CHAPTER 1A

Embryologic development of the liver, biliary tract, and pancreas

Yousef El-Gohary and George K. Gittes

OVERVIEW OF LIVER AND BILIARY TRACT DEVELOPMENT

Developmental biologists have often marveled at the enormous regenerative capacity of the liver after injury, and such growth represents one of the fastest by mammalian tissues. Presumably this process is based on the recapitulation of embryonic signals in the liver, but our understanding of the mechanisms of liver development is relatively poor. The liver is the largest internal organ and consists of diverse cell types that arise from various embryologic origins. The two principle cell types of the liver are the *hepatocytes*, which comprise nearly 70% of the mass of the adult organ, and the *cholangiocytes*. Both cells are derived from the embryonic endoderm. Other cell types of the liver include hematopoietic, Kuppfer, stromal, and stellate cells, all of which are of mesodermal origin (Fig. 1A.1). Despite their homogeneous appearance, hepatocytes do not all function identically; they perform various roles, depending on their physical location within a hepatic lobule, the primary functional unit of the liver. Thus, liver development entails not only hepatocyte and cholangiocyte differentiation but also further cellular differentiation within the hepatocyte population (Fig. 1A.1).

During the third week of gestation, the liver primordium first appears as an outgrowth of the ventral foregut endoderm at the caudal end of the foregut. The proliferation of the epithelial cells in this liver bud leads to its growth and branching with resulting expansion of the growing bud into the surrounding mesenchyme, giving rise to the liver and intrahepatic biliary tree. As it grows caudally, traversing the septum transversum, the persistent connection between the branching epithelium and the foregut develops into the extrahepatic bile ducts and gallbladder (Sadler & Langman, 2006). The hepatoblasts eventually differentiate into hepatocytes and cholangiocytes. The final liver structure continues to develop through the postnatal period. In addition to giving rise to the liver and biliary tract, the proximal endoderm (foregut) also gives rise to respiratory epithelium and the glandular cells of the thyroid, thymus, and pancreas.

ENDODERMAL PATTERNING

Embryologically, the liver, biliary tract, and pancreas develop through a series of reciprocal interactions between the endoderm and the surrounding mesenchyme. The primitive gut tube, which is derived from the endodermal germ layer during gastrulation, is divided into the foregut, midgut, and hindgut domains, each of which gives rise to specialized regions (Grapin-Botton, 2005). This specialization is initiated by transcription factors expressed in different regions, such as pancreatic and duodenal homeobox gene 1 (*PDX1*) and pancreas-specific transcription factor 1a (*PTF1A*), whose coexpression in the endoderm gives rise to the pancreas (Fig. 1A.2) (Grapin-Botton, 2005; Moore-Scott et al, 2007). The definitive endoderm is formed at the ventral side of the vertebrate embryo during gastrulation. Evagination of the endoderm at the anterior end of the embryo generates the ventral foregut, which will eventually give rise to the liver, lung, thyroid, and the ventral pancreas. The dorsal region of the definitive endoderm develops into the intestines and the dorsal pancreas (see Fig. 1A.2).

This complex dialogue between the endoderm and mesoderm appears to be critical for the final patterning of the gut tube, where several signaling pathways have been implicated in the regulation of foregut endoderm development, promoting specification along its anterior–posterior axis for organs such as the thyroid, lung, liver, and pancreas. The plasticity of the endoderm was demonstrated by experimentally recombining the posterior mesoderm with early foregut endoderm, leading to repression of liver and pancreatic development in favor of intestinal development (Wells & Melton, 2000; Kumar et al, 2003).

Specific signals from the surrounding mesoderm in the foregut region lead to hepatic specification and subsequent morphogenesis (Guadi et al, 1996). The molecular pathway linking endodermal patterning to the initiation of liver and pancreatic development has been partially elucidated by recent studies in the *Xenopus* model, supporting a role for *FGF4* and *WNT* signaling from the posterior mesoderm in inhibiting foregut fate and promoting hindgut formation; these signals are inhibited in the anterior endoderm to allow foregut development (McLin et al, 2007). β-Catenin repression in the anterior endoderm is specifically necessary to initiate liver and pancreas development; β-catenin repression in the endoderm then initiates reciprocal signaling with the mesoderm, leading to hepatic induction. To illustrate β-catenin's role in this process, forced β-catenin expression in the anterior endoderm led to downregulation of the hematopoietically expressed homeobox gene (*HHEX*) and inhibition of liver formation, whereas repressing β-catenin in the posterior endoderm—future hindgut that normally expresses β-catenin—induced ectopic *HHEX* expression and ectopic liver bud initiation (McLin et al, 2007). *HHEX* is a direct target of β-catenin and is one of the earliest foregut markers (Thomas et al, 1998) that is essential for ectopic and normal liver and ventral pancreas development in mice (Keng et al, 2000; Bort et al, 2004). In addition to repressing *HHEX,* β-catenin also downregulates

other foregut markers for liver (for1) (Seo et al, 2002), pancreas (*PDX1*), lung/thyroid (*NKX2-1*) (Goss et al, 2009), and intestine (Endocut) (Costa et al, 2003). Similarly, inhibiting β-catenin in the posterior mesoderm led to ectopic expression of other liver and pancreas markers (for1, *PDX1,* elastase, and amylase) along with inhibition of the intestinal marker Endocut (McLin et al, 2007).

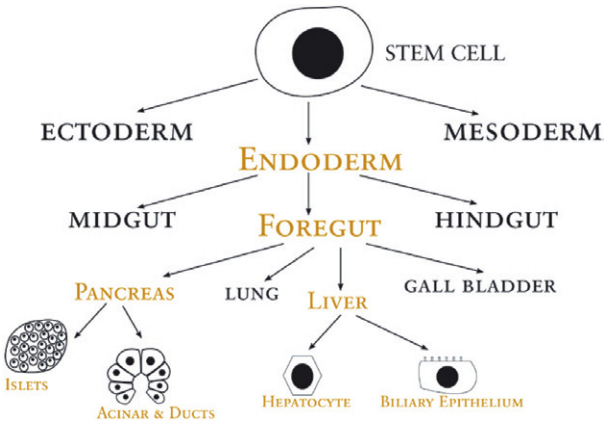

FIGURE 1A.1. Cell lineage schematic for hepatic and pancreatic development from a multipotent progenitor stem cell.

Studies in mouse and chick models demonstrated the need for an *FGF2* signal from the cardiogenic mesoderm and bone morphogenetic proteins (BMPs) from the septum transversum mesenchyme (Rossi et al, 2001; Zhang et al, 2004) for liver development. In addition, *WNT2B* has also been shown to be an important signal for liver specification in Zebrafish (Ober et al, 2006).

Other examples of transcription factors implicated in foregut patterning include the *HOX* genes. *HOXD13* is expressed in the hindgut of mouse and chick embryos (Yokouchi et al, 1995; Roberts et al, 1995; Dolle et al, 1991). Knockout mice homozygous and null mutant for *HOXD13* develop with hindgut defects (Kondo et al, 1996). Similarly, when *HOXD13* is misexpressed in chick embryo midgut mesoderm, hindgut features are seen in the midgut epithelium (Roberts et al, 1998). The exact mechanism of how the *HOX* genes induce endodermal patterning remains unknown, as the exact downstream targets are not clear. In addition to *HOX* genes, retinoic acid signaling has been implicated in this foregut patterning, probably through regulating *HOX* gene expression. Specifically, retinoic acid signaling appears to specify the position of the pancreatic domain in the foregut of *Xenopus*, Zebrafish, and mice (Huang et al, 1998; Chen et al, 2004; Martin et al, 2005; Stafford et al, 2004). Goss and colleagues (Goss et al, 2009) demonstrated that *WNT2* and *WNT2B* play an essential role in specifying lung endoderm without affecting the specification of other foregut-derived tissues. *WNT2/2B* double-knockout (DKO) mutants display complete lung agenesis. *NKX2-1,* the earliest known transcription factor marker for the developing lung,

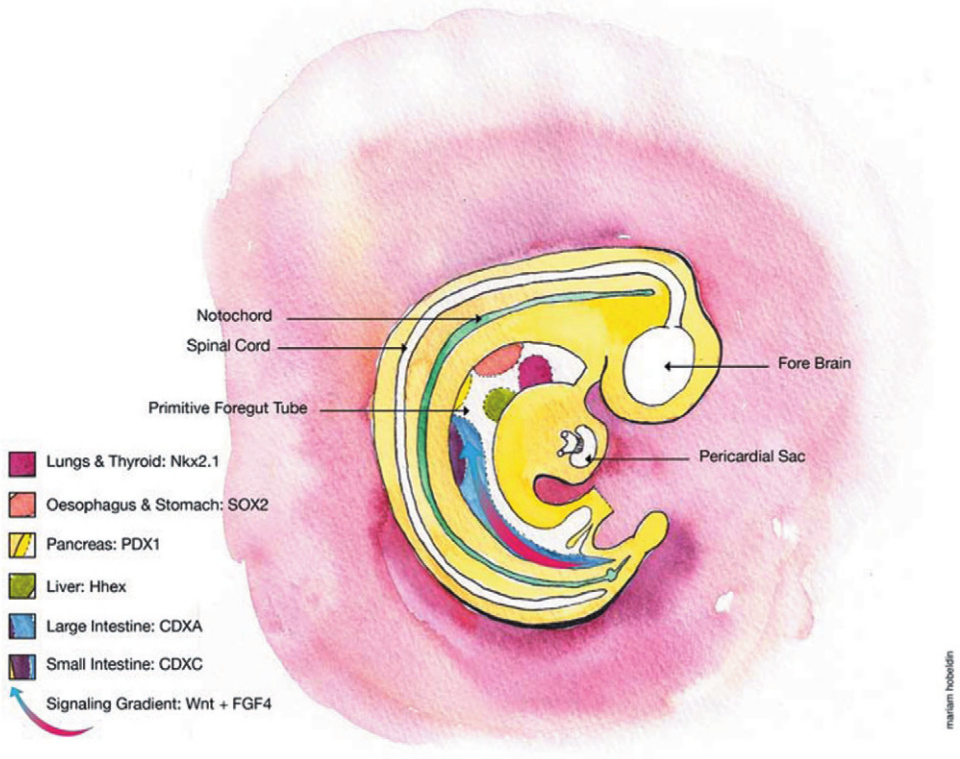

FIGURE 1A.2. Schematic representation of the regional specification of the primitive foregut tube (~E8.5) with the various transcription factors. Wnt and FGF4 (a fibroblast growth factor) are secreted from the posterior mesoderm in a gradient and repress foregut fate and promote hindgut development. Wnt and FGF4 inhibition in the anterior endoderm promote foregut fate. *(Image courtesy Mariam Hobeldin.)*

was also lost from the anterior foregut, confirming the loss of trachea and lung development.

Despite our growing knowledge of molecular signals that regulate endodermal patterning of the primitive foregut tube, most of the pathways remain poorly understood; exactly how these pathways confer regional identity remains unresolved. For example, the way in which the Wnt, Fgf, Bmp, and retinoic acid pathways functionally interact in the endoderm is not known.

Hepatic Competence

Hepatic competence, or the ability to form liver from the foregut endoderm, is considered the first step in a two-step process for the specification of the liver in vertebrates. Competence is a prerequisite for the endoderm to respond to specific signals, such as Fgfs from the surrounding mesoderm, which then leads to the second step, the induction of liver specific genes such as *ALB* (albumin). This "competence" is facilitated through the *FOXA* gene transcription factor family that includes *FOXA1* and *FOXA2* (forkhead box proteins A1 and A2). *FOXA* gene expression precedes the induction of the hepatic program by *FGF* signals in the endoderm, and *FOXA2* binding revises α-fetoprotein (*AFP*) gene transcription in vitro (Crowe et al, 1999). Deletion of *FOXA1* and *FOXA2* led to no liver bud formation with the loss of *AFP* expression in the ventral foregut, which would indicate that hepatic specification had failed to initiate (Lee et al, 2005). The forkhead box (*FOX*) proteins are an extensive family of transcription factors that share homology with the winged helix/forkhead DNA binding domains (Kaestner et al, 2000) that play important roles in regulating expression of genes involved in cellular differentiation, proliferation, transformation, and metabolic homeostasis (Wang et al, 2001; Zaret et al, 1999; Duncan, 2000). In vitro explant cultures demonstrated that Fgf was sufficient to induce ventral foregut endodermal cells to differentiate into hepatoblasts (Guadi et al, 1996). However, when *FOXA1*/*FOXA2*-deficient endoderm was cultured with exogenous Fgf2, no liver expression was seen (Lee et al, 2005). This result would indicate the need for *FOXA1* and *FOXA2* for the onset of hepatogenesis. In vivo DNA-binding studies revealed that the liver-specific albumin gene *ALB* has an important upstream regulatory binding site for *FOXA* factors (Guadi et al, 1996; Bossard & Zaret, 1998). Prior to *FOXA* or *GATA4* binding, the *ALB* gene is transcriptionally silent with a closed chromatin. After binding with *FOXA* and *GATA4,* the chromatin domain is thought to become exposed (Cirillo et al, 2002), thus increasing the ability of the gene to be activated. By the E9.5 gestation stage, other transcription factors—CCAAT/enhancer binding protein-β (*CEBPB)* and *NF1,* nuclear factor 1—bind to sites adjacent to the *FOXA* site, and as a result, the albumin gene becomes active (Zaret, 2002). The critical binding of *FOXA* to chromatin increases the ability of the gene expression to be activated by allowing other transcription factors to bind, hence the hepatic competence.

Hepatic Induction

Fgf from the cardiogenic mesoderm and Bmps from the septum transversum mesenchyme have been implicated in the induction of liver fate in mouse and chick embryonic endoderm. In vitro studies were performed in which the ventral foregut and cardiogenic mesoderm were cocultured in the presence of fibroblast growth factor inhibitors, resulting in the inhibition of liver induction (Jung et al, 1999). Culturing foregut endoderm without the cardiogenic mesoderm in the presence of a low concentration of exogenous FGF2 (2 to 5 ng/mL) rescued hepatic gene expression (Jung et al, 1999) and simultaneously suppressed the expression of the pancreas program (*PDX1* expression) (Deutsch et al, 2001), whereas a high concentration of FGF2 (10 to 500 ng/mL) induced *NKX2-1,* an early marker for respiratory epithelium but not albumin gene expression (Serls et al, 2005). Ventral foregut endoderm cocultured with noggin (Nog), a Bmp inhibitor, inhibited hepatic gene induction, an effect that was rescued when Bmp2 or Bmp4 were added. Despite these results, however, embryos that were homozygous mutant for *BMP4* still exhibited normal hepatic gene induction (Rossi et al, 2001; Smith & Harland, 1992). These data indicate that the cardiac mesoderm, a source for *FGF* signaling, is crucial for the hepatic induction from the ventral foregut endoderm and subsequent morphogenesis, whereas Bmp aids in the process as well (Fig. 1A.3).

Morphogenesis of the Hepatic Bud

Following hepatic specification (E8.5 to E9.0), the liver starts to express liver-specific genes (*ALB, AFP, HNF4A*) that eventually form the liver bud. Hepatic bud morphogenesis is facilitated by two transcription factors, *HHEX* (hematopoietically expressed homeobox, discussed above) (Crompton et al, 1992) and *PROX1* (prospero-related homeobox 1) (Oliver et al, 1993). *HHEX* is expressed in the anterior endoderm at E7.0, eventually giving rise to the ventral pancreas and liver. *HHEX*-null embryos grow without a liver, thyroid and develop forebrain defects at E11.5; however, evidence of endodermal epithelial thickening suggest a possible defect in differentiation as evidence of possible hepatic induction (Martinez-Barbera et al, 2000).

In a separate study on *HHEX*-null embryos, liver genes *ALB* and *PROX1* were expressed in the ventral foregut endoderm at around E8.5, with the thickening of the hepatic endoderm region at E9.0 being smaller compared with heterozygote embryos. In addition, a significantly lower proliferation rate was seen in the prospective hepatic domain compared with controls, as demonstrated by bromodeoxyuridine (BrdU) staining, with no evidence of apoptosis (Bort et al, 2004). The basal membrane layer, which is rich in laminin, surrounds the hepatic endoderm and degrades around E9.0 to E9.5, so that the hepatocytes start migrating into the septum transversum mesenchyme (STM) to form the liver bud. This degradation is facilitated by the hepatoblasts, which under normal conditions downregulate E-cadherin. However, in *PROX1*-null mutant embryos, the progenitor liver cells fail to migrate into the STM as a result of excess E-cadherin and basement membrane proteins laminin and collagen 4. The basal lamina fails to degrade, and the cells remain trapped in the hepatic diverticulum with an overall reduction in liver size (Sosa-Pineda et al, 2000). The bulk of the liver lobe lacks hepatocytes, suggesting that the mesenchymal component contributes most of the liver mass in *PROX1*-null mutant embryos. A similar phenotype is seen with *ONECUT1* and *ONECUT2* double mutants, which are required for basal lamina degradation (Margagliotti et al, 2007). Furthermore, pharmacologic inhibition of matrix metalloproteinases (MMPs), extracellular matrix remodeling enzymes usually expressed by hepatoblasts and STM cells,

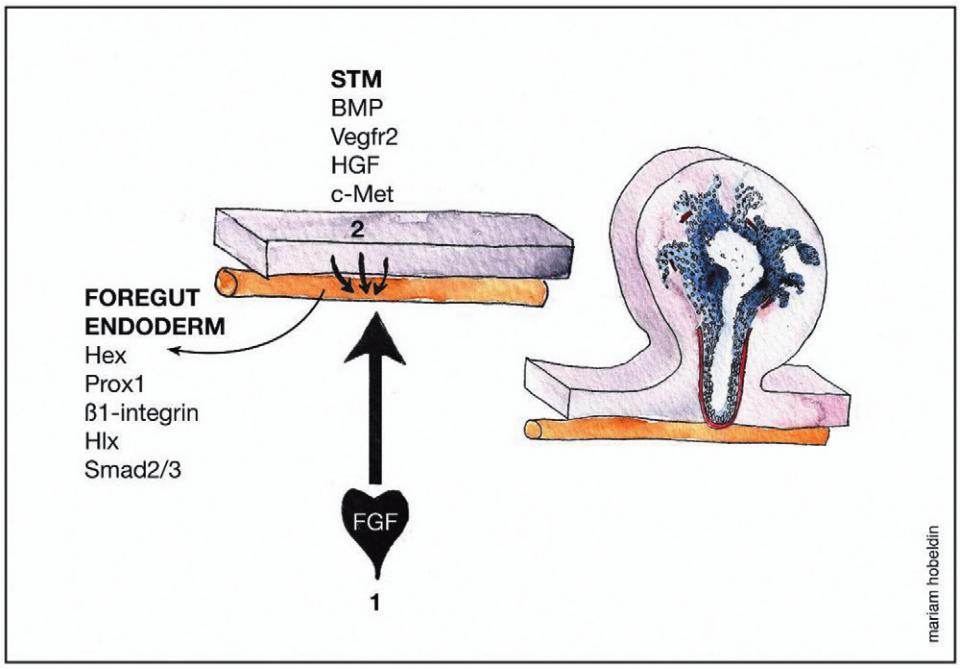

FIGURE 1A.3. Schematic for liver ontogeny controlled by factors released from the cardiogenic mesenchyme (*1*) and septum transversum mesenchyme (*STM, 2*), which induce hepatic specification. Signaling molecules (e.g., Vegfr2, HGF) and transcription factors (e.g., Prox1, Hlx) from STM and endothelial cells leads to delamination and migration of endodermal cells into the STM to subsequently form the liver bud. BMP, bone morphogenetic protein; HGF, hepatocyte growth factor; c-Met, HGF receptor; Vegfr2, vascular endothelial growth factor receptor 2. *(Image courtesy Mariam Hobeldin.)*

inhibits hepatoblast migration in culture (Margagliotti, 2008). To further illustrate the importance of the extracellular matrix in hepatic bud morphogenesis, hepatoblasts deficient in laminin receptor β1-integrin fail to colonize the liver bud (Fassler & Meyer, 1995). These β1-integrins are among those that act as receptors for extracellular matrix proteins, such as laminins and collagens (Hynes, 1992).

In summary, *PROX1* and *ONECUT* factors are important in regulating delamination and in controlling hepatoblast migration through regulating MMPs and hepatoblast interactions with the extracellular matrix. Without an appropriate extracellular matrix, cell migration into the STM will be disrupted.

The role of endothelial cells in liver organogenesis has also been studied, with the liver vasculature providing a vital source for hematopoiesis in early life. Endothelial cells are positioned as a loose chain of cells interceding between the thickening hepatic epithelium and the STM (Matsumoto et al, 2001). Embryos that were null mutant for *VEGFR2* (also known as *KDR*) had failure of delamination and subsequent migration by the hepatoblasts (Matsumoto et al, 2001). These results imply that the endothelial cells interact with nascent hepatic cells and aid in liver bud outgrowth.

Liver Bud Growth

The STM cells are closely related to the ventral endoderm and contribute to hepatic induction and growth. This epithelial–mesenchymal interaction is essential for the formation of the liver bud as well as for further expansion and differentiation. During this phase (E9.5 to E15), the liver bud undergoes a tremendous amount of growth and also becomes an important site for hematopoiesis. Factors and signals regulating this critical stage arise from both the hepatic mesenchyme and the STM. These signals include Fgf and Bmp, which promote liver growth in addition to their role in hepatic specification. Bmp4 is strongly expressed in the STM and continues to be expressed at E9.0, during which the liver bud migrates into the STM (Rossi et al, 2001). *BMP4*-null mutant embryos were developed to assess for a role in liver organogenesis. These null-mutant mice had a delay in the growth of the liver bud, which would indicate that Bmp constitutes an important growth signal for the liver (Rossi et al, 2001).

Another factor that has been implicated in liver growth is *HLX,* which is expressed prominently in the visceral mesenchyme (STM), into which the liver will expand (Hentsch et al, 1996). *HLX*-null embryos exhibited severe liver hypoplasia without affecting liver specification (Hentsch et al, 1996). A similar finding was observed in embryos that were null mutant for hepatocyte growth factor (Hgf) (Schmidt et al, 1995). In contrast to *HLX*–/– embryos, apoptosis was the underlying cause for the severe reduction in liver size. Hgf is produced by the cells lining the sinusoids, which are of mesenchymal origin, mediating its effects through the c-Met tyrosine kinase receptor produced by hepatocytes (Schmidt, 1995). TGF-β signaling is also involved in liver outgrowth. It mediates its signals through SMAD2 and SMAD3, which after phosphorylation translocate to the nucleus to either upregulate or downregulate gene expression. Embryos that were heterozygous mutants for both *SMAD2* and *SMAD3* exhibited severe liver hypoplasia as a result of a decrease in β1-integrin expression (Weinstein et al, 2001).

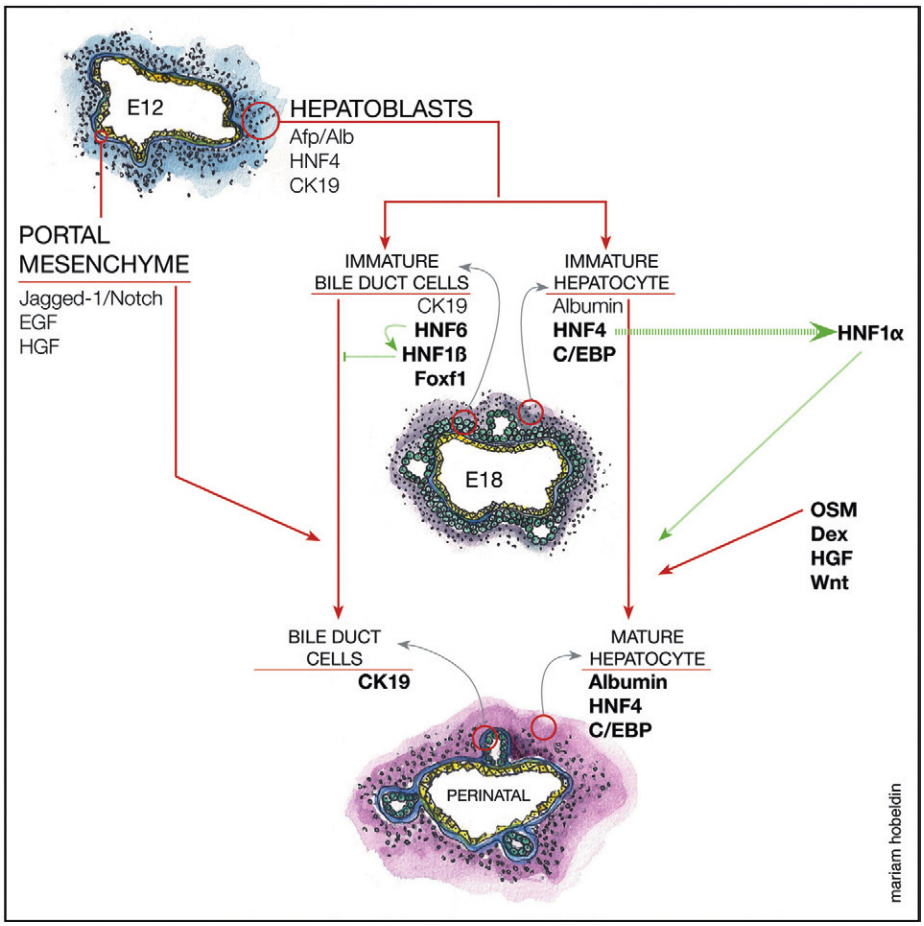

FIGURE 1A.4. Overview of differentiation of hepatoblasts into mature hepatocytes and bile duct cells. Bipotential hepatoblasts initially express markers for both hepatocytes (Alb, Afp) and biliary epithelial cells (KRT19). Hepatoblasts in the periportal mesechymal area upregulate KRT19 and downregulate hepatogenic transcription factors (HNF4, CEBP) to form mature biliary epithelial cells. Further signaling from the portal mesenchyme (Notch, HGF) aid duct remodeling. The rest of the hepatoblasts upregulate hepatogenic factors. Other factors (OSM, dexamethasone) help in maturation of mature hepatocytes. HGF, hepatocyte growth factor; EGF, epidermal growth factor; OSM, oncostatin M; Dex, dexamethasone; Alb, albumin; Afp, α-fetoprotein; HNF, hepatocyte nuclear factor. *(Image courtesy Mariam Hobeldin.)*

Intriguingly, this phenotype was rescued when HGF, a potent hepatotrophic growth factor, was added to the culture medium. Presumably, this was a result of the restoration of β1-integrin expression (Kagami et al, 1996), which plays an important role in hepatocytic adhesion to the extracellular matrix; TGF-β and HGF are known to induce the gene (Kagami et al, 1996; Kawakami-Kimura et al, 1997).

OVERVIEW OF HEPATOBLAST DIFFERENTIATION

Hepatoblasts begin to differentiate into mature hepatocytes and biliary epithelial cells at around E13.5. Prior to differentiation, the hepatoblasts express genes for adult hepatocytes (*ALB, HNF4A*), biliary epithelial cells (*KRT19*), and fetal liver (*AFP*) (Lemaigre, 2003; Shiojiri et al, 1991). Hepatoblasts in proximity to the portal vein form a bilayer and eventually differentiate into biliary epithelial cells, upregulating biliary-specific cytokeratin-19 (*KRT19*) and downregulating the other hepatic genes in the process. This bilayer around the portal vein begins to form focal dilations incorporated into the portal mesenchyme to form intrahepatic biliary ducts at E17.0 until birth. Those parts of the ductal bilayer plate not involved in the formation of the ducts progressively regress, and the rest of the hepatoblasts differentiate into mature hepatocytes, arranged in hepatic cords with the bile canaliculi on the apical surfaces (Lemaigre et al, 2003). The bile is produced by the hepatocytes and is secreted into the canaliculi, which are connected to the network of intrahepatic biliary ducts. The bile then flows to the hepatic ducts, transits through the cystic duct, and is stored in the gallbladder; eventually, the bile is excreted into the bowel via the common bile duct. The biliary epithelial cells delineate the lumen of the intrahepatic and extrahepatic biliary tree (hepatic, cystic, and common bile ducts) and the gallbladder (Fig. 1A.4).

Biliary Epithelial Cell Differentiation and Formation of the Ductal Plate

The exact origin of the biliary epithelial cells has been greatly debated; however, the popular school of thought is that they are derived from bipotential hepatoblasts that can differentiate into

either hepatocytes or biliary epithelial cells. This theory is based on the observation that immature hepatoblasts coexpress markers of both hepatocytes (*ALB*) and biliary epithelial cells (*KRT19*). The biliary-specific marker *KRT19* becomes strongly expressed at a later gestational age, as the cells become ductal cells, whereas other cells transiently express the hepatocyte markers *ALB* and *AFP* as they develop into mature hepatocytes (Shiojiri et al, 1991). This theory was further supported when embryonic liver was transplanted into the testes of syngeneic animals, before the emergence of intrahepatic biliary ducts, as it subsequently gave rise to both hepatocytes and typical bile ducts (Shiojiri et al, 1991). However, this finding does not exclude the possibility that ductal cells may be derived from other embryonic cell types. Suzuki and colleagues (Suzuki et al, 2002) used in vitro studies on hepatic "stem" cells from E13 embryonic livers identified as having self-renewing capability and multilineage differentiation potential, to show that these cells could form differentiated hepatocytes, biliary epithelial cells, pancreatic, and intestinal cells.

The first step in triggering the initiation of the transition from a hepatoblast to a biliary epithelial cell is thought to be facilitated through the *ONECUT* transcription factor hepatocyte nuclear factor 6 (*HNF6*), which is expressed in the biliary epithelial cells of the developing intrahepatic biliary ducts and in hepatoblasts, gallbladder primordium, and the extrahepatic bile ducts (Landry et al, 1997; Rausa et al, 1997). HNF6–/– embryos displayed severe biliary anomalies that resulted in an absent gallbladder and the extrahepatic bile duct network being replaced with an enlarged structure connecting the liver to the duodenum. In the intrahepatic biliary ducts, however, it caused abnormal differentiation of biliary epithelial cells, resulting in cholestasis. Closer histologic examination revealed an increased number of *KRT19*-positive cells compared with controls at E13.5, with the development of abnormal large cysts at E15.5 to E16.5 that contained an epithelium of *KRT19*-expressing cells. These abnormal cysts are similar to those seen in Caroli disease, a disorder with ductal plate malformation and ectasias. Although *HNF6* might play a role in the disease, not all of the malformations seen in *HNF6*–/– mice are manifested in Caroli disease, such as the absence of the gallbladder. The abnormal increase in *KRT19*-positive cells at E13.5 lacked any proliferative marker, suggesting that they are postmitotic, resulting from an increased number of hepatoblasts that have differentiated toward a biliary lineage prematurely (Clotman et al, 2002). In addition, the excess *KRT19*-positive biliary epithelial cells formed cordlike extensions within the liver parenchyma, rather than being restricted to the vicinity of the portal vein, as seen in the controls. This observation supports the role of *HNF6* in controlling the differentiation of hepatoblasts into biliary epithelial cells and the morphogenesis of the intrahepatic biliary ducts, confining biliary epithelial cells to the periportal area. A similar morphologic defect of intrahepatic biliary ducts was observed in *HNF1B*–/– embryos. These findings suggest that *HNF6* controls intrahepatic biliary duct development via *HNF1B* (Clotman et al, 2002).

With regard to mesenchymal–epithelial induction of liver primordium and gallbladder, studies have suggested that the mesenchyme contributes to biliary epithelial cell differentiation, where differentiation of hepatoblasts into biliary epithelial cells was stimulated when cocultured with hepatic or lung mesenchyme (Shiojiri & Koike, 1997). It was also noted in the *HNF6*–/– study that biliary epithelial cell differentiation occurred at the interface between the portal mesenchyme and the liver parenchyma (Clotman et al, 2002). A recent study revealed that the forkhead box f1 (*FOXF1*) transcription factor may play an important role in mesenchymal–epithelial signaling, an interface required for the development of organs derived from foregut endoderm, such as the pancreas, liver, gallbladder, and lung (Kalinichenko et al, 2002). *FOXF1* expression is restricted to the gallbladder mesenchyme and STM. In *FOXF1*+/–, the gallbladder develops severe structural abnormalities with significant reduction in size and reduced mesenchymal cell numbers, an absent biliary epithelial cell layer, and a deficient external smooth muscle layer. The reduction in mesenchymal cell numbers was attributed to the reduction in the vascular cell-adhesion molecule (*VCAM1*) and cell-adhesion α5 integrin (*ITGA5*) genes, both of which are essential for mesodermal formation (Mahlapuu et al, 2001; Yang et al, 1993). Defective smooth muscle layer formation was attributed to diminished levels of platelet-derived growth factor receptor α (*PDGFRA*), which is essential for smooth muscle cell differentiation (Jacob et al, 1994). *FOXF1* is not expressed in intrahepatic biliary duct mesenchyme in wild-type mice, and no defects were seen in the intrahepatic biliary ducts of *FOXF1*+/– mice; however, *FOXF1* mRNA levels in the liver were increased, suggesting that it may be a compensatory mechanism to prevent defects in the liver (Kalinichenko et al, 2002). All these data suggest that *FOXF1* is crucial for the development of the extrahepatic bile ducts and gallbladder, with the mesenchyme playing an essential role in biliary epithelial cell differentiation. The interaction between the biliary epithelial cells and the extracellular matrix is also thought to contribute to biliary epithelial cell differentiation.

Integrins are membrane receptors for extracellular matrix proteins that play an important role in mediating the interaction between differentiating cells and the extracellular matrix (Hynes, 1992; Couvelard et al, 1998). Hepatoblasts express integrin heterodimers containing the β1 subunit (α1β1, α5β1, α6β1, and α9β1), and when hepatoblasts differentiate into immature intrahepatic biliary epithelial cells when in contact with the mesenchyme, the morphology of the integrins changes. The primitive intrahepatic biliary epithelial cells upregulate α6β1 expression and lose α1β1, while acquiring several other integrin dimers not previously expressed on hepatoblasts, including α2β1, α3β1, α5β1 and α6β4 (Couvelard et al, 1998). This change is likely due to the different pericellular environment. Intrahepatic biliary epithelial cells are contacted by a basement membrane containing collagen, entactin, and laminin (Desmet, 1985); however, hepatocytes are surrounded by the perisinusoidal matrix, which is devoid of laminin and entactin (Schuppan, 1990). The increase in α6β1 expression—along with the acquisition of biliary-specific expression of α2β1, α3β1, and α6β4, which are integrin receptors for laminin—correlated with the deposition of laminin at the contact points of the portal mesenchyme with the ductal plate (Couvelard et al, 1998).

Remodeling of the Ductal Plate

As mentioned earlier, the double-layered ductal plate around the portal vein begins to form focal dilations incorporated into the portal mesenchyme to form intrahepatic biliary ducts, while the parts of the ductal bilayer plate not involved in the formation of the ducts progressively regresses. This mechanism

of regression is thought to be carried out by apoptosis (Terada & Nakanuma, 1995; Sergi et al, 2000). Cell-matrix interactions are also thought to contribute to the remodeling process. Tenascin was found to be expressed in the mesenchyme around the biliary epithelial cells of primitive ducts migrating into the mesenchyme. In contrast, tenascin was absent in the mesenchyme of peripheral ducts (Terada & Nakanuma, 1994).

Tubulogenesis of ductal cells is thought to be controlled by soluble factors secreted from hepatocytes or biliary epithelial cells. When coculturing human biliary epithelial cells with hepatocytes, a marked ductular morphogenic response was induced, and the biliary epithelial cells formed well-organized luminal ducts. This result was reproduced when biliary epithelial cells were grown in a conditioned medium from previous hepatocyte and biliary epithelial cell coculturing (Auth et al, 2001); however, it remains to be seen whether soluble factors do contribute to tubulogenesis in in vivo studies (Fig. 1A.5).

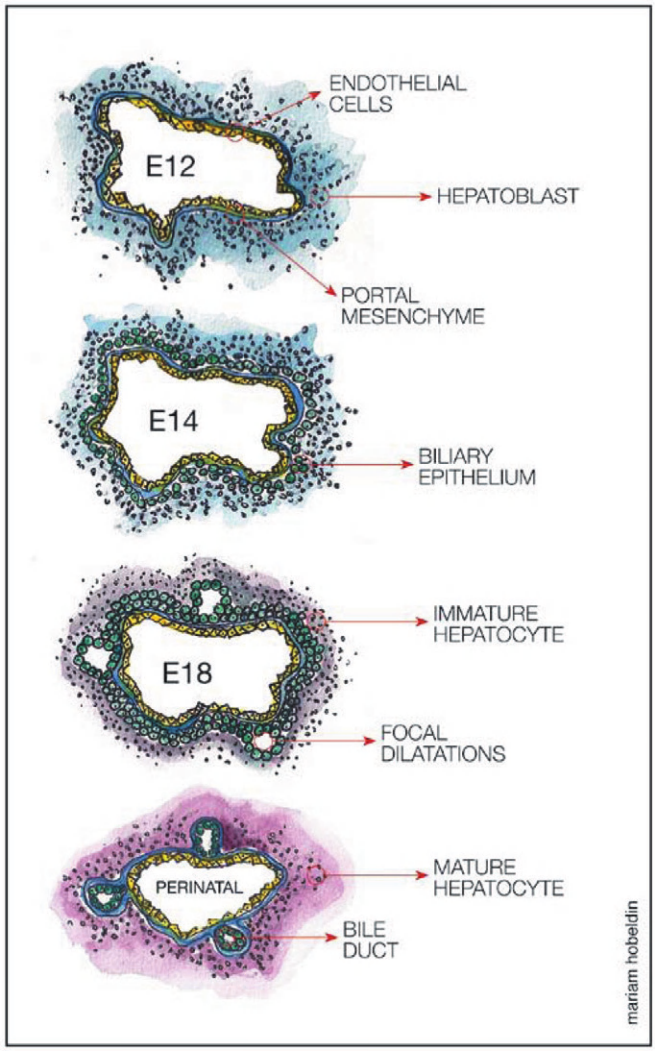

FIGURE 1A.5. Overview of intrahepatic bile duct formation around the portal vein. Hepatoblasts in the portal mesenchyme vicinity begin to acquire the biliary epithelial cell marker (KRT19) and downregulate hepatic genes, first forming a single layer at E14 then a bilayer at E18 with focal dilations that eventually form the intrahepatic bile ducts. The rest of the bilayer regresses. *(Image courtesy Mariam Hobeldin.)*

Developmental Relationship Between the Ducts, Vessels, and Mesenchyme of the Portal Tract

A functional relationship appears to exist between the contents of the portal tract (bile duct, hepatic artery, portal vein) based on observations of a number of human diseases termed *ductal plate malformations*. These diseases include biliary atresia, Caroli disease, and Meckel and Alagille syndromes, in which abnormal biliary ducts are associated with anomalies of the portal mesenchyme and of the portal blood vessels (Lemaigre, 2003). This association was also demonstrated in studies on Notch pathway defects. In Alagille syndrome, an autosomal dominant disease, bile ducts are absent in the portal tract associated with an increased number of arteries and fibrosis. Haploinsufficiency of JAG1, a Notch receptor ligand, is associated with Alagille syndrome, where JAG1 is persistently expressed in the ductal epithelium in humans (Li et al, 1997; Louis et al, 1999). It is also expressed in the endothelial cells of the developing portal vasculature (Crosnier et al, 2000). The animal model for Alagille syndrome was replicated in double-heterozygous mice for mutations in the *JAG1* and *NOTCH2* genes (J1N2+/–). JAG1 protein was expressed in the hepatic vasculature, and NOTCH2 was expressed in a subset of hepatoblasts surrounding the portal vein, hepatic artery, and bile ducts. Interestingly, although neither JAG1 nor NOTCH2 protein was expressed in the bile duct epithelium of these mice, JAG1 is expressed in bile duct epithelium in humans (Louis et al, 1999; McCright et al, 2002). The differences in JAG1 expression between human and mouse most likely reflects species specificity rather than technical artifacts, as mice that are heterozygous or homozygous for the *JAG1* gene did not show the liver symptoms of Alagille syndrome (Xue et al, 1999). Similar biliary abnormalities were observed in *NOTCH2*-null mutant mice (McCright et al, 2002).

Hepatocyte Differentiation

During later stages of development, hepatocytes undergo a transition period from a hematopoietic support role to a mature adult hepatocyte. This change occurs under the control of the transcription factor CEBPα and *HNF4*, the latter being a crucial factor in hepatocyte differentiation. Loss of *HNF4* function led to disruption of the expression of several genes associated with the mature hepatocyte phenotype. In *HNF4*–/– mice, hepatocytes failed to express many mature hepatic enzymes and lacked normal morphology, leading to low glycogen stores, disrupted sinusoids, and gap junction disruption. These results demonstrate that *HNF4* is essential for liver differentiation.

Other factors that have been shown to promote hepatocyte differentiation include oncostatin M (OSM), an interleukin-6 family cytokine, Hgf, and Wnt (Michalopoulos et al, 2003; Tan et al, 2008). Although as discussed earlier in the chapter, the repression of Wnt signaling in the foregut endoderm is necessary for hepatic specification, its role is reversed at later gestational stages to promoting hepatocyte differentiation. β-Catenin, a central component of the canonical Wnt pathway, is essential for normal development; its aberrant activation in liver was associated with tumors, including hepatic adenomas and hepatocellular cancers (Peifer & Polakis, 2000; de La Coste et al, 1998; Zucman-Rossi et al, 2006). Livers that were deficient in

β-catenin displayed decreased numbers of hepatocytes with hepatoblasts that lacked maturation, proliferation, and function (Tan et al, 2008). In addition, CEBPα, a fundamental regulator of hepatocyte differation and maturation (Tan et al, 2008), was decreased. Also noted in these livers was a complete absence of CK-19-positive intrahepatic biliary ducts, suggesting that β-catenin may play a role in biliary differentiation (Tan et al, 2008). In vitro studies showed that OSM, produced by hematopoietic cells in midfetal liver, and Hgf induce hepatic differentiation in the presence of dexamethasone, both working through different pathways (Kamiya et al, 2001). It was demonstrated that embryonic livers at E14.5 expressed G6Pase, tyrosine amino transferase (TAT), and accumulated glycogen, all signs of a mature and differentiated liver when cultured with Hgf or Osm. This finding was further supported when TAT levels, as well as glycogen storage, was significantly reduced in livers derived from mice null mutant for gp130, the common receptor subunit of the IL-6 family cytokines (Kamiya et al, 2001). CEBPα is also critical for the acquisition and maintenance of hepatocyte differention, with knockout mice exhibiting defects in liver growth and architecture as well as an increase in cell proliferation (Flodby et al, 1996). CEBPα is also thought to be a key factor in controlling the switch in the differentiation of bipotential hepatoblasts to become either biliary epithelial cells or hepatocytes. CEBPα starts to be expressed in the endodermal liver primordium at E9.5, and its expression in the nuclei of hepatoblasts and hepatocytes becomes stronger with development. During biliary cell differentiation, CEBPα expression was suppressed in periportal biliary cell progenitors, suggesting that its suppression may be a prerequisite to biliary cell differentiation from hepatoblasts (Shiojiri et al, 2004). Lineage tracing experiments have recently shown that Sox9+ biliary epithelial cells themselves differentiate into mature hepatocytes under normal physiologic conditions (Furuyama et al, 2011). Hepatocyte differentiation from the lineage tagged Sox9+ bile duct cells increased during the hepatic regenerative process, suggesting that the biliary and pancreatic ductal tree (Sox9-expressing domains) contains a previously unappreciated pool of progenitor cells.

OVERVIEW OF PANCREATIC DEVELOPMENT

The pancreas consists of two morphologically distinct tissues, *exocrine* and *endocrine,* which must derive from one simple epithelium. This feature has intrigued developmental biologists for years. The morphologic development of the pancreas is dictated by its two major functions: production of digestive enzymes by the exocrine acinar tissue and regulation of blood chemistry by the endocrine tissue. Some have even described the pancreas as two organs in one because of the disparate function and organization of these two tissues in the pancreas.

The endocrine pancreas is organized into islets of Langerhans, which consist of five cell subtypes—α, β, δ, ε, and PP cells—that secrete glucagon, insulin, somatostatin, ghrelin, and pancreatic polypeptide, respectively. All totaled these cells occupy only 2% of the adult pancreatic mass (Gittes, 2009). The exocrine pancreas, on the other hand, produces digestive enzymes, is composed of acinar and ductal epithelial cells, and accounts for nearly 98% of the adult pancreatic mass.

Basic Pancreatic Embryology

During early development, the pancreas is formed by the dorsal and ventral bud, each originating from the endodermal lining of the caudal part of the primitive foregut tube after regional specification with transcription factor Pdx1 followed by Ptf1a (Sadler & Langman, 2006; Grapin-Botton, 2005; Moore-Scott et al, 2007). The first morphologic evidence of pancreas development is in the form of mesenchymal condensation overlying the dorsal aspect of the primitive foregut tube at the level of the duodenal anlagen, distal to the stomach. Shortly after, at around E9.5 gestation in mice and day 26 of gestation in humans, the dorsal bud begins to evaginate into the overlying mesenchyme (Kallman & Grobstein, 1964; Picte et al, 1972). Approximately 12 hours later in mice, and 6 days after dorsal bud evagination in humans, the ventral bud begins to arise.

The morphologic development of the ventral pancreatic bud is similar to the dorsal bud; however, it is markedly different at the molecular level. After this initial bud evagination, the pancreatic bud then undergoes elongation of the stalk region, a precursor to the main pancreatic duct and branching morphogenesis of the apical region of the bud. Unlike growth patterns seen in the developing lung, kidney, and salivary glands, in which the branching morphogenesis undergoes a typical 90-degree pattern, the pancreas grows in an acute-angled branching pattern, which can lead to the exclusion, or "squeezing out," of mesenchyme from between the closely apposed branches of epithelium. This exclusion of mesenchyme may influence epithelial–mesenchymal interactions and lineage selection (Fig. 1A.6). The ventral pancreatic bud, which arises from the base of the hepatic diverticulum, rotates dorsally and eventually fuses with the dorsal pancreatic bud (6 to 7 weeks gestation in humans, E12 to E13 in mice), contributing to the formation of the uncinate process and inferior part of the head of the pancreas, with the rest of the pancreas arising from the dorsal pancreatic bud. The entire ventral pancreatic duct and the distal part of the dorsal pancreatic duct fuse together to form the main pancreatic duct of Wirsung. The remaining proximal part of the dorsal pancreatic duct is either obliterated or persists as a small accessory pancreatic duct, the duct of Santorini (Sadler & Langman, 2006).

During development the pancreas undergoes a major amplification of the endocrine cell population through two waves of differentiation: an early *primary transition* (pre-E13.5 in mice) followed by the *secondary transition* (E13.5 to E16.5 in mice) (Picte et al, 1972; Jensen, 2004). In a similar gestational window, the exocrine pancreatic precursors undergo rapid branching morphogenesis and acinar cell differentiation (see Fig. 1A.6).

Endodermal Patterning of the Pancreas

As mentioned earlier, the pancreas develops through epithelial–mesenchymal interactions. Prior to this, the dorsal foregut became competent to receive propancreatic signals from the notochord (FGFs) (Wells & Melton, 2000) and from the anterior foregut (retinoic acids and BMPs) (Stafford & Prince, 2002; Tiso et al, 2002). The prepancreatic region of the definitive foregut comes into contact with the notochord, whereas the ventral pancreas contacts the lateral plate mesoderm (Kumar et al, 2003).

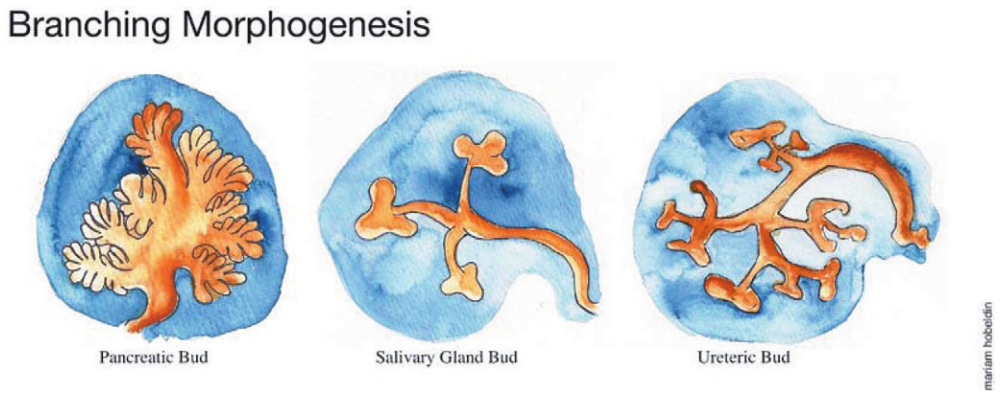

FIGURE 1A.6. Pancreatic branching morphogenesis is different than in other organ systems—such as lungs, kidneys, and salivary glands—which branch in a 90-degree pattern to be fully exposed to the mesenchyme. However, the pancreas has an acute branching pattern; thus some areas are excluded from mesenchymal contact. Mesenchyme contains factors that regulate pancreatic growth and differentiation. *(Image courtesy Mariam Hobeldin.)*

Dorsal and Ventral Pancreatic Bud Development

The notochord is key to the development of the dorsal pancreas, where it remains in contact with the dorsal prepancreatic endoderm until the paired dorsal aortae fuse in the midline (~E8.0). The dorsal pancreas failed to form when the notochord was removed from early chick embryos in vitro (Kim et al, 1997), but no effect was seen on ventral pancreas development, further emphasizing the different molecular controls for dorsal versus ventral pancreas development. The ventral pancreas develops under the control of signals from the overlying cardiogenic mesenchyme, which also produces prohepatic signals (FGFs) to induce liver formation. Lack of prohepatic FGF signaling in regions of the cardiogenic mesenchyme will lead to the endoderm by "default" differentiating into ventral pancreas (Deutsch et al, 2001). Sonic Hedgehog (*SHH*) in the prospective pancreatic endoderm is suppressed by the notochord, which is necessary for dorsal pancreatic development, and *SHH* is otherwise expressed along the entire primitive gut tube epithelium. When the notochord was deleted in chick embryo cultures, ectopic *SHH* was seen in the pancreatic region of the foregut endoderm, and the pancreas failed to develop (Hebrok et al, 1998).

Pancreatic Mesenchyme

The pancreatic epithelium becomes enveloped by mesenchyme, which contains important factors that are pivotal for pancreatic morphogenesis. The mesenchyme has a general proexocrine effect on the pancreas through cell contact and through proendocrine effect, mediated by diffusible factors secreted from the mesenchyme (Li et al, 2004). Mesenchymal contact with the epithelium both enhances notch signaling (*HES1*), which favors the acinar lineage and also inhibits neurogenin 3 expression (*NEUROG3*), leading to the suppression of endocrine differentiation (Duvillie et al, 2006). The "default" differentiation of the pancreatic epithelium in the absence of mesenchyme is endocrine (Gittes et al, 1996). Thus the mesenchyme has both an inductive effect on the exocrine tissue development and a repressive effect on the development of endocrine cells.

The interaction between the mesenchyme and the pancreatic epithelium is regulated by several factors, the most important of which appears to be the FGFs, which are expressed in several epithelial–mesenchymal interface regions of the pancreas and are particularly important in regulating branching morphogenesis (Hogan, 1999). FGFs 1, 7, and 10 mediate their effect through FGF receptor 2B (FGFR2B) to induce epithelial proliferation, favoring exocrine differentiation (Elghazi et al, 2002; Celli et al, 1998; Dichmann et al, 2003). Null mutation for *FGF10* or *FGFR2B* leads to blunting of branching pancreatic morphogenesis with a lack of proliferation of endocrine progenitor cells, indicating that FGF10 induces proliferation of epithelial cells and prevents endocrine differentation (Bhushan et al, 2001; Pulkkinen et al, 2003). These roles for FGFs are primarily for ongoing development of the buds, in contrast to the role of FGF from the cardiogenic mesenchyme, which inhibits ventral pancreatic bud formation in favor of liver development (Deutsch et al, 2001).

TGF-β Signaling

The TGF-β superfamily has been implicated in early pancreatic development. TGF-β isoforms (TGF-β1, -β2, and -β3) are localized to the pancreatic embryonic epithelium as early as E12.5 and progressively become focused to the acinar cells (Crisera et al, 1999). The ligands mediate their actions through TGF-β receptor type II (TBR-II), a heterodimer receptor; however, in late gestation it localizes to the pancreatic ducts (Tulachan et al, 2007). TBR-II inhibition has been shown to recruit an inappropriately high number of ductal cells to become endocrine progenitor cells, suggesting that TBR-II signaling is important for regulating the flow of endocrine progenitors out of ducts (Sanvito et al, 1995; Lee et al, 1995).

Activins, part of the TGF-β superfamily, also play a role in pancreatic development. When exogenous activin was added to embryonic pancreas explant cultures, it inhibited branching morphogenesis, a process associated with ductal and acinar differentiation (Ritvos et al, 1995). This observation was further supported when follistatin, an activin inhibitor expressed in the pancreatic mesenchyme by E12.5, was added to the pancreatic epithelium; it mirrored the mesenchymal effect, promoting exocrine and repressing endocrine development

(Miralles et al, 1998). These observations would support a role for activin in promoting and regulating endocrine differentiation and suppressing exocrine differentiation in the early pancreas. Along similar lines, transgenic mice that express a dominant-negative activin receptor display reduced levels of differentiated islet cells (Kim et al, 2000; Shiozaki et al, 1999; Yamaoka et al, 1998). In vitro in cell lines, activin A favors β-cell differentiation.

SMADs are intracellular signals for the *TGF* superfamily and have gained interest among developmental biologists, since *SMAD4* was specifically identified to be mutated in 50% of pancreatic cancers (Hahn et al, 1996). However, a key role for *SMAD4* has not yet been identified in pancreatic development (Simeone et al, 2006; Bardeesy et al, 2006). *SMAD7* on the other hand, which acts as a general *TGF* signaling inhibitor when expressed under the *PDX1* promoter, results in a dramatic decrease in β cells at birth—by around 90%—and replacement with glucagon cells (Smart et al, 2006).

Notch Signaling

A key step in pancreatic development is the lineage decision by pancreatic progenitor cells between the endocrine and exocrine lineage. Notch signaling has been identified as a master regulator of this fate decision switch (Apelqvist et al, 1999). However, the exact mechanism for Notch signaling in pancreatic lineage selection remains elusive, and ambiguity still surrounds the exact role of Notch signaling through pancreatic development. It appears that the downstream factors of Notch targets are variably expressed at certain times in development of the pancreas. The early pattern of downstream molecules is a key mediator of Notch signaling in determining endocrine versus exocrine differentiation of progenitor cells and in maintaining a stem cell state in some progenitor cells. Later in gestation, the downstream molecules for Notch signaling change to foster cell maturation and differentiation beyond this initial lineage decision between endocrine and exocrine differentiation.

Hedgehog Signaling

As mentioned earlier, Shh suppression in the prospective pancreatic endoderm is a prerequisite for pancreas formation, however, Hedgehog signaling in pancreatic development appears to be complex. *SHH*-null mutant mice do not exhibit an expanded pancreatic field; in contrast, Indian Hedgehog (*IHH*) null mutant mice that develop with a small pancreas indicate a propancreatic role for *IHH* (Hebrok et al, 2000). However, when combining *SHH*-null mutation with heterozygous mutation for *IHH,* an annular pancreas develops. Mice that are null mutant for the Hedgehog Patched receptor Ptc lack Pdx1 and glucagon expression at E9.5, supporting the need to suppress Shh for early pancreatic development (Hebrok et al, 2000). Similarly, transgenic overexpression of Shh or Ihh under the Pax4 promoter led to a significant decrease in endocrine and exocrine tissue mass (Smith et al, 2000).

WNT

As mentioned earlier in the chapter, β-catenin repression in the anterior endoderm is necessary to initiate liver and pancreas development. Consistent with this, *PDX1–WNT1* and *PDX1–WNT5A* transgenic mice developed pancreatic agenesis and severe hypoplasia, respectively, confirming that early Wnt signaling is detrimental for pancreatic development (Heller et al, 2002). Similar to Notch signaling, the role of Wnt signaling beyond endodermal patterning is complex and depends on the time and place of Wnt signaling. β-catenin, which is mostly expressed in the mesenchyme (Heller et al, 2002), when ablated from Pdx1-positive cells resulted in the loss of acinar tissue at birth, confirming earlier studies that exocrine tissue development is mesenchyme dependent (Murtaugh et al, 2005; Wells et al, 2007). Others found a role for Wnt signaling in promoting postnatal pancreatic growth (Heiser et al, 2006), illustrating the complex and multiple roles that Wnts play in pancreatic development.

Endothelial Cells

Recently, an important role for endothelial cells in pancreatic endocrine development has been demonstrated. As mentioned earlier, the notochord separates from the gut endoderm by the fusion of the dorsal aortas around E8.0. Lammert and colleagues (2001) demonstrated that the removal of the dorsal aorta from *Xenopus* embryos led to the absence of pancreatic endocrine development. In addition, aortic endothelial cells were able to induce pancreatic bud formation and subsequent insulin cell differentiation in the adjacent endoderm. Importantly, ectopic *VEGFA* in the intestine and stomach led to ectopic formation of islets in the stomach (Lammert et al, 2001). Interestingly, it appears that ventral pancreas development seems to be not dependent on the endothelium despite its close proximity to the vitelline veins (Yoshitomi & Zaret, 2004).

Glucagon

The first detectable endocrine cells during pancreatic development are the glucagon-containing cells at around E9 in the mouse, and recent studies have shown that glucagon signaling is necessary for early differentiation of insulin-expressing cells, which appear around E13.0 (Picte et al, 1972; Prasadan et al, 2002). Glucagon hormone is generated from proglucagon by the action of prohormone convertase 2 (PC2). When either PC2 or the glucagon receptor is knocked out, mutant mice are generated without glucagon, displaying a delay in islet cell differentiation and maturation but still retaining the large amplification of insulin-positive cells ("secondary wave") later in gestation (Vincent et al, 2003). Exogenous addition of exendin-4, a glucagon-like peptide-1 (GLP-1) analog, was able to rescue the delay in early insulin differentiation (Prasadan et al, 2002). Exendin-4 was also shown also to convert AR42J cells (Zhou et al, 1999; Yew et al, 2004) and ARIP cells (Hui et al, 2001) into insulin-expressing cells. Together these studies strongly support the role of glucagon signaling, through its receptor, in initiating early insulin differentiation.

Extracellular Matrix

The pancreatic epithelium is contained within a continuous sheath of basement membrane, which constitutes the epithelial-mesenchymal interface and plays an important role in guiding pancreatic development (Hisaoka et al, 1993). Basement membrane has also been shown to play an important role in regulating branching morphogenesis in many other organs. Laminin-1

was found to induce duct formation in isolated E11 mouse pancreatic epithelium (Gittes et al, 1996) and to mediate the proexocrine inductive effect of the mesenchyme and the pro–β-cell role later in gestation (Li et al, 2004; Jiang et al, 2001). Cadherins—**ca**lcium-dependent **adhe**sion molecules, critical for cell–cell adhesions—play an essential role in migration and differentiation of pancreatic endocrine progenitor cells. E-cadherin and R-cadherin are initially localized to the ducts, but they become downregulated as cells move out of the ducts to form islets (Dahl et al, 1996; Sjodin et al, 1995). N-CAM, another cell-adhesion molecule expressed in mature α and PP cells (Cirulli et al, 1994), when knocked out led to improper aggregation of endocrine cells within the islet (Esni et al, 1999). Thus, cell-adhesion molecules regulate the adhesive properties of endocrine cells, and these adhesive properties are essential for endocrine cell aggregation into islets.

Transcription Factors

The role of transcription factors has been extensively studied in pancreatic development. The most heavily studied is Pdx1, an early marker for pancreatic progenitors that later restricts to the β cells. It is expressed in the prepancreatic region of the primitive foregut tube at E8.5 then expands to be expressed in distal stomach, common bile duct, and duodenum by E10.5 to 11.5 (Offield et al 1996; Guz et al, 1995). Pdx1 is initially expressed throughout the epithelium; however, its expression becomes suppressed in cells as they commit to the endocrine (Jensen et al, 2000) lineage or ducts (Gu et al, 2002). Its expression reappears as cells differentiate to the insulin-positive β-cell lineage. *PDX1*-null mutant mice and humans developed pancreatic agenesis (Jonsson et al, 1994; Yee et al, 2001; Stoffers et al, 1997a; Stoffers et al, 1997b). Delayed Pdx1 inhibition using a tetracycline-regulatable transgenic knock-in system demonstrated severe blunting of pancreatic development with complete absence of acini and β cells (Holland et al, 2002), indicating that Pdx1 continues to play a role in pancreas development beyond regional specification during endodermal patterning.

PTF1α

Pancreas-specific transcription factor 1α (PTF1α) is an early marker of pancreatic progenitor cells, expressed slightly later than Pdx1 at around E9.5; by E18.5, it becomes progressively restricted to acinar cells (Cras-Meneur et al, 2009). *PTF1A*-null mutant mice develop a phenotype similar to that seen with *PDX1*-null mutants, with severe pancreatic hypoplasia and absent acini and ducts; however, endocrine cells still develop; interestingly, the endocrine cells migrate out through the pancreatic mesenchyme to populate the spleen (Kawaguchi et al, 2002; Krapp et al, 1998). A *PTF1A* nonfunctioning mutation has been seen in humans born without a pancreas (Sellick et al, 2004). Furthermore, *PTF1A* has complex interactions with downstream targets of Notch to control exocrine lineage selection.

NEUROG3

NEUROG3 is one of the earliest markers specific to the pancreatic endocrine lineage, and it is a key driver of endocrine differentiation. It is first expressed at E9.0, and it peaks at around E15.5; it is thought to be antagonized by Notch signaling in cells with an acinar fate (Jensen et al, 2000; Gradwohl et al, 2000). *NEUROG3* cells then proliferate, giving rise to postmitotic cells expressing transcription factors NeuroD, Nkx6.1, and Pax6. *NEUROG3* shuts off at around E17.5 (Jensen et al, 2000; Gu et al, 2002), and forced overexpression of *NEUROG3* leads to cells prematurely committing to an endocrine lineage, with the development of only glucagon-positive clusters (Johansson et al, 2007). Overexpressing *NEUROG3* at different times later in gestation (E11 to E12) resulted in the formation of insulin-positive and pancreatic polypeptide–positive cells (Johansson et al, 2007). However, when *NEUROG3* is deleted from cells, no pancreatic endocrine cells form (Gradwohl et al, 2000); thus it appears to be a critical and essential factor for pancreatic endocrine differentiation.

PAX6

PAX6 is also another marker of endocrine lineage, but unlike *NGN3,* it is not absolutely necessary for endocrine formation because mice null mutant for Pax6 still formed endocrine cells, albeit at a reduced rate (St-Onge et al, 1997). Pax6 expression is retained in cells committed to the endocrine lineage as early as E9.5 in glucagon-positive cells or in insulin-positive cells at E12.5, thereafter beginning hormone expression (St-Onge et al, 1997). Transgenic expression of *PAX6* under the *PDX1* promoter led to islet and ductal hyperplasia, indicating that *PAX6* may have roles in the formation of ducts and in islet growth (Yamaoka et al, 2000). However, when *PAX6* was ectopically expressed in β cells under the insulin promoter, it led to β-cell apoptosis, indicating that *PAX6* promotes proliferation only in pancreatic progenitors, not in mature cells.

PAX4/ARX

PAX4 is another endocrine cell marker and is expressed as early as E9.5; it then peaks at around E13-15, coinciding with the secondary transition of insulin-positive cells (Wang et al, 2004). Its importance was further delineated when β cells and δ cells failed to develop in *PAX4*-null mutant mice. Early embryonic insulin-positive cells were present in these mice, indicating that *PAX4* is only needed for the formation of mature β cells (Wang et al, 2004; Sosa-Pineda et al, 1997). In these mice, the β and δ cells seem to have been replaced by cells coexpressing glucagons and ghrelin, indicating that *PAX4* may act as a transcriptional inhibitor for this expression (Wang et al, 2008). *PAX4* seems also to inhibit the expression of *ARX,* a homeobox-containing gene that enhances glucagon-positive cell differentiation (Collombat et al, 2005). *ARX,* which is downstream of *NEUROG3* and is absent in *NEUROG3*-null mutant mice, when overexpressed in *PDX1*-positive progenitor cells diverted most β- and δ-cell precursors instead toward α- and PP-cell lineages, without a change in the overall number of endocrine cells. When *ARX* was knocked out, no α cells were seen (Collombat et al, 2003). These findings further emphasize the opposing roles for *PAX4* and *ARX* in α and PP cells versus β and δ cells (Collombat et al, 2007).

NKX2-2

NKX2-2 is expressed as early as E9.5, is coexpressed with *PDX1* as a marker of multipotent pancreatic progenitor cells, and eventually becomes restricted to *NGN3*-positive cells, persisting in all endocrine lineages except for δ cells (Sussel et al 1998; Chiang & Melton, 2003). *NKX2-2*–null mutant mice develop with no β cells, reduced PP cells, an 80% reduction in α cells, and no effect on δ cells. However, a large number of

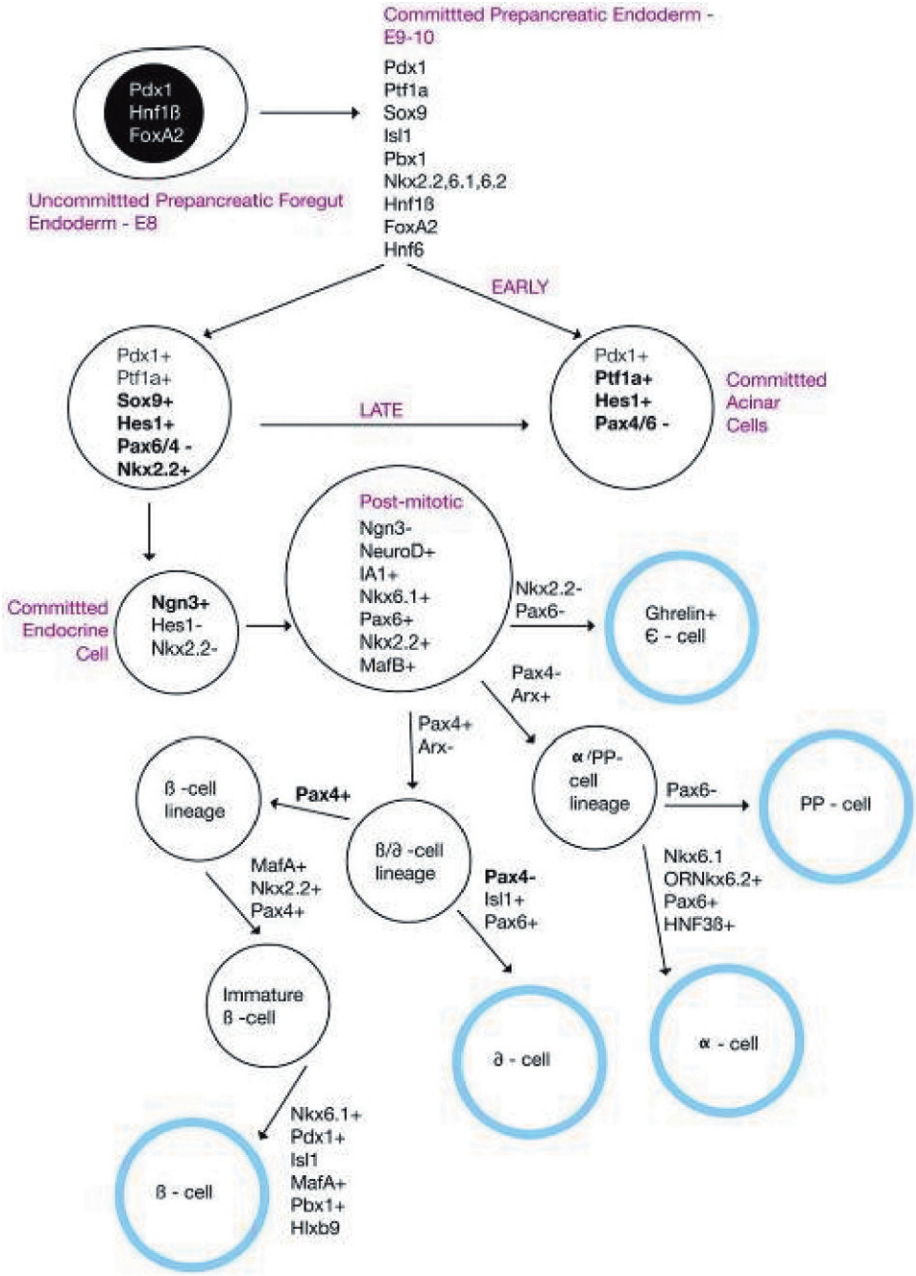

FIGURE 1A.7. Overview of the pancreatic endocrine and exocrine cell lineage.

ghrelin-positive ε cells were found with no glucagon coexpression, indicating that *NKX2-2* normally induces insulin-positive differentiation and represses ε cell formation (Sussel et al, 1998).

