics, and advances in anesthetic and perioperative critical care (see Chapters 97A and 97B); however, perfection of the donor and recipient operations was the crucial factor on which all else ultimately depended. Surgical techniques used at the University of Colorado—and since January 1981, at the University of Pittsburgh—are presented in this chapter, with an emphasis on principles rather than details.

DONOR OPERATION

The use of multiple organs from a single cadaveric donor became practical with the development of standard procurement methods in the early 1980s (see Chapter 98A). Subsequently, the University of Wisconsin (UW) and histidine-tryptophan-ketoglutarate (HTK) preservation solutions made storage of hepatic grafts relatively safe for 12 to 18 hours. The availability of this much time has allowed widespread sharing of livers while permitting an accurate assessment of the grafts by histologic and metabolic criteria.

Standard Liver Procurement

In the standard procurement technique, a midline incision is made from the suprasternal notch to the pubis to expose the abdominal and thoracic organs of potential interest (Fig. 99.1). After verification that the liver has a normal consistency and color, the left suspensory ligament is incised, allowing the left lobe to be retracted anteriorly and to the right. This retraction exposes the upper part of the gastrohepatic ligament, which contains the left gastric artery, the smallest branch of the celiac axis, and the arterial supply of the liver (Fig. 99.2). If an anomalous left hepatic arterial branch originates from the left gastric artery (Fig. 99.3), it must be preserved in continuity with the main left gastric artery (see Fig. 99.3, inset). When present, this anomalous left hepatic arterial branch is nearly always present just posterior to the vagus nerve branch, as it courses from the lesser curvature of the stomach through the gastrohepatic ligament to the liver.

The largest branch of the celiac axis usually is the common hepatic artery. The right gastric and gastroduodenal arteries are ligated and divided (Fig. 99.4; see also 99.2). If the left gastric, right gastric, and gastroduodenal arteries are ligated in that order, the subsequent dissection of the common duct and the portal vein is rendered relatively bloodless. The common bile duct is transected near the duodenum, and the gallbladder is incised, permitting the bile to be irrigated out with saline (see Fig. 99.3); this avoids autolysis of the extrahepatic and intrahepatic bile duct epithelium during storage. The portal vein now is dissected inferiorly to the confluence of the splenic and superior mesenteric veins (see Fig. 99.4).

After completing the hilar dissection, the aorta is encircled superiorly, where it passes through the diaphragm, and inferiorly, just proximal to its distal bifurcation. Cannulae for infusion are placed into the inferior mesenteric vein (or splenic vein) and, after total body heparinization, into the distal aorta (see Fig. 99.4). When all procurement teams are ready, the aorta is cross-clamped at the diaphragm or in the chest by the abdominal surgeon (see Fig. 99.4), while the thoracic surgical team clamps the ascending aorta. Moderately rapid infusion of cold preservation solution is started into the portal circulation and aortic cannula. At the same time, a cardioplegia solution is infused into the midportion of the ascending aorta. Congestion of the various organs is prevented by an incision in the suprahepatic inferior vena cava at the level of the right atrium, which allows the blood and infusate to drain into the pericardium (see Fig. 99.4).

In adults, the liver is usually perfused with 2 L of HTK infused through the splenic vein or inferior mesenteric vein and 10 L infused through the aorta, although smaller volumes are used for children. When the liver becomes cold and blanched, and the heart has been removed, the total hepatectomy is completed. The remaining dissection must be performed expeditiously but methodically. If the celiac axis is retained with the graft, a proximal segment of its splenic arterial branch also should be conserved for potential reconstruction of an anomalous hepatic artery (see later). The most common hepatic artery anomaly is an aberrant right hepatic artery that originates from the superior mesenteric artery, commonly found posterior to the portal vein (Fig. 99.5; see Chapter 1B). If the pancreas is to be discarded, the anomalous retroportal artery can be kept in continuity with the superior mesenteric artery (see Fig. 99.5, inset), where its origin can be incorporated into a Carrel patch that is shared with the origin of the celiac axis.

The liver now remains attached primarily by the vena cava above and below the liver. The vena cava below the liver is transected above the entry of the left and right renal veins

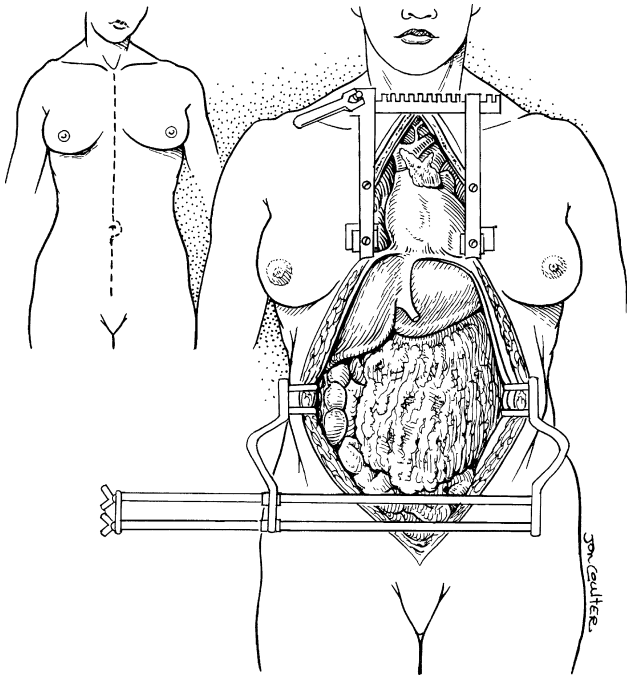

FIGURE 99.1. Initial steps for liver retrieval, including complete dissection of the hepatic hilum with the standard multiple-organ procurement technique.

(Fig. 99.6). The vena cava above the liver is transected with a surrounding rim of diaphragm that is carefully excised on the back table. The retrohepatic vena cava is dissected free, including ligation of the right adrenal vein and posterior lumbar tributaries. The liberated liver is immediately placed in a solution-filled preservation bag packed in ice (Fig. 99.7); some surgeons flush the common bile duct with HTK before packaging the liver.

Modified Donor Procedures

Rapid Procurement

Use of the standard technique in stable donors has allowed the training of relatively inexperienced surgeons in the performance of a donor hepatectomy. When the technique is mastered, faster methods can be applied electively or, if required, by urgent clinical circumstances. With the rapid techniques, little or no preliminary dissection is done except for encirclement of the supraceliac aorta and cannulation of the inferior mesenteric vein and terminal aorta (Fig. 99.8). If the heart is to be removed, the cardiac surgeon proceeds as if other organs are not to be harvested but gives warning before the circulation is stopped.

At the moment heart function ceases, the abdominal aorta is cross-clamped above or just below the diaphragm, and an infusion of cold HTK solution is started in the inferior mesenteric vein and distal aorta (see Fig. 99.8). The amount of preservation fluid with the rapid technique is approximately the same

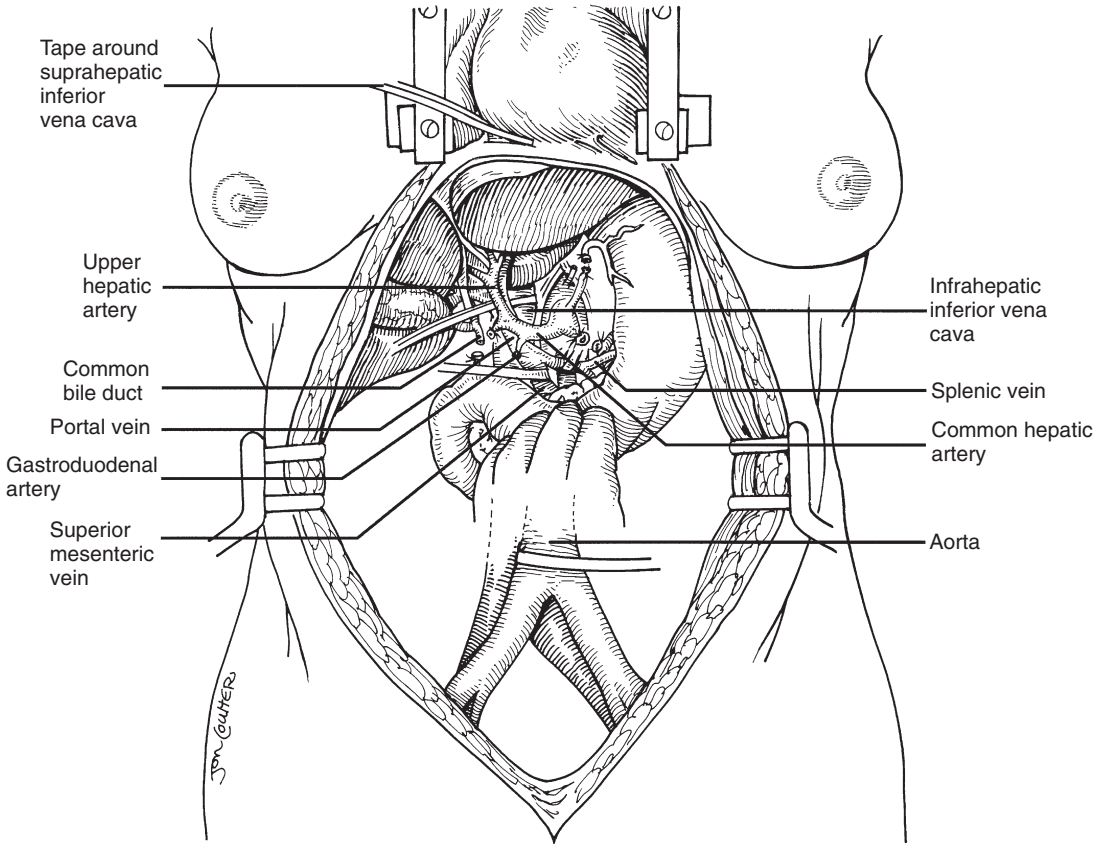

FIGURE 99.2. Exposure for multiple organ retrieval in the cadaveric donor.

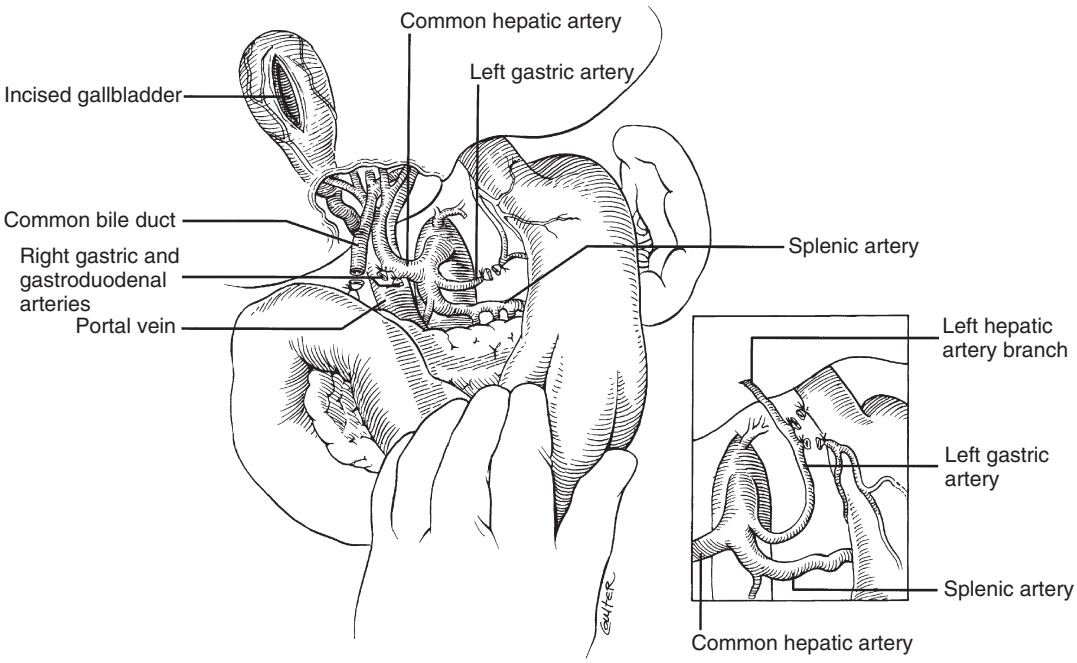

FIGURE 99.3. Normal arterial anatomy. The liver arterial supply is entirely from the common hepatic artery. The inset depicts a common anomaly in which all or part of the left lobar supply is from the left gastric branch of the celiac axis. The anomalous branch must be preserved. During the hilar dissection, the common duct is divided distally, and the gallbladder is incised to flush the biliary tree.

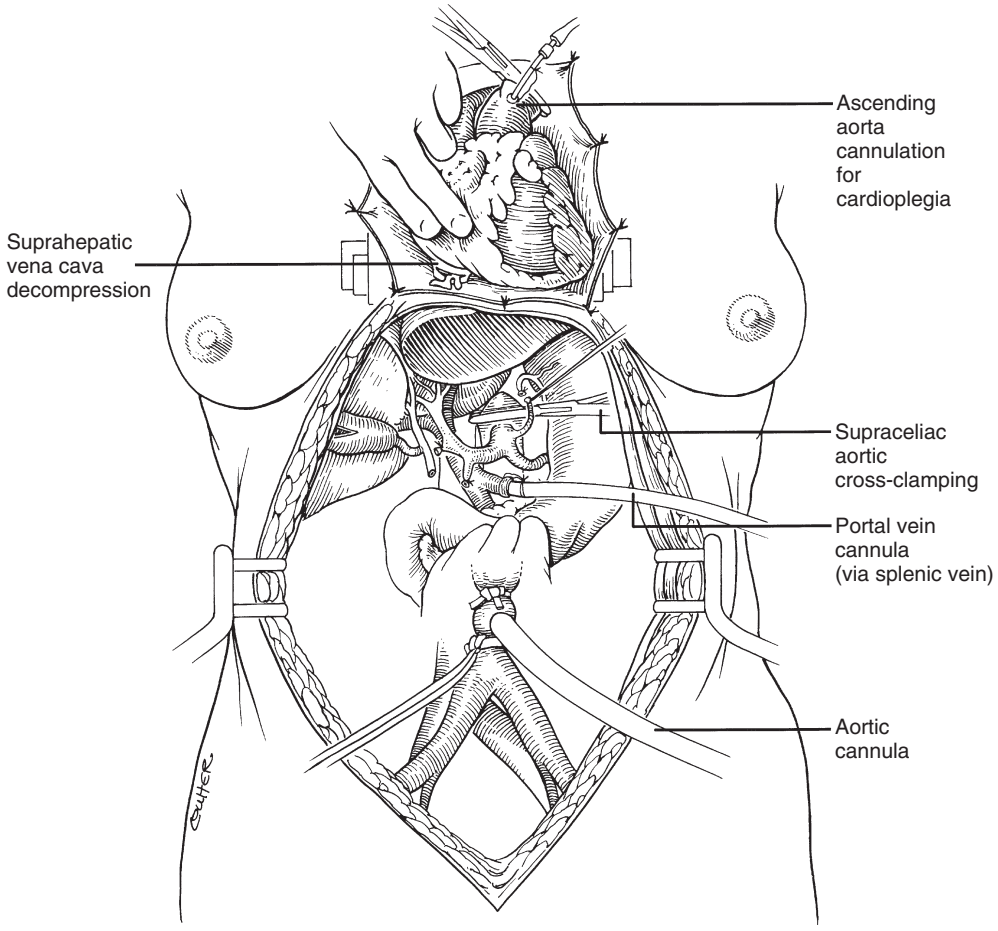

FIGURE 99.4. In situ perfusion technique used when the heart, kidneys, liver, and other viscera are removed from the same donor. University of Wisconsin or histidine-tryptophan-ketoglutarate (HTK) preservation solution are infused into the inferior mesenteric vein or splenic vein and distal aorta with simultaneous venting of the suprahepatic inferior vena cava into the pericardium. Note the aortic cross-clamp above the celiac axis. The cannulation and cross-clamping of the thoracic aorta for infusion of a cardioplegia solution also are shown.

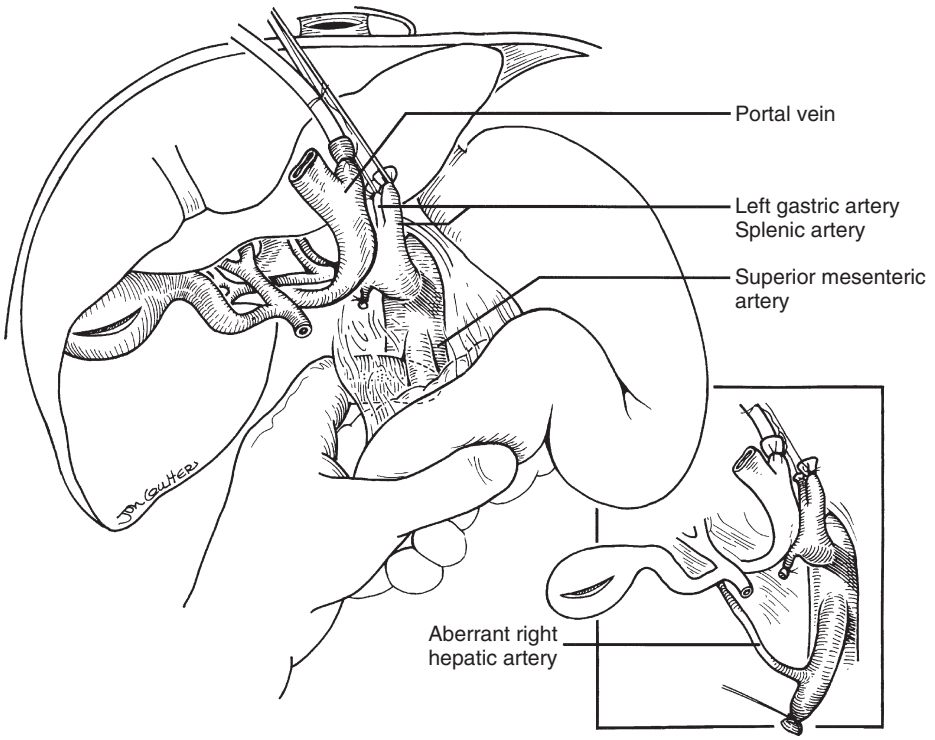

FIGURE 99.5. Retraction of the liver and its portal structures to the right and performance of a Kocher maneuver to free up the duodenum and head of the pancreas. An anomalous right hepatic artery, originating from the superior mesenteric artery (*inset*) just posterior to the portal vein, is sought out.

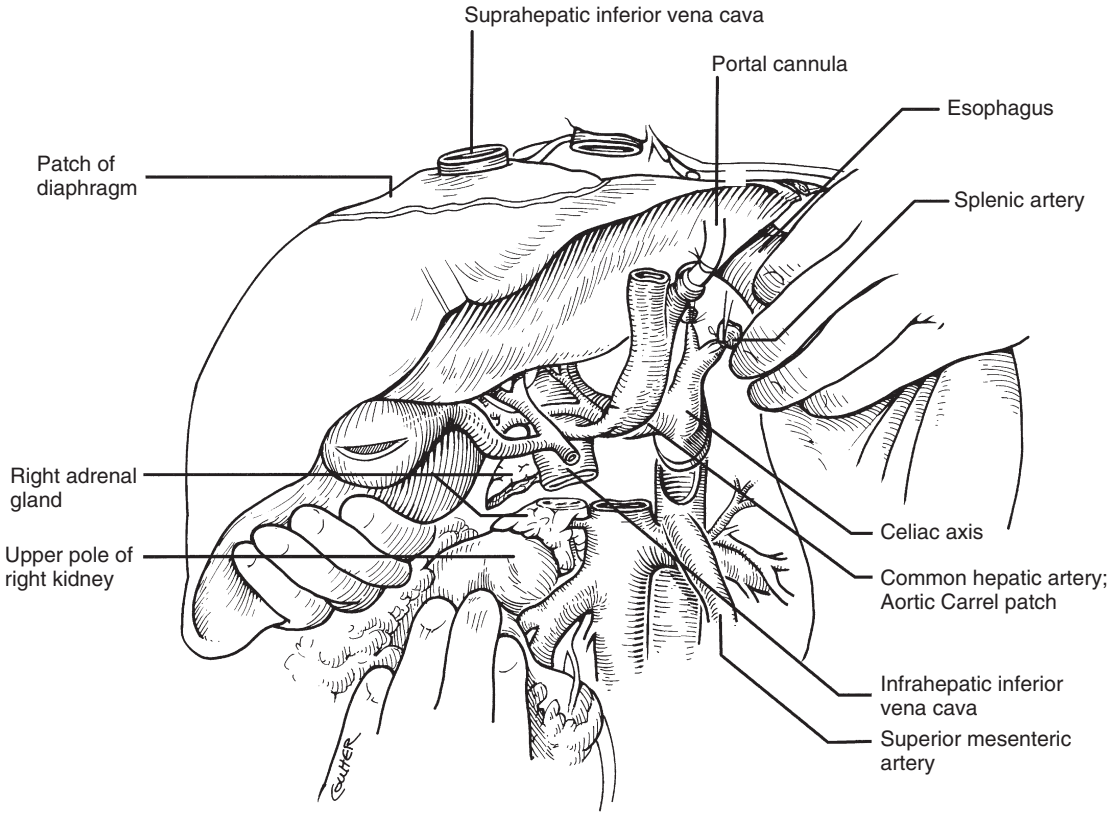

FIGURE 99.6. The suprahepatic vena cava has been transected with inclusion of a generous patch of diaphragm on the liver side. The infrahepatic vena cava is divided just above the origin of the renal veins, and the celiac axis is removed with a Carrel patch of anterior aorta. If an anomalous right hepatic artery originates from the superior mesenteric artery (SMA), the origin of the SMA may be included in the Carrel patch (see Fig. 99.10A).

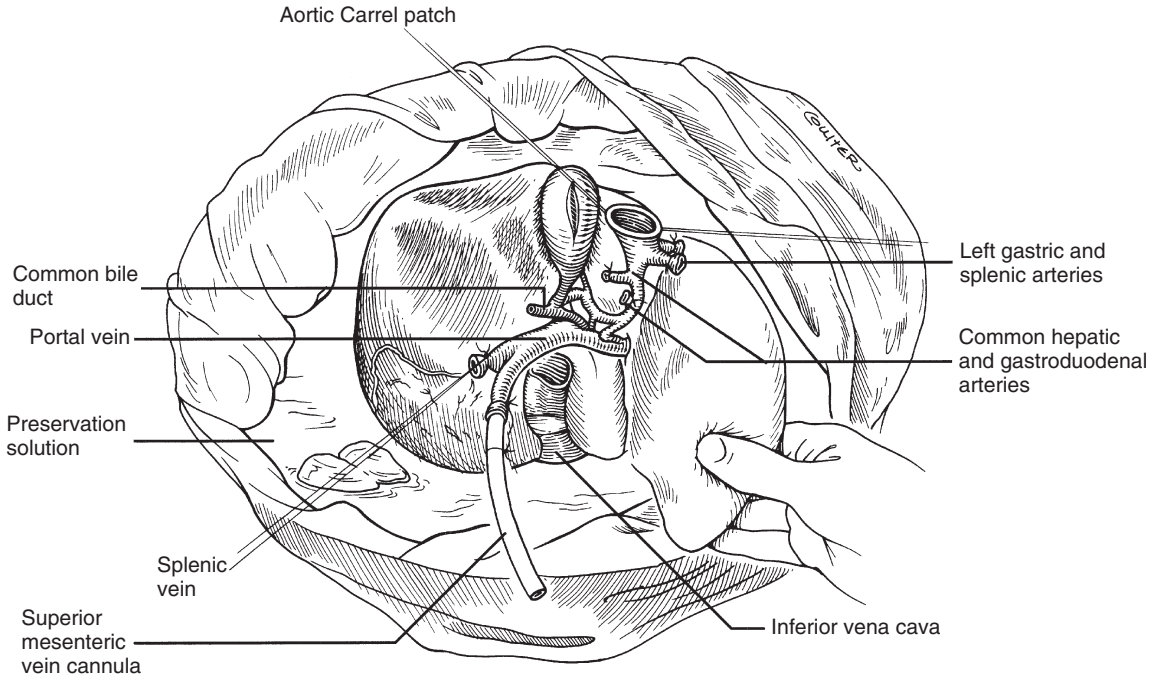

FIGURE 99.7. The liver graft is placed in a basin containing iced preservation solution for back-table preparation. The vascular cuffs are debrided of excess tissue, and any needed arterial reconstruction is performed (see Fig. 99.10).

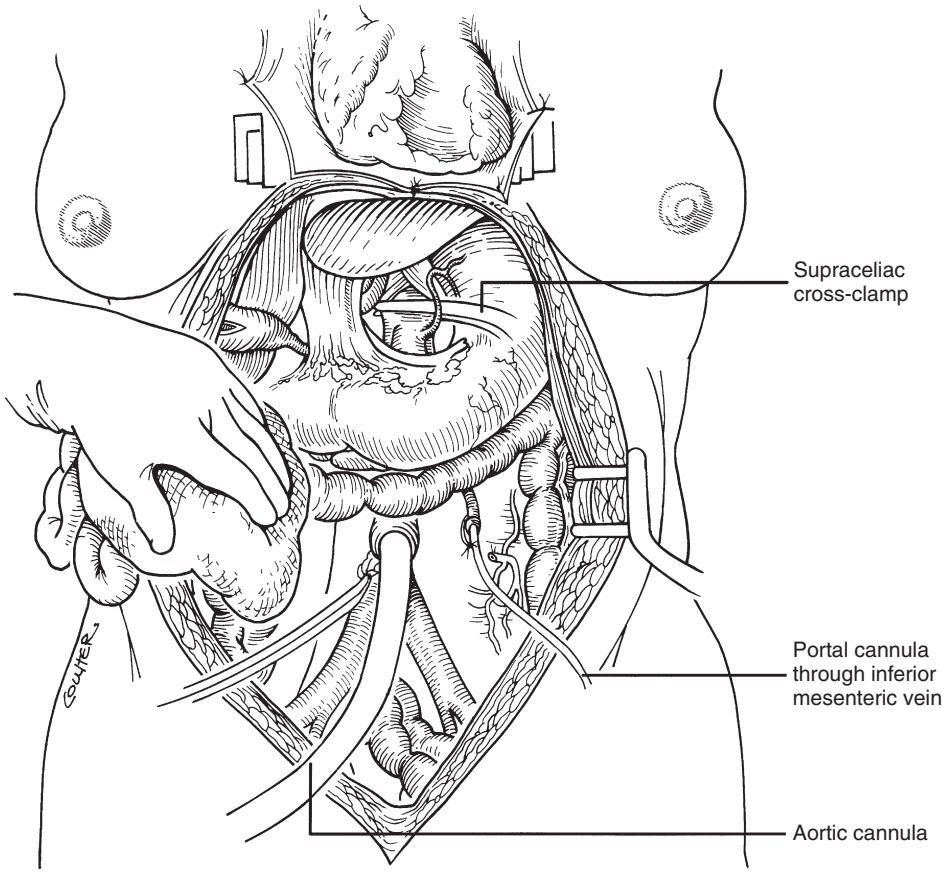

FIGURE 99.8. Rapid technique of organ retrieval in which the initial dissection is limited to the exposure needed for the insertion of perfusion cannulae in the inferior mesenteric vein and distal aorta. If only the abdominal organs are to be used, the aorta is cross-clamped above or below the diaphragm.

as that used for the standard method (i.e., 2 L into the inferior mesenteric vein (IMV)/splenic vein and 10 L through the aorta). When the liver becomes cold, the infusions are slowed. In the now bloodless field, the main vessels of the celiac axis can be quickly dissected, and the hilar dissection can be completed in a matter of minutes.