NKX6-1 and NKX6-2

Single- and double-null mutant studies for *NKX6-1* and *NKX6-2* have been done and suggest that both molecules, which are expressed early in pancreatic endodermal cells, play central roles in pancreatic development, especially in β-cell development (Henseleit et al, 2005). *NKX6-1,* which is downstream of *PDX1,* becomes restricted to insulin-positive cells; whereas *NKX6-2* is restricted to glucagon-positive and amylase-positive cells, after E15.5, it disappears (Sander et al, 2000). In *NKX6-1*–null mutant mice, an 85% reduction in β cells is seen, whereas *NKX6-1* and *NKX6-2* double-null mutants developed a 92% and 65% reduction in β cells and α cells, respectively, suggesting that *NKX6-1* has an important role in generating β cells. *NKX6-2* plays an important role in β-cell formation and can compensate for *NKX6-1* absence in β-cell formation (Henseleit et al, 2005; Sander et al, 2000). β-cell loss was rescued with transgenic expression of *NKX6-1* or *NKX6-2* under the *PDX1* promoter (Nelson et al, 2007).

MAFA and MAFB

The transcription factor MAFA is a critical regulator of the insulin gene, and it also regulates glucose-responsive expression of insulin (Matsuoka et al, 2003). *MAFA* is first expressed in insulin-positive cells during the "secondary transition" wave of

insulin-cell differentiation; however, it is not absolutely necessary for β-cell formation, because *MAFA*-null mutant mice have a normal proportion of insulin-positive cells at birth (Nishimura et al, 2009). *MAFB* is expressed early in pancreatic endocrine development and, as the pancreas develops, it switches off in insulin-positive forming cells as they form mature β cells that then express *MAFA* (Nishimura et al, 2006). It was demonstrated that early expression of *MAFA* under the *PDX1* promoter was detrimental to pancreatic development, with a severe reduction in pancreatic mass and in the proliferation of progenitors, suggesting that MAFA is a key regulator for the maturation of pancreatic β cells rather than β-cell specification (Nishimura et al, 2009). The same conclusion was drawn in *MAFB*-null mutants mice, in which a delay was seen in the development of early insulin- and glucagon-positive cells, with a reduction by almost half of their total mass (Artner et al, 2007).

HNF *Cascade*

Three *HNF* factors—*HNF6/ONECUT1, HNF1B,* and *HNF3B* (renamed *FOXA2*)—appear to have an interwoven, complex set of interactions that all impact on pancreatic development, starting from the earliest pancreatic specification all the way through to mature pancreatic cell differentiation and function. They are all expressed in the pancreatic epithelium at around E9.0 to E10.0 with *HNF6* appearing to be a key determinant of pancreatic specification (Maestro et al, 2003). This conclusion comes from observations that *HNF6*–/– embryos developed ventral pancreatic agenesis, with an atrophic dorsal pancreas, along with severe biliary anomalies as described earlier (Jacquemin et al, 2003; Haumaitre et al, 2005). *HNF6* is expressed in the foregut–midgut endoderm junction at E8.0 under the control of *HNF1B* (Poll et al, 2006). *HNF6* in turn regulates the expression of *FOXA2,* which is essential for gut formation (Weinstein et al, 1994). *FOXA2,* however, is not necessary for pancreas formation, because its deletion did not affect pancreatic development (Lee et al, 2005). As discussed earlier in the bile duct formation section, *HNF6* also acts upstream of *HNF1B,* where *HNF6* activates *HNF1B* to initiate the formation of endocrine progenitors (Clotman et al, 2002).

SOX9

SOX9 acts as a marker for pancreatic progenitor cells that can give rise to all pancreatic cell types, and it is necessary for maintaining cells in a progenitor state (Akiyama et al, 2005). *SOX9* mutants display pancreatic hypoplasia as a result of depletion of the pancreatic progenitor pool (Seymour et al, 2007). It has also been suggested that *SOX9* mediates *HNF6* and the control of *NEUROG3*-cell formation, because conditional deletion of *SOX9* led to the formation of cystic structures similar to those seen in *HNF6*–/– embryos, associated with absent pancreatic endocrine cells (Seymour et al, 2007). Furthermore, it was found that *SOX9* is transiently coexpressed with *NEUROG3* and frequently colocalizes with *HES1,* which acts as a precursor to *NEUROG3*-positive cells. It was suggested that *SOX9* helps mediate the transition of endocrine progenitors from the nonendocrine *HES1*-positive, *NEUROG3*-negative state to an *HES1*-negative, *NEUROG3*-positive endocrine-committed state (Seymour et al, 2007). Thus, *SOX9* acts as a key mediator of the commitment of *NEUROG3*-positive endocrine progenitors (Fig. 1A.7).

CHAPTER 2

Assessment of hepatic function: implications for the surgical patient

Charles Cha

PREOPERATIVE CONSIDERATIONS

The proper preoperative evaluation of liver function is arguably one of the most important and challenging assessments to make prior to hepatic resection. It requires analysis and interpretation of a wide variety of factors, including the determination of baseline parenchymal disease (fibrosis, steatosis, cirrhosis), the appropriate extent of resection required, and the predicted volume of the remnant liver, culminating in the prediction of risk of postoperative hepatic failure. The multiple and diverse functions of the liver preclude easy evaluation; therefore it is not difficult to understand that no individual test, or even a panel of tests, completely and accurately assesses preoperative liver function prior to resection.

In recent years, surgeons have increasingly pushed the limits of hepatic resection for a number of diseases, given the improvements in long-term outcome that can be achieved; a particularly striking example is resection for metastatic colorectal cancer (see Chapters 81A and 90A). Additionally, laparoscopic and nonanatomic resections are being performed with increasing frequency, as excellent oncologic outcome is being reported for both primary and secondary hepatic neoplasms. These liver parenchymal–sparing procedures are often performed in the setting of cirrhosis or treatment with potentially hepatotoxic chemotherapy and therefore require a very precise assessment of both preoperative and predicted postoperative liver function.

An ideal assessment of liver reserve would allow surgeons to make real-time decisions, when unexpected lesions or other findings are encountered intraoperatively that require a greater extent of parenchymal sacrifice than anticipated. Preoperative assessment of the functional liver remnant following resection is clearly critical, as it may help select high-risk patients for alternative procedures, such as staged resection, nonanatomic resection, or the incorporation of ablative procedures. Furthermore, such assessment will help select patients for preoperative portal vein embolization (PVE) to induce hypertrophy of the remnant liver prior to resection.

Despite a long list of available functional studies, imaging techniques, and markers to assess preoperative liver function (Table 2.1), no single measure or combination of measures has been demonstrated to be more predictive of outcome following resection than clinical assessment by an experienced hepatic surgeon. With improvements in surgical technique, anesthesia support, and ICU care, surgical mortality following hepatic resection has fallen to less than 3% at many institutions. However, death or complications related to liver failure following resection remains a significant cause of overall morbidity and mortality, with 16% to 50% of all mortality the result of liver failure, even in the setting of metastatic colorectal cancer (Nagao et al, 1987; Nagasue et al, 1993; Doci et al, 1995; Nordlinger et al, 1996). The continued search for an ideal measure of liver function before and after resection promises to allow for better selection of patients as well as better selection of operative procedures. This chapter reviews the measures of liver reserve that are currently available, which can broadly be divided into four categories: 1) clinical scoring systems using standard assessment and laboratory values, 2) measurements of hepatic uptake and excretion, 3) measurements of hepatic metabolism and excretion, and 4) measurements of predicted postoperative liver volume.

CLINICAL SCORING SYSTEMS

The clinical assessment of hepatic function has evolved from the Child's system (Child et al, 1964) and its subsequent modification, the Child-Pugh score (Pugh et al, 1973) as shown in Table 2.2. This scoring system was originally developed to predict mortality in patients with portal hypertension after portocaval shunt operations, and it has evolved to become a useful predictor of liver-related mortality in patients with cirrhosis.

Using a combination of clinical assessments and standard laboratory values, the Child-Pugh score is a quick assessment that can be easily performed on a preoperative patient (see Chapter 70B). The laboratory values included in the scoring system include total bilirubin, serum albumin, and prothrombin time (PT)/international normalized ratio (INR) levels. Bilirubin alone is neither sensitive nor specific for intrinsic liver disease but serves as an indirect measure of the ability of the liver to take up and conjugate bilirubin and to eventually secrete it. Other causes of bilirubin elevations include biliary obstruction, primary biliary cirrhosis, sclerosing cholangitis, and hemolytic conditions. Serum albumin level is a measure of the liver's synthetic ability, as albumin is produced exclusively in the liver. Its half-life is approximately 20 days; therefore it is not sensitive in detecting acute hepatic decompensation. Additionally, protein-losing enteropathies, malnutrition, renal disease, and burns can lead to hypoalbuminemia. PT/INR is also an important measure of liver synthetic function, because the liver is the major site for synthesis of blood clotting factors. Clotting factors V, VII, and prothrombin are critical components of the intrinsic clotting cascade, which the PT directly measures. The half-life of factor VII is around 2 hours; therefore INR is a much more dynamic measure of liver synthetic function than serum albumin levels. Problems with vitamin K absorption and intravascular consumption of clotting factors can lead to elevations in PT/INR as well.

Table 2.1

Overview of Assessment of Hepatic Function

Assessment
Clearance/retention/metabolism tests
Indocyanine green (ICG)
Lidocaine/monoethylglycinexylidide (MEGX)
Galactose elimination capacity (GEC)
Aminopyrine breath test
Caffeine clearance
Antipyrine
Urea synthesis
Sulfobromophthalein clearance
Scintigraphy
Technetium-99m–galactosyl human serum albumin (^{99m}Tc-GSA)
Volumetry
Computed tomography (CT)
Magnetic resonance imaging (MRI)

Table 2.2

Child-Pugh Scoring System

Points	1	2	3
Ascites	None	Small or diuretic controlled	Tense
Encephalopathy	Absent	Mild	Significant
Albumin (g/L)	>3.5	2.8-3.5	<2.8
Bilirubin (mg/dL)	<2	2-3	>3
PT (sec > control) *or*	<4	4-6	>6
INR	<1.7	1.7-2.3	>2.3

INR, International normalized ratio; *PT,* prothrombin time
Class A: 5 to 6 points; class B: 7 to 9 points; class C: 10 to 15 points

Table 2.3

Summary Data from Studies Reporting ICG Clearance and Outcome Following Liver Resection

			TUMOR CHARACTERISTICS		
Study	**Year**	**ICG Measurement**	**HCC**	**CRC**	**Findings**
Sawada et al	2007	Serum 15 min	—	61	ICG >10% was not associated with increased morbidity after hepatic resection.
Lee et al	2007	Serum 15 min	117	—	Liver remnant volume combined with ICG retention correlated with liver dysfunction postoperatively ($P < .001$).
Shimada et al	2007	Serum 15 min	319	—	ICG retention compared with long-term survival after resection (no correlation). ICG retention >15% was associated with decreased survival after initial recurrence.
Sugimoto et al	2006	Pulse densitometry	51	—	Postoperative ICG clearance predicted liver failure after surgery.
Ohwada et al	2006	Pulse densitometry	75	—	Perioperative ICG clearance rate predicted postoperative liver failure (sensitivity, 88%; specificity, 82%).
Erdogan et al	2004	Serum 15 min	54	25	Good correlation between ^{99m}Tc-mebrofenin and ICG clearance; no correlation was made with postoperative liver dysfunction.
Okochi et al	2002	Pulse densitometry	22		ICG clearance constant demonstrated a significant decrease after hepatectomy and was able to predict postoperative morbidity.
Lau et al	1997	Serum 15 min	127		ICG clearance was the best discriminating test for evaluating postoperative mortality after liver resection (>14%).

ICG, Indocyanine green; *HCC,* Hepatocellular carcinoma; *CRC,* colorectal carcinoma liver metastases; *spectro,* spectrophotometry; *GEC,* galactose elimination capacity; *MEGX,* monoethylgycinexylidide formation.

Adapted from Garcia G, 2009: Predicting liver failure following major hepatectomy. Dig Liver Dis 41:798-806.

Two additional components of the Child-Pugh classification include a subjective assessment of ascites and encephalopathy. Patients are divided into three classes based on points given for each category. In patients with cirrhosis, the 1-year mortality related to liver failure is minimal (<5%) for Child-Pugh class A patients, compared with 20% and 55% for class B and C patients, respectively (Conn, 1981; Table 2.3).

When used for risk stratification prior to hepatic resection, class B and C patients clearly have a higher mortality rate and lower survival rate compared with class A patients (Franco et al, 1990; Nonami et al, 1997). Indeed, very few patients with Child-Pugh class B cirrhosis would be considered candidates for even limited hepatic resection, and none would tolerate a major hepatectomy; class C cirrhosis is an absolute contraindication for even the most minor intervention. The major limitation of the Child-Pugh system is that it is not considered applicable to noncirrhotic patients or to those with other conditions, such as steatosis (see Chapters 65 and 87). Furthermore, there is variability among class A patients in terms of their ability to tolerate a major hepatectomy, but a few good-risk class B patients may also be candidates. Therefore surgeons are faced with using their best judgment to determine "poor-risk" class A patients and exclude or alter plans for resection and to identify "good-risk" class B patients.

Within the class A category, an additional means of determining risk of postoperative hepatic decompensation is to

assess for subtle signs of portal hypertension prior to resection. In the absence of splenomegaly or varices on imaging, which are rarely present in such patients, the platelet count may be used as a surrogate marker of subclinical portal hypertension. In a cirrhotic patient with otherwise good hepatic function, thrombocytopenia is highly suggestive of significant hypersplenism and portal hypertension severe enough to contraindicate resection in most cases. A direct way to assess for this is measurement of portal venous wedge pressure (Bruix et al, 1996), which can effectively stratify class A patients into high- and low-risk groups; however, this test requires expertise that is not widely available and is not routinely used.

The model for end-stage liver disease (MELD) is a clinical scoring system currently used to predict survival of patients with end-stage liver disease awaiting liver transplantation (Kamath et al, 2001; Wiesner et al, 2001). The MELD score considers bilirubin, INR, and creatinine to assess kidney function. The MELD score is derived from a complex calculation as follows:

$$0.957 \times \mathrm{Log_e}(\text{creatinine mg/dL}) + 0.378 \times \mathrm{Log_e}(\text{bilirubin mg/dL}) + 1.120 \times \mathrm{Log_e}(\text{INR}) + 0.6431$$

In cirrhotic patients, the MELD score predicts the development of postoperative liver failure following hepatectomy for hepatocellular carcinoma (HCC), with a cutoff score greater than 11 predictive of worse outcome (Freeman et al, 2002; Teh et al, 2005; Cucchetti et al, 2006; see Chapters 70B, 90A and 90F, 97A).

Both the MELD and Child-Pugh scores are meant to assess cirrhotic patients in particular and are considered unreliable in noncirrhotic patients (see Chapters 65 and 87). Furthermore, the subjective assessment of ascites and encephalopathy requires considerable input from the hepatic surgeon with regard to the suitability for resection. It is likely that it is this input that allows the experienced surgeon to impart clinical judgment to selected patients for resection, and it is why the Child-Pugh score alone has been demonstrated to be equivalent to most of the functional dynamic liver reserve studies published (Albers et al, 1989).

DYNAMIC LIVER TESTS

Measurement of Hepatic Uptake and Elimination

Indocyanine green (ICG) is an anionic organic dye that is protein bound and selectively taken up by hepatocytes and excreted unchanged via the bile. Plasma extraction of ICG by the liver is an active process that can be saturated with high doses of ICG (Faybik et al, 2006). Therefore maximal removal of ICG can be measured, and it reflects the uptake and excretional capabilities of the liver, which can be extrapolated to reflect hepatocyte blood flow and functional hepatocyte mass (Caesar et al, 1961).

Assessment of ICG clearance typically involves measuring serum levels at several points following intravenous administration (see Table 2.3). Clearance at 15 minutes is the most commonly used measurement; ICG retention values above 10% to 15% at 15 minutes are considered abnormal and are used as a cutoff to identify patients at high risk for liver failure following liver resection (Lam et al, 1999; Fig. 2.1). Poon and colleagues

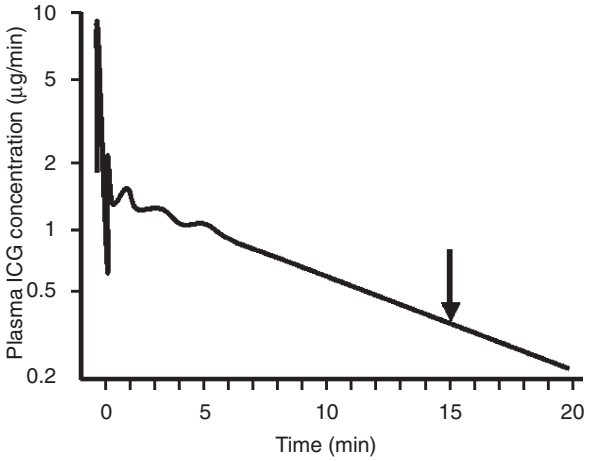

FIGURE 2.1. A typical Indocyanine green (ICG) clearance curve, which can be obtained by serial plasma sampling or optical pulse spectrophotometry. The arrow marks the ICG 15-minute retention value used most frequently to judge the adequacy of liver function.

have recently recommended a safe limit as high as 20% in Child-Pugh class A patients (Poon et al, 2004). Pulse infrared spectroscopy can also be used detect real-time, continuous blood levels, similar to pulse oximetry, without the need to obtain serum measurements (Okochi et al, 2002).

ICG elimination is by far the most widely used and published functional assessment of liver reserve worldwide (Yumoto et al, 1994; Kwon et al, 1997; Fujioka et al, 1999; Tanaka et al, 1999; Wakabayashi et al, 2002; Kokudo et al, 2003; Satoh et al, 2003; Bennink et al, 2004). Imamura and colleagues (2003) reported a 0% mortality rate in a series of 1056 hepatic resections for HCC and cirrhosis using an ICG-15 cutoff of less than 10% for a safe extended resection, 10% to 20% for hemihepatectomy, 20% to 30% for segmentectomy, and only enucleation for an ICG-15 greater than 40%. Noguchi and colleagues (1990) used the ICG maximal removal rate of 0.8 μg/kg cm^3 as a cutoff for safe resection, and Ohwada and collagues (2006) found real-time monitoring of ICG beneficial in evaluating hepatic reserve before, during, and after hepatic resection. ICG clearance has also been useful in predicting short-term prognosis in liver transplant patients (Clements et al, 1988; Lamesch et al, 1990; Oellerich et al, 1991; Yamanaka et al, 1992; Jalan et al, 1994; Tsubono et al, 1996; Igea et al, 1999; Plevris et al, 1999; Jochum et al, 2006). Tsubono and colleagues (1996) noted that a day 1 ICG elimination constant was a better predictor of graft outcome than any other conventional liver function test, and Clements and colleagues (1988) found ICG clearance to be impaired with graft rejection, but it improved as rejection resolved.

Unfortunately, the findings for ICG have not been consistent, with many authors finding a lack of correlation between ICG levels and successful liver resection (Wakabayashi et al, 1997; Lam et al, 1999). This has been particularly true in the setting of PVE, and this variability is thought to be the result of the dependence of ICG clearance on total hepatic blood flow, with regional variations markedly altering retention values (Cherrick et al, 1960). This has led a number of surgeons to suggest that no quantitative liver function tests provide a clear advantage beyond Child-Pugh score for predicting outcome following resection (Albers et al, 1989; Bennett et al, 2005).

In a recent study of 111 patients, Child-Pugh score better predicted postoperative morbidity secondary to transient liver failure compared with ICG clearance tests, and this lack of superiority of ICG clearance compared with Child-Pugh score has been confirmed by others (Albers et al, 1989; Merkel et al, 1989; Kokudo et al, 2002). Bennett and Blumgart noted significant overlap in ICG parameters between patients with cirrhosis and healthy controls, and in their institutional experience of 1800 liver resections, there were only six deaths without the reliance on any dynamic functional tests (Jarnagin et al, 2002; Bennett et al, 2005).

Hepatobiliary Scintigraphy and Single-Photon Emission Computed Tomography

Radionuclide scintigraphy of the liver can provide information far beyond basic liver anatomy, allowing for assessment of functioning hepatocyte mass as well as hepatic hemodynamics. Uptake of liver-specific radionuclides can be used to quantify overall hepatic function, and calculations of the relative contributions to perfusion by the portal vein and hepatic artery can be used to estimate the presence of liver metastases and cirrhosis. Beyond the classic sulfur and gold colloid scans and liver uptake and excretion imaging of aminodiacetic acid derivatives (HIDA, DISIDA), more recent synthetic, radiolabeled asialoglycoproteins have been developed that are taken up by hepatocyte-specific receptors through an active transport process (Kudo et al, 1990). Reduction in receptor numbers is seen in patients with chronic liver disease; because receptors are absent from the surface of hepatocellular carcinoma cells, scintigraphy can be used to provide a functional assessment of the liver through its ability to take up and clear these compounds. One such asialoglycoprotein is technetium-99m-galactosyl human serum albumin (^{99m}Tc-GSA). Patients undergoing a Tc-GSA scan receive a bolus injection of 185 MBq of ^{99m}Tc-GSA, and a dynamic scintigraph is obtained with gamma cameras located over the heart and liver. Typical curves are shown in Figure 2.2 (Ha-Kawa et al, 1997).

Kwon and colleagues (1995) were among the first to use ^{99m}Tc-GSA to evaluate preoperative and postoperative hepatic reserve, finding that GSA uptake was similar to ICG-15 clearance in terms of its ability to predict liver function. Fujioka and colleagues (1999) assessed ^{99m}Tc-GSA uptake at 15 minutes and found it to correlate with postoperative complications, hepatic regeneration, and ICG-15 clearance.

Single-photon emission computed tomography (SPECT) has also been used to assess liver function prior to surgery. Hwang and colleagues (1999) used ^{99m}Tc-GSA with SPECT in 114 patients, 55 of which underwent hepatectomy. A good correlation was found between SPECT results and ICG clearance and between predicted versus actual ^{99m}Tc-GSA clearance postoperatively. Five patients with postoperative complications as a result of hepatic insufficiency had significantly lower ^{99m}Tc-GSA clearance than those without complications. Satoh and colleagues (2003) developed a predictive residual index and found that a cutoff of greater than 0.38 predicted postoperative hepatic failure (see Chapter 15).

Scintigraphic imaging of the liver has the added advantage of providing an assessment of liver volume, and some authors suggest the volumetric analysis is better than that obtained with CT volumetry, because it measures only the functional volume; stromal and fibrous tissues are excluded because of the lack of the asialoglycoprotein receptors (Kwon et al, 2006). Scintigraphy may be a more accurate assessment of the regenerating liver than CT volumetry, given the lag time in cross-sectional imaging changes that are not seen with ^{99m}Tc-GSA clearance (Kwon et al, 2001; Kokudo et al, 2002). Age-related differences seen in ^{99m}Tc-GSA scintigraphic clearance in patients with similar CT liver volumes also seem to suggest a more accurate functional assessment of the liver (Wakabayashi et al, 2002), and ^{99m}Tc-GSA scintigraphy has also been used to assess liver volume following PVE (Hirai et al, 2003; Nanashima et al, 2006). Hirai and colleagues looked at liver volume and function using CT and ^{99m}Tc-GSA and found a rapid increase in uptake during the first week following PVE, but little thereafter. These changes were more pronounced on scintigraphy when compared with changes seen on CT alone, and patients with hepatic insufficiency postoperatively had poorer ^{99m}Tc-GSA uptake. Nanashima and colleagues (2006) had similar findings, demonstrating that ^{99m}Tc-GSA scintigraphy was better than CT alone for demonstrating functional liver volume following PVE.

In addition, ^{99m}Tc-GSA scintigraphy has also been investigated for use in the assessment of graft parenchymal function following liver transplantation (Kita et al, 1998; Sakahara et al, 1999; Hori et al, 2006). Most recently, Hori and colleagues (2006) found good correlation between ^{99m}Tc-GSA and ICG clearance following liver transplantation; however, the advantages of ICG over scintigraphy was that ICG clearance is

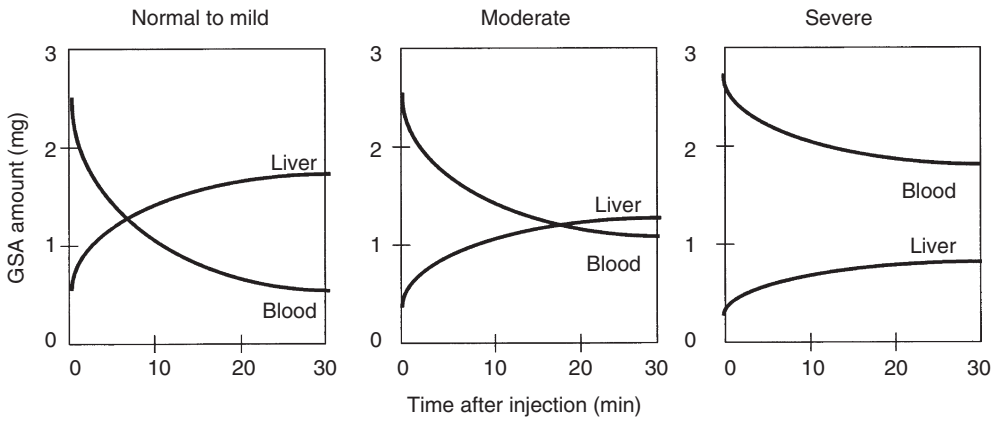

FIGURE 2.2. Tc-GSA curves for normal to mildly impaired, moderately impaired, and severely impaired liver function.

portable, quick, and can be easily repeated without the need for a radioactive tracer. Other disadvantages of ^{99m}Tc-GSA scintigraphy is its complex tracer kinetics in terms of uptake and distribution. Finally, ^{99m}Tc-GSA is currently only available for clinical use in Japan; it is not available in the United States or in Europe.

Measurements of Hepatic Metabolism and Elimination

Lidocaine Metabolism

Unlike ICG, lidocaine is metabolized by hepatocytes and converted to monoethylglycinexylide (MEGX) by oxidative N-dealkylation using the cytochrome P-450 system and is the basis of the MEGX test of liver function (Bargetzi et al, 1989). Thus, both MEGX and galactose elimination capacity (GEC) require uptake and metabolism by the liver to quantify hepatic function, unlike IGC clearance, which relies on uptake alone. Serum MEGX levels are measured at regular intervals after infusion of 2% lidocaine hydrochloride at 1mg/kg over 1 to 2 minutes. Typical values at 15 minutes after infusion are between 60 and 96 ng/mL. Oellerich and colleagues (2001) noted that in patients with chronic liver disease awaiting transplantation, only those with a MEGX value less than 10 ng/mL died; Lee and colleagues (2005) used a cutoff level of 30 ng/mL as a predictor of prolonged hospital stay following hepatic resection.

Recently, preoperative MEGX levels at 30 minutes after administration of lidocaine also predicted postoperative liver failure and mortality in noncirrhotic patients following liver resection (Lorf et al, 2008). Ravaioli and colleagues (2003) found that MEGX levels below 25 ng/mL were associated with a higher level of liver dysfunction and postoperative complications in cirrhotic patients following hepatectomy.

The main drawback of the MEGX test is the wide variability in test results among individuals, as evidenced by the lack of a standard cutoff level for what is considered safe for resection. Furthermore, because it requires liver metabolism via the cytochrome P-450 pathway, medications may interfere with the results.

Galactose Elimination Capacity

The galactose elimination capacity (GEC) is another dynamic liver function test that assesses hepatic metabolism in addition to uptake and elimination. Galactose is not protein bound and has up to 95% hepatic extraction. In this test, 50% galactose (0.5 g/kg) is administered intravenously, and its elimination is measured via serum at 20 to 50 minutes after injection. Urine and breath samples have also been utilized to assess GEC. A normal level is greater than 6 mg/kg/min. A comparison of GEC, MEGX, and ICG tests by Zoedler and colleagues (1995) revealed that GEC and ICG were best at predicting postoperative liver failure following hepatic resection. Redaelli and colleagues (2002) demonstrated that GEC was predictive of postoperative complications and liver failure in 258 patients undergoing hepatectomy, using a cutoff of less than 6 mg/kg/min to predict poorer outcome. GEC has also been demonstrated to correlate to severity of cirrhosis and predict complications in these patients (Merkel et al, 1992), but a paucity of data exists regarding GEC in liver transplantation. Nadalin and colleagues (2004) combined GEC with MRI volumetry in live-donor transplantation and found that GEC decreased 25% by day 30 and then increased to 125% by day 180.

The main disadvantage of the GEC test is the variable renal excretion that can occur, requiring close monitoring. Furthermore, genetic variation in galactokinase activity may occur among individuals, leading to inaccurate assessments. Finally, a large number of serial samples must be acquired to obtain an accurate measurement, making the test cumbersome to perform.

Measurement of Predicted Postoperative Liver Volume

Volumetric Assessment of the Liver

Cross-sectional imaging can be used to provide quantitative information regarding tumor size, overall liver volume, and an estimate of liver volume following a planned resection. Hepatic functional reserve is based both on the presence of underlying liver dysfunction and on the quantity of liver cells; radiologic quantification of liver volume represents an assessment of liver cell mass only, and as an isolated measurement, it provides no information regarding function.

COMPUTED TOMOGRAPHY

CT volumetry is the most common means of predicting the volume of functional liver remnant following a proposed resection. It typically involves the ratio of resected volume to total liver volume (see Chapter 16). More sophisticated analyses include a three-dimensional reconstruction of images, often combined with CT angiography, to allow for better visualization of a tumor in relation to vascular and biliary structures, which can alter surgical plans related to resection margin and devascularized areas of the liver that would need to be incorporated into the resection (Yamanaka et al, 2007). Such images can help to better predict surgical resection planes and can allow for "virtual" simulations of the resections.

Shoup and colleagues (2003) found that in noncirrhotic patients who had less than 25% liver volume following resection, 90% of patients developed hepatic insufficiency, compared with 0% of patients who had more than 25% residual volume, using a volumetric analysis of CT scans. Schindl and colleagues (2005) confirmed these findings, reporting a cutoff of 26.6% residual volume, below which a high risk of hepatic dysfunction was found. Shirabe and colleagues (1999) reported that hepatic failure after resection in patients with cirrhosis was associated with a postoperative liver volume of less than 250 mL/m^2. Other authors have combined volumetric analysis with ICG-15 scores and Child-Pugh scores to guide indications for resection (Kubota et al, 1997; Yigitler et al, 2003; Hsieh et al, 2006). The benefits of volumetric analysis is seen in the setting of preoperative PVE, which is typically used before extended resections that push patients to the limit in terms of size of residual liver remnant; PVE will be discussed in detail in Chapters 65 and 93A and 93B. However, a number of investigators have noted that a remnant liver volume of 25% or less is associated with increased risk of postoperative hepatic failure and that PVE can provide an additional 10% to 15% parenchymal mass that can make resection safer (Vauthey et al, 2000; Hemming et al, 2003).

Magnetic resonance imaging (MRI) has also been used to evaluate patients before and after resection to predict outcome. Nadalin and colleagues (2004) combined MRI with GEC clearance and found that patients had a 61% volume loss following right hepatectomy in the setting of a live donor transplant, and that these patients recovered function within 10 days, yet this

only represented 74% of initial liver size. GEC tests performed suggested that actual recovery of hepatic function was much slower than volume recovery.

The main drawback of volumetric imaging is that there is no information with regard to hepatocyte parenchymal function, other than response to PVE, because the calculated volume of liver mass does not necessarily correlate to liver function. This is exacerbated in situations of liver parenchymal dysfunction, such as toxic injury following chemotherapy, fibrosis, or cirrhosis, or simply older patient age (Wakabayashi et al, 2002). In patients with cirrhosis, the predicted remnant-liver cutoff for safe resection has been established by a number of investigators to be 40% in patients without cirrhosis, rather than 25%; the use of PVE in patients with cirrhosis also appears to be helpful (Azoulay et al, 2000; Hemming et al, 2003).

Ultimately, a combination of imaging volume assessment and grading of parenchymal function would represent the ideal test; however, results have been mixed (Table 2.4). Unfortunately, many of these multiassessment trials merely compared one test with another, rather than analyzing efficacy of the combination. The few trials that did specifically look at a combined approach found only moderate improvement over individual assessments in predicting outcomes after hepatectomy (Tu et al, 2007). It is apparent from these studies that, in patients analyzed by both volumetric and functional analyses, volume recovery precedes functional recovery after hepatectomy.

Other Measures of Liver Function

A number of other measures of liver function with varying degrees of success have been reported in the literature. Serum levels of hyaluronate, hepatocyte growth factor, prealbumin, retinol-binding protein, and lectin-cholesterol acyltransferase have all been described as simple markers of liver function (Mizuguchi et al, 2004; Katsuramaki et al, 2006). Many of these markers are used as nutritional indicators and as such are affected by overall nutritional status. However, following trends or following postoperative levels may be useful in determining how the liver reacts to resection. Sinusoidal endothelial cells take up hyaluronan and degrade it by a receptor-mediated mechanism with a short half-life of 2 to 5 minutes (Yachida et al, 2000). Thus serum levels of hyaluronate are a function of hepatic clearance, rather than mesenchymal cell production, and they have been shown to predict liver function in patients with cirrhosis. Serum hyaluronate levels can also predict hepatic regeneration following resection (Ogata et al, 1999; Mehta et al, 2008).

Elastography, the assessment of liver fibrosis using an intraoperative tactile sensor, has been proposed as a measure of liver function; however, this requires direct contact with the liver surface (Kusaka et al, 2000). Ultrasound-guided transabdominal elastography has been investigated as well to determine fibrosis or cirrhosis noninvasively, although minimal data are available in the prehepatectomy setting (Berzigotti et al, 2010; Laurent et al, 2008). Other methods of assessing functional liver reserve with varying degrees of success include preoperative measurement of portal vein pressures (Bruix et al, 1996), Doppler ultrasound measurement of hepatic flow (Annet et al, 2003; Lim et al, 2005), and bromosulfophthalein clearance (Yamanaka et al, 2001). The aminopyrine breath test (Merkel et al, 1992), antipyrine clearance (Sotaniemi et al, 1986), and caffeine clearance (Shrestha et al, 1997) are utilized infrequently, as they have largely been replaced by the less cumbersome and more predictive ICG clearance (Fan et al, 1995; Lau et al, 1997a; 1997b).

CONCLUSION

As surgeons have pushed the limits of extensive resections for metastatic and primary tumors of the liver and biliary tree, adequate assessment of liver reserve prior to resection, as well as the prediction of adequate functioning liver parenchyma following a major liver resection, has assumed great importance. Furthermore, with the increased utilization of laparoscopic approaches and a trend toward more limited anatomic resections, assessment of hepatic function must also be a dynamic and flexible one. Several major surgical organizations have established guidelines and consensus statements regarding indications and contraindications for surgical resection of liver tumors (Vauthey et al, 2006), and the main limitation of resection is no longer the size or number of tumors but rather the ability to leave adequate functioning liver behind, while preserving vascular and biliary support. This typically means leaving behind at least 20% of a normal liver or 40% of a diseased liver.

Recent liver-related mortality following hepatectomy in noncirrhotic patients has been reported to be as low as 2.8% in

Table 2.4

Summary Data from Studies Investigating Volumetric Analysis in Combination with Other Hepatic Functional or Scintographic Tests in Patients Undergoing Hepatic Resection

Study	Year	Assessment Method	n	Findings
Dinant et al	2007	^{99m}Tc-GSA, CT volumetry	46	^{99m}Tc-GSA was an independent predictor of postoperative liver failure.
Kwon et al	2006	^{99m}Tc-GSA using SPECT, CT volumetry	178	Postoperative liver failure was predicted by ^{99m}Tc-GSA.
Bennink et al	2004	^{99m}Tc mebrofenin, ICG, and CT volumetry	15	Remnant volume on scintigraphy correlated well to CT volume postoperatively, but not as well to regeneration.
Kwon et al	2006	^{99m}Tc-GSA, ICG, and CT volumetry	47	Correlation was seen among scintigraphy, ICG retention, and CT volumetry preoperatively; ^{99m}Tc-GSA recovery lagged behind CT-assessed regeneration postoperatively.
Kokudo et al	2002	^{99m}Tc-GSA, ICG, and CT volumetry	111	Scintigraphy in remnant liver predicted morbidity following resection.

^{99m}Tc-GSA, Technetium-99m-diethylenetriamine-pentaacetic acid-galactosyl-human serum albumin; *CT,* computed tomography; *SPECT,* single-photon emission computed tomography; *ICG,* Indocyanine green.

1059 resections (Mullen et al, 2007), calling into question whether any routine preoperative functional liver assessment is necessary in patients without cirrhosis beyond standard clinical assessment, including preoperative labs and contrast-enhanced cross-sectional imaging. For patients with cirrhosis, some additional assessment of preoperative liver function would likely be useful in subcategorizing good-risk from poor-risk Child-Pugh class A patients and to identify a population of Child's class B patients who would potentially do well following resection. The Child-Pugh score can be supplemented by the addition of volumetric measurements, ICG retention, MEGX clearance, and perhaps Tc-GSA scintigraphy. However, no test has been demonstrated to reliably augment or improve upon the Child-Pugh score alone, in the hands of an experienced surgeon, in the selection of patients for hepatic surgery. The ideal preoperative liver assessment would include a combination of functional and volumetric analyses with clear anatomic imaging; until such a test is available, clinical assessment by an experienced hepatic surgeon using the Child-Pugh score remains the gold standard.

CHAPTER 3

Pancreatic physiology and functional assessment

Michael Steer

THE PANCREAS

The pancreas is a complex organ. In addition to nerves, blood vessels, and connective tissue, it is composed of endocrine and exocrine elements. The *endocrine pancreas* consists of 10^5 to 10^6 islets of Langerhans, each of which contains approximately a thousand endocrine cells. Together the islets constitute approximately 2% of the normal human pancreas. The *exocrine pancreas* includes the *acinar cells,* which account for 75% to 90% of the pancreatic mass, and the *duct cells,* which account for approximately 5%. Most of the currently available evidence indicates that all endocrine and exocrine pancreatic cells are derived from a common stem or progenitor cell (Fishman & Melton, 2002; Zaret & Grompe, 2008). Commitment to become either a duct cell or an acinar cell is believed to occur relatively early during embryogenesis. Subsequently, the endocrine cells undergo terminal differentiation into islet and acinar cells, but some also still may be capable of differentiating into duct cells (Gu et al, 2003). Conversely, some duct cells may be capable of differentiating into endocrine cells.

The endocrine and exocrine elements of the pancreas are under tight and complex neurohormonal control, and derangements of endocrine and exocrine pancreatic function are commonly noted in association with various pancreatic diseases. This chapter reviews some of the basic features that characterize normal pancreatic endocrine and exocrine physiology, and it describes the various approaches that can be used clinically to evaluate pancreatic function in patients suspected of having common pancreatic diseases, such as chronic pancreatitis. The literature regarding each of these issues is extensive, and a comprehensive review of these subjects is beyond the scope of this chapter; however, this chapter will provide a selective review that focuses on general concepts and clinically relevant issues.

ENDOCRINE PANCREAS

Structure and Innervation

The islets of Langerhans are composed of four different cell types evenly distributed throughout the pancreas. Approximately 15% of islet cells are *α cells,* which secrete glucagon; 70% to 80% are *β cells,* which secrete insulin; 5% to 10% are *δ cells,* which secrete somatostatin; and 15% to 25% are pancreatic polypeptide (*PP*) *cells,* which secrete pancreatic polypeptide (Kulkarni, 2004). The PP cell type is only sparsely present in the dorsal pancreas, neck, body, and tail; most PP cells are found in the portion of the pancreas derived from the ventral pancreatic bud (the head and uncinate process). Rodent islets consist of a core composed of β cells surrounded by the other cell types, but in humans, the various cell types are intermixed within each islet. These islets contain a rich capillary network, and they receive substantial blood flow.

The islets of Langerhans are innervated by parasympathetic and sympathetic nerves. Vagal stimulation increases insulin release, and vagal stimulation may play a key role in mediating the cephalic phase of insulin secretion; that is, insulin release in response to the sweet taste of glucose. Although a cephalic phase of insulin secretion has been shown to occur in rats and dogs, it is not certain that a cephalic phase occurs in humans. Stimulation and inhibition of insulin release have been associated with sympathetic nervous stimulation in experimental animals, but the role of sympathetic nerves in regulating insulin release in humans has not been established (Nauck, 1998).

Synthesis and Storage of Insulin

Insulin is assembled within the endoplasmic reticulum as preproinsulin (Madsbad et al, 1992; Malaisse, 1992; Steiner & James, 1992). With cleavage of a signal sequence, the intermediate product proinsulin is formed, packaged within Golgi-derived vesicles that evolve into immature storage granules and eventually become mature secretory granules. During this process of granule maturation, proteolytic processing of insulin continues, liberating mature insulin from its C-peptide. Mature insulin, its C-peptide fragment, and other processing intermediates are stored together within the secretory granules, until they are all discharged at the cell surface. Normally, that secretion occurs primarily in response to external stimuli (regulated secretion). In insulinomas, insulin and its processing intermediates often are released continuously, however, without the need for external stimuli (constitutive secretion; see Chapter 61).

Stimulus–Secretion Coupling for Insulin Secretion

Glucose, certain amino acids (e.g., arginine), acetylcholine, and incretins such as gastric inhibitory peptide (GIP) and glucagon-like peptide (GLP-1) are the most important regulators of insulin release by β cells (Nauck, 1998). To varying degrees, the intracellular mechanisms responsible for insulin release in response to each of these types of regulators are different (Fig. 3.1). The "first phase" of insulin release seems to involve mechanisms that differ from the mechanisms in the later phase of sustained insulin secretion. This review focuses on

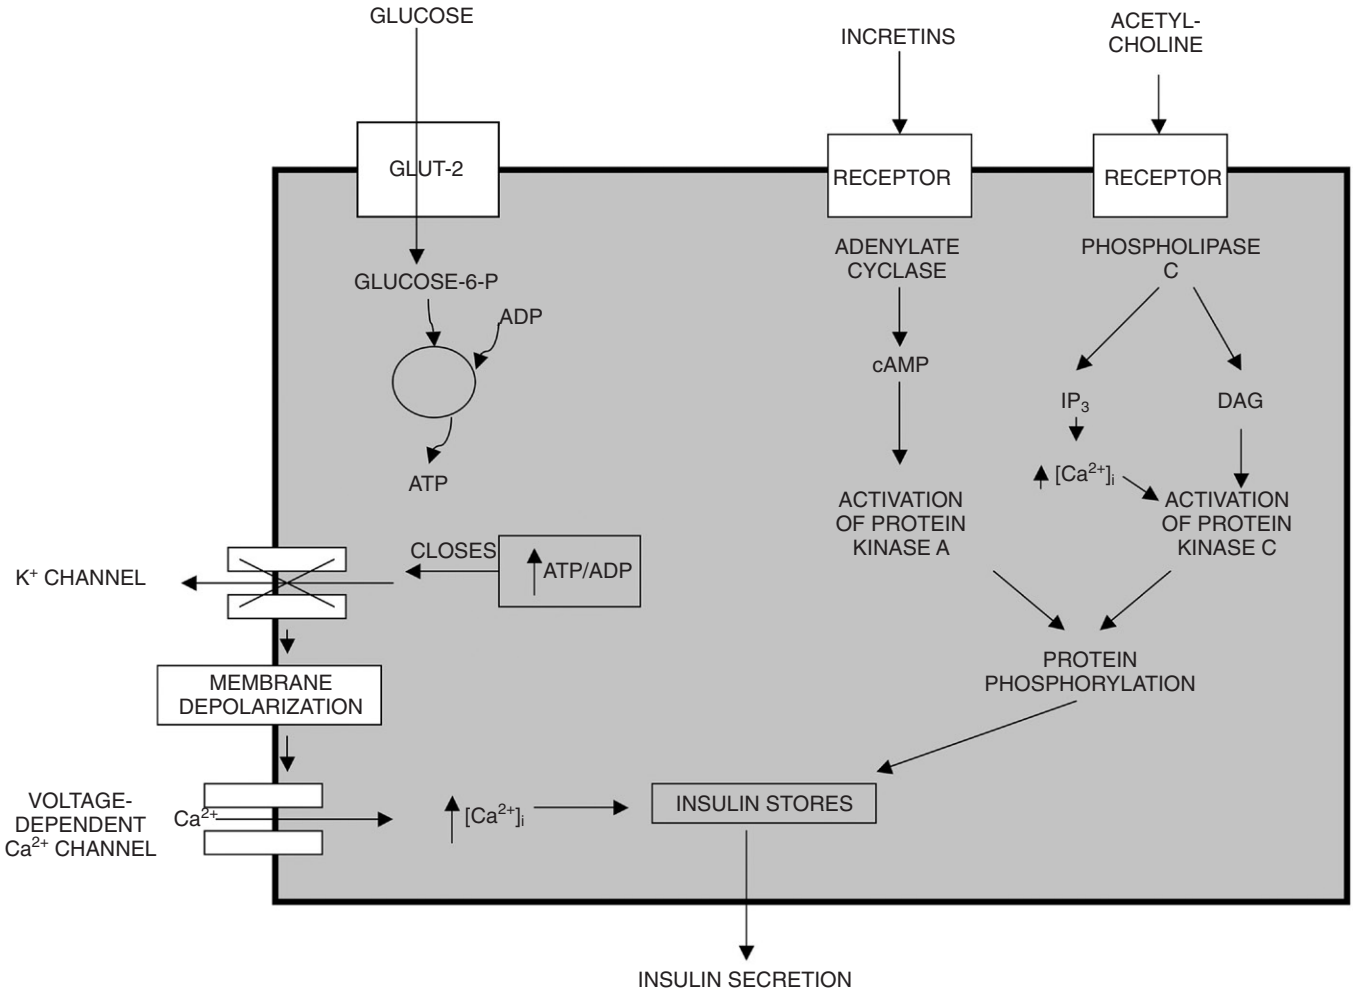

FIGURE 3.1. Stimulus–secretion coupling for insulin secretion. The major stimulants of insulin secretion are glucose, acetylcholine, and the incretins. Glucose enters the cell via the GLUT-2 transporter, and it is phosphorylated to glucose-6-phosphate by hexokinase. Metabolism of glucose-6-phosphate yields ATP (adenosinetriphosphate), and the increased ATP–ADP (adenosinediphosphate) ratio closes a membrane K^+ channel. This depolarizes the membrane, opening voltage-dependent calcium channels and causing calcium levels in the cell to increase. The increase in cytoplasmic calcium triggers exocytosis of secretory vesicles containing insulin. Acetylcholine, released from vagal efferents, binds to surface membrane receptors coupled to phospholipase C. Activation of phospholipase C yields IP_3, which triggers release of intracellular calcium and DAG, which activates protein kinase C. The incretins (GIP and GLP-1) bind to receptors coupled to activation of adenylate cyclase. Elevated cAMP levels lead to activation of protein kinase A. Activation of protein kinase C and protein kinase A leads to protein phosphorylation and secretion of insulin. *cAMP,* cyclic adenosine monophospate; *DAG,* diacylglycerol; *GIP,* gastric inhibitory peptide; *GLP,* glucagon-like peptide; *IP_3,* inositol triphosphate.

events believed to underlie that first phase of insulin secretion (Rutter, 2001).

Glucose, the most important regulator of insulin release, enters β cells via a highly efficient glucose transporter, GLUT-2, which for the most part equalizes intracellular and extracellular glucose concentrations (Unger, 1991). Subsequent to its uptake by the cell, glucose is phosphorylated by glucokinase (Meglasson & Matschinsky, 1986), which, because of its high michaelis-menten constant (K_m), acts as a glucose sensor. Glucokinase catalyzes the formation of glucose-6-phosphate, and as a result, glucose-6-phosphate accumulates within the cell at concentrations closely related to the intracellular concentration of glucose. Glucose-6-phosphate is metabolized, leading to formation of adenosine triphosphate (ATP); this results in an increased ATP–ADP (adenosine diphosphate) ratio, which causes closure of an ATP-dependent potassium channel in the plasma membrane of β cells (Henquin, 1988). Closure of this channel results in membrane depolarization, which leads to activation of voltage-dependent L-type calcium channels and calcium influx into the cell (Misler et al, 1992). The resulting increase in cytoplasmic calcium levels triggers exocytosis of the secretory granules that contain insulin (Eliasson et al, 2008). In contrast to the initial phase of insulin secretion, it is believed that the later phase of sustained secretion does not involve closure of ATP-dependent potassium channels (Rutter, 2001).

Amino acids such as arginine also upregulate insulin secretion by being metabolized and causing ATP levels to increase, increasing the ATP–ADP ratio and triggering calcium influx. The incretins, including GIP and GLP-1, are believed to upregulate insulin secretion by activating adenylate cyclase, increasing cyclic adenosine monophosphate (cAMP) levels, activating protein kinase A, and causing phosphorylation and activation of exocytosis-related proteins; cAMP also may promote insulin secretion by mechanisms that involve activation of L-type

calcium channels and accelerated calcium influx. Insulin secretion also can be stimulated by acetylcholine released from cholinergic nerves. Acetylcholine binds to receptors on the cell surface, causing activation of phospholipase C and generation of the secondary messengers, inositol triphosphate (IP_3), and diacylglycerol (DAG). IP_3 triggers release of calcium (Ca^{2+}) from intracellular storage pools, which causes release of insulin. DAG binds to and activates protein kinase C, which, like protein kinase A, promotes insulin secretion by phosphorylating and activating exocytosis-related proteins (Persaud et al, 1989; Prentki & Matschinsky, 1987).

Incretins and the Regulation of Insulin Secretion

Insulin secretion in response to orally administered glucose and other nutrients is 25% to 50% greater than that after intravenous administration (Creutzfeldt, 1979; Tillil et al, 1988). This so-called incretin effect is mediated by hormones released from the gut, primarily GIP and GLP-1 (Fiesler et al, 1995; Nauck et al, 1993). GIP is produced by K cells in the duodenum and upper jejunum, and it is released into the circulation after ingestion of nutrients. GLP-1 is synthesized in enteroglucagon or L cells, which also contain peptide YY (PYY) and enteroglucagon. These L cells are primarily located in the distal small bowel, colon, and rectum. Of the two hormones GIP and GLP-1, GIP is probably the major physiologic incretin. Glucose and amino acids are considered to be "primary" or "direct" stimulants of insulin secretion, but insulin secretion is also modulated by the incretins. These incretins cause little or no insulin release in the absence of glucose or amino acids, but they can alter insulin release dramatically in response to either glucose or amino acids.

Glucagon and Other Islet Hormones

In addition to insulin, the islets of Langerhans secrete somatostatin, pancreatic polypeptide, glucagon, and possibly ghrelin. Clinically, pancreatic diseases generally are not associated with disorders of somatostatin, because somatostatin is synthesized and released by many other organs besides the pancreas. Pancreatic polypeptide, released from the ventral region of the pancreas in response to food, does not seem to have any specific physiologic function, and as a result, abnormal pancreatic polypeptide secretion is not associated with clinically recognizable abnormalities. Glucagon, released from islet α cells, is a functionally important hormone, and disorders of glucagon secretion can result in clinically recognizable functional changes (Lefebvre, 1992).

Glucagon is a 29–amino acid hormone that functions to regulate hepatic glucose output. Acting via adenylate cyclase and cAMP, glucagon stimulation of hepatocytes accelerates glycogenolysis and gluconeogenesis, causing blood glucose levels to increase. Hypoglycemia promotes glucagon release, and hyperglycemia inhibits glucogon release (Lefebvre, 1992; Unger, 1985). In some species, glucagon has other effects, including accelerating lipolysis, promoting gastric emptying, and stimulating insulin secretion. In type 1 diabetes, there is a low insulin–glucagon ratio, and this worsens hyperglycemia by promoting hepatic glucose output. In type 2 diabetes, glucagon secretion seems to be increased, and it is not suppressed by hyperglycemia. As a result, plasma glucagon levels are normal or elevated. With total pancreatectomy, patients become profoundly glucagon deficient and consequently prone to hypoglycemia. This leads to so-called brittle diabetes, which is characterized by swings in blood glucose levels, from marked hyperglycemia to marked hypoglycemia.

Endocrine Pancreas in Diabetes

Type 1 diabetes is a chronic autoimmune disease that leads to the destruction of β cells (Powers & Eisenbarth, 1995). Consequently, disordered insulin secretion in type 1 diabetes is primarily related to progressive loss of β cells, and clinical diabetes occurs when 80% to 90% of β cells are destroyed. In type 1 diabetes, serum insulin and C-peptide levels are usually extremely low (Polonsky et al, 1986). In contrast, the islets of Langerhans usually appear histologically normal in patients with type 2 diabetes, or the cells may be normal, but the islet may contain deposits of islet amyloid polypeptide. Despite this appearance, however, β-cell mass may be reduced by 50% in patients with type 2 diabetes, especially in patients who require insulin therapy. For the most part, patients with type 2 diabetes secrete increased amounts of insulin, proinsulin, and insulin conversion intermediates such as C-peptide, and elevated circulating levels of these factors can be detected (Porte, 1991).

Endocrine Pancreas in Chronic Pancreatitis

In chronic pancreatitis, there is progressive scarring of the pancreas with replacement of the gland by fibrous tissue. The islets become embedded in these areas of fibrosis, and eventually islets and islet cell mass are lost. This loss leads eventually to the loss of β cells and α cells (Diem, 2002). Functional testing may reveal a reduced response to oral and intravenous glucose and to glucagon and arginine. Approximately 10% of patients with exocrine pancreatic insufficiency secondary to chronic pancreatitis have clinically significant diabetes, whereas 30% have impaired glucose tolerance (Larsen et al, 1987; Sjoberg & Kidd, 1989).

EXOCRINE PANCREAS

On a tissue-weight basis, the exocrine pancreas synthesizes and secretes more protein per day than any tissue in the body other than the lactating breast, and approximately 90% of that newly synthesized protein consists of digestive enzymes. On a daily basis, the normal human pancreas secretes 6 to 20 g of digestive enzyme protein in 2.5 L of bicarbonate-rich fluid (Case, 1998). Derangements of exocrine pancreatic function commonly are observed in patients with pancreatic disease, and pancreatic functional assessment mostly involves tests of exocrine pancreatic function. The structure of the exocrine pancreas, its neurohormonal control, and the cell physiology of exocrine pancreatic secretion are reviewed in this section, and when possible, this review emphasizes information known to be valid for humans. Most of the literature concerning these issues is based, however, on work performed using various nonprimate species—rats, mice, guinea pigs, cats, rabbits, dogs, and pigeons—or work performed in vitro using isolated cells. To a great extent, this literature has indicated that there may be important differences in pancreatic exocrine function and physiology among the various species as well as important differences between the in vivo and in vitro setting. Although many

of the overall concepts covered in this section are no doubt relevant to the human in vivo setting, there may be important exceptions to this generalization (Case, 1998).

Structure

The exocrine pancreas is composed of two functional elements: a *ductal tree* and a mass of *pancreatic acini* (Case, 1998; Konturek et al, 2003). Each acinus consists of a grapelike cluster of acinar cells that surround a central or acinar lumen, which is continuous with the ductal space. Acinar cells constitute 75% to 90% of the gland. They are highly polarized cells that possess abundant, rough endoplasmic reticulum, located almost entirely within the basolateral region of the cell. The nucleus also is located in the basolateral region, and a prominent Golgi complex is located near the center of the cell. Secretory vesicles consisting of zymogen granules and their immature condensing vacuole precursors fill the apical portion of acinar cells.

The ductal component of the exocrine pancreas includes centroacinar cells present at the junction between the acinar and ductal lumina and cells lining the progressively larger ducts that connect the acinus to the duodenum (intercalated ducts, intralobular ducts, interlobular ducts, and main pancreatic ducts). These cells contain large numbers of prominent mitochondria but few secretory vesicles. Centroacinar cells are cuboidal cells, but the ductal cells become more columnar with progression distally in the ductal tree.

The pancreas is innervated by extrinsic and intrinsic parasympathetic and sympathetic nerves. These autonomic nerves have been shown to use a vast array of neurotransmitters in addition to acetylcholine and catecholamines, including nitric oxide, vasoactive intestinal peptide (VIP), gastrin-releasing peptide, neuropeptide Y, galanin, substance P, calcitonin gene-related peptide, gastrin/cholecystokinin (CCK), and enkephalins (Case, 1998; Case & Argent 1993). From a purely functional standpoint, the most important of the neurotransmitters seems to be acetylcholine, which in addition to functioning as a neurotransmitter also acts as a paracrine hormone released near acinar cells to regulate their function. Evidence indicates that many of the intrapancreatic cholinergic vagal nerves possess CCK receptors, and that at least in humans, the hormonal effects of CCK on pancreatic acinar cells may be mediated by vagal afferents in response to CCK stimulation (Owyang & Logsdon, 2004). Whether or not CCK can directly stimulate acinar cell secretion of enzymes in humans is a controversial issue (Murphy et al, 2008; Owyang & Logsdon, 2004).

Neurohormonal Regulation of Exocrine Pancreatic Function

The exocrine pancreatic response to a meal traditionally is considered to involve three phases (Konturek et al, 2003): 1) the *cephalic phase,* triggered by the sight or smell of food, accounts for 10% to 20% of the pancreatic secretion during a meal; 2) the *gastric phase,* triggered by food entering the stomach and by gastric distention, accounts for 15% to 20% of meal-stimulated pancreatic secretion; and 3) the *intestinal phase,* triggered by food and acid entering the duodenum and proximal jejunum, accounts for 60% to 70% of meal-stimulated pancreatic secretion (Table 3.1). In humans, the cephalic and gastric phases are thought to be vagally mediated and to primarily involve stimulation of digestive enzyme secretion rather than bicarbonate secretion (Anagnostides et al, 1984; Case, 1998; Konturek et al, 2003). The intestinal phase is neurally and hormonally regulated, however, and it involves secretion of a pancreatic juice that is rich in bicarbonate and digestive enzymes.

Table 3.1

Three Phases of Pancreatic Secretion

Phase	Contribution Output	Stimulus	Mediators
Cephalic	10%-20% enzymes	Sight and smell	Vagus
Gastric	15%-20% enzymes	Gastric distension Food in stomach	Vagus
Intestinal	60%-70% enzymes and bicarbonate	Food and acid in duodenum	Vagus, CCK, secretin

CCK, Cholecystokinin.

The intestinal phase of meal-stimulated pancreatic secretion has been the most fully characterized phase (Fig. 3.2). The entry of gastric chyme into the duodenum and proximal jejunum triggers vagovagal (centrally acting) reflexes and enteropancreatic neural reflexes that together primarily stimulate digestive enzyme secretion from pancreatic acinar cells. Acidification of the duodenum (pH <4.5) causes specialized cells within the mucosa to release secretin into the circulation, and secretin potently stimulates duct cell secretion of fluid and bicarbonate (Case & Argent, 1993). Release of secretin and stimulation of fluid/bicarbonate secretion also are elicited by various products of digestion, especially fatty acids and bile salts (Rhodes et al, 1988; Riepl et al, 1990). Fatty acids and polypeptides released by the partial digestion of food also stimulate release of CCK from other specialized cells within the duodenal and jejunal mucosa, and elevated CCK levels cause acinar cells to secrete digestive enzymes and other proteins into the pancreatic juice (Dale et al, 1989).

Pancreatic duct cells express secretin receptors, and it is generally believed that secretin stimulation of fluid/bicarbonate

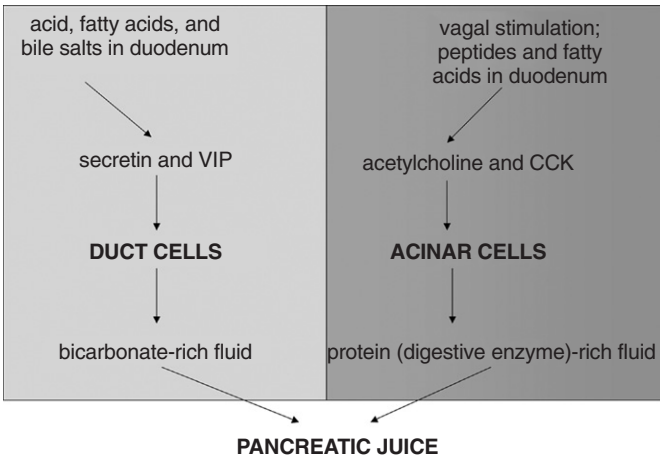

FIGURE 3.2. The two components of the exocrine pancreas. Acidification of the duodenum and the entry of fatty acids or bile salts into it trigger release of secretin and vasoactive intestinal peptide (*VIP*). Secretin and VIP stimulate pancreatic duct cells to secrete a bicarbonate-rich fluid. Vagal stimulation and the entry of either peptides or fatty acids into the duodenum cause release of acetylcholine and cholecystokinin (*CCK*), which stimulate acinar cells to secrete a fluid rich in digestive enzyme proteins.

secretion by duct cells reflects the direct effect of secretin—and possibly other hormones, such as VIP—on those duct cells. Acinar cells express receptors for acetylcholine and several other candidate secretagogues, and it is generally believed that neurally stimulated acinar cell secretion of digestive enzymes reflects the direct effects of those neurally released factors on acinar cells, acting via their specific receptors. However, the mechanisms responsible for CCK-stimulated acinar cell secretion seem to be more complex and may be species specific. The acinar cells of many species (e.g., mice, rats) express CCK receptors, and in those species, CCK may stimulate secretion by directly interacting with those acinar cell receptors (Owyang & Logsdon, 2004; Soudah et al, 1992). For many years, it was widely believed that human acinar cells do not express CCK receptors (Ji et al, 2001). This has been recently challenged by Murphy and colleagues (2008), who suggested that human acinar cells may express functional CCK receptors coupled to digestive enzyme secretion. On the other hand, it has long been known that human CCK-stimulated digestive enzyme secretion can be almost entirely prevented by cholinergic blockade (Li & Owyang, 1993; Li et al, 1997), which would suggest that CCK-stimulated secretion is mediated via cholinergic mechanisms and that CCK receptors on acinar cells, even if they do exist, are unlikely to play a major role in mediating meal-stimulated secretion in humans.

Diversion of pancreatic juice from the duodenum causes circulating levels of secretin and CCK to increase. This increase stimulates pancreatic secretion of fluid, bicarbonate, and digestive enzymes. The mechanisms behind this phenomenon have been the subject of considerable interest, and at present, diversion-induced upregulated secretion is believed to reflect the presence of trypsin-sensitive "releasing factors" for secretin and CCK within the duodenal lumen. These factors are believed to be released into the duodenum from specific cells of the mucosa (Lu et al, 1989; Miyasaka et al, 1989) or secreted into pancreatic juice (Iwai et al, 1987) and degraded by luminally active trypsin when food-stimulated secretion is adequate; as a result, the stimulus for further secretion is dampened. When food-stimulated secretion is inadequate, however, all of the secreted trypsin is bound to proteins within the duodenal lumen; as a result, trypsin-induced degradation of the releasing factors does not occur, and CCK or secretin release into the circulation is increased.

The physiologic importance of this "feedback" mechanism for regulating pancreatic secretion in humans is unclear, but it has been invoked to explain the observation that, at least in some series, patients with painful, chronic pancreatitis seem to obtain pain relief by ingesting exogenous pancreatic enzyme preparations that contain trypsin. It is argued that patients with chronic pancreatitis secrete inadequate amounts of digestive enzymes (trypsin) into the duodenum, and as a result, levels of intraluminal CCK-releasing factor may be chronically elevated, leading to continuous CCK-induced stimulation of the pancreas and possibly to chronic pain. In this setting, provision of exogenous enzyme preparations that include trypsin could terminate that signal for pancreatic secretion by promoting intraluminal degradation of the CCK-releasing factors, and this could ameliorate the pain of chronic pancreatitis (Toskes, 2002). Most patients with painful chronic pancreatitis and steatorrhea continue to have pain, however, despite ingesting exogenous pancreatic enzymes (Mossner et al, 1992); this has led many investigators to question the role of the feedback mechanism in the regulation of human pancreatic function and the role of CCK in the genesis of chronic pancreatitis pain.

Electrolyte Secretion

Small interlobular ducts are the major site of fluid and bicarbonate secretion in the pancreas. That secretion is primarily regulated by secretin, but VIP and acetylcholine also may play a role in this process. CCK and acetylcholine also may augment fluid and electrolyte secretion by stimulating the secretion of a chloride-rich fluid from acinar cells, but little is known regarding the events involved in acinar cell fluid and electrolyte secretion. Most knowledge regarding cellular mechanisms responsible for fluid and electrolyte secretion in the pancreas has been derived from studies involving duct cells in nonprimate species, and its applicability to humans remains to be established.

Currently, the most widely accepted model for duct cell secretion in humans is the one shown in Figure 3.3 (Case & Argent 1993; Ishiguro et al, 2009). Initially, carbon dioxide diffuses into the cell from the circulation, and it is hydrated by carbonic anhydrase to form H_2CO_3 (carbonic acid), which dissociates into H^+ and HCO_3^-. The H^+ back-diffuses across the basolateral cell membrane and is cleared into the circulation. The HCO_3^- is carried across the luminal cell surface by a Cl^-/HCO_3^- exchanger, SLC26A6, the activity of which depends on

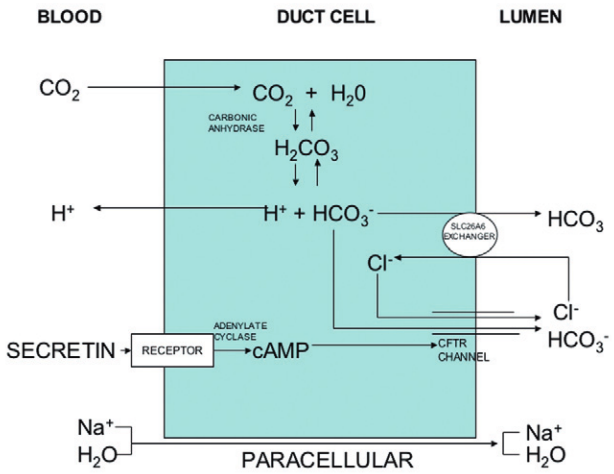

FIGURE 3.3. Stimulus-secretion coupling in pancreatic duct cells. Carbon dioxide (CO_2) diffuses from the blood across the basolateral surface of duct cells and is hydrated by carbonic anhydrase within the duct cell to yield carbonic acid. Carbonic acid dissociates into protons and bicarbonate. The bicarbonate is transported across the luminal plasma membrane into the ductal space by a chloride–bicarbonate exchanger (SLC26A6). In some species (e.g., human, guinea pig), bicarbonate secretion through the apical membrane may also reflect passage of bicarbonate through the cystic fibrosis transmembrane regulator (CFTR). The function of CFTR is regulated by the hormone secretin, which binds to receptors on the basolateral surface of duct cells, activating adenylate cyclase and accelerating the formation of cAMP, which in turn activates CFTR on the luminal cell surface, thus opening a channel that allows chloride and, in at least some species, bicarbonate to pass from the cell into the ductal space. The net passage of bicarbonate across the duct cell generates an ionic and osmotic gradient, which favors paracellular passage of sodium and water into the ductal space.

the availability of Cl^- in the duct lumen; this luminal Cl^- is maintained by the cAMP-stimulated opening of the cystic fibrosis transmembrane regulator (CFTR), which is a Cl^- channel. In this system, cAMP is generated by secretin-induced activation of adenylate cyclase at the basal surface of the cell. In many species, including mice, the maximal concentration of HCO_3^- in pancreatic juice is only 80 mmol/L, which can be achieved by secretion of HCO_3^- via the HCO_3^-/Cl^- exchanger SLC26A6. In humans and guinea pigs, however, maximal HCO_3^- concentrations in pancreatic juice can reach 140 mmol/L; to achieve these high concentrations, another mechanism is required—secretion via CFTR in response to activation by cAMP (Ishiguro et al, 2009). In an overall sense, the secretion of HCO_3^- at the luminal surface generates a net negative transepithelial current and an ionic gradient, and these changes draw Na^+ and water into the lumen via paracellular pathways.

The electrolyte composition of pancreatic juice varies widely among different species and with different rates of juice flow. For the most part, Na^+ and K^+ concentrations resemble those in serum. At high flow rates, HCO_3^- and Cl^- concentrations are approximately 140 and 20 mmol/L, respectively; but in some species, and at lower flow rates, HCO_3^- and Cl^- concentrations may be equal.

Stimulus-Secretion Coupling in Duct Cells

Duct cells express seven-transmembrane G protein–coupled receptors for secretin, acetylcholine, and other possible regulators of fluid and electrolyte secretion. Occupancy of secretin receptors leads to G protein changes that trigger activation of adenylate cyclase, generation of cAMP, and activation of protein kinase A. As noted earlier, this leads to the activation of CFTR and to the opening of the Cl^- channel, which may mediate both Cl^- secretion and HCO_3^- secretion at the luminal cell surface. Occupancy of acetylcholine receptors leads to changes in other G proteins that trigger activation of phospholipase C, generation of IP_3 and DAG, elevation of intracellular free calcium levels, and activation of protein kinase C, but it is not clear how this ultimately promotes fluid and electrolyte secretion into the ductal space (Case, 1998).

Acinar Cell Biology

Amino acids enter the acinar cell, against a concentration gradient, through at least four membrane transporters, and they bind to vacant transfer RNA in the cytoplasm. They are used to assemble newly synthesized proteins within the rough endoplasmic reticulum by a complex, extensively studied process that involves docking to the endoplasmic reticulum surface and elongation of the nascent polypeptide chain within the cisternae of the rough endoplasmic reticulum. On reaching a termination sequence, translation ceases and cleavage occurs, leaving the newly synthesized protein free to assume its tertiary and quaternary structure within the cisternae of the endoplasmic reticulum. After their synthesis, many of the newly synthesized proteins within acinar cells, particularly the proteins destined for secretion, are transported to the Golgi stacks in small vesicles; within those stacks, they are posttranslationally modified, usually by glycosylation or phosphorylation or both, and sorted into three groups: *secretory, lysosomal,* or *structural.* Secretory proteins, including digestive enzymes and their inactive zymogens, are packaged in immature secretory vesicles (condensing vacuoles), which migrate toward the cell surface as they mature into more dense zymogen granules. At the cell surface, and in response to secretory stimulation, the limiting membranes of the zymogen granules fuse with the luminal plasmalemma, secretory or fusion pores develop, and the granule contents are discharged into the acinar lumen (Palade, 1975; Rothman, 1994).

Digestive Enzyme Activation

The acinar cells of the pancreas synthesize and secrete numerous digestive enzymes. Some (amylase, lipase, RNase, and DNase) are synthesized as active enzymes, whereas others (trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase) are synthesized as inactive proenzymes or zymogens. Zymogen activation usually involves proteolytic cleavage of the zymogen, exposing the activated enzyme after an activating peptide has been released. For the most part, the digestive enzyme zymogens are not activated until they reach the duodenum, where the brush-border enzyme enteropeptidase activates trypsinogen, and trypsin activates the other zymogens. Considerable evidence suggests that the synthesis of specific digestive enzymes may be controlled to some extent by diet—in other words, that ingestion of a high-fat diet promotes synthesis of lipolytic enzymes, ingestion of a high-protein diet favors synthesis of proteolytic enzymes, and ingestion of a starch-rich diet increases the synthesis of amylolytic enzymes—but the mechanisms underlying this control are unclear (Case, 1998).

Stimulus–Secretion Coupling in Acinar Cells

Many neurohormones can stimulate acinar cell digestive enzyme secretion; but to a great extent, the mechanisms involved differ, depending on the hormone involved (Fig. 3.4; Williams, 2001, 2002). Secretin and VIP bind to their specific G protein–coupled receptors and cause activation of adenylate cyclase, generation of cAMP, and activation of protein kinase A. Acetylcholine, bombesin/gastrin-releasing peptide, CCK, PAR-2–activating proteases, and substance P bind to their specific G protein–coupled receptors. CCK appears to bind to high-affinity CCK-A receptors, which in humans may be located on intrapancreatic cholinergic nerves; in other species these are on the surface of acinar cells. The receptors for acetylcholine and substance P are on acinar cells, and they are type 4 muscarinic receptors and NK-1 receptors, respectively. Activation of those receptors causes activation of phospholipase C, leading to the generation of DAG and IP_3; release of calcium from intracellular stores, leading to a rise in cytoplasmic calcium levels; and activation of protein kinase C. The ultimate process of secretion is believed to be regulated by specific proteins that are phosphorylated (activated) by the activated protein kinases A and C (Williams, 2001, 2002; Yule & Williams, 1994).

ASSESSMENT OF PANCREATIC FUNCTION

Endocrine Function

In the past, numerous attempts were made to use changes in circulating glucagon or pancreatic polypeptide levels or both in response to stimulation as a diagnostic test for patients with suspected mild to moderate chronic pancreatitis; because of very poor sensitivity, those tests were abandoned and are of

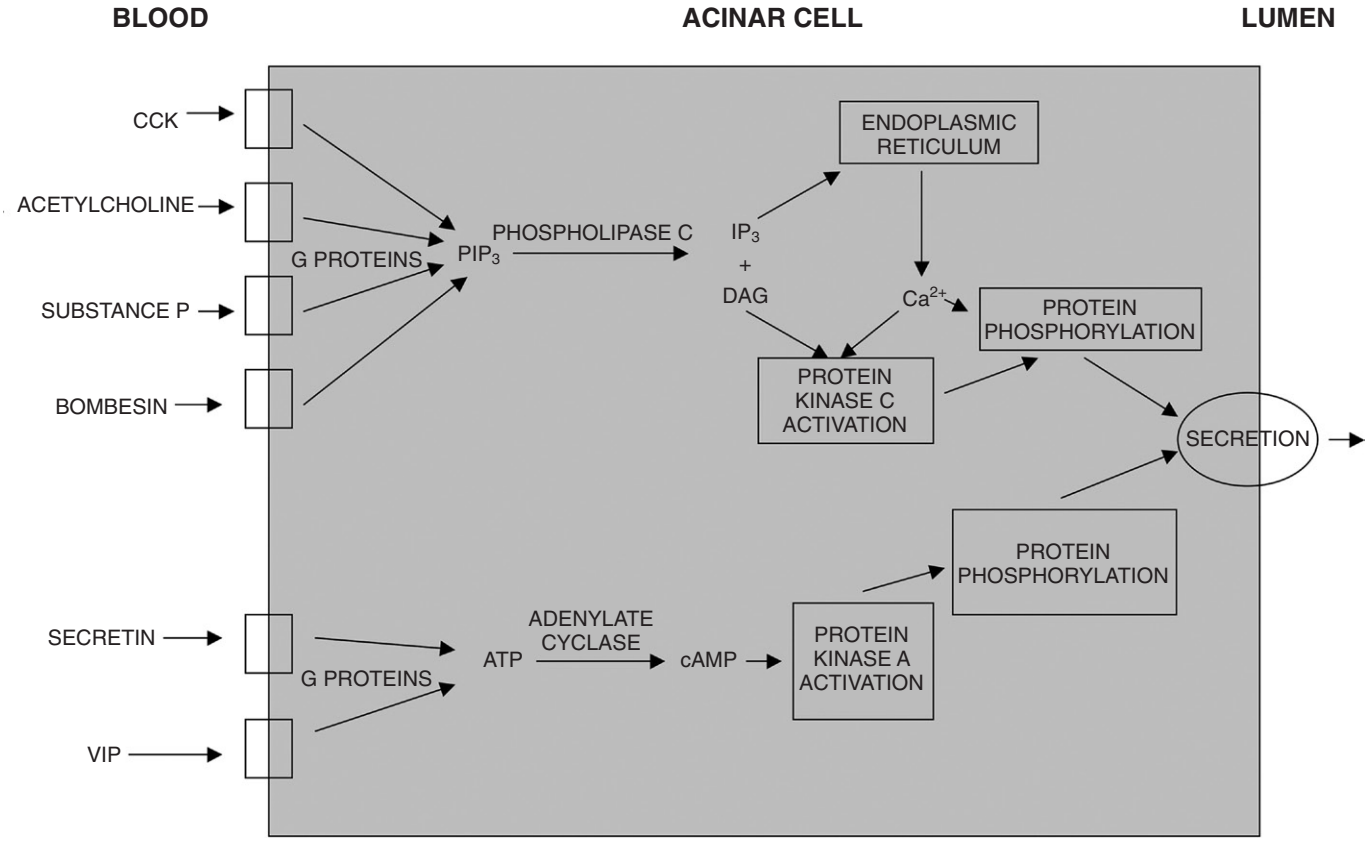

FIGURE 3.4. Stimulus–secretion coupling in pancreatic acinar cells. Stimulating factors and hormones bind to two types of cell surface receptors: G protein–coupled receptors associated with phospholipase C and G protein–coupled receptors associated with adenylate cyclase. Activation of phospholipase C leads to the formation of inositol triphosphate IP_3 and diacylglycerol (DAG), whereas activation of adenylate cyclase leads to generation of cyclic adenosine monophosphate (cAMP). IP_3 stimulates release of calcium into the cytoplasmic space from stores in the endoplasmic reticulum, which promotes calcium influx into the cell. Elevated cytoplasmic calcium and DAG levels cause activation of protein kinase C, leading to protein phosphorylation and digestive enzyme secretion. Elevated cAMP levels cause activation of protein kinase A, which also leads to protein phosphorylation and digestive enzyme secretion. Cholecystokinin (CCK) regulates secretion by binding directly to acinar cells in many species, but more recent evidence indicates that human acinar cells lack CCK receptors; in humans, CCK may regulate acinar cell secretion via a vagal, cholinergic pathway. *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophospate; *CCK,* cholecystokinin; *DAG,* diacylglycerol; *IP_3,* inositol triphosphate; *PIP_3,* phosphatidyl inositol, *VIP,* vasoactive intestinal peptide.

historical interest only (Toskes, 1986). At present, functional assessment of the endocrine pancreas in patients suspected of having chronic pancreatitis involves evaluation of insulin secretion and glucose metabolism. Endocrine pancreatic insufficiency in chronic pancreatitis may eventually result in clinical diabetes mellitus, because with time, functional islet cell mass and insulin secretion are lost; approximately 90% of β-cell mass must be lost before clinical diabetes develops. Twenty-five years after the onset of chronic pancreatitis, the incidence of clinical diabetes mellitus has been reported to exceed 80%, and more than 50% of the patients have insulin-dependent diabetes mellitus (Malka et al, 2000). With careful testing, many patients with lesser degrees of endocrine loss can be identified at an earlier time after the onset of chronic pancreatitis (Diem, 2002). In addition to an abnormal glucose tolerance test, these patients have depressed C-peptide secretion; consequently, circulating and urinary C-peptide levels may be low. In most cases, insulin-dependent diabetes develops, but in some patients, non–insulin-dependent diabetes may be seen; in these patients, C-peptide secretion may be normal. Diabetic ketoacidosis is unusual in patients with diabetes caused by chronic pancreatitis, but glucagon secretion is also often depressed, and a "brittle" form of diabetes may evolve (Angelopoulos et al, 2005). Pancreatic endocrine and exocrine insufficiencies in chronic pancreatitis evolve with different time dependencies, and in most cases, clinically apparent exocrine insufficiency precedes endocrine insufficiency by many years (Layer et al, 1994). Exocrine insufficiency is more closely correlated with morphologic changes (fibrosis, calcifications) than is endocrine insufficiency.

Assessment of Exocrine Function

Pancreatic exocrine functional testing is needed most often in the assessment of patients suspected of having chronic pancreatitis. For patients with severe and advanced chronic pancreatitis, the diagnosis usually is easily made on the basis of imaging studies, and the purpose of functional testing is to confirm the severity of the exocrine insufficiency and to gauge the adequacy of therapy with exogenous enzymes. Functional assessment also might be used to identify patients with milder or earlier forms of chronic pancreatitis, in whom imaging studies may be of less value; over the past century, numerous attempts have been made to develop tests for that purpose. That goal has remained elusive, primarily because the normal exocrine pancreas

Table 3.2

Tests of Pancreatic Function

Indirect Tests	Direct Tests
Fecal fat staining	**Noninvasive tests**
72-hour fecal fat excretion	Serum trypsinogen
Bentiromide test	Fecal chymotrypsin

	MRCP function tests
	Invasive tests
	Secretin test
	Secretin-CCK test
	Intraductal secretin test
	Lundh test

MRCP, magnetic resonance cholangiopancreatography; *CCK,* cholecystokinin.

possesses considerable functional reserve, and the tests that have been developed do not identify changes until much of that reserve has been lost. For the most part, pancreatic function tests have the common characteristic of being relatively specific but very poorly sensitive as diagnostic tests of chronic pancreatitis.

Tests of exocrine pancreatic function can be divided into two major groups (Table 3.2): *indirect tests* monitor the intestinal effects of secreted pancreatic digestive enzymes; *direct tests* monitor the actual secretion of pancreatic exocrine products (enzymes, fluid, and bicarbonate). The indirect tests are the least invasive and most widely available of the tests, but they also are the least sensitive, and such tests are most likely to be normal in patients with mild degrees of pancreatic functional loss.

Indirect Pancreatic Function Tests

Conceptually, fecal fat analysis is the simplest of the indirect pancreatic function tests. It is based on the fact that pancreatic lipase is the enzyme responsible for most fat digestion, and diminished lipase secretion results in fat malabsorption. Fecal fat analysis can be accomplished by staining stool samples for fat with Sudan stain or by quantifying fecal fat when the patient is on a controlled-fat diet (Chowdhury & Forsmark, 2003; Lieb & Draganov, 2008). In the latter case, the patient is placed on a diet consisting of 100 g of fat per day for 5 days. Stool is collected on days 3 to 5, and fat content is measured. Fecal fat output of greater than 7 g/day is considered to be abnormal and diagnostic of steatorrhea; but fecal fat measurement is notoriously insensitive for the diagnosis of chronic pancreatitis, and it is most commonly abnormal only in patients with overtly symptomatic steatorrhea.

The bentiromide and the pancreolauryl tests are noninvasive, indirect pancreatic function tests. The former involves ingestion of the chymotrypsin substrate bentiromide, which is hydrolyzed by chymotrypsin to yield paraaminobenzoic acid, which is absorbed in the small intestine, conjugated in the liver, and excreted in the urine. The test is completed by collecting urine for 6 hours and quantifying urinary paraaminobenzoic acid recovery, which is considered to be abnormal if less than 50% (Niederau & Grendell, 1985). The pancreolauryl test involves ingestion of fluorescein dilaurate, which is hydrolyzed by pancreatic esterases to yield lauric acid and free fluorescein. The fluorescein is absorbed, conjugated in the liver, and excreted in the urine. Similar to the bentiromide test, the pancreolauryl test is completed by collecting urine, in this case for 10 hours, and measuring fluorescein excretion; in this test, excretion is compared with the patient's excretion of orally ingested free fluorescein several days later. The bentiromide and pancreolauryl tests may be falsely abnormal in the face of liver or kidney disease and when certain drugs are present. The pancreolauryl test is not available in the United States, but the bentiromide test is commercially available and widely used, primarily because it is easy to perform; however, low sensitivities of 37% to 46% have been reported in patients with mild degrees of chronic pancreatitis (Naruse et al, 1980; Toskes, 1983; Ventrucci et al, 1983), so this test is of only limited value.

Other indirect tests of pancreatic function include the triglyceride breath tests (Loser et al, 1998) and the dual-label Schilling test (Brugge et al, 1980; Chen et al, 1989). Both tests have been the subject of numerous clinical studies, but for the most part, their sensitivity and reproducibility have been poor. At present, they are not used clinically for the diagnosis of chronic pancreatitis.

Direct Pancreatic Function Tests

Direct pancreatic function tests can be subdivided further into *noninvasive* and *invasive* tests. The noninvasive tests involve measuring fecal or serum levels of pancreas-derived digestive enzymes (serum trypsinogen, fecal chymotrypsin, and fecal elastase). Recently, direct function tests combining MRCP with secretagogue stimulation have been proposed (Schneider et al, 2006; Czako, 2007). These MRCP functional tests aim to either quantify juice flow into the duodenum or to provide contrast enhancement of the pancreatic parenchyma after hormonal stimulation; to date, however, the overall sensitivity and specificity of these MRCP-based tests remain to be determined, and their overall value as diagnostic tests for early chronic pancreatitis is unproven. The invasive tests involve placing a collecting device into the duodenum or pancreatic duct, stimulating pancreatic exocrine secretion, and measuring the output or concentration of exocrine pancreatic products.

Circulating levels of trypsinogen are easily measured and frequently low in patients with severe pancreatic insufficiency (Jacobson et al, 1984). Although measurement of serum trypsinogen may be helpful in evaluating the severity of chronic pancreatitis, the test has low sensitivity for the diagnosis of mild pancreatitis. Fecal levels of chymotrypsin and elastase also can be measured and used to assess exocrine pancreatic function (Dominguez-Munoz et al, 1995; Dominici & Franzini, 2002; Goldberg, 2000; Katschinski et al, 1997; Loser et al, 1996; Luth et al, 2001). Because trypsin is degraded as it passes through the intestinal tract, measurement of fecal trypsin levels is not a useful pancreatic function test. Fecal levels of chymotrypsin and elastase can be measured easily using commercially available assays; the levels of these enzymes are reduced in patients with advanced chronic pancreatitis; however, the sensitivity of fecal chymotrypsin and elastase measurement in diagnosing mild or moderate pancreatic insufficiency is only 40% to 60%.

The invasive, direct pancreatic function tests are the most sensitive of the tests used to identify patients with mild to moderate chronic pancreatitis. In these tests, pancreatic secretions are continuously aspirated from either the duodenum or the pancreatic duct after administration of a pancreatic

stimulant; this stimulant varies among the different tests. In some, secretin is administered to stimulate pancreatic secretion, and bicarbonate in duodenal juice is measured. In others, a combination of secretin and CCK or one of its analogs is used, and bicarbonate and protein (or pancreatic enzymes) in duodenal juice are measured (Chowdhury & Forsmark, 2003). The Lundh test involves stimulating pancreatic secretion by administration of a standardized meal and measuring pancreatic enzymes in the aspirated duodenal juice (Lundh, 1962). Secretin usually is used as the stimulant when pancreatic secretions are collected directly from the cannulated pancreatic duct; these so-called intraductal pancreatic function tests usually involve measurement of bicarbonate (Denyer & Cotton, 1979; Ochi et al, 1997).

Hundreds of reports have described these various invasive, direct pancreatic function tests and their seemingly endless minor variations (Chowdhury & Forsmark, 2003). Most tests that involve aspiration of duodenal juice require the use of multilumen tubes that permit the investigator to aspirate separately and discard gastric secretions to prevent the secretions from diluting or neutralizing the secreted pancreatic juice. Some tests involve measurement of either bicarbonate or enzyme output (amount/time), and in those tests, markers such as polyethylene glycol or distally occluding balloons or both may be needed to ensure high recovery rates. The markers add an additional level of complexity, and for this reason, those tests of output are less commonly employed than tests that simply measure the peak concentration of the secreted element (bicarbonate).

Perhaps the most frequently employed and most reproducible of the invasive, direct pancreatic function tests is the secretin test performed using a double-lumen (Dreiling) tube. Under fluoroscopic control, the tube is passed into the third or fourth portion of the duodenum, while the "discard port" is positioned in the stomach. Passage can be time consuming and difficult for the investigator and the patient, and for this reason, I prefer to pass the tube over a wire that is itself passed through an endoscope. In my experience using this approach, the total time needed to pass and position the tube properly rarely exceeds 10 minutes (Waxman et al, 1996). When the tube is properly positioned, secretin is intravenously administered, and duodenal juice is collected over four consecutive 15-minute periods. Peak bicarbonate concentration is measured in each of the four samples, and a positive test diagnostic of pancreatic insufficiency is defined as one in which the peak bicarbonate concentration does not exceed 60 mEq/L. Borderline values are defined as ranging from 60 to 80 mEq/L; a normal response is defined as one in which at least one of the values exceeds 80 mEq/L. The sensitivity of this secretin test in diagnosing chronic pancreatitis has been reported to be 60% to 100%, but to a great extent, the sensitivity depends on the gold standard being used to confirm the diagnosis of chronic pancreatitis—endoscopic retrograde cholangiopancreatography (ERCP)—and on the case mix of pancreatitis severity.

General Approach to Exocrine Pancreatic Function Testing

Tests of pancreatic function have little or no role in the diagnosis and management of patients with advanced chronic pancreatitis and well-established morphologic changes that can be shown by imaging studies, although in this setting, exocrine function testing may play a role in gauging the adequacy of enzyme therapy. Function tests may be useful in a patient with symptoms suggestive of chronic pancreatitis (i.e., "pancreatic" pain), whose imaging studies show no changes and who have no obvious symptoms of pancreatic maldigestion (clinical steatorrhea). In that setting, an initial noninvasive test might be preferred, and because of its simplicity, measurement of fecal elastase-1 or the bentiromide test may be the most appropriate of those tests. Measurement of fecal fat is aesthetically unpleasant to patients and technicians, and it requires administration of a diet with measured fat content. Because of the poor sensitivity, however, chronic pancreatitis cannot be excluded in patients with normal fecal elastase-1 or bentiromide tests, and in this setting, performance of an invasive pancreatic function test would be appropriate. For this purpose, the secretin test is generally considered to be the gold standard pancreatic function test in the United States. In Europe, many clinicians prefer the secretin-cerulein test or the intraductal secretin test (Boeck et al, 2001). Performance of magnetic resonance cholangiopancreatography (MRCP) or ERCP should be considered in patients with convincing symptoms and a normal or borderline invasive pancreatic function test.

CHAPTER 4

Liver blood flow: physiology, measurement, and clinical relevance

Flavio G. Rocha

LIVER BLOOD FLOW OVERVIEW

The hepatic circulation is the most complicated of any organ system. This chapter outlines the physiologic control of the liver's blood supply, describes the techniques used for its measurement in both human and animal models, and explores its function in various clinical situations.

PHYSIOLOGY

Liver Blood Supply

The liver normally receives about one quarter of the total cardiac output despite constituting only 2.5% of total body weight; it obtains its blood supply from two main sources, the hepatic artery and the portal vein. Approximately 75% to 80% of the blood entering the liver is partially deoxygenated portal venous blood drained from the stomach, intestine, spleen, and pancreas. The remainder is well-oxygenated blood from the aorta, carried by the hepatic artery. Mixing of arterial and portal blood occurs in the sinusoids, which are drained by the hepatic venous system into the inferior vena cava. Hepatic blood volume accounts for 10% to 15% of total blood volume with 40% of hepatic blood held in large vessels such as the hepatic arteries, portal vein, and hepatic veins; the remaining 60% is held in the sinusoids (Lautt, 1977; Greenway & Stark, 1971).

Hepatic Artery

The hepatic artery normally supplies about 25% of the total blood flow to the liver, or 30 mL/min per 100 g of liver tissue; however, it provides 30% to 50% of the liver's oxygen requirement because of the greater oxygen content found in arterial blood. In addition, the hepatic artery provides the exclusive blood supply to the intrahepatic bile ducts through the peribiliary plexus.

The hepatic arterioles empty directly or via a peribiliary plexus into the sinusoids and terminal portal venules. Direct artery-to-hepatic vein connections do not usually exist but may arise in liver disease. Reduction of pressure in the arterial system toward that existing in the portal circulation is achieved mainly by 1) the presinusoidal arteriolar resistance in the peribiliary plexus and 2) the intermittent closure of the arterioles, which protect the portal bloodstream from arterial pressure (Rappaport, 1973).

In the event of hepatic arterial occlusion, numerous small arteries provide a source for the formation of a collateral circulation. Upon interruption of hepatic arterial flow, collaterals can arise from 1) the inferior phrenic arteries, which can develop connections with hepatic arteries within the liver, and 2) from the gastroduodenal arteries, which derive blood flow from the superior mesenteric artery and supply the liver via the peribiliary arterial plexus around the intrahepatic bile ducts (Rappaport & Schneiderman, 1976). The precise nature of the functional collateral supply after hepatic arterial ligation depends on the site of occlusion. If the common hepatic artery is interrupted, revascularization occurs through both major routes; if only the right or left hepatic artery is interrupted, intrahepatic translobar anastomoses reestablish arterial flow in the ligated system (Mays & Wheeler, 1974). Ligation of the proper hepatic arteries leads to revascularization mainly via a hypertrophied inferior phrenic circulation (Jefferson et al, 1956). Complete long-term dearterialization of the liver by any form of arterial vascular occlusion is difficult to achieve.

Portal Vein

The inferior and superior mesenteric veins join with the splenic vein to form the portal vein, and jointly they collect the venous outflow from the entire prehepatic splanchnic vascular bed (the intestinal tract from the lower esophagus to the rectum plus the pancreas and spleen). This valveless system is a low-pressure/low-resistance system regulated by the degree of constriction of mesenteric and splanchnic arterioles coupled with the intrahepatic vascular resistance. The portal vein normally carries about 75% of the total blood flow to the liver, or 90 mL/min per 100 g of liver weight; normal portal pressure is 5 to 8 mm Hg. Portal blood is postcapillary and partly deoxygenated, but because of its large volume flow rate, it may supply 50% to 70% of the liver's normal oxygen requirement. During fasting states, the oxygen saturation in the portal blood approaches 85%, which is greater than other systemic veins. Hepatic oxygen supply is diminished if portal blood flow is significantly reduced, but the effect is minimized by an increase in oxygen extraction from the hepatic arterial blood and not by increasing flow. In fact, isovolemic hemodilution or upregulation of hepatic enzymes leading to oxygen deprivation does not result in hepatic artery dilatation, refuting the concept that arterial flow is regulated by liver cell metabolism (Lautt et al, 1987).

Hepatic Veins

The hepatic venous system is the systemic drainage tract of the entire splanchnic circulation. A total liver blood flow (LBF) of 1.5 L/min is considered the normal value in the average male, but the range can be quite wide (1 to 2 L/min). Although the free pressure in a hepatic vein is 1 to 2 mm Hg, the wedged

hepatic venous pressure, which is useful for estimating sinusoidal pressure, may be an indicator of portal venous pressure (Boyer et al, 1977). The sinusoidal pressure is estimated to be slightly higher than that of the vena cava, or 2 to 4 mm Hg (Eipel et al, 2010). Hepatic venous blood is normally about two-thirds saturated with oxygen, but this may be markedly reduced during periods of low delivery of oxygen to the liver, when oxygen is extracted by hepatocytes. In resting states, the liver accounts for approximately 20% of the total oxygen consumption of the body.

Control of Liver Blood Flow

Hepatic blood flow is controlled by physiologic mechanisms that are independent of extrinsic innervation or vasoactive agents. Instead, the interrelationship of arterial and portal inflow circuits is the major contributor to hepatic perfusion. The portal venous blood supply normally encounters minimal resistance in the portal venules and in the hepatic sinusoids and is effectively controlled outside the liver by the action of the arterial resistance vessels within the splanchnic organs.

Some controversy surrounds the autoregulation of hepatic arterial vasculature. Although some studies have suggested nonlinear pressure-regulated changes in arterial resistance in denervated dogs (Hanson et al, 1966), others have demonstrated a more direct relationship (Torrance, 1961). The pressure-flow dynamic in the portal system has been found to have little to no autoregulation, as evidenced by partial collapse of the portal vascular bed in response to reduced portal pressure (Condon et al, 1962).

Intrahepatic Vascular Resistance in Health

Intrahepatic vascular resistance (IHVR) seems to be located at the level of the portal venules (presinusoidal) or sinusoids (Sherman et al, 1996; Shibayama & Nakata, 1985; Zhang et al, 1994, 1995). Knisley suggested the presence of sphincter-like structures at the entrance and exit of sinusoids that maintain tremendous portal venous pressure gradients, but these may be species dependent (Knisley et al, 1957). In dogs and cats, IHVR is located at the level of hepatic venules (postsinusoidal) under resting conditions (Lautt et al, 1986, 1987), whereas it may be shifted to presinusoidal sites during neural stimulation (Greenway & Lautt, 1970; Legare & Lautt, 1987). Sinusoidal contraction in response to the vasoconstrictor endothelin (ET) 1 has been observed despite the lack of smooth muscle (Bauer et al, 1994, 1995; Okumura et al, 1994; Zhang et al, 1994, 1995). This contractility is mainly attributed to hepatic stellate cells—also called *Ito cells, lipocytes,* and *fat-storing cells*—which are distinguished by autofluorescence derived from their intracellular vitamin A (Suematsu et al, 1995; Zhang et al, 1994). ET-1 causes reversible and graded contraction of isolated stellate cells in tissue culture and results in narrowing of sinusoidal lumens in perfused livers (Pinzani et al, 1992; Rockey & Weisiger, 1996; Rockey et al, 1992; Zhang et al, 1994). Hepatic stellate cells have been compared to pericytes, because they contain smooth muscle–specific intermediate desmin-like and actin-like filaments that encircle neighboring sinusoids (Greenwel et al, 1991; Martinez-Hernandez, 1985; Martinez-Hernandez & Amenta, 1993; see Chapter 6).

Studies using intravital fluorescent microscopy showed that the sites of sinusoidal dilation and constriction is colocalized with that of an autofluorescent vitamin A substance (Suematsu et al, 1995, 1996; Zhang et al, 1994, 1995). Hepatic stellate cells acting as liver-specific pericytes (Friedman, 1997; Martinez-Hernandez, 1985; Martinez-Hernandez & Amenta, 1993) may play a crucial role in modulating IHVR and blood flow, especially at the sinusoidal level (Bauer et al, 1994; Okumura et al, 1994; Pannen et al, 1996; Zhang et al, 1994, 1995). Endothelium-derived nitric oxide (NO) in the hepatic sinusoids may modulate portal resistance under physiologic circumstances (Bauer et al, 1997; Shah et al, 1997). Electron microscopy studies have also demonstrated the presence of smooth muscle cells in the sublobar veins (Aharinejad et al, 1997), as well as terminal hepatic venules (Sasse et al, 1976), which may contribute to IHVR.

Relationship between Hepatic Artery and Portal Vein Blood Flow

Individual control of the hepatic arterial and portal venous circulations is complicated by the existence of a complex interaction between the two systems within the liver. Studies have shown an increase in hepatic arterial blood flow following reduction of portal blood flow (Kock et al, 1972; Mathie et al, 1980a; Schenk et al, 1962); however, a compensatory increase in portal flow following decreased arterial perfusion has rarely been observed (Mathie, 1997). Intraoperative measurements of hepatic artery and portal vein flow in anesthetized patients demonstrated a significant increase in hepatic arterial flow, up to 30% of baseline, with temporary occlusion of the portal vein and no effect on portal flow on occlusion of the hepatic artery (Jakab et al, 1995).

The ability of the hepatic artery to respond acutely to changes in portal flow is referred to as the *hepatic arterial buffer response* (Lautt, 1981). Highlighting its early embryonic origin, in experiments measuring fetal hepatic arterial blood flow, it has been shown that this regulatory process is even present prenatally (Ebbing et al, 2008). Experimental studies support the view that adenosine, accumulating in the liver as a result of reduced hepatic outflow or released from the walls of blood vessels in response to partial tissue hypoxia, has a significant role in the regulation of the buffer response (Lautt & Legare, 1985; Mathie & Alexander, 1990). This adenosine washout hypothesis is supported by the fact that portal infusion of adenosine increases hepatic arterial blood flow by one half to one third the amount of direct arterial instillation (Lautt et al, 1987). The demonstration of receptors mediating dilation to adenosine in the hepatic arterial vascular bed reinforces this view (Mathie et al, 1991; Fig. 4.1).

Metabolism

Hepatic arterial blood flow has not been traditionally linked to liver metabolism (Lautt, 1983; Mathie & Blumgart, 1983a). It has been shown that neither altered oxygen supply nor bile secretion causes a dependent change in arterial flow (Lautt, 1983); instead, the physiologic role of the buffer system is to maintain hepatic clearance in the face of reduced portal flow and to maintain adequate tissue oxygenation. This is despite the fact that the liver receives more oxygen than it requires and can therefore extract more by hepatocyte metabolism if needed. Therefore arterial flow is independent of oxygenation and is secondary to the nutrient and hormonal needs of the liver.

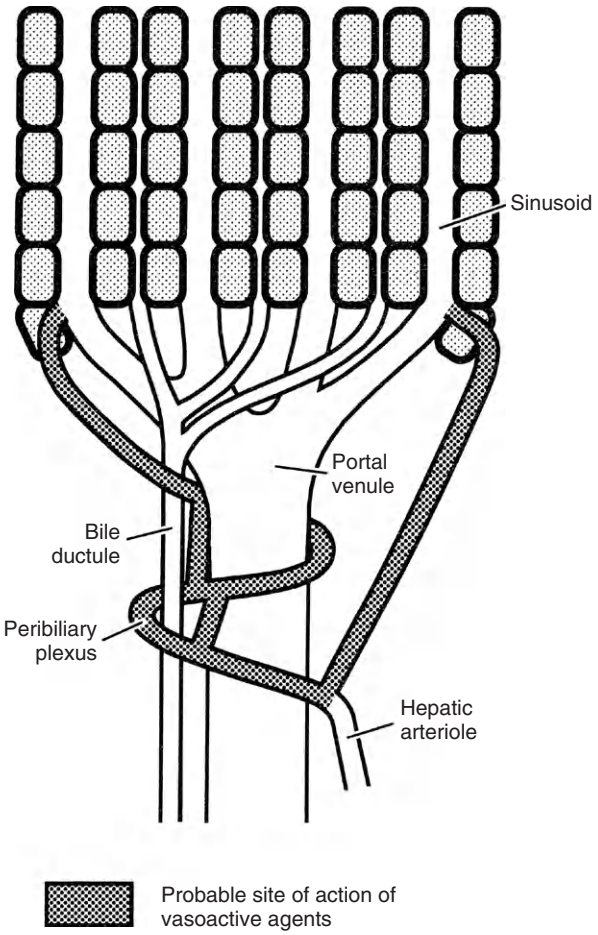

FIGURE 4.1. Diagrammatic representation of the microvascular bed of the liver, showing the anatomic association between hepatic arterioles, portal venules, and bile ductules. The probable site of action of vasoactive agents on the hepatic arterial circulation is indicated.

Blood Gas Tensions

Experimental studies have attempted to clarify the role of arterial blood gas tensions and pH on the hepatic circulation. Hypercarbia ($Paco_2$ > 70 mm Hg) increases portal venous flow and decreases hepatic arterial flow in dogs (Hughes et al, 1979a), whereas hypocarbia ($Paco_2$ < 30 mm Hg) decreases both (Hughes et al, 1979b). Systemic hypoxia (Pao_2 < 70 mm Hg) causes a decrease in arterial flow but has no effect on the contribution from the portal vein (Hughes et al, 1979c). The response to metabolic acidosis is similar to that induced by hypercarbia, whereas metabolic alkalosis has essentially no significant effect (Hughes et al, 1980b). The sympathetic nervous system is thought to be responsible for the hepatic arterial vasoconstriction observed in hypercarbia and hypoxia (Mathie & Blumgart, 1983b).

Sympathetic Nervous System

Denervation experiments have shown that the sympathetic nervous system is not involved in basal arterial tone in the liver (Mathie & Blumgart, 1983b). Hepatic sympathetic nervous stimulation causes hepatic arterial vasoconstriction and reduced blood flow, but this is secondary to the autoregulatory response (Greenway & Stark, 1971). Sensory denervated rats and pigs have a diminished arterial buffer response on partial occlusion of the portal vein (Ishikawa, 1995). Portal pressure increases as a result of an increase in portal venous resistance, but portal flow does not decrease, unless there is a decrease in intestinal or splenic blood flow caused by simultaneous sympathetic stimulation of these vascular beds. The liver is a significant blood reservoir, and 50% of its blood volume may be mobilized by nerve stimulation (Greenway & Lautt, 1989).

Although the hepatic artery contains both α-adrenergic and β-adrenergic receptors, the portal venous system is believed to contain only α-receptors (Richardson & Withrington, 1981). At low doses, epinephrine causes hepatic and mesenteric arterial vasodilation, whereas at high doses, vasoconstriction occurs in the hepatic arterial and portal venous vascular beds and in the mesenteric circulation (Greenway & Stark, 1971; Richardson & Withrington, 1981).

Other Endogenous Vasoactive Agents

Hepatic blood flow is profoundly increased by glucagon as a consequence of its strong vasodilatory action on the mesenteric vasculature, but insulin has little hemodynamic effect on the hepatic circulation. Histamine causes hepatic arterial dilation and, in the dog only, hepatic venous constriction. Bradykinin is a potent hepatic arterial vasodilator that has little effect on the portal venous system. The hepatic arterial vascular bed is dilated by most prostaglandins; however, prostacyclin does not affect hepatic arterial flow but increases portal blood flow through a vasodilator effect on the prehepatic vascular bed. NO causes vasodilation in the hepatic arterial and mesenteric vascular beds as discussed earlier. Each of the gut hormones—gastrin, secretin, cholecystokinin, and vasoactive intestinal peptide—causes vasodilation of the hepatic artery. In addition, antagonists of calcitonin gene–related peptide and neurokinin significantly reduce hepatic arterial blood flow, suggesting the presence of their receptors on the arterial vasculature (Biernat et al, 2005).

Angiotensin decreases hepatic arterial and portal blood flow and is one of the few substances to produce a significant vasoconstrictor effect on the hepatic artery. However, the ETs that can exert a powerful and prolonged generalized systemic constriction (Miller et al, 1989; Zhang et al, 1994) also have a direct effect on the hepatic blood flow. ETs reduce hepatic perfusion (Kurihara et al, 1992), increase portal pressure (Bauer et al, 1994; Isales et al, 1993; Tanaka et al, 1994; Tran-Thi et al, 1993), and reduce sinusoidal diameter (Bauer et al, 1994; Okumura et al, 1994; Zhang et al, 1994). Vasopressin decreases portal flow and pressure by mesenteric arterial vasoconstriction but has variable effects on the hepatic artery. Serotonin is believed to mediate vasoconstriction of portal radicles and has been targeted as a substance involved in the maintenance of portal hypertension, which will be discussed later. In contrast, hydrogen sulfide either endogenously or exogenously can reverse the norepinephrine-induced vasoconstriction in an NO-independent fashion (Fiorucci et al, 2005). Intraportal administration of exogenous vasoactive agents affects hepatic arterial resistance (Lautt et al, 1984); the mechanisms underlying this intrahepatic transvascular effect are not understood, but

it is likely that the close anatomic association between arterioles and venules (see Fig. 4.1) could permit this and may be a means by which hepatic arterial blood flow is finely controlled by endogenous agents such as gut hormones.

Anesthetic Agents

Hepatic arterial and portal venous blood flow decreases passively in parallel with cardiac output during halothane inhalation, with little change in vascular resistance (Hughes et al, 1980a; Thulin et al, 1975). Hepatic oxygen consumption is not diminished by halothane because of a marked increase in the oxygen extraction rate from the reduced blood supply (Andreen et al, 1975). Enflurane has been found to have similar effects to those of halothane, although there is a decrease in hepatic arterial vascular resistance as part of a generalized decrease in peripheral vascular resistance (Hughes et al, 1980a). Cyclopropane and methoxyflurane reduce LBF, mainly by increasing the mesenteric vascular resistance (Batchelder & Cooperman, 1975). NO in concentrations of 30% to 70% reduces hepatic artery and portal vein flow, possibly as a result of a generalized stimulatory action on α-adrenergic receptors (Thomson et al, 1982). Isoflurane seems to have minimal effects on hepatic arterial and portal venous flows, and the intravenous agent fentanyl may have little effect on prehepatic splanchnic blood flow (Nagano et al, 1988); thiopentone in low doses vasoconstricts the hepatic arterial and mesenteric vascular beds (Thomson et al, 1986).

MEASUREMENT OF LIVER BLOOD FLOW

The earliest methods of measuring LBF involved direct invasive techniques, such as intravascular devices or venous outflow collection (Burton-Opitz, 1910, 1911; MacLeod & Pearce, 1914). Indirect determination of blood flow by the use of a variety of indicator-clearance techniques were subsequently developed but were confounded by the presence of liver disease. The available methods are discussed under three broad headings: 1) flow in single blood vessels, 2) total LBF, and 3) hepatic tissue perfusion. The techniques currently employed for experimental and clinical investigations are listed in Table 4.1.

Table 4.1

Summary of Methods Currently Used for Measuring Liver Blood Flow

Flow in Single Vessels	Total Liver Blood Flow
Electromagnetic flowmeter	Clearance techniques
Doppler ultrasound	Hepatocyte excretion
	Indocyanine green
Hepatic Tissue Perfusion	Galactose
Inert gas clearance	Reticuloendothelial uptake
Krypton 85	Sulfur colloid (technetium 99m)
Xenon 133	Indicator dilution
Hydrogen	Red blood cells (chromate 51)
Laser Doppler flowmetry	Serum albumin (iodine 131, technetium 99m)
	Indicator fractionation
	Microspheres (various labels)

Flow in Single Vessels

Electromagnetic Flowmeter

The direct and continuous measurement of hepatic arterial and portal venous blood flow with electromagnetic flow probes remains the best available means of assessing individual vessel flow. Although the technique has found widespread application in experiments using large animals, its use in clinical situations has been limited by the relatively extensive vascular dissection required for placement of the probes and by the overestimation of true hepatic tissue blood flow, which occurs in the presence of portosystemic shunts. In addition, relative movements of the probes can give rise to errors and the need for repetitive calibrations. Total LBF in anesthetized subjects was determined to be approximately 1 L/min, of which about 25% was supplied by the hepatic artery (Schenk et al, 1962). Electromagnetic probes have been used intraoperatively to assess the hemodynamic status of the liver in cirrhosis (Ohnishi et al, 1987) after liver surgery or transplantation (Takaoka et al, 1990). A typical experimental preparation using electromagnetic flow probes is illustrated in Fig. 4.2.

Doppler Ultrasound

Named after Christian Doppler for the phenomenon he described, the principle of flow estimation by Doppler flowmetry is simple: flow is a product of the average velocity of the blood measured in the vessel of interest and the cross-sectional area of the vessel. Two forms of Doppler ultrasound devices exist: The first consists of a flowmeter with an ultrasound probe that is placed directly on the vessel; measurement with such a device is invasive. The second consists of a combined image scanner and flowmeter (duplex) with which flow in a vessel can be measured transcutaneously and noninvasively.

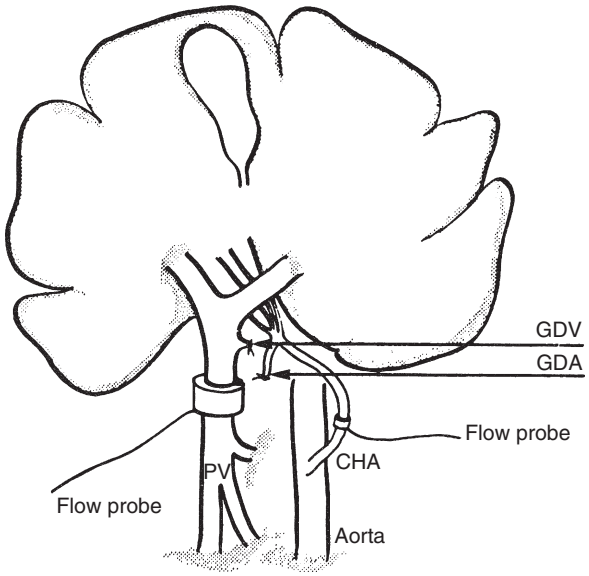

FIGURE 4.2. Experimental arrangement for measuring liver blood flow in the dog with electromagnetic flow probes. Probes are placed around the portal vein (*PV*) and common hepatic artery (*CHA*). The gastroduodenal vein (*GDV*) and gastroduodenal artery (*GDA*) are ligated as illustrated to ensure that the flows measured by the probes are those that actually perfuse the liver.

INVASIVE. Because the ultrasound probes are fitted directly to the vessel, such systems have been used successfully in the intraoperative (Henderson et al, 1991) and postoperative measurement of portal venous and hepatic arterial blood flow in liver transplant patients (Payen et al, 1990).

NONINVASIVE. In experiments performed on anesthetized dogs, good correlation was found between portal venous flow measured by a transcutaneous Doppler duplex system and electromagnetic flow probes fitted to the portal vein (Dauzat & Layrargues, 1989). However, the clinical application of transcutaneous Doppler ultrasound to obtain quantitative hepatic blood flow measurements in the portal vein have been more difficult (Burns et al, 1987). This technique has been utilized to assess postoperative hemodynamic consequences of portosystemic shunt procedures, such as transjugular intrahepatic portosystemic stent shunt (TIPS) (see Chapter 96; Fung et al, 1998), and for diagnosis of cirrhosis and portal hypertension (Iwao et al, 1997). In normal subjects, portal blood flow of 600 to 900 mL/min was reported (Brown et al, 1989; Moriyasu et al, 1986), whereas blood flow in the common hepatic artery was reported to be approximately 250 mL/min (Nakamura et al, 1989). The use of color Doppler has improved the suitability of the Doppler method for routine clinical use (Rosemurgy et al, 1997). The availability of ultrasound echo-enhancing materials, such as the galactose-based microbubble agent Levovist (Ernst et al, 1996), may further improve the precision of hepatic blood flow measurement and imaging using the Doppler technique.

Total Liver Blood Flow

Clearance Techniques

The rate of disappearance from the bloodstream of an indicator substance exclusively cleared by the liver is proportional to LBF. First applied to humans by Bradley and colleagues in 1945, indirect clearance methods of LBF measurement rely on the Fick equation. The flow measurement obtained by Bradley's group depended on the fact that intravenously injected bromosulfophthalein is removed from the bloodstream and into the bile entirely by hepatocytes. They derived a value for the rate of hepatic bromosulfophthalein removal indirectly by determining the rate of intravenous infusion of dye that maintained the arterial concentration at a constant level, and by measuring the arteriovenous concentration difference of bromosulfophthalein, they were able to calculate total hepatic blood flow. The mean value obtained in a group of normal subjects was 1.5 L/min.

Other substances dependent on hepatocyte extraction into bile have also been applied, such as indocyanine green (Caesar et al, 1961). None of these substances achieve complete hepatic removal, and hepatic vein cannulation is necessary to allow calculation of the true extraction efficiency. Many investigators now use a simplified version of the original method, in which indocyanine green is administered as a bolus, instead of as an infusion, and hepatic extraction efficiency is determined from an analysis of the clearance curve derived from blood samples taken from a peripheral vein, instead of from the hepatic vein (Grainger et al, 1983). Limitations of this technique include extrahepatic shunting, which is common in liver disease and results in an underestimation of blood flow. Other hepatic clearance techniques have been used, such as colloidal clearance by the hepatic Kupffer cells (Dobson & Jones, 1952) and hepatocyte removal of galactose (Keiding, 1988), sorbitol (Zeeh et al, 1988), rose bengal (Combes, 1960), or propranolol (George, 1979). The more complete hepatic extraction of these substances overcomes the need to cannulate a hepatic vein in patients with normal liver function.

A modification of the colloid extraction method developed in the 1980s allows the derivation of the ratio of hepatic arterial to total LBF, termed the *hepatic perfusion index*. The basis of the technique is the ability to determine by dynamic scintigraphy the temporal separation of accumulating hepatic activity from the arterial and portal supplies after the intravenous administration of a bolus of technetium-99m–sulfur colloid (Fleming et al, 1981; Parkin et al, 1983).

Indicator Dilution

The indicator dilution method relies on the application of the Stewart-Hamilton principle, also derived from the Fick equation (Stewart, 1897). In principle, the hepatic blood flow is proportional to the amount of hepatic blood that has diluted an introduced indicator. This method involves the injection into the hepatic artery and portal vein of a labeled substance that is not removed by the liver; changes in hepatic vein concentration are measured by blood sampling or by monitoring the hepatic isotope activity with an external detector. Such a method is therefore independent of hepatocellular function and reliable, provided the indicator remains in the vascular space and is not excreted prior to sampling. In addition, sampling must not be done in such a manner that affects hepatic circulation, or not more than 30 mL/min in dogs (Cohn et al, 1969).

Portal vein flow may be determined separately using a modification of this technique by sampling portal blood after splenic vein or superior mesenteric artery injection (Chiandussi et al, 1968; Huet et al, 1973). Hepatic artery flow may be calculated as the difference between total hepatic flow and portal flow. In addition, a modified thermal dilution technique has been used to measure portal blood flow in humans (Biber et al, 1983). Indicator dilution methods overestimate true blood flow to hepatic tissue when intrahepatic or extrahepatic shunts are present, although it is possible to measure azygos blood flow by thermal dilution in patients with cirrhosis (Bosch & Groszmann, 1984).

Indicator Fractionation

The measurement of regional blood flow by fractional distribution of cardiac output was first described by Sapirstein in 1956. Briefly, a known amount of radioactive microspheres is injected into the left ventricle, and a reference sample is withdrawn from a peripheral artery at a known rate. The microspheres are then extracted from the various vascular beds, where they have lodged in proportion to the cardiac output. The hepatic arterial blood flow is determined directly by this method, but the portal flow contribution is found indirectly by addition of the flow values in the prehepatic splanchnic organs. Examination of the intrahepatic distribution of microspheres provides a means of assessing the pattern of arterial flow in different regions of the liver (Greenway & Oshiro, 1972). Because the microsphere method requires the postmortem removal of the organs of interest for radioactivity or colorimetric measurement, the additional determination of tissue weight enables flow per gram (i.e., tissue perfusion) to be calculated. Microspheres

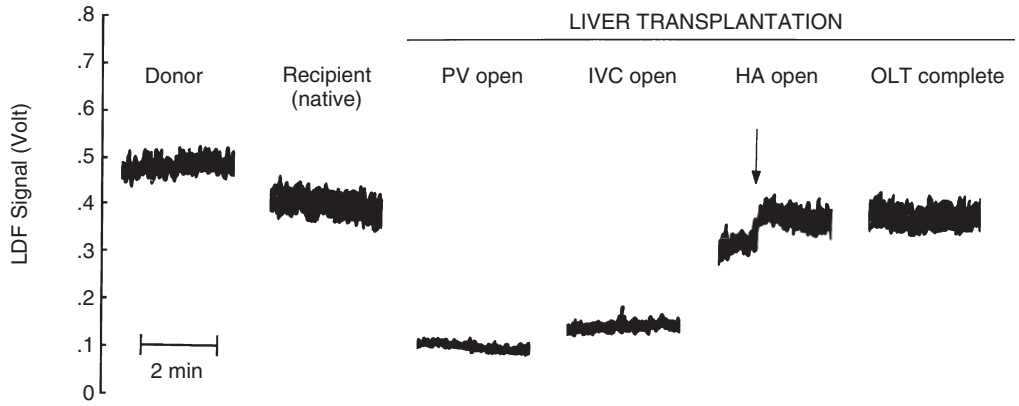

FIGURE 4.3. LDF measurements during a single liver transplantation in the rat. The *arrow* shows the point at which the hepatic artery was opened. HA, hepatic artery; IVC, inferior vena cava; LDF, laser Doppler flowmetry; OLT, orthotopic liver transplantation; PV, portal vein. *(From Wheatley AM, Zhao D, 1993: Intraoperative assessment by laser Doppler flowmetry of hepatic perfusion during orthotopic liver transplantation in the rat. Transplantation 56:1315-1318.)*

may be employed to determine the extent of portosystemic shunts: the fractional distribution in the liver may be measured with respect to systemic (lung) activity after portal vein injection, or it may be estimated by injecting a second radioactive microsphere directly into the splenic or mesenteric venous system (Groszmann et al, 1982).

Hepatic Tissue Perfusion

Inert Gas Clearance

By exploiting the fact that radioactive gases such as krypton (^{85}Kr) and xenon (^{133}Xe) distribute equally between tissue and blood according to a specific partition coefficient, the rate of clearance of such gases can be measured after their injection into the hepatic blood supply. After injection and rapid diffusion throughout the liver, the gas clears from the tissue into the blood and is almost completely eliminated from the body after a single passage through the lungs. The clearance rate is proportional to hepatic tissue perfusion, which may be calculated using a standard formula (Leiberman et al, 1978). Beta-emissions of ^{85}Kr are recorded by a Geiger-Müller tube or semiconductor (silicon) detector placed on or immediately above the exposed liver surface, while the γ-emissions of ^{133}Xe are monitored transcutaneously by a single scintillation crystal or a γ-camera; the latter device allows simultaneous measurement of hepatic tissue perfusion in many regions of interest.

Inert gas techniques involve minimal trauma to the patient, and their accuracy is not markedly affected by the presence of hepatic cellular disease or nonperfusion shunts; however, some variability does occur, even within the same subject, when multiple studies are performed. The first to use the inert gas method in the hepatic circulation were Aronsen and colleagues (1966), who recorded the γ-emissions of ^{133}Xe after the injection of a saline solution of the isotope into the portal vein.

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) is a more recent but established technique for the real-time measurement of microvascular red blood cell perfusion in the liver. By illuminating the tissue with low-power laser light and capturing the backscattered light with independent photodetectors, the Doppler shift of moving cells can be transmitted as an electrical signal. Linearity of the LDF signal from the liver with total organ perfusion has been shown (Almond & Wheatley, 1992; Shepherd et al, 1983, 1987), and the technique has been shown to be sensitive to rapid changes in organ flow (Almond & Wheatley, 1992). In a rat model, the technique provided a good measure of hepatic perfusion in vivo (Wheatley et al, 1993a; Fig. 4.3). LDF has also been used successfully to assess LBF during shock and resuscitation (Wang et al, 1995) and during drug-induced changes in LBF in the rat (Kurihara et al, 1992), and the technique has been applied successfully to measure LBF during liver transplantation in humans (Seifalian et al, 1997). A major drawback of the technique is that, owing to the small volume of tissue interrogated by the laser, the LDF signal can only be used to measure arbitrary, instead of absolute, blood perfusion in a single area. The development of laser Doppler perfusion imaging devices that estimate tissue perfusion by scanning an area of tissue using a laser may overcome the problem of signal calibration (Wardell et al, 1993).

In Vivo Fluorescent Microscopy

Intravital microscopy was first described in the microvessels of the frog tongue by Waller in 1846. Using this technique, individual sinusoids and terminal venules can be visualized, and changes in their diameters and the velocities with which erythrocytes pass through them can be seen (Menger & Messmer, 1991; Fig. 4.4). The introduction of fluorescent dyes has broadened the spectrum of in vivo microscopy in the liver from morphologic analysis to the study of pathologic events. However, from a hemodynamic point of view, intravital fluorescent microscopy has problems of interpretation (Sherman et al, 1990). In perfused liver, a 2.5-fold increase in portal venous blood flow has been found to be associated with only a 22% increase in sinusoidal red blood cell velocity, suggesting that changes in portal venous blood flow have only a minor effect on the capillary transit time (Sherman et al, 1996). In the regenerating liver; however, a 50% increase in portal venous blood flow resulted in a similar (66%) increase in sinusoidal red blood cell velocity (Wheatley et al, 1996; Zhang et al, 1997).

Near-Infrared Spectroscopy

Near-infrared spectroscopy is a new noninvasive technique that utilizes light transmission and absorption to measure

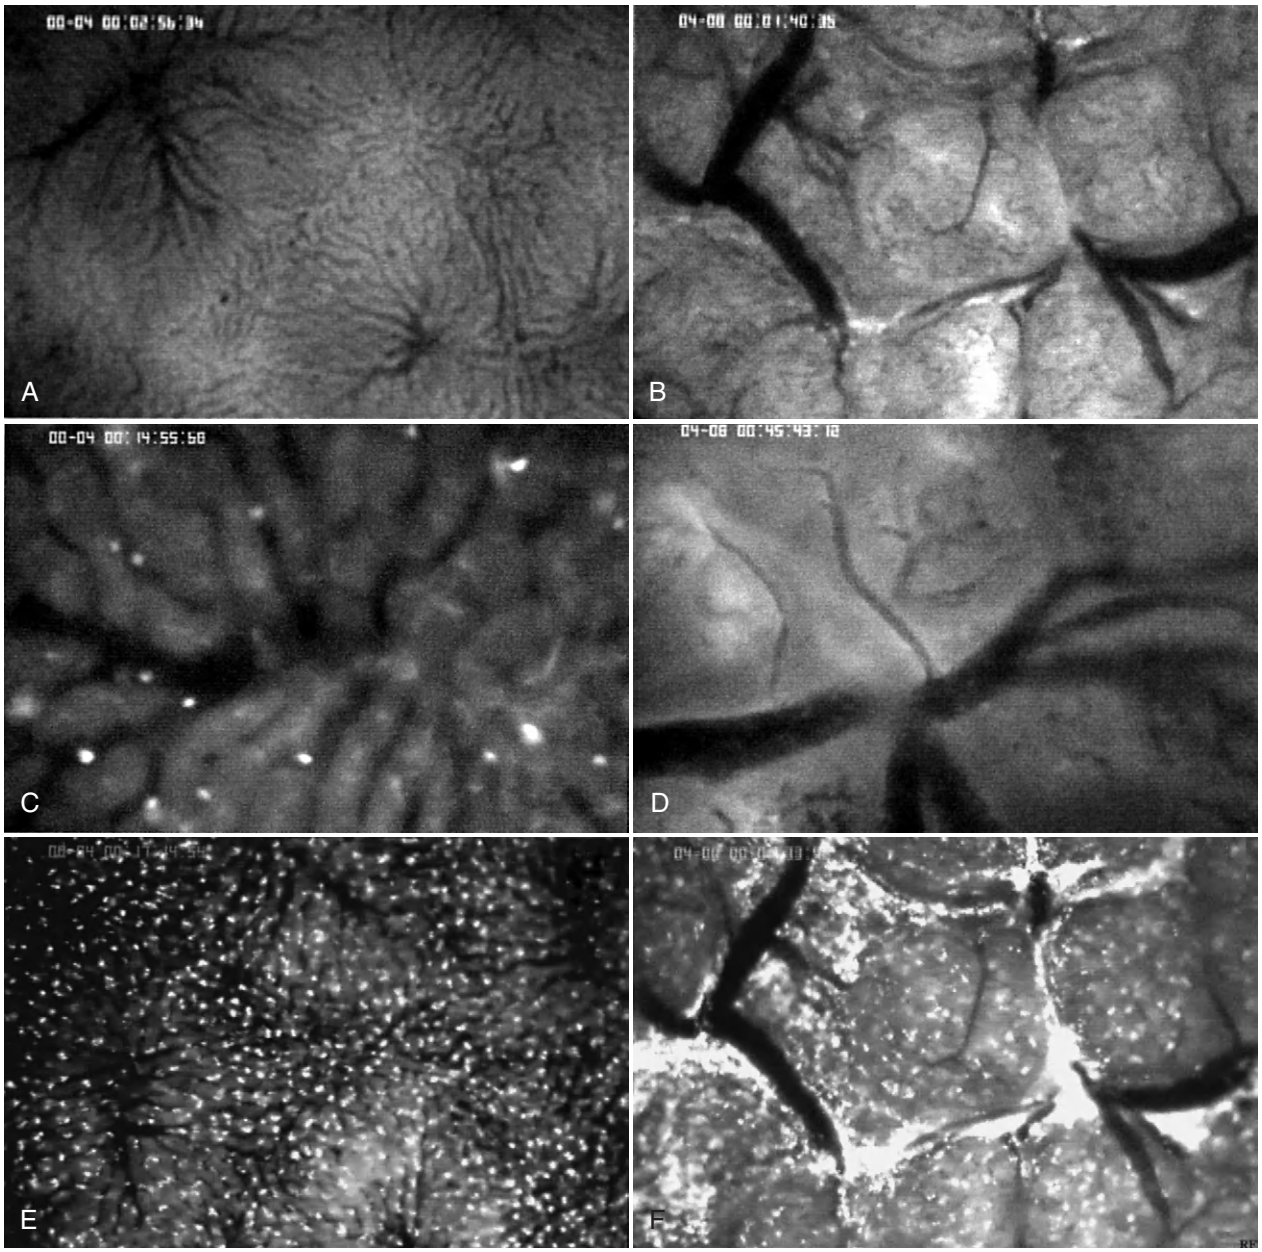

FIGURE 4.4. Hepatic hemodynamic and cellular alterations observed in cirrhotic livers with intravital fluorescent microscopy. Note the characteristic alterations in cirrhotic livers with regard to distension of the central veins (**A,** control vs. **B,** cirrhotic), reduction in number of sinusoids feeding directly into the central veins (**C,** control vs. **D,** cirrhotic), and movement of hepatic stellate cells (as measured by their vitamin A autofluorescence) from a homogeneous distribution in control livers (**E**) to a heterogeneous distribution focused around and along fibrous bands connecting the central veins (**F**).

hemoglobin and mitochondrial oxygenation. In contrast to visible light, which can only penetrate a few millimeters, near-infrared light (700 to 1000 nm) can be detected through up to 80 mm of tissue. The application of this technology to monitor liver oxygenation has been validated in models of endotoxic shock in pigs (Nadhum, 2006) and by intraoperative quantification of congestion and mitochondrial redox during hepatic vein occlusion in living-donor transplantation (Ohdan, 2003).

New and Future Developments

Orthogonal polarized spectral imaging has been used to obtain images of the liver microcirculation comparable to those of fluorescence microscopy but without the need for fluorescent dyes (Langer, 2001). This system relies on the absorbance of hemoglobin and can discriminate a single red blood cell in an individual capillary with a diameter of 5 microns. Studies with hand-held devices using this technology have been applied to healthy living donors to obtain sinusoidal red blood cell velocity and columetric blood flow (Puhl et al, 2003). A recent successor to spectral imaging is sidestream dark field imaging, whereby a light guide surrounded by diodes can detect both red and white blood cells in the microcirculation without the surface reflections (Czerny et al, 2009). Portal venous blood flow measured by noninvasive magnetic resonance imaging (MRI) has been

found to correlate well with flow measured by Doppler ultrasound flow probes (Pelc et al, 1992); subsequently, the technique has been used to measure portal venous blood flow in human liver transplantation candidates (Kuo et al, 1995). Further methodology improvements in MRI (e.g., dynamic contrast enhancement) and in other techniques, such as positron emission tomography, may lead to their increasing use in the study of hepatic hemodynamics in humans (Chow et al, 2003).

CLINICAL RELEVANCE

Hemorrhagic Shock, Hypoperfusion, and Ischemia-Reperfusion Injury

Total LBF decreases approximately in relation to the degree of the hemorrhage, and portal venous blood flow decreases in parallel to cardiac output; but similar to the coronary, pulmonary, and cerebral circulations, hepatic arterial flow does not decrease until extremely low blood pressures are reached. As a result, the hepatic oxygen supply tends to be maintained, although oxygen extraction greatly increases to preserve normal total oxygen consumption (Smith et al, 1979). Hepatic blood volume can increase significantly in cardiac failure and can compensate up to 25% of hemorrhage from its large capacitance vessels (Lautt, 2007).

The clinical entity known as *shock liver* has long been recognized, typically related to cardiogenic or hemorrhagic shock (Birgens et al, 1978; Bynum et al, 1979). Hepatic dysfunction caused by hypoperfusion is manifested pathologically by centrilobular necrosis and clinically by abdominal pain, cholestatic jaundice, and marked elevation of serum transaminases. Three phases of liver injury attributed to ischemia were proposed by Champion, whereby the initial hepatic dysfunction would resolve as long as no additional insults (e.g., sepsis) were incurred (Champion et al, 1976). Gottlieb and colleagues (1983) showed that hepatic dysfunction in humans after trauma was related to a reduced hepatic blood flow rate up to 70% of resting levels. Hepatic blood flow was markedly reduced after injury, and although total splanchnic oxygen delivery was decreased, oxygen consumption remained normal as a result of increased hepatic extraction.