The portal vein is cleaned inferiorly to the junction of the splenic and superior mesenteric veins, and these two tributaries are divided. As in the standard method, the surgeon must promptly exclude the possibility of a retroportal right hepatic artery originating from the superior mesenteric artery as well as other arterial vascular anomalies. The hepatectomy is then completed. The kidneys, which are excised only after the liver has been removed from the field, are kept cold throughout by continued, slow, intraaortic infusion of the preservation solution. By performing all dissections in the bloodless field, it is possible to remove multiple organs in about half an hour, including the heart, liver, and both kidneys. Procurement of the intestine adds only a few additional minutes.

Super-Rapid Procurement

In arrested or non–heart-beating donors, an even quicker procedure can be used to procure satisfactory organs. This method also can be applied in countries that do not have "brain death" laws or under special legal or religious circumstances. Here, cooling requires urgent cannulation and cold fluid infusion into the distal aorta (Fig. 99.9A). Sternum splitting, thoracic aortic cross-clamping, and severance of the suprahepatic inferior vena cava for venous decompression are performed (Fig. 99.9B), deferring cannulation and perfusion of the portal venous system until after the various organs are at least partly cooled intraarterially (Fig. 99.9C). The various dissections are done in the same way as with the standard and rapid techniques. Effective application of this method requires an extremely high level of skill.

Back-Table Surgery

No matter which procurement method has been used, further preparation of the liver is performed on a separate back table before delivering the graft to the recipient surgeon. The liver should be kept cold by submerging it in a basin containing ice-cold preservation solution surrounded by a bag containing sterile ice slush (see Fig. 99.7). Back-table preparation includes the following:

1. Dissection and removal of extraneous tissue, such as diaphragm, adrenal gland, lymph node, pancreatic, peripancreatic, and ganglionic tissue
2. Preparation of cuffs of the suprahepatic and infrahepatic vena cava, cleaning of the portal vein and hepatic artery, and inspection of the bile duct
3. Verification of secure ligatures on small retrohepatic caval, portal vein, and hepatic arterial branches
4. Ensuring the continuity and integrity of all major structures that must be anastomosed to the companion recipient structures

Failure to have the graft completely ready for implantation when it is brought to the recipient operative field can result in irreversible damage to the graft or may make it impossible to complete the recipient operation. Several methods of back-table vascular reconstruction have been designed to repair technical accidents or to accommodate aberrant vessels or congenital anomalies. A common reason for back-table reconstruction is the presence of an anomalous right hepatic artery originating from the superior mesenteric artery (Fig. 99.10).

Liver, Pancreas, and Intestine Procurement from the Same Donor

The pancreas and intestine can be retrieved independently or together with the liver. Before starting the procurement, the operation should be discussed among the surgeons involved. Considerations include organ priority, type and amount of preservation solution to be used, presence of aberrant hepatic arteries, length of portal vein, and a decision about which organ retains the celiac axis or superior mesenteric artery.

An important step in any cadaveric donor operation is the removal and storage of long segments of the donor iliac arteries and veins as well as other arteries and veins. These vessels can be used as vascular grafts to reconstruct the blood supply of the individual organs. With increased experience, it is rare to see any of the abdominal visceral organs discarded for purely technical reasons.

RECIPIENT OPERATION

The recipient procedure tends to be long and physically demanding. Its different parts are so remarkably dissimilar that a single surgeon operating from "skin to skin" may find it difficult to change emotional and intellectual gears to keep pace with the evolving events. Removal of the diseased liver may be one of the most difficult challenges a surgeon faces. Yet, the vascular anastomoses can be among the most delicate and sophisticated procedures one performs, especially in very small children.

Achieving perfect hemostasis after the donor liver has been revascularized is crucial, because failure of this step can ruin all that has been accomplished; however, this is often an exhausting exercise, particularly at the end of many hours of demanding surgery. Finally, the delicate biliary tract reconstruction becomes the final thread on which the whole enterprise is suspended.

Abdominal Incision and Exposure

The exact location of the incision may be influenced by previous right upper quadrant surgery, the presence of an ileostomy, the size and configuration of the liver, or other factors. A bilateral subcostal incision is the most commonly used, extending on the right to just beyond the midaxillary line and on the left to the lateral edge of the rectus, with an upper midline extension and excision of the xiphoid process (Fig. 99.11A). In unusual circumstances, a lower midline extension may also be needed, especially if exposure of the distal aorta is required for reconstruction of the hepatic arterial supply. Thoracic extensions are rarely needed.

A bilateral subcostal incision (Fig. 99.11B) or a right subcostal incision with or without an upper midline extension (Fig. 99.11C) may also be used. The upper midline extension, shown in Figure 99.11C, is usually unnecessary in pediatric patients. Massive hepatomegaly, extensive prior abdominal surgery, or other factors may mandate the selection of a more extensive incision (see Fig. 99.11). In patients who require concomitant splenectomy or interruption of a prior splenorenal shunt, the incision may need to be extended to the left subcostal region.

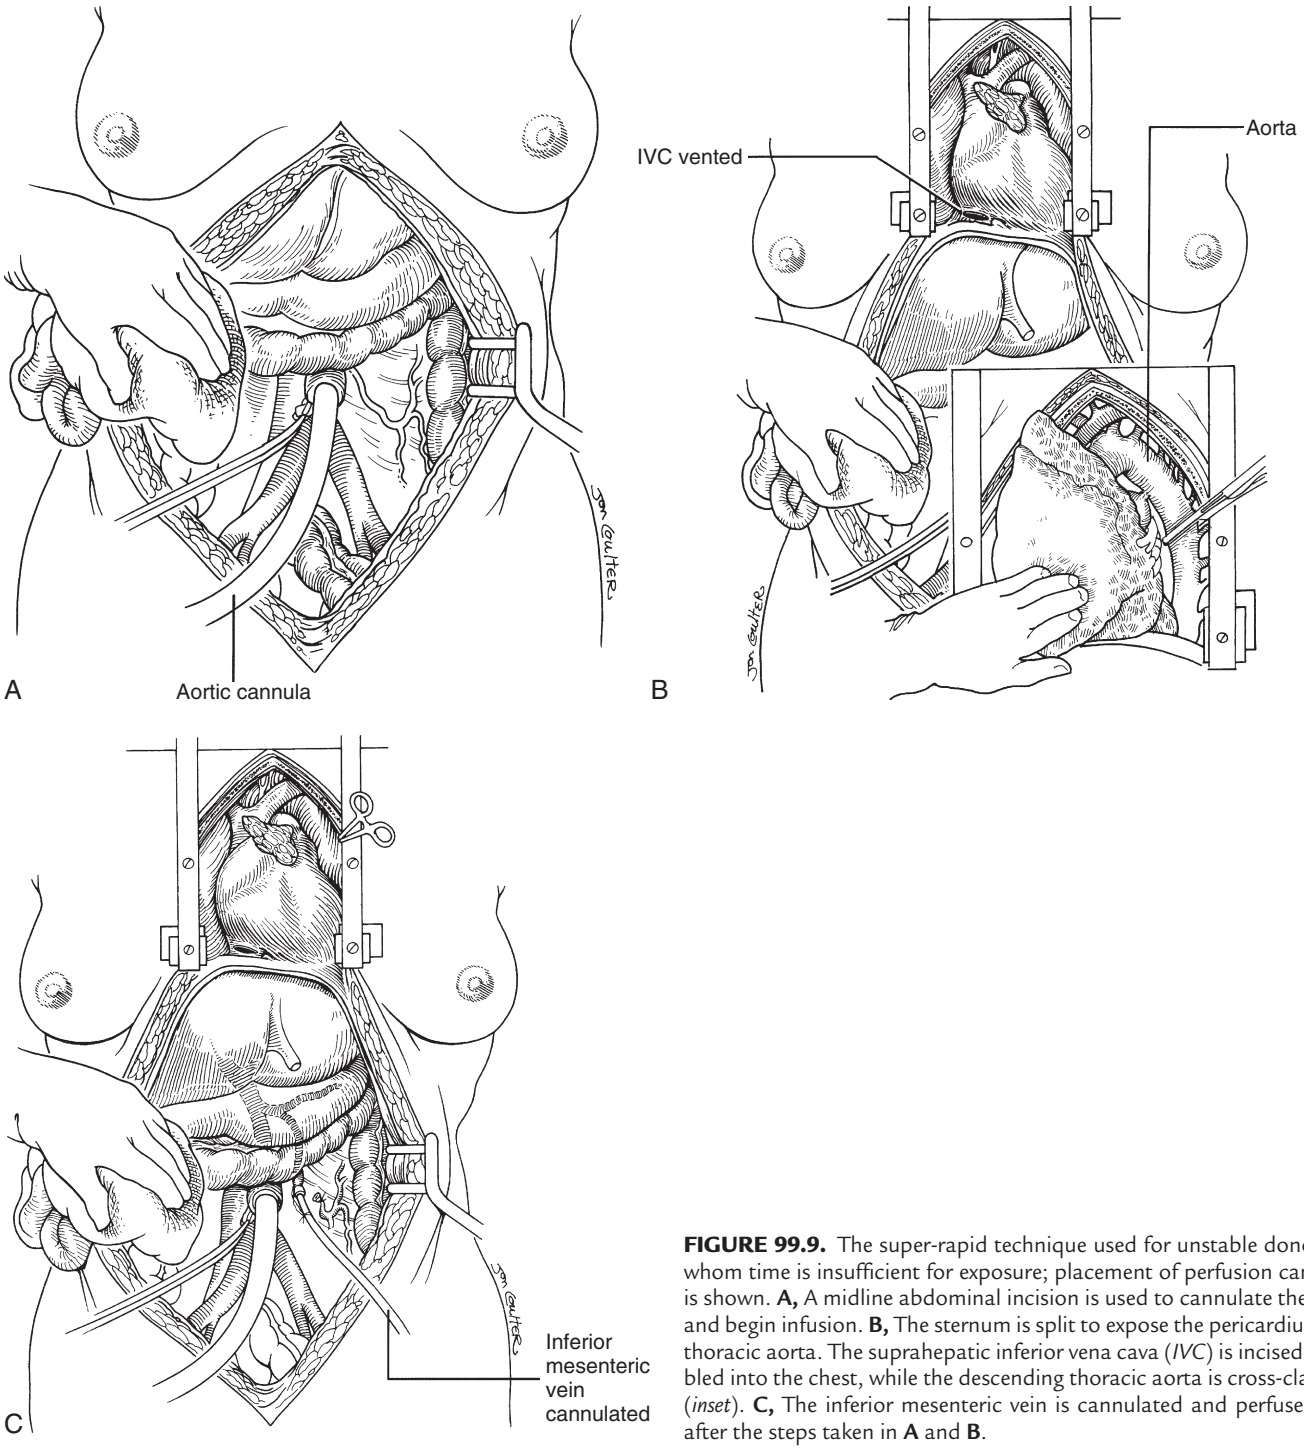

FIGURE 99.9. The super-rapid technique used for unstable donors for whom time is insufficient for exposure; placement of perfusion cannulae is shown. **A,** A midline abdominal incision is used to cannulate the aorta and begin infusion. **B,** The sternum is split to expose the pericardium and thoracic aorta. The suprahepatic inferior vena cava (*IVC*) is incised and is bled into the chest, while the descending thoracic aorta is cross-clamped (*inset*). **C,** The inferior mesenteric vein is cannulated and perfused only after the steps taken in **A** and **B**.

Improved exposure with any of these incisions can be obtained with use of the Bookwalter, Thompson, or another retractor that permits access to the hepatic veins and suprahepatic vena cava (Fig. 99.12). In making the incision, it may be necessary to abandon delicate celiotomy techniques of meticulous hemostasis and resort to continuous hemostatic suturing along the cut edges of the fascia and preperitoneum or to the use of hemostatic devices such as the Salient Surgical Technologies (Portsmouth, NH) Monopolar sealer. When the abdomen is entered, an effort must be made to find a plane of dissection just outside the liver capsule. Movement away from this plane risks an encounter with major venous collaterals, which can result in disastrous hemorrhage early in the operation.

Intraoperative Determination of Surgical Strategy

There is no single best way to carry out orthotopic liver transplantation. When exposure has been obtained, it is important to assess the pathology and decide on the technical approach that best fits the pathologic circumstances. A surgeon who insists on following the same steps in unvarying order for all liver

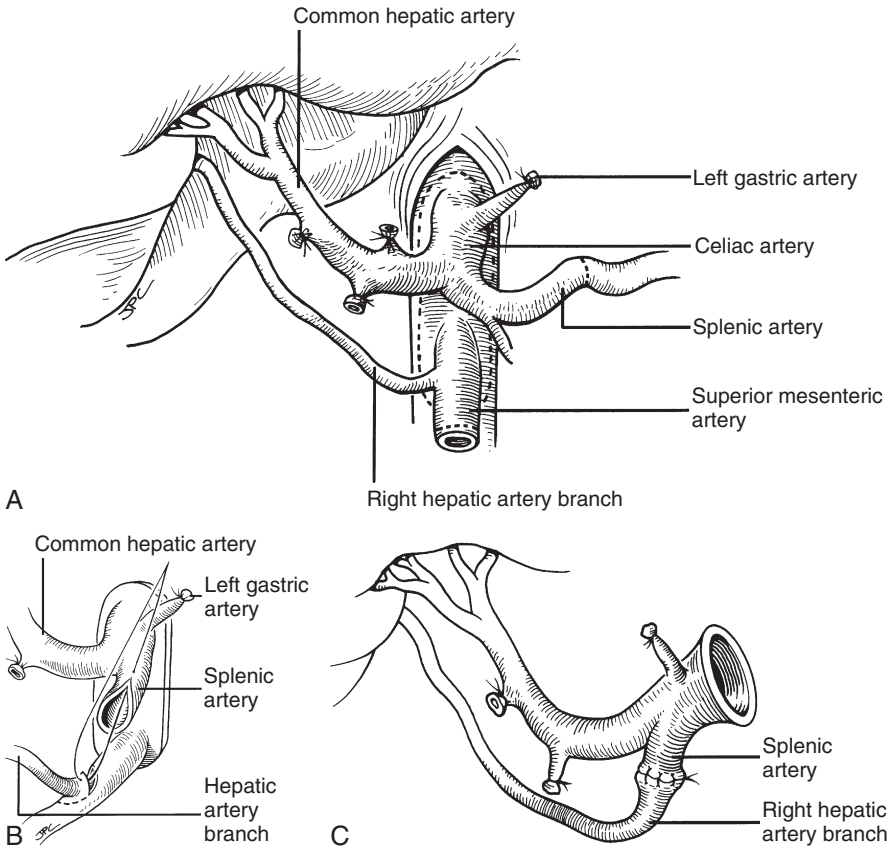

FIGURE 99.10. Examples of reconstruction of an anomalous arterial supply to the liver. **A,** The origins of the celiac axis and superior mesenteric artery are removed from the anterior aorta in a common Carrel patch. **B** and **C,** An anomalous right hepatic artery is anastomosed to the graft splenic artery, leaving only the origin of the celiac axis for anastomosis in the recipient.

recipients experiences unnecessary hardship. The following is a description of the basic ingredients of the recipient operation, with particular emphasis on variations of host hepatectomy.

Venovenous Bypass

The most critical stage of the recipient operation is the anhepatic phase, during which the diseased liver is removed and replaced with the allograft. Obstruction of the portal vein and vena cava during this period results in splanchnic and lower body systemic venous hypertension. This situation can have devastating consequences in some patients. During the early 1980s, a pump-driven venovenous bypass, used without recipient heparinization, was developed in Pittsburgh to allow splanchnic and systemic blood to return to the heart by way of an inflow cannula placed in the axillary vein (Fig. 99.13). This technique permitted the hepatectomy and implantation to be done with significant reductions in blood loss, intestinal edema, and postoperative renal failure.

Infants and small children weighing less than 15 kg tolerate venous occlusion reasonably well. Currently in adults, experienced surgeons use bypass selectively, avoiding it until it becomes apparent that its use cannot be avoided. When required, the cannulae are often now placed percutaneously in the groin and neck, thereby obviating the need for cut-downs as previously required. If bypass is not routine, the decision for or against its use should be made as early as possible in the course of the operation. The decision can be aided by testing the cardiocirculatory effects of test occlusion of the inferior vena cava and portal triad. If the test is conducted after preliminary dissection of the portal triad, and after the triangular and coronary ligaments are cut with entry into the right and left bare areas, it also is possible to evaluate the extent to which bleeding from raw surfaces can be anticipated without bypass. Alternatively, a temporary end-to-side portocaval shunt can also be constructed to prevent mesenteric congestion during the anhepatic phase. This is often created using a small segment of donor iliac vein in order to retain the full length of the recipient portal vein and for ease of creating the shunt. The portocaval shunt should be placed on the vena cava as inferiorly as possible, so its location does not interfere with placement of the vena caval clamp.

Hilar Dissection

In "easy" cases, the individual hilar structures can be readily skeletonized. The hepatic artery and common duct are ligated as close to the liver as possible, and the hepatic artery is dissected proximal to the origin of its gastroduodenal branch, facilitating exposure of the proximal portal vein (Fig. 99.14). If needed, venovenous bypass can be initiated with cannulation of the transected portal vein at this time or later.

Host Hepatectomy with or Without Vena Cava Removal

If the hilar dissection has been accomplished uneventfully, the liver is devascularized and now can be excluded from the circulation by cross-clamping the vena cava above and below the liver (Fig. 99.15A). The diseased organ with or without a

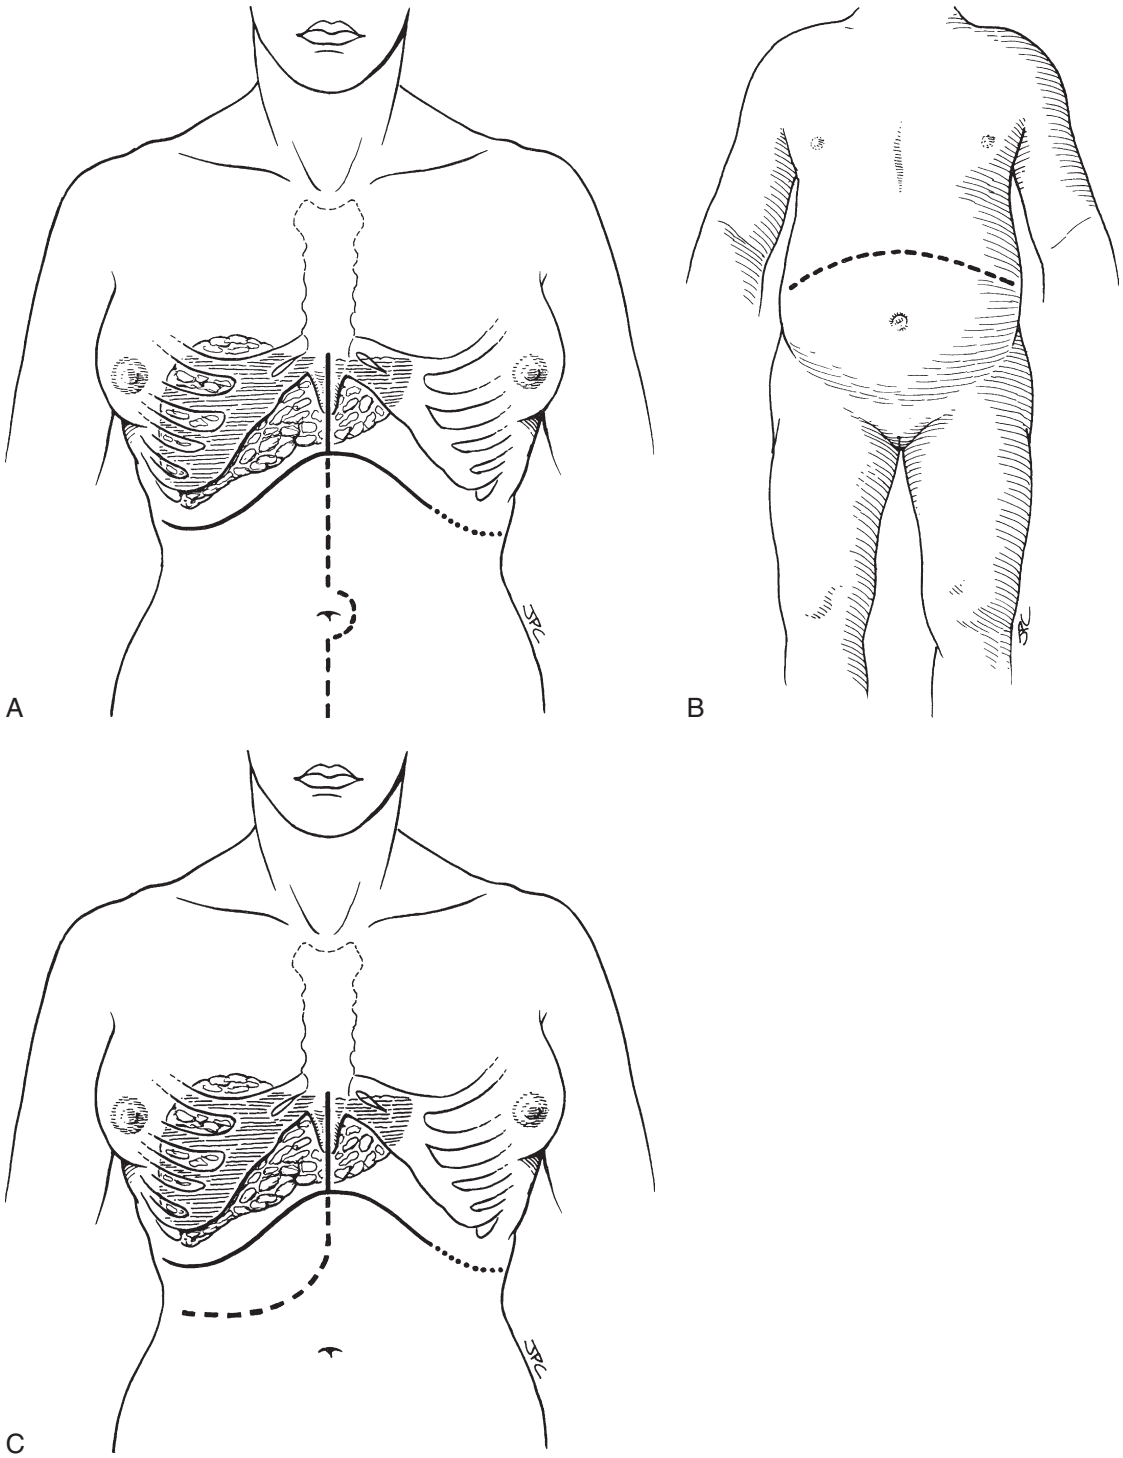

FIGURE 99.11. Potential incisions for orthotopic liver transplantation. **A,** Bilateral subcostal incision with potential superior or inferior extensions. **B,** Inverted half-moon incision sometimes used in infants and small children. **C,** Simple subcostal incision that may be converted to a hockey-stick incision by an upper midline extension, which may include xyphoid resection.

segment of retrohepatic vena cava can be "peeled" out, working from the hilum up or from the diaphragm down. If the vena cava is part of the specimen, the obligatory ligation of the right adrenal vein (Fig. 99.15C) imposes a risk of adrenal infarction. If this occurs with venous hypertension and bleeding, the right adrenal gland should be removed immediately. Other systemic venous tributaries to the vena cava segment from the lumbar regions also must be scrupulously ligated. Because of regional venous hypertension in the right-sided bare area, it may be necessary then or later to obtain hemostasis by closing or oversewing the edges of the exposed bare areas with a continuous suture or by the use of such devices as the LigaSure (Covidien, Mansfield, MA) or the Monopolar or Bipolar sealer (Fig. 99.15D).

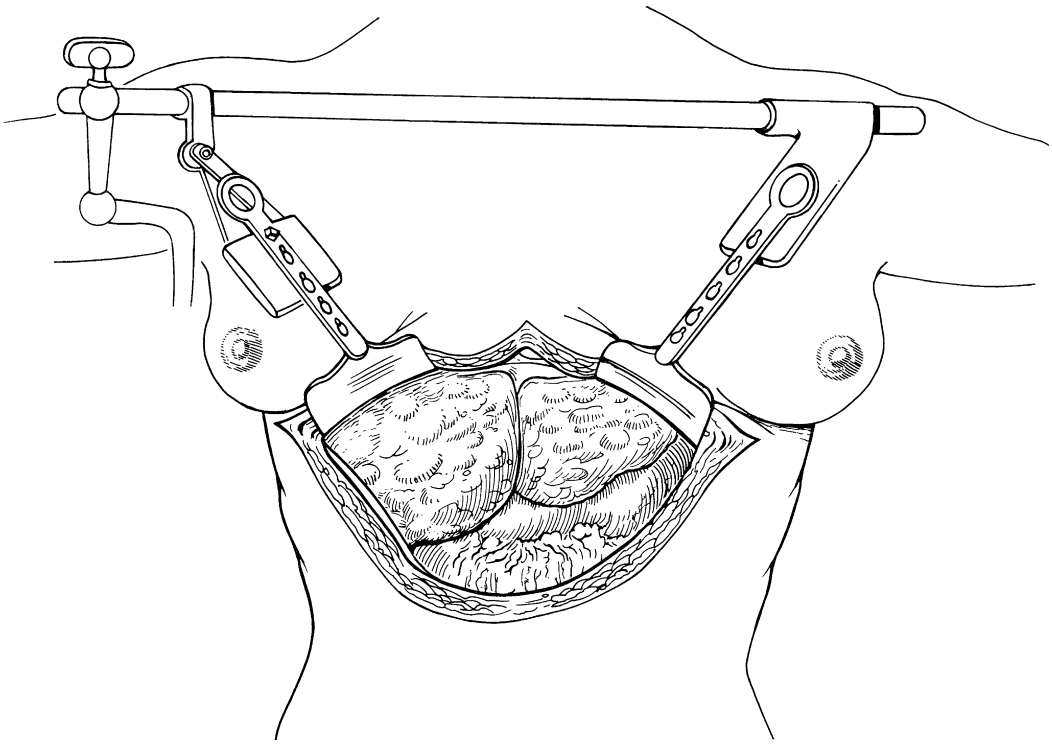

FIGURE 99.12. Exposure, especially of the suprahepatic vena cava, can be facilitated by the use of self-retaining retractors.