In the ischemic state, upregulation of acute-phase proteins (C-reactive protein, fibrinogen, ceruloplasmin, haptoglobin) is prioritized over production of other hepatic proteins such as albumin and transferrin (Sganga et al, 1985).

More recently, hemorrhagic shock has been recognized to result in generalized vascular endothelial dysfunction and impaired endothelial biosynthesis of NO. Endothelial NO that continues to be expressed by the liver during ischemia is believed to protect against the initial hepatic injury arising from severe hemorrhage. By contrast, more prolonged hemorrhagic shock (>6 hours' duration) induces greatly increased production of NO owing to activation of an inducible NO synthase enzyme in hepatocytes and Kupffer cells (Peitzman et al, 1995).

Survival has been demonstrated after portal vein ligation to control hemorrhage after traumatic injury (Pachter et al, 1979) or after temporary portal occlusion during difficult biliary tract surgery. Similarly, survival after hepatic artery ligation for trauma, aneurysm, hemobilia, or neoplasms has been described (Rappaport & Schneiderman, 1976). In the transplantation era, the consequences of ischemia and reperfusion for the liver have been increasingly investigated and understood. The damage to the hepatic endothelium and parenchyma that results from postischemic reperfusion is caused by numerous interrelated phenomena, including the action of locally liberated oxygen-derived free radicals and excess formation of vasoconstrictor agents (Wendon, 1999). Endogenous NO tends to protect the liver in the early reperfusion period after hepatic ischemia (Shimamura et al, 1996; Wang et al, 1995). Ischemia is also the primary signal for heat-shock protein production in liver tissue. Experimental studies of heat-shock protein preconditioning through intermittent portal clamping demonstrated attenuated transaminase elevations and improved bile production after ischemia (Terajima et al, 1999).

Liver Atrophy

Liver atrophy results from a significant reduction of LBF containing hepatotrophic substances (see Chapter 5). The degree of atrophy depends on the degree of blood flow deprivation and may be distributed according to the source of deprivation, including portal venous or hepatic artery blood flow or their combination.

Atrophy and fatty degeneration of the canine liver after total portal diversion through an Eck fistula initially was reported more than a century ago (Hahn et al, 1893). Partial or complete diversion of portal vein blood flow from the liver results in atrophy. Complete portal venous flow diversion with interruption of all portal venous collaterals results in more profound liver atrophy than the partial deviation of portal venous flow resulting from side-to-side portacaval anastomoses (Bollman, 1961). A precise relationship between the degree of liver atrophy and the reduction of portal venous blood flow is still to be determined, primarily because of the relative composition and contribution of portal flow and resultant compensatory hepatic arterial flow.

Liver atrophy after portal diversion is not believed to be the result of a decrease in absolute volume flow but instead is due to the effective loss of hepatotrophic substances in the portal blood. Rats subjected to portal flow diversion with portacaval transposition had a decrease in relative liver weight (Guest et al, 1977) despite the effective preservation of portal perfusion from the inferior vena cava (Ryan et al, 1978). Dogs with "partial portacaval transposition" (Marchioro et al, 1967) or "splanchnic flow division" (Starzl et al, 1973, 1975) with diversion of pancreaticogastroduodenosplenic blood had atrophy in liver lobes, although normal tissue perfusion was shown in all regions of the liver (Mathie et al, 1979). Starzl hypothesized that insulin was the factor responsible for preventing atrophy.

The fate of the liver after ligation of the hepatic artery depends largely on the extent of a functional collateral arterial circulation (Rappaport & Schneiderman, 1976). If limited collaterals are present, liver infarction and necrosis may occur after hepatic artery ligation, resulting in death. However, hepatic artery ligation results only in transient ischemic changes in the periphery of the hepatic acinus (zone 3) in the presence of adequate collaterals. Atrophy after hepatic artery ligation can occur in liver segments that have compensatory collateral supply to prevent necrosis. The effects of hepatic artery flow absence are magnified by the presence of low portal venous blood flow, limited oxygen saturation, and superimposed infection (Rappaport & Schneiderman, 1976). Histologically, arterial obstruction results in ischemic changes such as mitochondrial swelling, cell membrane disruption, platelet

aggregation, and widening of the spaces of Disse (Mallet-Guy et al, 1972).

Liver Resection and Regeneration

As exemplified in Greek mythology by the myth of Prometheus, the adult liver exhibits a remarkable potential to restore its cellular mass in response to injury through hepatocyte hyperplasia. After the removal of two thirds of liver mass in the rat by partial hepatectomy, liver mass and function are fully recovered by 2 to 3 weeks. In the early stages of regeneration, as a consequence of hepatocyte division, clusters of hepatocytes develop with a reduced distribution of sinusoids (Martinez-Hernandez & Amenta, 1995). Hepatic regeneration of the normal liver remnant proceeds rapidly after partial hepatic resection (see Chapters 4 and 80; Aronsen et al, 1970; Blumgart et al, 1971).

Major resection is associated with a significant and persistent increase in portal pressure (Lee et al, 1987; Morsiani et al, 1995; Wu et al, 1993). Partial liver resection without devascularization normally would be expected to produce little change in total blood flow to the liver. This occurs because the major contributor to total flow, the portal vein, is affected less by events occurring within the liver than by control mechanisms in the arterial resistance vessels of the prehepatic splanchnic bed. On the other hand, the failure of the liver to directly control its portal venous flow may have the result of portal hyperperfusion of a reduced parenchymal mass. Because essentially the same total blood flow is redistributed to a smaller mass of liver tissue, a corresponding increase in tissue perfusion (mL/min per unit tissue weight) would be anticipated in the in situ remnant. Experimental studies support these expectations; an increase in hepatic tissue perfusion was observed in rats immediately after two-thirds hepatectomy (Rice et al, 1977; Wheatley et al, 1993b; Wu et al, 1993). This increase in hepatic perfusion is due primarily to portal venous inflow (Wu et al, 1993), because hepatic arterial blood flow is low, and hepatic arterial resistance is high even 24 hours after partial hepatectomy in rats (Wheatley et al, 1996). Similar studies in patients showed an immediate increase in tissue perfusion of approximately 120% in the remnant (Mathie & Blumgart, 1982). Recent experimental evidence has suggested that intrahepatic shear stress from increased portal flow is a regulator of liver regeneration (Schoen et al, 2001). The significance of blood flow in relation to liver regeneration has been debated frequently in the years since Mann (1944) suggested that regenerative hyperplasia of the liver after partial resection was a function of portal blood flow, and that the process could be prevented by portal flow diversion. However, regenerative hyperplasia normally occurs after partial liver resection in portacavally transposed animals, in which there is no direct supply of portal blood nor the usual posthepatectomy increase in hepatic tissue perfusion. A similar response is seen during portal vein embolization for preoperative expansion of the liver remnant (see Chapter 93).

Blood Flow in Hepatic Tumors

It has been demonstrated that tumors of the liver, whether primary or secondary, are perfused almost exclusively with arterial blood (Breedis & Young, 1954). Several investigators have attempted to achieve differential diagnosis of patients by measuring the proportion of the hepatic arterial contribution to total flow, adopting the hepatic perfusion index obtained by scintigraphy (Leveson et al, 1985) or the Doppler perfusion index obtained by ultrasound (Leen et al, 1991a). Such measurements have shown an increased hepatic arterial contribution in patients with confirmed liver metastases compared with normal subjects. Patients who have colorectal cancer with no observed liver metastases were found to have altered hemodynamics that overlapped those of the other groups, suggesting the presence of occult hepatic disease (Leen et al, 1991b). The Doppler perfusion index has been shown to be more sensitive than computed tomography, conventional ultrasound, or laparotomy alone in the detection of colorectal liver metastases (Leen et al, 1995).

Taking advantage of this phenomenon, the application of the vasoconstrictors epinephrine, phenylephrine, or angiotensin has improved cytotoxic drug delivery to tumor-bearing areas in human and animal models (Bloom et al, 1987; Goldberg et al, 1991; Hemingway et al, 1991). This approach is feasible because the neovasculature of tumor tissue lacks smooth muscle and therefore does not respond to vasoconstrictor agents, enabling increased delivery of chemotherapeutic drugs. Biodegradable microspheres also have been used for enhancing targeted therapy; they cause temporary blood flow interruption, resulting in improved uptake of chemotherapeutic agents in tumor tissue and consequent reduced systemic toxicity (Ball, 1991). Multiple drugs have been utilized in the palliative setting for percutaneous intrarterial instillation, and these can be loaded into the two current commercially available microsphere systems, DC Bead and QuadraSphere (Liapi et al, 2010).

Bile Duct Obstruction

Bile duct obstruction can affect hepatic hemodynamics significantly (see Chapter 7). In general, LBF is reduced in the presence of chronic biliary obstruction, leading to hepatic dysfunction. Conversely, acute increases in bile duct pressure from early obstruction result in a reflexive increase in LBF, which attempts to maintain adequate flow in the face of an increased pressure gradient opposing secretion and excretion of bile. Most evidence suggests that the hemodynamic response of the liver to biliary obstruction is related, directly or indirectly, to changes in bile duct pressure. Given the limited space of Mall in the portal triad, it is conceivable that increased biliary pressures may compress the portal capacitance vessels, leading to increased arterial flow (Kanda et al, 1996). Nagorney and colleagues (1982) showed that acute serial increases in bile duct pressure in dogs with complete bile duct obstruction increased hepatic arterial blood flow by 250% but did not affect portal venous blood flow.

Chronic bile duct obstruction is associated with a decrease in total LBF. In addition, dilation of the sinusoids and elevation of portal pressure in dogs was noted after 4 weeks of complete bile duct obstruction (Ohlsson et al, 1970). Relief of long-term obstruction does not result in the return of normal hemodynamics, suggesting irreversible intrahepatic vascular damage (Aronsen et al, 1969). Furthermore a 23% reduction in effective LBF persisted for 1 to 5 years after operative decompression in patients with choledocholithiasis and jaundice for more than 2 weeks preoperatively (Aronsen, 1968). Hunt (1979) serially measured LBF daily for 1 week after bile duct ligation in rats, using the ^{133}Xe clearance technique to document the early hemodynamic response. Total LBF decreased steadily after the first postoperative day to a plateau level of approximately 50%

of the preoperative value 5 days after operation. Mathie and colleagues (1988) confirmed the decrease in total LBF after bile duct ligation by measuring the individual portal venous and hepatic arterial components of LBF. Using electromagnetic flowmeters in dogs with complete bile duct ligation, hepatic arterial and portal venous blood flow were observed to decrease by 36% and 44%, respectively; they also showed a 200% increase in intrahepatic portal resistance but a lesser increase in hepatic arterial resistance. Similarly, Bosch and others (1983) showed that dogs with chronic bile duct ligation had decreased portal venous flow and had developed sinusoidal portal hypertension and extensive portosystemic shunting.

The precise mechanism for reduction in LBF after chronic bile duct obstruction is unknown. Although increased portal vascular resistance is the accepted underlying cause, the primary site of this resistance change has been considered to be presinusoidal (Reuter & Chuang, 1976), sinusoidal (Bosch et al, 1983), or postsinusoidal (Tamakuma et al, 1975). Bosch and colleagues (1983) also showed the development of significant portosystemic shunting with an inverse correlation between shunting and portal venous blood flow, suggesting that the site of shunting is predominantly extrahepatic (Ohlsson, 1972).

Chronic biliary obstruction results in two hemodynamic consequences: portal hypertension associated with secondary biliary fibrosis and shock after biliary tract decompression. Approximately 20% of patients with prolonged biliary obstruction develop clinically significant portal hypertension (Adson & Wychulis, 1968; Blumgart et al, 1984; Sedgwick et al, 1966). The operative risk of biliary decompression in these patients is significant. Technical difficulties of stricture repair—dense fibrous adhesions, hilar ductal involvement, and infection—are complicated by the risk of hemorrhage from subhepatic and periductal varices and potential postoperative liver failure. Portosystemic shunts may be performed before biliary decompression in patients with bleeding esophageal varices or previous intraoperative hemorrhage that precluded successful stricture repair (Adson & Wychulis, 1968; Sedgwick et al, 1966).

In addition to the hemodynamic consequences of chronic bile duct obstruction, sudden decompression of the obstructed biliary tree also may have profound hemodynamic effects. Tamakuma and colleagues (1975) studied the significance of clinical shock after biliary decompression and noted that hypotension and shock could develop in the immediate postoperative period. They showed that biliary decompression resulted in an abrupt decrease in wedged hepatic vein pressure, portal vein pressure, and arterial pressure within 30 minutes of decompression. Similarly, Steer and colleagues (1968) reported that rapid needle decompression of an obstructed biliary tree in jaundiced dogs induced a decreased arterial pressure, central venous pressure, and portal venous pressure within 1 hour; they concluded that sudden decompression of chronic biliary obstruction leads to sequestration of fluid within the liver, resulting in a decrease in the effective circulating plasma volume and subsequent hypotension.

Portal Hypertension (See Chapters 70 and 74)

Hemodynamics

Portal hypertension is a state of sustained increase in the intraluminal pressure of the portal vein and its collaterals. A mean pressure greater than 12 mm Hg is the accepted target, as variceal bleeding does not occur at lower pressures than this (Garcia-Tsao et al, 1985). Hemodynamic factors that influence portal hypertension are best understood by application of the flow-resistance principle that applies to the portal venous system. Portal pressure depends on two basic components: portal blood *flow* and hepatic portal vascular *resistance*. Portal hypertension may result from a significant increase in hepatic portal inflow from the prehepatic splanchnic vasculature, an increase in intrahepatic portal resistance, or both. Although simple in concept, multiple factors may influence both the components of the system and the pathophysiology of portal hypertension.

Increased portal pressure, diminished hepatic portal blood flow, and an extensive extrahepatic collateral venous network supplied by a hyperdynamic splanchnic and systemic circulation characterize the hemodynamics of portal hypertension (e.g., in cirrhosis). The traditional view of the source of increased portal pressure is fibrotic encroachment around portal radicles, leading to increased intrahepatic portal resistance. In cirrhotic patients, extrahepatic shunts may account for at least 50% of the portal flow, whereas 80% of portal flow actually reaching the liver has been observed to bypass the sinusoidal vascular bed via intrahepatic shunts (Okuda et al, 1977). The magnitude of extrahepatic shunt flow in patients with cirrhosis was measured directly by thermal dilution assessment of azygos blood flow; a value 300 mL/min greater than in patients without portal hypertension was noted (Bosch & Groszmann, 1984). The hepatic artery probably provides a greater relative contribution to the total LBF in patients with cirrhosis than in normal subjects, although it also was shown that 33% of the arterial blood may flow through intrahepatic shunts to the systemic venous circulation (Groszmann et al, 1977).

The direction of portal blood flow has been proposed as a contributor to the pathophysiology of portal hypertension. The progression of intrahepatic disease and increasing sinusoidal pressure has been postulated as contributing to reversal of flow in the portal vein, which further aggravates the injury by depriving the liver of nutrients (Warren & Muller, 1959). However, reversed, or *hepatofugal,* portal vein flow has rarely been documented. Hemodynamic information from 273 cirrhotic patients collected from the literature in the 1970s revealed no case of spontaneous flow reversal (Moreno et al, 1975), and Gaiani and colleagues (1991) reported an incidence of only 3.1% in a sample of 228 patients.

The hypothesis that the low peripheral vascular resistance in portal hypertension may be caused by the stimulated production of NO induced by endotoxemia was proposed by Vallance and Moncada in 1991. The initial experimental evidence was provided by Pizcueta and others (1992), who showed an increase in systemic and splanchnic vascular resistance in cirrhotic rats after the administration of an NO inhibitor. Although endotoxemia is likely responsible for the decompensation in end-stage cirrhosis, the hemodynamic alterations are due to NO (Lee et al, 1995; Niederberger et al, 1995). Constitutive NO synthase seems to be upregulated in discrete anatomic locations, such as in the endothelium of the mesenteric artery and in the esophageal, gastric, and jejunal mucosa (Mathie, 1999).

Intrahepatic Vascular Resistance in Liver Cirrhosis

Liver cirrhosis occurs in response to chronic liver injury and is characterized primarily by a disruption of hepatic architecture, with the development of fibrous septa and abnormal nodules

and circulation, leading to a sustained increase in portal vascular resistance and portal pressure. In addition, afferent (portal venules and hepatic arterioles) and efferent vessels (hepatic venules) can be found within the fibrous septa (Kelty et al, 1950). The pathogenesis of cirrhosis involves initial hepatocyte necrosis and inflammation with subsequent transformation of hepatic stellate cells into myofibroblasts (see Chapter 6). Microscopically, excessive accumulation of collagen leads to the collagenization of the space of Disse and to Ito cell activation (Greenwel et al, 1991; Martinez-Hernandez, 1985; Martinez-Hernandez & Amenta, 1993). Capillarization of sinusoidal endothelial cells occurs by defenestration or loss of endothelial cell pores and the appearance of a basement membrane (Varin & Huet, 1985). In the cirrhotic liver, the sites of vascular resistance are still unclear; however, because portal and hepatic venules can be found within the fibrous septa, constriction or distortion of portal venules, hepatic venules, or both may be involved (Kelty et al, 1950). As portal venous blood flow progressively decreases in cirrhosis, arterial resistance may decrease through an increase in arterial flow, suggesting an intact buffer response. Studies in cirrhotic rats have demonstrated higher hepatic arterial flows compared with normal controls under baseline conditions (Richter et al, 2000). This finding was confirmed using intraoperative measurements in patients with end-stage cirrhosis undergoing living-donor liver transplantation (Aoki et al, 2005).

Until recently, it was thought that the elevated IHVR in cirrhosis was irreversible. Evidence now suggests that it can be reduced pharmacologically with vasodilators (Bhathal & Grossman, 1985; Reichen & Le, 1986). IHVR can be marginally reduced by prostaglandin E_2 (Ballet, 1991) and isoprenaline and more substantially by nitroprusside, papaverine, and verapamil (Ballet, 1991; Bhathal & Grossman, 1985; Reichen & Le, 1986). Groszmann (1990) reported that intravenous nitroglycerin caused a 24% decrease in IHVR in cirrhotic patients.

In alcoholic patients, a significant correlation is seen between the extent of hepatic stellate cell activation and the level of portal vascular resistance (Rockey & Chung, 1995). Several factors have been implicated in stellate cell activation such as inflammatory mediators, cytokines, and growth factors (Friedman, 1993, 1997; Gandhi et al, 1994; Greenwel et al, 1991) and ET (Pinzani et al, 1996; Rockey & Weisiger, 1996; Rockey et al, 1998). ET-induced contractility of isolated hepatic stellate cells increases in proportion to the degree of hepatic stellate cell activation (Rockey & Weisiger, 1996). Overexpression of ET-1 has been found in patients with cirrhosis (Housset et al, 1993; Rockey & Weisiger, 1996), which probably contributes to the elevated IHVR, probably by increased hepatic stellate cell contraction (Housset et al, 1993; Rockey & Weisiger, 1996). Microscopically, ET-1 receptors (ET_a and ET_b) are detected on all cell types in rat liver, especially Ito cells, as well as in cirrhotic human subjects (Leivas et al, 1995; Pinzani et al, 1996; Rockey et al, 1998). ET-1-induced hepatic sinusoidal contractility is enhanced in ethanol-induced fatty liver but not in cirrhotic liver, indicating that ET-1 may be involved in the regulation of sinusoidal flow in the early stage of liver cirrhosis in rats (Bauer et al, 1995).

Decreased endothelial NO synthesis and release by the liver (Gupta et al, 1998; Rockey & Chung, 1998) coupled with an associated increase in portal vascular resistance may potentiate by the effect of increased ET-1 expression by hepatic endothelial and hepatic stellate cells (Pinzani et al, 1996). The interplay between NO, ET, and other local regulatory mechanisms controlling sinusoidal hemodynamics is depicted in Figure 4.5. Groszmann (1990) suggested that the increased mesenteric blood flow in the hyperdynamic stage of portal hypertension may be relatively less important than the elevated intrahepatic portal resistance in maintaining increased portal pressure. Clinically, the vasodilaton of the splanchnic circulation likely serves to increase flow in the extrahepatic collateral circulation, leading to variceal hemorrhage.

Treatment (See Chapters 70 and 74)

Medical and surgical management strategies for portal hypertension strive to improve patient survival by the reduction of pressure and flow in extrahepatic variceal vessels, mainly esophageal and gastric vessels, while preserving adequate portal flow to the liver. Portosystemic shunting and pharmacologic reduction of portal flow can provide effective decompression, but both deprive the liver of portal flow. Surgical treatment of portal hypertension may be performed by one of the many portosystemic shunt procedures (see Chapter 76B); the initial clinical application of the portacaval shunt was reported 50 years after its description by Eck (Whipple, 1945). The hemodynamic consequences of shunt surgery depend on the particular shunt performed, the nature and severity of the disease, and the hemodynamic condition of the patient. End-to-side portacaval shunts divert all portal blood flow away from the liver, whereas less complete diversions reduce portal flow in proportion to the degree to which the shunt reduces portal pressure. The hepatic artery flow may increase by 100%, but even a maximal flow increase can usually only partly compensate for loss of portal flow (Mathie & Blumgart, 1983a). Hepatic oxygen consumption tends to be maintained by increased oxygen extraction from the available arterial supply.

Total portacaval shunts are very effective in reducing portal pressure and preventing bleeding from esophageal varices. However, because of bypass of the hepatic circulation, liver failure and encephalopathy are common complications of the operation (see Chapter 76A). Therefore, partial shunts—such as the side-to-side (see Chapter 76B), mesocaval (see Chapter 76D), and proximal or distal splenorenal shunts (see Chapter 76C)—have gained popularity. Transjugular intrahepatic portosystemic shunting (TIPS), first reported by Rössle and colleagues (1989), is currently the treatment of choice for recurrent variceal bleeding in patients who are refractory to conservative medical management (see Chapters 75A and 76E; Iannitti & Henderson, 1997).

Pharmacologic reduction of portal hypertension (see Chapter 75B) initially was based largely on an attempt to diminish hepatic portal inflow from the mesenteric vascular bed by the use of vasoconstrictor agents. At a dose that decreases the heart rate by 25%, the β-adrenoceptor antagonist propranolol significantly reduced the risk of rebleeding in cirrhotic patients who were otherwise in good condition (Lebrec et al, 1981). Propranolol exerts its action by two mechanisms: decreased cardiac output as a result of β_1-adrenergic cardiac receptor blockade and antagonism of β_2-adrenoceptors in the splanchnic vasculature that leaves the vasoconstrictive influence of α-adrenergic receptors unopposed, resulting in a decrease portal flow and pressure. Vasopressin causes generalized peripheral vasoconstriction (Bosch et al, 1988), whereas the effect of somatostatin is specific to the splanchnic vascular bed (Kravetz et al, 1984) and is the result of an inhibition of glucagon release

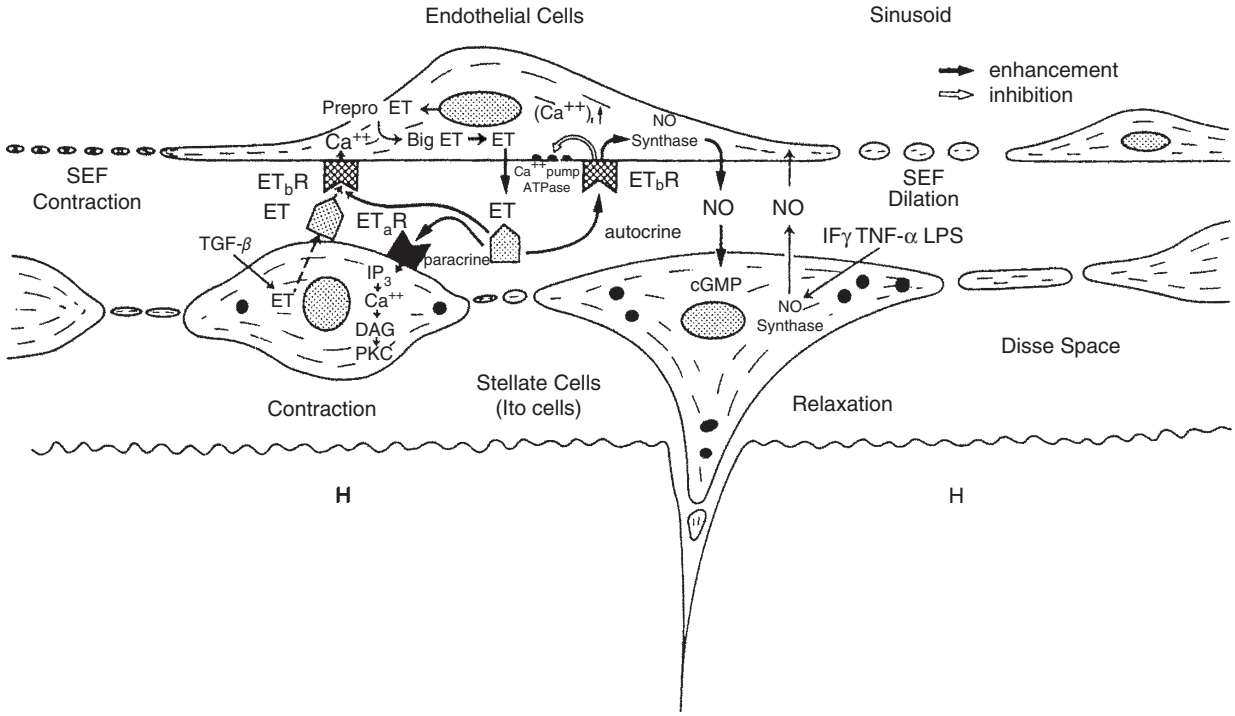

FIGURE 4.5. Local regulatory mechanisms of hepatic sinusoidal microcirculation. [Ca^{++}], concentration of intracytoplasmic free calcium ion; cGMP, cyclic guanosine monophosphate; DAG, diacylglycerol; ET, endothelin; ET_aR, endothelin-α receptor; ET_bR, endothelin-β receptor; H, hepatocyte; IFγ, interferon-γ; IP_3, inositol triphosphate; LPS, lipopolysaccharide; PKC, protein kinase C; SEF, sinusoidal endothelial fenestrae; TGF-β, transforming growth factor-β; TNF-α, tumor necrosis factor-α.

and direct vasoconstriction. Somatostatin is at least as effective as vasopressin in controlling bleeding, and with fewer side effects; it may be the agent of choice in acute management of variceal hemorrhage. Serotonin may play a significant role in maintaining increased portal pressure, and smooth muscle serotonin-receptor antagonists have been shown to lower the pressure in cirrhosis (Hadengue et al, 1987; Mastaï et al, 1989).

The nitrovasodilators isosorbide dinitrate and isosorbide mononitrate were observed to lower the portal pressure in portal hypertensive animals (Blei & Gottstein, 1986) and to increase hepatic (but not azygos) blood flow in cirrhotic patients (Navasa et al, 1989), suggesting that they may act by reducing intrahepatic portal vascular resistance. Application of nitroglycerin by transdermal tape to cirrhotic patients resulted in a reduction in portal pressure without affecting hepatic blood flow (Iwao et al, 1991).

These experiments support the previous discussion of NO and ET-1 control of hepatic sinusoidal tone. An ET receptor antagonist was reported to reduce portal pressure in cirrhotic rats by nearly 30% (Reichen et al, 1998). The combined effects of the long-acting nitrovasodilator molsidomine plus propranolol have been found by some (Hori et al, 1996) but not others (Garcia-Pagán et al, 1996) to be a more effective portal hypotensive regimen than propanolol alone.

Hemodynamic Studies and Human Liver Transplantation

Orthotopic liver transplantation (OLT) (see Chapters 97 and 98) of a normal donor organ does not normalize the splanchnic and systemic hemodynamic alterations of end-stage liver disease (Henderson, 1993). In fact, total hepatic blood flow remains elevated 6 months after OLT (Hadengue et al, 1993; Henderson et al, 1989; Navasa et al, 1993) mainly because of portal venous blood flow (Henderson et al, 1992a, 1992b; Henderson, 1993; Paulsen & Klintmalm, 1992). Azygos flow also remains elevated, and other portosystemic shunts have been documented up to 4 years after OLT (Navasa et al, 1993). Ligation of these portosystemic collateral pathways has been shown to increase portal venous blood flow (Fujimoto et al, 1995). Cardiac output data have been conflicting, with one group reporting persistently elevated values (Hadengue et al, 1993) and others showing decreases 2 weeks and 2 months after OLT (Navasa et al, 1993). Gadano and colleagues (1995) emphasized that factors such as anemia and sepsis may account for the deranged hemodynamics after OLT.

Effect of Liver Transplantation on Liver Blood Flow

Henderson and others (1989) demonstrated that LBF remains elevated for a prolonged period after liver transplantation, suggesting that baseline LBF may be under direct sympathetic control, which is lost after OLT, leading to an unopposed rise. The hemodynamic consequences of OLT in human patients are difficult to interpret for several reasons: 1) the causes of liver failure in end-stage transplant candidates are diverse; 2) immunosuppressive drugs are used, such as cyclosporine, which causes arterial hypertension; and 3) to control systemic hypertension after OLT, patients may also be given vasodilators such as hydralazine, which can cause persistently increased cardiac output.

The hepatic artery buffer reponse is conserved following OLT despite denervation. This was demonstrated in a series of experiments by Payen and colleagues (1990), who serially clamped the portal vein every 12 hours for 7 days following OLT and reported reciprocal increases in hepatic arterial flow.

The advent of living-donor partial liver transplantation has introduced the phenomenon of small-for-size syndrome, whereby the pressure of the full portal flow traveling through a small liver remnant leads to decreased arterial flow, presumably through an intact hepatic arterial buffer response (Michalopoulos, 2010). The reduced hepatic arterial flow is hypothesized to be diverted to the splenic and gastroduodenal circulation. Prospective studies have demonstrated that ligation or embolization of the splenic artery leads to improved hepatic arterial inflow and improved graft function (Lo et al, 2003; Umeda et al, 2007).

Effect of Laparoscopy on Liver Blood Flow

The use of a carbon dioxide pneumoperitoneum in laparoscopic donor surgery has been demonstrated to substantially reduce portal venous flow in parallel with the intraperitoneal pressure (Schilling et al, 1997; Jakimowicz et al, 1998). The hepatic artery buffer response is usually preserved during laparoscopy, however, conflicting data exist in support of the maintenance of this effect in high-pressure pneumoperitoneum. Rat models using fluorescent microspheres supported preserved hepatic arterial flow during decreased portal venous flow (Yokoyama et al, 2002), but this was not supported by others (Richter et al, 2001), who saw a parallel decrease in arterial and portal venous flows during laparoscopy. Some groups have suggested the avoidance of head-up positioning and pressures greater than 15 mm Hg during laparoscopy to preserve LBF (Junghans et al, 1997; Klopfenstein et al, 1998).

CHAPTER 5

Liver regeneration: mechanisms and clinical relevance

Jeroen De Jonge and Kim Marie Olthoff

LIVER REGENERATION

The ability of the liver to regenerate was recognized by the Greeks in the ancient myth of Prometheus, the Titan god of forethought, who gave fire to the mortals and angered Zeus. Prometheus was chained to the Caucasus mountains, and each day he would be tormented by Zeus' eagle, Ethon, as it devoured Prometheus' liver. Each night, the damaged liver would mend, so the eagle could begin anew, illustrating the incredible capacity of the liver to regenerate.

In contrast to other solid organs, the human liver has the unique ability to regenerate after toxic injury, chronic inflammation, and surgical resection. The terms *regeneration, hyperplasia,* and *hypertrophy* are used synonymously in literature, but *hyperplasia* is the most precise term from a cellular standpoint. The damaged hepatic lobes do not grow back in the same way a lizard's tail regrows, but rather a hyperplastic response is seen, defined as increasing cell numbers in the remnant liver, leading to its hypertrophic appearance and enlargement of the liver (Lory et al, 1994). This process is highly regulated and involves multiple cell types, extrahepatic signals, complex molecular pathways, and cellular interactions. A delicate balance is achieved in the initiation of regeneration and exertion of an intracellular growth response to restore lost liver mass, while maintaining the normal metabolic function necessary for survival. The inability to maintain this process may lead to poor liver function and ultimately liver failure after surgery.

CLINICAL RELEVANCE OF LIVER REGENERATION

Today, liver surgery is routinely and safely accomplished for malignant and benign disease. This substantial progress in both resection and transplantation relies on the ability of the liver to regain most of its functional mass within 2 weeks (Marcos et al, 2000a; Humar et al, 2004; Kamel et al, 2003; Pomfret et al, 2003). Factors that limit the achievement of curative tumor resection and small-for-size (SFS) transplantation are the high morbidity and mortality rates associated with insufficient volume of the liver remnant or graft (Fig. 5.1).

As hepatobiliary and transplant surgeons continue to expand the magnitude and complexity of liver resection and explore beyond the boundaries of transplantation, understanding liver regeneration becomes increasingly relevant. Many tumors once considered unresectable are now amenable to complete resection through induction chemotherapy and innovative treatment strategies to increase liver remnant volume (see Chapters 86 and 88) (Clavien et al, 2007). Portal vein embolization (PVE) or ligation causes atrophy of the ipsilateral hemiliver and hypertrophy of the contralateral side and appears to be particularly valuable in patients who have underlying liver disease (see Chapter 93A). Because of the increased success of liver surgery and improved anesthetic techniques, more patients with underlying liver disease are now considered suitable candidates for liver resection.

There remains, however, a subset of patients who cannot tolerate significant liver resection, often because of the inability of the liver to regenerate appropriately. Patients with underlying cirrhosis have increased morbidity and mortality (Das et al, 2001; Nagasue et al, 1987), and patients with metabolic syndrome, morbid obesity with concomitant steatosis, or nonalcoholic steatohepatitis (NASH) have increased risk of liver failure after liver surgery (Belghiti et al, 2000; McCormack et al, 2007) as do elderly patients with restricted hepatic reserve and decreased regenerative capacity (McCormack et al, 2007). In colorectal malignant disease, about 50% of patients will develop liver metastases in the course of their disease. With substantially improved chemotherapy for colorectal cancer over the last decade, the resectability rate has gradually increased to 20% to 30% (Khatri et al, 2005). As a consequence, more patients are having liver surgery after neoadjuvant or induction chemotherapy, which also has considerable side effects on liver regeneration.

Regeneration is also crucial in liver transplantation (see Chapter 97A). In deceased-donor transplantation, hepatocyte loss occurs in the form of ischemia/reperfusion (I/R) injury owing to the necessary preservation period from procurement to implantation and damage that may have occurred in the donor. Due to the scarcity of organs, more marginal organs are accepted for transplantation; this has increased the need for regeneration in the environment of I/R injury and use of immunosuppressive drugs. One of the landmark advances in liver transplantation is the ability to use partial liver grafts obtained from either a deceased donor or a living donor. In the latter setting, success of the procedure relies on hepatic regeneration in both donor and recipient. The minimal amount of functional liver necessary for successful transplantation is a major concern. Because of the need for regeneration, as well as recovery from concomitant I/R injury, a larger liver mass is needed for transplantation than might be required after liver resection (Tanaka & Yamada, 2005).

BASIC CHARACTERISTICS OF LIVER REGENERATION

Models of Liver Regeneration

In the past 50 years, much has been learned about what initiates liver regeneration, how it is sustained, and what inhibits it. Liver

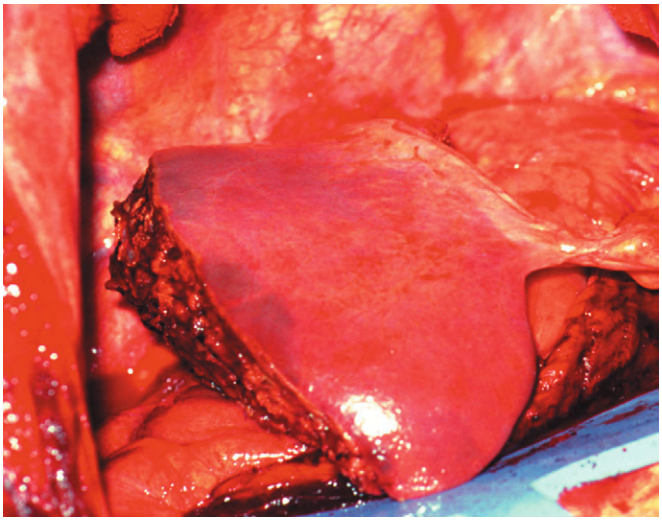

FIGURE 5.1. Remnant liver or liver graft volume limits tumor resection and small-for-size transplantation. Here an example of an "extreme" liver resection, leaving only segment IV of the liver, in case of colorectal liver metastases. In this situation, the patient's recovery depends solely on robust liver regeneration. *(Courtesy C. Verhoef, MD, PhD, Rotterdam, The Netherlands, Erasmus MC).*

regeneration is most clearly shown in the experimental model that was pioneered in 1931 by Higgins and Anderson. In this model, a simple two-thirds partial hepatectomy (PHx) was performed, without damage to the lobes left behind. This led to enlargement of the residual lobes, which made up for the mass of the removed lobes in 5 to 7 days. Other well-known models of liver regeneration are associated with extensive tissue injury and inflammation and include the use of hepatic toxins—such as ethanol (EtOH) (Kaplowitz, 2002), carbon tetrachloride (CCl_4) (Reynolds, 1963), and galactosamine (GalN) (Dabeva & Shafritz, 1993)—bile duct ligation (Kountouras et al, 1984) or portal vein ligation (Bilodeau et al, 1999), and I/R injury (Jaeschke, 1998). Newer models include transgenic albumin promoter urokinase-type plasminogen activator (u-PA) fusion constructs (Heckel et al, 1990) and PHx in Zebrafish (Kan et al, 2009). In each model, different toxic agents injure specific liver cell subpopulations; PHx is therefore the preferred in vivo model to study the regenerative response. It has also been demonstrated that regenerative signaling observed in a rat liver transplant model of I/R injury is similar to that observed after PHx (Debonera et al, 2001).

General Features of Liver Regeneration

Liver regeneration after surgical resection is carried out by proliferation of existing mature cellular populations. These include hepatocytes, biliary and fenestrated endothelial cells, Kupffer cells, and cells of Ito (stellate cells; Fig. 5.2) (Gressner, 1995).

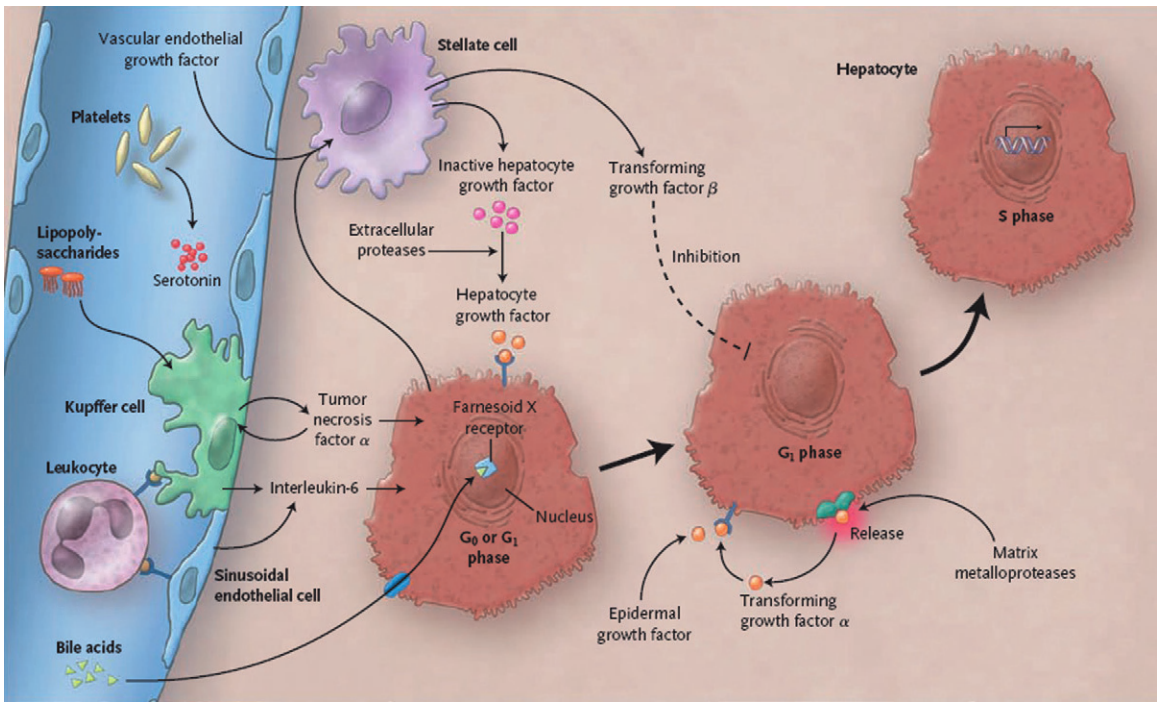

FIGURE 5.2. Pathways of liver regeneration initiated by major hepatectomy. After hepatectomy, nonparenchymal cells—stellate cells, Kupffer cells, leukocytes, and platelets—are activated by soluble factors. As a result, Kupffer cells release tumor necrosis factor-α and interleukin-6. The cytokines cause a priming of the remnant hepatocytes, and concurrently, extracellular proteases, such as urokinase-type plasminogen activator, convert inactive hepatocyte growth factor to its active form. The cytokines and the growth factors act in concert to initiate the reentry of quiescent hepatocytes (in the G_0 phase) into the cell cycle from the G_1 phase to the S phase, resulting in DNA synthesis and hepatocyte proliferation. The metabolic burden is indicated by the accumulation of bile acids in the blood, which enter the hepatocytes and drive increased protein and DNA synthesis. To signal the end of proliferation, transforming growth factor-β blocks further replication. *(From Clavien P-A, et al, 2007: Strategies for safer liver surgery and partial liver transplantation. N Engl J Med 356:1545-1559. Reprinted with permission.)*

The kinetics of cell proliferation and the growth factors produced by proliferating hepatocytes suggest that hepatocytes provide the mitogenic stimuli that lead to proliferation of the other cells; the degree of hepatocyte proliferation is directly proportional to the degree of injury (Bucher & Swaffield, 1964).

Immediately after liver resection, the rate of DNA synthesis in hepatocytes begins to increase, as they exit the resting state of the cell cycle (G_0) and enter G_1, traverse to DNA synthesis (S phase), and ultimately undergo mitosis (M phase). The induction of DNA synthesis occurs later in the nonparenchymal cells, at about 48 hours for Kupffer and biliary epithelial cells and at about 96 hours for endothelial cells (Grisham, 1969; Widmann & Fahimi, 1975). The first peak of DNA synthesis occurs at 40 hours after resection in rodents and at 7 to 10 days in primates. In small animals, the regenerative response returns the liver to the preresection mass in 1 week to 10 days. Clinical studies suggest that significant regeneration in humans is evident within 2 weeks after resection and is nearly complete at 3 months (Nagasue et al, 1987; Yamanaka, 1993). Studies in living donors, however, suggest that many donors do not reach 100% of starting liver volume by 3 months after donating their right lobe, and some are even lacking at one year (Pomfret et al, 2003; Nadalin et al, 2004; Ibrahim et al, 2005).

On a cellular level, hepatocyte proliferation starts in the periportal areas of the lobules (Rabes et al, 1976) and proceeds to the pericentral areas by 36 to 48 hours. Liver histology at day 3 to 4 after PHx is characterized by clumps of small hepatocytes surrounding capillaries, which change into true hepatic sinusoids. The hepatic matrix composition also changes from high laminin content to primarily containing fibronectin and collagen types I and IV. After a 70% hepatectomy, restoration of the original number of hepatocytes theoretically requires 1.66 proliferative cycles per residual hepatocyte. In fact, most of the hepatocytes in the residual lobes (95% in young and 75% in very old rats) participate in one or two proliferative events (Stocker & Heine, 1971). However, hepatocytes have an almost unlimited capacity to regenerate, and transplantation of several hundred healthy hepatocytes can repopulate a whole, damaged liver in a calculated minimum of 69 doublings (Rhim et al, 1994).

Liver Stem Cells

In contrast to other regenerating tissues, such as bone marrow and skin, primary liver regeneration after surgical trauma is not dependent on a small group of progenitor cells (stem cells). However, in some circumstances, such as in response to liver damage inflicted by agents such as galactosamine, hepatocytes are unable to replicate.

Endogenous Hepatic Progenitor Cells

In this situation a population of cells known as *oval cells* proliferates to replace the hepatic parenchyma (Fausto & Campbell, 2003). In humans, hepatic progenitor cells (HPCs) participate in repopulation of the liver after acute massive necrosis and have also been identified in chronic liver disease (Roskams et al, 1998). The oval cells are thought to derive from biliary epithelial cells, and human HPCs seem to originate from the canals of Hering (Theise et al, 1999) and play an important role in acetaminophen-induced injury (Kofman et al, 2005). Recent data suggest that in addition to mature hepatocytes and HPCs, a third compartment of cells can participate in liver regeneration (Alison et al, 2009; Duncan et al, 2009). Several studies in rodents and humans have demonstrated that transplanted bone marrow stem cells can enter the liver from the circulation and give rise to hepatocytes and cholangiocytes (Petersen et al, 1999; Theise et al, 2000a; Alison et al, 2000). These stem cells usually make little contribution to regeneration, but after fusing with metabolically defective hepatocytes, they can be reprogrammed to contribute in a major way to restoring liver function or to stimulating liver regeneration via paracrine effects (Lagasse et al, 2000; Wang et al, 2003a; Kallis et al, 2007).

Exogenous Mobilized Progenitor Cells

Mesenchymal stem cells (MSCs) isolated from human umbilical cords (Yan et al, 2009), adipose tissue (Banas et al, 2008), and bone marrow (Kuo et al, 2008; Abdel Aziz et al, 2007) have been shown to promote liver repair in cases of acute liver damage (e.g., carbon tetrachloride injections). The major fraction of mobilized progenitor stem cells expresses the chemokine receptor CXCR4. At the same time, the mRNA level of its ligand, SDF-1, was increased in the damaged liver tissue. These results provide a clue that CXCR4–SDF-1 interaction may be important for the mobilization of progenitor stem cells from bone marrow to the damaged liver (Khurana & Mukhopadhyay, 2007). In the damaged liver, these MSCs could generate cells that function as normal hepatocytes, but a second mechanism by which MSCs could promote liver repair is secretion of soluble factors. For instance, infusion of human MSC-conditioned medium into rats with acute liver damage improved liver function after 24 hours (Parekkadan et al, 2007; van Poll et al, 2008) with a 90% decrease in apoptotic hepatocytes and a threefold increase in the number of proliferating hepatocytes. Very recently, human liver-derived stem cells were shown to accelerate hepatic regeneration after hepatectomy by shuttling mRNA from microvesicles into the regenerating hepatocytes (Herrera et al, 2009).

Induction of Proliferation: Priming and Cell-Cycle Progression

Within minutes after PHx, specific immediate early genes are activated in remnant hepatocytes (Haber et al, 1993). These genes include protooncogenes, which play an important role in normal cell-cycle progression—such as in *JUN, FOS, MYC,* and *KRAS* (Thompson et al, 1986; Morello et al, 1990; Taub, 2004)—and the transcriptional factors nuclear factor (NF) κB, signal transducer and activator of transcription 3 (STAT3), activator protein-1 (AP-1), and CCAAT enhancer–binding protein β (CEBPβ) (Cressman et al, 1995; FitzGerald et al, 1995). Historically, the onset of liver regeneration has been attributed to a flow-dependent response, by which increased relative flow after PHx resulted in hepatocyte proliferation and hyperplasia (Starzl et al, 1977). Experiments in parasymbiotic rats demonstrated the existence of humoral factors in the induction of liver growth after PHx (Moolten & Bucher, 1967). Interleukin (IL)-6 and tumor necrosis factor (TNF)-α have since been identified as the earliest factors triggering activation of several transcription factors during regeneration (Fig. 5.3) (Cressman et al, 1996; Yamada et al, 1997). In IL-6–deficient or TNF-α receptor–deficient mice, liver regeneration after hepatectomy is delayed (Streetz et al, 2000) but not completely abolished (Michalopoulos et al, 1984; Fujita et al, 2001). Therefore, other blood-derived mitogens, such as hepatocyte growth factor (HGF), were identified as a putative hepatic

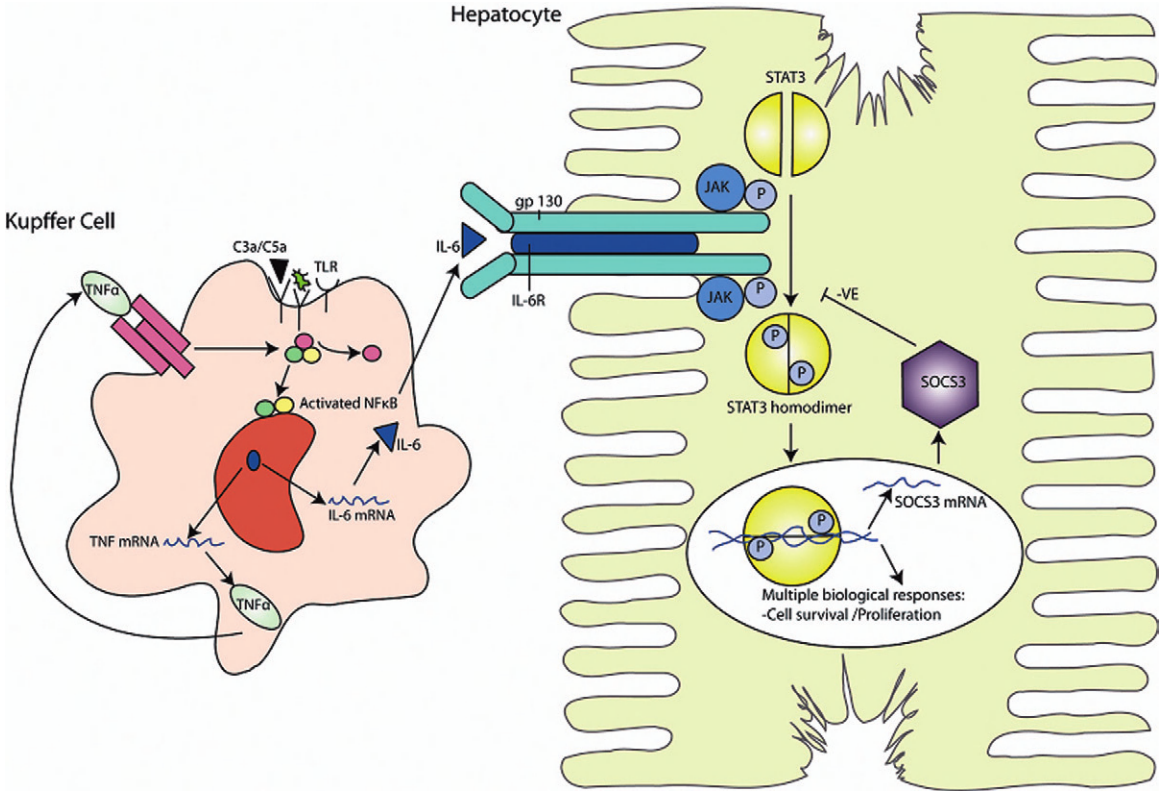

FIGURE 5.3. Stimulated by components of the innate immune system, Kupffer cells produce and secrete interleukin (IL)-6 and tumor necrosis factor-α (TNFα) to kick-start the regenerative response. IL-6 helps stimulate hepatocyte proliferation via transcription 3 (*STAT3*) activation; in turn, this response is negatively regulated by cytokine signaling-3 (SOCS3). *(From Alison et al, 2009: Stem cells in liver regeneration, fibrosis and cancer: the good, the bad and the ugly. J Pathol 217:282-298. Reprinted with permission of John Wiley & Sons.)*

growth factor during liver regeneration (Fausto, 2000). Hepatocytes in normal liver will not respond to mitogenic signals without a set of "priming" events that switch them into a responsive state. This has been described by Webber and colleagues (1994), who identified *priming factors*, involved in initiating and triggering hepatic response to injury, and concomitant *growth factors* and their receptors, which allow competent hepatocytes to progress through the cell cycle. Priming is accomplished by the release of preformed cytokines that subsequently activate transcription factor complexes and allow the cell to exit G_0 into G_1 in the cell cycle. This group includes TNF-α and IL-6 (Aldeguer et al, 2002). Growth factors include the potent hepatocyte mitogens HGF, transforming growth factor (TGF)-α, and heparin-binding epidermal growth factor (HB-EGF). This process is further controlled by *comitogens*—such as insulin, glucagon, steroid and thyroid hormones, and epinephrine—that facilitate activity of the mitogens and by downregulation of growth factor inhibitors, such as activin A and TGF-β.

So far, few factors have been identified as possibly responsible for the release of these priming cytokines and growth factors in the onset of liver regeneration. The first is endotoxin lipopolysaccharide (LPS), produced in the gut by gram-negative bacteria. Circulating LPS appears to be a strong signal for Kupffer cells to start the cascade that results in hepatocyte replication. Rats treated with antibiotics and germ-free rodents have a delayed peak of DNA replication after PHx, confirming the importance of LPS (Cornell et al, 1990). Another major finding is the demonstration that cytokine activation and DNA replication are severely impaired in mice lacking the complement components C3a and C5a (Strey et al, 2003). In particular, mice lacking both C3a and C5a have impaired production of TNF-α and IL-6 after PHx and poor activation of NFκB and STAT3. In the initiation of growth factors, urokinase-type plasminogen activator (uPA) appears to play an important role; uPA and its downstream effector, plasminogen, increase within 1 to 5 minutes after PHx and rapidly cleave the HGF precursor, pro-HGF. Blocking uPA delays the appearance of HGF and thereby delays liver regeneration, whereas blocking plasminogen-activator inhibitor (PAI) accelerates the release of HGF and accelerates liver regeneration (Currier et al, 2003).

More recently, new important factors in the initiation of liver regeneration have been identified. Extracellular adenosine triphosphate (ATP) has emerged as a rapid-acting signaling molecule that leads to quick and transient activation of JNK signaling after PHx, induction of immediate early genes c-*FOS* and c-*JUN*, and activator protein 1 (AP-1) DNA-binding activity (Thevananther et al, 2004; Gonzales et al, 2009). Also recently, an important role for blood platelets in I/R injury and after partial liver resections has been demonstrated. Thrombopenic animals exhibited reduced hepatocyte proliferation 48 hours after the initial ischemic insult, with diminished expression of TNF-α and IL-6 as early as 4 hours after reperfusion (Nocito et al, 2007). In a model of partial hepatectomy, the effect was shown to be mediated by serotonin, because mice lacking platelet serotonin displayed a lack of liver regeneration (Lesurtel et al, 2006). About 95% of all serotonin found in blood is stored in platelets and in vitro, and serotonin is a potent mitogen that stimulates hepatocyte mitosis (Balasubramanian

& Paulose, 1998). The platelet effect on liver regeneration after PHx was mediated through the 5-HT2A and 2B receptor subtypes on hepatocytes and could be restored by injection with the serotonin precursor 5-HTP. These results suggest that a molecular action of serotonin is involved in the induction of hepatoctye proliferation after a major loss of hepatic tissue and that it may involve the release of growth factors, such as IL-6 (Clavien, 2008).

Intracellular Pathways and New Profiling Techniques

The importance of liver regeneration in sustaining life is characterized by the plethora of pathways involved and the fact that liver regeneration is usually only blunted or delayed in experimental models that lack a "critical" pathway. There are nonetheless several well-described patterns in liver regeneration. The immediate early genes that are activated in regenerating liver were first identified by Mohn and colleagues (1990) and Haber and colleagues (1993), who described induction patterns of more than 70 genes activated in the first week after two-thirds PHx in a rat model, genes normally not expressed in the quiescent liver. The development of cDNA microarray technologies set the stage for studying genome-wide expression and expanded this list to about 180 genes (Su et al, 2002; Arai et al, 2003).

A mouse cDNA array has also been used to study the crucial role of IL-6 in liver regeneration in IL-6–deficient mice after hepatectomy, showing a 36% reduction in the early gene expression compared with wild-type mice. In the absence of IL-6, activation of genes such as u-PA receptor (*PLAUR*) and *SERPINE1,* crucial for HGF activation and the MAPK pathway, were remarkably delayed (Li et al, 2002). IL-6 activates the JAK/STAT3 and MAPK signaling pathways via the gp130/IL-6R complex. This leads to activation of an array of immediate and delayed early genes required for normal liver-specific metabolic functions, repair, and protection from injury (Taub, 2003; Zimmers et al, 2003; Wuestefeld et al, 2003). STAT3 is crucial for cells to progress from the G_1 to S phase and for activating the *MYC* gene required for cell-cycle progression. Other intracellular signaling pathways that involve the receptor tyrosine kinases p38 MAPK, pERKs, and *c-jun* N-terminal kinase (JNK) are also rapidly activated.

Progression through the cell cycle is regulated by cyclins and cyclin-dependent kinases (CDKs). Various combinations bind to form kinase complexes that are active at distinct points within the cell cycle and tightly controlled by several mechanisms, including binding by CDK-inhibitory proteins, such as p21. Feedback signals to this process are provided by the suppressor of cytokine signaling-3 (SOCS3) and TGF-β, also regulated by IL-6. Other studies confirmed the importance of NFκB (Arai et al, 2003; Fukuhara et al, 2003; Togo et al, 2004) and showed immediate upregulation of apoptotic genes (*FAS* and caspases) in livers that failed owing to excessive resection (Fig. 5.4) (Morita et al, 2002). The cytokine-induced form of nitric oxide

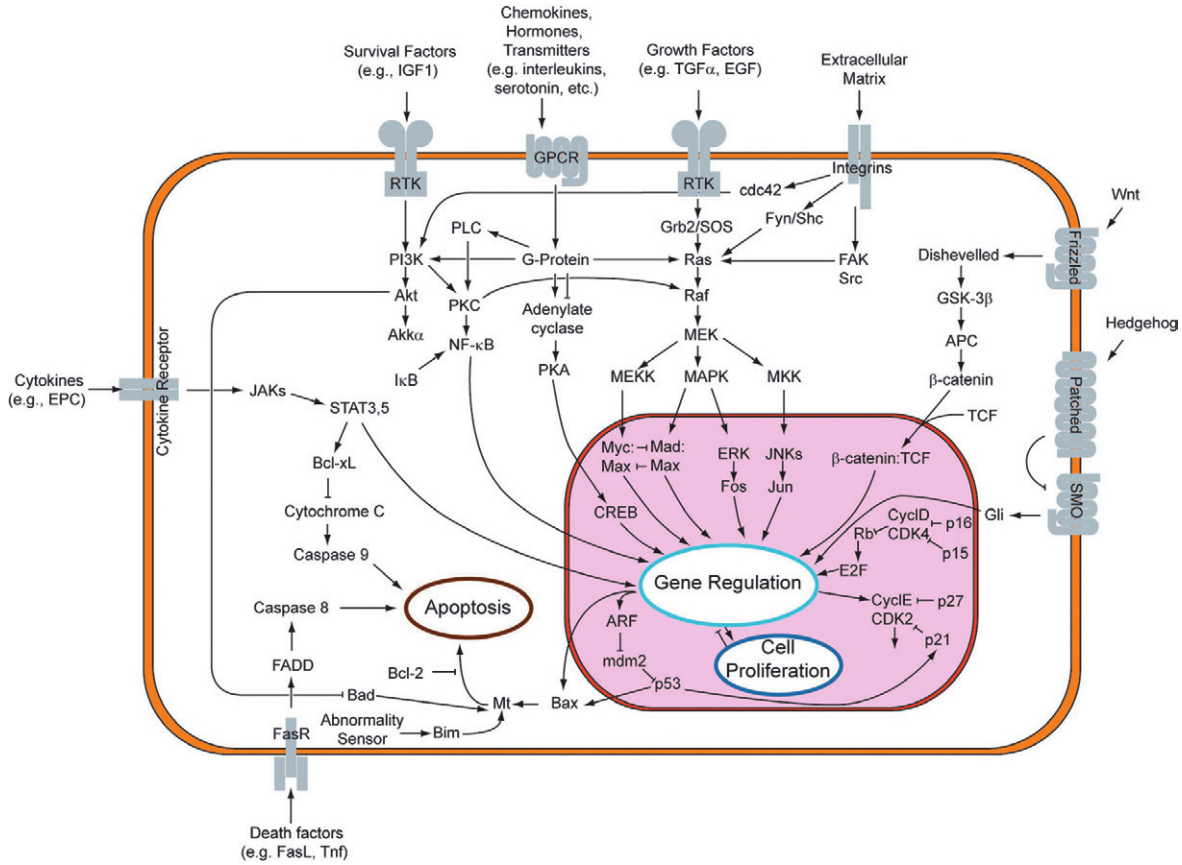

FIGURE 5.4. Intracellular pathways of liver regeneration. Multiple intracellular signaling pathways are rapidly activated. Progression through the cell cycle is regulated by cyclins and cyclin-dependent kinases (CDKs) tightly controlled by several mechanisms, including binding by CDK-inhibitory proteins, such as p21. *(From http://en.wikipedia.org/wiki/File:Signal_transduction_pathways.png.)*

synthase (iNOS) seems to plays an important role in scavenging oxygen radicals and offering protection from apoptosis caused by a proinflammatory response mediated through IL-6 and TNF-α (Rai et al, 1998).

The HGF/*c-Met* pathway is important for sustaining DNA synthesis after injury and activates various downstream pathways that involve PI3K, ERK/MAPK, and AKT1 (Huh et al, 2004). This pathway cross talks with the wnt/β-catenin signaling pathway, which has come to the forefront in liver biology over the last several years (Monga, 2009). Increased levels of HGF results in β-catenin dissociation along with nuclear translocation (Monga, 2002) and upregulation of downstream targets of this pathway, such as cyclin D1, *MYC, PLAUR,* matrix metalloproteinases (MMPs), and epidermal growth factor receptor (Michalopoulos & DeFrances, 1997). Vascular endothelial growth factor (VEGF) interacts with endothelial cells in the liver to increase HGF production from nonparenchymal cells (LeCouter et al, 2003).

In the transplant setting, microarray analysis of SFS rat liver grafts showed upregulation of vasoconstrictive and adhesion molecule genes at early time points postreperfusion, with later increases in genes associated with inflammation and cell death and downregulation of genes related to energy metabolism (Man et al, 2003), which was recently confirmed in the situation of clinical deceased-donor and living-donor liver transplantation (de Jonge et al, 2009).

Remodeling of the Liver

Remodeling of the newly regenerated liver tissue begins with the repopulation and maturation of nonparenchymal cells, such as endothelial cells, stellate cells, and biliary epithelial cells. Newly formed hepatocytes form clusters into which replicating endothelial cells invade to form new sinusoids. To restore normal architecture, stellate cells, located between endothelial cells and hepatocytes, synthesize extracellular matrix proteins and TGF-β1, which can regulate the production of hepatic extracellular matrix (see Chapter 6). VEGF, angiopoietins 1 and 2, TGF-α, fibroblast growth factors (FGFs) 1 and 2, and HGF all are likely involved in the angiogenic process. Angiostatin, an inhibitor of angiogenesis, causes delayed and suppressed liver regeneration in mice (Drixler et al, 2002; Vogten et al, 2004). Remodeling of the extracellular matrix is associated with the activation of the urokinase-plasminogen pathway and the membrane-bound matrix metalloproteinase (MMP) pathway. MMP-9 is one of the most active proteins during liver remodeling and regeneration (Kim et al, 2000). The MMPs—in combination with HGF, EGF, and TGF-β1—act to remodel the extracellular matrix, changing the levels of several extracellular matrix proteins such as collagen, fibronectin, laminin, and entactin. The maturation and thickening of the extracellular matrix seems to have an inhibitory effect on proliferating hepatocytes, potentially signaling the end of rapid regeneration (Kim et al, 1998).

Maintaining Liver Function During Regeneration

After volume loss, hepatocytes must adapt rapidly and seek a compromise between maintenance of continued differentiated function and cellular replication to permit survival. After toxic injury, resection, or transplantation, the balance is dramatically shifted to the crucial tasks of recovery and regeneration at the expense of normal hepatic metabolism. The success of restoring lost liver mass, repairing tissue injury, and resolving inflammation determines the ability of the liver to support normal metabolic function and determines its ability to recover (Fig. 5.5) (Strey et al, 2004). Several of the expressed immediate early genes encode enzymes and proteins involved in regulating gluconeogenesis, a critical process after PHx to compensate for the lost glycogen content and to produce sufficient glucose for the whole organism (Haber et al, 1995; Rosa et al, 1992). Rapid and increased expression of genes involved in glucose homeostasis is seen after PHx in animal models. Most notably, these include *PCK,* glucose-6 phosphatase (G6Pase), and *IGFBP1,* controlled at the level of transcription by insulin (downregulation), glucagon and cAMP (upregulation), and glucocorticoids (upregulation) (Mohn et al, 1990; Diamond et al, 1993). Livers lacking *IGFBP1* display abnormal liver regeneration (Leu et al, 2003).

Decreased expression of genes that oppose gluconeogenesis also occurs rapidly posthepatectomy. Insulin itself can be a potent growth factor mediated through the insulin receptor, and insulin and glucagon have long been established as important "gut-derived" growth factors (Starzl et al, 1975). Liver-specific transcription factors—hepatocyte nuclear factors (HNFs)—play an important role in determining the level of glucose production, fatty acid metabolism, and liver-specific secreted proteins. CAAT/enhancer binding protein (C/EBP) α regulates expression of genes involved in hepatic glucose and lipid homeostasis, has antiproliferative proprieties, and is downregulated during liver regeneration after hepatectomy (Mischoulon et al, 1992; Costa et al, 2003).

During early regeneration, the liver accumulates fat. Neither the mechanisms responsible for nor the functional significance of this transient steatosis has been determined. Suppression of hepatocellular fat accumulation is associated with impaired hepatocellular proliferation after PHx, indicating that hepatocellular fat accumulation is specifically regulated during, and may be essential for, normal liver regeneration (Shteyer et al, 2004). Some data show that decreasing lipid peroxidation levels by vitamin treatment after PHx produces an attenuation of cellular apoptosis and a marked increase in the proliferation process, suggesting that the modulation of lipid peroxidation has a role in the liver regeneration process (Ronco et al, 2002). Hepatocytes in the periportal regions that divide and replicate after PHx require mitochondrial fatty acid β-oxidation. Peroxisome proliferator-activated receptor α, *PPARα,* may be a crucial modulator, controlling energy flux important for repair of liver damage and regeneration (Anderson et al, 2002). Expression of many other liver-specific genes, such as *IGFBP1* and G6Pase, is regulated in the basal state by hepatic nuclear factor-1 (*HNF1A*). The transcriptional activity of *HNF1A* is upregulated during liver regeneration by the binding of *HNF1A* to the growth-induced transcription factors STAT3 and AP-1 (Leu et al, 2001). Together, growth-induced and tissue-specific transcription factors enable the liver to maintain metabolic function, despite the loss of two thirds of its functional mass.