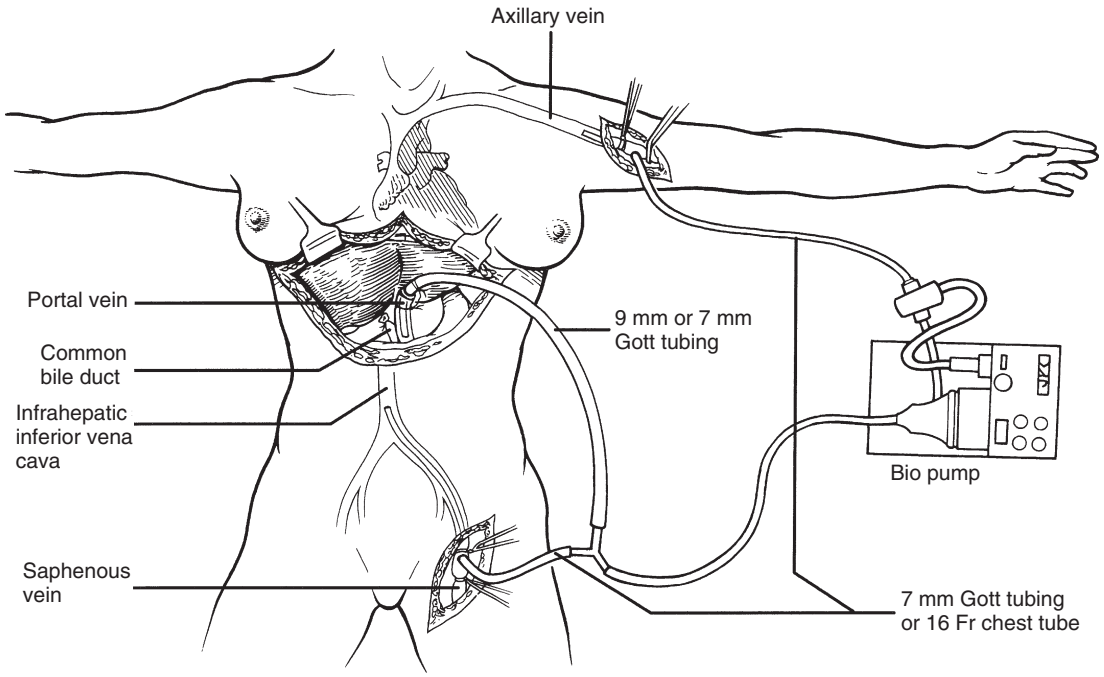

FIGURE 99.13. Pump-driven venovenous bypass used to decompress the systemic and splanchnic venous beds during the anhepatic phase of liver transplantation. The groin and venous return cannulae, when used, are usually placed percutaneously in the left groin and right neck.

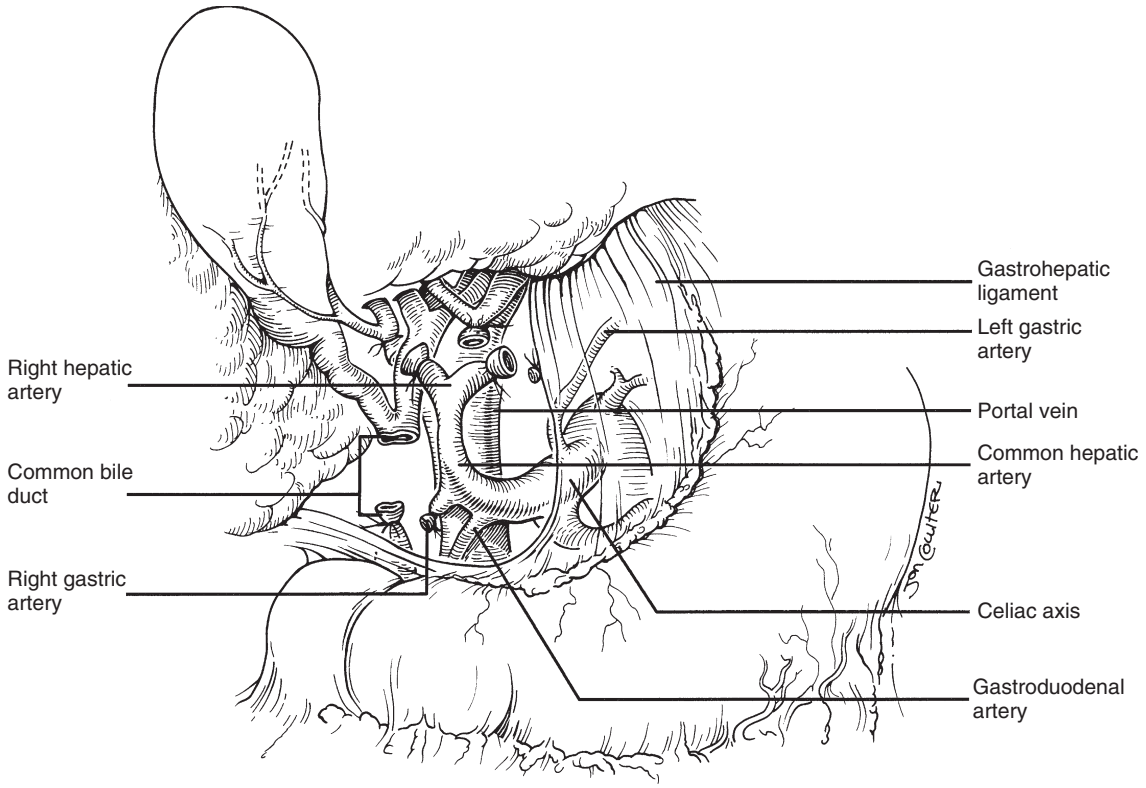

FIGURE 99.14. Hilar dissection in the liver recipient.

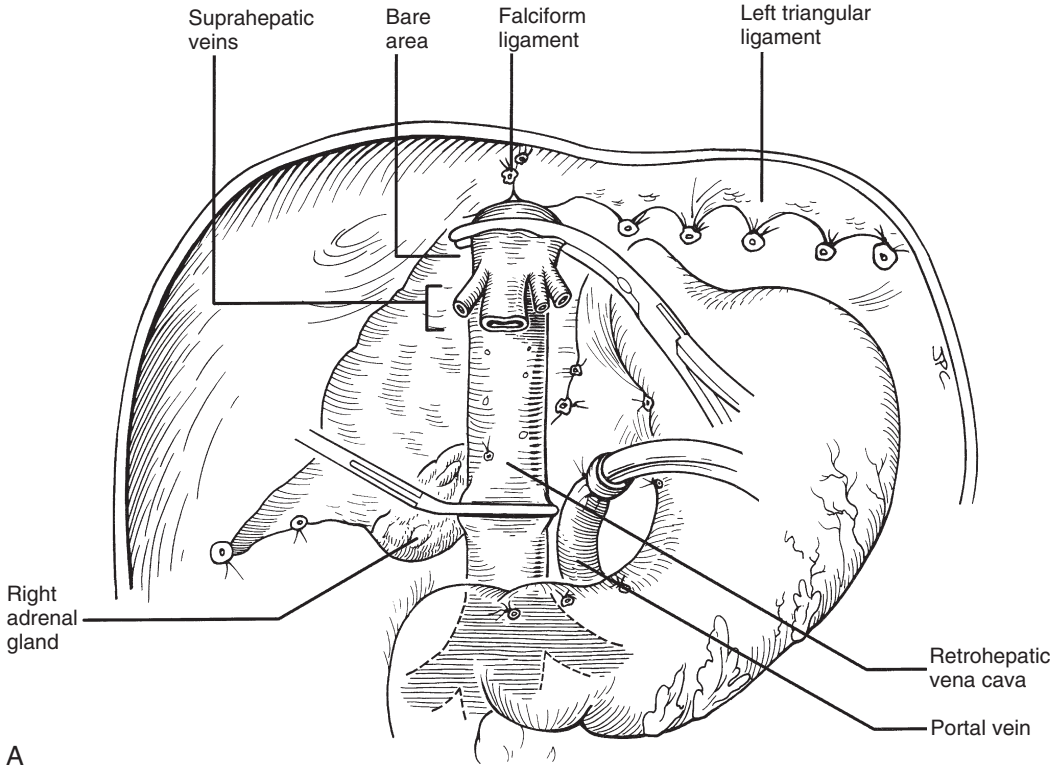

FIGURE 99.15. Completed recipient hepatectomy on venovenous bypass. **A,** With preservation of host retrohepatic vena cava. Note the hepatic vein cuffs.

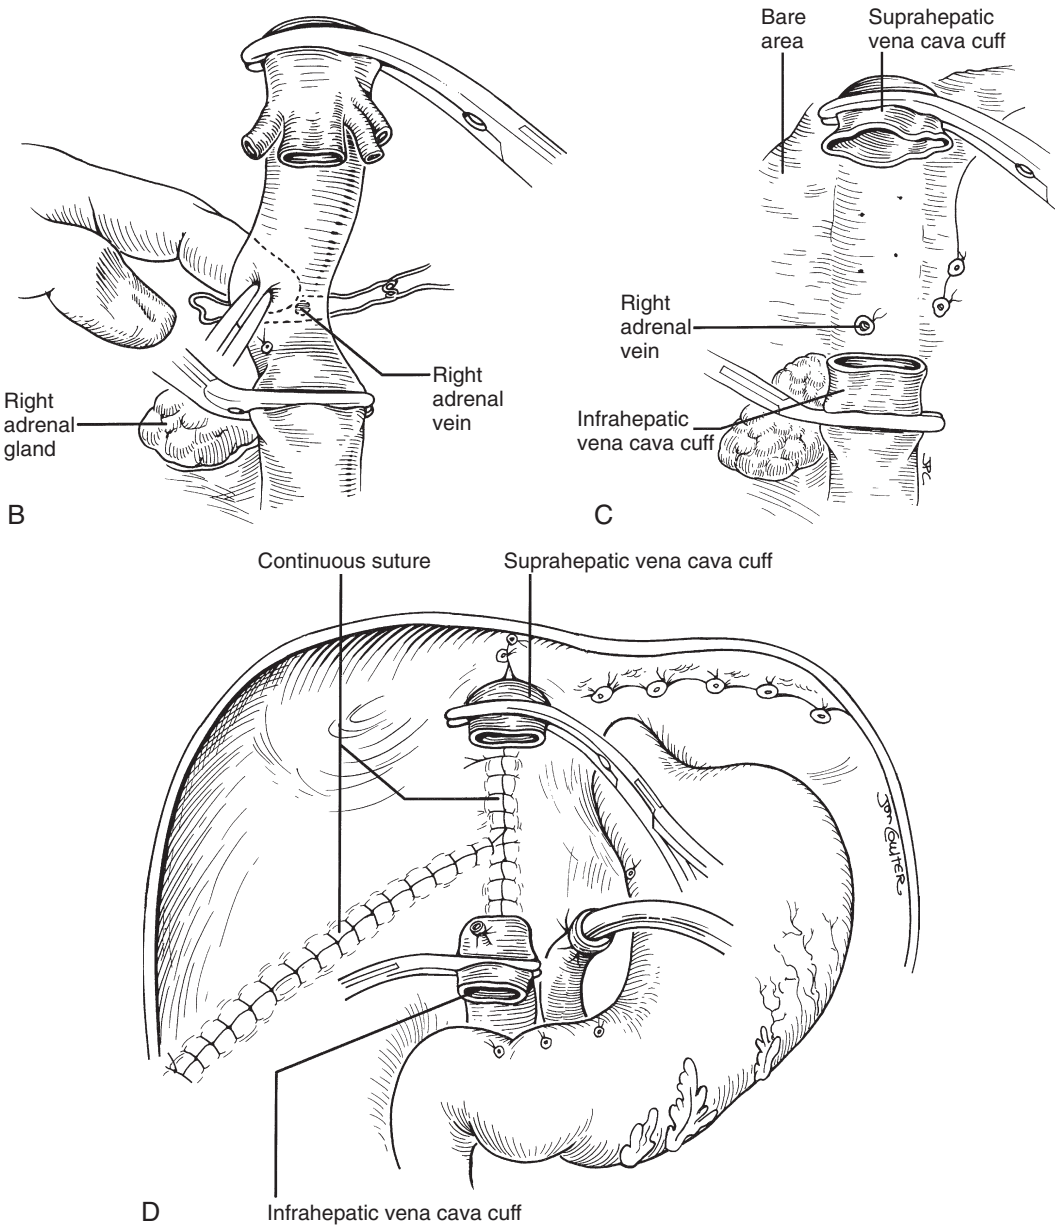

FIGURE 99.15, cont'd **B,** As in **A,** but with an injury to the right adrenal vein, which is being ligated. **C,** The retrohepatic vena cava has been included in the hepatectomy, necessitating ligation of its tributary lumbar veins and the right adrenal vein. **D,** Closure of the bare area to provide hemostasis. Bleeding from the bare area is more severe if the retrohepatic cava is removed or thrombosed because of the loss of venous drainage.

Many of these problems can be circumvented if the host retrohepatic vena cava can be conserved (see Fig. 99.15A). Separation of the diseased liver from the vena cava is done in the same way as in the classic experimental procedure of total canine hepatectomy. With this kind of hepatectomy, stumps of one or more of the main host hepatic veins are retained (Fig. 99.16A) for eventual receipt of the allograft's venous outflow (Fig. 99.16B and C); this is known as the *piggyback method* of liver transplantation. To the extent vena cava flow can be maintained during the sometimes tedious and difficult denudation of the retrohepatic vena cava, the need for venovenous bypass is potentially eliminated, and the extent of retroperitoneal dissection is considerably reduced. Finally, the risk of right adrenal infarction is eliminated, unless the right adrenal vein is injured (see Fig. 99.15B).

Alternative Approaches to Hepatectomy

In many if not most cases, hepatectomy with or without inclusion of the retrohepatic vena cava is uncomplicated; however, dissection of the liver hilum sometimes is difficult or impossible because of scarring or the presence of varices. In these situations, the suprahepatic vena cava can be approached first. After transecting the suprahepatic vena cava, removal of the liver can be done from the top down, approaching the hilar structures from behind the liver (Fig. 99.17). If it is not possible to occlude the hepatic veins on the liver side, bleeding can be minimized by

FIGURE 99.16. placing the fingers into the hepatic veins and retrohepatic vena cava or by squeezing shut the venous outflow of the liver. Alternatively, the inferior vena cava below the liver can be used as a "handle" to extract the liver from bottom to top, with cross-clamping or transection of the hilar structures at the earliest possible opportunity (Fig. 99.18). Finally, if adhesions are present that block access to the upper and lower vena cava and to the portal triad, the liver can be split in a superior-inferior direction, exposing the anterior surface of the retrohepatic vena cava from inside the liver (Fig. 99.19). Once bleeding from the raw surfaces is controlled, the two hepatic halves are stripped away from the surrounding structures. All these hepatectomy variations are made easier by venovenous bypass.

Vascular Anastomoses

It is important to have the surgical field completely prepared for implantation before the new liver is brought from the back table. The first graft vessel to be anastomosed is always the

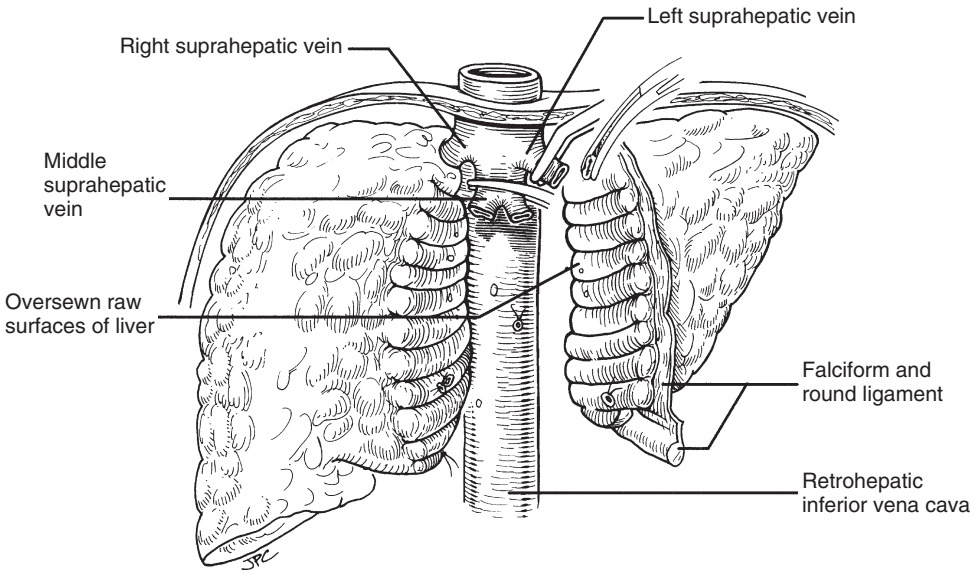

FIGURE 99.19. Splitting technique of hepatectomy. The split is facilitated by inserting a finger along the relatively vein-free anterior midsurface of the vena cava. The correct plane must be determined carefully by finger probing before any pressure is applied.

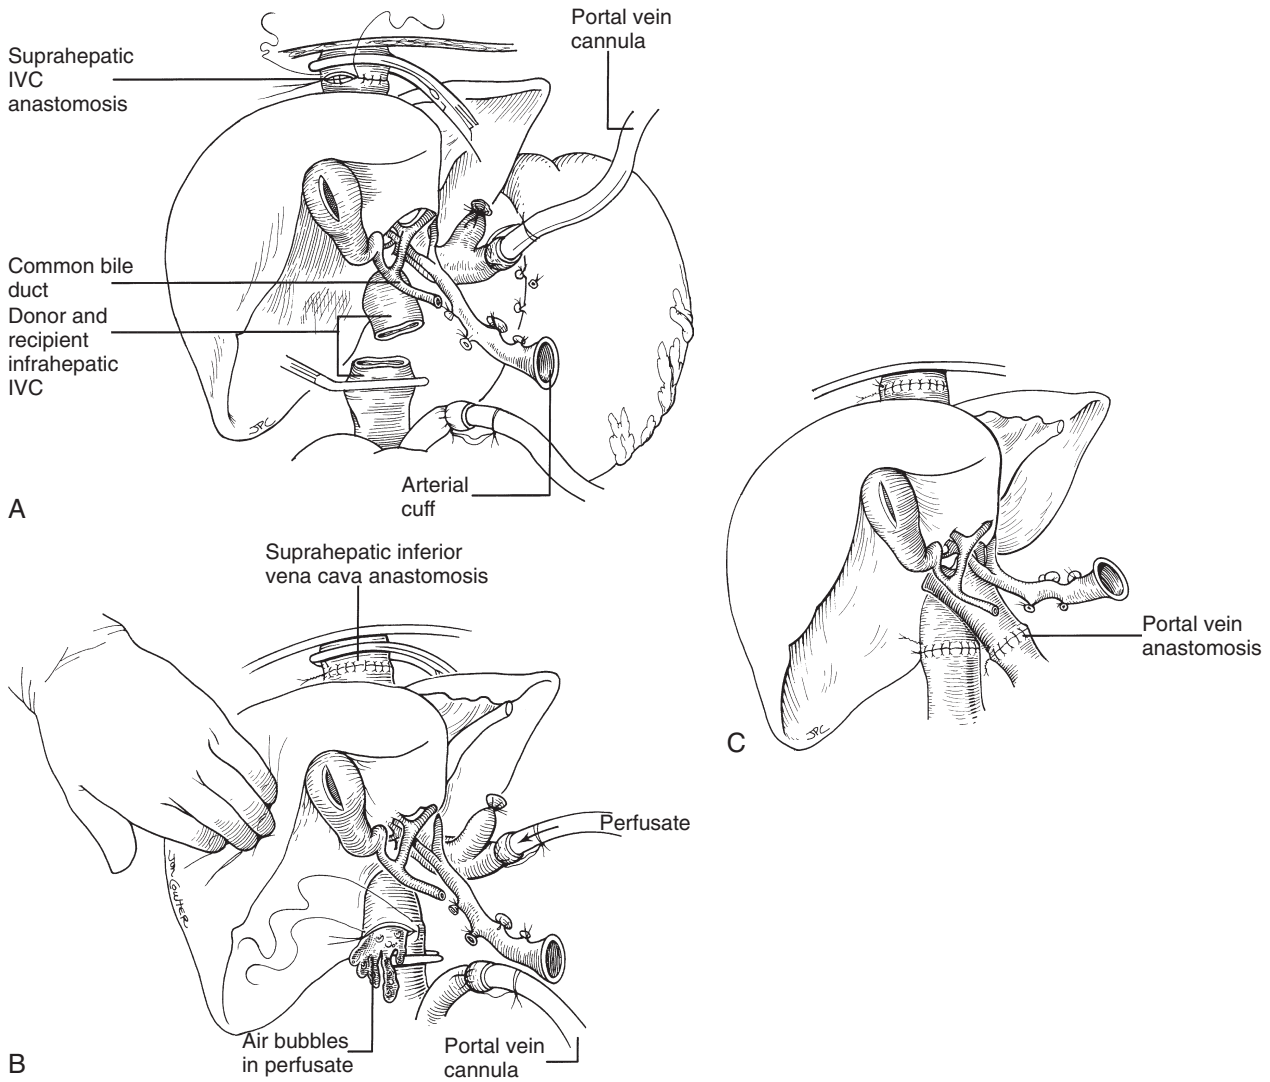

FIGURE 99.20. Implantation steps. **A,** Suprahepatic vena cava anastomosis. **B,** Infrahepatic vena cava anastomosis. Before completing the anastomosis, the portal vein is infused with cold albumin or electrolyte solution when University of Wisconsin solution is used as the preservation solution. This allows air and the potassium-rich preservation fluid to be removed. (Alternatively, the liver can be flushed on the back table, and heparized saline can be used to remove air before completion of the portal vein anastomosis.) **C,** The portal vein anastomosis after removal of the bypass cannula. IVC, inferior vena cava.

segment of donor vena cava into which all the hepatic veins of the transplanted liver drain. If host hepatectomy has included removal of the retrohepatic vena cava, the anastomosis is an end-to-end, suprahepatic to suprahepatic vena cava connection at the diaphragm (Fig. 99.20A). With the piggyback operation, in which the host vena cava is conserved, the suprahepatic vena cava is emptied into a cuff of host hepatic veins (see Fig. 99.16) or by a side-to-side anastomosis between the two vena cava segments (not shown).

The order of the other vascular anastomoses may vary. With the caval-sparing piggyback operation, the infrahepatic vena cava of the graft is ligated or stapled (see Fig. 99.16). When the host caval segment is excised (standard technique), a common practice is to anastomose the infrahepatic vena cava (Fig. 99.20B), followed by removal of the recipient from the portal (but not systemic) bypass and subsequent portal vein anastomosis (Fig. 99.20C). These anastomoses may be done in reverse order (i.e., portal vein first). An experienced surgeon may prefer to perform the arterial anastomosis before the portal vein reconstruction or may complete all four anastomoses before unclamping. These decisions are influenced by the anatomic and physiologic circumstances in the individual case, including the efficiency with which the bypass system has functioned or the degree of venous hypertension when bypass is not used.

In all cases if the preservation solution used is UW solution, it is important before liver reperfusion to flush the allograft with Ringer's lactate solution, although some surgeons prefer albumin or blood. Flushing is done through the cannula placed in the graft portal circulation at the time of procurement (see Fig. 99.20A), either on the back table before beginning implantation or in situ before beginning the portal vein anastomosis. After its passage through the microvasculature of the allograft, the infusate is vented from the vena cava (see Fig. 99.20B). The objectives are to remove air and to rid the graft of any high-potassium solutions (UW solution) used for organ preservation

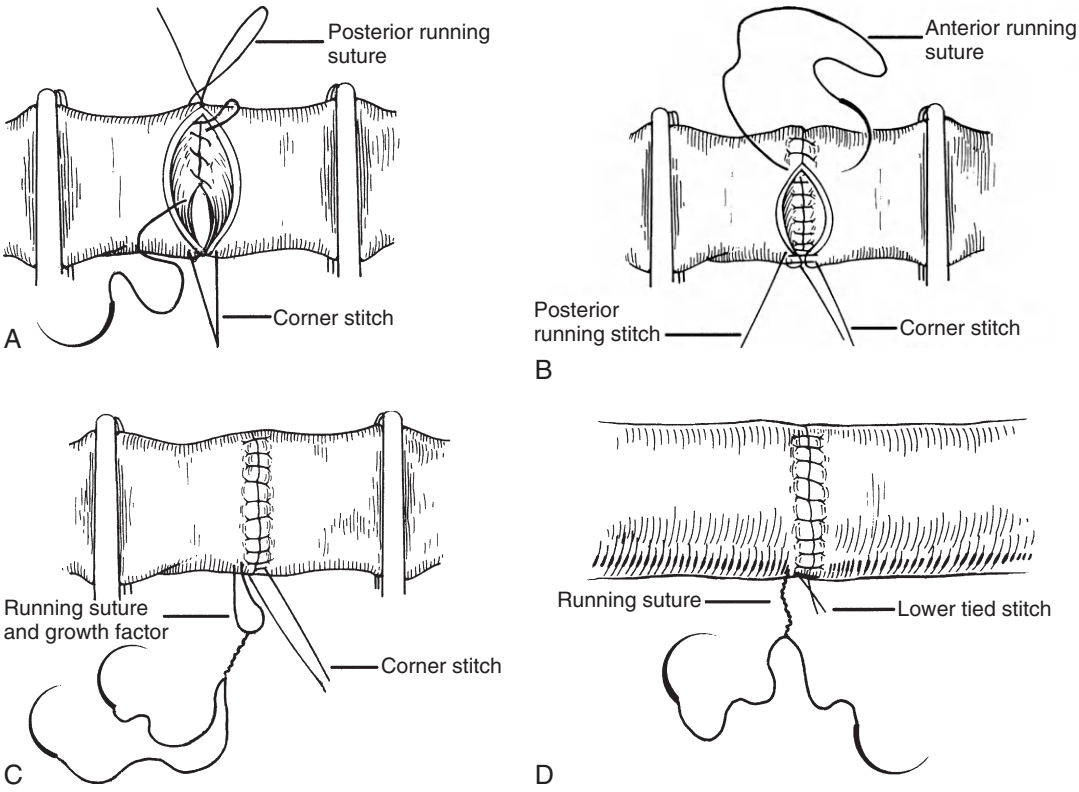

FIGURE 99.21. Technique of venous anastomosis. **A,** Traction sutures are placed at each corner. One end of the far suture is brought to the inside and run in continuous fashion to approximate the back wall. **B,** The other end of the far suture is used from the outside to approximate the anterior wall. **C,** The continuous suture is tied away from the vein wall to allow for a "growth factor." The near corner suture is tied next to the running suture to prevent separation of the vessel. **D,** The excess suture is drawn into the vessel, allowing the circumference to expand when blood flow is restored.

(see Fig. 99.20B). Failure to perform this flush can result in air embolism or hyperkalemic cardiac arrest or dysrhythmias, although this step is not necessary if HTK is used.

All of the venous vascular anastomoses are routinely performed with continuous suture. To avoid anastomotic strictures, particularly of the portal anastomosis, special techniques are developed that are made feasible by the ability of polypropylene (Prolene) suture to glide freely through tissue. A growth factor is left by tying the sutures at a considerable distance above the vessel wall. After flow is restored through the anastomosis, the excess polypropylene recedes back into the vessel and redistributes itself throughout the circumference of the suture line (Fig. 99.21). If leaks develop, these are readily controlled with additional single sutures.

Rather than being whimsical, variations of the order and details of revascularization frequently are mandated by anatomic anomalies or by pathologic factors, including thrombosis of the portal vein that once contraindicated liver transplantation, until techniques were developed to deal with them. Declotting a thrombosed portal vein may be possible (Fig. 99.22A); if not, iliac or other veins from the donor may be used as interposition grafts (Fig. 99.22B) or as mesoportal jump grafts (Fig. 99.22C). A mesoportal graft may be anastomosed end-to-side to the superior mesenteric vein and tunneled through the transverse mesocolon in a relatively avascular plane anterior to the pancreas to reach the hepatic hilum for end-to-end anastomosis to the donor portal vein (see Fig. 99.22C).

Numerous techniques also have been used to restore the hepatic arterial supply. The ideal reconstruction, when the allograft and recipient have normal arterial anatomy, is shown in Figure 99.23A. If anomalies, vascular injuries, or pathologic changes are present in the donor or recipient blood vessels, such as from radiation for cholangiocarcinoma, that preclude effective rearterialization, grafts obtained from the donor can be used (Fig. 99.24; see also Fig. 99.23B and C).

Biliary Tract Reconstruction

Good hemostasis must be achieved before the biliary reconstruction is performed. If the recipient duct is disease-free, and if there is a reasonable size match between the donor and recipient ducts, an end-to-end anastomosis is performed with or without a T-tube stent (Fig. 99.25). The anastomosis usually is performed with 8 to 10 interrupted absorbable sutures, such as 5-0 or 6-0 polyglycolic acid, or with a continuous suture, if the ducts are large enough. Because the integrity of the anastomosis depends primarily on an adequate blood supply of donor and recipient ducts, minimal dissection is performed in the periductal tissues. A small purse-string suture is usually placed around the T-tube exit site to prevent leakage, and the T-limb is brought out through a stab incision on the lateral side of the recipient duct.

If the recipient duct is diseased or otherwise inadequate for anastomosis, a choledochojejunostomy is performed. A 45-cm Roux-en-Y limb of proximal jejunum is brought, usually

antecolic, to the hepatic hilum; the donor duct is then anastomosed end-to-side to the jejunal limb with a running or interrupted 5-0 or 6-0 absorbable polyglycolic acid suture with or without a stent (see Fig. 99.25, inset). When used, the stent is secured in place with a rapidly absorbed suture with the assumption that the stent will later pass spontaneously through the intestinal tract; however, occasionally the stent is retained and must be pushed into the bowel by an interventional radiologist, or it can be removed by push enteroscopy. Rarely does the stent require removal at laparotomy.

REDUCED-SIZE LIVER TRANSPLANTATION

The scarcity of pediatric donors and the constraints of size matching often prohibit transplantation of a whole donor liver into a child or small adult (see Chapter 98C). Since 1980, the option of using a partial liver has been exercised at most large transplant centers with results equal to or approaching those achievable with whole liver transplantation. Partial liver transplantation, its application in live donors; and the use of divided cadaveric livers, which allow one organ to be used for two recipients, are described elsewhere in this text (see Chapters 98B and 98C).

CHAPTER 100

Early and late complications of liver transplantation

James J. Pomposelli and Roger L. Jenkins

OVERVIEW

Liver transplantation has evolved from a risky procedure with high morbidity and mortality to a standard treatment for patients with liver failure. Patients who undergo successful liver replacement have 5-year survival rates that exceed 70% (Muraji et al, 1997; see Chapter 97). Despite this dramatic improvement in outcome, a significant percentage of patients experience life-threatening complications that can result in the need for reoperation. As expertise in the procedure grows, surgeons are willing to attempt liver transplantation in patients who previously were considered poor candidates for surgery. Recipient portal vein thrombosis (PVT) was considered an absolute contraindication to surgery, but now transplantation is commonly performed in the presence of PVT (Shaked & Busuttil, 1991; Stieber et al, 1991).

As surgeons continue to develop new surgical procedures, such as transplantation of reduced-size and split-liver grafts and living-donor liver transplantation (LDLT), a new series of complications unique to these procedures is emerging (Broelsch et al, 2000; Emond et al, 1993). The incidence of hepatic artery thrombosis, bile leaks, and stricture is at least two times higher in patients who receive living-donor grafts compared with those who receive cadaveric grafts (Malago et al, 2003). Despite a higher morbidity rate in recipients of living-donor grafts, patient and graft survival are similar or superior to those observed with deceased donors (Fan et al, 2002; Lo et al, 2002; Pomposelli et al, 2006). This chapter reviews common early and late complications encountered during and after liver transplantation. Because complications after liver transplantation represent a continuum, most can occur at any time after surgery.

PROCUREMENT INJURY TO THE GRAFT

The process of organ transplantation begins with identification of a suitable organ for a particular recipient. When an organ is identified, procurement teams are dispatched for recovery of various organs. In general, the liver procurement team dictates the conduct of dissection below the diaphragm, while the cardiac team works in concert with the thoracic team, if lungs and heart also are to be recovered. Because the infradiaphragmatic dissection takes considerably longer than the thoracic dissection, careful planning is required to minimize cold ischemia time for the heart and lungs, which are more time sensitive. The heart procurement team stays in contact with the recipient heart team to minimize total ischemic time.

Under ideal conditions, the conduct of the operation is orderly and well controlled; however, a patient who progresses to brain death rapidly can show cardiac instability and be difficult to manage. This situation can result in an expedited operation in which perfusion cannulae are hastily placed, and organ procurement rapidly follows. During such events, identification of appropriate anatomy is difficult, and technical errors are more likely to occur.

To increase the number of organs available, donation after cardiac death (DCD) is a new form of donation that is increasing in incidence (Chin et al, 2002). In this form of donation, a patient who is deemed hopeless but has not met criteria of brain death is allowed to die naturally after removal of supportive measures. After a period of usually 5 minutes of asystole, organs can be procured for transplantation. Despite the various periods of hypotension and warm ischemia that develop, outcomes with donation after cardiac death have been acceptable (Chin et al, 2002; Cooper et al, 2004). In liver grafts procured from DCD donors, increased biliary strictures and worse long-term graft survival have been suggested (D'Alessandro et al, 2004).

The most common injury during liver procurement is aberrant hepatic artery ligation and division. This injury occurs by failure to recognize a replaced or accessory right or left hepatic artery during hilar dissection or by unintentional division during organ removal. Such injuries are serious, because segments of the liver are not perfused during recovery and usually require reconstruction on the back table before reimplantation. An additional anastomosis on the back table prolongs ischemic time, increases the chances of thrombosis, and increases the need for retransplantation. Prolonged ischemic time, especially longer than 12 hours, increases the risk for graft loss and bile duct necrosis (Mor et al, 1993; Quiroga et al, 1991). To minimize dissection-related injuries, some authors prefer to use the en bloc method of removing abdominal organs, with back-table dissection (Imagawa et al, 1996). Regardless of the technique used, attention to detail and identification of the appropriate anatomy help avoid graft procurement injury.

INTRAOPERATIVE HEMORRHAGE AND COAGULOPATHY (SEE CHAPTER 70B)

All patients with end-stage liver disease come to the operating room with derangements in coagulation, and many present with severe portal hypertension. The combination of these two conditions results in a significant challenge for the surgeon and anesthesiologist. Patients who have undergone previous operations are at particular risk, because prolonged lysis of adhesions may greatly increase the duration of the operation, create additional raw surface areas for bleeding, and lead to derangements in temperature and fluid homeostasis. The net result is worsening coagulopathy, which creates a vicious cycle during the procedure.

Improvements in surgical techniques and better patient selection have led to the performance of liver transplantation without the need for blood transfusion in selected patients. The advent of the transjugular intrahepatic portosystemic shunt (TIPS) can significantly lower portal hypertension preoperatively and may help to reduce blood loss during transplantation (Forster et al, 1994); however, a misplaced TIPS in the vena cava or portal vein can be a life-threatening complication during liver transplantation. In these situations, TIPS removal is difficult and may lead to massive hemorrhage, if vascular control of the native vessels cannot be achieved.

In the presence of severe portal hypertension and underlying coagulopathy, the infusion of fresh frozen plasma and antifibrinolytic agents is the mainstay of therapy during liver transplantation (Palareti et al, 1991). These modalities cannot supplant the need for sound surgical technique with adequate control of all surgical bleeding sites. Bleeding observed after reperfusion may be related to poor initial graft function but also has been related to the release of heparin and heparin-like substances from the graft. Kettner and colleagues (1998) used heparinase-modified thromboelastography (TEG) to identify patients who developed bleeding secondary to the release of heparin-like substances. Such screening methods may help stratify patients at particular risk for the development of reperfusion fibrinolysis and may offer future therapeutic strategies to control coagulopathy encountered immediately after reperfusion (Kettner et al, 1998).

When medical strategies fail to halt reperfusion fibrinolysis, intraabdominal tamponade with laparotomy packs provides the most conservative management. If the graft functions well, and the patient responds to core temperature warming and continued resuscitation, packs usually can be removed within 24 to 48 hours. Prophylaxis against intraabdominal sepsis with parenteral antibiotics is of unproven benefit but may be prudent in the setting of immunosuppression.

PRIMARY GRAFT DYSFUNCTION OR NONFUNCTION

Numerous conditions can interfere with the initial function of the allograft after transplantation, including donor-related, procurement-related, and recipient-related factors. Donor-related factors that can affect graft function adversely include hemodynamic instability, poor nutritional status, extremes of age, drug toxicity, and steatosis (D'Alessandro et al, 2004; Marsman et al, 1996; Washburn et al, 1996).

Although no uniform definition exists, the severity and prognosis for graft dysfunction vary considerably. The most ominous syndrome is primary graft nonfunction, which usually requires immediate retransplantation. In such instances, a progressive increase is typically seen in serum transaminase levels (>8000 IU/L) within the first 24 to 48 hours in association with diminished bile and urine output. In our practice, postoperative trends in the prothrombin time (PT) have been the most reliable predictor of graft function and outcome. Laboratory studies drawn immediately after surgery serve as the baseline: the PT should plateau and then trend toward normalization in a matter of days with good graft function; any increase in the PT portends a worse prognosis and may represent primary graft nonfunction, especially if this occurs rapidly. An elevated PT that neither increases nor decreases may suggest primary graft dysfunction; recovery usually occurs with time, if no additional insults occur, such as infection or rejection. In these situations, infusion of prostaglandin E_1 may be beneficial in resolving or preventing renal or graft dysfunction (Chavin et al, 1996; Klein et al, 1996).

In addition to trends in the PT, clinical assessment can be helpful in identifying patients with graft dysfunction or nonfunction. Resolution of hepatic encephalopathy, adequate urine production, and absence of metabolic acidosis are reassuring in the early postoperative period. In patients who have received significant quantities of blood products, the development of metabolic alkalosis may be a sensitive indicator of early graft function (Driscoll et al, 1987). Such indicators are based on the ability of the liver graft to process citrate in the administered blood products to bicarbonate; failure to metabolize citrate to bicarbonate may reflect early allograft dysfunction.

In patients with progressive graft dysfunction or nonfunction, early consideration for relisting with a higher urgency (status 1) may be the only way to salvage the patient and prevent mortality. In this situation, aggressive metabolic supportive measures are needed to prevent bleeding complications, maintain acid-base status, and prevent permanent brain injury.

VASCULAR COMPLICATIONS

Hepatic Artery Thrombosis

Vascular complications are a major source of morbidity and graft loss in liver transplant patients. Arterial complications, of which hepatic arterial thrombosis (HAT) is the most common, account for 64% to 82% of the vascular complications encountered (Bell et al, 1990; Leonardi et al, 2004). The overall incidence of HAT is 1.6% to 8% in various adult series, but it can be 15% to 26% in pediatric patients (Busuttil et al, 1991; Mazzaferro et al, 1989; Tan et al, 1988). The incidence of HAT in LDLT varies widely and is influenced by the type of graft, surgeon experience, and donor anatomy.

Doppler ultrasound (US) is the best screening method and should be used liberally in the first 2 weeks after transplantation with any change in graft function or significant elevation in bilirubin or transaminases. Because collateral blood flow through the gastroduodenal artery can result in a false-negative result, care must be taken to establish arterial flow within the hepatic parenchyma. In cases of suspected HAT revealed by US, confirmation should be made by celiac arteriography (Fig. 100.1) or multiphase computed tomography (CT). Failure to make a rapid diagnosis can result in hepatic necrosis and graft loss.

Intimal dissection of the recipient hepatic artery down to the origin of the celiac axis is a common cause of intraoperative HAT. In these cases, immediate reconstruction with a donor iliac allograft is indicated (Fig. 100.2). Under no circumstances should the patient leave the operating room without a completely revascularized graft. When a donor iliac allograft is unusable or unavailable, an autogenous saphenous vein graft should be used. Rarely, an artificial conduit made from Dacron or expanded polytetrafluoroethylene can be used.

The clinical presentation of HAT observed postoperatively ranges from a completely asymptomatic patient with minimal alterations in liver function to a critically ill patient with fulminant hepatic necrosis. A more common presentation of HAT is with postoperative biliary complications, including leaks and stricture formation (Margarit et al, 1998; Orons et al, 1995). Treatment for HAT in the early postoperative period is the

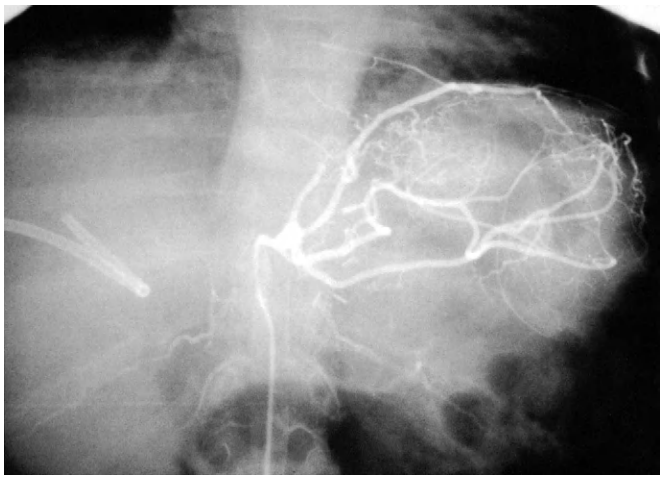

FIGURE 100.1. Hepatic artery thrombosis. The patient developed a rapid increase in serum transaminases in the early postoperative period. Ultrasound could not locate an intrahepatic arterial signal. Celiac arteriography shows left gastric and splenic arterial flow and fails to show any contrast in the liver. This is consistent with intimal dissection of the entire common hepatic artery. The T-tube within the common bile duct is visible.

same, whether symptoms are present or not: rapid reestablishment of arterial inflow should be attempted, which generally requires urgent operation with arterial reconstruction using a donor iliac artery allograft or autogenous graft material. Some authors have attempted thrombolysis using tissue plasminogen activator and urokinase, but this can be expected to be successful only when no technical factors are contributing to the thrombosis (Hidalgo et al, 1989). Hepatic artery intimal dissection is not amenable to thrombolytic therapy, and attempts at systemic thrombolysis waste valuable time and resources and worsen outcome. In most cases, 50% to 70% of patients ultimately require retransplantation (Langnas et al, 1991).

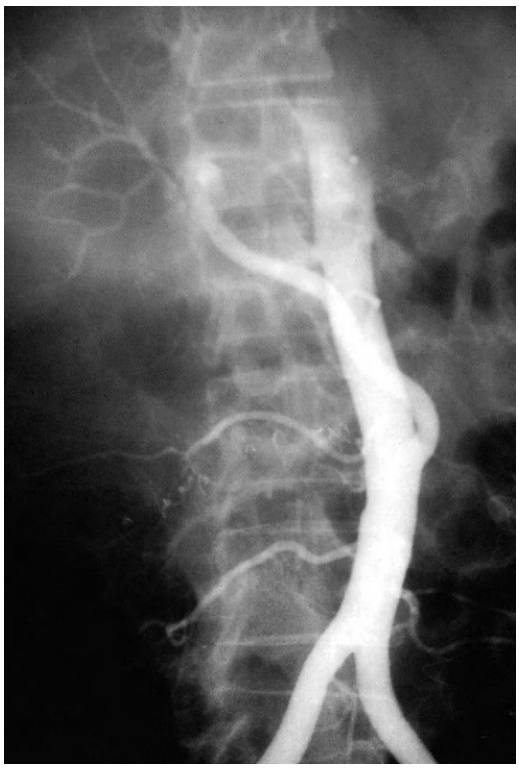

FIGURE 100.2. Hepatic artery reconstruction. With early diagnosis of hepatic artery thrombosis, immediate reconstruction with a donor iliac artery allograft can be performed. In this case, the iliac artery graft is anastomosed between the infrarenal aorta and liver allograft common hepatic artery.

Portal Vein Thrombosis

PVT observed prior to surgery was previously considered an absolute contraindication to orthotopic liver transplantation (OLT). Although this problem no longer precludes successful liver transplantation, its presence may substantially increase the surgical complexity and perioperative morbidity.

Reconstitution of portal flow usually can be obtained through portal vein thrombectomy in most cases or by using a donor iliac vein allograft anastomosed between the superior mesenteric vein and liver allograft portal vein (Davidson et al, 1994; Shaked & Busuttil, 1991). Living-donor grafts that have relatively short portal vein segments can be difficult to reconstruct, and approximately 10% of institutions consider PVT an absolute contraindication to LDLT (Kadry et al, 2002).

PVT observed after transplantation is a rare complication that can occur in the immediate postoperative period, usually for technical reasons, such as incomplete thrombectomy or twisting of the anastomosis. PVT observed several months to years after transplantation usually results from intimal hyperplasia with gradual cavernous transformation with collaterals. A high index of suspicion is needed to make the diagnosis. Accumulation of ascites, splenomegaly, or the presence of varices after transplantation should prompt investigation. Early thrombosis is best treated with reoperation, thrombectomy, and systemic coagulation. The treatment of late thrombosis is more controversial, because direct repair is difficult. Transhepatic angioplasty with the placement of metal stents has been successful in some patients, whereas other patients have responded to selective shunting procedures to control variceal hemorrhage in the setting of adequate liver function (Jenkins et al, 1999; Raby et al, 1991).

Inferior Vena Cava Obstruction

Inferior vena cava (IVC) obstruction is a rare complication that occurs in 1% to 2% of patients after liver transplantation (Wozney et al, 1986). Most surgeons prefer to anastomose the donor IVC to the suprahepatic and infrahepatic IVC. A growing trend is to perform a so-called piggyback transplantation, with the anastomosis of the donor suprahepatic IVC to the confluence of the recipient middle and left hepatic veins, leaving the recipient IVC in situ (Neuhaus & Platz, 1994; Tzakis et al, 1989).

In our experience in 90 consecutive liver transplantations using the piggyback technique, two patients developed thrombus in their native IVC. The first IVC thrombosis developed in a patient with Budd-Chiari syndrome, who had occluded middle and left hepatic veins and a misplaced TIPS in the right hepatic vein that extended into the IVC at the time of transplantation. Postoperatively, the patient developed profound pedal edema and ascites. US confirmed the diagnosis, and the condition was treated successfully with anticoagulation and balloon dilation without further surgery. The second patient was a

young man who was urgently transplanted for fulminant liver failure secondary to hepatitis A. Complicating this operation was the presence of a high-grade bacteremia with *Staphylococcus aureus* at the time of transplantation. Postoperatively, the patient did well but developed persistent fevers of an unknown source. Gallium scanning ultimately disclosed a nearly occluding infected thrombus in the infrarenal IVC. This thrombus was treated with long-term antibiotics and systemic anticoagulation with complete resolution after 6 weeks of therapy.

Treatment of an IVC thrombosis usually depends on the cause. Direct surgical removal is difficult in a critically ill patient and requires extensive mobilization of the right colon and small bowel mesentery to facilitate exposure. Medical management of IVC thrombosis was successful in our experience and that reported by others (Kraus et al, 1992). Our experience suggests that a more conservative management algorithm that employs invasive radiologic procedures and systemic anticoagulation can treat this complication satisfactorily (Kraus et al, 1992). Thrombolytic therapy can also be adjunctive in resolving "fresh" thrombus formation.

BILIARY COMPLICATIONS

Biliary tract complications related to bile duct reconstruction previously were considered the Achilles heel of liver transplantation, but improvements in operative technique have reduced these complications markedly. Nevertheless, bile duct obstruction and leaks are the cause of approximately half of all technical failures after transplantation and require reoperation in 10% to 20% of patients (Lerut et al, 1987). In general, recipients of living-donor grafts have an incidence of biliary complications approximately two times higher than recipients of cadaveric grafts (Pomfret et al, 2001). HAT is associated with biliary complications and may explain the increased incidence among living-donor graft recipients.

Biliary Leaks

The reported incidence of biliary leaks after liver transplantation varies widely from 10% to 50% (Rabkin et al, 1998; Reichert et al, 1998). Leaks are observed most commonly at the site of choledochal anastomosis or the choledochal T-tube insertion site. Leaks at the choledochal tube insertion site are observed most commonly at the time of tube removal and occur in 25% to 40% of patients (O'Connor et al, 1995). Most of these patients can be managed conservatively with a short course of analgesics and antibiotics. To minimize this risk, some surgeons prefer not to place stents.

In our practice, rather than using a conventional T-tube, we stent our choledochal anastomosis with a 5-Fr pediatric feeding tube placed through the cystic duct stump, which is secured with a hemorrhoidal band and polydioxanone suture (PDS). In theory, the hemorrhoidal band obliterates the lumen of the preformed tract at the time of stent removal, usually 6 to 8 weeks postoperatively. Anastomotic leaks encountered in the early postoperative period are related to technical errors, tension at the anastomotic site, or ischemic necrosis after hepatic artery thrombosis.

The bile ducts of living-donor or split-liver grafts can be reconstructed with a duct-to-duct (choledochocholedochostomy) or Roux-en-Y hepaticojejunostomy. The leak rate is similar with both types of reconstructions (Gondolesi et al, 2004). Signs and symptoms related to biliary leaks include bilious fluid in drains (biliary fistula), abdominal or shoulder pain or both, increased serum bilirubin, nausea, vomiting, and fever. Diagnosis can be confirmed by cholangiography if a choledochal tube is in place; otherwise, endoscopic retrograde cholangiography (ERC) or percutaneous transhepatic cholangiography (PTC) can be performed. We favor ERC, because treatment with endoscopic stent placement can be readily achieved without the risk associated with the indwelling transhepatic catheters used during PTC. Large biliary leaks resulting in bile collections adjacent to the liver require percutaneous drainage.

Leaks associated with ischemic necrosis require surgical revision with Roux-en-Y hepaticojejunostomy. The development of early postoperative leaks is associated with late stricture formation, and lifelong surveillance by the surgeon is warranted.

Biliary Stricture or Obstruction

Biliary obstruction occurs in approximately 7% to 15% of patients after liver transplantation (Klein et al, 1991; Lerut et al, 1987). As with leaks, the site of obstruction aids in determining the cause. Anastomotic stricture accounts for 50% of obstruction cases and can occur early in the postoperative period, secondary to edema, or later, as a result of compromised blood supply (Fig. 100.3). Biliary strictures usually present within weeks but may occur years after transplantation. Two types of biliary obstruction usually are found: *anastomotic* and *nonanastomotic*. Nonanastomotic obstruction or stricture can be caused by or associated with bile duct ischemia or sludge and debris that can accumulate in the biliary system after transplanting (Fig. 100.4).