In a microarray analysis of gene expression profiles after living-donor liver transplantation, it was recently demonstrated that C/EBPα was immediately downregulated, as was as HNF4α and PPARα (de Jonge et al, 2009). The immediate, marked downregulation of genes associated with pathways of lipid, fatty acid, and carbohydrate metabolism demonstrate how a liver segment needs to balance regenerating efforts with

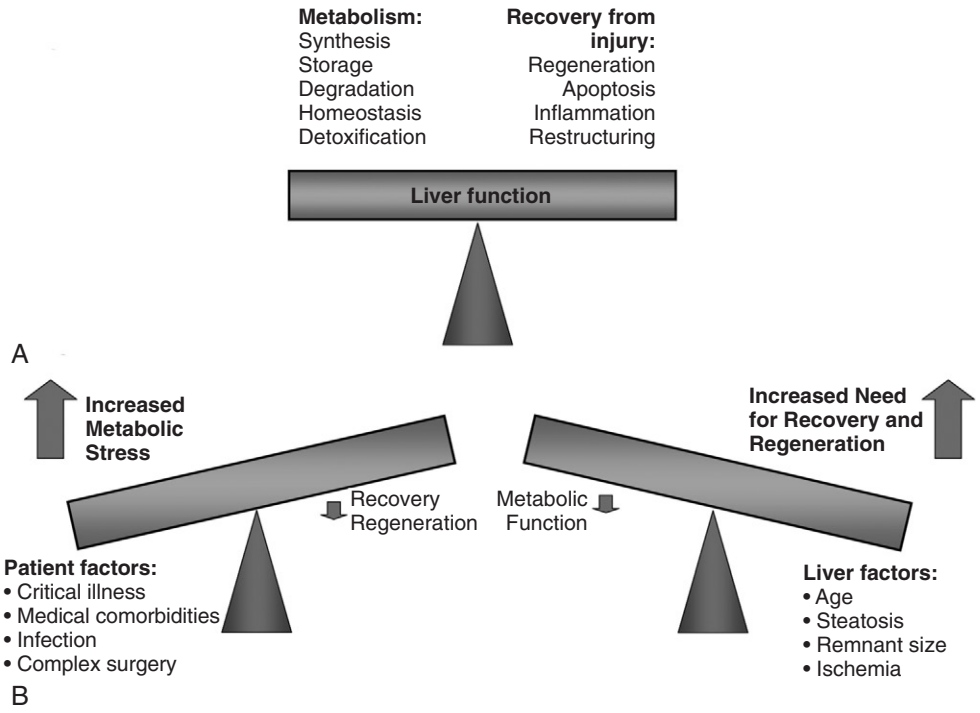

FIGURE 5.5. Metabolic balance between regeneration and maintaining liver function. **A,** In times of relative quiescence, there is a balance within the liver of metabolic function and continuous liver cell replacement or restructuring as needed. **B,** In times of stress or after injury or resection, the need for metabolic function or regeneration and recovery is increased. If metabolic need is great as a result of conditions within the patient, energy balance within the liver may not be sufficient to regenerate sufficiently, and the liver may not recover. If the requirements for regeneration and repair are overwhelming, metabolic function may be decreased, affecting patient outcome.

metabolic needs. It is this balance that limits the size of liver segment that can be transplanted or the size of remnant liver after donation or resection.

Termination of Proliferation

The size of the liver is highly regulated and is controlled by the functional needs of the organism. The most well-known antiproliferative factors within the liver are TGF-β and related family members such as activin (Derynck & Zhang, 2003). TGF-β is produced mainly by hepatic stellate cells, but in the early phase, it forms inhibitory complexes with SNoN and SKI proteins (Macías-Silva et al, 2002), rendering hepatocytes initially resistant to TGF-β (Koniaris et al, 2003). Later on, TGF-β acts through a heteromeric receptor complex, which subsequently phosphorylates proteins of the SMAD family, particularly SMAD2 and SMAD3 (Lonn et al, 2009). The SMAD2/SMAD3-SMAD4 complex translocates into the nucleus and activates target genes that negatively regulate the cell cycle (Nakao et al, 1997). Reactive oxygen species (ROS) enhance synthesis and activation of TGF-β (Koli et al, 2008), which may account for the reduced regeneration after ischemia and reperfusion. Interacting with the TGF-β/SMAD signaling could restore regeneration in a model of SFS liver grafts (Zhong et al, 2010).

Similarly, activin A blocks hepatocyte mitogenesis and shows diminished signaling during liver regeneration when its cellular-receptor level is reduced; its receptor level is restored once liver regeneration is terminated (Date et al, 2000). The level of activin-receptor mRNA expression was shown to be an important determinant in the magnitude of regeneration in portal vein ligation and PHx (Takamura et al, 2005a, 2005b). Suppressors of cytokine signaling (SOCS) are important negative regulators of cytokine signaling that prevent the tyrosine phosphorylation of STAT proteins. It has been shown that IL-6 signaling in the liver causes rapid upregulation of *SOCS3,* which correlates with the subsequent downregulation of phosphorylated *STAT3,* thereby terminating the IL-6 signal (Campbell et al, 2001).

Recent work strongly implicates the detection of blood bile acid levels by nuclear receptors as a regulator of liver growth (Huang et al, 2006). In addition, mammalian genes comparable to those in the *Drosophila* Hippo kinase-signaling cascade, which regulates wing mass during development, can also control hepatocyte proliferation (Dong et al, 2007). Overexpression of *YES1*-associated protein (YAP), the mammalian counterpart to *yorkie* (yki)—the last gene in the *Drosophila* Hippo kinase cascade—in a transgenic mouse model leads to massive liver hyperplasia, reaching 25% of body weight. YYA1P1 transcriptionally activates cell-cycle proteins, such as Ki-67 and c-Myc, and also activates inhibitors of apoptosis, and its phosphorylation by way of activation of the Hippo pathway blocks its ability to shuttle to the nucleus (Reddy & Irvine, 2008). It is therefore possible that the Hippo kinase pathway has a decisive role in determining overall liver size (Duncan et al, 2009).

LIVER ATROPHY

Classically, atrophy is triggered by an obstruction of portal venous blood flow or is the result of chronic obstruction of the bile duct. When atrophy occurs unilaterally, the opposite lobe of

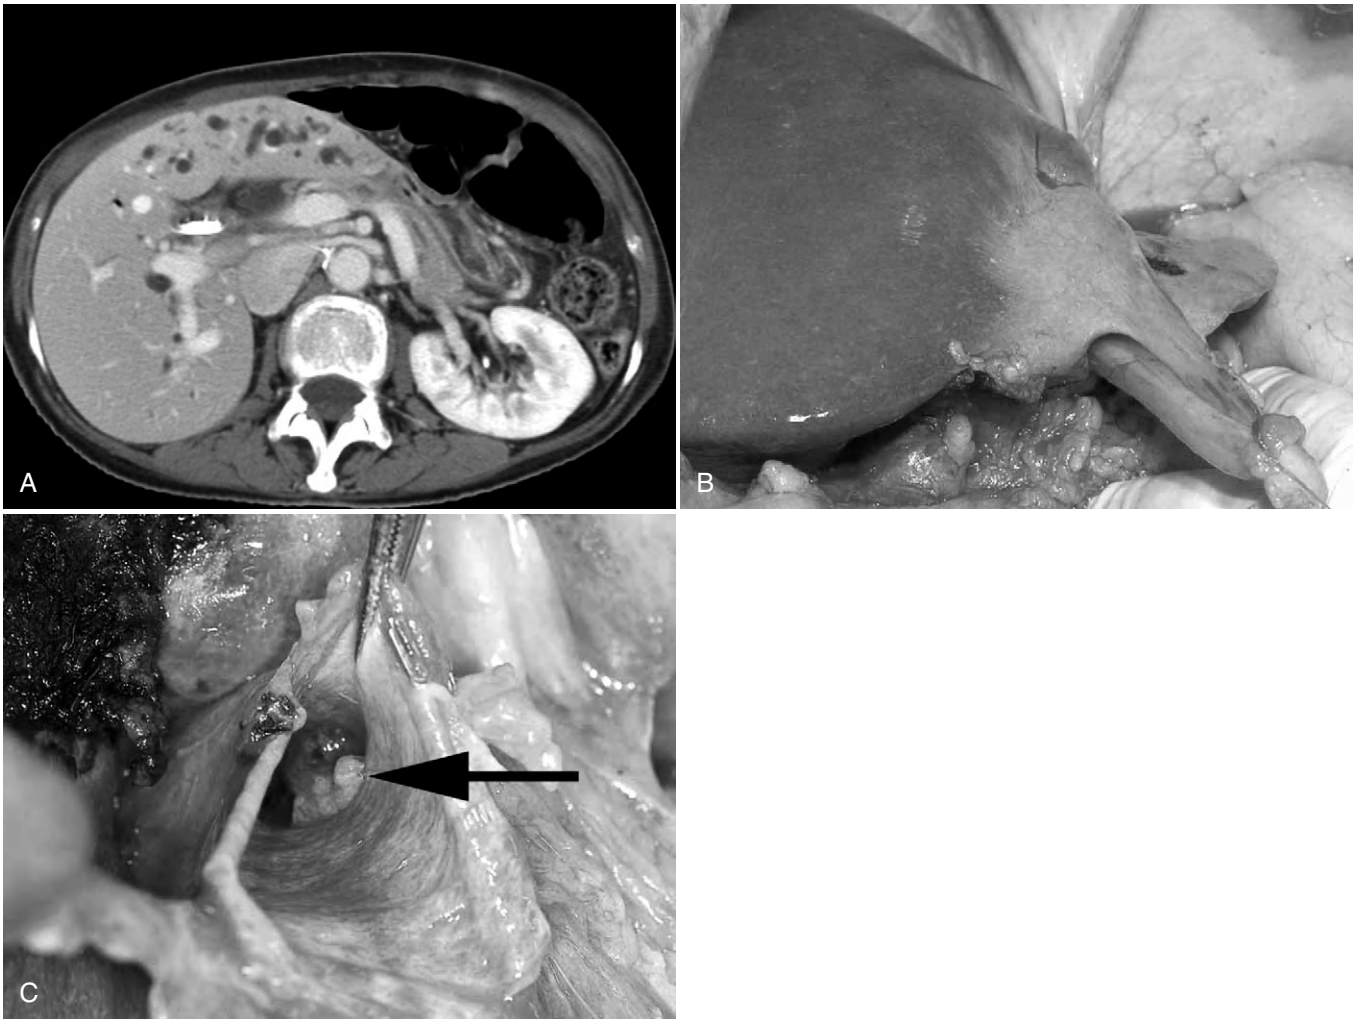

FIGURE 5.6. Hepatic atrophy. **A,** Appearance of the liver on computed tomography in a patient with papillary hilar cholangiocarcinoma involving the left hepatic duct. Note the atrophic left lobe and intrahepatic ductal dilation, predominantly on the left. **B,** Gross appearance of the liver in the same patient. **C,** Intraluminal view of the common bile duct, with tumor extruding from the left hepatic duct (*arrow*).

the liver responds with a hypertrophic response, which may result in a rotation of the liver around the hilar axis. The liver can become grossly distorted with marked changes in anatomic landmarks, most commonly seen accompanied by a rotation of the portal triad structures (Fig. 5.6). In recent years, the anatomic changes accompanying atrophy led surgeons to utilize preoperative embolization of the portal vein in areas involved with malignancy, hoping to induce hypertrophy in areas of the contralateral liver to increase the potential for resection and to reduce postoperative morbidity (see Chapter 93A).

Mechanisms of Liver Atrophy

The cause of liver cell death in atrophy is generally divided between necrosis and apoptosis. The distinction is important, because necrosis is a nonregulated traumatic disruption of a cell that occurs when it encounters overwhelming injury, whereas apoptosis is an inducible, highly orchestrated cascade of physiologic events. Necrotic cells lose membrane integrity, leak lysosomal enzymes, and induce a substantial inflammatory response. Apoptosis is energy dependent and allows cells to shrink and die without inducing inflammation. Apoptotic cells are characterized by plasma membrane blebbing, chromosomal condensation, and nuclear DNA fragmentation (Steller, 1995).

Portal Vein–Induced Hepatic Atrophy

The most common clinical scenario of hepatic atrophy is portal vein–induced atrophy, wherein occlusion of the portal vein leads to ischemia in areas of the liver; atrophy in this setting is a result of liver cell death secondary to necrosis and apoptosis (Ikeda et al, 1995; Shibayama et al, 1991). Ischemic necrosis of centrilobular areas of the liver predominates in the first 3 days of cell death. Areas peripheral to the necrotic liver cells predominantly undergo apoptotic cell death, and apoptosis persists long after necrosis subsides. Oxygen levels and mitochondrial function help determine which cells will undergo necrosis or apoptosis (Nishimura et al, 1998). Models of portal vein ischemia in rats have confirmed a caspase-dependent apoptosis and have indicated that Kupffer cells are involved in generating reactive oxygen substrates and other acute-phase reactants, culminating in mitochondrial dysfunction and apoptosis (Kohli et al, 1999).

Biliary-Induced Hepatic Atrophy

The molecular mechanisms involved in biliary obstruction leading to hepatic atrophy are much more centered on apoptosis, with little or no involvement of acute necrosis. Cholestasis results in the accumulation of toxic bile salts, which induce apoptosis through the Fas-mediated pathway. In this case, TNF-α and Fas ligand bind to the Fas death receptors, leading to a cascade of intracellular events, including cytochrome-c release from mitochondria and activation of apoptosis-mediating caspases. In Fas-deficient mice, bile duct ligation resulted in impaired apoptosis and less injury and fibrosis compared with wild-type mice (Canbay et al, 2002; Gujral et al, 2004; Miyoshi et al, 1999). More recent data, however, suggest a nonischemic model of necrosis/oncosis as the predominant process leading to cell death after common bile duct ligation, with cell swelling and without apoptotic caspase 3 activation (Fickert et al, 2005).

Clinical Causes of Atrophy

Hilar cholangiocarcinoma is a frequent cause of biliary atrophy, induced by occlusion of a major bile duct. Biliary occlusion, often accompanied by portal vein compromise, leads to atrophy of the liver approximately 20% of the time with this disease and has significant surgical implications. Also, postcholecystectomy bile duct strictures lead to hepatic atrophy 10% to 15% of the time (Hadjis & Blumgart, 1987; Pottakkat et al, 2009). Choledocholithiasis and hepatolithiasis are infrequent causes of atrophy, as are benign tumors such as papillomas, cystadenomas, and granular cell tumors (Blumgart et al, 1984; Blumgart & Kelley, 1984). Strictures caused by parasitic biliary infections, such as by *Clonorchis sinensis* and *Ascaris lumbricoides,* also have been known to cause biliary obstruction and associated atrophy of the liver. Occlusion of the hepatic artery alone would not induce atrophy.

Compensatory Regeneration Triggered by Atrophy

In the embolized portion of the liver, Kupffer cells release TNF-α and induce hepatocyte swelling and hyperplasia in the contralateral liver. Additionally, increased portal flow in the nonembolized lobe induces proliferation and activates several cytoplasmic growth-promoting signal-transduction pathways involved in hepatic regeneration, including JUN and the mitogen-activated protein kinase pathways. Kupffer cells in the contralateral liver begin to produce TNF-α as well, stimulated either by increased portal flow or through the direct effect of circulating growth factors (Kim et al, 2001). Nonparenchymal cells in the injured portion of the liver produce HGF. Messenger RNA levels of HGF in the ischemic portion of liver were noted to be 10 to 20 times that of normal, with most upregulation occurring in Kupffer cells (Hamanoue et al, 1992).

FACTORS INFLUENCING LIVER REGENERATION

Patient-Related Factors

Age

Liver age is a significant factor in hepatocellular regeneration. Older livers do not regenerate as quickly as younger livers and show delayed regeneration after acute injury and impaired function after liver transplantation (Burroughs et al, 2006; Feng et al, 2006). Rodent models have shown reduced and delayed thymidine kinase uptake in older animals after PHx, and a striking difference is seen in the magnitude of DNA synthesis and timing of hepatocyte replication between young and old livers (Taguchi et al, 2001). Treatment of old mice with growth hormone could restore hepatocyte proliferation (Krupczak-Hollis et al, 2003; Jin et al, 2009). Aging also represses activation of the c-Myc promoter in old livers after hepatectomy and in tissue culture models(Timchenko, 2009; Iakova et al, 2003).

On a clinical level, little is known regarding differential gene expression in old versus young livers, but results from the United Network for Organ Sharing (UNOS) database show reduced resistance in old donor livers to prolonged cold ischemia times (Cassuto et al, 2008), possibly as a result of high mitochondrial susceptibility to oxidative stress (Lenaz et al, 2000). In living-donor transplantation, some studies have shown that increasing donor age significantly affects posttransplant function (Abt et al, 2004; Iida et al, 2009) and rate of regeneration in the donor (Yokoi et al, 2005).

Biliary Obstruction

Cholestasis results in the accumulation of toxic bile salts, which induce apoptosis through the Fas-mediated pathway. In this pathway, TNF-α and the Fas ligand bind to the Fas death receptors, leading to cytochrome-c release from mitochondria and activation of apoptosis-mediating caspases. In Fas-deficient mice, bile duct ligation resulted in impaired apoptosis and less injury and fibrosis compared with wild-type mice (Canbay et al, 2002; Gujral et al, 2004; Miyoshi et al, 1999). Other molecular mechanisms involved in reducing regenerative capacity with biliary obstruction are suppressed expression of *MYC* (Tracy et al, 1991), *C/EBP*, and cyclin E (Nakano et al, 2001). Production of HGF (Hu et al 2003), EGF (Bissig et al, 2000), and IL-6 (Fujiwara et al, 2001) is also altered. Finally, biliary obstruction also impairs enterohepatic circulation and thus negatively affects the regenerative capacity. It is clinically relevant that external biliary drainage for obstructive jaundice markedly suppresses liver regeneration after hepatectomy (Suzuki et al, 1994), whereas internal biliary drainage preserves this capacity (Saiki et al, 1999).

Diabetes Mellitus

Insulin is one of the most important hepatotrophic factors in portal venous blood (Starzl et al, 1975). The binding protein of insulin-like growth factor (IGF), a molecule similar to insulin, also rises substantially after hepatectomy (Demori et al, 2000; Ghahary et al, 1992). Thus, impaired secretion of insulin and IGF in diabetic patients prevents liver regeneration following hepatectomy, as reflected by decreased synthesis of RNA, DNA, and protein on the first postoperative day (Yamada et al, 1977). Enhancement of mitochondrial phosphorylative activity in the remnant liver following hepatectomy is inhibited in proportion to the severity of impaired insulin secretion. Insulin gene transfer via the spleen enhances liver regeneration without causing liver damage and improves nutritional status after hepatectomy in diabetic rats (Matsumoto et al, 2003). Multiple regression analysis in clinical portal vein embolization (PVE) has shown that diabetes mellitus is a risk factor for reduced hypertrophy in the nonembolized lobe (Imamura et al, 1999). These results demonstrate the importance of insulin in hepatic regeneration,

and strict glucose control should be aimed for in liver surgery and PVE (Yokoyama et al, 2007a).

Nutritional Status

Hepatic regeneration is metabolically intensive and requires a great deal of energy. Liver regeneration after hepatectomy is associated with a derangement in energy metabolism, measured by a decrease in the ratio of ATP to its hydrolysis product, inorganic phosphate. This depleted energy status is mirrored in biochemical indices of liver function, and restitution parallels the course of restoration of hepatic cell mass (Mann et al, 2002). Nutritional support is undoubtedly the most physiologically sound means to enhance liver regeneration, but there is still little if any clear information regarding the effects of specific nutrients on liver regeneration in humans (see Chapter 24) (Holecek, 1999). From animal models we know that malnutrition is associated with higher postoperative mortality and reduced regeneration following PHx (Skullman et al, 1990). When improving nutritional status, enteral feeding should be preferred, as rats given enteral nutrition showed much better weight gain after 70% hepatectomy than those given isocaloric nutrition parenterally (Delany et al, 1994). Supplementation of glutamine, one of the sources of DNA and protein synthesis, has been shown to promote liver regeneration in dogs (Ito & Higashiguchi, 1999). Essential fatty acids, components of the cell membrane and precursors of several functional mediators, also play an important role in hepatic regeneration. Interestingly, dextrose supplementation had an inhibitory effect on liver regeneration, associated with increased expression of *C/EBPα, CDKN1A*, and *CDKN1B* in mice (Weymann et al, 2009), but in a randomized clinical trial, dextrose infusion was associated with improved nutritional status and earlier normalization of nitrogen balance (Nishizaki et al, 1996).

Gender

Sex steroids are known to induce transient hepatocellular proliferation and to improve fatty acid metabolism (Repa et al, 2000). Estrogen receptors are found on hepatocytes, and serum estradiol is increased substantially after hepatectomy in rodents and humans (Francavilla et al, 1989a). Pretreatment of rats with 17β-estradiol induces hepatocyte DNA synthesis in vitro and accelerates liver regeneration in vivo; administration of tamoxifen, a mixed estrogen agonist/antagonist, slows regeneration when given soon after PHx (Francavilla et al, 1989b). In contrast, testosterone levels decline in men and in male rats after PHx; however, there is no clinical evidence in humans that shows significant differences between the sexes after liver resection.

Intrinsic Liver Disease

The regenerative response of the liver can be seriously affected by preexisting intrinsic liver conditions such as steatohepatitis, fibrosis, and cirrhosis. Hepatic steatosis affects regeneration on several molecular levels. Lipid accumulation has been associated with hepatocyte mitochondrial damage caused by free-radical injury. Steatotic livers in rats show delayed mitosis and increased mortality after PHx, which may be due to abnormal TNF-α and IL-6 signaling (Selzner et al, 2000). The coordinated induction of Jnks and Erks is disrupted after partial hepatectomy in fatty livers of ob/ob mice (a model for steatohepatitis), with enhanced AKT and inhibition of PEPCK (Yang et al, 2001). Cyclin D1 induction is abolished along with Stat3 and reduced ATP levels, which may arrest cell-cycle progression. Hepatocyte mitochondrial damage associated with lipid accumulation is caused by free-radical injury from fatty acid oxidation. Abnormalities in induction of cytochrome P-450 may be one mechanism in the pathophysiology of these findings in fatty livers and may contribute to poor regeneration (Farrell, 1999; Kurumiya et al, 2000; Neuschwander-Tetri & Caldwell, 2003).

In clinical practice, the presence of underlying steatosis has considerable impact on operative morbidity and mortality after major hepatic resection (Behrns et al, 1998), with a significantly higher rate of complications if marked steatosis (≥30%) is present (see Chapters 65 and 87; Kooby et al, 2003). Steatohepatitis, or acute inflammation in the setting of fatty infiltration, carries an even higher risk and eventually results in fibrosis and cirrhosis. In transplantation, liver grafts with severe steatosis (≥60%) have higher rates of primary nonfunction, higher transaminases, and poorer graft survival in the transplant setting (Verran et al, 2003), possibly as a result of the inability to initiate repair and regeneration mechanisms. Progressive scarring and hepatic fibrosis lead to accumulation of abnormal collagen secreted into the extracellular matrix by stellate cells (Kim et al, 1998). Impaired regeneration is thought to be the result of the decreased diffusion of nutrients and hepatotrophic factors to the hepatocytes, and ultimately the architectural liver abnormalities created by scar contracture form a physical barrier that prevents hepatocytes from proliferating (Poynard et al, 1997).

Pharmacologic Therapy

Many exogenous agents can affect liver regeneration, including frequently prescribed drugs and neoadjuvant chemotherapy. Numerous medications are associated with impaired liver regeneration secondary to the induction of steatosis, including certain antiarrhythmic agents, antibiotics, antiviral agents, anticonvulsants, steroids, calcium channel blockers, statins, and antiglycemic medications. β-Blockers and nonsteroidal antiinflammatory drugs (NSAIDs) exert a more direct negative influence on liver regeneration. Liver regeneration after PHx is delayed in rodents treated with β-blockers and NSAIDs (Hong et al, 1997; Rudnick et al, 2001). β-Blockers may impair liver regeneration by decreasing portal blood flow to the liver and blocking the trophic effects of epinephrine. NSAIDs directly inhibit cyclooxygenase, part of the *C/EBPA*-mediated liver regenerative pathway. Although these effects have not been reflected in increased morbidity or mortality after liver resection in patients taking β-blockers or NSAIDs, the potential harmful effect of any medication on hepatic regeneration must be considered before resection.

In the past decade, more patients had liver surgery after neoadjuvant or induction chemotherapy. Major drawbacks of this hepatotoxic chemotherapy are the sinusoidal obstruction syndrome (SOS) associated with oxaliplatin (Rubbia-Brandt et al, 2004) and chemotherapy-associated steatohepatitis (CASH) (Vauthey et al, 2006), which is associated with irinotecan (see Chapters 65 and 87). Sinusoidal obstruction impairs liver regeneration after extensive liver resection and increases postoperative morbidity, but this may be prevented by administration of aspirin; CASH increases postoperative mortality—specifically, it increases deaths from postoperative liver failure (Fernandez et al, 2005).

Bevacizumab, a monoclonal antibody targeting vascular endothelial growth factor (VEGF) in combination with cytotoxic chemotherapy, appears to improve survival in patients with metastatic colorectal cancer (Hurwitz et al, 2004). Well-designed preclinical studies have demonstrated that inhibition of angiogenesis can inhibit wound healing (Scappaticci et al, 2005). Interestingly, no published studies have examined the effect of anti-VEGF therapy on human liver regeneration. Animal studies have demonstrated that liver regeneration depends on VEGF and angiogenesis (Drixler et al, 2002). In a murine model, anti-VEGF receptor therapy slightly impaired liver regeneration and cell proliferation after PHx compared with controls (Van Buren et al, 2008); however, no preclinical animal data on the effect of bevacizumab on liver regeneration has been shown, because it specifically recognizes human VEGF, not murine VEGF. Clinically no differences in postoperative liver insufficiency were seen if therapy was stopped at least 6 to 8 weeks before hepatic resection (Reddy et al, 2008; Zorzi et al, 2008).

Liver Transplantation

Regeneration is also crucial in liver transplantation. In deceased-donor transplantation, hepatocyte loss occurs in the form of I/R injury owing to the necessary preservation period from procurement to implantation and damage that may have occurred in the donor. Regenerative mechanisms are actively engaged after transplantation, depending on the length and degree of preservation injury (Debonera et al, 2001; Olthoff, 2002). Similarly, hepatocytes lost to the alloimmune response require replacement. Regeneration is also necessary when transplanting an SFS graft into a larger recipient. This is the sometimes the case in the setting of adult-to-adult living-donor transplantation (AALDLT) (Olthoff, 2003) and split-liver transplantation. Ischemic injury is minimized in AALDLT, because the preservation period is short; however, this technique supplies a graft that is by definition too small, requiring vigorous and immediate hepatocyte proliferation. By transplanting only 50% to 60% of what is the expected liver volume in adults, recipients (and donors) must rely on the rapid regeneration of a partial liver in addition to maintaining the basic metabolic functions required of the liver.

Warm and cold ischemic injury is an unavoidable component of transplantation. After prolonged cold ischemia of whole liver grafts, initiation of the cell-cycle pathways with upregulation of markers of liver regeneration occurs as described earlier. When ischemic injury is significant, a greater expression and activation of cytokines, transcription factors, and immediate early genes and a greater magnitude of hepatocellular replication is seen (Debonera et al, 2001). However, the liver can tolerate ischemic injury only to a certain "point of no return," after which the damage is too extensive, and the liver or allograft cannot maintain functional homeostasis and regenerative capabilities, which results in liver dysfunction and graft failure (Debonera et al, 2002).

The amount of liver mass transplanted has been shown to be an important variable after transplantation. Early experimental studies addressing regeneration after transplantation showed that an SFS graft adapts to its environment and achieves a size equal to the original native liver (Kam et al, 1987). It became apparent that graft size–recipient ratio was crucial, as grafts that were too small had decreased survival (Francavilla et al, 1994). These findings correlated with clinical experience, in that SFS grafts regenerate to an appropriate size for the recipient; however, significant functional impairment of these grafts can occur, shown by prolonged cholestasis and histologic changes consistent with ischemic injury (Emond et al, 1996; Kiuchi et al, 1999; Lo et al, 1999; Zhong et al, 2006).

Using animal models of partial liver graft transplantation, the interplay between the regenerative response and ischemic injury in the setting of 50% and 30% size grafts was studied. The partial grafts showed a robust regenerative response if the ischemic injury was minimal. It became apparent, however, that when these partial grafts were subjected to ischemic injury for moderate to prolonged periods, a significant effect on survival was seen, with extensive hepatic necrosis, the inability to initiate or maintain the regenerative response, and decreased survival. These findings show the diminished tolerance of SFS grafts for additional injury beyond transplantation itself (Selzner et al, 2002; Debonera et al, 2004).

The amount of critical liver mass required for transplantation in living donation remains in question. Most centers have defined liver mass as graft-to-recipient body weight ratio (GRBWR) or as a percentage of the standard liver volume. No uniform method of measuring or reporting graft volume in relation to the recipient has been established. Clinical experience with living-donor and split grafts has led to an accepted lower limit of 0.8% GRBWR, or 40% of the standard liver volume (SLV), although significantly smaller grafts have been transplanted successfully. As mentioned before, donor liver and recipient characteristics may significantly influence these minimal accepted standard volumes. Patients with fulminant hepatic failure and those with significant metabolic stress may require more liver volume than stable patients transplanted under elective conditions (Marcos et al, 2000b).

Although it has been performed successfully, many centers are not performing AALDLT in acutely ill patients with fulminant failure because of the uncertainty of knowing whether a partial graft offers enough volume to support the recovery of such a recipient. As seen in experimental models, the accumulation of additional stressful stimuli, such as sepsis or renal failure, may push a relatively small graft into failure. Despite the actual measurement, if a small graft has any dysfunction, it can progress to what is termed *small-for-size syndrome* (SFSS). Within only 3 to 5 days after surgery, signs of liver failure—presence of two of the following on three consecutive days: bilirubin greater than 100 μmol/L, INR greater than 2, encephalopathy grade 3 or 4—with ascites, as well as renal and pulmonary failure, may become apparent (Dahm et al, 2005).

Effect of Immunosuppression

Within the graft environment, the host immune response needs to be inhibited to avoid acute allograft rejection, and inhibition of this response may interfere with the recovery of liver grafts, requiring active regeneration of hepatocytes. Glucocorticoids routinely used in immunosuppression protocols have been shown to inhibit cell-cycle progression markedly in PHx models and in transplant models with ischemic injury (Debonera et al, 2003; Nagy et al, 1998; Tamasi et al, 2001). Cyclosporine and tacrolimus may have differential effects on regeneration in a dose-dependent fashion (Francavilla et al, 1991). Sirolimus, with its antiproliferative action, interferes with hepatocyte replication (Francavilla et al, 1992; Palmes et al, 2008). The rapid hepatocyte replication and smaller liver

mass may also interfere with the metabolism and pharmacokinetics of certain drugs. Preliminary studies have shown that AALDLT recipients require lower doses of tacrolimus in the early postoperative period than patients receiving whole grafts (Trotter et al, 2002). The ability to measure functional recovery of these recipients would help in the assessment of hepatocellular function and metabolic demands in those regenerating partial liver grafts.

Donor Age

As with liver regeneration in the nontransplant setting, old grafts do not regenerate as quickly as young livers. A clinical study of living donors showed a greater graft/standard liver volume in the young donor livers posttransplant compared with middle-aged and old donor grafts. The old livers also had a higher prothrombin time in the early period postoperatively (Ikegami et al, 2000). Statistics from the UNOS database show that the graft survival of older living-donor grafts is inferior to those of grafts from younger living donors (Abt et al, 2004). In the deceased-donor transplant setting, grafts older than 55 to 60 years of age have poorer long-term survival combined with those exposed to longer cold ischemic times (Cassuto et al, 2008). Age may affect the regeneration and recovery of the living donor and the recipient, and many groups limit the age of the donor, although no definite age limit has been specified.

Viral Hepatitis and Bacterial Infections

Very little is known about how rapid hepatocellular proliferation affects other processes. Some viral infections, such as hepatitis B and C and murine cytomegalovirus (Tralhao et al, 2002; Marshall et al, 2005; Sun & Gao, 2004), have been reported to inhibit hepatic regeneration. The precise mechanism responsible for viral infection–related suppression is unclear, but it may be partly mediated by the inhibition of cell-cycle–dependent molecules. Because most transplant recipients in the United States have the hepatitis C virus (HCV), it is important to know whether this vigorous regenerative response in the transplanted graft has a significant effect on the kinetics of viral replication in HCV-positive individuals. Investigators have noted that HCV RNA replication is enhanced in proliferating cells, suggesting that viral replication is regulated by cell-cycle–dependent factors (Erhardt et al, 2002). Clinically, progressive liver disease has been reported to be associated with increased hepatocyte proliferation (Poynard et al, 1997). Alternatively, HCV core proteins have been shown to have significant interaction with cellular promoters and regulators of cell growth, which may affect liver regeneration (Ray et al, 1998; Shrivastava et al, 1998; Hayashi et al, 2000; Lee et al, 2002; Blindenbacher et al, 2003). Early single-center studies suggest that recipients of living-donor liver transplants may have an earlier and more severe recurrence of HCV compared with recipients of whole deceased-donor liver grafts; however, this has not been shown in a prospective controlled study (Ghobrial et al, 2002; Shiffman et al, 2004; Berenguer, 2006).

Concomitant bacterial infections also alter liver regeneration. Earlier reports showed enhanced liver regeneration in rats after inflammation prior to hepatic resection as the result of stimulation of lipopolysaccharide upregulation of proinflammatory cytokines, such as IL-6 and TNF-α, and HGF (Weiss et al, 2001; Sekine et al, 2004), all of which are chief mediators of hepatic regeneration. A recent study more in line with clinical observations showed a significantly delayed regeneration kinetic in a rat model of combined liver resection and intraperitoneal sepsis with hyperinflammation and increased liberation of proinflammatory cytokines (Seehofer et al, 2007).

Other Factors

Several other factors may influence the regenerative response after transplantation. Increased portal venous flow has been implicated in more rapid regeneration (Jiang et al, 2009). In addition to the reduced cell mass of the graft itself, portal blood flow dynamics are altered, and the graft is subjected to increased portal blood flow and pressure. The significance of this situation is unclear: increased portal flow is associated with increased recovery (Eguchi et al, 2003); however, portal hyperperfusion is on the other hand regarded as central to the problem in SFS grafts, leading to decreased regeneration and increased mortality (Tracy et al, 1991). Some centers advocate surgical manipulations—such as splenic artery ligation, splenectomy, or portocaval shunting—to minimize portal hypertension in the setting of a SFS graft (Tucker & Heaton. 2005). Poor hepatic venous drainage has been shown to inhibit regeneration (Scatton et al, 2008), and segments with poor venous drainage become atrophied with time.

As in liver resection, female gender may have a positive effect on regeneration of partial grafts in murine models (Yokoyama et al, 2007b). Estrogen may be responsible for the better tolerance to various stresses as a result of reduced inflammatory response and reduced oxygen radical production, leading to improved hepatic regeneration. However, also in transplantation, no clinical evidence supports the results of these experimental studies.

EXPERIMENTAL STRATEGIES TO PROMOTE LIVER REGENERATION

After major hepatectomy or in the setting of an SFS liver graft in liver transplantation, usually a robust priming reaction by highly elevated levels of IL-6 and TNF-α is present, but induction of cell-cycle progression fails (Debonera et al, 2004). In an animal model, this problem was overcome by a single injection of heparin-binding epidermal growth factor (HB-EGF) (Mitchell et al, 2005). Another strategy that may be useful in an SFS situation is blockage of the receptor for advanced glycation endproducts (RAGE). Blockage of RAGE greatly improved survival after an 85% hepatectomy in a mouse model by increasing TNF-α and IL-6 production and enhancing expression of the antiinflammatory cytokine IL-10 (Cataldegirmen et al, 2005).

Recently, the role of TGF-β as the most potent growth-inhibitory polypeptide currently known was assessed in a model of SFS liver transplantation, after which a sharp rise in TGF-β1 was found, forming a heteromeric receptor complex. Phosphorylation of this complex activates proteins of the Smad family, particularly Smad2 and Smad3 (Lonn et al, 2009). Activated Smad2 and Smad3 form a complex with Smad4, move into the nucleus, and activate target genes, expressing regulatory proteins and exerting an inhibitory effect on hepatocyte proliferation. Smad7, an inhibitory Smad, associates stably with the TGF-β receptor complex and was shown to inhibit the TGF-β–dependent cell-cycle arrest (Zhong et al, 2010). Therefore anti–TGF-β therapy holds promise as a new strategy to improve regeneration of SFS grafts in clinical practice.

CLINICAL IMPLICATIONS

Stimulating Liver Regeneration Preoperatively

The assessment of hepatic function before resection is difficult, but we do know that the risk for perioperative complications increases when the remnant liver volume is too small, particularly in diseased livers (see Chapter 2; Yigitler et al, 2003). Hepatic function seems to recover quickly after resection but is difficult to measure. Conventional clinical blood tests and liver biopsy are inadequate measures of hepatic function. Child-Turcot-Pugh classification and the Model for End-Stage Liver Disease (MELD) score apply primarily to patients with cirrhosis and are only rough estimates of functional reserve. Bilirubin, albumin, international normalized ratio, and platelet count become abnormal only in advanced cirrhosis. Magnetic resonance imaging or computed tomography can measure residual liver volume accurately, but quantitative functional testing is not as precise. Traditional techniques to measure the volume of resection prior to hepatectomy can lead to inaccurate estimates of functional residual liver (FRL) volumes because of the presence of dilated bile ducts, multiple tumors, undetected lesions, compromised liver volume as a result of cholestasis or previous chemotherapy, cholangitis, vascular obstruction, steatosis or cirrhosis, or segmental atrophy and/or hypertrophy from tumor growth (Azoulay et al, 2000; Kubota et al, 1997).

In living-donor liver transplantation, volumetric imaging is used to determine total liver volume (TLV) and what the FRL volume will be following resection, and it can roughly be used to predict postresection function, as the donor liver is normal. In the recipient, the TLV of the diseased liver is not a useful index of function. Values calculated from GRBWR or standardized liver volume (SLV) based on recipient body surface area are used to predict minimum adequate graft volume (Vauthey et al, 2000; Higashiyama et al, 1993). A GRBWR greater than 0.8% or SLV greater than 35% are recommended to achieve successful graft and patient survival (Lo et al, 1999). For donor safety, the transplant community has recommended that at least 35% of TLV remain in the donor following resection for living donation. In comparison, extended resection of 80% of functional parenchyma can be performed in the absence of chronic liver disease for hepatobiliary malignancies (Abdalla et al, 2002). Recommended minimal FRL volume following extended hepatectomy is greater than 25% in a normal liver and greater than 40% in an injured liver, with moderate to severe steatosis, cholestasis, fibrosis, or cirrhosis, or following chemotherapy (Shoup et al, 2003).

Quantitative liver function tests measure the liver's ability to metabolize or extract test compounds and can identify patients with impaired function at earlier stages of disease, but these tests have limited application in predicting a liver's ability to regenerate after major resection (see Chapter 2). Clearance of indocyanine green is regarded as an accurate assessment of functional reserve that can help predict mortality (Lau et al, 1997), but more is being learned about measuring hepatic function in diseased livers using quantitative functional testing, such as methionine breath tests, cholate clearance, liver single-photon emission computed tomography scans, liver scintigraphy, and phosphorus 31 magnetic resonance spectroscopy (Corbin et al, 2002). When compared with indocyanine green (ICG) clearance and computed tomographic volumetric data, hepatobiliary scintigraphy is a reproducible and accurate tool to assess functional liver uptake and excretion, preoperative liver function reserve, and remnant liver function, and it allows monitoring of postoperative liver function regeneration (Dinant et al, 2007). Assessment of future remnant volume distinguishes those who will most likely benefit from preoperative liver enhancement techniques with PVE or hepatic artery embolization.

Portal Vein Embolization to Promote Liver Regeneration

Selective embolization techniques increase tolerance to major hepatic resection by reducing the liver volume that requires resection and inducing hypertrophy of the FLR to approximate target limits in patients with large tumors or abnormal liver function. Criteria for selection of patients for PVE prior to major hepatectomy are FLR size, factors compromising liver function—including previous chemotherapy, hepatitis, and cirrhosis—and the planned complexity of the procedure (Yigitler et al, 2003; Abdalla et al, 2001). PVE is recommended when predicted FLR is less than 20% to 25% in a normal liver and less than 40% in a liver with compromised function (Hemming et al, 2003). Stimulation by PVE increases circulating IL-6 and TNF-α (Koga & Ogasawara, 1991; Feingold et al, 1988), with activation of the mitogenic cascade similar to partial hepatectomy. In fact, marginal (<5%) contralateral regeneration after PVE is a strong predictor of liver failure after subsequent liver resection (Ribero et al, 2007). A significant increase in DNA synthesis and mRNA expression of HGF has been observed in the nonligated lobe (Uemura et al, 2000), whereas HGF expression is only slightly elevated; negative regulators of hepatocyte proliferation, such as TGF-β and IL-1β, are strongly expressed in the shrinking ligated lobe. It is important to keep in mind that these factors may also promote tumor outgrowth in the FLR, and continuation of chemotherapy during PVE for malignant conditions should be considered (Covey et al, 2008; Pamecha et al, 2009).

Ischemic Preconditioning to Stimulate Regeneration

Liver resection, transplantation, and trauma can result in prolonged deprivation of tissue oxygen, converting cellular metabolism to anaerobic pathways. Reperfusion and, consequently, the restoration of oxygen delivery lead to liver injury, and this ischemia/reperfusion injury impairs liver regeneration (Selzner et al, 1999).

The first clinical attempt to minimize ischemic injury during liver resection was performed by interrupting long ischemic intervals with multiple short periods of reperfusion (Makuuchi et al, 1987). The protective effect of ischemic preconditioning (IPC) involves many different mechanisms, including inhibition of apoptosis and preservation of cellular ATP content in patients undergoing major liver resection (Clavien et al, 2003; Rudiger et al, 2002). A recent cDNA microarray study in humans demonstrated that IPC triggers the overexpression of IL-1Ra, iNOS, and Bcl-2, which counteracts the ischemia-induced proinflammatory and proapoptotic activation (Barrier et al, 2005). IPC has also been described as promoting liver regeneration via the upregulation of cytokines such as TNF-α and IL-6, various heat-shock proteins, and the downregulation of TGF-β (Gomez et al, 2007). IPC by 10 minutes of portal triad inflow occlusion and 10 minutes of reperfusion proved effective both in liver resection, particularly noted in patients with mild to moderate steatosis (Clavien et al, 2003), and in liver transplantation (Jassem et al 2009; Franchello et al, 2009). No

difference was seen in protection between intermittent clamping (15 minutes ischemia and 5 minutes reperfusion) or IPC with subsequent inflow occlusion for a maximum of 75 minutes, except for patients older than 65 years, who benefited more from intermittent clamping to attenuate liver injury. Pharmacologic induction of heat-shock proteins could play a beneficial role in the recovery of liver function after hepatectomy, but clinical trials have yet to be performed to confirm this.

Regenerative Potential of the Liver After Chemotherapy

As discussed earlier, an increasing number of patients with tumors undergo extensive chemotherapy with multiple drugs before surgery (see Chapter 87). The complication rate and mortality after major liver resection is increased in those patients, compared with patients not receiving these drugs (Vauthey et al 2006; Fernandez et al, 2005). The deleterious effect of chemotherapy on regeneration seems to increase with the total number of cycles given and shows a sharp rise after five courses (Karoui et al, 2006). Therefore no more than six cycles of chemotherapy containing 5-fluorouracil, leukovorin, and oxaliplatin/irinotecan are generally recommended before liver resection, with a 3-week interval in between. The anti-VEGF monoclonal bevacizumab has a long half-life and theoretically should be stopped 6 to 8 weeks prior to surgery, necessitating close collaboration with the medical oncologist in the timing of surgery. Results from PVE before major liver resection under continuous bevacizumab, however, showed no deterioration in increase in FLR volume 4 weeks after PVE (Zorzi et al, 2008). Recently, significantly impaired hypertrophy was reported in the same situation (Aussilhou et al, 2009), but this might also be attributed to extensive concomitant chemotherapy (Vauthey et al, 2009). Therefore the optimal window between the completion of bevacizumab and surgery remains uncertain (Clavien et al, 2007).

Supporting Liver Regeneration Under Difficult Clinical Conditions

After major liver resection or transplantation of an SFS liver graft, the energy balance is dramatically shifted to the critical task of regeneration of functional mass and injury recovery at the expense of normal hepatic metabolism (de Jonge et al, 2009; Mann et al, 2002; Corbin et al, 2002; Mann et al, 2001). In the situation of a severely ill recipient, which requires the expenditure of an unusual amount of metabolic energy by the liver, this balance may be disrupted and may lead to blunted regeneration. Similarly, when factors in the remnant liver or donor graft demand increased efforts for repair or regeneration of the graft, the balance tips in the opposite direction, not leaving enough energy to maintain metabolic function (Mann et al, 2001). The clinical consequences of this postoperative liver failure are jaundice, coagulopathy, ascites, edema, and/or hepatic encephalopathy (Sass & Shakil, 2005). Data concerning liver function on different days after uncomplicated hepatic resection show an initial increase of serum bilirubin and a decrease of prothrombin time before normalization of these values on the seventh postoperative day (Suc et al, 1992). However, when the prothrombin index dropped below 50% and serum bilirubin exceeded 50 µmol/L on postoperative day 5, the risk of early mortality increased significantly (Balzan et al, 2005). In this situation, avoidance of any new energy-costing challenge, such as systemic infection, is pivotal to graft regeneration. The number of major complications is progressively increasing, from about 30% after resection of two segments to 75% in patients who underwent resection of six segments, with a similar trend in operative mortality, from less than 1% in those who had five or six segments resected to 5% and 7.8%, respectively (Jarnagin et al, 2002).

Management principles resemble those applied to patients with acute liver failure, acute-on-chronic liver failure, or sepsis; the focus is put on support of liver and end-organ function (Rivers et al, 2001). Goal-directed therapy should be provided for circulatory disturbances, renal and ventilatory dysfunction, coagulopathy, malnutrition, and hepatic encephalopathy (Jalan, 2005). A strong link between infection and postoperative liver failure is evident, so frequent cultures for bacteria and fungi are essential. The use of prophylactic antibiotics after hepatectomy for the prevention of infectious complications is not supported by evidence from the literature (Wu et al, 1998); however, the administration of antibiotics in patients suffering from acute liver failure is associated with a significant decrease in infectious complications, and this practice can be advocated in the presence of liver failure following resection (Rolando et al, 1993). An aggressive approach to intraabdominal infection is also advocated—such as percutaneous treatment of biloma, infected hematoma, and abscesses—as is vigorous control of ascites in the setting of imminent postoperative liver failure.

NEW HORIZONS AND FUTURE PERSPECTIVES

Therapeutic Use of Stem Cells

In addition to the classical first pathway (hepatocyte proliferation) and second pathway (hepatic progenitor cells) in liver regeneration, new evidence using bone marrow transplantation has begun to crystallize the existence of a third, extrahepatic pathway: the ability of bone marrow and cord-blood derived cells to engraft as hepatocytes (Friedman & Krause, 2009; Theise & Kraus, 2002).

Adult bone marrow includes two well-defined populations of stem cells: *hematopoietic stem cells* (HSCs), which give rise to all mature lineages of blood, and *mesenchymal stem cells* (MSCs), which can differentiate into bone, cartilage, muscle, and fat. Evidence for transition from bone marrow (BM) to hepatocyte has been demonstrated by analyzing liver samples after male-to-female BM transplantation in rodents and humans (Alison et al, 2000; Lagasse et al, 2000; Theise et al, 2000b). However, the extent to which this occurs and the mechanisms involved are still under debate (Fausto, 2004; Oertel & Shafritz, 2008). Estimates of repopulation by hematopoietic stem cells vary from 0.01% up to 40%, depending on the experimental conditions.

In the discussion about the mechanisms whereby the HSCs acquire a hepatocytic phenotype, both fusion of stem cells and hepatocytes (Wang et al, 2003b; Vassilopoulos et al, 2003) and transdifferentiation of stem cells into hepatocytes have been proven (Harris et al, 2004; Jang et al, 2004). The highest levels of BM-derived hepatocytes were found in humans with severe liver disease, suggesting that tissue damage may promote BM-derived cells engraftment as hepatocytes. Also, the release of adult stem cells from BM was shown after partial liver resection for benign and malignant conditions (Gehling et al, 2005; De Silvestro et al, 2004), and BM-derived stem cells increased the regeneration of contralateral liver after clinical PVE by 250% (Esch et al, 2005).

Recent studies report that MSCs promote liver repair in cases of liver damage (Alison et al, 2009). MSCs isolated from human umbilical cords (Yan et al, 2009), adipose tissue (Banas et al, 2008), bone marrow (Kuo et al, 2008), or rat bone marrow (Abdel Aziz et al, 2007) improved liver function in rodents suffering from acute liver damage (e.g., carbon tetrachloride injections). Infusion of hepatocyte-like cells, which were differentiated in vitro from MSCs, improved liver function following acute injury and appears to be therapeutically useful to animals with ongoing chronic hepatic damage (Fang et al, 2004; Zhao et al, 2005; Sakaida et al, 2004; Oyagi et al, 2006; Higashiyama et al, 2007). MSC therapy is sometimes considered to be a double-edged sword, and concerns were raised about MSCs promoting liver cirrhosis by differentiatng into myofibroblasts, which are involved in the fibrotic response (Russo et al, 2006; di Bonzo et al, 2008). The latest publications in this field indicate that the use of MSCs is safe and has a beneficial effect on liver fibrosis (Zhao et al, 2009; Chang et al, 2009; Roderfeld et al, 2009). Some phase I trials involving the injection of autologous BM cells into patients with cirrhosis have reported modest improvements in clinical scores (Lin et al, 2008; Houlihan & Newsome, 2008). Thus MSC-mediated liver therapy is a highly promising field; such therapy significantly improves liver function and increases animal survival in experimental liver-injury models; however, its role in liver regeneration after surgery remains to be determined.

Use of Antisense MicroRNAs

Recent studies have uncovered profound and unexpected roles for a family of tiny regulatory RNAs known as *microRNAs* (miRNAs) in the control of diverse aspects of hepatic function and dysfunction, including hepatocyte growth, stress response, metabolism, viral infection and proliferation, gene expression, and maintenance of hepatic phenotype (Elmen et al, 2008; Ambros, 2004). Some of these miRNAs are specific to the liver, and silencing of these resulted in increased expression of several hundred genes, including those normally repressed in hepatocytes. The significance of miRNAs in regenerating liver has not been established, but in a murine model, there was upregulation of some miRNAs with increasing age (Maes et al, 2008). In particular, three upregulated miRNAs may contribute to the aging-related decline in oxidative defense by targeting various classes of glutathione S–transferases. Other proteins in decline in old liver and targeted by the upregulated miRNAs are involved in mitochondrial functions or maintenance. Antagonizing these miRNAs may reverse the decline of regeneration and oxidative defense mechanisms in aging liver.

SUMMARY

In the last century, knowledge about liver regeneration has rapidly evolved from a truly mythical black-box event into a growing understanding of the pathways involved in this amazing, multistep process. However, even with our better understanding, large knowledge gaps still exist. Interestingly, much was learned about the dynamics and redundant intracellular signaling pathways of liver regeneration. Still, much less is known about the exact signals that initiate and stop liver regeneration. The advances in our knowledge of liver regeneration have led to safer extreme liver resections for benign and malignant diseases and the use of live donors in liver transplantation. New challenges lie ahead in the use of therapeutic strategies to enhance liver regeneration in patients in whom normal regeneration fails and will thus push the possibilities of liver resection to the next level. Furthermore, even as we promote liver cell proliferation, we must be very cautious not to stimulate tumor growth in patients with primary or metastatic liver tumors with our therapy.

CHAPTER 6

Liver fibrogenesis: mechanisms and clinical relevance

Diana Vetter and Scott L. Friedman

LIVER FIBROGENESIS

Liver fibrosis represents a scarring response to either acute or chronic cellular injury. Following acute liver injury, parenchymal cells regenerate to successfully preserve hepatocellular mass and function. This acute process is associated with an inflammatory and fibrogenic response but limited deposition of extracellular matrix (ECM). In contrast, prolonged liver injury leads to sustained production of growth factors, proteolytic enzymes, angiogenic factors, and fibrogenic cytokines. These events culminate in the accumulation of ECM, forming septa that coalesce into broad bands of scar tissue that encircle nodules of hepatocytes and lead to altered microvascular structure (Friedman, 2004). This late stage of fibrosis, termed *cirrhosis*, ultimately impairs liver function and leads to portal hypertension and its complications (see Chapter 70A).

Progression of fibrosis to cirrhosis typically evolves over decades before clinical events ensue, but disease may progress more rapidly following repeated episodes of severe acute alcoholic hepatitis; subfulminant hepatitis, especially as a result of drug toxicity; and fibrosing cholestasis in patients with hepatitis C virus (HCV) reinfection after liver transplantation (Berenguer et al, 2003). In addition, rapidly progressive acute HCV with fibrosis in men coinfected with human immunodeficiency virus (HIV) has been reported recently (Fierer et al, 2008).

Genetic and environmental factors also influence the course of the disease. For example, polymorphisms in a number of candidate genes involving the inflammatory (TLR4; Guo et al, 2009) or immune response (specific human leukocyte antigen-II [HLA-II] alleles; Powell et al, 2000) may influence the progression of liver fibrosis in humans. Validated groups of single nucleotide polymorphisms (SNPs) can be used to calculate a disease-specific risk assessment for fibrosis progression (HCV: DDXminor allele, DDX-5POLG2 haplotype [Huang et al, 2006]; alcohol-related or chronic cholestatic disorders: TNF-α, interleukin [IL]-1B [Jarvelainen et al, 2001; Donaldson et al, 2001]). These findings have led to the development of a seven-gene signature with good prognostic value in assessing the risk for cirrhosis development in HCV patients (Huang et al, 2007).

The main etiologies of liver fibrosis in Western countries are chronic HCV and HBV infection, alcohol abuse, and nonalcoholic steatohepatitis (NASH; see Chapters 64 and 65). As a generalized tissue response to chronic injury, fibrosis also occurs in many other organs—including the heart, lung, and kidneys—and typically represents the result of ongoing inflammation. Remarkably, up to 45% of all deaths are related to some kind of fibrosis, which emphasizes the importance of this response and explains the growing interest in this field of research (Fig. 6.1).

For decades fibrosis was seen as an irreversible disease that progresses to cirrhosis, with a greater risk for developing hepatocellular carcinoma (see Chapters 8C and 80) and liver failure. This meant the only potential treatment for liver fibrosis once it had progressed to cirrhosis was transplantation. Research over the past 30 years has yielded increasing insight into the cellular and molecular mechanisms of this disease, uncovering an orchestrated pathophysiology and identifying the hepatic stellate cell (HSC) as the central cell type in fibrogenesis (Friedman, 1985). Most importantly, this revealed the potential reversibility of this disease and the discovery of potential therapeutic targets.

MOLECULAR AND CELLULAR MECHANISMS OF FIBROSIS

The anatomical arrangement of parenchymal and nonparenchymal cells of the liver contributes to its unique role as an immunity-modulating organ (see Chapter 9) and helps explain how the liver responds to an insult. The liver is composed primarily of epithelial cells, hepatocytes and cholangiocytes, and resident nonparenchymal cells that include hepatic macrophages (Kupffer cells), sinusoidal endothelium, and HSCs. In addition to Kupffer cells, a growing list of specialized immune cells have been characterized, including dendritic cells (DCs), natural killer (NK) cells, and natural killer T (NKT) cells, which indicate that the liver represents a key organ in the regulation of innate immunity.

The liver capsule extends as septa into the liver, delineating hepatic lobules that form the structural units of the liver. The lobule forms a hexagonal structure with portal triads—including branches of the hepatic portal vein, the hepatic artery, and the bile duct—localized in the periphery of the lobule and with a portal vein branch in the center. Hepatocyte plates radiate outward from the central vein and are separated from each other by sinusoids. The latter form the connecting element between the branches of the hepatic portal veins and hepatic arteries with the central vein. Kupffer cells, NK cells, NKT cells, and DCs, all of which are important components of the innate immune system, reside in the hepatic sinusoids. The subendothelial space between the sinusoidal endothelium and hepatocytes is termed the *space of Disse*. Thus the HSCs, which lie in the space of Disse, have direct contact with

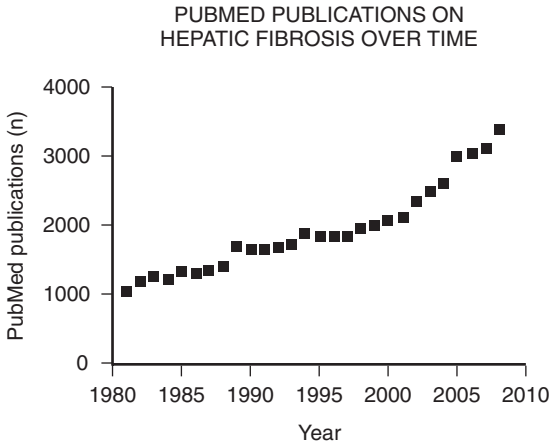

FIGURE 6.1. Growing interest in hepatic fibrosis based on numbers of publications. Hepatic fibrosis is gaining accelerating interest based on citations in PubMed. Graph shows number of citations based on a search of "hepatic fibrosis" annually over a 30-year period.

endothelial cells and hepatocytes. Sinusoidal endothelial cells are highly fenestrated, which allows unimpeded flow of plasma from sinusoidal blood into the space of Disse. Through this arrangement, hepatocytes and HSCs are exposed directly to plasma derived largely from venous blood draining the small intestine.

Common Triggers of Hepatic Fibrogenesis

Ongoing insult to the liver will lead to an increased inflammatory state with activation of hepatic stellate cells, which ultimately tilts the profibrotic–antifibrotic balance toward fibrosis. Ethanol, viral infection, reactive oxygen species (ROS), and bile acids are among the most common stress signals for the liver (Fig. 6.2). An in vitro study further suggests that free fatty acids promote fibrogenesis by indirect activation of HSCs (Wobser, 2009). Less common causes of hepatocellular injury are autoimmune hepatitis, Wilson disease, or hemochromatosis.

Alcohol decreases gut motility, increases epithelial permeability, and promotes overgrowth of gram-negative bacteria. Consequently, lipopolysaccharide concentration is elevated in portal blood, which activates Kupffer cells through the Toll-like receptor (TLR) 4 complex to generate ROS via reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (Wheeler, 2001). Oxidants then upregulate NF-κB in Kupffer cells, which leads to increased tumor necrosis factor (TNF)-α production. TNF-α in turn induces neutrophil infiltration and stimulates mitochondrial oxidant production in hepatocytes, which are then sensitized to undergo apoptosis. Furthermore, acetaldehyde, the main degradation product of alcohol, and ROS both activate HSCs and stimulate inflammatory signals (Maher et al, 1994).

In HCV infection, the virus escapes the HLA-II immune response and infects hepatocytes. This causes oxidative stress,

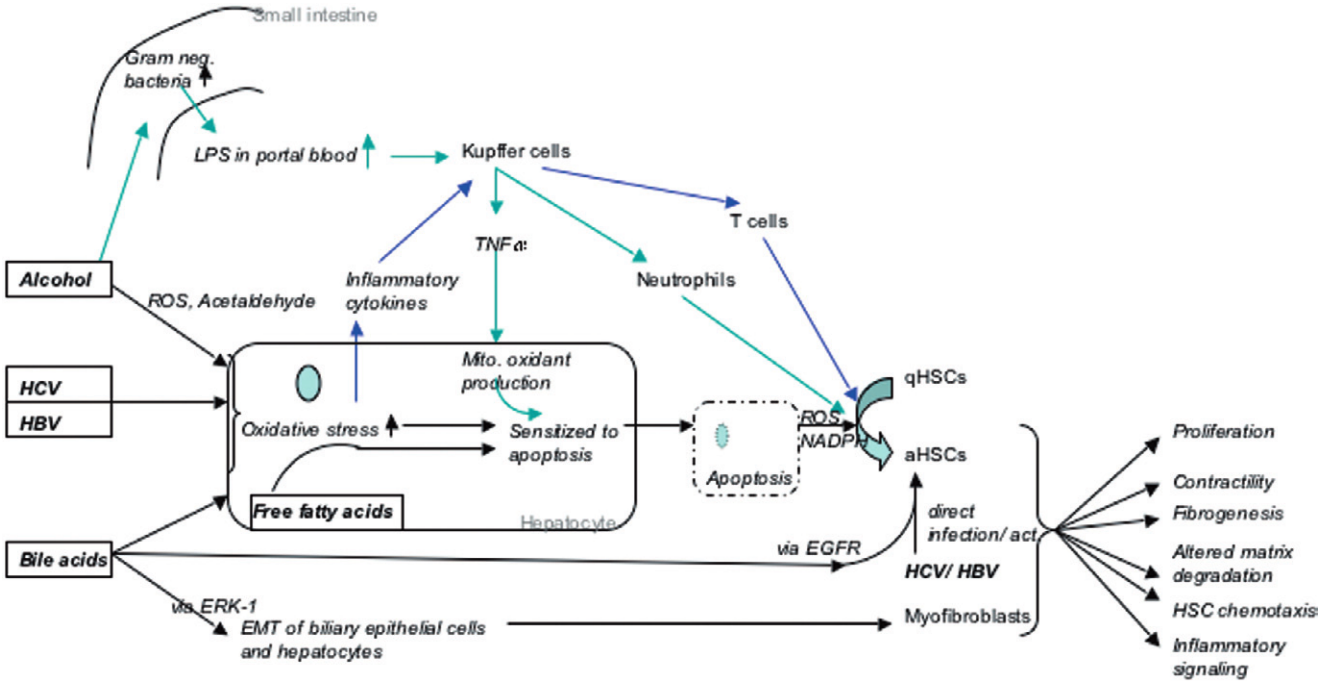

FIGURE 6.2. Pathways of liver injury and fibrosis. This diagram depicts the key pathways of cellular injury and fibrosis. The main causes of chronic liver injury are alcohol, viral infection, and injury by bile acids. All factors activate hepatic stellate cells (HSCs), which is a key event in liver fibrogenesis. Alcohol leads to gram-negative bacteria overgrowth of the small intestine with consequent increase of lipopolysaccharide (LPS) in the portal blood. LPS activates Kupffer cells, which increase the mitochondrial oxidant production in hepatocytes by way of tumor necrosis factor (TNF)-α, thereby sensitizing them to apoptosis. Kupffer cells also support local accumulation of T cells and neutrophils, which, along with apoptotic hepatocytes, stimulate the activation of HSCs. Infection of hepatocytes by hepatitis B and hepatitis C virus (*HCV, HBV*) promotes oxidative stress, further sensitizing hepatocytes to apoptosis. Free fatty acids also increase the intracellular oxidative stress of hepatocytes. Bile acids are directly toxic to hepatocytes and lead to increased secretion of inflammatory cytokines by hepatocytes, which activate Kupffer cells. Bile acids also directly activate HSCs and can promote epithelial–mesenchymal transition (EMT) of biliary epithelial cells and hepatocytes into myofibroblasts. ROS, reactive oxygen species; ERK-1, extracellular signal-regulated kinase-1; mito., mitochondrial; NADPH, nicotinamide adenine dinucleotide phosphate; EGFR, endothelial growth factor receptor; qHSC, quiescent HSC; aHSC, activated HSC.

again leading to recruitment of inflammatory cells and HSC activation. HSCs can also be directly activated by either HCV, through membrane receptors (Mazzocca et al, 2005, Schulze-Krebs et al, 2005), or by HBV (Martin-Vilchez et al, 2008).

Bile acids are hepatotoxic agents that typically target hepatocytes, but they may also injure biliary epithelium (Higuchi & Gores, 2003). Damaged hepatocytes turn apoptotic or necrotic, thereby releasing ROS (Nieto et al, 2002) and NADPH oxidase, which both activate HSCs (Canbay et al, 2004a). Injured hepatocytes also release inflammatory cytokines and soluble factors that activate Kupffer cells and stimulate the recruitment of activated T cells. This inflammatory milieu further stimulates the activation of resident HSCs. Bile acids also directly stimulate proliferation of HSCs by activating the epidermal growth-factor receptor (Svegliati-Baroni et al, 2005). In contrast to hepatocytes, HSCs are protected from bile acid–induced apoptosis by excluding bile acids (Svegliati-Baroni et al, 2005).

Nonalcoholic fatty liver disease (NAFLD) is increasingly prevalent as a result of increased obesity in the United States and Western Europe. NAFLD can progress to NASH with consequent fibrosis and cirrhosis (Carter-Kent et al, 2009). The pathogenesis is not fully understood; however, a two-hit model has been proposed with hyperglycemia and insulin resistance representing the first hit, leading to elevated serum levels of free fatty acids. Histologically this correlates to hepatic steatosis. Additional oxidative stress or proinflammatory cytokines are thought to promote hepatocyte apoptosis and recruitment of inflammatory cells, thereby enhancing fibrogenesis.

Hepatic Stellate Cell Activation and Hepatic Myofibroblasts (MFBs)

The HSC has emerged as a central regulator of the liver's fibrotic and repair responses (Friedman, 2000). In normal liver the HSC is a quiescent cell type that contains cytoplasmic retinoid droplets, representing the major storage site for vitamin A in the body, and expresses the markers desmin and glial fibrillary acidic protein (GFAP; Friedman, 2008).

During liver injury, HSCs undergo activation in response to a range of inflammatory and injury signals (Casini, 1997) produced by damaged hepatocytes and biliary cells; changes in the composition of the ECM; proangiogenic growth factors, like VEGF and angiopoietin; and fibrogenic cytokines that include TGF-β1, angiotensin II, and leptin.

Activation of HSCs is accompanied by loss of retinoid droplets and accumulation of α-smooth muscle actin, a myogenic filament that confers increased cellular contractility. Activated HSCs are characteristically desmin- and α-SMA–positive cells. Highly activated subsets of HSCs are known as *hepatic myofibroblasts* (MFBs; Friedman, 2008), a cell type that is also characteristic of wound healing in a range of tissues: skin, kidney, lung, bone marrow, and pancreas, among others.

HSC activation can be divided conceptually into two phases: *initiation* begins with early changes in gene expression and phenotype that result from paracrine stimulation, primarily due to changes in surrounding ECM and exposure to lipid peroxides and products of damaged hepatocytes (Fig. 6.3); *perpetuation* results from the effects of these stimuli on maintaining the activated phenotype and generating fibrosis. Within the nucleus, a growing number of transcription factors regulate HSC behavior, including peroxisomal proliferator–activated receptors (PPARs), retinoid receptors, NF-κB, JUND, Kruppel-like factor 6 (KLF6), and FOXF1 (Mann & Mann, 2009). A range of general and cell type–specific membrane receptors and signaling pathways also control HSC biology, including receptor tyrosine kinases, chemokine receptors, and integrins (Dodig et al, 2007).

Portal fibroblasts (Beaussier et al, 2007; Ramadori & Saile, 2004) and bone marrow–derived MFBs (Russo et al, 2006) have also been identified as collagen-producing cells in the injured liver. Another emerging source of fibrogenic cells is epithelial-mesenchymal transition (EMT), in which adult hepatocytes of biliary epithelium transdifferentiate into fibrogenic cells (Rygiel et al, 2008). EMT has been extensively characterized in kidney and lung fibrosis, in subsequent animal models and human samples of liver fibrosis, and in the context of hepatocarcinogenesis. Interestingly, key signals regulating EMT also drive activation of HSCs, including TGF-β, RAS, extracellular signal-regulated kinase 1 (ERK1; Zhong et al, 2009), SMAD7, and SHH (Dooley et al, 2008; Lahsnig et al, 2009; Syn et al, 2009).

The relative importance of each cell type in liver fibrogenesis may depend on the origin of the liver injury. In cholestatic liver diseases and ischemia, portal fibroblasts may be especially important (Clouzeau-Girard et al, 2006), whereas hepatic MFBs may be of predominant importance in alcoholic liver disease. In chronic liver injury, progressive recruitment of bone marrow–derived cells may occur over time. However, bone marrow–derived cells may have both fibrogenic and antifibrotic effects (Karlmark et al, 2009). To date, the quantitative contribution to fibrogenesis of nonstellate cell–derived fibroblasts remains unclear.

Functions of Hepatic MFBs

Hepatic MFBs have functions that are distinct from their quiescent cells of origin. They are profibrogenic and promitotic, play a chemotactic and vasoregulatory role, and control the degradation of the ECM (see Fig. 6.3). They also have important immune and phagocytic functions (Friedman, 2008). The regulation of ECM accumulation and degradation by HSCs is reviewed in the next section.

Fibrogenesis

The major profibrogenic signal in the liver is the cytokine TGF-β1 (Bachem et al, 1989a). TGF-β1 is secreted mainly by MFBs (Bissell et al, 1995) but also by platelets (Bachem et al, 1989b) and Kupffer cells (Bilzer et al, 2006). It acts by activating the TGF-βII receptor, which recruits the TGF-βI receptor. SMAD2 and SMAD3 then associate with the TGF-βI receptor (Dooley et al, 2001), are phosphorylated, and recruit SMAD4. This triheteromeric complex then translocates to the nucleus, where it activates profibrogenic transcription factors. TGF-β also activates the MAPK p38 pathway (Cao et al, 2002), which leads to additional, SMAD-independent collagen type 1 synthesis and, in contrast to the SMAD-dependent collagen type 1 synthesis, also leads to a posttranscriptionally regulated stabilization of the collagen type 1 mRNA (Tsukada et al, 2005; Fig. 6.4).

Proliferation

The predominant stimulus to MFB proliferation is the mitogen platelet-derived growth factor (PDGF; Borkham-Kamphorst et al, 2004), in addition to other mitogens that include EGF, VEGF, and FGF. All pathways downstream of PDGF receptor

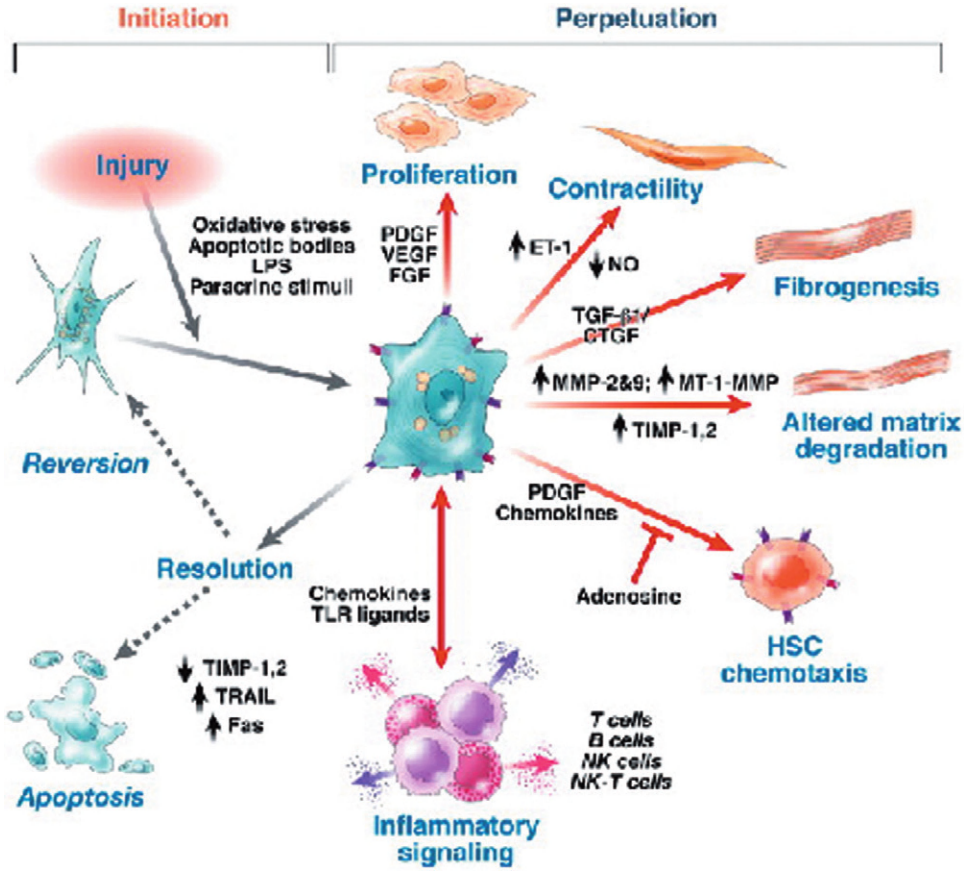

FIGURE 6.3. Key effectors, cellular features, and mediators in HSC activation during liver injury. Features of stellate cell activation can be differentiated into two stages: *intiation* begins with early changes in gene expression and phenotype that results from paracrine stimulation, primarily as a result of changes in surrounding extracellular matrix (ECM) as well as exposure to reactive oxygen species (ROS), apoptotic bodies, lipopolysaccharide (LPS), and paracrine activation by Kupffer cells; *perpetuation* results from the effects of these stimuli on maintaining the activated phenotype and generating fibrosis. PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor; FGF, fibroblast growth factor; ET-1, endothelin-1; NO, nitric oxide; TGF-β, transforming growth factor β; CTGF, connective tissue growth factor; MMP, matrix metalloproteinase; TIMP, tissue inhibitor metalloproteinase; TRAIL, TNF-related apoptosis-inducing ligand. *(Modified from Ghaissi-Nejad Z, Friedman SL (2008). Advances in antifibrotic therapy. Expert Rev Gastroenterol Hepatol 2:803-816.)*

activation promote proliferation. First, JNK is stimulated through MAPK (Schnabl et al, 2001); second, PDGF receptor stimulates the Ras/Raf complex, followed by MEK and ERK engagement (Schnabl et al, 2001); and third, activation of the PI3K pathway leads to Akt activation and phosphorylation of the 70s6 kinase (see Fig. 6.4; Reif, 2003).

Immunoregulation

The liver is a microenvironment of diminished immunogenicity, which is necessary to cope with the high exposure of antigens from the portal vein (Crispe, 2003). This feature also accounts for the tolerance of liver transplantation across ABO barriers and may contribute to the chronic nature of hepatitis B and C, where the virus persists despite the development of an immune response. Upon entry of antigen into the sinusoid, classical antigen-presenting cells (Kupffer cells, dendritic cells) are first encountered. Subsequently, HSCs in the space of Disse may contact antigens. Indeed, HSCs display a wide range of immunoregulatory functions and are an essential part of the local immunogenicity (Gao et al, 2008; Mehal, 2007; see Chapter 9).

Hepatic MFBs produce a range of proinflammatory (e.g., TNF-α; Tiggelman et al, 1995) and antiinflammatory IL-10 cytokines (Tiegs & Lohse, 2009; Safadi et al, 2004) and they recruit lymphocytes through secretion of chemokines (MCP-1, IL-8, CCL21, RANTES; Marra et al, 1998, 1993; Maher et al, 1998), thus amplifying the inflammatory response. However, upon activation, they exert a profound immunosuppressive activity by inducing T-cell apoptosis (Yu et al, 2004). In the setting of liver transplantation, MFB-induced T-cell apoptosis via programmed death ligand-1 (Yu et al, 2004) may enable local immunotolerance of the liver. In liver fibrosis, MFBs may further regulate the contribution of lymphocytes to the course of hepatic fibrosis by ingesting disease-associated lymphocytes (Muhanna et al, 2008).

The interaction between HSCs and immune cells is bidirectional. T cells activate HSCs by IFN-γ, which upregulates both stimulatory (CD80, CD86, CD54) and inhibitory (B7-H1) surface molecules and enhances both inflammatory and suppressive cytokines. However, the inhibitory molecules are thought to override the stimulatory counterparts, resulting in immunosuppression. Lymphocytes can also mediate hepatic fibrosis by activating HSCs. CD8-positive T lymphocytes are more fibrogenic toward stellate cells than CD4-positive T lymphocytes (Safadi et al, 2004). This may explain in part why

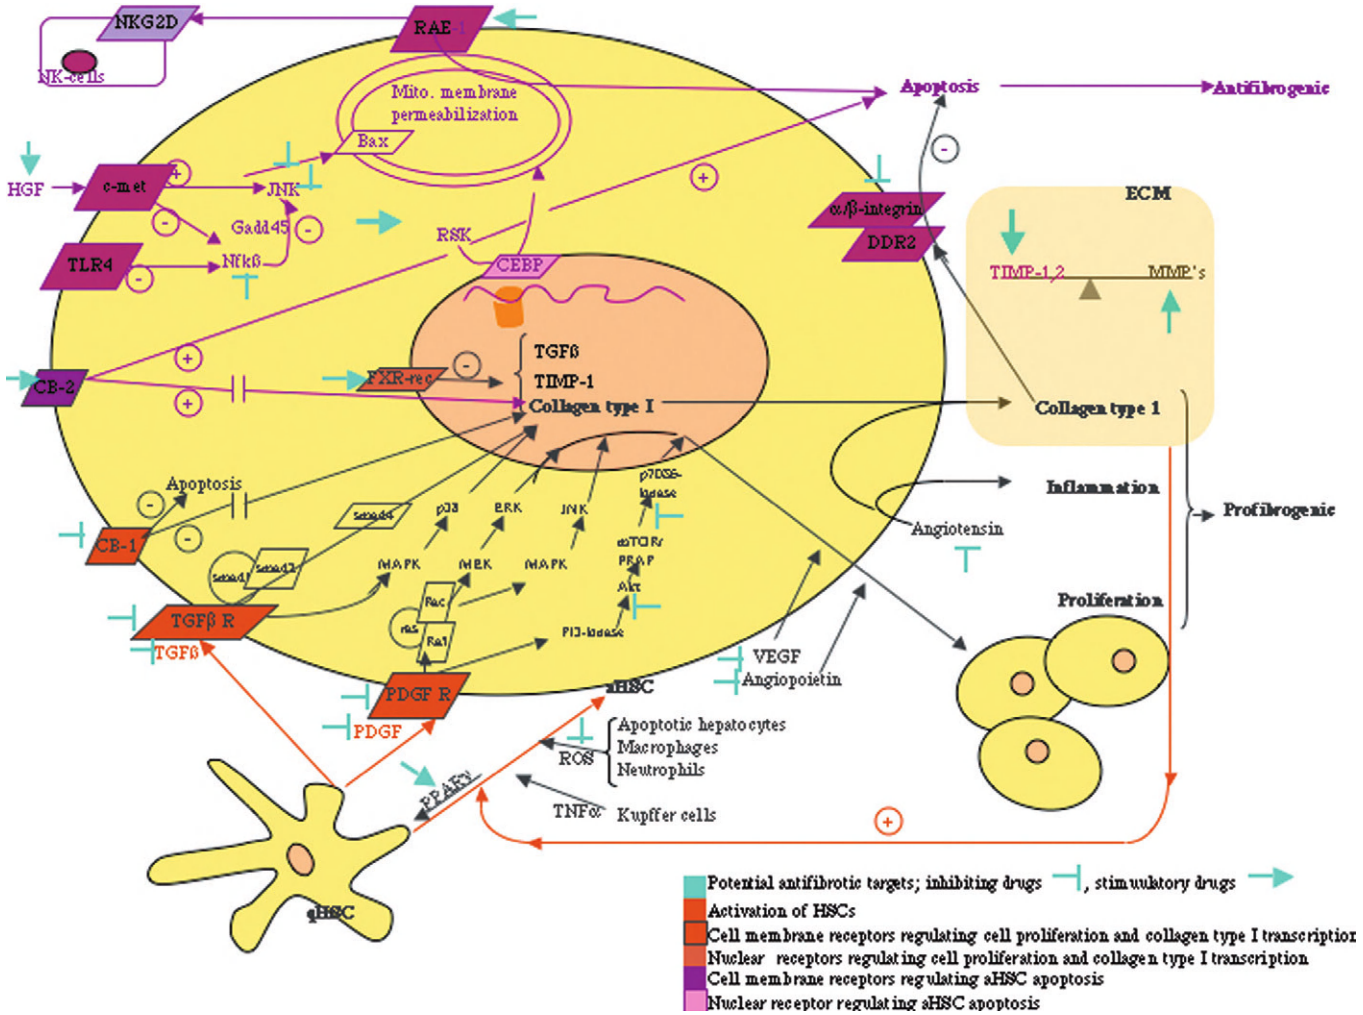

FIGURE 6.4. Cellular and molecular mechanisms of hepatic stellate cell (HSC) activation and potential antifibrotic targets.The HSC can be activated by paracrine stimuli, such as platelet-derived growth factor (PDGF) and transforming growth factor (TGF); by reactive oxygen species (ROS) produced by macrophages, neutrophils, or apoptotic hepatocytes; and by tumor necrosis factor (TNF) secreted by Kupffer cells. The activated HSC or hepatic myofibroblast (MFB) has multiple cell membrane receptors that can either upregulate proliferation (e.g., PDGFR), stimulate collagen type I synthesis (e.g., TGFR, cannabinoid [CB] 1 receptor), inhibit collagen type I transcription (e.g., cannabinoid [CB] 2 receptor), or regulate apoptosis of MFBs (e.g., c-Met receptor, Toll-like receptor 4 [TLR4]), retinoic acid early-inducible protein 1 receptor (RAE-1R), discoidin domain receptor (DDR), or integrin receptor. There are also nuclear receptors that regulate transcription of collagen type I, tissue-inhibitor metalloproteinase-1, and TGF farnesoid X receptor (FXR-R) and that regulate apoptosis of MFBs (CCAAT/enhancer-binding protein [C/EBP]). All of these pathways are potential targets of antifibrotic therapy, as depicted in the figure. NK, natural killer (cells); NKG2D, natural killer group 2D; Bax, Bcl-2–associated X protein; RSK, ribosomal S-6 kinase; TIMP, tissue-inhibitor metalloproteinase; MMP, matrix metalloproteinase; ECM, extracellular matrix; PPARγ, peroxisome proliferator-activated receptor γ; MAPK, mitogen-activated protein kinase; ERK, extracellular signal-related protein kinase; MEK, mitogen-activated protein kinase ; JNK, Jun N-terminal kinase; P3K, phosphoinositide 3-kinase; mTOR/FRAP, mammalian target of rapamycin/FKBP12-rapamycin–associated protein; VEGF, vegetative epidermal growth factor.

patients coinfected with HIV and HCV have accelerated fibrosis, as their CD4–CD8 cell ratios are reduced. Of the CD4-positive T lymphocytes, previously called *T helper cells*, the humoral-mediated immunity by T helper-2 (Th2) cells is profibrogenic in liver injury, whereas the cell-mediated immunity by T helper-1 (Th1) cells via IFN-γ, TNF-α, and IL-2 is antifibrogenic (Shi, 1997).

HSCs can also function as antigen-presenting cells (Winau et al, 2007). They can interact with bacterial lipopolysaccharides directly via TLR4, which amplifies their activation. TLR4 signaling leads to downregulation of a TGF-β pseudoreceptor, BAMBI, which thereby amplifies fibrogenic activity of MFBs (Seki & Brenner, 2008). This might contribute to an accelerated progression of liver cirrhosis, as microbial translocation from the gut to the liver is increased, which is the case in alcoholic liver disease.

Vasoregulation

MFBs play an important role in the regulation of sinusoidal blood flow and may contribute to portal hypertension that is characteristic of advanced liver disease. The release of endothelin-1 (ET-1) can stimulate their contraction through

the ETA receptor (Shi-Wen et al, 2004), thereby promoting tissue contraction, increasing portal resistance, and generating portal hypertension. On the other hand, MFBs and endothelial cells also secrete nitric oxide (NO), which is the physiologic antagonist of ET-1.

Structural Features of Hepatic Fibrogenesis

In hepatic fibrosis the total amount of collagen is increased up to sixfold, whereas the parenchymal mass (e.g., hepatocytes) is progressively diminished. The composition of the ECM changes with progression of disease. Collagen type IV in the space of Disse is replaced by interstitial collagen types I and III. Additionally, the discontinuous basal membrane beneath the sinusoidal endothelial cells is replaced by a continuous basement membrane, and sinusoidal fenestrations are reduced. This decreased porosity, also known as *capillarization*, combined with perisinusoidal fibrosis, scar contraction, and formation of intrahepatic shunts contributes to increased hepatic venous pressure and portal hypertension. Fibrillar collagens produced by MFBs interact with MFBs via discoidin domain receptors and integrins (Olaso et al, 2001), thereby inhibiting apoptosis and increasing MFB proliferation.

With the maturation of the fibrotic scar, not only is the amount of collagen increased, but the scar also becomes increasingly insoluble through chemical cross-linking by transglutaminase, and assembly of collagen fibrils through increased generation of collagen monomers by metalloproteinases from the "ADAM metallopeptidase with thrombospondin type 1 motif"; in addition, metalloproteinase with thrombospondin-type repeats metalloproteinase with thrombospondin type I motif (ADAMTS2; Kesteloot et al, 2007) family. This makes the fibrous septa progressively resistant to proteolysis by matrix metalloproteinases (MMPs). The long-standing clinical dogma—the slower the pace of injury, the less reversible the scar—is supported by animal studies in which even advanced fibrosis of short duration is reversible. Thus, the reversibility of a scar may be limited primarily by the extent of collagen cross linking. Clinically, increased septal thickness and smaller nodule size, both of which reflect more advanced stages of fibrosis, are significant predictors of worse clinical outcomes (Nagula et al, 2006).

Regulation of Collagen Deposition and Degradation

The deposition and degradation of collagen is tightly regulated. MMPs are the key enzymes that degrade fibrillar collagens (types I and III) and noncollagenous ECM substrates. The tissue inhibitor metalloproteinases (TIMPs) are their major antagonists by inactivating proteases and by inhibiting MFB apoptosis (Murphy et al, 2002).

Both decreased levels of interstitial collagenases and increased levels of MMP inhibitors in liver injury create an imbalance that favors reduced degradation of fibrillar collagens in hepatic fibrosis. The interstitial collagenases MMP-1, MMP-8, and MMP-13 in humans and MMP-13 in rodents (Emonard & Grimaud, 1990) unwind the triple-helical collagen type I, which is the principal collagen in the fibrotic liver (Williams & Olsen, 2009), so that each α-chain is presented to the active site of the enzyme (Chung et al, 2004), which cleaves the collagen. Other MMPs (e.g., MMP-2) cannot unwind the triple-helical collagen and thus cannot degrade intact collagen type I alone. In early liver injury, MMP-2 degrades the low-density basement membrane present in the subendothelial space (Zhou et al, 2004a). Its replacement with fibril-forming matrix impairs hepatocyte differentiation and function. During progressive fibrosis, expression of MMP-1 (humans) or MMP-13 (rodents) is decreased, and MMP-2 expression increases (Preaux et al, 1999; Milani et al, 1994). In parallel, the expression of TIMP-1 and TIMP-2, which inhibit the collagen-degrading matrix metalloproteinases, are increased (Kossakowska et al, 1998; Murawaki et al, 1993).

Hepatic macrophages also regulate matrix remodeling (Mitchell et al, 2009), and they are an important source of proteases, including MMP-13 (Hironaka et al, 2000; Fallowfield et al, 2007) in rodents. Macrophages might even be more critical to ECM degradation than HSCs, whose degradation potential is impaired during activation by elevation of the inhibitor TIMP-1. Kupffer cells can further stimulate TIMP-1 expression by hepatic MFBs (Wang et al, 2009), leading to inhibition of MMP activity and also protection of MFBs from apoptosis. In mouse models, macrophages augment fibrogenesis during progression of liver fibrosis, whereas during resolution they hasten matrix degradation through increased production of MMP-13 (Fallowfield et al, 2007).

Although both macrophages and MFBs secrete MMP-1 in humans and MMP-13 in rodents, it is not clear which is the major interstitial collagenase in fibrosis regression, because MMP-1 is only expressed at low levels in liver. Moreover, the cellular origin of those MMPs deemed essential to fibrosis regression remains controversial. Dendritic cells and T lymphocytes are also potential sources, as both can secrete MMP-9 (Chabot et al, 2006; Owen et al, 2003).

DIAGNOSIS AND CLINICAL MONITORING OF HEPATIC FIBROSIS

Many patients with chronic liver disease may initially present with late-stage fibrosis, as earlier stages are often asymptomatic. Thus clinicians must have a high index of suspicion for occult fibrosis, especially in patients with unexplained elevations of liver enzymes, splenic enlargement, stigmata of liver disease, or laboratory or imaging findings suggestive of portal hypertension. When chronic liver disease is suspected, liver biopsy remains the gold standard for diagnosing and staging liver fibrosis, but it is an invasive procedure with risk of adverse events (Bravo et al, 2001; Poynard et al, 2000) and, equally important, a high likelihood of sampling variability (Bedossa et al, 2003) and interpathologist and intrapathologist variability (Bedossa & Poynard, 1996). At least one third of biopsies may deviate by one fibrosis stage between the right and left hepatic lobes in HCV (Regev et al, 2002). Shorter biopsies are associated with an increase in reported diagnoses of mild and moderate fibrosis at the cost of more severe fibrosis, representing an understaging of fibrosis (Colloredo et al, 2003); the smaller the tissue sample, the milder the apparent disease.

Several commonly used histologic staging systems for fibrosis exist. The Histology Activity Index (HAI) score reported by Knodell includes three stages (Knodell et al, 1981), and the Ishak score differentiates six stages, including two stages of cirrhosis, *incomplete* and *complete* (Ishak et al, 1995). The METAVIR score, developed by the French METAVIR Cooperative Study Group, is a simple, widely applied five-stage

scoring system (Bedossa & Poynard, 1996) that is most commonly used worldwide. It incorporates the fibrosis scores F0 through F4 (F0, no fibrosis; F1, fibrosis without septa; F2, few septa; F3, numerous septa without cirrhosis; F4, cirrhosis) and activity scores A0 through A3 that assess the amount of necroinflammation (A0, no necroinflammatory activity; A1, mild; A2, moderate; A3, severe). All these systems were developed primarily for scoring fibrosis associated with viral hepatitis, with the main emphasis on the degree of necroinflammation. The fewer fibrosis stages within a scoring system, the higher the reproducibility among observers.

Scoring systems have also been specifically developed for different etiologies of liver fibrosis: Ludwig and colleagues proposed a four-stage system to describe fibrosis stages for both primary biliary cirrhosis (Ludwig et al, 1978) and sclerosing cholangitis (Ludwig et al, 1981), and Kleiner and colleagues (Kleiner, 2005) quantified fibrosis in NAFLD with a seven-stage system. The Kleiner stages are stage 0, no fibrosis; stage 1, perisinusoidal or periportal fibrosis (1a: mild, zone 3; 1b: moderate, zone 3; 1c: portal/periportal); stage 2, periportal and perisinusoidal fibrosis; stage 3, bridging fibrosis; and stage 4, cirrhosis.

There is a great need for reliable, quantitative, noninvasive diagnostics of fibrosis, and recent studies indicate steady progress. Cross-sectional imaging studies, such as those provided by computed tomographic (CT) and magnetic resonance imaging (MRI) scans, can reliably demonstrate features of advanced liver disease, including nodularity and signs of portal hypertension (splenomegaly, enlarged caudate lobe, esophageal varices). Diffusion-weighted MRI measures the apparent diffusion coefficient of water, a parameter that depends upon tissue structure, and it has compared favorably to other noninvasive measures for determining advanced fibrosis (Lewin et al, 2007).

Biochemical parameters associated with hepatocyte injury (AST, ALT), cholestatic liver injury (bilirubin, alcaline phosphatase), impaired liver synthetic function (apolipoproteins, cholesterol, coagulation factors, α_2-macroglobulin, hyaluronic acid, albumin, globulins), or impaired hepatic clearance of endogenous or exogenous substances from the circulation (bilirubin, bile acid, caffeine, lidocaine metabolites, bromosulfophthalein, indocyanine green, ammonia) can provide information on the presence and cause of the disease. These tests all assess impaired liver function in fibrosis. However, because abnormalities are likely only in more advanced stages of fibrosis, normal values will only exclude severe fibrosis but not mild to moderate fibrosis (METAVIR stages F1, F2). A more direct approach incorporates serum molecules associated with fibrosis, including those involved in deposition or degradation of ECM as well as specific fibrogenic cytokines associated with fibrosis.

Biochemical Tests

A number of combination serum tests have been evaluated for predicting fibrosis stage and outcomes with improving sensitivity and specificity. To date, no single molecule, but rather combinations of different components, demonstrates the best sensitivity and negative predictive values to exclude significant fibrosis.

The most studied combination serum tests are the AST platelet ratio index (APRI; Wai et al, 2003), the FIB-4 index (Sterling et al, 2006), the Forns test (Forns et al, 2002), and the proprietary FibroTest (Imbert-Bismut et al, 2001). Newer, proprietary biomarker scores include the HepaScore (Adams et al, 2005) and the FibroMeter (Cales et al, 2005). The factors included in the various tests were chosen upon multivariate analysis and are included in Table 6.1. All these biochemical tests are sufficient to excellent in ruling out significant fibrosis (F3 to F4) when the proper cutoff value is chosen, but they are less useful in distinguishing mild from moderate fibrosis. The sensitivities of these tests vary based on the etiology of the liver disease. A further difficulty with these tests involves the absence of an ideal "gold standard" in view of the liver biopsy's significant sampling variability and interlaboratory differences (Gressner et al, 2009). A key advantage of the biochemical tests, on the other hand, is that the patients most at risk for false-positive results are well defined, so that the results from these individuals can be evaluated more critically or complemented with further diagnostics.

Table 6.1

Common Noninvasive Tests for Detecting and Staging Liver Fibrosis

Test	Content
FIB-4 (Sterling, 2006)	Age, AST, platelets
APRI (Wai, 2003)	AST, platelets
Forns (Forns, 2002)	Age, GGT, cholesterol, platelets
FibroTest (Imbert-Bismut, 2001)	GGT, haptoglobin, α_2-macroglobulin, bilirubin, apolipoprotein A1, adjusted by age and gender
FibroTest-ActiTest (Imbert-Bismut, 2001)	ALT, GGT, haptoglobin, α_2-macroglobulin, bilirubin, apolipoprotein A1, adjusted by age and gender
Hepascore (Adams, 2005)	Total bilirubin, GGT, α_2-macroglobulin, hyaluronic acid, adjusted by age and gender
Fibrometer (Cales, 2005)	P1, α_2-macroglobulin, hyaluronic acid, age
SHASTA (Kelleher, 2005)	Hyaluronic acid, AST, albumin
ELF (Guha, 2008)	TIMP-1, hyaluronic acid, amino-terminal peptide of pro-collagen III (P3NP)
Fibroscan (Sandrin, 2003)	Liver elasticity measurement (in kilo-Pascals) by pulse-echo ultrasound (50 MHz)

AST, Aspartate aminotransferase; *GGT*, gamma-glutamyl transferase; *ALT*, alanine aminotransferase; *TIMP*, tissue inhibitor of metaloproteinases.

Of the biochemical tests, the FibroTest has been shown to be equal to or better than the others (Thabut et al, 2003; Le Calvez et al, 2004). In particular, it is more sensitive for discriminating between F1 and F2 stages and is more linearly correlated to fibrosis stages when compared with the other markers. Further improvement in prognostic value can be achieved by combining the FibroTest with the ActiTest and/or the FibroScan. The FibroTest combines the parameters gamma-glutamyl transferase (GGT), haptoglobin, α_2-macroglobulin, bilirubin, and apolipoprotein A1, corrected for age and gender; it has a high predictive value for significant fibrosis in patients with chronic hepatitis C and B and nonfatty liver disease (Imbert-Bismut et al, 2001; Poynard et al, 2007) and in patients with chronic alcoholic liver disease (Naveau et al, 2005; Thabut et al, 2006). In contrast to the other tests, the FibroTest has also been evaluated in a longitudinal study in which patients with HCV were followed up by a liver biopsy after α-interferon treatment. Promisingly, FibroTest results correlated well with the

progression or regression of fibrosis after antiviral therapy, and it compared favorably with liver biopsy (Poynard et al, 2002a).

The diagnostic value of the FibroTest has been compared to those of the HepaScore and FibroMeter in patients with chronic HCV (Halfon et al, 2007; Leroy et al, 2007), and the diagnostic and prognostic value was evaluated in patients with alcoholic liver disease (Naveau et al, 2009). All three tests have similar diagnostic accuracy in discriminating between advanced and nonadvanced fibrosis and between cirrhotic and noncirrhotic stages, however, the FibroTest was significantly better than the HepaScore or FibroMeter at predicting 10-year mortality in patients with alcoholic liver disease, and it was similar or even slightly better than the liver biopsy.

Serum Assays of Extracellular Matrix Molecules

Serum assays have been developed that measure circulating molecules involved either in the deposition of ECM or its degradation as well as cytokines involved in fibrogenesis. The best validated of these tests is the Enhanced Liver Fibrosis (ELF) panel (Guha et al, 2008). This test incorporates markers of ECM turnover: TIMP-1, hyaluronic acid, and aminoterminal peptide of procollagen III (P3NP). The ELF test was better at identifying minimal, moderate, or severe fibrosis than a clinical-biochemical panel that considered age, body mass index, presence of diabetes or impaired fasting glucose, aspartate aminotransferase/alanine aminotransferase (AST/ALT) ratio, platelets, and albumin. The combination of both clinical and biochemical scores showed further improved area under the receiver operating characteristic curve (AUROC) values in the subset of patients with an altered clinical-biochemical panel in reference to liver biopsies that were staged according to the Kleiner score (Angulo et al, 2007). If the ELF test was used to delineate any fibrosis, using thresholds with a sensitivity and specificity of 90%, the authors concluded that liver biopsy could have been avoided in 48% of patients.

Cytokines and Chemokines Associated with Hepatic Fibrosis

Of the cytokines and chemokines associated with hepatic fibrosis, TGF-β1 is the dominant stimulus for the production of ECM by HSCs. Hepatic mRNA levels of TGF-β1 are increased in chronic liver disease in association with increases in mRNA levels of type I collagen (Annoni et al, 1992). In HCV-related chronic liver disease, serum TGF-β levels correlate with the Knodell fibrosis score but not with clinical, biochemical, or virological parameters (Nelson et al, 1997). Interestingly, TGF-β levels also decreased in a group of HCV patients with histologic decreases in necroinflammation in the absence of changes in fibrosis following interferon treatment (Roulot et al, 1995). Thus TGF-β serum levels not only correlate with fibrosis scores but may also indicate necroinflammation (see Chapter 10). PDGF is upregulated following liver injury (Ikura et al, 1997), and at least one study suggested that the amount of PDGF correlates with the severity of fibrosis (Shiraishi et al, 1994).

Proteomics and Glycomics

Proteomics and glycomics are promising new technologies suitable as noninvasive diagnostic methods. Patterns of proteins or glycoprotein can be assessed by mass spectroscopy of serum samples (Petricoin et al, 2004). Profiles of serum protein N-glycans were found to have AUROC values similar to the FibroTest for the diagnosis of compensated cirrhosis. The combination of serum protein N-glycans with the FibroTest (FT) was able to increase the sensitivity and specificity of glycoprotein assessment alone (Callewaert et al, 2004).

FibroScan

An alternative approach to fibrosis assessment is the measurement of liver stiffness using a device that performs transient elastography. Currently, FibroScan (FS) is the only device to utilize this approach. It measures liver elasticity by using a pulse-echo ultrasound. A vibration of low frequency induces an elastic shear wave that propagates through the liver. The stiffer the liver tissue, the faster the shear wave propagates. Results are expressed in kilopascals (kPas; (Sandrin et al, 2003; Kettaneh et al, 2007). With FS, the virtual cylinder of tissue that is assessed is at least 200 times larger than a biopsy sample and therefore is far more representative of the hepatic parenchyma; thus the FS may provide a more accurate and reproducible picture of cirrhosis than liver biopsy. There is also potential value of FS in early stages of disease, when fibrosis may be unevenly distributed and thus underestimated by liver biopsy. Furthermore, FS has very low interobserver variability, although its accuracy is limited in patients with obesity, ascites, or acute hepatitis. FS has been evaluated extensively (Ziol et al, 2005; Cross et al, 2009; Sanchez-Conde et al, 2009; Boursier et al, 2009), is licensed in several European countries, and is currently being evaluated by the Food and Drug Administration (FDA) in the United States. When FS was combined with the FT in HCV patients, both tests agreed in 70% to 80% of subjects, with increasing concordance in higher stages of liver fibrosis. Compared with the liver biopsy, results were confirmed in 84% to 94% of cases with a tendency of FS/FT to underestimate fibrosis (Castera et al, 2005).

In aggregate, all the noninvasive approaches can accurately distinguish between patients with little or no fibrosis and those with advanced disease, but they are less reliable at discriminating intermediate stages of fibrosis. They show a high level of variability due to interlaboratory differences, but on the other hand, the patients at risk for false-positive results are well defined.

Although the combination of FT, FS, the ActiTest, and the ELF panel in NAFLD patients seems to be a good noninvasive alternative to liver biopsy, the value of these tests in individual patient management over time needs to be established. These tests may even be superior to liver biopsy at correctly staging and grading fibrosis (Poynard et al, 2004), but proving this remains a challenge with liver biopsy being the gold standard. A way to surmount this problem may be to assess the prognostic value of a test with the hard clinical end point of liver-related mortality compared with liver biopsy.

Despite these limitations, to date no single test can match the overall information obtained from liver biopsy histology regarding inflammation, fibrosis, steatosis, and architecture. The role of noninvasive alternatives so far lies in improving the fibrosis staging and grading made from liver biopsies and reducing the number of liver biopsies by screening patients with abnormal liver tests to identify patients with a higher probability of liver fibrosis who need further evaluation or therapy.

There is legitimate hope for the prognostic value of noninvasive tests, and that disease progression or response to therapy can be assessed by serial measurements of serum markers, thereby reducing the need for liver biopsies and improving the treatment of patients with liver disease. This, however, remains to be clarified by longitudinal studies measuring serum markers against clinical outcomes.

THERAPEUTIC STRATEGIES

The elucidation of pathways of hepatic fibrogenesis has provided a rational framework for developing antifibrotic therapies in chronic liver disease. Several points of attack are under development, and it may ultimately be advantageous to combine more than one therapy for maximal efficacy. To date, no antifibrotic therapy has been approved for clinical use, however, the basis for developing such agents is now well established, and meaningful success seems imminent.

Reversibility of Fibrosis: The Point of No Return

The concept of fibrosis as an irreversible and constantly progressing state is no longer accurate. Liver fibrosis of various etiologies is usually reversible by removing the causative agent (Friedman & Bansal, 2006). For example, a decrease in the viral load of HBV patients; clearance of HCV with pegylated interferon and ribavirin (Poynard et al, 2002b), but not maintenance interferon monotherapy (Di Bisceglie et al, 2008); cessation of ethanol intake; weight loss or bariatric surgery in patients with NASH; and decrease in iron or copper or immunosuppressive therapy in autoimmune diseases have been shown experimentally and clinically to limit fibrosis progression and to even regress cirrhosis in some cases. In fact, removing the causative agent is still the most effective therapy.

Although fibrosis, inflammation, and bile duct proliferation decrease when the damaging stimulus is withdrawn, regenerative nodules may become autonomous and grow progressively (Quinn & Higginson, 1965). This raises a key question, whether a "point of no return" exists, wherein even complete clearance of the underlying disease will no longer yield an improvement in cirrhosis. Increased cross linking of the collagen fibrils over time makes the fibrous septa progressively resistant to proteolysis by metalloproteinases, and hypoxia stimulates secretion of proangiogenic factors such as VEGF and angiopoietin-1 by HSCs, which induce proliferation and motility (Nakamura et al, 2007). These findings suggest there may be a positive feedback loop between angiogenesis and fibrogenesis, which persists even when the primary etiology is cleared, leading to sustained abnormalities of the intrahepatic vasculature.

Prevention of Hepatocyte Apoptosis in Liver Injury

Apoptosis of hepatocytes during liver injury is a proinflammatory event associated with Kupffer cell and HSC activation (Canbay et al, 2004); thus agents have been developed to minimize apoptotic death of hepatocytes in chronic liver injury by inhibiting those caspases that contribute to the apoptotic cascade. In the surgical setting, reduced hepatocyte damage is pursued by decreasing the time of vascular occlusion (Pringle maneuver) during resection or by shortening the ischemia/reperfusion (I/R) time in transplant surgery. Experimental approaches to reduce I/R injury (e.g., intermittent clamping, drugs) merit continued development to preserve hepatocyte integrity.

Caspase Inhibitors

Apoptosis is a functional antagonist to mitosis, and together these two processes regulate homeostatic cell turnover. The two main pathways of apoptosis are the *extrinsic pathway*, which is death ligand–death receptor mediated and dependent on caspase 8, and the *intrinsic pathway*, which is regulated by Bcl2-induced mitochondrial dysfunction and downstream activation of caspase 9 and its effector caspases 3, 6, and 7. Blocking caspases downstream of the mitochondria, however, only delays apoptosis; it does not inhibit it (Chen et al, 1998; Strobel et al, 1996). Thus pancaspase inhibitors are being used to assess the therapeutic effect of apoptosis inhibition. In preclinical studies, the pancaspase inhibitor ZVAD-fmk was able to reduce mortality in rats with acute hepatic failure after major hepatic resection (Yoshida et al, 2007). Other caspase inhibitors have reduced I/R injury in rodents (Natori et al, 1999, 2003; Hoglen et al, 2007), decreased fibrogenesis in mice after bile duct ligation (Canbay et al, 2004), and decreased fibrogenesis in a diet deficient in methionine and choline, induced in a NASH mouse model in which hepatic steatosis and fibrogenesis improved without improvement of liver injury (Witek et al, 2009).

Only one clinical trial has been done in which a pancaspase inhibitor was administered in a dose-ranged manner to patients with liver disease of different etiologies. However, this agent, IDN-6556, also inhibits caspase 1, which has an inflammatory effect; thus the drug should be antiinflammatory. In the two weeks of treatment, in the subset of patients with HCV as their underlying disease, AST and ALT levels were significantly reduced without affecting the HCV mRNA levels. No adverse events occured (Pockros et al, 2007). Caspase inhibitors thus far are considered safe, as animals with genetic deletions of death receptors do not show increased spontaneous tumors (Adachi et al, 1995; Pfeffer et al, 1993; Yue et al, 2005). Nonetheless, the potential emergence of tumors following long-term administration remains a lingering concern.

Inhibition of HSC Activation or Inactivation of MFBs

Oxidative stress in the form of ROS released by injured hepatocytes through the action of NADPH represent a major fibrogenic stimulus. Thus antioxidants including vitamin E, silymarin, CYP2E1 inhibitors (Nieto et al, 2002), phosphocholine, or S-adenosyl-L-methionine may benefit fibrosis, particularly in patients with alcohol-induced liver disease and NASH, where oxidative stress plays an especially important role. Efforts to establish the activity of antioxidants are confounded by the uneven quality of commercially available products, because these compounds are typically sold over the counter, and their potency is not monitored.

Immune manipulation also holds promise but is not yet ready for clinical testing. Th1 cells that mediate cellular immunity through IFN-γ, TNF-α, and IL-2 are antifibrogenic, whereas Th2 cells that promote humoral immunity are more profibrogenic via IL-4, IL-5, IL-6, and IL-13 (Shi et al, 1997;

Lee et al, 2001). Thus a shift toward the Th1 cells, away from the Th2 cells, might be beneficial for fibrosis development.

Given their widespread use in diabetes, PPARγ agonists are now being tested in clinical trials both in NASH and HCV (Belfort et al, 2006). PPARγ nuclear receptors are expressed in HSCs, and PPARγ overexpression can regress MFBs to their quiescent state experimentally (Hazra et al, 2004). However, the total amount of HSCs detected by αSMA- or desmin-positive staining is decreased in animals with fibrosis regression (Kim et al, 2005), which suggests that MFB apoptosis, and not reversion into the quiescent form, is the predominant mechanism in vivo that leads to fibrosis regression. Synthetic PPARγ ligands downregulate HSC activation (Zhao et al, 2006).

Wnt signaling has been implicated in pulmonary and renal fibrosis and has also been reported to promote hepatic fibrosis by enhancing HSC activation and survival. This suggests that Wnt antagonism may be a useful target in liver fibrosis (Cheng et al, 2008).

Induction of MFB Apoptosis

Because the natural resolution of fibrosis leads to apoptosis and clearance of MFBs, approaches that exploit these native pathways of resolution merit attention. More specifically, because TIMP is antiapoptotic and blocks matrix proteases, reduced expression or neutralization favors clearance of MFBs through increased apoptosis and enhanced breakdown of scar (Iredale et al, 1998). The translation of this approach to humans will be challenging, however, as human cells appear to have more enhanced antiapoptotic activity through increased expression of the antiapoptotic protein Bcl-2 (Novo et al, 2006).

NF-κB is a nuclear transcription factor that inhibits apoptosis of MFBs, thus any compound that inhibits NF-κB merits evaluation (see Fig. 6.4). For example, bortezomib, a proteosomal inhibitor, prolongs the half-life of IκB-α, which is the naturally occurring cytosolic inhibitor of NF-κB (Oakley et al, 2003), preventing it from translocating to the nucleus and acting as a transcription factor. Related compounds, including gliotoxin or sulfalazine, exert similar effects by regulating transcription of NF-κB. For example, treatment of rodents with the NF-κB–inhibitor gliotoxin that specifically targets MFBs, with the help of targeting technologies (C1-3) selectively induced MFB apoptosis and accelerated regression of fibrosis in experimental liver injury (Douglass et al, 2008). Further, an NF-κB decoy increased TNF-α–induced MFB apoptosis and decreased CCl4-induced fibrosis in comparison to controls (Son et al, 2007).

Affecting the phosphorylation of CCAAT/enhancer-binding protein β (C/EBP-β) may lead to caspase activation and enhanced HSC apoptosis (see Fig. 6.4). C/EBP-β is a transcription factor predominantly expressed in adipose, hepatic, and immune tissue. When C/EBP-β is phosphorylated by ribosomal S-6 kinase (RSK), this leads to activation of caspase 8, which leads to MFB apoptosis (Buck & Chojkier, 2007). Thus, activating RSK or caspase 8 directly will lead to MFB apoptosis.

There are also receptor-ligand–mediated pathways of MFB apoptosis that are potential drug targets. For example, the cannabinoid-1 (CB1) receptor leads to increased collagen deposition and protects MFBs from apoptosis, whereas the cannabinoid-2 (CB2) receptor is proapoptotic via induction of intracellular oxidative stress (see Fig. 6.4). Correspondingly, CB1-knockout mice, CB1 antagonist–treated mice (Teixeira-Clerc et al, 2006), and CB2 receptor–stimulated mice (Munoz-Luque et al, 2008) display less fibrosis and more MFB apoptosis than controls after CCl4 or TAA treatment or bile duct ligation, and CB2-knockout mice showed increased CCl4-induced fibrosis (Julien et al, 2005). Whereas trials of a systemic CB1-receptor antagonist for obesity and NASH were discontinued because of central nervous system (CNS) effects, a new generation of peripheral CB1 antagonists that do not enter the CNS are under development and could play a major role in an antifibrotic strategy.

Natural killer (NK) cells directly interact with the RAE-1 ligand expressed by early-activated MFBs and can lead to apoptosis (Radaeva et al, 2006). This effect is lost, however, in mature MFBs, as these cells lose RAE-1 expression (Radaeva et al, 2007), thereby limiting the potential of therapeutic NK cell–mediated MFB death in advanced fibrosis.

The adipokines adiponectin and leptin are natural counterregulators. Leptin is produced by MFBs, which contributes to their activation (Marra, 2002; Ikejima et al, 2002), and it has a profibrogenic effect on MFBs in hepatic injury (Saxena et al, 2002). In contrast, adiponectin promotes MFB apoptosis (Ding et al, 2005) and inhibits liver fibrogenesis in vitro and in vivo (Kamada et al, 2003). Adiponectin may become a useful antifibrotic agent, particularly in NASH.

Blocking MFB–ECM Interactions

MFBs and ECM interact in a positive feedback mechanism that could be amenable to therapeutic antagonism. MFBs interact with ECM via α- and β-integrins (Zhou et al, 2004b), thereby decreasing apoptosis and increasing proliferation of MFBs. This leads to increased collagen type I deposition, which further promotes survival of fibrogenic MFBs (Issa et al, 2003); thus blocking the MFB–ECM interaction could lead to increased MFB apoptosis (see Fig. 6.4). This has been confirmed by α3β2-integrin disruption with echistatin, neutralizing antibodies, or small interfering RNA (Zhou et al, 2004b). Similar studies exploring antagonism of integrin α5β6 are ongoing.

Antagonizing Compounds That Mediate Inflammation

As inflammation precedes and stimulates liver fibrosis, the use of antiinflammatory drugs has been proposed. A number of agents have antiinflammatory activity. For example, corticosteroids have been used for decades to treat autoimmune hepatitis, and pentoxifylline may exert its antifibrotic activity by downregulating TGF-β1 and connective tissue growth factor signaling (Raetsch et al, 2002). However, pentoxifylline can upregulate TIMP-1, thereby reducing its antifibrotic effect. It also inhibits NF-κB in Kupffer cells, thereby reducing TNF-α production, the impact of which is uncertain.

The renin–angiotensin system may also amplify inflammation, and its role in hepatic fibrosis research has grown. Angiotensin II is a vasoconstrictive peptide expressed by activated HSC in chronically injured livers (Paizis et al, 2002; Bataller et al, 2003a). It induces hepatic inflammation and stimulates fibrogenic actions of HSCs including cell proliferation and migration, secretion of proinflammatory cytokines, and collagen synthesis (Bataller et al, 2000, 2003b, 2003c; see Fig. 6.4). Inhibitors of this system have been in clinical use for antihypertensive therapy for a substantial time, which makes their use in

humans attractive. Preliminary studies in patients with chronic hepatitis C and nonalcoholic steatohepatitis suggest a positive effect on fibrosis progression by administering blocking agents (Yokohama et al, 2004), and several human trials are currently underway (Oakley et al, 2009, Colmenero et al, 2009).

Ursodeoxycholic acid (UDCA) has a beneficial effect on fibrosis in primary biliary cirrhosis. Similarly, a nitric oxide–releasing derivative of UDCA reduces inflammation, fibrosis, and portal pressure in an animal model (Fiorucci et al, 2003). Interestingly, UDCA also activates the pregnane X receptor (PXR), which has antifibrotic properties (Beuers et al, 2009). More recently, ligands of the farnesoid X receptor (FXR), another nuclear receptor, have been developed that are also antifibrotic in animal models (Zhang et al, 2009).

Selectively Antagonizing Pathways of HSC Activation

Fibrogenic, proliferative, proangiogenic, vasoconstrictive, and proinflammatory mediators work synergistically toward hepatic fibrogenesis in the setting of chronic liver injury. Thus, efforts are underway to antagonize the specific mediators driving these pathways. Multiple approaches have been directed toward blocking the profibrogenic TGF-β signaling pathway. The effects of soluble TGF-β receptor type II (George et al, 1999), TGF-β–blocking antibodies, TGF-β–antisense oligonucleotides, or agents that interfere with TGF-β downstream signal transduction have been assessed experimentally (see Fig. 6.4). Systemically blocking the TGF pathway has theoretical limitations; however, because apart from stimulating wound healing and fibrosis, TGF-β is also a central inhibitor of uncontrolled inflammation, and it is essential in inducing epithelial differentiation and in triggering apoptosis. This raises safety concerns for the general and long-term use of TGF-β inhibition, especially in patients with chronic hepatic inflammation. The concern regarding use of TGF-β–blocking agents has further increased as a result of the first clinical study using CAT-192, a recombinant human antibody that neutralizes TGF-β in patients with cutaneous systemic sclerosis, in which a significant increase in morbidity and mortality was shown, with no evidence of a therapeutic effect (Denton et al, 2007). Nonetheless, there are currently two monoclonal antibodies against TGF-β, lerdelimumab and meselimumab, in clinical Phase I through phase III trials for pulmonary fibrosis, systemic sclerosis, and postoperative scarring in glaucoma patients (Yingling et al, 2004).

To antagonize PDGF, administration of a PDGF kinase inhibitor with an HSC-selective carrier (mannose-6-phosphate–modified human serum albumin) significantly reduced bile duct ligation–induced fibrosis (Gonzalo et al, 2007). Imatinib mesylate, a clinically used PDGF receptor tyrosine kinase inhibitor, also attenuates proliferation, migration, and expression of αSMA and α2-(I)-procollagen mRNA in MFBs in a dose-dependent manner (Yoshiji et al, 2005). Furthermore, rapamycin, an immunosuppressive drug used after liver transplantation, has the added benefit of inhibiting HSC proliferation. It acts by inhibiting the p70s kinase, which is a downstream target of PDGF and leads to HSC proliferation (Gabele, 2005; see Fig. 6.4).

Proangiogenic growth factors, such as VEGF-A and angiopoietin 1, induce HSC proliferation and motility. The efficacy of the small-molecule VEGF receptor antagonist sunitinib in hepatocellular carcinoma (HCC) has been complemented by evidence of antifibrotic activity in an animal model (Tugues et al, 2007; see Fig. 6.4).

Apart from blocking HSC-stimulating factors, activating HSC-inhibitory factors is yet another possibility. Hepatocyte growth factor (HGF) inhibits HSC activation, decreases TGF-β, and increases HSC apoptosis (Kim et al, 2005; see Fig. 6.4). However, potential procarcinogenic effects are likely to limit its therapeutic use. Clinical trials with HGF deletion variants and mimetics are underway.

Bone marrow–derived mesenchymal stem cells have an antifibrotic effect, on the one hand increasing HSC apoptosis through secretion of HGF and on the other decreasing proliferation of HSCs through release of IL-10 and TNF-α upon stimulation by IL-6 from hepatic MFBs (Parekkadan et al, 2007). This makes stem cell therapy an interesting direction for fibrosis therapies. However, the bone marrow–derived mesenchymal stem cells also contribute to scar-forming MFBs in various organs, including the liver (Russo et al, 2006).

In rodents the blockade of the ETA receptor, which leads to vasoconstriction or scar contraction upon binding of ET-1, and the administration of vasodilators (prostaglandin E2 and nitric oxide donors) have antifibrotic qualities (Cho et al, 2000). This effect has yet to be confirmed in human studies.

Enhancing ECM Degradation

A number of rational approaches are under development to increase ECM degradation rather than solely block its production. As mentioned earlier, the two main families regulating ECM turnover are the *matrix metalloproteinases* (MMPs) that degrade the collagenous and noncollagenous ECM substrates and the *TIMPs* that inhibit MMP activities and also have an antiapoptotic effect on MFBs (Murphy et al, 2002; see Fig. 6.4). Blocking TIMP-1 with a monoclonal antibody reverses CCl4-induced fibrosis (Parsons et al, 2004).

Other experimental ways to shift the balance toward collagen degradation are the administration of uroplasminogen activator (uPA); it promotes formation of plasminogen out of plasmin, which upregulates MMP-9 synthesis (Hsiao et al, 2008; Hu et al, 2009; see Fig. 6.4). The administration via viral vector of recombinant proteolytically active MMP has shown antifibrotic potential in rodents (Iimuro et al, 2003; Siller-Lopez et al, 2004). However, there is a theoretical concern that MMP administration will lead to increased tumor formation. An advance using proteolytically inactive MMP-9 to solely neutralize TIMP-1 showed promising results without having this potential side effect (Roderfeld et al, 2006, 2007).

Although no antifibrotic drug is approved for clinical use in patients with liver fibrosis, the broad and rational development of a range of promising compounds means that success is likely in the near future. The challenge ahead is to find further targeting points and to show efficiency of these new drugs in vivo and ultimately in clinical trials, thus long follow-up studies are required. Equally challenging is the need to define clear and robust end points for clinical trials to ensure that a therapeutic benefit is apparent. Finding good, noninvasive alternatives for diagnosis and follow-up and assessing prognosis of liver fibrosis are important first steps for developing and evaluating better treatment options.

CHAPTER 7

Bile secretion and pathophysiology of biliary tract obstruction

Henry A. Pitt, Attila Nakeeb, and N. Joseph Espat

OVERVIEW

Bile secretion is one of the major functions of the liver, and it serves two major purposes: 1) the excretion of hepatic metabolites—including bilirubin, cholesterol, drugs, and toxins—and 2) the facilitation of intestinal absorption of lipids and fat-soluble vitamins. Alterations in bile secretion may contribute to cholelithiasis (see Chapter 30) and its potential complications, such as cholecystitis (see Chapter 31) and choledocholithiasis (see Chapters 35, 36, and 37). On the other hand, obstruction of bile flow results in alterations of coagulation, the immune system, and all organ function. This chapter will discuss the physiology of bile secretion, the pathophysiology of bile obstruction, and the management of obstructive jaundice.

BILE SECRETION

Bile Formation

The two primary roles of bile in normal physiology are the excretion of organic compounds, such as bilirubin and cholesterol, and the intestinal absorption of lipids. Bile secretion results from the active transport of solutes into the canaliculus, followed by the passive flow of water. Water constitutes about 85% of the volume of bile. The major organic solutes in bile are bilirubin, bile salts, phospholipids, and cholesterol. Bilirubin, the breakdown product of spent red blood cells, is conjugated with glucuronic acid by the hepatic enzyme glucuronyl transferase and is excreted actively into the adjacent canaliculus. Normally, a large enzyme reserve exists to handle excess bilirubin production, which might exist in hemolytic states.

Bile salts are steroid molecules synthesized by the hepatocyte. The primary bile salts in humans, cholic and chenodeoxycholic acid, account for more than 80% of those produced. The primary bile salts, which are then conjugated with either taurine or glycine, can undergo bacterial alteration in the intestine to form the secondary bile salts, deoxycholate and lithocholate. The purpose of bile salts is to solubilize lipids and facilitate their absorption. Phospholipids are synthesized in the liver in conjunction with bile salt synthesis, and lecithin is the primary phospholipid in human bile, constituting more than 95% of its total. The final major solute of bile is cholesterol, which is also produced primarily by the liver with a small contribution from dietary sources.

The normal volume of bile secreted daily by the liver is 750 to 1000 mL. Bile flow depends on neurogenic, humoral, and chemical control. Vagal stimulation increases bile secretion, whereas splanchnic stimulation causes vasoconstriction with decreased hepatic blood flow and thus results in diminished bile secretion. Gastrointestinal hormones—secretin, cholecystokinin, gastrin, and glucagons—all increase bile flow, primarily by increasing water and electrolyte secretion. This action probably occurs at a site distal to the hepatocyte. Finally, the most important factor in regulating the volume of bile flow is the rate of bile salt synthesis by hepatocytes. This rate is regulated by the return of bile salts to the liver by the enterohepatic circulation.

Bile Composition

The components of hepatic and gallbladder bile are essentially the same, but the concentration varies considerably because of the ability of the gallbladder to absorb water (Table 7.1). The gallbladder absorbs water both actively via sodium–hydrogen (Na^+/H^+) pumps and passively through aquaporin channels. Both chloride (Cl^-) and bicarbonate (HCO_3^-) are absorbed by the gallbladder epithelium via the cystic fibrosis transmembrane regulator (CFTR; Swartz-Basile et al, 2007). The secretion of hydrogen ions and the absorption of bicarbonate by the gallbladder alter the acid-base balance from basic in hepatic bile to acidic in gallbladder bile.

The gallbladder mucosa also absorbs the calcium (Ca^{++}) and magnesium (Mg^{++}) cations. However, calcium absorption is not as efficient as the absorption of sodium and water, which leads to a significantly greater relative increase in the concentration of calcium in the gallbladder. Similarly, the concentration of bilirubin, which is not actively absorbed by the gallbladder, may be as high as 10-fold. Thus precipitation of calcium bilirubinate crystals, the major component of pigment gallstones, is much more likely to occur within the gallbladder. In addition, the biliary lipids, bile salts, phospholipids, and cholesterol all become more concentrated in the gallbladder. As the gallbladder bile becomes concentrated, several changes occur in the capacity of bile to solubilize cholesterol. The solubility in the micellar fraction is increased, but the stability of the phospholipid–cholesterol vesicles is greatly decreased. Because cholesterol crystal precipitation occurs preferentially by vesicular, rather than micellar, mechanisms, the net effect of concentrating bile is an increased tendency to form cholesterol crystals (Klein et al, 1996).

Bile Salt Secretion

Bile is secreted from the hepatocyte into canaliculi, which drain their contents into small bile ducts. Secretion of bile salts is the major osmotic force for the generation of bile flow. Bile acids are formed at a rate of 500 to 600 mg per day. The bulk of the bile salt pool is maintained in the gallbladder, followed by the liver,

Table 7.1

Composition of Hepatic and Gallbladder Bile

Characteristics*	Hepatic Bile	Gallbladder Bile
Sodium	160	270
Potassium	5	10
Chloride	90	15
Bicarbonate	45	10
Calcium	4	25
Magnesium	2	4
Bilirubin	1.5	15
Protein	150	200
Bile acids	50	150
Phospholipids	8	40
Cholesterol	4	18
Total solids	—	125
pH	7.8	7.2

Significant ranges may be seen.
*All determinations are milliequivalents per liter, except for pH.

the small intestine, and the extrahepatic bile ducts. Bile acids are synthesized from cholesterol via two main pathways: a *classic pathway* leads to the formation of cholic acid, and an *alternate pathway* results in the synthesis of chenodeoxycholic acid. The classic pathway is the predominant mode of bile acid synthesis in humans. As a result, approximately 70% of the bile acid pool consists of cholic acid and its metabolite deoxycholic acid, with chenodeoxycholic acid occurring less commonly in human bile (Kullack-Ublick, 2004).

In plasma, bile acids circulate bound to either albumin or lipoproteins. In the space of Disse within the liver, bile salt uptake into the hepatocytes is very efficient. This process is mediated by sodium-dependent and sodium-independent mechanisms. The sodium-dependent pathway accounts for more than 80% of taurocholate uptake but less than 50% of cholate uptake (Meier & Stieger, 2002). In recent years a number of transport proteins have been identified that play a key role in this process (Fig. 7.1). The bile salt transporter is termed the *sodium-taurocholate cotransporting polypeptide* (NTCP), and it is exclusively expressed in the liver and located in the basolateral membrane of the hepatocyte. Sodium-independent hepatic uptake of bile acids is mediated primarily by a family of transporters termed the *organic anion transporting polypeptides* (OATPs). In contrast to NTCP, these transporters have a broader substrate affinity and transport a variety of organic anions, including the bile salts. OATP-C is the major sodium-independent bile salt uptake system, but OATP-A also takes up bile acids, and OATP-8 mediates taurocholate uptake.

Intracellular bile acid transport occurs within a matter of seconds. Two mechanisms may be responsible for bile acid transcellular movement: one involves transfer of bile acids from the basolateral membrane to the canalicular membrane via bile acid–binding proteins (Crawford, 1996), the other moves cellular bile salt through vesicular transport. In contrast, the transport of bile salts across the canalicular membrane of hepatocytes represents the rate-limiting step in the overall secretion of bile salts from the blood into bile.

Bile salt concentrations are 1000-greater within the canaliculi than in the hepatocytes. This gradient necessitates an active transport mechanism, which is an ATP-dependent process. This bile salt export pump (BSEP) is closely related to the proteins encoded by the multidrug resistance (MDR) gene family of ATP binding cassette (ABC) transporters (Kullack-Ublick, 2004). The ABC transporters mediate the

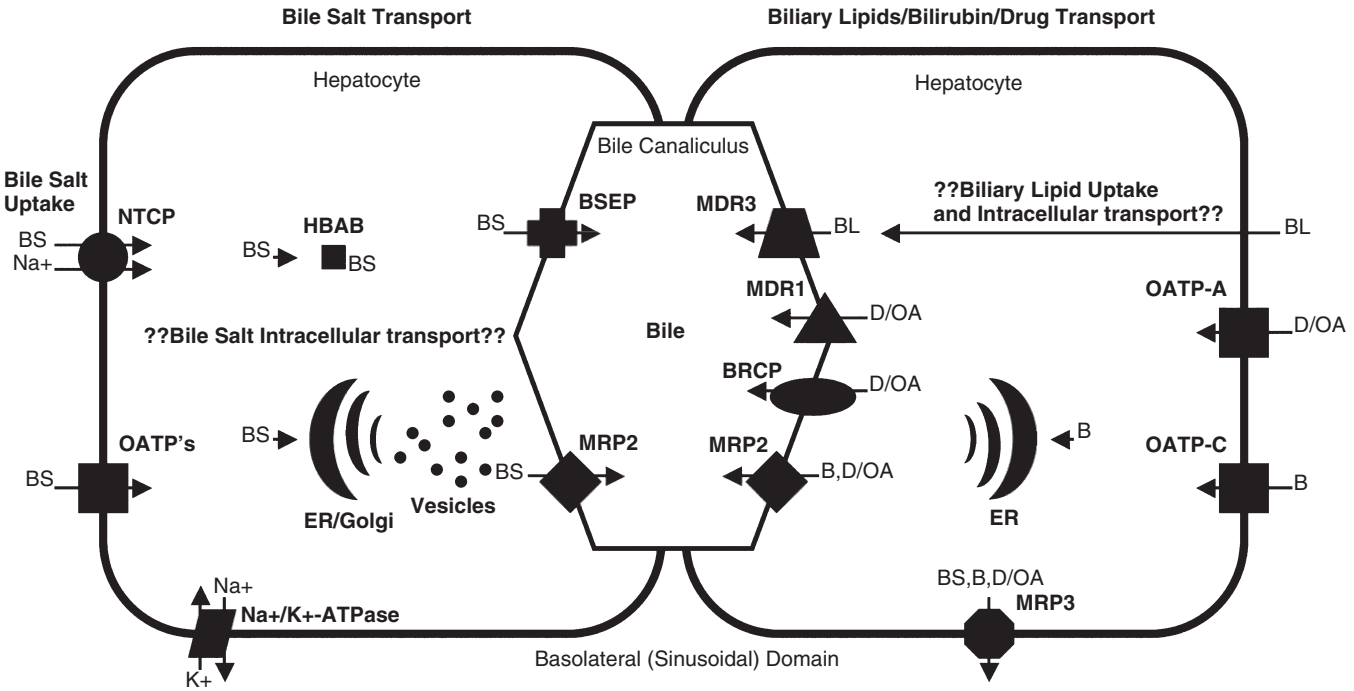

FIGURE 7.1. Bile formation in human liver. B, bilirubin; BL, biliary lipids; BRCP, breast cancer–related protein; BS, bile salts; BSEP, bile salt export pump; D/OA, drugs/organic anions; ER, endoplasmic reticulum; HBAB, hepatic bile acid–binding protein; MDR1 and MDR3, multidrug resistance proteins 1 and 3; MRP3, MDR-related protein-3; NTCP, Na^+–taurocholate cotransporting polypeptide; OATPs (A, C, 8), organic anion transporting polypeptides.

transport of metabolites, peptides, fatty acids, cholesterol, and lipids in the liver, intestines, pancreas, lungs, kidneys, brain, and in macrophages. Although BSEP is the major transporter for monovalent bile salts into the canaliculus, MDR-related protein-2 (MRP2), a member of the multidrug resistance protein family, also transports sulfated and glucuronidated bile salts into the canaliculus. MRP2 also mediates the export of multiple other organic anions, including conjugated bilirubin, leukotrienes, glutathione disulfide, chemotherapeutic agents, uricosurics, antibiotics, toxins, and heavy metals (Gerk & Vore, 2002).

Biliary Lipid Secretion

Compared with bile salts, the biliary lipids, phospholipids, and cholesterol play a secondary role in the formation of bile. Phospholipids and cholesterol are formed primarily from low-density lipoproteins circulating in plasma and from de novo synthesis by hepatocytes. Less is known about the secretion of biliary lipids compared with bile salt secretion; however, biliary lipid secretion is key for cholesterol disposal, intestinal absorption of dietary lipids, and cytoprotection against bile acid–induced hepatocyte and cholangiocyte injury (Arrese & Accatino, 2002).

Phospholipid secretion involves the delivery of phospholipids to the inner leaflet of the canalicular plasma membrane (Elferink & Groen, 2000). In humans the MDR3 transporter translocates phospholipids from the inner to the outer leaflet of the canalicular membrane. Humans with an MDR3 deficiency develop progressive familial intrahepatic cholestasis type 3 (Kullak-Ublick, 2004). These patients have no phosphatidylcholine in bile and therefore do not form mixed micelles with bile salts. As a result, toxic bile salts injure the biliary epithelium, resulting in neonatal cholestasis, cholestasis of pregnancy, and cirrhosis in adults.

Less is known about the role of transporter proteins in cholesterol secretion, but the ABC transporters, ABCG5 and ABCG8, have been demonstrated to be involved in the elimination of plant steroids (Lee, 2004). Cholesterol is highly nonpolar and insoluble in water; thus it is insoluble in bile. The key to maintaining cholesterol in solution is the formation of micelles, a bile salt–phospholipid–cholesterol complex. Bile salts are amphipathic compounds that contain both a hydrophilic and hydrophobic portion. In aqueous solutions, bile salts are oriented with the hydrophilic portion outward. Phospholipids are incorporated into the micellar structure, allowing cholesterol to be added to the hydrophobic central portion of the micelle. In this way, cholesterol can be maintained in solution in an aqueous medium. The concept of mixed micelles as the only cholesterol carrier has been challenged by the demonstration that much of the biliary cholesterol exists in a vesicular form. Structurally, these vesicles are made up of lipid bilayers of cholesterol and phospholipids. In their simplest and smallest form, the vesicles are unilamellar, but an aggregation may take place, leading to multilamellar vesicles. Present theory suggests that in states of excess cholesterol production, these large vesicles may also exceed their capability to transport cholesterol, and cystal precipitation may occur (Fig. 7.2).