The diagnosis of biliary stricture or obstruction is implied by an obstructive pattern on routine liver function tests. Commonly, patients are seen with constitutional symptoms of rigor, fever, headache, and fatigue. Occasionally, patients present with

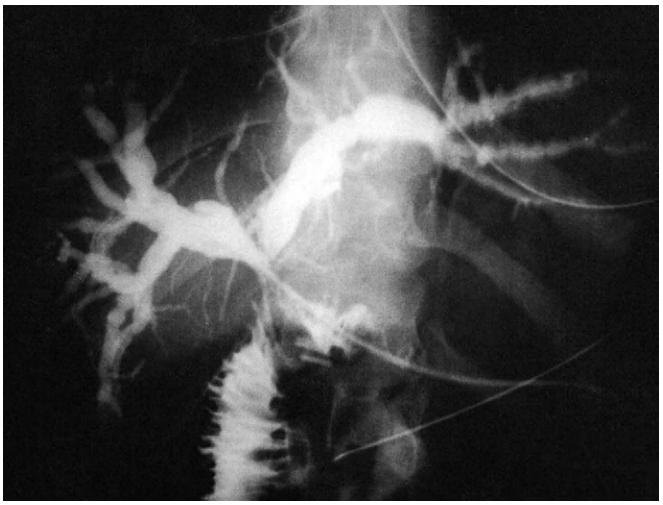

FIGURE 100.3. Biliary stricture. This patient had a previously created Roux-en-Y hepaticojejunostomy and now has an anastomotic stricture. Note the dilated intrahepatic ducts. Percutaneous access of the Roux-en-Y limb affords the ability to make the diagnosis and treat with balloon dilation. Using this technique, placement of transhepatic catheters is avoided.

FIGURE 100.4. Nonanastomotic biliary stricture observed from ischemic injury to a liver graft in a patient who received a liver from a donor who died from cardiac death rather than brain death. Donation after cardiac death (*DCD*), rather than after brain death, is an attempt to expand the organ donor pool; but such grafts are more prone to ischemic injury problems such as bile duct stricture.

severe symptoms of cholangitis and sepsis. Because patients with "mild" signs and symptoms also may reflect the presence of any number of serious conditions—acute rejection, HAT, cytomegalovirus (CMV) infection, or recurrent disease—diagnosis can be difficult. To ascertain the correct diagnosis rapidly, a series of diagnostic studies that include abdominal US, cholangiography, and liver biopsy is obtained immediately after the onset of abnormal clinical signs and symptoms (Kuo et al, 1994).

Regardless of the method used to reestablish the biliary continuity, the most common site of a biliary stricture in the posttransplantation setting is at the biliary anastomosis. Technical error during reconstruction is an important causative factor, but the patency of the hepatic artery also should be assessed, particularly in pediatric recipients. Other factors that have been implicated in the development of biliary stricture include ABO incompatibility, prolonged preservation times, chronic rejection, CMV infections, and recurrence of primary ductal disease, such as sclerosing cholangitis (Feller et al, 1996; Greif et al, 1994; Sebagh et al, 1995).

Biliary reconstruction after LDLT is by Roux-en-Y hepaticojejunostomy or duct-to-duct anastomosis (Kawachi et al, 2002). Anastomotic leak or stricture is generally two times more common after living-donor versus cadaveric liver transplantation (Miller et al, 2001). Nonanastomotic strictures can occur in the hilar region or intrahepatically. As with anastomotic strictures, thrombosis of the hepatic artery or one of its branches should be suspected. Nonanastomotic strictures also have been reported in association with chronic ductopenic rejection, ABO blood group incompatibility, and as a result of ischemia-reperfusion injury associated with allograft preservation (Sanchez-Urdazpal et al, 1992).

After appropriate fluid resuscitation and antibiotic coverage, we recommend ERC to confirm the diagnosis and to implement treatment with immediate stenting if possible. Failure to cross the stricture through endoscopic means requires PTC or surgical revision with Roux-en-Y hepaticojejunostomy. Intrahepatic strictures are best treated with percutaneous balloon dilation. Rarely, stents are needed to achieve a satisfactory outcome (Colonna et al, 1992).

RENAL DYSFUNCTION

Renal dysfunction is observed to some degree in almost every patient who undergoes liver transplantation (Baliga et al, 1992; Lam et al, 2004). Early renal dysfunction usually is characterized by a period of oliguria with a transient increase in serum creatinine but can also be manifested as anuria with acute renal failure. Risk factors include preexisting renal dysfunction and primary graft nonfunction. In patients with normal preoperative serum creatinine and good initial graft function, the usual mechanism is prerenal azotemia secondary to periods of hypotension and hypovolemia during the operative procedure. An additional insult to renal function can be incurred by the administration of nephrotoxic agents, especially the calcineurin inhibitors (CNIs) cyclosporine and tacrolimus; renal failure induced by CNIs occurs in approximately 5% of transplanted patients (Myers et al, 1986).

Although the etiology of renal failure in transplant patients can be multifactorial, long-term exposure (dose/time) to CNIs is a clear risk factor. As a result, there has been increasing interest in automatic dose reduction in patients many years out from transplantation and in those showing signs of progressive renal dysfunction. Another strategy to reduce calcineurin renal toxicity has been substitution of the immunosuppressive regimen by drugs that do not cause renal dysfunction, such as the mammalian target of rapamycin (mTOR) inhibitors.

Sirolimus (rapamycin) is a macrocyclic antibiotic originally developed as an anticandidal and antitumor agent (Vezina et al, 1975). It is often used for renal sparing but has the disadvantage of increasing the risk for dyslipidemia and impaired wound healing. The impairment of wound healing may be related to alterations in vascular endothelial growth factor (VEGF) and may explain the apparent benefit of sirolimus in reducing cancer formation in patients (Fuereder et al, 2010). Because sirolimus has been associated with early hepatic artery thrombosis (HAT) after liver transplantation, the manufacturer recommends waiting at least 4 weeks after transplantation before initiating therapy.

Posttransplantation renal failure so acute as to require dialysis is uncommon, unless the patient is diagnosed with preexisting hepatorenal syndrome or severe hypotension, and hemorrhage is encountered during surgery that results in acute tubular necrosis. In our experience, dialysis for these patients is best performed with continuous venovenous hemodialysis using a dedicated, large-bore, double-lumen venous access device. Recovery of normal renal function usually is achieved within 2 weeks, if no other metabolic stress is incurred.

FLUID AND ELECTROLYTE DISTURBANCES

Fluid and electrolyte disturbances and alterations in acid-base status are universal after liver transplantation. Preoperative protein calorie malnutrition and end-stage liver disease lead to derangements in total body water and electrolyte balance that are worsened initially by the metabolic stress of surgery and massive fluid and blood product resuscitation. The rapidity of recovery depends in large part on the patient's renal and liver

allograft function postoperatively. For a patient with stable postoperative renal and liver graft function, little metabolic manipulation is required to correct such derangements.

The early development of metabolic alkalosis secondary to metabolism of citrate in blood products is a favorable sign of graft function but can be serious if alkalemia develops (Driscoll et al, 1987). In this situation, judicious replacement of chloride in the form of hydrogen chloride is warranted.

Excess total body water and excess sodium are best treated with gentle diuresis with furosemide. Careful repletion of potassium should be instituted, but it must be monitored closely in the setting of medications such as tacrolimus, which tends to increase serum potassium levels (Oishi et al, 2000). Derangements in serum calcium, magnesium, and phosphorus are common in patients with cirrhosis and should be repleted to avoid neurologic, skeletal, and cardiac muscle dysfunction.

ACUTE CELLULAR REJECTION

In the early days of liver transplantation, the importance of rejection was overshadowed by technical complications. As surgical technique has evolved, with concomitant improvement in graft preservation, rejection has taken on greater clinical importance. *Acute cellular rejection* is defined as an acute deterioration in allograft function associated with specific histologic changes in the liver allograft. These changes include a mixed inflammatory cell infiltrate, predominantly lymphocytes, that involves the portal triads and disrupts the biliary, hepatic artery, and portal venous endothelia (*endotheliitis*) (Sedivy et al, 1998).

The incidence of acute rejection is approximately 45% (range, 24% to 80%), depending on the series reported. Although acute rejection has little to no impact on mortality, significant morbidity results in increased hospitalization and higher overall costs (Bucuvalas et al, 2001; Khettry et al, 2002). In the early stage, most patients are asymptomatic, but a variety of clinical signs and symptoms may develop that include fever, abdominal pain, malaise, fatigue, and poor appetite.

The earliest laboratory indicator of acute rejection is elevated bilirubin level, which may be associated with a modest increase in alkaline phosphatase and aminotransferase levels. PT and serum albumin levels are usually unaffected. Because laboratory measurements are neither sensitive nor specific for acute cellular rejection, liver histology obtained from a percutaneous biopsy specimen remains the standard for the diagnosis of cellular rejection (Khettry et al, 2002).

The initial treatment for acute cellular rejection includes high-dose pulse steroids, which is successful in approximately 80% to 90% of cases (Klintmalm et al, 1989). OKT3, a murine monoclonal antibody to the CD3 antigen–receptor complex, is reserved for the approximately 10% to 20% of patients whose acute cellular rejection cannot be not reversed with high-dose corticosteroid therapy. The major risks posed by using this treatment for acute cellular rejection include increased susceptibility to infection and the association between OKT3 use and posttransplantation lymphoproliferative disease (PTLD; Deschler et al, 1995). In addition, a severe systemic inflammatory response can be initiated from OKT3 infusion that can lead to pulmonary edema, hypotension, and shock.

Chronic ductopenic rejection affects approximately 10% of liver transplant patients. *Ductopenic rejection* rarely occurs during the first 2 months after liver transplantation; it is defined as loss of bile ducts in more than 50% of portal tracts, when 20 or more portal tracts are available for evaluation, and is diagnosed on the basis of histologic criteria (van Hoek et al, 1992). In addition, arteriopathy has been described that affects large and medium-sized arteries, characterized by foam-cell infiltration of the intima. The most important manifestation of chronic rejection, the term *ductopenic rejection* is used synonymously with the histologic description *vanishing bile duct syndrome*. No treatment exists with the exception of retransplantation (Koukoulis et al, 2001).

INFECTION

With few exceptions, all patients who undergo transplantation are committed to lifelong immunosuppression therapy to prevent graft rejection. Inadequate immunosuppression can result in graft loss, whereas injudicious use of immunosuppression can result in life-threatening infection or the development of PTLD. A tenuous balance exists between the proper amount of immunosuppression to prevent rejection and minimization of the risk for nosocomial and opportunistic infection. Despite better understanding of the immune response and proliferation of more selective immunosuppressive agents, approximately two thirds of transplant patients experience at least one episode of serious infection, which accounts for more than half of the observed mortality associated with liver transplantation (Kibbler, 1995).

Risk factors for postoperative infection after liver transplantation include those incurred from the donor, recipient, and intraoperative course: donor and recipient viral status, underlying medical comorbidities, and nutritional status all can contribute. Prolonged surgery with massive blood loss, prolonged ischemia time, and violation of the gastrointestinal tract also are risk factors for nosocomial infection (George et al, 1992).

Bacterial infections tend to occur within the first month after liver transplantation and vary from center to center (range, 35% to 68%) (Kibbler, 1995; Kusne et al, 1992). Early risk factors include prolonged operating time, indwelling catheters, biliary obstruction, PVT, and poor graft function. In addition, vascular ischemia, recurrent hepatitis C virus (HCV) infection, patient exposure to resistant organisms, and chronic rejection can contribute to nosocomial infection (Singh et al, 1997). Common bacterial pathogens include gram-negative organisms found in the bile (*Escherichia coli, Enterobacter* spp., *Pseudomonas* spp.) and gram-positive organisms (*S. aureus,* coagulase-negative staphylococci, and group D streptococci). Rarely, *S. aureus* can result in the development of toxic shock syndrome in the early postoperative period. *Listeria, Nocardia,* and *Legionella* are uncommon but significant pathogens (George et al, 1992).

Viral infections are common in immunocompromised patients after transplantation. In addition to the more common viral infections described here, other equally important but less common viral infections can be devastating to immunocompromised transplant patients; these include human immunodeficiency virus (HIV), adenovirus, influenza, and respiratory syncytial virus (RSV). In addition, transplant patients are at risk for acquiring viral hepatitis from infected organs, blood transfusions, and illicit drug use.

Cytomegalovirus (CMV) infection is the single most important infection observed in organ transplant patients. An asymptomatic infection in the general population, CMV attains significant potential severity in immunosuppressed transplant recipients and is the most important pathogen in clinical transplantation (Kusne & Shapiro, 1997). CMV disease usually

occurs 30 to 50 days after transplantation, with clinical manifestations that include fever, malaise, arthralgia, leukopenia and thrombocytopenia, hepatitis, interstitial pneumonitis, enterocolitis, and disseminated disease. Differentiation between *CMV disease* and *CMV infection* is clinically important: *CMV disease* is defined as a histologically evident invasive CMV infection or a positive CMV culture from deep tissue specimens—liver biopsy, endoscopic mucosal biopsy or brushing, bronchoscopic mucosal biopsy or brushing—in the setting of clinical manifestation. The presence of positive blood, body fluid, or serologic tests is insufficient to establish the diagnosis of CMV disease. Liver biopsy with immunostaining using a monoclonal antibody against CMV antigen enables early diagnosis. Common histologic findings include hepatocyte necrosis, parenchymal microabscesses, and a magenta-colored intranuclear inclusion surrounded by a clear halo, the so-called owl's eye nucleus (Everson & Kam, 1997).

Risk factors for the development of CMV disease include a seronegative recipient who received an organ from a seropositive donor, the use of antilymphocyte antibody therapy (particularly OKT3), and retransplantation. In general, the level of immunosuppressive therapy influences manifestation of CMV infection (Furukawa et al, 1996). Chronic CMV infection with persistent CMV replication within hepatocytes is associated with cholestatic hepatitis and vanishing bile duct syndrome.

Patients who manifest CMV disease are treated with a reduction, if possible, of the immunosuppressive regimen, particularly tapering of the steroid dose. For years, intravenous ganciclovir had become the mainstay of therapy and is safe and effective for prophylaxis and treatment. Occasionally, foscarnet is required as an alternative in cases of ganciclovir resistance, but it is less well tolerated and can be nephrotoxic.

Prophylaxis against CMV disease using oral and intravenous ganciclovir after transplantation has been effective. Other prophylaxis regimens using intravenous gancyclovir plus oral acyclovir for 3 months after transplantation or oral acyclovir used alone have been less successful (Nakazato et al, 1993; Oldakowska-Jedynak et al, 2003). More recently, prevention and treatment of mild CMV infection using oral valganciclovir has been demonstrated to be as effective as intravenous ganciclovir (Eid et al, 2010). Because of the effectiveness of oral valganciclovir, most transplant centers have switched to prophylactic regimens that range from 3 to 6 months of daily oral treatment (450 or 900 mg, depending on renal function). Side effects are minimal, but leukopenia can occur. Late-onset CMV disease remains a potential problem, especially in patients on higher doses of immunosuppression and in high-risk groups, whose donor was CMV positive when the recipient was CMV negative (CMV D+/R–).

Herpes simplex seropositivity is present in most patients undergoing liver transplantation. Herpes simplex infection observed postoperatively usually is related to immunosuppression-induced reactivation. Herpesvirus infection usually manifests as a mild mucocutaneous oral or genital disease that responds to acyclovir treatment; however, prompt recognition is important to prevent progression to lethal disseminated disease or fulminant hepatitis with coagulopathy, disseminated intravascular coagulation, and death. Graft involvement is diagnosed by a characteristic histologic picture on liver biopsy.

Epstein-Barr virus (EBV) belongs to the herpes family, and infection in a transplant patient is characterized by a mononucleosis-like syndrome that differs from that observed in the normal host by the absence of a heterophil antibody response and the infrequency of pharyngitis or splenomegaly (Alshak et al, 1993). The clinical significance of EBV infection in a liver transplant patient has to do with its role in the pathogenesis of PTLD (Manez et al, 1997), the development of which is thought to reflect the unrestricted proliferation of B cells stimulated by EBV infection. The incidence and treatment for established PTLD are discussed later.

Opportunistic infections also are commonly encountered. The incidence of clinically significant fungal infection is 20% to 25% in liver transplant recipients. Risk factors for fungal infection include poor nutrition status, retransplantation, bacterial infection with prolonged antibiotic use, high doses of immunosuppression, and biliary reconstruction using Roux-en-Y hepaticojejunostomy (Castaldo et al, 1991).

Disseminated fungal infection with *Candida* or *Aspergillus* can be difficult to diagnose and is associated with a high mortality rate in these patients. If the suspicion of invasive fungal infection is high, every effort should be made to obtain histologic or culture evidence to establish early diagnosis. *Aspergillus*, the second most frequent fungal infection in transplant patients after *Candida*, is acquired by inhalation and colonizes the airways before causing invasive disease. *Aspergillus* is angioinvasive and tends to disseminate to the central nervous system (CNS) and can cause infarcts and cavitation in the lungs. The incidence of invasive aspergillosis is approximately 1% in liver transplant recipients, with a mortality rate close to 100% despite adequate treatment (Kusne et al, 1992).

Infection by *Cryptococcus neoformans* usually occurs months to years after transplantation and affects approximately 0.25% of liver transplant patients (Patel et al, 1996). Because signs and symptoms may be subtle, delayed diagnosis is common. Symptoms that bring the patient to medical attention include changes in mental status, headache, and fever. In our experience, one patient was seen initially with lesions in the CNS and large cavitating masses in the thorax that required operative removal.

Pneumocystis carinii pneumonia was previously a common pathogen in the immunocompromised host. With the introduction of routine use of prophylaxis with daily low-dose oral trimethoprim/sulfamethoxazole for 6 to 12 months, or aerosolized pentamidine in patients intolerant to trimethoprim/sulfamethoxazole, the incidence of *P. carinii* pneumonia has decreased dramatically. Because prophylaxis has been so effective, *P. carinii* pneumonia has occurred almost exclusively in patients who do not receive prophylaxis. Given the low morbidity associated with the prophylactic regimens, no patient should be excluded.

Legionella pneumophila is an uncommon cause of pneumonia in patients after liver transplantation. As in the normal host, the source of legionellosis is usually the water supply. Traditionally, treatment of *Legionella* pneumonia has been with erythromycin, but quinolones also have been proven effective and have the advantage of not interacting with immunosuppressive agents such as cyclosporine and tacrolimus.

POSTTRANSPLANTATION LYMPHOPROLIFERATIVE DISORDER

PTLD is a life-threatening complication of chronic immunosuppression. Lymphoproliferative disorders have been strongly associated with the replication of EBV in B cells induced by

enhanced immunosuppression (Manez et al, 1997; Newell et al, 1996); this has been observed primarily in patients who have received more than one course of polyclonal antilymphocyte globulin or monoclonal OKT3 (Davis et al, 1995). An association with CMV infection also has been noted. The incidence of PTLD varies from 1% to 3% among liver transplant recipients, and prognosis depends on the histologic characteristics of the tumor. Polyclonal PTLD is treatable with discontinuation of immunosuppression with relatively low risk of rejection (Hurwitz et al, 2004). Monoclonal PTLD is more difficult to treat and can result in death. Antibody against CD20 represents a novel approach in treating monoclonal PTLD, with favorable outcome (Yedibela et al, 2003; Zompi et al, 2000). The clinical presentation of PTLD varies and includes fever, malaise, and lymphadenopathy with or without tonsillitis. In addition, gastrointestinal bleeding, perforation, or obstruction; hepatocellular dysfunction; and CNS manifestations, such as seizures, mental status changes, and focal neurologic symptoms also have been described.

Lymphoproliferative disorders occurring after transplantation have characteristics distinct from the lymphoproliferative disorders that occur in the general population. Non-Hodgkin lymphoma accounts for 65% of lymphomas in the general population, compared with 93% in transplant recipients. These tumors are mostly large-cell lymphomas, and most are of the B cell type. Extranodal involvement is common and occurs in approximately 70% of cases (Zompi et al, 2000).

Treatment of polyclonal PTLD consists of reduction of immunosuppressive medications and antiviral therapy (Starzl et al, 1984). Patients with monoclonal PTLD and patients with polyclonal disease that does not respond to reduced immunosuppression have been treated with radiation, chemotherapy, and occasionally surgical resection. Therapy using monoclonal antibody against CD20 shows promising results for patients with monoclonal PTLD (Dotti et al, 2001; Zompi et al, 2000).

ACUTE IMMUNOSUPPRESSIVE DRUG TOXICITY

Immunosuppression after transplantation must achieve a balance between the beneficial effects of the drugs in preventing or reversing rejection and the dangers of excess immunosuppression with the development of acute toxicity symptoms, nosocomial infection, and lymphoproliferative disorders. The most common agents used for immunosuppression in liver transplant patients are the CNIs cyclosporine and tacrolimus (FK506) in combination with steroids. Azathioprine is used less frequently in liver transplant than in kidney transplant recipients, who usually receive triple-drug therapy. Mycophenolate mofetil has essentially replaced azathioprine in the immunosuppression regimen after liver and kidney transplantation. After the initiation of immunosuppression therapy, development of infection and acute toxicity are usually seen early during treatment, whereas lymphoproliferative disorders and other malignancies are long-term sequelae as previously mentioned.

In addition to PTLD, chronic immunosuppression has been associated with an increased frequency of many other neoplasms, including basal skin cancer, non-Hodgkin lymphoma, Kaposi sarcoma, uterine cervical carcinoma, and carcinomas of the external genitalia (Busuttil et al, 1991). As with PTLD, patients who received repeated doses of antilymphocyte antibody have a particularly high incidence of neoplasms (Millis et al, 1995). Long-term use of steroids, particularly at high doses, is associated with obesity, hypertension, bone disease, glucose intolerance, pancreatitis, muscle weakness, hirsutism, and fluid and sodium retention; in children, growth retardation is a major problem (Busuttil et al, 1991).

The side-effect profiles of cyclosporine and tacrolimus are similar and include gastrointestinal disturbances, headache, and tremor. Gingival hyperplasia and hirsutism are encountered frequently during cyclosporine and steroid treatment, whereas glucose intolerance is reported more often with tacrolimus treatment than with cyclosporine therapy. Hyperkalemia, hyperuricemia, hypophosphatemia, and hypomagnesemia are manifestations of renal tubular dysfunction and usually can be controlled by adjusting the dose according to drug levels. Nephrotoxicity is the most clinically significant adverse effect of both drugs and is manifested as acute azotemia. This effect is largely reversible after reducing the dose of the drug and providing adequate hydration. Occasionally, progressive chronic renal disease can develop, which is usually irreversible. In such a situation, dialysis or kidney transplantation is required. Other renal effects of cyclosporine include chronic tubular dysfunction and, rarely, hemolytic uremic syndrome (Cohen et al, 2002).

RECURRENT HEPATITIS (SEE CHAPTER 64)

In patients who develop cirrhosis secondary to chronic hepatitis B virus (HBV) infection, the recurrence rate as evidenced by signs of viral replication (HBV e-antigen–positive or positive titers of HBV DNA) is approximately 80% to 90% in the first year. Given the almost universal recurrence of HBV antigenemia in the early postoperative period, some authors have questioned the utility of liver replacement in these patients. With the advent of hepatitis B immunoglobulin (HBIg) and other adjuvant therapies, such as interferon and lamivudine, to prevent recurrent disease, transplantation now is routinely offered to patients with chronic HBV infection, with excellent results (Dodson et al, 2000; Grellier et al, 1996).

Recurrent HCV infection is universal after liver transplantation (Gordon et al, 1997). In 90% of patients, hepatitis can be confirmed on routine biopsy. Of these, 60% have mild hepatitis, whereas 30% develop a more severe pattern seen on histologic examination. In patients with severe recurrent HCV, 20% go on develop to cirrhosis within 5 years (Gordon et al, 1997). Of 100 patients with HCV infection who are transplanted, approximately 6 will require retransplantation (Gordon et al, 1997). Prophylaxis with ribavirin and interferon has been shown to be beneficial in reducing viral loads to zero, with significant prolongation of graft survival (Ahmad et al, 2001). Given the epidemic growth in HCV infection, it is likely to dominate the indications for liver replacement for years to come.

BONE DISEASE

Almost all patients who undergo liver transplantation have some degree of hepatic osteodystrophy. The mechanism seems to vary according to the underlying disease. The causes are multifactorial and include corticosteroid therapy, bed rest, and cholestasis. Osteoporosis is particularly common 3 to 6 months after transplantation; however, by the end of the first year after transplantation, patients start gaining bone density. This late improvement is probably because of a reduction in corticosteroid therapy and the resolution of the pretransplantation

condition that was deleterious to skeletal health. Atraumatic bone fractures are more frequent within the first 6 months after transplantation as a result of the extensive bone loss that occurs during this period (Navasa et al, 1996). Avascular necrosis and vertebral body collapse may also occur.

NEUROPSYCHIATRIC COMPLICATIONS

Severe neuropsychiatric changes can occur after liver transplantation. In addition to the acute neurophysiologic changes associated with fluid and electrolyte shifts during the perioperative period, anxiety and depression are common psychiatric conditions observed in many transplant patients. Seizures, alterations of the levels of consciousness, and infections of the CNS are infrequent but are significant causes of morbidity and mortality. Encephalopathy observed after transplantation can be related to poor initial graft function, but it is more commonly multifactorial in etiology. Metabolic derangements, hypoxia, sedation, and drug interactions all can contribute.

Neurologic signs and symptoms associated with immunosuppression toxicity related to cyclosporine and tacrolimus include tremors, headaches, and seizures. These can be avoided by close monitoring of drug levels. High-dose steroids can result in emotional lability or mania. Any patients presenting with new neuropsychiatric symptoms should have a cranial CT scan and lumbar puncture to rule out other causes of mental status changes, such as intracerebral bleeding or an infectious etiology.

HYPERTENSION AND HYPERLIPIDEMIA

Common sequelae of immunosuppression are the development of hypertension and hyperlipidemia in the posttransplantation period (Fernandez-Miranda et al, 1998). As patient survival improves, the consequences of these conditions have greater importance on long-term prognosis. Hypertension is observed in approximately 70% of liver transplant recipients at 1 year, and nearly 40% of patients develop sustained hypercholesterolemia and hypertriglyceridemia during the same time period. The pathophysiology of posttransplantation hyperlipidemia is complex. Rapamycin immunosuppression does not cause glucose intolerance, but it can lead to hyperlipidemia (Trotter, 2003). Omega-3 fatty acids found in fish oil can reduce hypertriglyceridemia significantly. In our experience, oral supplementation with over-the-counter fish oil capsules (4 to 6 g/day) has shown a dose-response reduction in serum triglycerides. Given the additional risk of development of coronary artery and peripheral vascular disease, aggressive therapy—with dietary changes, exercise, and medication—is indicated.