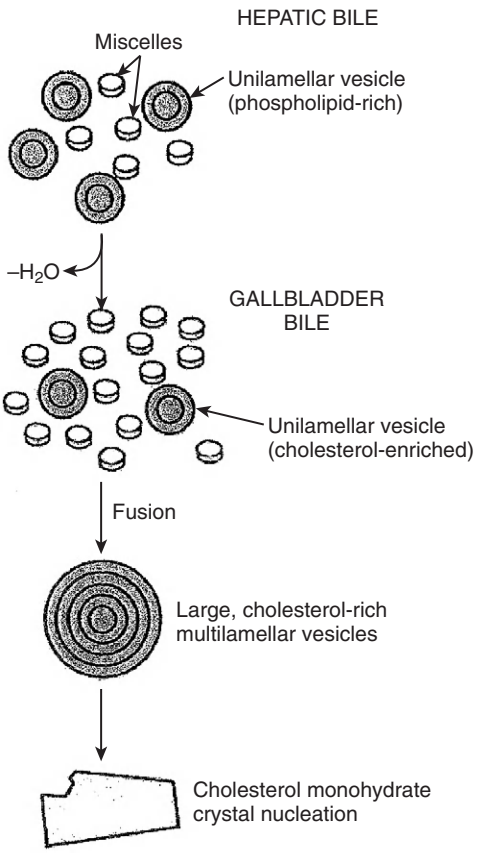

FIGURE 7.2. Concentration of bile leads to net transfer of phospholipids and cholesterol from vesicles to micelles. Phospholipids are transferred more efficiently than cholesterol, leading to cholesterol enrichment of the remaining (remodeled) vesicles. Aggregation of these cholesterol-rich vesicles forms multilamellar liquid crystals of cholesterol monohydrate. *(Modified from Vessey DA, 1990: Metabolism of drugs and toxins by the human liver. In Zakin D, Boyer TD [eds]: Hepatology: A Textbook of Liver Disease, 2nd ed. Philadelphia, WB Saunders, p 1492.)*

Bilirubin Secretion

Released at the time of degradation of senescent erythrocytes by the reticuloendothelial system, heme is the source of approximately 80% to 85% of the bilirubin produced daily. The remaining 15% to 20% is derived largely from the breakdown of hepatic hemoproteins. Both enzymatic and nonenzymatic pathways for the formation of bilirubin have been proposed. Although both may be important physiologically, the microsomal enzyme hemeoxygenase—found in high concentration throughout the liver, spleen, and bone marrow—plays a major role in the initial conversion of heme to biliverdin, which is then reduced to bilirubin by the cytosolic enzyme biliverdin reductase in a nicotinamide adenine dinucleotide (NADH)-dependent reaction before being released into the circulation. In this "unconjugated" form, bilirubin has a very low solubility, and it is bound avidly to plasma proteins, primarily albumin, before uptake and further processing by the liver. The liver is the sole organ capable of removing the albumin–bilirubin complex from the circulation and esterifying the potentially toxic bilirubin to water-soluble, nontoxic, monoconjugated and deconjugated derivatives.

In the sinusoidal membrane of the hepatocyte, bilirubin is taken up by OATP-C, a membrane transporter belonging to the OATP family (Cui et al, 2001). OATP-C is involved with the uptake of both conjugated and unconjugated bilirubin, but unconjugated bilirubin also can cross hepatic sinusoidal

membranes by a diffusion process. In the hepatocyte, bilirubin binds to a driver of gluthathione-S-transferase and is catalyzed by bilirubin uridine-5-diphosphate (UDP)-glycosyltransferase to form bilirubin glucuronides. Mutations in the gene encoding bilirubin UDP-glycosyltransferase are associated with the unconjugated hyperbilirubin syndromes, Crigler-Najjar and Gilbert syndromes (Iganagi, 1998).

Bilirubin glucuronides are excreted into the bile canaliculus primarily via MRP2, which also plays a role in the transport of glucuroniductal bile salts and a wide spectrum of organic anions, including the antibiotic ceftriaxone. MRP3, which is expressed in the basolateral membrane of hepatocytes and cholangiocytes, also participates in the transport of bilirubin monoglucuronide. MRP3 also may prevent intracellular accumulation of conjugated bilirubin, bile salts, and other organic anions in cholestatic situations.

Bile Flow

The bile ducts, gallbladder, and sphincter of Oddi act in concert to modify, store, and regulate the flow of bile. Bile flow is primarily driven by bile salt secretion. During its passage through the bile ductules, canalicular bile is modified by the absorption and secretion of electrolytes and water. Bicarbonate secretion by the bile ducts plays an important role in bile salt–independent bile flow. The gastrointestinal hormone secretin increases bile flow primarily by increasing the active secretion of chloride-rich fluid by the bile ducts. Bile duct secretion is also stimulated by other hormones, such as cholecystokinin and gastrin. The bile duct epithelium is capable of water and electrolyte absorption also, which may be of primary importance in the storage of bile during fasting in patients who have previously undergone cholecystectomy.

The main functions of the gallbladder are to concentrate and store hepatic bile during the fasting state and deliver bile into the duodenum in response to a meal. The usual capacity of the human gallbladder is about 40 to 50 mL. Only a small fraction of the bile produced each day would be stored, were it not for the gallbladder's remarkable absorptive capacity.

The enterohepatic circulation provides an important negative feedback system on bile salt synthesis. Should the recirculation be interrupted by resection of the terminal ileum or by primary ileal disease, abnormally large losses of bile salts could occur. This situation increases bile salt production to maintain a normal bile salt pool. Similarly, if bile salts are lost through an external biliary fistula, increased bile salt synthesis is necessary. However, except for those unusual circumstances in which excessive losses occur, bile salt synthesis matches losses, maintaining a constant bile salt pool size. During fasting, approximately 90% of the bile acid pool is sequestered in the gallbladder.

Enterohepatic Circulation

Bile salts are synthesized and conjugated in the liver; secreted into bile; stored temporarily in the gallbladder; passed from the gallbladder into the duodenum; absorbed throughout the small intestine, especially in the ileum; and returned to the liver via the portal vein. This cycling of bile acids between the liver and the intestine is referred to as the *enterohepatic circulation* (Fig. 7.3). The total amount of bile acids in the enterohepatic circulation is defined as the *circulating bile pool.* In this highly efficient system, nearly 95% of bile salts are reabsorbed. Thus, of the total bile salt pool of 2 to 4 g, which recycles through the enterohepatic cycle 6 to 10 times daily, only about 600 mg is actually excreted into the colon. Bacterial action in the colon on the two primary bile salts, cholate and chenodeoxycholate, results in the formation of the secondary bile salts, deoxycholate and lithocholate. Although some deoxycholate is reabsorbed passively by the colon, the remainder is lost in fecal waste; however, the physiology of bile salt, biliary lipid, bilirubin, bile flow, and the enterohepatic circulation are dramatically altered when the bile ducts become obstructed.

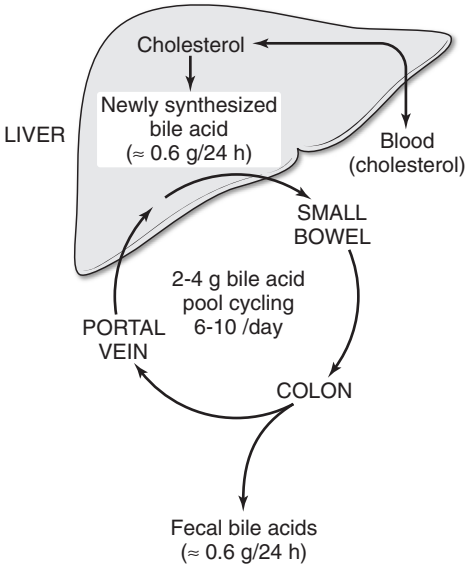

FIGURE 7.3. Enterohepatic circulation of bile salts. Cholesterol is taken up from plasma by the liver. Bile acids are synthesized at a rate of 0.6 g/24 h and are excreted through the biliary system into the small bowel. Most of the bile salts are reabsorbed in the terminal ileum and are returned to the liver to be extracted and reextracted. *(Modified from Dietschy JM, 1972: The biology of bile acids. Arch Intern Med 130:472-474.)*

BILIARY OBSTRUCTION

The evaluation and management of the patient with biliary obstruction is a common problem facing the general surgeon. Over the past 30 years, significant advances have been made in our understanding of the pathophysiology, diagnosis, and management of the jaundiced patient. Similarly, advances have been made in perioperative and operative management that have resulted in improved survival of the jaundiced patient. Obstructive jaundice affects multiple organ systems including hepatic, renal, cardiovascular, hematologic, and immune systems. This section will review the causes, pathophysiology, and management of biliary obstruction.

Causes of Jaundice

Jaundice may result from 1) increased production of bilirubin, 2) impaired hepatocyte uptake of bilirubin, 3) impaired conjugation of bilirubin, 4) impaired transport or excretion of bilirubin into the bile canaliculus, or 5) obstruction of the

Table 7.2

Classification of Jaundice

Defect in Bilirubin Metabolism	Predominant Hyperbilirubinemia	Examples
Increased production	Unconjugated	Congenital hemoglobinopathies, hemolysis, multiple transfusions, sepsis, burns
Impaired hepatocyte uptake	Unconjugated	Gilbert disease, drug induced
Reduced conjugation	Unconjugated	Neonatal jaundice, Crigler-Najjar syndrome
Impaired transport and excretion	Conjugated	Hepatitis, cirrhosis, Dubin-Johnson syndrome, Rotor syndrome
Biliary obstruction	Conjugated	Choledocholithiasis, benign strictures, chronic pancreatitis, sclerosing cholangitis, periampullary cancer, cholangiocarcinoma

intrahepatic or extrahepatic biliary tree (Table 7.2). Overproduction, impaired uptake, and impaired conjugation of bilirubin all lead to a predominently unconjugated hyperbilirubinemia. Impaired transport and excretion and biliary ductal obstruction result in hyperbilirubinemia that is primarily conjugated. Some patients have multiple defects in normal metabolism. For example, a patient with biliary obstruction from a tumor may develop secondary hepatocellular dysfunction. Therefore these classification systems may be simplifications of more complex disease processes.

Diseases causing bile duct obstruction may be further divided into conditions causing 1) complete obstruction, 2) intermittent obstruction, 3) chronic incomplete obstruction, or 4) segmental duct obstruction (Table 7.3). Patients with complete biliary obstruction will have clinical jaundice, and those with intermittent obstruction may develop symptoms (pain, pruritus, fevers) and biochemical changes without necessarily developing clinical jaundice. Patients with chronic incomplete obstruction can eventually develop hepatic fibrosis (see Chapter 6) and biliary cirrhosis (see Chapter 70A).

Table 7.3

Lesions Commonly Associated with Biliary Tract Obstruction

Type I Complete Obstruction

Tumors of the head of the pancreas
Common bile duct ligation
Cholangiocarcinoma
Parenchymal liver tumors (primary or secondary)

Type II Intermittent Obstruction

Choledocholithiasis
Periampullary tumors
Duodenal diverticula
Choledochal cyst
Polycystic liver disease
Biliary parasites
Hemobilia

Type III Chronic Incomplete Obstruction

Strictures of the common bile duct
Congenital
Traumatic (iatrogenic)
Sclerosing cholangitis
Post radiotherapy
Stenosis of biliary-enteric anastamosis
Chronic pancreatitis
Cystic fibrosis
Sphincter of Oddi stenosis

Type IV Segmental Obstruction

Traumatic
Intrahepatic stones
Sclerosing cholangitis
Cholangiocarcinoma

Pathophysiology

Biliary obstruction produces local effects on the bile ducts, which leads to derangements of hepatic function and ultimately to widespread systemic effects. Jaundiced patients are at increased risk for developing hepatic dysfunction, renal failure, cardiovascular impairments, nutritional deficiencies, bleeding problems, infections, and wound complications, and their perioperative mortality is higher.

Hepatobiliary

Hepatocytes are arranged in plates along which blood flows from portal to central veins. Within these plates, the small apical domains of adjacent hepatocytes form a tubular lumen, the canaliculus, which is the site of primary bile formation. From the canalicular network, bile flows to the small ductules and subsequently to the larger ducts. With biliary obstruction, the bile canaliculi become dilated, and the microvilli are distorted and swollen. In patients with long-standing obstruction, intrahepatic bile ductule proliferation occurs with an increase in the length and tortuosity of the canaliculi.

The biliary system normally has a low pressure (5 to 10 cm H_2O); however, in the setting of complete or partial biliary obstruction, biliary pressure can approach 30 cm H_2O. As biliary pressure increases, the tight junctions between hepatocytes and bile duct cells are disrupted, resulting in an increase in bile duct and canalicular permeability. Bile contents can freely reflux into liver sinusoids, causing a marked polymorphonuclear leukocyte infiltration into the portal triads. This inflammatory response is followed by increased fibrinogenesis with deposition of reticulin fibers, which undergo conversion to type I collagen (see Chapter 6). The extrahepatic bile ducts exhibit mucosal atrophy and squamous metaplasia followed by inflammatory infiltration and fibrosis in the subepithelial layers of the bile duct (Karsten et al, 1991).

In addition to the structural effects of biliary obstruction on the bile ducts, elevated biliary pressure can alter bile production by hepatocytes. In the setting of biliary obstruction and elevated biliary pressure, bile becomes less lithogenic because of a relative decrease in cholesterol and phospholipid secretion compared with bile acid secretion. With the relief of biliary obstruction and the normalization of biliary pressures, the

recovery of cholesterol and phospholipid secretion is more rapid than bile acid secretion, therefore bile is more lithogenic in this setting. This phenomenon may lead to premature occlusion of decompressive bilary stents placed for the management of obstructive jaundice.

Several authors have reported impairment of both macrovascular and microvascular perfusion of the liver in obstructive jaundice. Intravital fluorescence microscopy has shown a significant increase in the number of nonperfused sinusoids after 3 days of extrahepatic obstruction. Moreover, in perfused sinusoids, a 35% decrease in the mean diameter and a 25% decrease in flow velocity were noted (Koeppel et al, 1997). This alteration in hepatic perfusion may help explain the increased risk of hepatocellular dysfunction when performing liver resections in patients with obstructive jaundice (see Chapters 50C and 93A). Extrahepatic biliary obstruction and jaundice can also alter important secretory, metabolic, and synthetic functions of the liver. When biliary pressure rises above 20 cm H_2O, hepatic bile secretion is diminished, and hepatocytes cannot excrete efficiently against the high pressure. As a result, excretory products of the hepatocytes reflux directly into the vascular system, leading to systemic toxicity.

Jaundiced patients have a decreased capacity to excrete drugs, such as antibiotics, that are normally secreted into bile (Blenkharn et al, 1985). The increased concentration of bile acids associated with obstructive jaundice results in inhibition of the hepatic cytochrome P450 enzymes and therefore a decrease in the rate of oxidative metabolism in the liver. In addition, bile acids in abnormally high concentrations can induce apoptosis (programmed cell death) in hepatocytes (Patel et al, 1994). The synthetic function of the hepatocyte is also decreased with obstructive jaundice, as evidenced by decreased plasma levels of albumin, clotting factors, and secretory immunoglobulins (IgA).

Kupffer cells are tissue macrophages that are the predominant cell type of the hepatic reticuloendothelial system (see Chapter 9). Normally, infectious agents, damaged blood cells, cellular debris, fibrin degradation products, and endotoxin absorbed or formed in the portal circulation are effectively filtered by Kupffer cells and removed from the systemic circulation. Kupffer cells also play an interactive role with hepatocytes, modulating synthesis of hepatic proteins. Obstructive jaundice has been shown to have profound effects on Kupffer cells, including decreased endocytosis, phagocytosis, clearance of bacteria and endotoxin, and expression of the major histocompatibility complex class II antigen with a consequent diminished ability to process antigen (Nehez & Anderson, 2002; Puntis & Jiang, 1996). Biliary obstruction also has been shown to increase levels of proinflammatory cytokines, including TNF-α and IL-6 (see Chapters 9 and 10).

Cardiovascular

In addition to hepatic dysfunction, obstructive jaundice may cause severe hemodynamic and cardiac disturbances. Experimental animals with obstructive jaundice tend to be hypotensive and exhibit an exaggerated hypotensive response to hemorrhage. Studies in experimental animals have demonstrated that bile duct ligation 1) decreases cardiac contractility; 2) reduces left ventricular pressures; 3) impairs response to β-agonist drugs, such as isoproterenol and norepinephrine; and 4) decreases peripheral vascular resistance (Ma et al, 1999). In a study of 9 patients with obstructive or cholestatic jaundice, Lumlertgul and colleagues (1991) showed a significantly blunted response in left ventricular ejection fraction compared with normal volunteers following the infusion of the positive inotrope dobutamine. Padillo and others (2001) also have shown a negative correlation between serum bilirubin and left ventricular systolic work in 13 patients with biliary obstruction and no previous history of heart, lung, or kidney disease. Successful internal biliary drainage in patients was associated with a significant increase in cardiac output, compliance, and contractility. The combination of depressed cardiac function and decreased total peripheral resistance most likely makes the jaundiced patient more susceptible to the development of postoperative shock than nonjaundiced patients.

Renal

The association between jaundice and postoperative renal failure has been known for many years. The reported incidence of postoperative acute renal failure has been reported to be as high as 10% but varies depending on the nature of the procedure. Moreover, the mortality rate in jaundiced patients who develop renal failure has been reported to be as high as 70% (Fogarty et al, 1995). Important factors that may play a role in the development of renal failure in obstructive jaundice include 1) depressed cardiac function, 2) hypovolemia, and 3) endotoxemia.

The decreased cardiac function associated with obstructive jaundice leads to a decrease in renal perfusion. Decreased cardiac output may also result in stretching of the atrium and increased production of atrial natriuretic peptide (ANP), a hormone known to cause natriuresis, to counter the action of water- and sodium-retaining hormones, to inhibit the thirst mechanism, and to produce peripheral vasodilation. Plasma levels of ANP have been shown to be increased in both experimental animals and in patients with extrahepatic biliary obstruction (Padillo et al, 2001).

In addition to the direct effects of jaundice on the heart and peripheral vasculature discussed above, the increased serum levels of bile acids associated with obstructive jaundice have a direct diuretic and natriuretic effect on the kidney that results in significant extracellular volume depletion and hypovolemia. In dogs, the infusion of bile into the renal artery results in increased urine flow, natriuresis, and kaliuresis. This diuretic effect may be mediated by increased prostaglandin E_2 (PGE_2) production by the kidney (Green & Better, 1994).

The third factor in the development of renal failure is endotoxemia (Fig. 7.4). Approximately 50% of patients with obstructive jaundice have endotoxin in their peripheral blood (Hunt et al, 1982). This phenomenon may be the result of decreased hepatic clearance of endotoxin by Kupffer cells and a lack of bile salts in the gut lumen that normally prevent absorption of endotoxins and inhibit anaerobic bacterial growth. Endotoxin also causes renal vasoconstriction and redistribution of renal blood flow away from the cortex, and disturbances in coagulation that include the activation of complement, macrophages, leukocytes, and platelets (Hunt et al, 1982). As a result, glomerular and peritubular fibrin is deposited. This factor, in combination with reduced renal cortical blood flow, results in the tubular and cortical necrosis observed in jaundiced patients with renal failure. Mechanisms of the pathophysiology of renal failure in obstructive jaundice are summarized in Figure 7.3.

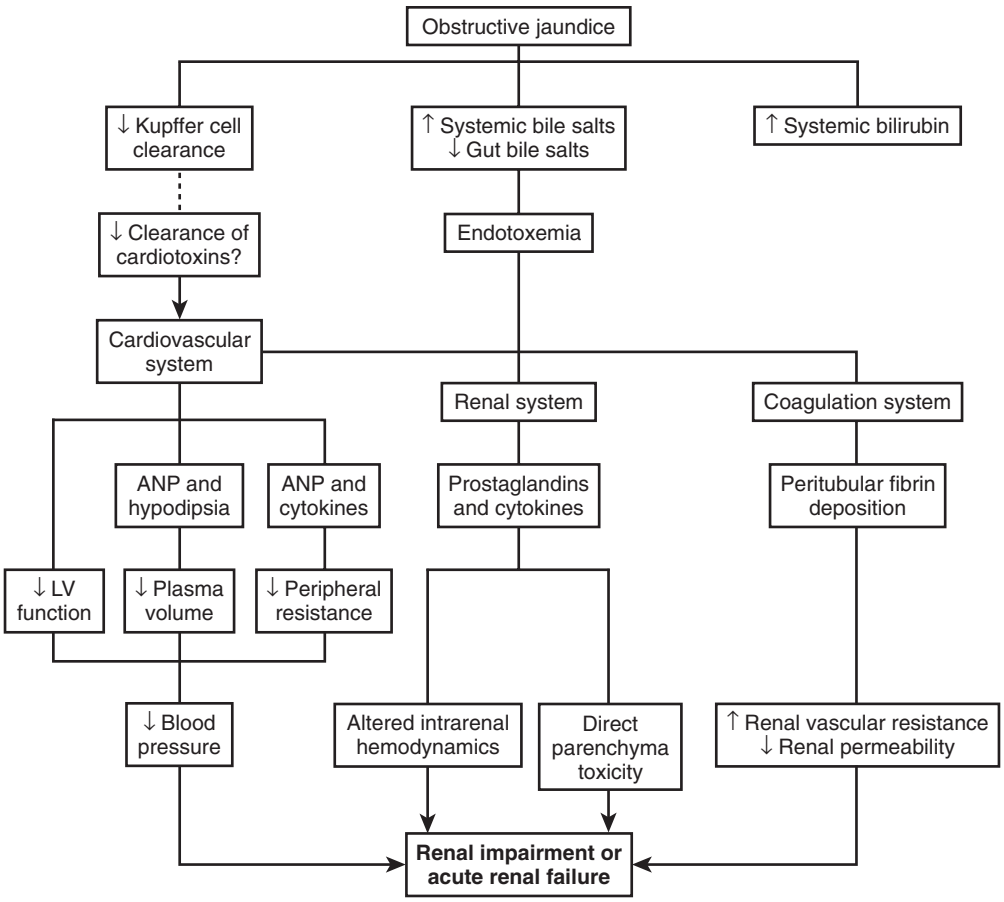

FIGURE 7.4. Obstructive jaundice leads to renal impairment or acute renal failure. ANP, atrial natriuretic peptide; LV, left ventricular.

Coagulation

Disturbances of blood coagulation are commonly present in jaundiced patients. The most frequently observed abnormality is prolongation of the prothrombin time. This problem results from impaired vitamin K absorption from the gut, secondary to a lack of intestinal bile. This coagulopathy is usually reversible with parenteral administration of vitamin K. Decreased bile levels in the small intestine may result in diminished absorption of other fat-soluble vitamins and fats, which results in weight loss and loss of calcium. This latter factor, as well as the above-mentioned increase in circulating endotoxin, may further contribute to clotting abnormalities.

In experimental animals, endotoxin affects metabolism of factors XI and XII and causes platelet and direct endothelial damage (Hunt et al, 1982). Moreover, endotoxin release in jaundiced patients results in a low-grade, disseminated intravascular coagulation with increased fibrin degradation products. Hunt and colleagues have shown that jaundiced patients with circulating endotoxin or increased fibrin degradation product levels before surgery are at increased risk for hemorrhagic complications. In addition to problems with endotoxemia, patients with coexisting cirrhosis often have additional problems related to thrombocytopenia from hypersplenism and fibrinolysis.

Immune System

Surgery in jaundiced patients is associated with a higher rate of postoperative septic complications compared with those without jaundice, due in large measure to defects in cellular immunity that make them more prone to infection (see Chapters 9 and 11). Cainzos and colleagues (1992) have demonstrated an association between jaundice and altered delayed-type hypersensitivity. Only 16% of 118 jaundiced patients were immunocompetent, compared with 76% of 59 healthy controls, when tested with a panel of seven skin antigens. Several authors have shown impaired T-cell proliferation (Thompson et al, 1990), decreased neutrophil chemotaxis (Andy et al, 1992), and defective bacterial phagocytosis (Scott-Conner et al, 1993) following bile duct ligation in rats. As mentioned earlier, the ability of the reticuloendothelial system, specifically Kupffer cells, to clear bacteria and endotoxin from the circulation also is reduced in obstructive jaundice.

The absence of bile from the intestinal tract also plays a role in the infectious complications seen in patients with obstructive jaundice. It has been shown that bacterial translocation from the gut is increased in the setting of bile duct obstruction (Deitch et al, 1990). Obstruction causes a disruption of the enterohepatic circulation and results in loss of the emulsifying antiendotoxin effect of bile acids; therefore a larger pool of endotoxin is available within the intestine for absorption into the portal circulation. The combination of reduced or absent bile in the intestine and impaired cellular immunity and reticuloendothelial cell function appears to be a major factor contributing to more frequent infective complications in the jaundiced patient.

Acute cholangitis is a bacterial infection of the biliary ductal system, and it varies in severity from mild and self-limited to

severe and life threatening (see Chapter 43). The clinical triad associated with cholangitis—fever, jaundice, and pain—was first described in 1877 by Charcot. Cholangitis results from a combination of two factors: significant bacterial concentrations in the bile and biliary obstruction. Although bile from the gallbladder and bile ducts is usually sterile, in the presence of common bile duct stones or other obstructing pathology, the incidence of positive cultures increases; likewise, instrumentation of the biliary tree also greatly increases rates of bile colonization. The most common organisms recovered from the bile in patients with cholangitis include *Escherichia coli*, *Klebsiella pneumonia*, the enterococci, and *Bacteroides fragilis* (Thompson et al, 1990). However, even in the presence of high biliary bacterial concentrations, clinical cholangitis and bacteremia will not develop, unless obstruction causes elevated intraductal pressures (Lipsett & Pitt, 1993).

Normal biliary pressures range from 7 to 14 cm H_2O. In the presence of bacteribilia and normal biliary pressures, hepatic venous blood and perihepatic lymph are sterile. However, with partial or complete biliary obstruction, intrabiliary pressures rise to 18 to 29 cm H_2O, and organisms rapidly appear in both the blood and lymph. The fever and chills associated with cholangitis are the result of systemic bacteremia caused by cholangiovenous and cholangiolymphatic reflux.

The most common causes of biliary obstruction are choledocholithiasis (see Chapter 35), benign strictures (see Chapter 42), biliary-enteric anastomotic strictures (see Chapters 29 and 42), and periampullary or proximal biliary cancers (see Chapters 49, 50, 58, and 59). Prior to 1980, choledocholithiasis was the cause of approximately 80% of the reported cases of cholangitis. In recent years, however, malignant strictures have become a frequent cause, particularly at tertiary referral centers. Endoscopic cholangiography, percutaneous transhepatic cholangiography, and stent placement via either the endoscopic or percutaneous route are all known to cause bacteremia, and these procedures are frequently performed in patients with a presumptive diagnosis of malignant obstruction.

Wound Healing

Delayed wound healing and a high incidence of wound dehiscence and incisional hernia have been observed in jaundiced patients undergoing surgery. Patients with obstructive jaundice have decreased activity of the enzyme propylhydroxylase in their skin. Propylhydroxylase is necessary for the incorporation of proline amino acid residues into collagen, and its activity has been used as a measure of collagen synthesis. Grande and colleagues (1990) measured skin propylhydroxylase activity in 95 patients with extrahepatic bile duct obstruction and 123 nonjaundiced control patients undergoing cholecystectomy. The jaundiced patients had only 11% of the skin propylhydroxylase activity of the controls. In the subgroup of patients with jaundice secondary to malignancy, propylhydroxylase activity was less than 7% of controls. With relief of obstruction, the activity increased to 22% of controls. Interestingly, in patients with jaundice secondary to benign obstruction, the activity increased to 100% of controls.

Other Factors

Other problems that face jaundiced patients are anorexia, weight loss, and malnutrition. Appetite is adversely influenced by the lack of bile salts in the intestinal tract. In addition, patients with pancreatic or periampullary malignant lesions may have partial duodenal obstruction or abnormal gastric emptying, perhaps secondary to tumor infiltration of the celiac nerve plexus. Patients with pancreatic or ampullary tumors also may have pancreatic endocrine and exocrine insufficiency. This latter problem may further compound other nutritional defects that in turn may exacerbate the immune deficits of the jaundiced patient.

Several recent observations suggest that the many physiologic derangements induced by obstructive jaundice take a long time to reverse. For example, Koyama and colleagues (1981) have shown that hepatic mitochondrial function does not return to normal even 7 weeks after relief of obstruction. This same prolonged effect of obstructive jaundice has been noted with lymphocyte, polymorphonuclear, and Kupffer cell function. Therefore even patients who have had temporary relief of biliary obstruction via percutaneous or endoscopic stents are likely to remain at risk for significant complications following surgery, because derangements in hepatic function are likely still present at the time of operation.

Management

In the past, the only option for the relief of obstructive jaundice was operative intervention; however, with the development of therapeutic techniques such as percutaneous (see Chapters 18, 28, and 50D) and endoscopic stenting (see Chapters 18 and 27), balloon dilation, and endoscopic sphincterotomy, many nonoperative options for the relief of obstructive jaundice are now available. The surgeon must determine the safest and most effective therapy for each individual patient and must adequately prepare each patient for surgery or nonoperative therapeutic intervention.

Patients with obstructive jaundice and those with hepatocellular disease severe enough to cause jaundice are prone to develop many secondary problems. Jaundiced patients are at increased risk for the development of renal failure, gastrointestinal bleeding, infections, and wound complications (see the earlier section on the pathophysiology of jaundice). Cardiac, pulmonary, and renal function must be considered in every patient undergoing major abdominal surgery. In addition, special attention must be focused on the jaundiced patient's nutritional status, coagulability, immune function, and presence or absence of biliary sepsis. Patients with chronic liver disease and cirrhosis also may develop complications related to portal hypertension, such as ascites, varices, and encephalopathy, and these may require specific treatment (see Chapters 70B, 74, and 75).

Cardiopulmonary

In assessing cardiopulmonary status, the patient's age, history of recent myocardial infarction, and the presence of congestive heart failure, significant valvular aortic stenosis, or a disturbance of normal cardiac rhythm have all been correlated with increased operative risk (Goldman et al, 1977). In addition, patients with severe pulmonary disease may not be candidates for extensive abdominal surgery.

Renal

Jaundiced patients, especially those with cirrhosis and cholangitis, are at increased risk of developing renal insufficiency. The maintenance of adequate blood volume and the correction of dehydration are extremely important if renal complications are

to be avoided. Fluid management can be quite complex in jaundiced patients, and selected patients may benefit from invasive hemodynamic monitoring with central venous catheters—and less commonly, pulmonary artery catheters—to assist in assessing intravascular volume.

Certain oral bile salts have been shown to be efficacious in preventing the development of postoperative renal dysfunction. In a study by Cahill (1983) 54% of 24 jaundiced patients not given oral bile salts before surgery were found to have systemic endotoxemia, which was associated with renal impairment in two thirds of the cases. In comparison, none of the 8 jaundiced patients given 500 mg of sodium deoxycholate every 8 hours for 48 hours before surgery had portal or systemic endotoxemia. Moreover, none of these 8 patients had evidence of renal impairment.

Nutrition

Malnutrition is a significant risk factor for surgery in the setting of obstructive jaundice (see Chapter 24). Halliday and colleagues (1988) noted that patients who died in the postoperative period following surgery for obstructive jaundice had had a significant reduction in body weight, midarm circumference, total body potassium, and reactivity to skin test antigens prior to operation. In a study from Italy (Foschi et al, 1986), enteral hyperalimentation was found to significantly decrease operative morbidity and mortality in a group of patients treated with 20 days of preoperative percutaneous biliary drainage. Although most patients with benign biliary problems are adequately nourished, various degrees of malnutrition are frequently present in patients with malignant obstruction; therefore patients with malignant obstructive jaundice should be evaluated for evidence of malnutrition and have nutritional support instituted if necessary.

Coagulation

Patients with obstructive jaundice, cholangitis, or cirrhosis are all prone to excessive intraoperative bleeding. The most common clotting defect in patients with obstructive jaundice is prolongation of the prothrombin time (PT), which is usually reversible by the administration of parenteral vitamin K. Patients with severe jaundice and/or cholangitis also may develop disseminated intravascular coagulation (DIC), which may require infusion of platelets and fresh frozen plasma. Reversal of DIC also requires control of the underlying sepsis, which should include biliary drainage in patients with cholangitis in addition to systemic antibiotics.

In cirrhotic patients, clotting abnormalities are often multifactorial and include thrombocytopenia secondary to hypersplenism, prolongation of PT and partial thromboplastin time (PTT), and fibrinolysis. Vitamin K should be administered if the PT is prolonged. If no effect is seen and/or if the PTT is also prolonged, fresh frozen plasma should be given. Thrombocytopenia can usually be managed by intraoperative platelet infusions. If the patient has a shortened clot lysis time and hypofibrinogenemia, ε-aminocaproic acid may be indicated.

Pruritus

Pruritus is often a distressing problem in the jaundiced patient. The exact cause of pruritus remains obscure, but increased circulating levels of bile salts, histamines, and central nervous system opiate receptors have been implicated. In some patients, relief from itching can be obtained by bile salt–binding agents, such as cholestyramine. Various sedatives and antihistamines also can provide relief of itching in jaundiced patients, however, relief of biliary obstruction remains the most effective method for managing pruritis.

Cholangitis

Biliary sepsis also has been identified as a major risk in jaundiced patients (see Chapter 43). Cholangitis occurs when partial or complete obstruction of the bile duct exists, resulting in increased intraluminal pressure and infected bile behind the obstruction. Patients with cholangitis present with right upper quadrant abdominal pain, fever, and jaundice (Charcot triad). Patients with "toxic" cholangitis, Charcot triad plus shock and mental confusion (Reynold pentad), have significant mortality with appropriate antibiotic therapy alone and therefore require emergent biliary decompression.

Gigot and colleagues (1989) identified seven prognostic factors that are indications for urgent biliary decompression: 1) acute renal failure, 2) liver abscess, 3) cirrhosis, 4) high malignant stricture, 5) percutaneous transhepatic cholangiography, 6) female gender, and 7) advanced age. However, emergent surgical treatment is associated with significant morbidity and mortality; therefore both percutaneous and endoscopic biliary drainage have been proposed as effective therapy for the 5% to 10% of patients with cholangitis who are unresponsive to conservative therapy. Lai and colleagues (1992) have shown in a series of 82 patients with severe acute cholangitis that endoscopic drainage is associated with a lower morbidity (34% vs. 66%) and mortality (10% vs. 32%) than operative drainage. A more complete discussion of the bacteriology and antibiotic management of patients with cholangitis can be found in Chapters 11 and 43.

Preoperative Drainage

The preoperative relief of jaundice and the reversal of its systemic effects by either endoscopic or transhepatic biliary decompression has been proposed as a method to decrease the risk of surgery in jaundiced patients. However, several prospective randomized studies have shown that the routine use of preoperative biliary drainage does not reduce operative morbidity or mortality in patients with obstructive jaundice (Hatfield et al, 1982; Lai et al, 1994; McPherson et al, 1984; Pitt et al, 1985; van der Gaag et al, 2010; Table 7.4). In addition, a meta-analysis also concluded that preoperative biliary drainage increased, rather than decreased, overall complications from surgery and the drainage procedure and provided no benefit in terms of reduced mortality or decreased hospital stay (Sewnath et al, 2002). In fact, several retrospective studies have documented a higher incidence of infectious complications (wound infection, pancreatic fistula) and even mortality in patients undergoing pancreatic or biliary tract resection after preoperative biliary decompression (Sewnath et al, 2002; Sohn et al, 2000).

A criticism of some of the prospective studies is that the duration of preoperative drainage (10 to 18 days) may have been inadequate to reverse the multiple metabolic and immunologic abnormalities associated with severe obstructive jaundice. Both animal and human studies demonstrate that the recovery of various metabolic and immune functions requires at least 6 weeks to pass after the relief of biliary obstruction (Clements et al, 1993; Kennedy et al, 1994; Thompson et al, 1990). Similarly, animal studies strongly suggest that return of

Table 7.4

Prospective Randomized Trials of Preoperative Biliary Drainage (PBD)

bile to the intestinal tract has significant advantages over external biliary drainage (Roughneen et al, 1986).

Although the data suggest that routine preoperative biliary drainage may be of limited benefit, it may have some value in selected patients with advanced malnutrition, biliary sepsis, and hilar malignancies that require liver resection. Regarding the latter, it should be emphasized that most of the published data regarding preoperative biliary drainage focuses on patients with periampullary malignancy. Patients with proximal biliary obstruction undergoing major hepatic resection represent an entirely different subgroup, and although no adequately powered study has addressed this issue specifically in this population, some evidence does suggest a benefit of preoperative biliary drainage of the future liver remnant (see Chapters 50B, 50C, and 93A). Preoperatively placed catheters also may be of value in the operating room during difficult biliary dissections in patients with proximal biliary tumors or strictures, and they may aid in the placement of long-term transhepatic stents.

SUMMARY

Over the past few decades, tremendous strides have been made in our understanding of bile secretion and our ability to care for the jaundiced patient. Clinicians now have a better understanding of normal bile salt, biliary lipid, and bilirubin physiology and can classify the diseases that cause jaundice as defects in normal metabolism. Similarly, investigators are beginning to elucidate more clearly the multiple pathophysiologic effects of jaundice to explain why jaundiced patients are at risk for increased perioperative morbidity and mortality.

CHAPTER 8A

Pancreatic cancer and premalignant tumors: molecular aspects

Jonathan R. Brody, David W. Rittenhouse, Agnieszka K. Witkiewicz, and Charles J. Yeo

PANCREATIC CANCER OVERVIEW

Pancreatic ductal adenocarcinoma (PDA), commonly known as *pancreatic cancer,* is the fourth leading cause of cancer death in the United States, preceded only by lung, colon, breast (in women), and prostate (in men) cancers (American Cancer Society, 2009). The diagnosis of PDA is devastating because it has one of the highest mortality rates of any cancer (American Cancer Society, 2009). To underscore this point, in 2009 approximately 42,470 Americans were diagnosed with PDA, and about 35,240 will die from it (American Cancer Society, 2009). A diagnosis of PDA is met with the daunting statistic that the patient has an overall 5-year survival rate of less than 5%.

The past 2 decades have seen an exponential increase in our understanding of the molecular basis and etiology behind PDA (Hruban et al, 2001; Jones et al, 2008, 2009). Still, the clinical management of this disease—including primary prevention, early detection, and better targeted treatment options—has not changed significantly over the past decade. Currently, the only cure for this disease is surgical resection. Unfortunately, only 20% of the patient population presents with resectable disease (Winter et al, 2002).

Research studying PDA can be simplistically divided into two eras (Fig. 8A.1). The first is highlighted by the discovery and development of technologies such as gene cloning and isolation of pure tumor tissue (i.e., xenografting primary tumors postresection; Fig. 8A.2, *left*). This era included landmark studies defining the genomic region of *BRCA2* (Goggins et al, 1996), discovering *SMAD4* (Hahn et al, 1996) as a tumor suppressor in PDA, activation of KRAS (Almoguera et al, 1988) as an early and frequent event in pancreatic tumorigenesis, and silencing of the *CDKN2A* (Caldas et al, 1994a) gene. As the result of advances in a number of molecular techniques, we are now upon the early stages of a new second era in genetic pancreatic cancer research, which combines high-throughput sequencing, gene expression and comparative genomic hybridization (CGH) arrays with statistical computational analysis, and large clinical databases (Fig. 8A.2, *right*) (Jones et al, 2008, 2009). This second era has already produced landmark publications that include a precise survey of multiple pancreatic cancer genomes both in sporadic and familial forms of the disease. This chapter aims to 1) provide a summary of the past two decades of pancreatic cancer research; 2) show that even though every tumor has a number of common molecular events, it is the differences between tumors that have clinical implications (Fig. 8A.3); and, finally, 3) set the stage for the future, which will include a discussion of successful early detection and treatment strategies for this deadly disease (Fig. 8A.3).

Progression Model of Pancreatic Ductal Adenocarcinoma

In the first era of pancreatic cancer research (see Figs. 8A.1 and 8A.2), the fields of molecular biology and pathology combined to establish a paradigm that PDA culminates from a multistep progression model (Hruban et al, 2001). This slow, sequential process may be the reason PDA is primarily a disease of people in their sixth and seventh decades of life. Definable pathologic markers on this stepwise progression—which follows a similar model first developed in colon carcinogenesis—are lesions referred to as *pancreatic intraepithelial neoplasia* (PanIN) (Hruban et al, 2001; Figs. 8A.4A and B). These lesions are believed to be precursor lesions to pancreatic cancer. PanIN lesions are thought to develop years before the emergence of PDA and are pathologically graded from low-grade PanIN lesions, PanIN-1 (Fig. 8A.4A), to high-grade lesions, PanIN-3 (see Fig. 8A.4B). Although low-grade PanIN lesions are common incidental findings, high-grade PanIN lesions are more common in pancreata with PDA.

Key evidence that PanIN lesions are precursors to PDA is that similar hallmark molecular defects are found in PanIN lesions adjacent to invasive cancers (Biankin et al, 2003; Luttges et al, 2001a; Maitra et al, 2002; van Heek et al, 2002; Wilentz et al, 2000a). However, although *KRAS* mutations are frequently found in early PanIN lesions (Shi et al, 2009), genes involved in DNA repair mechanisms, such as *TP53* and *BRCA2,* are altered late in this progression model. Because these data are based on limited sample numbers and data points, it remains somewhat counterintuitive that an oncogenic stimulus or stimuli (e.g., *KRAS* activation) precedes DNA damage (mutations). Recently, it was shown that higher density PanIN lesions were found in familial PDA patients compared with patients with sporadic forms of PDA, again arguing in favor of the hypothesis that PanIN lesions are true precursors to PDA (Shi et al, 2009).[15]

Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasms (IPMNs) are a well-accepted clinical and pathologic entity (Fig. 8A.4C and D; see

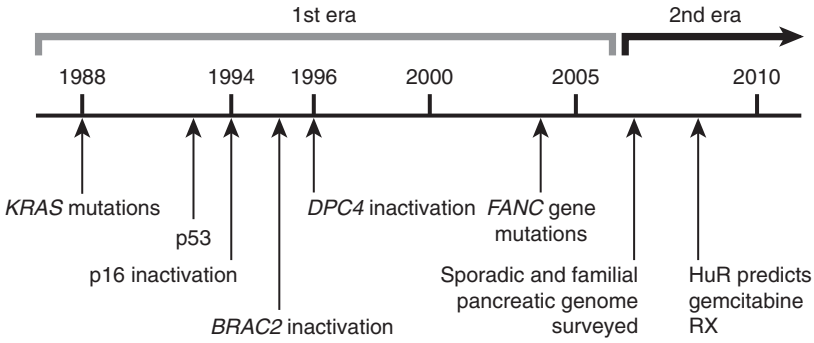

FIGURE 8A.1. Genetic landmark discoveries in pancreatic cancer research. The first era is highlighted by the discovery of tumor suppressor genes such as *DPC4* and loss of p16. The second era is highlighted by genomic profiling of discovery and validating sets of isolated and purified tumors from pancreatic cancer patients.

Chapter 57) (Hruban et al, 2004). IPMNs typically produce radiographically identifiable pancreatic ductal dilation, which may predominantly involve the main pancreatic ducts (main-duct type IPMN), the secondary ducts (branch-duct type IPMN), or both types of ducts (mixed type). The distinction between the branch-duct type and main-duct type is important, because the former arise in younger patients, are more likely to involve the head and uncinate process of the pancreas, and are associated with lower-grade dysplasia and fewer invasive carcinomas. Approximately 30% to 40% of resected IPMNs harbor an invasive adenocarcinoma, and adenocarcinoma is most strongly associated with main-duct IPMNs. Approximately half of invasive carcinomas arising within IPMNs are so-called colloid (mucinous) carcinomas, and most of the remainder are tubular adenocarcinomas, the latter being histologically indistinguishable from invasive ductal adenocarcinomas that arise in the setting of PanINs (Adsay et al, 2002). Colloid carcinomas associated with IPMNs have a relatively good prognosis compared with other pancreatic carcinomas of the ductal type, which have a 5-year survival of 60% (Maire et al, 2002).

PanINs and IPMNs show some overlapping features, such that both are inherently intraductal lesions composed predominantly of columnar, mucin-producing cells that may grow in a flat configuration or may produce papillae; these lesions show a range of cytologic and architectural atypia and can give rise to invasive adenocarcinomas of the pancreas (Fig. 8A.4E

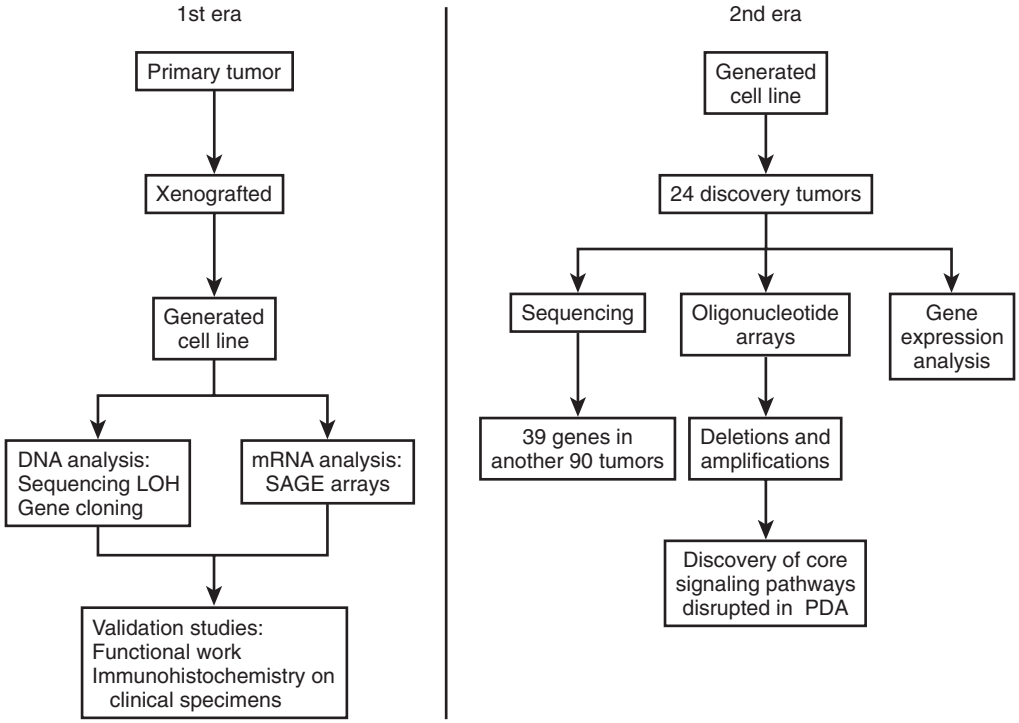

FIGURE 8A.2. Simplified flowchart of genetic discoveries performed in the two eras of genetic research. In the first era (*left*), resected pancreatic cancers were xenografted, and genomic DNA was isolated for genetic analysis of a region or putative tumor suppressor or oncogene. In the second era (*right*), combining advances in equipment and techniques and high-throughput sequencing allowed for a genomic survey of the pancreatic cancer genome. LOH, loss of heterozygosity; PDA, pancreatic ductal carcinoma; SAGE, serial analysis of gene expression.

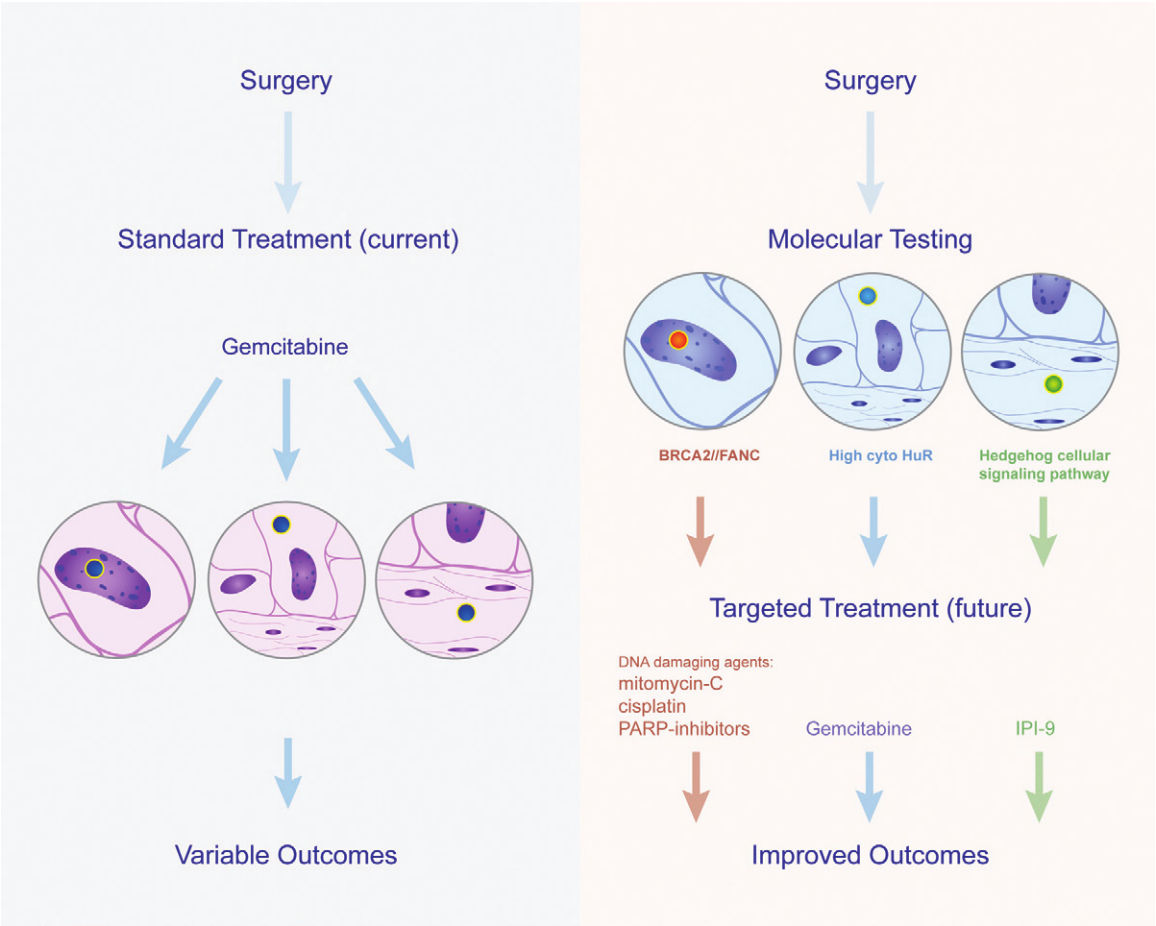

FIGURE 8A.3. Targeted treatment strategy of PDA. *Left*, The current strategy. *Right*, The future. IPI-9 is the abbreviation for IPI-926, an agent that inhibits the Hedgehog cellular signaling pathway (the stromal component of PDA). and F). An important feature that distinguishes the two lesions is that PanINs are microscopic lesions, and IPMNs are macroscopic. Nevertheless, recognition of an IPMN and its distinction from a PanIN lesion is important for two reasons: 1) IPMN-associated colloid carcinomas have a significantly better prognosis than either PanIN- or IPMN-associated tubular adenocarcinomas (Adsay et al, 2001), and 2) IPMNs have a propensity to be multifocal lesions, therefore patients who undergo partial pancreatectomy and are left with a remnant pancreas need to be followed for life, even when the lesion originally resected was a noninvasive IPMN (Sohn et al, 2004).[20]

Genetic analyses of IPMNs have disclosed abnormalities in many of the same genes altered in conventional ductal adenocarcinoma, including mutations in the *KRAS2*, *TP53*, and *CDKN2A* genes, although the frequency and stage of neoplastic progression at which these alterations occur in IPMNs differ from PanINs (Hruban et al, 2004; Sessa et al, 1994). For example, the Peutz–Jeghers gene *STK11* is inactivated in one third of IPMNs, and some patients with Peutz–Jeghers syndrome develop IPMNs (Sahin et al, 2003); this is in contrast to conventional ductal adenocarcinomas, in which loss of *STK11* is a rare event. In contrast to ductal adenocarcinomas and PanIN-3 lesions, abnormalities in the *SMAD4* gene seem to be rare in IPMNs (Iacobuzio-Donahue et al, 2000).

Another distinction between PanINs and IPMNs relates to the expression of the caudal differentiation factor CDX2, a marker of intestinal differentiation. Most IPMNs express *CDX2*, in particular IPMNs associated with an invasive colloid carcinoma, whereas this is uncommon both in PanINs and in the subset of IPMNs that give rise to invasive cancers resembling ductal adenocarcinomas (Adsay et al, 2004). *CDX2* expression in IPMNs usually is associated with expression of *MUC2*, an intestinal epithelial apomucin, whereas absence of *CDX2* usually is associated with expression of *MUC1*, a biliary apomucin, and concomitant lack of expression of *MUC2*. These findings have suggested that there may be two divergent pathways of carcinogenesis within the pancreatic ducts (Adsay et al, 2002). The first is a so-called *intestinal pathway* that gives rise to *CDX2*- and *MUC2*-expressing IPMNs that progress to the better-prognosis colloid carcinomas. The second is a *pancreatobiliary pathway* that gives rise to *CDX2*-negative, *MUC2*-negative, *MUC1*-expressing PanINs and a subset of IPMNs, both of which can progress to the poorer-prognosis conventional ductal adenocarcinomas. More

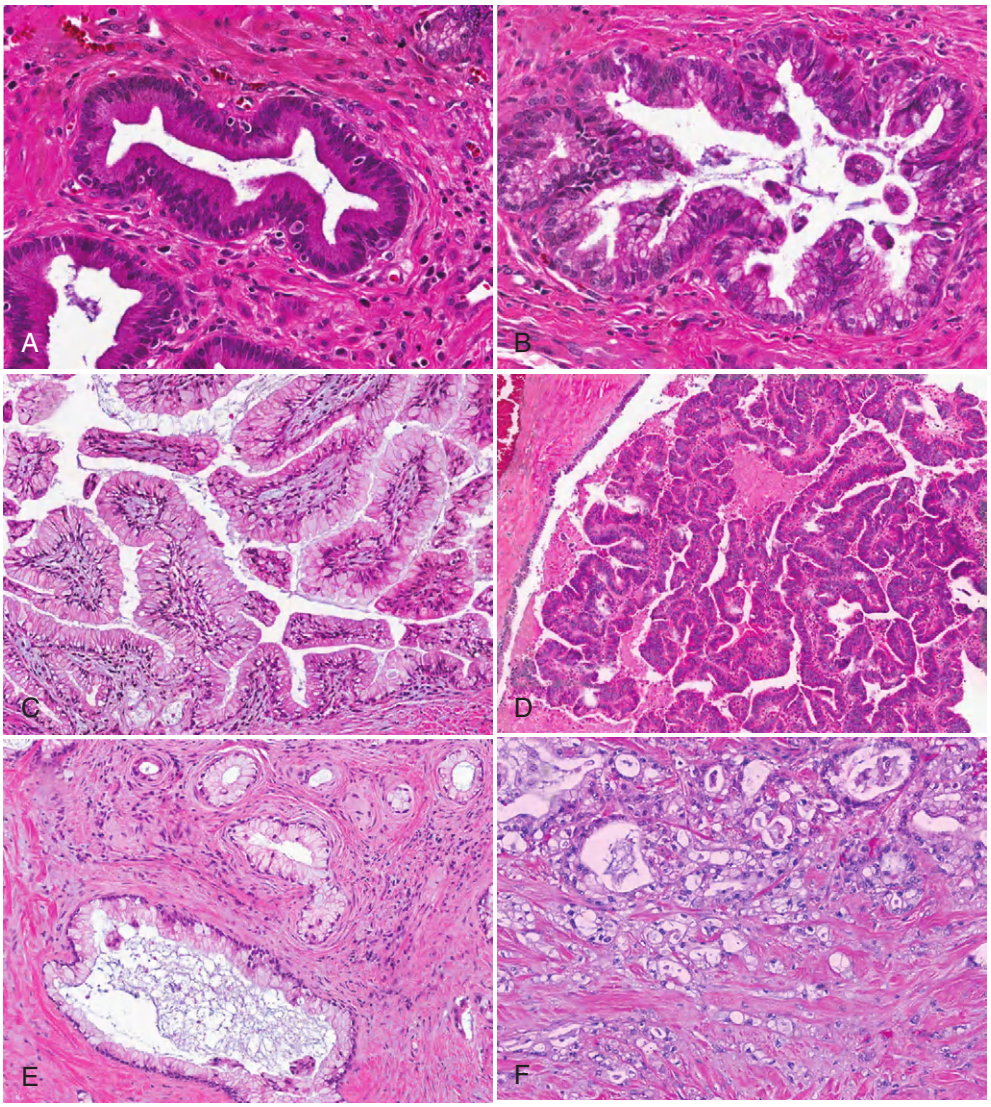

FIGURE 8A.4. Pathologic features of precursor lesions of pancreatic ductal adenocarcioma (PDA). **A,** Pancreatic intraepithelial neoplasia (PanIN). PanIN-1, flat lesion composed of columnar cells with basally located benign appearing nuclei and supranuclear mucin. **B,** PanIN-3 showing complex papillary architecture with budding of epithelial cells into lumen and cytologic atypia of lining cells. **C,** Intraductal papillary mucinous neoplasm (IPMN) with low-grade dysplasia showing well-formed papillae lined by mucin-containing cells. **D,** IPMN with high-grade dysplasia with complex branching papillae and cells showing marked cytologic atypia. **E,** Well-differentiated PDA forming glands and showing mild nuclear pleomorphism. **F,** Poorly differentiated PDA with solid growth pattern and infiltration of individual cells. The neoplastic cells show marked nuclear pleomorphism.

recently, it has been observed that IPMNs with moderate dysplasia had reduced or absent pp32 nuclear expression (Brody et al, 2007). This may be functionally significant, because *ANP32A* acts as a tumor suppressor in pancreatic and other cancers, and the absence of this protein may facilitate the tumorigenesis process.

Future Perspective of Precursor Lesions

Continued surgical resection, pathologic identification, and molecular dissection of PanIN and IPMN lesions will hopefully provide molecular signatures that will enlighten us about early events that drive tumorigenesis. Further, proteomic analysis of sera and blood from patients with these precursor lesions will likely reveal early detection markers that can be used for screening purposes.

GENETICS OF PANCREATIC DUCTAL ADENOCARCINOMA

Genomic (DNA) Alterations in Pancreatic Cancer

The multitude of genetic abnormalities in pancreatic cancer have many characteristics similar to other solid tumors, thus they include point mutations in critical genes, chromosomal (copy number) aberrations, mitochondrial DNA mutations, telomeric abnormalities, and epigenetic silencing by methylation of defined promoter DNA sequences. Recently, it was estimated that an individual pancreatic tumor contains, on average, 63 genetic alterations, primarily point mutations. It is also believed that only a small subset of these mutations is required for tumorigenesis (Jones et al, 2008).

The field of analyzing the genetics of pancreatic cancer can be broken down chronologically (see Fig. 8A.1). First, landmark studies starting in the late 1980s and spanning nearly two decades are highlighted by the discovery of *KRAS* activation, *SMAD4* and *BRCA2* mutations, and *CDKN2A* silencing (see Fig. 8A.1 and Fig. 8A.2, *left*). Some of these discoveries not only opened up lines of investigation in the field of pancreatic cancer but also opened up avenues with other tumor types and specific classification of PDA subtypes (Iacobuzio-Donahue et al, 2009). Then, in 2008 and 2009, Jones and colleagues, with the help of advanced DNA sequencing technology, were able to perform high-throughput genetic analysis on various pancreatic cancer genomes (see Figs. 8A.1 and 8A.2, *right*).

Copy-Number Aberrations

Although now considered primitive, valuable cytogenetic analysis performed over a decade ago found that chromosomal aberrations occur in virtually every pancreatic cancer. Cytogenetic analyses of pancreatic cancers have shown multiple, nonrandom numerical and structural changes (Griffin et al, 1995; Sirivatanauksorn et al, 2001). The most common numerical abnormalities include losses of chromosomes 6, 12, 13, and 18 and gains of chromosomes 7 and 20. Structural abnormalities (intrachromosomal break points) frequently involve 1p and 1q, 3p, 4q, 6q, 7q, 17p, 11p, 11q, 15q, 16q, and 19q (Rigaud et al, 2000). The technical limitations of conventional cytogenetics has presented challenges for identifying genes that are affected by chromosomal breaks. Allelotyping identifies areas of gross chromosomal loss by using polymorphic microsatellite markers to determine regions of genomic loss compared with matched normal tissues, also known as *loss of heterozygosity* (LOH) analysis. Allelotyping operates on the basic principle of the two-hit hypothesis, which postulates that tumor suppressor genes require biallelic inactivation. This most commonly happens by intragenic mutation in one allele, followed by loss of genetic material in the other allele. Identifying regions of single or biallelic loss or mutation holds the potential to understand the role of neighboring novel and well-known tumor suppressor genes. A landmark allelotype analysis of pancreatic cancers was performed using approximately 80 pancreatic cancer xenografts and 386 microsatellite markers (Iacobuzio-Donahue et al, 2004). This work discovered allelic losses in chromosome regions in proximity to tumor suppressor genes *CDKN2A*, *TP53*, and *SMAD4*. Allelotype analysis of PanIN lesions also has been performed using microdissected samples, and as expected, LOH is seen in many of the same chromosomal regions as invasive cancer, including 9p, 17p, and 18q (Luttges et al, 2001b; Yamano et al, 2000). Although the changes are conserved in most synchronous precursor lesions (i.e., the same allele is lost in PanIN and associated cancers), there is occasional clonal divergence between high-grade PanIN lesions harboring genetically distinct changes from the synchronous invasive cancer (Yamano et al, 2000). These findings may have important clinical implications in regard to tumor heterogeneity and clonal cancer cell drug resistance.

CGH identifies genomic amplifications and deletions and differentially labels normal and tumor genomic sequences with different dyes. The relative ratio of the two dyes indicates regions of cancer-associated losses or gains, with a ratio of 1 : 1 consistent with no change in copy number compared with normal DNA. Conventional CGH is performed on metaphase spreads and suffers from low resolution and inability to precisely map the various regions of amplifications and deletions (Mahlamaki et al, 1997). The resolution of array CGH is significantly better than the conventional technique, ranging from 500 kb to 30 kb, permitting the precise mapping of deletion and amplicon boundaries and genes targeted therein. Array technology also provides the ability to more efficiently use probes to study amplification of a larger number of genes. Array CGH analysis of pancreatic cancers has identified numerous recurrent copy-number aberrations, including amplifications of c-*MYC* (8q), *EGFR* (7p), *KRAS* (12p), *AKT2* (19q), and *NCOA3* (20q) and deletions *of SMAD4* (18q), *CDKN2A* (9p), *FHIT* (3p), and *MAP2K4* (17p) (Aguirre et al, 2004; Calhoun et al, 2006; Holzmann et al, 2004).

Utilizing high-density single-nucleotide polymorphism arrays, Calhoun and colleagues surveyed all the commercially available pancreatic cancer cell lines. In brief, this study provided high resolution and detailed break-point mapping of these cell lines and found two subclasses of cancer cell lines, original chromosomal instability (CIN) and holey CIN genotypes (Calhoun et al, 2006). Perhaps global classification of tumor cells with high-density arrays will become part of a prognostic or predictive molecular signature panel in the future.

Specific Gene Mutations

Allelotyping provides insight into areas harboring tumor suppressor genes, but it cannot qualify areas of enhanced genomic expression as happens with oncogene activation. Simplistically, wild-type tumor suppressor genes can "put the brakes" on the speeding vehicle (the cell), but if mutated, these "brakes" become defective, and the vehicle cannot stop. Using a similar automobile analogy, protooncogenes, in a mutated form known as *oncogenes,* become the "accelerators," and these "go signals" are often critical in transforming normal cells to a malignant phenotype.

Much like other solid tumors, genes altered in pancreatic cancer include three functional classes*: oncogenes, tumor suppressor genes,* and *caretaker genes.* A family of caretaker genes recognized as being disrupted in pancreatic cancer are genes of the Fanconi anemia complementation group, which are involved in homologous recombination-based DNA damage repair (D'Andrea et al, 2003). Patients with Fanconi anemia present with a wide variety of clinical issues, including aplastic anemia and a high risk of developing cancer. *BRCA2* is a member of this DNA repair pathway and is mutated in a subset of familial pancreatic cancers (Murphy et al, 2002). This has led to the search for mutations in other Fanconi anemia genes in pancreatic cancer. Somatic mutations of two genes in the core complex, *FANCC* and *FANCG*, were discovered but are rare in sporadic pancreatic cancers (van der Heijden et al, 2003). Through other modern techniques, Jones and colleagues (2009) discovered *FANCN (PALB2)* as another mutated gene found in familial pancreatic cancers.

Mutations in this core complex and in this DNA repair mechanism have major therapeutic implications (Fig. 8A.5, Table 8A.1; see the Familial Pancreatic cancer section below) (van der Heijden et al, 2004). Unlike most in vivo experiments, xenografted mice with isogenic cell lines (*FANCC* deficient and proficient) experienced regression of tumor after a single dose of the available mitomycin C intrastrand cross-linking drug (van der Heijden et al, 2005). Although other mutations in the Fanconi complementation group have not yet been described—other than *FANN, FANCC,* and *FANCG*—and the frequency of

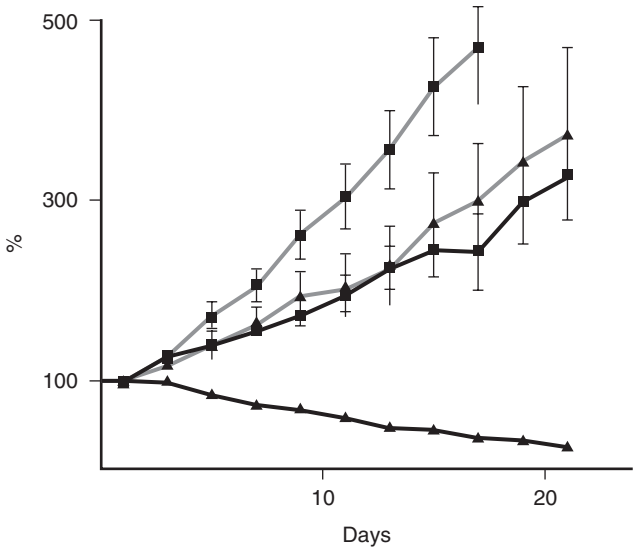

FIGURE 8A.5. Preclinical model shows an example of a successful targeted treatment strategy against a Fanconi-deficient tumor. A single-dose treatment with mitomycin C (5 mg/kg) of pancreatic cancer cell lines xenografted into nude mice. Note the hypersensitivity and tumor regression in the *FANCC*-deficient PL11 cells (*squares*) compared with the retrovirally corrected *FANC*-proficient PL11 cells (*triangles*). *Solid lines* indicate treated mice; *gray lines* indicate no treatment controls. Similar sensitivity was seen in the *BRCA2*-deficient CAPAN1 xenografted cells (van der Heijden et al, 2005).

these mutations in PDA appear to be low, it is likely that defects in other *FANC* genes yet to be thoroughly investigated (i.e., *FANCA*) are the direct cause of some familial and sporadic PDAs.