SUMMARY

Liver transplantation is a lifesaving treatment modality for patients with end-stage liver disease. The wide range of comorbidities that develop preoperatively contributes significantly to the development of postoperative complications. Aggressive use of immunosuppression is successful in preventing rejection in many cases, but therapy can be complicated by the development of life-threatening neoplasms. Recent trends favor significant reduction of immunosuppression over time and early withdrawal of steroids, once the mainstay of immunosupressive regimens. The reduction of immunosuppression in selected patients and early withdrawal of steroids have significantly reduced morbidity and life-threatening complications.

Positive outcomes after liver transplantation require a multidisciplinary team approach that comprises surgeons, transplant coordinators, hepatologists, and internists to maintain constant surveillance for the inevitable complications that arise. Early diagnosis with rapid treatment provides the best opportunity for disease-free survival.

CHAPTER 101

Whole-organ pancreas and pancreatic islet transplantation

Niraj M. Desai and James F. Markmann

OVERVIEW

Type 1 diabetes mellitus, formerly known as *juvenile diabetes,* is characterized by hyperglycemia as a result of the nearly complete destruction of the insulin-producing β-cells of the pancreatic islets of Langerhans. The loss of β-cells is the result of a T-cell–mediated autoimmune attack that typically occurs during childhood or early adolescence. Insulin replacement can lead to acceptable control of blood glucose levels; however, affected individuals are subject to the development of various secondary complications that include cardiac disease, stroke, retinopathy and blindness, nephropathy and renal failure, peripheral and autonomic neuropathy, and amputation (Atkinson & Eisenroth, 2001). Although tight glycemic control has been shown to decrease the number of diabetes-related secondary complications, it also has been shown to lead to an increased number of dangerous hypoglycemic episodes (Diabetes Control and Complications Trial [DCCT] Research Group, 1993).

Transplantation therapy for type 1 diabetes was developed as an alternative to insulin administration with the additional theoretic benefit of reducing or eliminating the development of secondary complications of the disease. Both whole-organ pancreas and isolated pancreatic islets are being transplanted into select individuals with type 1 diabetes. Whole-organ transplantation is already an established and widely available therapy, whereas clinical islet transplantation remains under investigation in diabetic individuals.

WHOLE-ORGAN PANCREAS TRANSPLANTATION

History and Early Results

On December 20, 1893, P. Watson Williams grafted three pieces of a sheep pancreas into the subcutaneous tissues of a diabetic child, who died 3 days later of unrelenting diabetic ketoacidosis (Williams, 1894). This first attempt to treat diabetes with transplantation, although unsuccessful, preceded decades of animal experimentation, in which investigators developed the methods necessary to perform a vascularized pancreas transplant; pancreas transplantation was subsequently used as a model to study diabetes and glucose homeostasis.

The first clinical vascularized pancreas transplantation was performed on December 17, 1966, by William Kelly and Richard Lillehei at the University of Minnesota. The patient had temporary insulin independence but eventually required graft removal and ultimately died of postoperative complications (Kelly et al, 1967). The subsequent early experience with pancreas transplantation at Minnesota and at a few other centers was characterized by some technical success, but no graft functioned beyond 1 year, and the enthusiasm for this procedure dwindled.

During 1975, only six pancreas transplantations were performed worldwide. However, the introduction of cyclosporine as an immunosuppressive medication and further technical refinements allowed for better outcomes following pancreas transplantation such that throughout the 1980s and early 1990s, the number of pancreas transplants performed increased dramatically: almost 1500 pancreas transplantations were performed in the United States during 2004. This number has declined slightly for the past several years, with fewer than 1200 pancreas transplantations performed in the United States during 2010.

Indications and Patient Selection

The majority of patients who undergo pancreatic transplantation have type 1 diabetes mellitus and renal failure. In these individuals, pancreas transplantation is performed with a simultaneous kidney transplantation (SPK; 72% of cases) or after a successful kidney transplantation (PAK; 20% of cases). The normal glucose control achieved by the pancreas transplant may protect the transplanted kidney from recurrent diabetic nephropathy and is beneficial from an overall quality of life perspective. In a small proportion of patients with diabetes that is very brittle and difficult to manage, but with preserved renal function, pancreas transplantation alone (PTA; 8% of cases) is performed. It should be noted that SPK and PAK recipients require immunosuppressive therapy to protect both the kidney and pancreas from rejection, whereas in the case of PTA recipients, the need for immunosuppression is solely for the pancreas itself. This difference becomes important when weighing the risk/benefit ratio for each type of recipient.

Potential pancreas recipients are carefully screened for contraindications to transplantation, such as an ongoing infectious process or malignancy. These candidates almost always have medical comorbidities as a result of secondary complications from diabetes; therefore a thorough assessment of a candidate's cardiovascular status is essential. Cardiac contraindications to pancreas transplantation include the presence of noncorrectable coronary artery disease, significantly decreased ejection fraction, or myocardial infarction within the preceding 6 months. Recipient age is also important, and in some programs, recipients older than 50 years are not considered candidates because of an increased risk of perioperative complications.

Donor Operation

Selection of an appropriate deceased pancreas donor includes standard donor selection criteria. In addition, a bias exists toward using organs from younger, leaner, and more hemodynamically stable deceased donors. Donors with hemodynamic instability or those that require high doses of vasopressors are considered higher risk. In addition, pancreata with significant steatosis are usually avoided, because they are associated with a greater likelihood of postoperative complications, such as pancreatitis, peripancreatic fat necrosis, and infection. Based on these selection criteria, which are relatively stringent compared with those applied to the liver or kidney, only a fraction of deceased donors are deemed suitable for whole-organ pancreas donation. In the United States, there were 8022 deceased donors during 2009. Of these, only 1233 pancreata were transplanted (15%), compared with 6101 livers (76%) and 10,442 kidneys.

The procurement of the pancreas must be performed in conjunction with the liver procurement, carefully delineating the blood supply to the liver to ensure that both organs can be removed and transplanted. In the vast majority of cases, blood supply should not preclude the transplantation of both organs. Initial dissection involves division of the gastrocolic ligament to expose the anterior surface of the pancreas. Visual inspection is considered to be an important element to the pancreas procurement process, because this is an opportunity to assess the organ for the presence of infiltrating fat or hematoma that might preclude transplantation. The portal triad is carefully dissected, with division of the common bile duct and the gastroduodenal artery. In addition, the common hepatic, left gastric, and splenic arteries are all dissected free of surrounding lymphatic tissues. Further dissection of the pancreas includes a Kocher maneuver, to mobilize the head, and division of the lienophrenic and lienocolic ligaments, to mobilize the body and tail. Of note, the spleen is left in continuity with the pancreas to serve as a handle to minimize manipulation of the gland itself. The duodenum is decontaminated by flushing povidone-iodine antifungal/antibiotic solution through a nasoduodenal tube.

After the patient has been systemically heparinized, the abdominal aorta is ligated at its bifurcation and is cannulated in a retrograde direction for perfusion. The liver team may also elect to place a cannula for portal perfusion through the inferior mesenteric vein. The supraceliac aorta is cross-clamped, the vena cava is vented, and the abdominal organs are flushed in situ with preservation solution, typically University of Wisconsin (UW) solution, at 4° C. In addition, topical cooling is also used.

Once the organs have been adequately flushed, the liver and pancreas are either separated in situ and removed individually from the donor, or both organs are removed en bloc and divided at the back bench. In the in situ separation situation, the liver is removed first by dividing the portal vein 1 cm cephalad to the superior margin of the pancreatic head, approximately the level of the coronary vein, and dividing the splenic artery about 3 mm beyond its origin, thus preserving the entire celiac axis with the liver.

Next, removal of the pancreas proceeds. The proximal duodenum just beyond the pylorus and the distal duodenum are divided with gastrointestinal anastomosis stapler. The small bowel mesentery that lies inferior to the pancreas is divided, and the superior mesenteric artery is divided at its origin from the aorta. Long segments of donor iliac vessels are removed to use for vascular reconstruction during back-bench preparation of the pancreas.

Back-Table Preparation of the Pancreas

Relative to other solid organs, the pancreas requires extensive preparation prior to implantation into the recipient. This back-bench preparation is performed in ice-cold preservation solution to minimize any further ischemic injury to the organ. The duodenum is often shortened with a gastrointestinal anastomosis stapler, being careful to exclude any gastric tissue and also being careful not to compromise the opening of the ampulla of Vater. The division of the small bowel mesentery in the donor is shortened by firing a stapler across this mesentery and then reinforcing the staple line with a running vascular suture. The spleen is removed by dividing the vessels in the splenic hilum, being careful not to injure the tail of the gland. Finally, the arterial inflow to the graft must be reconstructed, because the organ has two major sources of blood supply that are not in continuity: the splenic artery supplies the body and tail, and branches of the superior mesenteric artery supply the head.

In most instances, arterial reconstruction can be performed using the donor iliac artery as a bifurcated Y graft. The internal iliac artery is joined to the splenic artery, and the external iliac artery is joined to the superior mesenteric artery. The common iliac artery of the donor Y graft can then be anastomosed to the recipient iliac artery, serving as the arterial inflow to the pancreas. In some instances, it is necessary to create a portal vein extension graft on the back bench using donor iliac vein; however, this technique is avoided if possible, because it may increase the risk of venous thrombosis of the graft.

Recipient Operation

The techniques used for transplanting the pancreas have changed dramatically over the past few decades. Partial segmental grafts that contained only the body and tail were once common; however, this technique is rarely used today. Exocrine secretions were previously managed by pancreatic duct ligation or by injection of a polymer that would cause duct obliteration, however, now exocrine secretions are handled by internal drainage.

In two areas of pancreas transplantation, current-day techniques differ: in the drainage of exocrine secretions and the venous drainage of the graft. Exocrine drainage is performed either via the intestinal tract or via the urinary tract. Throughout most of the 1980s and 1990s, drainage of the pancreatic secretions into the recipient bladder was the most common form of exocrine drainage. This technique is convenient for monitoring organ function by measurement of amylase levels in the urine; however, problems with hematuria, cystitis, bicarbonate loss, and dehydration are all associated with bladder drainage. These complications necessitate surgical revision to enteric drainage in up to 20% of bladder-drained pancreas recipients (Stratta, 2005). Based on these issues, and on the lower rejection rates observed with newer immunosuppressive medications, the majority of transplant centers now perform enteric drainage of the exocrine secretions. This enteric drainage is either directly into a loop of jejunum in a side-to-side fashion or into a Roux-en-Y limb of jejunum.

The venous drainage of the graft is either to the systemic circulation, via an iliac vein or the inferior vena cava, or to the

portal circulation. Portal venous drainage has the theoretic advantage of delivering insulin in a more physiologic manner, because insulin undergoes a "first pass" through the liver, and the hyperinsulinemia that results from systemic drainage is avoided (Gaber et al, 1995). There is also an immunologic advantage of portal drainage that has been observed in several experimental studies, in which the delivery of foreign antigen via the portal system results in diminished immune responses. Despite these potential advantages, no demonstrable difference has been found in outcomes between human transplants drained by the portal vein and those drained by the systemic vein, and systemic venous drainage is how the majority of pancreas transplantations are performed.

There are two common locations in the abdomen where the transplant is placed based on the type of venous drainage planned: either in the pelvis, most commonly the right side, for systemic venous drainage or in the midabdomen for portal venous drainage. When the graft is placed in the pelvis, the donor portal vein is anastomosed to the external iliac vein, the common iliac vein, or the inferior vena cava. In this pelvic position, the graft is oriented with the duodenum in an inferior position, if bladder drainage is planned (Fig. 101.1A), or with the duodenum in either the superior (Fig. 101.1B) or inferior position if enteric drainage is planned. Alternatively, for portal venous drainage, the pancreas is placed in the mid-abdomen below the transverse colon with the duodenum oriented superiorly. The portal vein of the pancreas is anastomosed to a major branch of the superior mesenteric vein, found in the small intestine mesentery, in an end-to-side fashion (Fig. 101.2). Enteric drainage for exocrine secretions must be used with the portal venous drainage technique. With either venous drainage technique, the donor arterial conduit to the pancreas graft is anastomosed in an end-to-side manner to the recipient common or external iliac artery.

Complications

The major complications following pancreas transplantation are often technical in nature. Pancreas graft thrombosis, arterial or venous, is more frequent after pancreas transplantation than after other solid-organ transplants, and the reported incidence is approximately 10%. Thrombosis usually occurs within the first week following transplantation and likely reflects the relatively low blood flow through the organ. In most instances of thrombosis, graft removal is necessary (Humar et al, 2000). Early pancreatitis occurs in 10% to 20% of cases and is largely a reflection of ischemic damage to the gland during preservation and reperfusion injury. Hyperamylasemia and graft edema are characteristic, and graft pancreatitis is usually treated nonsurgically with octreotide. Leakage at the site of pancreatic exocrine drainage is another early complication, with management often dictated by the method of drainage. Bladder-drained transplants with a small leak at the duodenocystostomy can often be managed by Foley catheter drainage of the bladder, allowing the site of leakage to heal over time. Enteric-drained transplants with a leak at the duodenojejunostomy will often result in peritonitis and usually require operative intervention to control the leak.

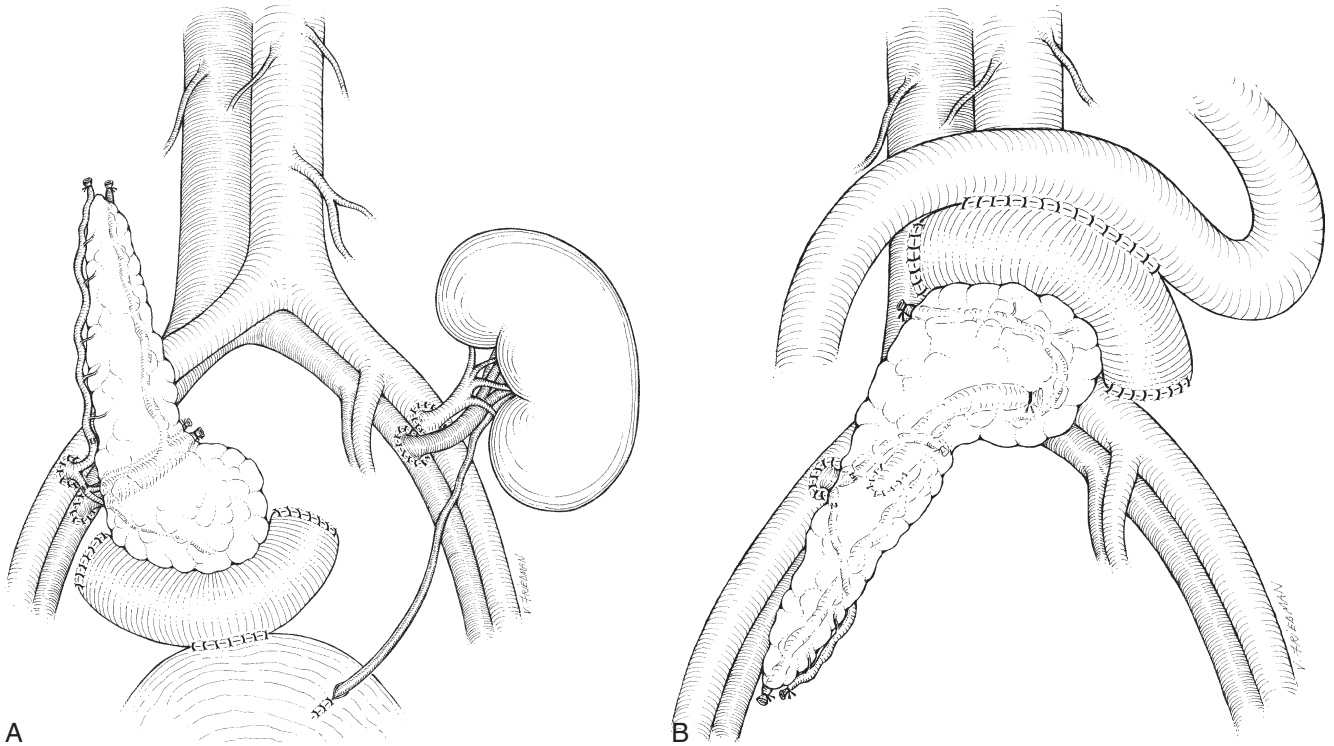

FIGURE 101.1. Whole-organ pancreas transplantation with systemic venous drainage. The pancreas is placed in the right pelvis with anastomosis of the donor iliac artery Y graft to the recipient iliac artery to provide arterial inflow to the graft and anastomosis of the donor portal vein to the recipient iliac vein for venous drainage. Simultaneous kidney transplantation can be performed using the left-sided iliac vessels. **A,** The duodenum is oriented in the inferior direction to allow anastomosis to the bladder (shown) or to the small intestine (not shown). **B,** Alternatively, the duodenum is oriented superiorly for anastomosis to the intestine.

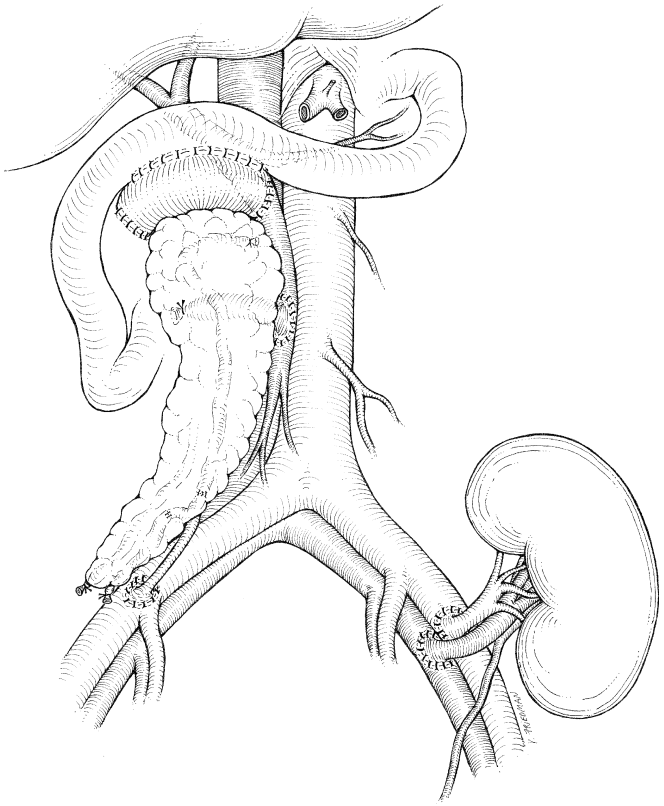

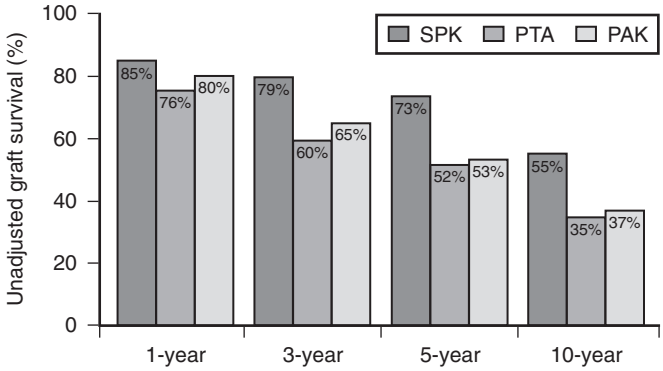

FIGURE 101.2. Whole-organ pancreas transplantation with portal venous drainage. The pancreas is placed in the mid-abdomen with anastomosis of the donor portal vein to a major branch of the superior mesenteric vein and anastomosis of the donor iliac artery Y graft to the recipient iliac artery. The duodenum is oriented in the superior direction for anastomosis to the intestine. A simultaneous kidney transplant can be performed using either the left (shown) or right iliac vessels.

Rejection following pancreas transplantation was once a very common occurrence. Pancreas rejection is often difficult to diagnose, and a variety of indicators are used to help make the diagnosis. These include tenderness over the area of the pancreas allograft, increased serum amylase and lipase, decreased urinary amylase excretion (if bladder drainage is used), biopsy of the pancreas, and hyperglycemia. It is noteworthy that hyperglycemia is a late indicator of rejection, and the pancreas is often difficult to salvage once hyperglycemia has occurred. If SPK transplantation is performed, renal allograft dysfunction can often assist with the diagnosis of pancreatic rejection, because the rejection process is often occurring in both organs. As a result of the high incidence of rejection and the difficulty in making the diagnosis, pancreas transplant recipients usually receive potent induction immunosuppression with a T–cell depleting agent and maintenance therapy with tacrolimus, mycophenolate mofetil, and corticosteroids.

The total amount of immunosuppression pancreas recipients receive is among the highest of any solid-organ transplantation. As a result, they are more susceptible to the complications of immunosuppressive therapy. These complications include infection with opportunistic bacteria, viruses, and fungi; malignancy; gastrointestinal complications; and others. The high incidence of these complications makes effective prophylaxis strategies important.

Death is included as an event.

FIGURE 101.3. Pancreas graft survival rates (unadjusted) at 1 year, 3 years, 5 years, and 10 years following whole-organ transplantation by transplant category. *(Modified from Axelrod DA, et al, 2010: Kidney and pancreas transplantation in the United States, 1999-2008: the changing face of living donation. Am J Transplant 10:987-1002, Copyright 2010 Blackwell Publishing, with permission.)*

Results

Patient and graft survival following pancreas transplantation have improved significantly in recent years. Depending upon the type of transplantation—SPK, PAK, or PTA—patient survival is approximately 96% to 98% at 1 year and 85% to 89% at 5 years after transplantation. Graft survival varies according to the type of transplantation performed (Fig. 101.3). For SPK recipients, 1-, 5-, and 10-year pancreas graft survival rates are 85%, 73%, and 55%, respectively. For PAK recipients, the respective rates are 80%, 53%, and 37%. Finally, for PTA recipients, rates of pancreas graft survival are 76%, 52%, and 35%, respectively (Axelrod et al, 2010).

The impact of a successful pancreas transplantation on the complications associated with diabetes mellitus is debated. Because the successful transplantation restores euglycemia and normal hemoglobin A1c levels, most proponents argue that diabetic complications should cease and perhaps reverse. Neuropathy appears to stabilize and even slowly improve following pancreas transplantation, whereas retinopathy progression is slowed after several years of graft function. The development of diabetic nephropathy in the transplanted kidney of SPK and early PAK recipients appears to be prevented by successful pancreas transplantation. In PTA recipients, diabetic nephropathy appears to stabilize following transplantation (Fioretto et al, 1998); however, the renal benefit is likely outweighed by the detriment to renal function caused by the immunosuppressive agents, specifically tacrolimus and cyclosporine.

Risk/Benefit Considerations

As outlined above, considerable evidence suggests that successful pancreas transplantation can retard, and in some cases reverse, the secondary complications of diabetes. Despite this evidence, the procedure is considered appropriate for only a subset of patients with type 1 diabetes because of its highly invasive nature, compared with insulin therapy, and the potential for significant surgical complications; thus considerations of risk to benefit are of utmost importance in pancreas transplantation and play an essential role in both the donor and recipient selection processes.

One analysis evaluated the survival benefit of pancreas transplantation by examining a large transplant database to compare the survival of pancreas recipients versus those patients listed for transplantation but who did not receive a transplant. Using this study design, the two patient groups were ensured to be as similar as possible. Because the indications, risks, and benefits differ, depending on whether the patient had underlying renal failure, the analysis was stratified based on whether the patient was listed for or transplanted with an SPK, PAK, or PTA (Venstrom et al, 2003). This analysis revealed a marked survival benefit for those patients who received a combined pancreas and kidney transplant; a 57% *reduction* in mortality rate was observed over 4 years compared with similar patients who remained on the waiting list.

In contrast to the clear survival benefit of SPK transplantation, the PAK and PTA recipients experienced an increased mortality following transplantation. During the 4-year follow-up period, PAK recipients experienced a 42% *increase* in mortality rate, and PTA recipients experienced a 57% *increase* in mortality rate compared with the comparable group of patients who remained on the waiting list. A similar analysis was reported that challenged the survival disadvantage of PAK and PTA (Gruessner et al, 2004a). Their analysis found again, as expected, that the SPK procedure conferred a marked survival advantage; however, unlike the Venstrom study, no survival disadvantage was evident in PAK or PTA transplant recipients.

There are two important caveats to these risk/benefit studies by Venstrom and Gruessner: The first is that the impact of pancreas transplantation on quality of life was not evaluated in these nonrandomized retrospective analyses and would likely heavily favor the group with successful PAK and PTA recipients, but whether this factor would outweigh any survival disadvantage in the short-term, and the significant cost of these complex procedures, has not been evaluated. A second critical outcome measure that is lacking from these studies is the long-term impact of successful pancreas transplantation on the secondary complications of diabetes. As noted above, evidence suggests that diabetic nephropathy, neuropathy, and retinopathy may be positively impacted by the long-term restoration of normoglycemia conferred by transplantation; however, these studies have not included well-controlled trials with large numbers of patients.

These results substantiate the marked clinical benefit observed when caring for patients who undergo the SPK procedure (Rayhill et al, 2000). Importantly, the relative contribution of the transplanted kidney versus the transplanted pancreas to overall patient survival has not been differentiated in a controlled study. This issue is significant given the marked patient survival benefit that has been attributed to kidney transplantation (Wolfe et al, 1999).

A recent retrospective database analysis lends important insight into the role that pancreas graft function contributes towards overall patient survival (Weiss et al, 2009). This analysis examined outcomes in individuals on the SPK waiting list who underwent either an SPK or transplantation of the kidney alone. Recipients of an SPK transplant who had pancreas allograft function 1 year after transplantation had significantly greater patient survival at 7 years (89%) compared with SPK recipients who lost their pancreas transplant within the first year after transplantation (74%) or to those recipients that underwent a kidney transplant alone from either a living donor (80%) or a deceased donor (65%).

Although the survival benefit for SPK recipients is clear, the survival benefit for PAK and PTA recipients has not been conclusively demonstrated (Sutherland et al, 2009). The same analysis by Weiss demonstrates improved patient survival at 5 years for diabetic recipients who underwent a PAK compared with kidney transplantation alone, although this did not reach statistical significance and was subject to selection bias. A recent single-center report demonstrates excellent outcomes 3 years after PAK, in which both patient and graft survival are similar to SPK recipients at that center (Fridell et al, 2009). In this report, PAK recipients had a 90% pancreas allograft, 92% kidney allograft, and a 92% patient survival 3 years after PAK transplantation, compared with 83% pancreas allograft, 86% kidney allograft, and 88% patient survival in SPK recipients. If these excellent PAK outcomes persist with further follow-up and can be replicated at other centers, it is reasonable to assume that a survival benefit to PAK could be demonstrated in future data analyses.

Currently, the most meaningful conclusion that can be drawn is that PAK transplantations should be performed in carefully selected recipients with well-preserved kidney allograft function, and these procedures should be performed at transplant centers with excellent outcomes. The field remains dynamic due to improvements in surgical technique and perioperative care and the frequent introduction of new immunosuppressive agents with more favorable safety profiles; however, improving outcomes with pancreatic islet transplantation may ultimately challenge the need to perform whole-organ pancreas transplantation for the treatment of type 1 diabetes.

PANCREATIC ISLET TRANSPLANTATION

History and Early Results

The original descriptions in rodents of successful islet isolation (Lacy & Kostianovsky, 1967) and subsequent transplantation (Ballinger & Lacy, 1972) caused great excitement in the medical community, in the hope that this type of therapy might be applied to patients with type 1 diabetes. Although the ability to obtain normal glucose control in diabetic rodents with an islet transplant was described decades ago (Reckard et al, 1973), translating this success to humans has been more difficult. Various centers worldwide have attempted human islet transplantation, starting in 1974, with 445 recipients receiving islets between 1974 and 2000. The vast majority of these recipients also received a kidney transplant, either prior to or at the same time as the islet transplant. Analysis of the reported cases between 1990 and 2000 demonstrated that only 19% of patients were off insulin for more than 1 week, and at 1-year follow-up, only 11% of recipients were insulin independent (Brendel et al, 2001).

These discouraging results were attributed to a number of factors, including the possibility that recurrent autoimmunity was causing progressive islet damage following transplantation, because the diabetes in these recipients was the autoimmune form. Support for this hypothesis came from a series of patients at the University of Pittsburgh who underwent upper abdominal exenteration, including total pancreatectomy, followed by liver and islet allotransplantation. In this group of 11 patients, who did not have autoimmune diabetes, 6 (55%) exhibited sustained insulin independence, a success rate far greater than what had been achieved in type 1 diabetic recipients (Carroll et al, 1995).

Islet Autotransplantation

Autotransplantation of pancreatic islets was developed for patients with chronic pancreatitis, in whom total pancreatectomy once provided the best option for treatment. Surgically induced diabetes is frequently brittle, characterized by an absence of both insulin and counterregulatory hormones, with a high rate of long-term morbidity. Treatment involves processing of the surgically removed pancreas in the islet isolation laboratory, followed by infusion of either purified islets or crude pancreatic digest into the liver via the portal vein.

Although the overall experience is limited, the success rate in recipients of autotransplantation has been far greater than in those who received allogeneic islets for the treatment of type 1 diabetes. The largest reported series is from the University of Minnesota, where between the years 1977 and 2007, 173 patients with chronic pancreatitis underwent total, near total (95%), or completion pancreatectomy with islet autotransplantation (Sutherland et al, 2008). These investigators achieved a 65% rate of graft function and a 32% rate of insulin independence, rates of success that correlate closely with the average yield of islets from the removed pancreatic tissue following digestion and processing. This group previously reported higher rates of successful islet autotransplantation in patients who had no prior surgery, or only a prior Whipple procedure, whereas those that had a prior Puestow procedure or distal pancreatectomy had lower chances of success (Gruessner et al, 2004b). Similar results have been reported by another group in a series of 22 patients, where 68% of patients showed acceptable graft function, and 41% were insulin independent (Rodriguez Rilo et al, 2003). Interestingly, both of these groups infused unpurified pancreatic digests, where the islets had not undergone the additional purification step performed during deceased-donor pancreas processing for allotransplantation.

The Edmonton Protocol and Beyond

Interest in islet transplantation was piqued by the Edmonton investigators reporting that, for the first time, diabetes in patients could be consistently reversed by transplantation of isolated pancreatic islets (Shapiro et al, 2000). The Edmonton approach relied on a novel immunosuppression regimen that completely avoided steroids and that utilized a unique combination of induction therapy with an anti–interleukin (IL)-2 receptor antibody and maintenance therapy with sirolimus and tacrolimus. The rationale for this combination was based on the desire to avoid agents with known β-cell toxicity. Although this particular drug combination was likely an important factor in the trial's success, perhaps of even greater impact was the large number of islets that patients received; these investigators infused a larger number of islets than were administered in prior islet transplantation trials, using two or three infusions per patient, acquired from multiple deceased donors.

Whereas previous trials in the late 1990s had often achieved partial success with single infusions of islets, as evidenced by a reduced insulin requirement and increased C-peptide levels, in no trial had the further step been taken to retransplant such patients to increase the net islet mass (Hering & Ricordi, 1999). In the Edmonton series, patients who showed evidence of partial success from the first infusion received an additional infusion, sometimes two, until they had accumulated a sufficient islet mass to gain insulin independence; in general, this occurred when a threshold of 8000 to 10,000 islets per kilogram of recipient body weight had been infused.

After the landmark report by the Edmonton investigators, almost 500 recipients received islet transplants at one of approximately 40 centers worldwide (Harlan et al, 2009). In the first concerted effort to replicate the provocative results of the Edmonton Protocol, a multicenter trial sponsored by the Immune Tolerance Network enlisted 10 centers in North America and Europe to each perform four islet transplants using the Edmonton regimen (Shapiro et al, 2006). Despite a diligent attempt to ensure uniformity in technique between centers, the rate of success varied dramatically, depending on the extent of experience at the transplanting site: at the three most experienced centers, reversal of hyperglycemia was routinely achieved; however, less experienced teams gained insulin independence in only a fraction of cases (approximately 20%). Thus, although these results confirmed the efficacy of Edmonton's approach, they also revealed the exacting nature of the technique and demonstrated the inherent difficulty in replicating an identical protocol at all centers.

A number of single-center reports have now validated the Edmonton Protocol (Goss et al, 2002; Markmann et al, 2003), and although this protocol represents a tremendous leap forward for the field, the Edmonton results also delineate the major problem that remains: the need for islets procured from multiple deceased donors to gain insulin independence in a single recipient. This requirement markedly increases costs and represents a distinct disadvantage when compared with whole-organ transplantation; however, it should be remembered that, thus far, the pancreata utilized for isolated islet transplantation have only been organs that were unsuitable for whole-organ transplantation. It seems reasonable to assume that these organs are inferior to those used in whole-organ transplantation, and that improved results may be achieved if islet transplantation candidates had access to the best organs.

The need for such a large number of islets to achieve insulin independence in clinical transplantation was unexpected in light of the finding that as little as 10% of the total islet mass can maintain normoglycemia following partial pancreatectomy. Because the total islet mass in normal individuals is estimated at 1 to 2 million, it would follow that transplanting only 200,000 islets should regain normoglycemia in the majority of diabetic recipients; instead, accumulating evidence from the islet transplant studies by Edmonton and others suggest that for an average individual, 600 to 700,000 islets are required. The nearly two-thirds loss of potency after transplantation has not been fully explained in patients, but experimental data from small animal studies indicates that the majority of transplanted islets fail to engraft (Davalli et al, 1995). Understanding and overcoming the loss of islet mass during the engraftment phase has been an important focus of recent islet transplantation clinical trials.

Some centers have reported improved success at gaining insulin independence with islets from a single donor by refining the Edmonton approach (Hering et al, 2004, 2005; Markmann et al, 2003). The most successful reports are from the University of Minnesota, where investigators have used potent induction immunosuppression and high-quality islets. In their first study, four of six consecutive patients were rendered insulin independent with single-donor islet infusions using induction therapy with the anti-CD3 monoclonal antibody hOKT3γ1 (alanine-alanine) (Hering et al, 2004). This was combined with

the selection of relatively larger donors and somewhat smaller recipients with low daily insulin requirements, thus maximizing the islet mass delivered per recipient body weight.

An even more impressive result was reported by the same group using polyclonal antithymocyte globulin (Thymoglobulin) for induction therapy; in a series of 10 consecutive patients treated with Thymoglobulin induction therapy, 9 were rendered insulin independent with a single infusion of islets (Hering et al, 2005). The 1 patient who did not become insulin independent still had a marked reduction in daily insulin requirement. Collectively, these studies suggest that insulin independence can be achieved consistently with single-donor islet infusions under the correct circumstances. Overcoming the single-donor hurdle will help in the establishment of isolated islet transplantation as a more widely applicable therapy for patients with type 1 diabetes.

A second, more daunting obstacle is the realization that the durability of function after islet transplantation is less than whole-organ pancreas grafts. Whereas it is clear that very experienced islet centers can gain insulin independence in most islet recipients, and that short-term (1-year) insulin-free survival may be close to that seen with whole-organ transplants, the intermediate (2- to 4-year) insulin-free survival is less encouraging. In a report by Edmonton investigators, with follow-up on patients in their ongoing series transplants of islets alone (Ryan et al, 2005), fewer than 25% of patients remained free from exogenous insulin administration at 3 years (Fig. 101.4B). Although a somewhat disappointing result, more encouraging was the observation that more than 85% of these patients had evidence of some islet graft function by C-peptide measurement (Fig. 101.4A). Similar findings of declining islet function over time have been reported by the multicenter Collaborative Islet Transplant Registry: of the recipients who achieved insulin independence, approximately 50% were back on insulin 2 years later (Alejandro et al, 2008).

Despite the eventual need for most recipients to resume doses of insulin, the partial graft function that persists is relevant, because many patients who were transplanted with the indication of hypoglycemia unawareness remain cured of this devastating complication. It is also evident that a partially functioning graft can significantly improve glycemic control as measured by serial hemoglobin A1c determinations. A small group of islet recipients who have resumed insulin therapy have been given supplemental islet infusions several years after the initial islet transplant and have regained durable insulin independence in most cases (Koh et al, 2010).

The mechanisms responsible for the gradual loss of islet function remain unclear. One hypothesis is that inadequate control of the deleterious alloimmune and autoimmune responses compromise islet function over time. The absence of a reliable measure of an antiislet immune reaction and the difficulty in obtaining biopsy tissue for pathologic diagnosis contribute to the complexity in clarifying this issue. One study reported durable insulin independence (>3 years) in islet recipients when more potent induction immunosuppression was used, compared with what was used in the Edmonton Protocol (Bellin et al, 2008). An alternative explanation is that the currently used immunosuppressive agents are toxic to the islets over time. This explanation may fit better with the pace of graft dysfunction and the fact that graft function often stabilizes without antirejection therapy. In addition, studies have documented very high immunosuppressive drug levels in the portal circulation, an expected consequence of the drugs being administered orally (Desai et al, 2003). The role of immune responses

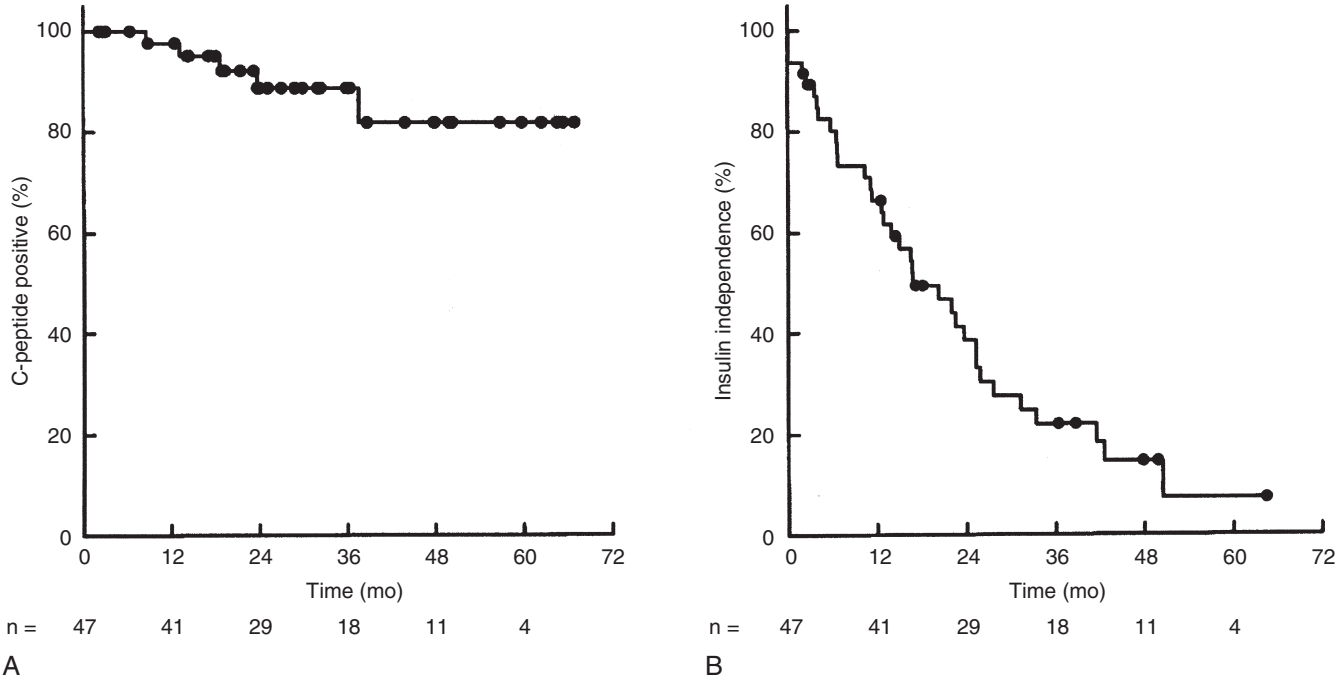

FIGURE 101.4. Islet graft survival rates following isolated islet transplantation at the University of Alberta, Edmonton (Ryan et al, 2005). **A,** Survival analysis for islet function as documented by C-peptide secretion over time, demonstrating 85% graft survival at 3 years. **B,** Survival analysis for insulin independence over time, demonstrating that fewer than 25% of patients are free from exogenous insulin therapy at 3 years. *(From Ryan EA, et al, 2005: Five-year follow-up after clinical islet transplantation. Diabetes 54:2060-2069. Copyright 2005 American Diabetes Association.)*

and medication toxicity to the loss of islet graft function should be clarified by the application of newer immunosuppressive agents in the next generation of islet transplantation studies.

Complications and Risk/Benefit Considerations

The demonstration that the procedure is relatively safe for the recipient has been important in the early trials of isolated islet transplantation. The most feared potential complications include bleeding and portal vein thrombosis. The Edmonton experience in 65 patients demonstrates that bleeding occurred in more than 20% of recipients, most of whom required either transfusion or surgical intervention. Main portal vein thrombosis, the most potentially troublesome complication of portal islet infusion, has fortunately been rare (<1%); however, in the Edmonton experience, 7% of recipients had evidence of segmental portal vein thrombus that resolved without sequelae (Ryan et al, 2005).

The risk of bleeding and thrombosis may be related in part to the technique used to perform the infusion. The procedure can be performed by an interventional radiologist, gaining access to the portal vein via a percutaneously placed transhepatic catheter and releasing the islets into the portal system (Froud et al, 2004). Alternatively, the procedure can be performed via a small laparotomy to gain access to a small mesenteric vein, through which a catheter can be advanced into the main portal vein for islet infusion (Gaber et al, 2004). The small vein is then ligated, eliminating the potential for hemorrhage. Thus the operative approach allows anticoagulation to be administered without the risk of bleeding from a puncture site in the hepatic parenchyma, although it usually requires a general anesthetic.

The relative safety advantage of islet transplantation over whole-organ pancreas transplantation was clearly evident in a comparison of the two approaches (Frank et al, 2004). In this study, major complications that included bleeding that required transfusion and reoperation were more common in the whole-organ group, although a number of minor complications were frequent in the islet transplant group. Some of these minor complications included immunosuppression-related toxicity (mouth ulcerations, edema), periportal hepatic steatosis, and mild liver function test abnormalities. A comparison of the major advantages and disadvantages of whole-organ pancreas and isolated islet transplantation can be seen in Table 101.1.

Islet transplantation also incurs the risk of infusion-related infection. This complication is minimized by screening potential donors for infection, administration of prophylactic antibiotics to the recipient, and by assessment of the islet preparation for bacterial contamination by microscopic examination and endotoxin testing. As with all forms of transplantation, the need for chronic immunosuppression carries with it a risk of opportunistic infection and a small but discernible risk for the development of malignancy, especially lymphoma and skin cancer. Similarly, exposure of the recipient to allogeneic tissue may induce an immune response in the recipient and generate cytotoxic antibodies against the HLA antigens of the donor. This exposure may be especially detrimental in islet recipients who receive transplants from multiple donors, thereby broadening their antigenic exposure. The presence of anti-HLA antibodies could hamper future attempts at islet transplantation or transplantation of lifesaving organs such as the kidney.

Table 101.1

Comparison of Whole Pancreas and Islet Transplantation

	Whole Pancreas Transplantation	Islet Transplantation
Indication	Diabetic patients with renal failure (92% of cases)	Diabetic patients with hypoglycemic unawareness
Availability	Widely available	Research protocols only
Procedure	Major abdominal operation under general anesthesia	Percutaneous or "mini-lap" approach
Metabolic control	Normal	Good on a diabetic diet
Longevity of transplant	79% function at 3 years (SPK)	85% function at 3 years but <25% insulin free
Effect on secondary complications of diabetes	Stabilization and improvement	Unknown

SPK, simultaneous pancreas and kidney transplantation

One of the most common and concerning potential complications of islet transplantation using the Edmonton protocol is calcineurin inhibitor–associated nephrotoxicity. Chronic renal failure in the setting of nonrenal solid-organ transplantation is well described, with an approximate 20% incidence at 10 years (Ojo et al, 2003). Similar results in islet transplant recipients would represent a particularly morbid complication given the well-established detrimental survival impact of renal failure in the diabetic population (Allen & Walker, 2003). A recent report of renal function in islet transplant recipients indicates that renal function remained stable in an appropriately selected and managed cohort of patients despite their being placed on potentially nephrotoxic immunosuppressive medications (Leitao et al, 2009). This study demonstrates that renal function can be adequately preserved in islet recipients under the correct circumstances.

Because of the side effects of chronic immunosuppression, the benefit of isolated islet transplantation, like that of isolated pancreas transplantation, may be for only select individuals. For this reason, most islet trials to date have enrolled type 1 diabetic participants with the most labile and dangerous form of the disease, specifically, diabetics attended by frequent episodes of hypoglycemia unawareness; patients are thought to be at greatest risk of severe morbidity or death from these events. Islet transplantation, even if only partially successful, has been universally found to be highly effective in reducing the frequency of these hypoglycemic episodes (Alejandro et al, 2008).

An alternative strategy has been to select recipients who are already on immunosuppressive therapy to support another organ transplant, such as a kidney (Kaufman et al, 2002). In this situation, the additional risk to the recipient relates mainly to the islet infusion procedure itself, which should be quite safe. In this setting, recipients usually lack severe hypoglycemia unawareness, although glucose control is usually suboptimal, it can be expected to improve following islet transplantation. An additional major concern in patients receiving an islet after kidney (IAK) transplantation is the function of the lifesaving renal allograft that is already in place. The experience to date suggests that IAK transplantation can be performed without

jeopardizing the kidney graft. An important study in this area, although not conducted in a randomized manner, found evidence that IAK transplantation is not only safe, but it likely has a beneficial impact on renal allograft function (Fiorina et al, 2003). They studied 36 IAK recipients and stratified them based on the success of the islet transplant at 1 year, defined by continued C-peptide production. There were 24 successful cases and 12 unsuccessful cases; the successful IAK recipients demonstrated superior renal graft survival up to 7 years after islet transplantation, and the unsuccessful islet recipients developed increased microalbuminuria over time, likely reflecting diabetic damage in the transplanted kidney.

In addition, successful IAK recipients had improved cardiovascular function in terms of ejection fraction and degree of diastolic dysfunction when compared with kidney-only recipients (Fiorina et al, 2005). Finally, an improvement in patient survival was noted in successful IAK recipients compared with recipients with failed IAK transplantation and with diabetic recipients who had undergone kidney transplantation alone. A major caveat to these findings is that they are derived from a small number of IAK patients, therefore they must be substantiated in larger cohorts. In addition, these results are not based on recipients randomized to either treatment arm, thus any benefit in secondary complications attributable to IAK transplantation is subject to selection bias and requires further investigation in properly controlled studies.

Future Directions in Islet Transplantation

There are many areas of active investigation in clinical and experimental islet transplantation, including an important set of collaborative studies being supported by the National Institutes of Health. These trials have the opportunity to secure a place for islet transplantation as a standard therapeutic modality. For isolated islet transplantation to gain equal footing with or to surpass whole-organ pancreas transplantation as the preferred therapy for patients with diabetes, a number of conditions will need to be met. First, improvements must occur so that reversal of diabetes is readily accomplished with the islets from a single donor in the majority of cases. This will require not only advances in isolation techniques that allow greater recovery of healthy islet tissue, it will also require a greater understanding of the events early after transplantation that are responsible for engraftment of only a fraction of the delivered islet mass (Harlan et al, 2009). Second, clarification is needed of the immunologic and physiologic mechanisms that contribute to islet dysfunction over time that lead to the need for reinstitution of low doses of exogenous insulin in a majority of islet transplant subjects.

Finally, should the hurdles mentioned above be overcome, the reliance on deceased donors as the sole source of islets will be insufficient to treat the large number of patients with type 1 diabetes who could benefit from islet transplantation. Living donors are one alternate source of islet tissue as shown in a report of living donor islet transplantation from Japan (Matsumoto et al, 2005); however, the potential for donor morbidity makes this approach highly controversial, until the long-term durability and efficacy of islet transplantation has been firmly established. Ultimately, derivation of β-cells from xenogeneic or stem cell sources promises to provide a limitless supply of transplantable β-cells. The ongoing trials of islet transplantation will provide a critical foundation for these future therapies by defining the optimal site for implantation, the best means to monitor survival, and the most conducive immunosuppression that avoids autoimmune and alloimmune damage without pharmacologic β-cell toxicity.

CHAPTER 102

Injuries to the liver and biliary tract

William P. Schecter and Asher Hirshberg

OVERVIEW

The surgeon attempting to control torrential bleeding from a high-grade liver injury faces a formidable challenge. The source of bleeding is often difficult to control, and there is only a narrow window of opportunity to save the patient's life prior to the onset of hypothermia, acidosis, and coagulopathy—the markers of an irreversible physiologic insult. Furthermore, the bloodless and meticulous resection techniques of elective hepatobiliary surgery do not apply in this dramatic race against time in a hostile physiologic environment. It is therefore not surprising that the management of major liver injuries has always been one of the most demanding aspects of trauma surgery.

The evolution of the management of liver injury over the past century reflects the rapid progression of trauma surgery as a surgical discipline. The initial therapeutic nihilism evolved as pioneers of a new era attempted formal major hepatic resections, and these were advocated and applauded. Disappointing results with this aggressive approach and better understanding of the injured patient's physiology led to a paradigm shift toward damage control that has dominated modern trauma surgery since the early 1990s. At the same time, better understanding of the natural history of liver injuries in hemodynamically stable patients has led to increased nonoperative management utilizing an array of modern imaging and minimally invasive technologies.

This chapter presents the current approach to hepatobiliary injuries from the perspective of the trauma surgeon, describing the approach to the three major clinical patterns of liver trauma and emphasizing the importance of tailoring the approach to the patient's specific anatomic and physiologic circumstances. Finally, the principles and techniques of operative management for hepatobiliary trauma are reviewed, emphasizing the fundamental differences between emergency and elective hepatobiliary operations.

EVOLUTION OF THE APPROACH TO HEPATIC TRAUMA

More than a century ago, Pringle (1908) described hepatic vascular inflow occlusion in a trauma patient by manual compression of the hepatoduodenal ligament, a maneuver that bears his name. Although less often appreciated, Pringle also described exsanguinating hemorrhage from the liver following hematoma decompression during laparotomy and discussed the use of packing to control bleeding from the liver. Packing is therefore not a new concept. Between the turn of the twentieth century and World War II, surgeons packed deep liver lacerations and sometimes added sutures over the pack to achieve tamponade (Schroeder, 1906).

As techniques for selective hemostasis of liver injuries evolved during World War II and later in Vietnam, packing acquired a bad reputation and was abandoned in favor of alternatives such as deep liver sutures and hepatic artery ligation (Aaron et al, 1975; Lewis et al, 1974; Mays, 1967). The report of anatomic right hepatectomy by Lortat-Jacob and Robert in 1952 and the subsequent dissemination of the technical aspects of the operation (Quattlebaum & Quattlebaum, 1959) was rapidly followed by enthusiastic reports of the successful application of these formal resection techniques to trauma (Ackroyd et al, 1969; McClelland et al, 1964).

In the late 1970s, packing reemerged as a valid hemostatic technique for major liver injuries. In 1976, Lucas reported 3 patients in a series of 637 who survived packing (Lucas & Ledgerwood, 1976), and 3 years later, Calne reported 4 additional patients transferred to their hospital with liver packs in place (Calne et al, 1979). These and other reports (Malhotra et al, 2000) coincided with a growing realization among surgeons that major formal hepatic resection in critically injured patients is ill advised, because the combination of severe trauma and extensive surgery often leads to an irreversible physiologic insult and death (Fang et al, 2000).

The reintroduction of packing in the 1990s was the harbinger of a major paradigm shift in trauma surgery, from long and complex definitive procedures to a staged approach that was aptly referred to as *damage control* (Rotondo et al, 1993). In this new paradigm, the goals of the initial operation are limited to rapid control of bleeding and spillage of intestinal contents. This is followed by resuscitation of the patient in the surgical ICU followed by a planned reoperation for definitive reconstruction of the anatomy several days later. By the beginning of the new millennium, this new approach had become the standard of care for major abdominal trauma (Johnson et al, 2001; Shapiro et al, 2000), thus packing and temporary abdominal closure replaced hepatectomy as the dominant approach for major hepatic wounds (Johnson et al, 2001; Knudson et al, 1990; Malhotra et al, 2000; Pachter et al, 1996).

The application of nonoperative management to liver injuries in the last 15 years represents a similarly dramatic revolution. Computed tomography (CT) permitted precise delineation of the anatomy of injured abdominal solid organs. With better appreciation of the natural history of these injuries came an increasingly conservative approach. Nonoperative management was initially implemented with striking success for pediatric splenic trauma (Aronson et al, 1977) and was then successfully applied to the pediatric liver (Karp et al, 1983) and subsequently to the adult spleen and liver (Meyer et al, 1985).

Since the early 1990s, nonoperative management has evolved into the standard of care for blunt hepatic trauma in hemodynamically stable patients (Stein & Scalea, 2006). However, in

Table 102.1

Liver Injury Scale (1994 Revision)

Grade*	Type of Injury	Description of Injury	ICD-9	AIS-90
I	Hematoma	Subcapsular, <10% surface area	864.01	2
			864.11	
	Laceration	Capsular tear, <1 cm	864.02	2
		parenchymal depth	864.12	
II	Hematoma	Subcapsular, 10%-50% surface area	864.01	2
		Intraparenchymal, <10 cm in diameter	864.11	
	Laceration	Capsular tear 1-3 cm parenchymal depth, <10 cm in length	864.03	2
			864.13	
III	Hematoma	Subcapsular, >50% of the surface area of the ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma >10 cm or expanding		3
	Laceration	>3 cm parenchymal depth	864.04	3
			864.14	
IV	Laceration	Parenchymal disruption involving 25%-75% hepatic lobe *or*	864.04	4
		Parenchymal disruption involving 1 to 3 Couinaud segments	864.14	
V	Laceration	Parenchymal disruption involving >75% of a hepatic lobe or >3 Couinaud segments within a single lobe		5
	Vascular	Juxtahepatic venous injuries; a retrohepatic vena cava/central major hepatic veins		5
VI	Vascular	Hepatic avulsion		6

*Advance one grade for multiple injuries up to grade III.

From Moore et al, 1995: Organ injury scaling: spleen and liver (1994 revision). J Trauma 38:323-324.

recent years, it has also become apparent that the conservative approach requires more than close monitoring. In fact, these patients often require adjunctive imaging and interventional techniques to manage the sequelae of major liver trauma (see Section II and Chapters 27 and 28; Carrillo et al, 1999). The most important of these adjuncts is selective angiographic embolization of hepatic artery branches, which has largely replaced operative ligation of the right or left hepatic artery at the hilum (see Chapter 28; Wahl et al, 2002).

SURGICAL ANATOMY OF THE LIVER FROM THE TRAUMA SURGEON'S PERSPECTIVE (SEE CHAPTERS 1A AND 1B)

Trauma surgeons view the liver as having two vascular pedicles: the *inflow pedicle*, comprising the portal vein and hepatic artery, is easily accessible in the hepatoduodenal ligament and is controlled by the Pringle maneuver; the *outflow pedicle*, comprising hepatic veins and retrohepatic inferior vena cava, is virtually inaccessible in the massively bleeding trauma patient, and total vascular isolation of the liver is rarely a practical option in this situation.

The American Association for the Surgery of Trauma (AAST) published a liver injury scale that creates a unified framework for describing the severity of hepatic trauma (Table 102.1, Fig. 102.1; Moore et al, 1995). This scale is useful not only as a descriptive tool but also as an outcome predictor that facilitates comparisons across groups of patients.

From the operating surgeon's perspective, the AAST Liver Injury Scale translates into three types of injuries:

1. Superficial parenchymal wounds that require only a simple suture or use of a local hemostatic technique
2. Deep parenchymal injury or extensive parenchymal disruption, which can be packed
3. Deep injury involving major vascular structures, which requires special maneuvers to achieve hemostasis and often carries a poor prognosis

The approach to each type of injury depends on the patient's hemodynamic stability and the cumulative physiologic insult. The segmental anatomy of the liver has little relevance in the trauma patient except as a way to describe the location of injuries.

The Stable Patient with Blunt Hepatic Injury

Blunt hepatic trauma in a hemodynamically stable patient is typically discovered on CT scan. If the patient is stable with no signs of peritoneal irritation, presumably indicating a hollow viscus injury, the current standard of care is nonoperative management, *regardless of the grade or extent of the injury* (McVay et al, 2008). Although the overall success rate of nonoperative management of hepatic trauma ranges between 85% and 98% (Croce et al, 1995; Malhotra et al, 2000; Pachter et al, 1996; Velmahos et al, 2003), high grades of injury carry a greater risk of failure and often require adjunctive measures and a multidisciplinary approach as described below (Carrillo et al, 1999; Sriussadaporn et al, 2002).

Practical Aspects of Nonoperative Management

Stable patients with high-grade liver injuries (grade III and above) are admitted to the intensive care unit for close hemodynamic monitoring and serial abdominal examination. This must include careful palpation of the liver to assess for new tenderness or any increase in liver size; both are indicative of

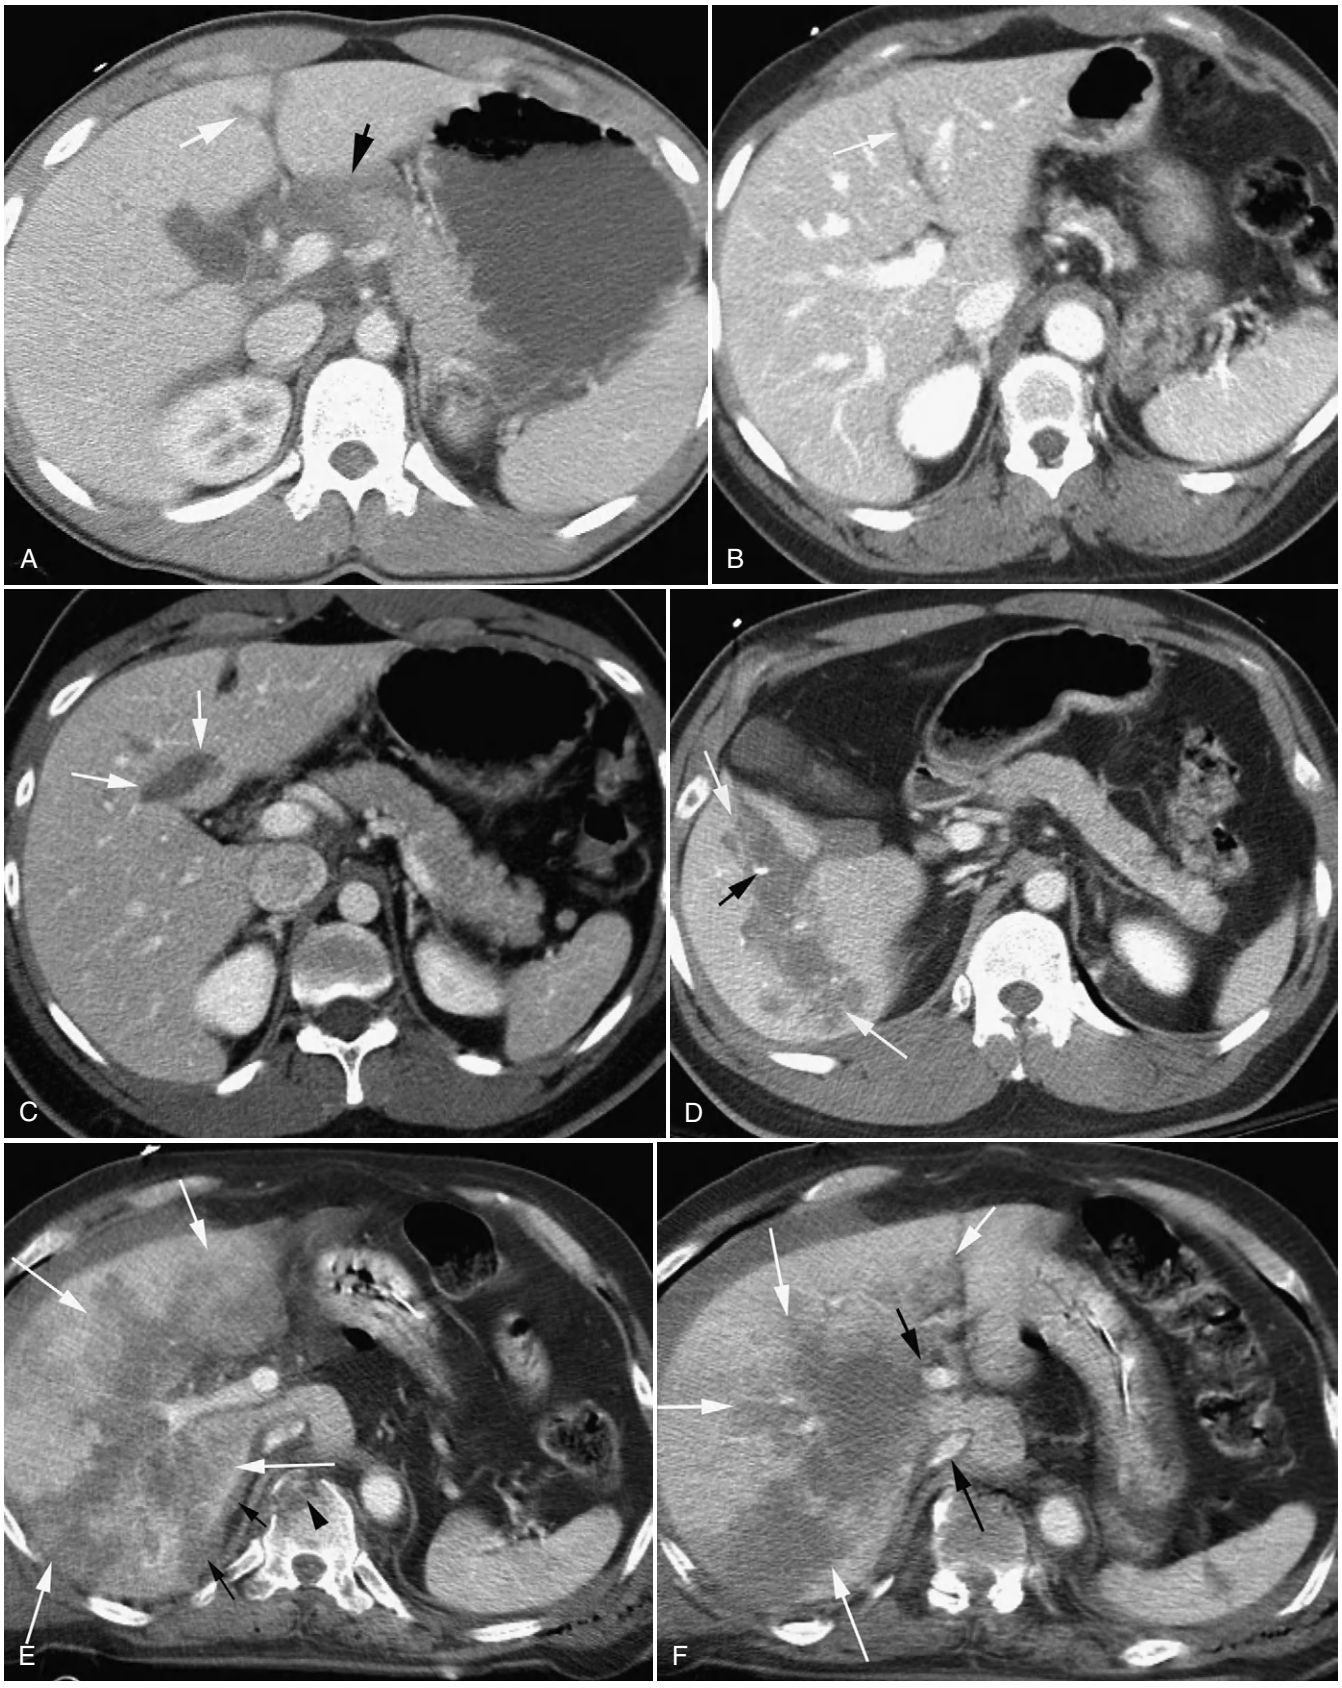

FIGURE 102.1. Liver injury scale. **A,** Grade I injury. **B,** Grade II injury. **C,** Grade III injury. **D,** Grade IV injury. **E,** Grade V injury. **F,** Grade VI injury. *(Courtesy Dr. R. Thoeni.)*

intrahepatic hemorrhage. Many of these patients have associated injuries, such as traumatic brain injury or lung contusions, which also require intensive care. Monitoring bladder pressures for early recognition of intraabdominal hypertension is indicated in patients who have received massive fluid resuscitation and in those who have a firm, distended abdomen (Fusco et al, 2001; Yang et al, 2002).

The duration of ICU monitoring depends on the grade of injury. In general, patients with isolated liver injuries who remain stable are transferred to ward beds after 36 to 48 hours and can be discharged within a week. Routinely obtained laboratory studies include a complete blood count, coagulation profile, and also liver function tests, although these are less important.

The question of routine follow-up imaging is controversial (Alonso et al, 2003). Although routine follow-up imaging is not indicated, most patients with high-grade injuries undergo subsequent CT scans in search of complications such as biloma or hepatic necrosis or because of associated injuries. Fever, leukocytosis, unexplained drops in hematocrit, and a rising bilirubin are obvious indications for repeat imaging (Pachter et al, 1996).

Faliure of Nonoperative Management

Failure of nonoperative management is an uncommon but potentially life-threatening complication that should be recognized early and addressed aggressively (Galvan & Peitzman, 2006). Ongoing bleeding is the major cause of failure. Evidence of ongoing hemorrhage includes hypotension, falling hematocrit, an increase in liver size, or the onset of new or increased pain in the right upper quadrant. If the patient is stable, a repeat CT scan will demonstrate the bleeding, which can then be controlled by angiographic embolization (Misselbeck et al, 2009). The patient in shock is urgently taken to the operating room for laparotomy. The complications of nonoperative management are listed in Box 102.1.

Adjuncts to Nonoperative Management

Adjunctive modalities have a crucial role in the nonoperative management of hepatic trauma. These modalities include angiography, image-guided drainage, endoscopic retrograde cholangiopancreatography (ERCP), and laparoscopy (see Chapters 18, 19, 21, and 28; Carrillo et al, 2010).

Angiography is by far the most important adjunct. A "blush" of intravenous contrast on CT scan (i.e., active extravasation) typically results from injury to a branch of the hepatic artery (Fig. 102.2). This blush is an indication for selective angiographic embolization of the bleeding vessel to prevent pseudoaneurysm formation and delayed hemorrhage (Demetriades et al, 2006; Eubanks et al, 2003).

Box 102.1

Complications of Nonoperative Management of Liver Injuries

Ongoing bleeding
Biloma
Biliary fistula
Intraabdominal abscess
Hepatic abscess
Hemobilia
Liver necrosis
Missed hollow viscus injury
Abdominal compartment syndrome

A blush on CT scan is by no means the only indication for angiography. Evidence suggests that liberal use of angiography for *any* high-grade liver injury is safe and effective, because significant injury to lobar and segmental vessels may occur without a blush, and if left untreated, this may lead to delayed hemorrhage (Mohr et al, 2003).

CT-guided percutaneous drainage plays a key role in nonoperative management, because bile collections are common around the injured liver (Castagnetti et al, 2006). Such drainage obviates the need for laparotomy in the majority of cases. Persistent high-output bile drainage from a percutaneously placed drain indicates injury to a segmental or lobar bile duct. In these patients, ERCP may be used to delineate the site of injury and to decompress the biliary tree by endoscopic papillotomy and stenting (Lubezky et al, 2006); however, in the absence of ductal isolation, adequate external drainage should be sufficient for fistula closure. Image-guided percutaneous drainage is also useful in addressing perihepatic or intrahepatic abscesses.

Delayed laparoscopic lavage is emerging as another useful adjunct to conservative management (Carrillo et al, 2001; Franklin et al, 2007). This minimally invasive procedure is indicated when the patient fails to thrive, with persistent low-grade fever and other signs of ongoing systemic inflammatory response. Port placement is similar to a laparoscopic cholecystectomy with a single subhepatic lateral port. The injured liver is inspected, perihepatic collections are drained and cultured under direct vision, and the infected "rind" of clotted blood and bile on the surface of the liver is gently and bluntly teased off the capsule. The area of injury is typically obvious and is carefully avoided. The liver is irrigated with the suction irrigator, and drains are placed under direct vision in the relevant spaces above or below it.

Other Complications of Nonoperative Management

Rarely, a false aneurysm of a branch of the hepatic artery (Schouten van der Velden et al, 2009) will decompress into an injured biliary radical in a delayed fashion, causing *hemobilia* (Green et al, 2001; see Chapters 104 and 105). The patient presents weeks or months after the injury with upper gastrointestinal bleeding, jaundice, and colicky abdominal pain as a result of blood and clots in the biliary tree that are subsequently passed through the ampulla of Vater. Angiographic embolization (see Chapters 28 and 83) of the source of bleeding is the treatment of choice (Mohr et al, 2003).

Occasionally, a devascularized area of liver will become necrotic. Small areas of *hepatic necrosis* are difficult to diagnose and do not require treatment; however, large areas of necrosis may lead to a systemic inflammatory response or may become infected. On rare occasions, hepatic necrosis may require resectional debridement and wide drainage.

The most devastating complication of nonoperative management is *missed hollow viscus injury*. This complication is very uncommon (Miller et al, 2002), but when it occurs, the mortality rate is high. The diagnosis is particularly difficult, because there is often free fluid in the peritoneal cavity as a result of the liver injury. The abdomen may be firm and difficult to examine, because the patient is intubated and sedated. The signs of a missed hollow viscus injury are therefore subtle, and timely diagnosis requires a high index of suspicion. The decision not to operate should be critically reevaluated with any signs of hyperdynamic physiology. Any adverse change in the abdominal findings or in the expected clinical trajectory should prompt a

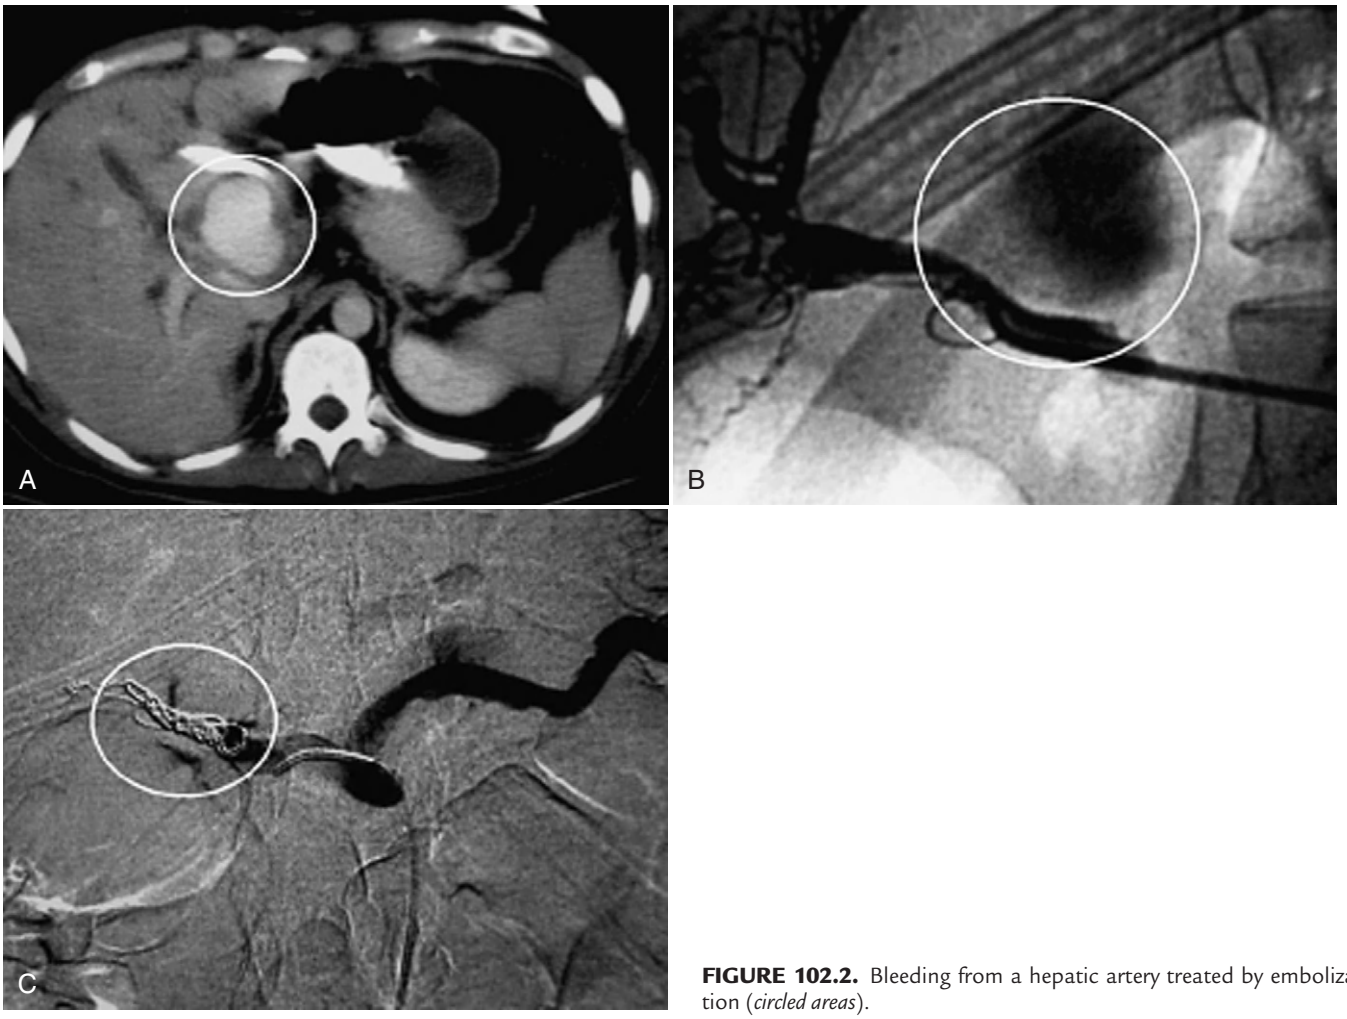

FIGURE 102.2. Bleeding from a hepatic artery treated by embolization (*circled areas*).

repeat CT scan or laparotomy in search of a missed injury. Failure to achieve timely source control results in the patient's death.

Nonoperative Management of Penetrating Hepatic Trauma?

It was only natural that following the dramatic success of nonoperative management for blunt hepatic trauma in the 1990s, attempts would be made to extend the concept to penetrating injuries. Although conservative management of stab wounds to the abdomen, including the liver, has been practiced for years, application of this approach to gunshot wounds is controversial. In 1994, Renz and Feliciano reported 32 patients with right thoracoabdominal gunshot wounds, of whom 7 had CT-documented liver injuries that were successfully treated nonoperatively. Five years later, Demetriades and colleagues (1999) reported 16 patients with penetrating liver injuries, 5 of whom needed a delayed laparotomy; 1 patient died. Clearly, nonoperative management of hepatic gunshot wounds must be applied carefully and selectively and is not currently the standard of care. Success hinges on complete CT delineation of the *entire* bullet trajectory within the liver and the ability to reliably exclude injury to adjacent hollow organs, especially the right colon (Demetriades et al, 2006).

The Unstable Patient with Hepatic Trauma

The patient in shock with hemoperitoneum requires immediate laparotomy to control the bleeding regardless of the injury mechanism. In this stressful situation, the keys to success are careful forethought and orderly conduct of the operation to achieve rapid hemostasis. Immediate availability of type-specific blood is mandatory, and early activation of a transfusion protocol providing for fresh frozen plasma and platelets reduces the risk of coagulopathy in the patient with massive hemorrhage (Dente et al, 2009). A full set of vascular instruments, a rapid infusion device, an autotransfuser, and competent assistance are other essential adjuncts.

Exploratory laparotomy is conducted through a generous midline incision followed by rapid evisceration of the small bowel and packing of all four abdominal quadrants. If hemostasis is achieved, and a liver injury is suspected, the right upper quadrant should be explored *last*.

Superficial, Low-Grade Injuries

Bleeding from a superficial laceration is controlled by local hemostatic techniques, such as temporary packing, while the surgeon is addressing other injuries, or argon beam coagulation. If an argon beam coagulator is not available, cauterization of

the bleeding liver by placing the electrocautery at its highest level and arching the current adjacent to the liver parenchyma without touching it can often achieve the same result. For deeper injuries, local hemostatic agents placed into the laceration followed by manual or pack compression of the edges is a useful adjunct. A portion of healthy omentum stuffed into the laceration and sutured to the liver capsule can serve the same purpose. If manual compression alone controls the bleeding, approximating the laceration with heavy chromic catgut "liver sutures" on a large blunt needle is another useful technique.

Packing of Deep Liver Lacerations

Packing is the workhorse of surgery for hepatic trauma and is especially useful for high-grade lacerations or parenchymal disruptions that are not amenable to the local hemostatic measures described above (Nicol et al, 2007). The technique of packing is often poorly executed, but the goal is to effect hemostasis by compressing the bleeding parenchyma between packs placed *above and below* it. Packing only over the injury without creating an opposing pressure vector often fails.

It is important to note that packing is most effective for venous injuries. For this reason, we advocate immediate postoperative angiography with selective embolization for high-grade liver injuries with arterial hemorrhage that cannot be directly addressed by suture-ligation of the bleeders (Gaarder et al, 2007).

Although assertive packing with laparotomy pads is essential to achieve hemostasis, sometimes overenthusiasm results in overpacking, which can result in hypotension as a result of vena caval compression (Meldrum et al, 1995). The problem should be recognized immediately, and the packs removed gradually, to identify the degree of packing that achieves hemostasis without the adverse effects.

It is important to spend time observing the packs in situ, because ineffective packing takes time to declare itself, as the blood seeps through multiple layers of cloth with very high absorptive capacity. Failure to wait a few minutes before closing the abdomen often results in an urgent reoperation.

Omentum can sometimes be stuffed into a liver defect and serve the same purpose as a laparotomy pad. Although it has the advantage of not requiring removal, rarely is there enough omentum to provide effective tamponade for a large laceration. In desperation, the senior author of this chapter (W.P.S.) once placed several large pieces of Vicryl mesh into a massively bleeding gunshot wound of the right lobe of the liver in a patient with an associated infrahepatic vena caval injury. The Vicryl packs were never removed, and the patient survived. Although this method cannot be routinely recommended, it is nevertheless an example of improvisations that are sometimes called for in a difficult situation.

Other Techniques for Hemostasis of Deep Liver Lacerations