Oncogenes

Perhaps the best evidence that *KRAS* activation is an early and important event in tumorigenesis comes from decades of research on pancreatic cancer. The *KRAS2* oncogene on chromosome 12p is the most commonly altered oncogene, with up to 90% of pancreatic cancers containing mutations on codons 12, 13, and 61 (Caldas et al, 1994b). Activating mutations impairs the intrinsic GTPase activity of the *KRAS2* gene product, resulting in a protein that is constitutively active in intracellular signal transduction. Inactivation of *KRAS2* happens early in the pathway to oncogenesis, with approximately 30% of PanIN-1 lesions harboring *KRAS2* mutations (Hruban et al, 2000; Moskaluk et al, 1997). The first mouse model of pancreatic cancer was generated by constitutive overexpression of mutant *KRAS2* in the murine pancreatic ductal epithelium, underscoring its importance in pancreatic oncogenesis (Hingorani et al, 2003). This model was further developed into a powerful and useful preclinical model for PDA progression (Hingorani et al, 2005). Several good sources on mouse modeling and pancreatic cancer have been published (Frese et al, 2007; Karreth et al, 2009; Olive et al, 2006; Tuveson et al, 2005).

Rarely, pancreatic cancers with wild-type *KRAS2* genes harbor point mutations of *BRAF*, another gene in the RAS/RAF/MAP kinase signaling pathway, thereby explaining why mutations of these genes occur in mutually exclusive patterns in pancreatic cancer (Calhoun et al, 2003). This highlights the importance of identifying different molecular targets that lead to similar pathways in pancreatic cancer development and of finding a drug that can target one pathway, not one gene. Studies have shown that targeting *KRAS* may have potential in modulating angiogenesis in tumorigenesis. Matsuo and colleagues showed that oncogenic overexpression of *KRAS* increases production of angiogenesis, promoting CXC chemokines and VEGF from human pancreatic duct epithelial cells. This upregulation acts through the mitogen-activated protein kinase pathway and c-*JUN* signaling (Matsuo et al, 2009). *KRAS* mutation has been shown to be associated with increased *VEGFA* expression and poorer prognosis in pancreatic carcinoma (Ikeda et al, 2001). Yet to date, targeting KRAS activation in PDA patients has shown no success. Perhaps KRAS activation is a critical early event in pancreatic tumorigenesis, but once cells become malignant, there is no need for constitutive *KRAS* activation or for oncogenic addiction for that matter.

Other oncogenes implicated in pancreatic cancers include *MYC* and *EGFR*, which can be amplified in various subsets of cancers. Overexpression of *MYC* transcripts occurs in approximately 50% to 60% of pancreatic cancers (Aguirre et al, 2004; Han et al, 2002). Therapeutic targeting using monoclonal antibodies or small-molecule tyrosine kinase inhibitors makes use of the constitutive activation of the *EGFR* signaling pathway in pancreatic cancers via amplification of the *EGFR* gene (Holzmann et al, 2004; Li et al, 2004). Lack of a rigorous and reliable immunohistochemical assay to detect overexpression of *EGFR* has proven to be difficult and limiting.

Tumor Suppressor Genes

CDKN2A, on chromosome 9p, is the most commonly inactivated gene in pancreatic cancers, occurring in 90% of patients (Caldas et al, 1994a; Schutte et al, 1997). *CDKN2A* belongs to the cyclin-dependent kinase inhibitor family and inhibits cell-cycle progression through the G_1-S checkpoint mediated by cyclin-dependent kinases such as CDK4 and CDK6. Homozygous deletions (40%), intragenic mutation with loss of the second allele (40%), and epigenetic silencing by promoter methylation (10% to 15%) all contribute to gene inactivation. Immunolabeling for nuclear p16 protein expression is a reliable surrogate for *CDKN2A* genetic status; however, such immunolabeling does not identify specific genetic mechanisms of inactivation (Geradts et al, 2000). Loss of *CDKN2A* function occurs throughout the process of oncogenesis, with lesions appearing in different PanINs: 30% of PanIN-1A and PanIN-1B, 55% of PanIN-2, and 71% of PanIN-3 lesions show loss of nuclear p16 protein expression (Wilentz et al, 1998). The *CDKN2A* homozygous deletions encompass the *MTAP* gene in approximately 30% of pancreatic cancers, which offers potential therapeutic benefit, because targeted therapies have been developed that specifically inhibit the growth of *MTAP*-deficient cells (Chen et al, 1996).

Approximately 50% to 75% of pancreatic cancers contain an inactivation of the *TP53* gene on chromosome 17p. Such inactivation almost always occurs via intragenic mutation combined with loss of the second allele. The TP53 (*p53*) protein leads to cell-cycle arrest and activates apoptosis in the presence of DNA damage. It is believed that loss of TP53 function allows cells to survive and divide, despite the presence of damaged DNA, leading to accumulation of additional genetic

Table 8A.1

Genetic Syndromes with Inherited Predisposition to Pancreatic Cancer and Potential Targeted Therapy

Syndrome/Disease	Gene(s)	Genetic Testing Considerations	Risk of Pancreatic Adenocarcinoma	Available Targeted Therapy/Clinical Correlates
Hereditary breast/ ovarian cancer syndrome (HBOCS)	*BRCA1* *BRCA2*	NCCN test criteria require personal or family history of breast and ovarian cancer	*BRCA1*: 2.26-fold* *BRCA2*: 3- to 9-fold†	Cross-linking chemotherapeutics (mitomycin C, cisplatin, chorambucil, melphalan) PARP inhibitors
Peutz-Jeghers syndrome (PJS)	*STK11 (LKB1)*	Diagnosis of index case is generally based on clinical findings/working definition‡	132-fold; lifetime risk ~36%§	Reports of a PJS associated cancer with loss of the wild-type *STK11* allele together with a germline mutation in the other allele Some sporadic PDAs exhibit somatic mutations of *STK11*‖
Hereditary pancreatitis	*PRSS1; SPINK1, CFTR, CTRC*	Testing guidelines are based on symptoms with or without family history of pancreatitis¶	50- to 67-fold; lifetime risk 44%[a,b]	Tumor susceptibility is presumably due to mitogenic stimulation and clonal outgrowth of PDA cells as part of the normal healing responses that occur subsequent to repeated rounds of tissue destruction[b]
FAMM melanoma syndrome	*CDKN2A*	Documented patients/ families with multiple melanomas	13- to 39-fold†	Somatic p16 alterations were identified in 80% of PDAs[c]
HNPCC-Lynch Syndrome	*MLH1, MSH2, MSH6,* and *PMS2*	Bethesda Guidelines (tumor MSI/IHC) and Amsterdam Clinical Criteria II (germline studies)	<5-fold†	MSI-H pancreatic cancer may have a better prognosis after resection, possibly because of intensive immunoreaction to the tumor[d]
Familial adenomatous polyposis (FAP)	*APC*	APC is considered in individuals with ≥20 colon adenomas	Relative risk 4.46[e] Lifetime risk ~2%[f]	Some theorize that pancreaticobiliary secretions affect the development of adenomas and cancer in this area[g]
Cystic fibrosis (CF)	*CFTR*	Genotyping identifies patients with class IV and V mutations, which are likely to represent those with a functioning pancreas[h]	Relative risk 5.3[i]	Modifier genes or environmental factors may also be important in stratifying risk (e.g., mucin genes are found in both CF and PDA)[j]

abnormalities and eventually to neoplasia. Nuclear overexpression of the TP53 protein does not correlate well with mutation status. By immunohistochemistry, TP53 accumulation is seen only in the advanced PanIN-3 lesions, consistent with TP53 being a "late" genetic event in pancreatic cancer progression (Maitra et al, 2003). PDA cells with a mutant *TP53* have been shown to have a greater propensity for metastases (Morton et al, 2010). Of note, in an experimental model, the *BRCA2* gene could not be artificially disrupted in cancer cells with intact wild-type *TP53* status (Hucl et al, 2008; Callmeier et al, 2007). This interplay between TP53 and a genome maintenance pathway may have therapeutic value (see discussion on synthetic lethality later in this chapter).

Inactivation of the *SMAD4* gene on chromosome 18q21 occurs in approximately 55% of pancreatic cancers by homozygous deletions (30%) or by intragenic mutations and loss of the

second allele (25%). Loss of *SMAD4* function interferes with intracellular signaling cascades downstream of the transforming growth factor (TGF) family of cell surface receptors, leading to decreased growth inhibition and uncontrolled proliferation. *SMAD4* is only rarely mutated in other types of cancer (Schutte et al, 1996). Similar to *TP53,* loss of *SMAD4* function is a late genetic event in pancreatic carcinoma progression, with loss of *SMAD4* seen only in a few PanIN-3 lesions (Maitra et al, 2003). Examination of resected tumor specimens found that *SMAD4* inactivation portends a poorer prognosis and greater potential to metastasize (Iacobuzio-Donahue et al, 2009; Blackford et al, 2009). In brief, upon autospy evaluation, PDA patients died, with either locally destructive pancreatic cancer (30%) or widespread metastatic disease (70%). At autopsy, intact DPC4 staining (wild-type DPC4 status) of the tumor tissue significantly correlated with a locally advanced tumor and no detectable widespread metastatic disease phenotype (22%), although the majority of patients who had widespread metastases, numbering in the hundreds and thousands, had loss of DPC4 (78%) (Iacobuzio-Donahue et al, 2009). Identification of downstream targets might allow restoration of DPC4-dependent signaling in pancreatic cancer, yielding an improved prognosis (Cao et al, 2008).

Several tumor suppressor genes are inactivated in smaller numbers (5% to 10%) of pancreatic cancers, including *STK11* (chromosome 19p) (Sahin et al, 2003), *TGFBR1* (chromosome 9q), *TGFBR2* (chromosome 3p), *RB1* (chromosome 13q) (Jaeger et al, 1997), and *MAP2K4* (chromosome 17p) (Su et al, 1998). *MAP2K4*s function has been explored in a number of models, yet the main reason for its loss in pancreatic cancer is still unknown (Cunningham et al, 2006).

Other Caretaker Genes

In addition to classic oncogenes or tumor suppressor genes, caretaker genes (beyond Fanconi anemia–related genes) have been shown to play a role in oncogenesis. In theory, caretaker genes do not influence cell growth and proliferation directly but rather prevent the accumulation of DNA damage and cumulative mutations within key exonic sequences that make up the human genome. Loss of function of the DNA damage repair genes (*MLH1*, h*MSH2*) occurs in a small subset of pancreatic cancers in the familial setting but can also be seen in occasional, sporadic, nonfamilial cases (Ghimenti et al, 1999). Histologically, these microsatellite instability (MSI) cancers comprise poorly differentiated cancers with a syncytial growth pattern, expanding tumor margins, extensive necrosis, and intratumoral lymphocytic infiltrates. This uncommon variant has been termed *medullary cancer* to distinguish it from the more common pancreatic ductal adenocarcinoma (Wilentz et al, 2000b). Although findings in colon cancer have attempted to correlate MSI status with response to 5-fluorouracil, other studies have questioned these claims (Brody et al, 2009a).

Telomere Length Abnormalities

Telomeres are hexameric repeats of the sequence TTAGGG at the ends of chromosome arms that confer stability to chromosomes during cell division and prevent the ends from becoming "promiscuous" (Gisselsson, 2003). In other words, intact telomere structure guards against chromosomal fusion and thus may prevent chromosomal instability (Greenberg et al, 2005; Raynaud et al, 2008). In fact, telomeric dysfunction has been hypothesized to be one of the more important gateways of chromosomal instability, a signature of most solid cancers characterized by aneuploidy and extensive chromosomal rearrangements. The development of direct visualization of in situ telomere length was a breakthrough for understanding telomere length abnormalities and cancer development (Meeker et al, 2004). A study by van Heek and colleagues showed that telomere length abnormalities are one of the earliest demonstrable genetic aberrations in pancreatic cancer, with greater than 90% of the lowest grade PanIN lesions showing marked shortening of telomeres, as compared with normal duct epithelium (van Heek et al, 2002). It has been hypothesized that intact telomeres may serve as "caretakers" in the pancreatic ducts, and that the loss of telomeres in PanIN lesions sets the stage for progressive accumulation of chromosomal abnormalities, eventually culminating in neoplasia. Of note, Dr. Carol Greider, the lead investigator on a number of landmark studies involving telomerase and telomere function, recently (2009) won the Nobel prize based on her work with telomeres. This underscores the importance of this molecule's involvement in both cancer and the aging process (Harley et al, 1994).

Alternative Genetic Silencing: Epigenetic Abnormalities

Although the classic two-hit hypothesis postulated that tumor suppressor gene silencing occurs by a combination of intragenic mutations and allelic loss, it has become apparent since the 1990s that epigenetic mechanisms of silencing are probably as important in terms of frequency and prevalence in many cancers (Baylin et al, 2000). Epigenetic silencing occurs predominantly through hypermethylation of so-called *CpG islands* in the promoter region of tumor suppressor genes, leading to transcriptional abrogation. Gene silencing by promoter methylation occurs physiologically at many sites in the human genome, where it is called *imprinting.* The most basic example is the one that occurs on an X chromosome in females, known as *X inactivation,* in which one of the two X chromosomes in females becomes silenced. In cancers, preferential hypermethylation of the promoter occurs in the neoplastic cells with consequent downregulation of gene expression, but this does not occur in the corresponding normal counterpart. Epigenetic silencing is seen frequently in pancreatic cancers and tends to involve genes that function in tumor suppression or in critical homeostatic pathways (e.g., *CDKN2A,* E-cadherin, retinoic acid β, osteonectin, *SOCS1*) or in both (Sato et al, 2003a; Ueki et al, 2000).

Aberrant methylation of genes is also found in precursor lesions of pancreatic cancers and tends to occur in intermediate- or late-stage lesions (PanIN-2 and PanIN-3) (Fukushima et al, 2002). The presence of promoter hypermethylation in noninvasive precursor lesions implies that the detection of aberrantly methylated DNA sequences in clinical samples might be useful as a strategy for early detection of pancreatic cancer. Methylated proenkephalin sequences can be detected in approximately 60% of pancreatic juice samples obtained from patients with pancreatic cancer but not in patients with nonneoplastic periampullary diseases, including chronic pancreatitis (Fukushima et al, 2003). The development of tumor-specific early detection panels using aberrantly methylated DNA sequences is currently an area of active investigation for many human cancers, including pancreatic cancer.

Although there has been extensive work on the role of promoter hypermethylation in the pathogenesis of cancers, more

recent data suggest that promoter hypomethylation in candidate genes also may be important in cancer development and progression. Genes showing preferential hypomethylation in pancreatic cancers—*SERPINB5, S100P, MSLN, PSCA,* and *CLDN4*—are usually overexpressed in the cancers compared with normal pancreas, suggesting that epigenetic mechanisms can affect gene expression in either direction (Sato et al, 2003b).

Aberrant epigenetic silencing by promoter methylation also has been reported in IPMNs, including methylation of the *SOCS1* and *CDKN2A* genes (Sato et al, 2002). Global analyses of gene expression in IPMNs have revealed the overexpression of *LCN2, LGALS3, CTSE, CLDN4,* and three members of the trefoil factor family, *TFF1, TFF2,* and *TFF3* (Sato et al, 2004a; Terris et al, 2002). These global analyses also have shown that *CLDN4,* CXCR4, S100A4, and *MSLN* all are expressed at significantly higher levels in invasive IPMNs than in noninvasive IPMNs, suggesting that these proteins may contribute to the process of invasion (Sato et al, 2004b).

SECOND ERA OF MOLECULAR BIOLOGY

Core Signaling Pathways Disrupted in Pancreatic Cancer

The modern era of molecular biology has progressed to allow high-throughput surveying of the pancreatic cancer genome (Figs. 8A.1 and 8A.2, *right*), bringing some clarity to our understanding of the interactions of molecular pathways in tumorigenesis. This high-throughput analysis revealed that pancreatic cancers contain an average of 63 genes that are genetically altered (Jones et al, 2008). In this work, Jones and colleagues used a combination of modern molecular techniques to report that 67% to 100% of all pancreatic cancer genomes surveyed had a genetic abnormality in 12 core signaling pathways and processes. These pathways include apoptosis, DNA damage control, regulation of G_1–S phase transition, Hedgehog signaling, hemophilic cell adhesion, integrin signaling, c-*JUN* N-terminal kinase signaling, *KRAS* signaling, regulation of invasion, small GTPase-dependent signaling (other than *KRAS*), *TGFB* signaling, and *WNT/NOTCH* signaling.

Unlike certain subtypes of leukemia that are driven by single "targetable" oncogenes, we have learned that pancreatic cancers result from genetic alterations of large numbers of genes that function through a distinct number of pathways. The study by Jones and colleagues suggests that it may be beneficial to target the physiologic effects of disrupted pathways rather than individual target genes.[4] In fact, targeting multiple pathways or multiple points in the pathway may be in line with the early preclinical and clinical success stories of the concept of "synthetic lethality" (Ashworth, 2008). This promising direction in therapeutic development is extracted from fruit fly (*Drosophila melanogaster*) and yeast genetic studies, in which deletion of multiple genes in the same pathway was found to be deleterious to the organism, although disruption in just one gene in the pathway is not. Thus, targeting an additional gene in an already disrupted pathway in a tumor may be deleterious for tumor cells and may thus be a promising therapeutic strategy.

Future Perspective of the Genetics and the Epigenetics of Pancreatic Ductal Adenocarcinoma

Certainly the rapid advancement of whole genome sequencing should find novel genes and genomic regions that are disrupted in pancreatic cancer. These genetic alterations may be used as biomarkers not only to predict prognosis but also to direct therapies. Not too far into the future, we will use single nucleotide polymorphisms (SNPs), which may contribute not only to the disease process but also to chemotherapy metabolism. The future opportunity of cancer genetics to yield therapeutic benefit is based on our ability to distinguish the subtle *differences* between individual pancreatic cancers, not the similarities. Because, in fact, it is these differences that will generate clinical success. Finally, once we thoroughly screen the complete landscape of the pancreatic cancer genome, we will still need to perform the basic laboratory studies to understand exactly how these disrupted genes contribute to the complex tumorigenesis process and how we may take advantage of these alterations therapeutically.

FAMILIAL PANCREATIC CANCER

Approximately 10% of pancreatic cancers show familial aggregation (Petersen et al, 2003). The presence of two first-degree family members with pancreatic cancer confers a 6- to 18-fold increased risk of the disease in other first-degree relatives. This risk is increased 32- to 57-fold in families with three or more first-degree relatives with pancreatic cancer (Klein et al, 2004; Tersmette et al, 2001). Only a minority of these familial cancers is caused by a recognized cancer syndrome associated with germline mutations in known genes. Included in Table 8A.1 are possible "targeted therapies" for the genes and disorders germane to pancreatic cancer. Thus, this table underscores the significance for understanding the inherited lesion that may have contributed to the pancreatic cancers found in these families.

For example, as mentioned earlier in this chapter, Fanconi anemia is characterized as a rare, autosomally recessive cancer syndrome that results initially from a mutation in one of the multiple *FANC/BRCA* complementation groups in the *FANC/BRCA* pathway (Mathew, 2006). One gene in this pathway, *BRCA2*, is associated with a greatly increased risk of cancer when deleted via a biallelic mutation. The *BRCA* genes play a critical role in DNA repair via RAD51 repair pathways (Gudmundsdottir et al, 2006). Loss of functional *BRCA1* and *BRCA2* conveys chromosomal instability to cells by impairing the critical function of DNA double-stranded break repair (Ashworth, 2008). It has been well established that DNA damaging agents such as mitomycin c or cisplatin effectively kill cells with loss of *BRCA2* or related genes (see Fig. 8A.5) (Hussain et al, 2004).

Currently, poly (ADP-ribose) polymerase (PARP) inhibitors have similar promising results as intrastrand cross-linking agents in early phase trials in other cancer types (ovarian, breast) (Farmer et al 2005). Certainly, pancreatic cancer is a logical tumor system in which to test novel PARP inhibitors in combination with other DNA-damaging agents. Targeting the *FANC-BRCA* pathway with PARP inhibitors similarly has been shown to lead to synthetic lethality, creating a convenient and fortuitous therapeutic window (Ashworth, 2008). The makeup of this therapeutic window relies on the fact that normal cells

will have an intact DNA repair mechanism and thus will be capable of managing and repairing the damage put forth by a DNA-damaging agent. In contrast, the tumor will be unable to repair such damage due to loss of a key aspect of this repair mechanism (i.e., *BRCA2;* see Fig. 8A.5).

Identification of mutations in the *FANC-BRCA* pathway in familial cancers has the potential to shed light on the treatment of sporadic cancers as well. It has been suggested that perhaps up to 25% of sporadic breast and ovarian cancers manifest a *BRCA*-like phenotype. (Turner et al, 2004). The data have been derived from *BRCA1, FANCC, FANCG,* and *FANCF* methylation studies (Turner et al, 2004). Further studies are warranted, but future banking of sporadic pancreatic cancers to study all of the tumor characteristics—posttranscriptional modification, polymorphisms, CGH analysis—along with thorough analysis of family history may reveal a "*BRCA*ness" among certain sporadic pancreatic tumors, aiding in the personalization of therapy (Martin et al, 2010). Focused DNA repair microarray analysis may also shed light on other cancer susceptibility genes.

Of note, a recent report demonstrated that *PALB2,* formerly known as *FANCN,* is a gene inherited in a mutant form that produces a stop codon in a small percentage of familial PDAs. This gene was discovered to be mutated in three of 96 familial pancreatic cancers, each producing a different stop codon (Jones et al, 2009). Truncating mutations in *PALB2* were not found in any of the 1084 patients of similar ethnicity used as a control cohort in a similar study, thus ruling out a polymorphic sequence variant. This information suggests that next to *BRCA2*, *PALB2* is the second most commonly mutated gene in hereditary pancreatic cancer (Jones et al, 2009). Thus most familial pancreatic cancers have no known genetic bases at this time, although many believe an autosomal dominant inheritance of a rare mutant allele is the most likely cause of these cancers. Of apparently "sporadic" (nonfamilial) pancreatic cancer patients, 7% harbor germline mutations in the *BRCA2* gene, and this low-penetrance pattern is peculiar to cancers arising in the Ashkenazi Jewish population (Goggins et al, 1996). Perhaps no single gene is responsible for the other familial forms of PDA, carcinogenesis of which may be the best example that core pathways collaborate with the environment (Yeo et al, 2009); thus no single gene from one pathway will prove to be disrupted in the complex process of tumorigenesis in this familial form of pancreatic cancer.

Finding Familial Patients

Canto and colleagues published a list of arguments for and against screening patients with a family history of pancreatic cancer. Arguments for screening include the fact that once the disease is symptomatic, it is often not curable, and that high-risk patients can be identified and are often very compliant with follow-up. Arguments against screening include lack of a standard protocol on screening patients with two or fewer first-degree relatives with PDA and technical limitations in screening (Steinberg et al, 2009).

TRANSCRIPTOMIC (RNA) ABNORMALITIES IN PANCREATIC CANCER

Although the presence of clonal genomic abnormalities in some ways defines the pancreatic cancer phenotype, recent years also have seen an explosion of new data characterizing the transcriptomic (RNA) abnormalities in human cancers. This cataloging has been greatly facilitated by the development of global expression analysis platforms, such as oligonucleotide microarrays, cDNA microarrays, and serial analysis of gene expression (SAGE). Several studies have analyzed pancreatic cancers and compared their gene expression profile with normal pancreas tissue to identify differentially overexpressed and underexpressed genes (Argani et al, 2001a; Crnogorac-Jurcevic et al, 2001; Geng et al, 1998; Iacobuzio-Donahue et al, 2002, 2003a, 2003b; Ryu et al, 2001, 2002). A comprehensive analysis of pancreatic cancer using high-density oligonucleotide microarrays identified 217 genes as being overexpressed threefold or higher in cancers versus normal tissue (Iacobuzio-Donahue et al, 2003a). Of these genes, 40 were determined to be overexpressed by more than one global expression profiling platform, and six genes—keratin 19, retinoic acid–induced 3, secretory leukocyte protease inhibitor, stratifin, tetraspan 1, and transglutaminase 2—were found to be overexpressed in pancreatic cancer by all three platforms: oligonucleotide and cDNA microarrays and SAGE. The future role of one or all of these six genes in early detection or therapy remains to be elucidated.

The identification of differentially expressed genes not only serves the further understanding of the basic biology of pancreatic cancers, it also provides a fertile ground to identify markers for early diagnosis, imaging, and novel therapeutic strategies. Mesothelin (*MSLN*) was identified by SAGE as a gene overexpressed in pancreatic cancers, and it was confirmed by immunohistochemistry to be restricted to the neoplastic epithelium (Argani et al, 2001b). These data were corroborated by a number of laboratories that included surveying of tumor tissues from diverse and distinct tumor banks (Showalter et al, 2008). This identification led to the development of a pancreatic cancer vaccine targeted to the mesothelin antigen and the development of antimesothelin antibody-conjugated immunotoxins, both of which are undergoing clinical trials in pancreatic cancer (Thomas et al, 2004). Moreover, a therapeutic strategy that delivers a suicide gene, *DT-A*, to pancreatic cancer cells under the regulation of the mesothelin promoter has showed early success (Showalter et al, 2008). Hucl and colleagues were able to define the exact sequence motif within the promoter region that was responsible for driving cancer-specific transcription, termed *CanScript*. This region was critical for binding of the TEF-1 transcription factor (Hucl et al, 2007). Interestingly, in the comprehensive SAGE analysis performed in the Jones and colleagues publication (see Fig. 8A.2) (Jones et al, 2009), mesothelin was labeled as not overexpressed, because it did not exceed the arbitrary tenfold-over-normal threshold. Future bench-work studies on these proteins should elucidate the functional significance of these overexpressed genes. Moreover, better tools in the laboratory will show that haploinsufficiency and/or modestly reduced and overexpressed molecules may have important effects on tumor phenotype and invasiveness.

More recently, the misexpression of two "embryonic" signaling pathways, Notch and Hedgehog, was described in most pancreatic cancers (Berman et al, 2003; Miyamoto et al, 2003; Thayer et al, 2003). These pathways are highly expressed in multiple tissues during in utero development, hence the term "embryonic"; but these are for the most part turned off in adult somatic cells, including those of the normal pancreas. Overexpression of genes in both the *NOTCH* and *HEDGEHOG* pathways have been described in invasive cancers and PanIN lesions but not in normal pancreatic duct epithelium (Miyamoto et al,

2003; Thayer et al, 2003). The neoplasia-specific activation of these pathways makes them an attractive target for therapy using specific small-molecule inhibitors. In fact, the *HEDGEHOG* small-molecule inhibitor cyclopamine has been shown to cause regression of pancreatic cancer growth in vitro and in vivo (Berman et al, 2003).

Posttranscriptional Regulation

In recent years, strong evidence has shown that posttranscriptional regulation of genes can directly affect both the tumorigenesis process (Lopez de Silanes et al, 2003, 2005) and cancer cell susceptibility to chemotherapy (Brody et al, 2009a; Constantino et al, 2009; Gorospe, 2003). Posttranscriptional gene regulation can have the same effect on gene expression as a genetic mutation or methylation of a promoter. One potent mechanism of posttranscriptional regulation involves RNA-binding proteins. One such RNA-binding protein that has been shown to be important in a number of tumor systems is Hu antigen R (HuR), a ubiquitously expressed member of the *HU* family that mediates cellular response to stress and DNA damage by posttranscriptional regulation (Hinman et al, 2008). Elevated HuR cytoplasmic expression is detected in tumors with poor pathologic features and poor predicted outcomes (Lopez de Silanes et al, 2005). It is has been shown that during times of certain cellular stressors—brought on by agents such as ultraviolet C (UVC) irradiation, heat shock, hypoxia, tamoxifen (Hostetter et al, 2008), and actinomycin D—HuR can bind to certain apoptotic or survival mRNA transcripts by binding to AU-rich elements in the 3′ untranslated region (UTR) of these mRNAs. In regard to tumorigenesis, HuR has been shown to bind to and stabilize proteins such as p21, p53, and cyclin A (Gorospe, 2003). For instance, Gorospe and colleagues showed that HuR can enhance translation of proteins such as p53 under stress from UVC irradiation (Gorospe, 2003). Thus HuR's role in cellular stress and damage gives it a likely pivotal role in both the tumorigenesis process and in the acute cellular response to chemotherapy in pancreatic cancer cells.

As an example, Costantino and colleagues showed that pancreatic cancer cell lines that overexpressed HuR were dramatically sensitive to gemcitabine, the standard chemotherapeutic treatment for pancreatic cancer, when compared with controls (Constantino et al, 2009). Treatment of cells with gemcitabine caused an increase in cytoplasmic HuR levels, and HuR associates with deoxycytidine kinase (dCK) mRNA and in turn regulates dCK protein levels (Constantino et al, 2009). This is important, because *DCK* encodes the protein that metabolizes gemcitabine. Clinically, cytoplasmic HuR levels in pancreatic cancer patients predicted response to gemcitabine therapy. In brief, patients who had low cytoplasmic HuR levels had a sevenfold increase in mortality compared with patients who had elevated cytoplasmic HuR levels (Fig. 8A.6) (Constantino et al, 2009). Prospective studies and attempts to manipulate HuR expression levels in tumor cells to optimize gemcitabine therapy are currently being investigated.

MicroRNAs

MicroRNAs (miRNAs) are defined as short, noncoding regions of RNA sequences (22 nucleotides) that can potently regulate gene expression patterns; miRNAs have been shown to regulate a number of disease- and developmental-related genes, and they are tissue specific in expression (Rosenfeld et al, 2008). These miRNA-specific attributes make them putative, powerful, and unique candidate biomarkers (Mardin et al, 2009). Discovering the presence of miRNAs in pancreatic cancer may be extremely valuable, although understanding the significance of these miRNAs may be more difficult and tedious, as miRNAs have been shown to distinguish between various disease states and tissues including pancreatitis, PDA, IPMN, and normal specimens (Mardin et al, 2009). Further, it has been shown that a miRNA molecular signature can stratify long- and short-term survivors (Bloomstron et al, 2007).

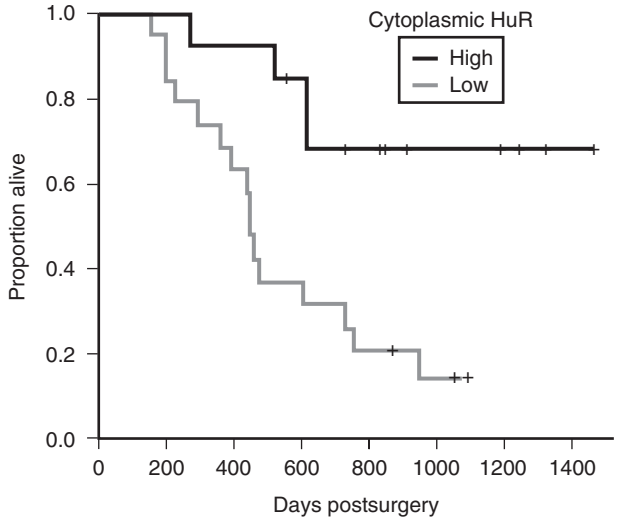

FIGURE 8A.6. Tumor human antigen R (*HuR*) cytoplasmic status can stratify pancreatic cancer patients treated with standard-of-care chemotherapy (gemcitabine) into two groups: responders (high cytoplasmic HuR) versus nonresponders (low cytoplasmic HuR) *(Constantino et al, 2009)*.

Future Perspectives on the Transcriptome

Genetic alterations have been proven over countless investigations to be critical for the development of PDA. Now that we have the technology to identify subtle mRNA expression changes, and also the ability to comprehend the complexity of numerous transcriptional regulatory mechanisms, we can begin to utilize this information for our understanding of PDA biology and therapeutic resistance mechanisms. Understanding the special plasticity of the pancreatic cancer transcriptome—not only in response to drugs (Brody et al, 2009b) but also in response to cancer-specific environmental concerns, such as hypoxia and radiation—will most likely be critical for our successful management of pancreatic cancer patients.

STROMAL CONTENT IN PANCREATIC CANCER

One of the reasons why pancreatic cancer remains such a lethal disease stems from its relative insensitivity to chemotherapeutic agents. The bulk of PDA tumor volume consists of stroma, thus identifying the signaling pathways disrupted in the stromal component adjacent to cancer cells may be extremely valuable.

A number of studies have been conducted using cell co-culturing (Sato et al, 2004b) as well as genetic evaluation (Walter et al, 2008) of the stromal component of pancreatic

cancer tissue. For example, Olive and colleagues studied the differences in gemcitabine delivery in mice that had tumors implanted in their tissue compared with mice that were genetically engineered (KPC mice) to conditionally express endogenous mutant *KRAS* and *TP53* alleles similar to pancreatic cancer cells (Olive et al, 2009). Mice with transplanted tumors showed greater tissue accumulation of the active metabolites of gemcitabine than the KPC mice. Visual microscopic studies revealed that the KPC mice had a much greater stromal content and reduced blood vessel density than the tumor-implanted mice, therefore increasing the space between neoplastic cells and blood flow. The decreased stromal content in the tumor-implanted mice apparently led to greater therapeutic efficiency of gemcitabine delivery. To pursue this issue, the investigators treated mice with IPI-926, an inhibitor of *SMO* that is normally upregulated in the *HEDGEHOG* pathway in stromal cells. Mice treated with IPI-926 exhibited depletion of desmoplastic stroma and increased tumor vascularity. In turn, the concentration of gemcitabine in KPC tumors was elevated by 60% after 10 days of pretreatment with the combined IPI-926/gemcitabine treatment. KPC mice treated with the combination therapy showed decreased tumor size and increased survival benefit when compared with mice treated with IPI-926 or gemcitabine alone (Olive et al, 2009). This study is a nice example of exploring and exploiting a potential target in stroma cells, and its results sheds light on the importance of identifying pathways (i.e., stromal development) that lead to tumorigenesis or impact drug delivery. Treating the stromal component of the tumor with IPI-926 and taking advantage of the tumor cell's HuR status is an example of how we may be able to powerfully target both the stromal and epithelial components of pancreatic cancer at the same time.

MOLECULAR GENETICS OF OTHER PANCREATIC NEOPLASMS

The discussion in this chapter has centered on precursor lesions and pancreatic ductal adenocarcinoma. Comparing the genetic changes in less common pancreatic lesions with those of ductal adenocarcinomas helps us better understand the mechanisms of carcinogenesis within different compartments of the pancreas. At the same time, many of these less common neoplasms have a significantly less ominous prognosis than conventional ductal adenocarcinomas, and histologic and molecular tools may be required to distinguish unequivocally the groups in diagnostic specimens.

FINAL THOUGHTS AND PERSPECTIVES

We are currently at an interesting and critical time in studying the molecular aspects of pancreatic cancer. The research community has incredible resources at its disposal, ranging from patient databases to complex sequencing equipment. This coming of age of pancreatic cancer research must include surgeons, pathologists, molecular biologists, and medical oncologists collaborating toward ultimately better and more personalized patient care. It is also time for the National Institutes of Health and other funding agencies to provide increased support and to step up their efforts at this exciting time in pancreatic cancer research. Hopefully, those in the field will take the time to connect the dots with all the rigorous and voluminous research that has been performed over the last few decades (see Fig. 8A.1), allowing future landmark progress. Current research will need to provide better early detection markers, so that physicians can have more opportunities to prevent cancer from forming, instead of attempting to cure it before it is too late. Our hope is that the treatment of pancreatic cancer will follow a paradigm similar to that of infectious disease specialists treating bacterial infections. Specific bacterial infections are easily cleared with specific antibiotics. Following this logical course, and based on the past decades of research, an individual pancreatic cancer patient of the future will likely benefit from personalized treatment. In the coming decade, we must translate our molecular research efforts into a better understanding of familial risk, earlier detection, and logical but innovative therapies in order to generate better outcomes for our patients.

CHAPTER 9

Liver immunology

Zubin M. Bamboat, Venu G. Pillarisetty, and Ronald P. DeMatteo

FUNDAMENTALS OF IMMUNOLOGY

The immune system is composed of two major components: *innate* and *adaptive* immunity (Fig. 9.1; Janeway, 2001). Innate immune cells are armed with hard-wired detection systems that recognize common structures found on pathogens or changes in surface molecules of host cells that signal danger. Such pattern recognition receptors (PRRs) account for the rapid response of innate immune cells to infection or host injury. A variety of PRRs exist, of which the best characterized is the Toll-like receptor (TLR) family. In humans, 11 TLRs are currently known that recognize various structurally conserved components of bacteria and viruses in addition to endogenous intracellular ligands. Engagement of PRRs by their respective ligands causes activation of innate immune cells, such as neutrophils, monocytes, macrophages, natural killer (NK) cells, and dendritic cells (DCs). The ensuing response results in destruction of the invading pathogen or tumor via phagocytosis or release of various cytotoxic or inflammatory agents.

In contrast, adaptive immunity refers to the arm of the immune system that is involved in antigen-specific responses, which occur either later in a particular immune response or rapidly after repeat exposure to a particular pathogen. The adaptive immune system is essentially comprised of T and B cells that circulate within the blood, lymphatic tissues, and organs. These lymphocytes interact with various antigen-presenting cells (APCs) of the innate immune system, such as DCs and macrophages. Activation occurs in the presence of specific signals between APCs and T or B cells. These signals include 1) stable antigen presentation within the context of major histocompatibility complex (MHC) molecules MHC-I or MHC-II, 2) appropriate costimulation by APCs and the corresponding receptor on T or B cells, and 3) cytokine-mediated signals that can modulate the overall response (Fig. 9.2). Innate and adaptive immune responses provide protection against a vast array of pathogens, preserving normal cells and tissues from attack. Failure of the immune system's ability to correctly recognize foreign or abnormal cells may facilitate the development or spread of infection or malignancy. In contrast, inability to distinguish self from foreign antigens may result in autoimmune disease.

Modern clinical and experimental work has shown that the liver is particularly important in immunity (Fig. 9.3). First, the fact that the liver is one of the most common sites for metastatic disease suggests that it may have an increased propensity toward immunologic acceptance. Second, allogeneic liver transplantation can be accomplished in certain strains of mice without the need for immunosuppression, and in humans it often requires less immunosuppression compared with kidney or other solid organ transplants. Third, the liver is home to chronic viral infection in the form of hepatitis B and C. Additionally, oral ingestion or portal vein injection of foreign proteins can lead to tolerance in animal models. Conversely, the liver is the site of several autoimmune processes, including primary sclerosing cholangitis and primary biliary sclerosis. Despite the significant role that the liver plays in altering the balance between tolerance and immunity, the study of liver immunology remains in its infancy. This chapter discusses our current understanding of the function of liver immune cells and their role in disease.

Anatomic Considerations

Because the vascular supply of the liver derives principally from the portal venous system draining the gut, a heavy antigen load is delivered to the liver, particularly after meals. Portal venous blood flows slowly through the vast network of hepatic sinusoids, which are discontinuously lined by fenestrated endothelium lacking a basement membrane (Fig. 9.4; see also Chapter 6). The sluggish flow of blood allows for the efficient capture of antigens by leukocytes traveling in the blood within the sinusoids and by the endothelial cells lining the sinusoids. The microscopic anatomy of the liver also favors the ability of blood-borne leukocytes to interact with hepatic parenchymal cells and resident immune cells of the liver.

Tolerance Versus Immunity

One of the most intriguing aspects of liver immunology is the propensity of antigens passing through the liver to produce tolerance rather than immunity. In experimental animal models and clinical studies of humans undergoing liver transplantation, a greater propensity for graft acceptance has been noted compared with transplantation of other solid organs. A liver transplant protects a kidney allograft transplanted simultaneously from the same donor (Creput et al, 2003). Trying to decipher the reasons for the liver's inherent propensity for tolerance has been a particularly active area of research in the field of transplantation and cancer immunobiology.

Multiple competing theories to explain the cause of liver tolerance have been advanced. One postulate is that, as in central thymic tolerance, clonal deletion of antigen-specific T cells occurs in the liver. Another theory is that liver allografts release large amounts of soluble MHC class I molecules that potentially could function to neutralize donor-specific antibodies or cytolytic T cells. Kupffer cells (KCs) and natural killer (NK) T cells have been implicated as being important in the

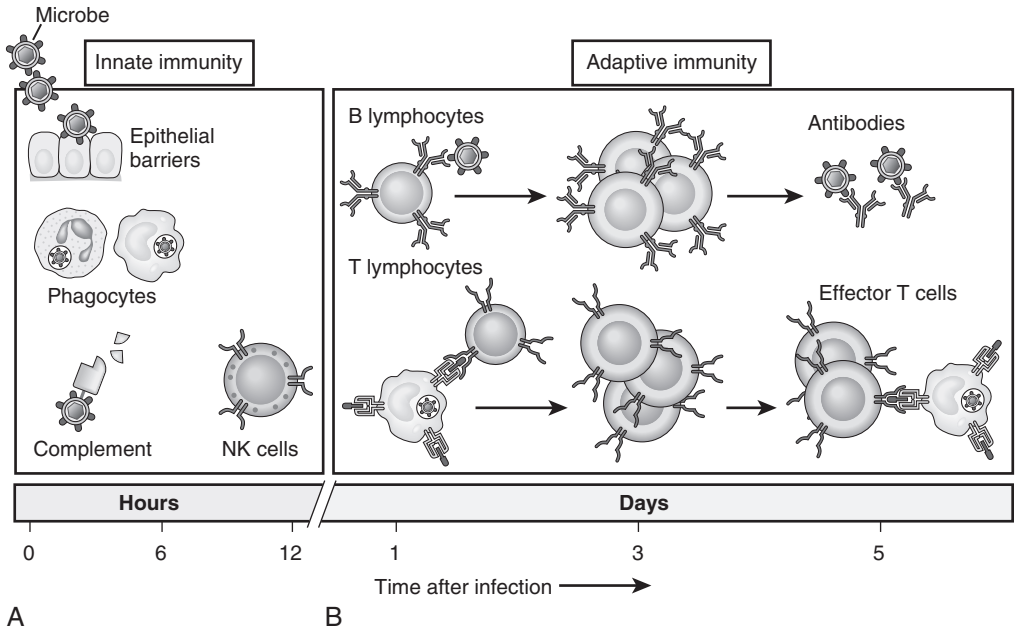

FIGURE 9.1. Innate and adaptive immunity. **A,** *Innate immunity* includes the body's initial defenses against infection. It includes certain complement proteins, epithelial defense, and phagocytes such as macrophages, natural killer (*NK*) cells, and dendritic cells (*DCs*). **B,** In contrast, *adaptive immunity* refers to the precisely targeted immune mechanisms that occur later in the immune response. The adaptive immune system has humoral (dissolved) and cellular components. B-cell secretion of antibodies functions to block infections and trigger the destruction of pathogenic organisms. T cell–mediated immunity occurs after phagocytosis and leads to direct cellular lysis. *(From Abbas AK, 2003: Cellular and Molecular Immunology. Philadelphia, Saunders.)*

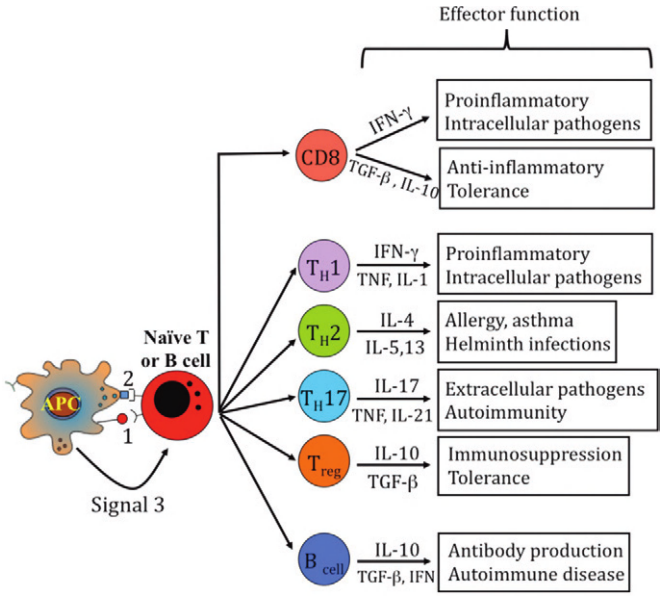

FIGURE 9.2. Antigen-presenting cell (*APC*) instruction of T and B cells. Signals 1 (antigen presentation), 2 (costimulation), and 3 (cytokine production) between APCs and naïve T or B cells govern the subsequent adaptive immune response. $CD8^+$ T cells can differentiate into either cytotoxic or regulatory cells capable of killing foreign pathogens or suppressing immune responses, respectively. Similarly, naïve $CD4^+$ T cells can differentiate into four types of T cells—Th1, Th2, Th17, and Treg—each with a distinct cytokine profile and specific effector function. B cells can also differentiate into cytokine and antibody-producing cells, which play a role in responses against tumors, pathogens, and autoimmune diseases. INF, interferon; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.

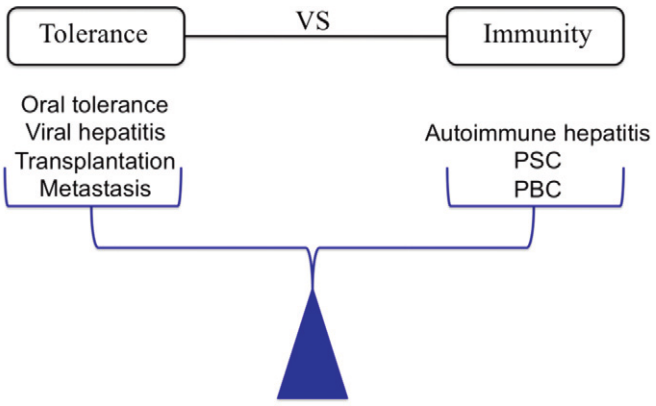

FIGURE 9.3. Role of the liver in tolerance and immunity. The liver exhibits a fine balance between the induction of tolerance and excessive immune responses. Examples of the liver as a tolerogenic organ include its role in oral tolerance, chronic hepatitis infection, and transplantation. In addition, the liver is among the most common sites of distant metastatic disease in patients with cancer. In contrast, the liver is also site of many autoimmune diseases such as autoimmune hepatitis, primary sclerosing cholangitis (*PSC*), and primary biliary cirrhosis (*PBC*).

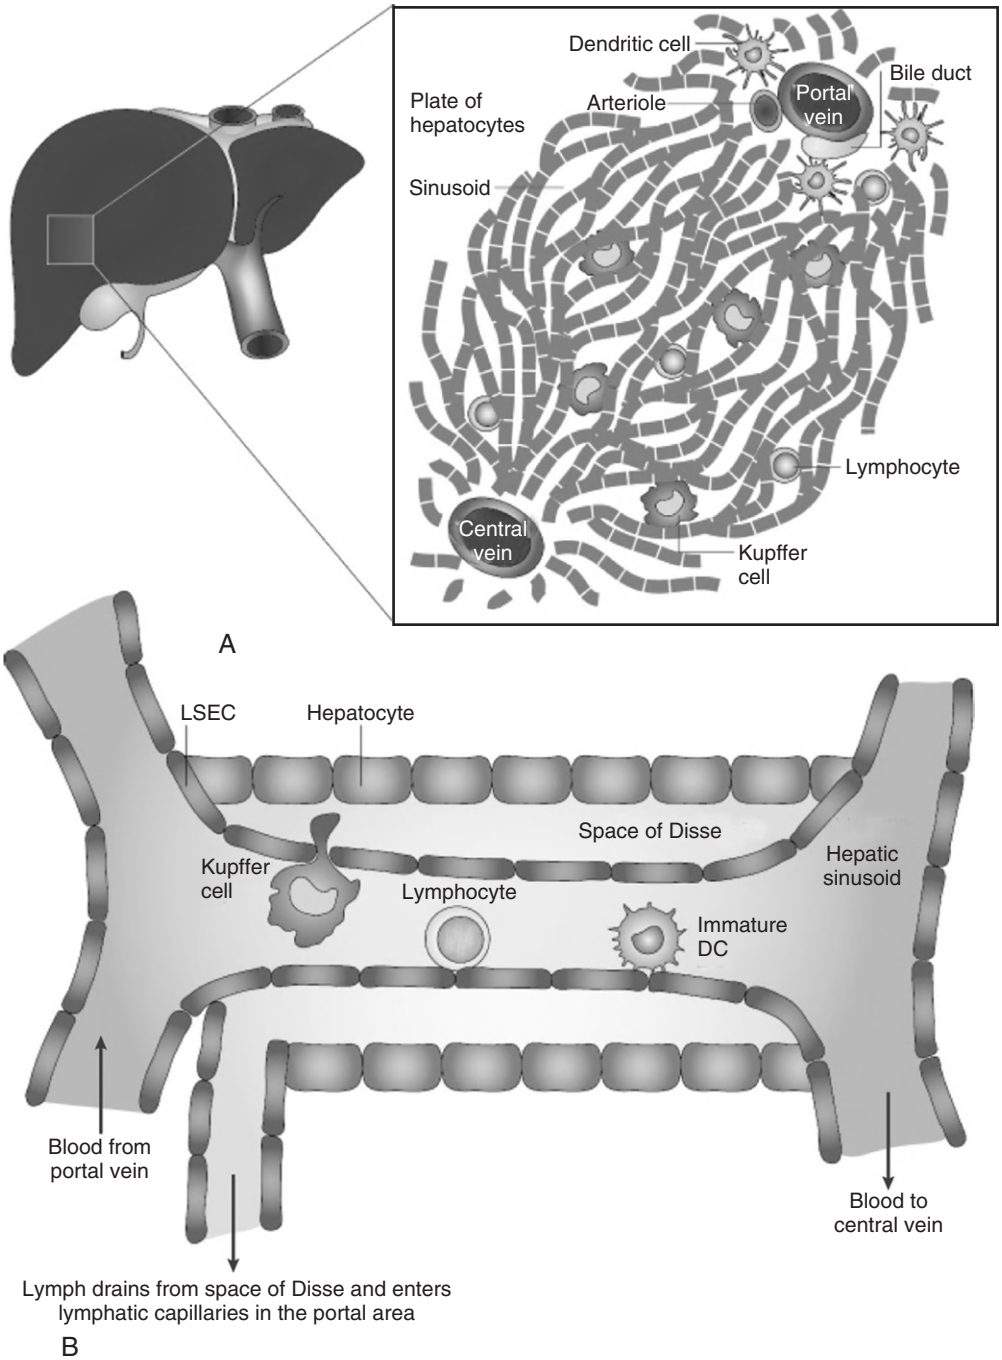

FIGURE 9.4. Microvascular hepatic anatomy. **A,** The liver is organized as lobules defined by their relation to portal vascular bundles and central veins. **B,** Liver sinusoidal endothelial cells (*LSECs*) line the hepatic sinusoids and have fenestrated membranes. A variety of immune cells exist within the sinusoids and are able to traverse the sinusoidal membrane to enter and exit the space of Disse, which is in contact with hepatocytes. *(From Crispe IN, 2003: Hepatic T cells and liver tolerance. Nat Rev Immunol 3:51-62. Copyright 2003, MacMillan Magazines Limited.)*

development of hepatic tolerance, because the depletion of either has been associated with a loss of oral tolerance. Liver DCs also have been suggested to play a role in liver tolerance, because as a group they have been shown to be less immunogenic than DCs from lymphoid organs such as the spleen (Bamboat et al, 2009). In addition, the numbers of several unusual cell types are elevated in the liver, and more recent studies have shown that multiple lineages of intrahepatic leukocytes are unique in function and phenotype compared with their counterparts from lymphoid organs. Controversy exists, however, as to whether these differences are due to de novo development, conditioning within the liver, or chemotactic signals in the liver that attract a unique population of cells. Regardless, the differences in composition and function are likely to play an important role in defining the nature of liver immunology. We devote a portion of this chapter to the major populations of liver immune cells and their role in various liver diseases.

LIVER IMMUNE CELLS

Although the liver is primarily a nonlymphoid organ, it contains numerous nonparenchymal cells (NPCs; see Chapter 6), one quarter of which are leukocytes. The composition of the intrahepatic leukocyte population is markedly different from that seen in other organs (Fig. 9.5). As in the rest of the body, however, the liver contains most of the cellular components of innate and adaptive immunity. Advances in technology have allowed for the precise delineation and isolation of cell types based on the expression of a distinct set of surface markers.

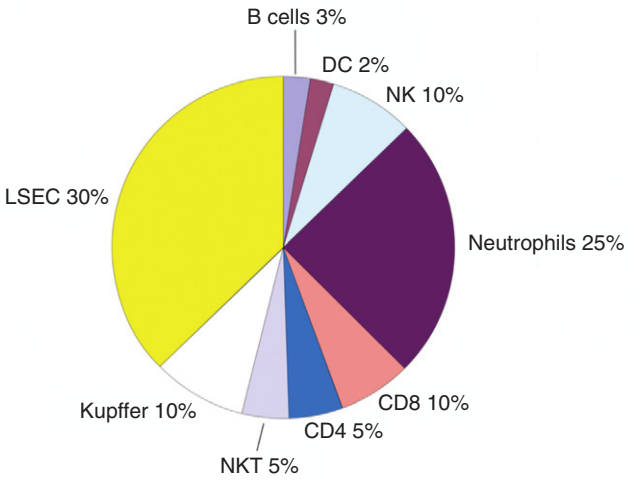

FIGURE 9.5. Human liver immune cell composition. After mehcanical and enzymatic digestion of freshly resected human liver specimens, hepatocytes were removed by centrifugation. Flow cytometry analysis was then performed on hepatic nonparenchymal cells (NPCs). Liver sinusoidal endothelial cells (*LSECs*) constitute most (~70%) of the liver NPCs. The liver has a particularly high proportion of CD8, natural killer (*NK*), NKT, and Kupffer cells. DC, dendritic cell.

Antigen-Presenting Cells

The experimental observation that antigens passing through the liver can lead to tolerance makes the understanding of antigen presentation in the liver particularly germane (Li et al, 2004). Antigen-presenting cells (APCs) play a crucial role in determining the nature of adaptive immune responses. The manner in which an APC presents any particular antigen can alter dramatically the response of antigen-specific T cells. Specifically, when antigen presentation occurs in conjunction with the appropriate costimulatory molecules, T cells proliferate and develop an immunogenic phenotypic and functional profile (Fig. 9.6). In contrast, antigens presented in the absence of costimulation lead to anergy or activation-induced T-cell death, two of the mechanisms of peripheral tolerance induction and maintenance.

Dendritic Cells

Dendritic cells (DCs) are rare, heterogeneous leukocytes that are primarily responsible for the capture of antigens in the periphery and subsequent presentation to immune effector cells. DCs are now recognized as the most potent APCs of the immune system and seem to arise from multiple hematopoietic cell lineages. Murine DCs are typically isolated based on their expression of the integrin CD11c. Immature DCs are specialized to capture antigens and then migrate to lymph nodes, where they can interact with T cells. After an encounter with pathogenic stimulus, such as bacterial lipopolysaccharide, DCs undergo phenotypic and functional changes, whereby their ability to capture antigens is diminished, but they increase their expression of MHC class II and T cell costimulatory molecules. Costimulatory molecule expression is essential in facilitating antigen presentation and efficient T cell activation. The ability of DCs to capture antigens in the periphery, translocate to areas rich in T cells, and then present antigens places DCs in a central role in immune regulation, bridging innate and adaptive immunity.

The body of literature studying the function of DCs grown in vitro from murine bone marrow progenitors or human

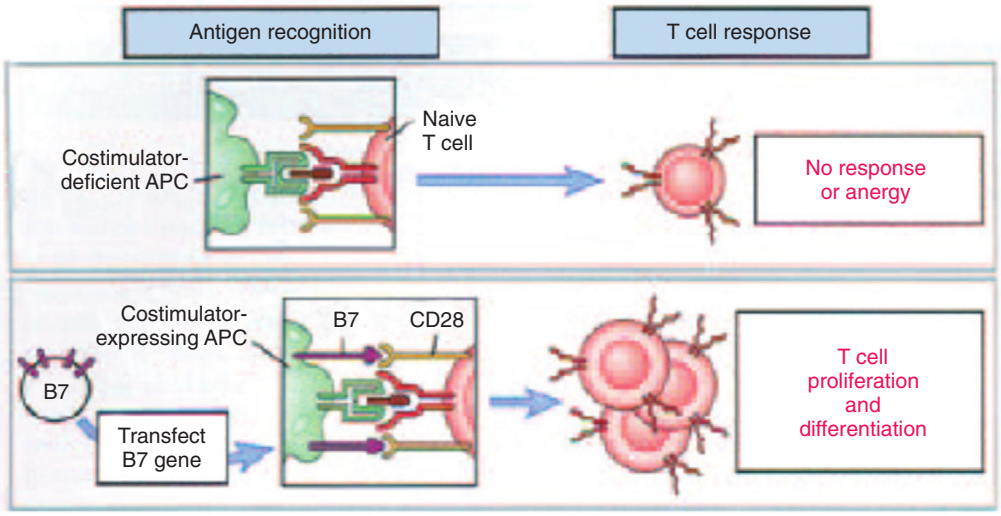

FIGURE 9.6. Antigen-presenting cells (*APCs*) and T-cell activation. The three main APCs are dendritic cells (*DCs*), macrophages, and B cells. The immune response depends on the context in which antigens are presented to T cells. The type of APC and the presence or absence of costimulatory molecules are important in determining whether a T cell has no response (anergy) or is activated. *(From Abbas AK, 2003: Cellular and Molecular Immunology. Philadelphia, Saunders.)*

peripheral blood mononuclear cells is vast. DCs isolated directly from the spleen, lymph nodes, or thymus also have been well studied. In contrast, because of the rarity of DCs in the liver, few studies have shown the phenotype or function of liver DCs. Initial studies focused on DC progenitors grown from liver nonparenchymal cells cultured with various cytokines, including granulocyte-macrophage colony-stimulating factor (GM-CSF). These early studies showed that liver DC progenitors are relatively immature cells with poor immunostimulatory ability that can promote immunologic tolerance and prolong solid organ transplants in animal models (Lu et al, 1994, 2001; Lau & Thomson, 2003).

To gain a better understanding of liver DCs as they function in situ, recent focus has been on studying freshly isolated liver DCs. In our initial studies, we wished to increase the number of liver DCs to facilitate their isolation. Because GM-CSF had been used to grow DC progenitors in culture from liver nonparenchymal cells, and because we had previously shown that in vivo GM-CSF overexpression increases the number of myeloid DCs in the spleen (Miller et al, 2002a), we suspected that it might expand liver DCs as well. We found that overexpression of GM-CSF using an adenoviral vector led to a dramatic increase in the number of highly immunostimulatory liver DCs (Pillarisetty et al, 2003). We also showed that a large proportion of the cells recruited to the liver by GM-CSF were DC precursor cells that develop into $CD11c^+$ DCs in culture, which suggests that DC development can occur in the liver. We used immunohistochemistry to locate both types of recruited cells. The liver DCs were concentrated around the central veins, whereas the DC precursors were distributed diffusely throughout the liver parenchyma.

Our experience with expanding liver DCs sheds light on in situ liver DC development, but we wished to understand the phenotype and function of liver DCs in normal, untreated mice. When our ability to isolate liver DCs from normal mice improved, we began to study them in depth. We found that compared with the relatively well-studied DCs from the spleen, $CD11c^+$ liver DCs were immature and only weakly immunostimulatory (Pillarisetty et al, 2004). We also noticed that, in contrast to spleen DCs, liver DCs are heterogeneous in their expression of MHC class II and costimulatory molecules. We further separated $CD11c^+$ liver DCs based on their expression of the myeloid marker CD11b and the lymphoid marker $CD8\alpha^+$, which have been commonly used to define murine DC subtypes. Myeloid ($CD11b^+$) and lymphoid ($CD8\alpha^+$) liver DCs, which each comprise approximately 10% of the total population of DCs in the liver, were as able to activate T cells as were their splenic counterparts. The bulk of the remaining cells, which had low to no expression of CD11b and CD8α, were only poorly immunostimulatory. This study showed that the presence of these atypical DCs was primarily responsible for the weakly activating nature of liver DCs on the whole. More recently, we discovered that despite having multiple APCs, the $CD11c^{hi}$ subset of DCs within the liver are required for effective presentation of soluble protein (Plitas et al, 2008). Using a transgenic mouse in which $CD11c^{hi}$ DCs can be depleted selectively, we found that activation of antigen-specific $CD8^+$ T cells in the liver only occurred in the presence of $CD11c^{hi}$ DCs.

Our investigation into liver DCs has now been extended into humans. We found that freshly isolated DCs from human liver exhibit tolerogenic properties when compared with autologous blood DCs. Liver DCs are weaker stimulators of T cells and favor the production of antiinflammatory IL-10, which induces the differentiation of naïve $CD4^+$ T cells into regulatory T cells with suppressive function (Fig. 9.7; Bamboat et al, 2009a).

Kupffer Cells

Liver macrophages, referred to as *Kupffer cells* (KCs), have long been believed to be the primary phagocytic cells of the liver. KCs represent the largest pool of macrophages in the body, derived from monocytic precursors in the blood. They are

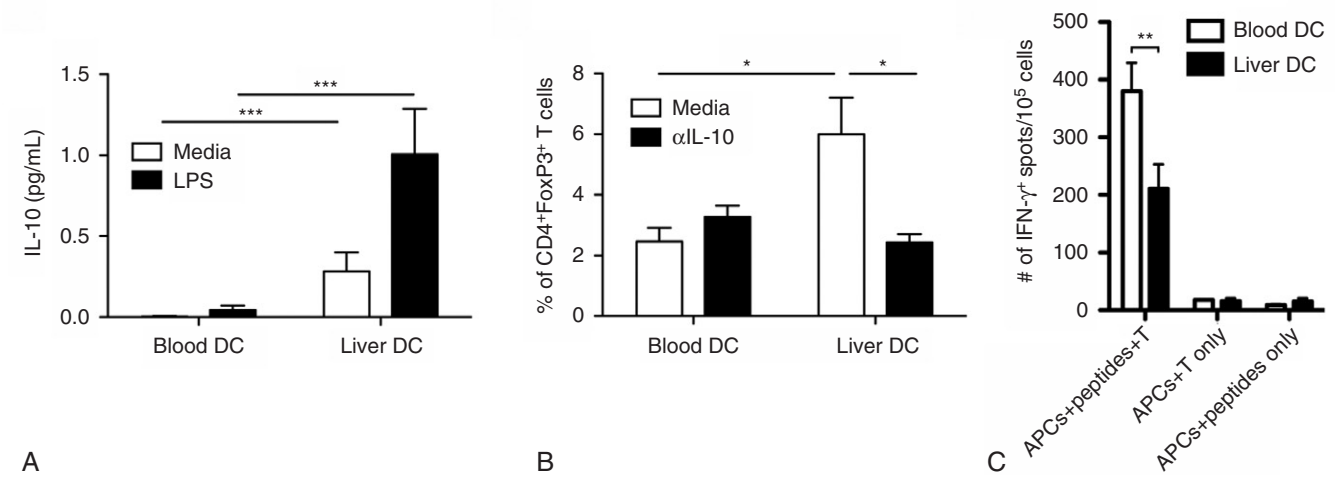

FIGURE 9.7. Human liver dendritic cells (*DCs*) are tolerogenic. **A,** Freshly isolated human liver and autologous blood DCs were cultured in media alone or in the presence of lipopolysaccharide (*LPS*). Supernatant interleukin-10 (*IL-10*) was measured 24 hours later. **B,** Liver and blood DCs were cultured with allogeneic naïve $CD4^+$ T cells in the presence or absence of an anti–IL-10 blocking antibody (αIL-10). After 5 days of culture, the T cells were restimulated using antibodies against CD3 and CD28. The percentages of $CD4^+FoxP3^+$ cells were determined 24 hours later using flow cytometry. **C,** Autologous antigen-specific $CD4^+$ T cells recognizing a pool of human leukocyte antigen (*HLA*) class II–restricted peptides (peptides) were generated by two rounds of stimulation with either liver or autologous blood DCs. The frequencies of interferon (*IFN*)-γ–producing $CD4^+$ T cells after 24 hours of culture with peptide-pulsed target cells (APCs + peptides + T) were then determined by enzyme-linked immunosorbent spot-forming analyses. Antigen-presenting cells (*APCs*) and T cells cultured alone made no detectable IFN-γ (not shown). $^*P < .05$; $^{**}P < .01$; $^{***}P < .001$.

typically found in the hepatic sinusoids; however, they also can migrate through the space of Disse to interact with hepatocytes (see Fig. 9.4). KCs have been thought to play a major role in antigen presentation and have been implicated in portal venous tolerance. Evidence also suggests that KCs may regulate T-cell responses to antigens and induce immune tolerance in the setting of liver allografts (Sun et al, 2003).

Techniques that allow for the more precise delineation of cellular subtypes have called into question some of the concepts about KCs and many other traditionally defined immune cells. Specifically, the advent of flow cytometry has allowed us to define cells by their surface marker expression, rather than simply by size or other crude physical characteristics shared by many cell types. This point is illustrated by the fact that many liver DCs express the cell surface marker CD11b, which is typically expressed by cells of monocytic lineage and has been used to define KCs in the liver. Much of the antigen-presenting ability previously attributed to KCs may be a result of DC function. The lack of consistent definitions of cells by cell surface marker expression and the continued use of less precise methods of cell isolation have led to continued ambiguity regarding KCs. An alternative explanation for the overlap in functional definitions for DCs and KCs is that DCs represent a more differentiated state of the KC lineage.

Liver Sinusoidal Endothelial Cells

Liver sinusoidal endothelial cells (LSECs) are highly specialized cells that line the hepatic sinusoids. LSECs are distinguished by the presence of fenestrations, or windows, in their cellular membranes. These fenestrations are believed to facilitate the selective passage of antigens between the sinusoid and the hepatic parenchyma. This strategic placement puts LSECs in the ideal position to interact with antigens and immune cells passing between the liver and the portal venous system.

Several studies have shown that in addition to serving as the building blocks lining the sinusoids, LSECs are immune cells with the ability to capture and present antigen and activate T cells (Knolle & Limmer, 2001). As with KCs, considerable controversy surrounds the immunologic function of LSECs. In contrast to earlier work, we have shown more recently that although LSECs are highly capable of capturing various antigens in vivo and in vitro, they lack the ability to activate T cells in the absence of exogenous costimulation (Katz et al, 2004). The differences in results may derive from the use of more specific methods of cell isolation in the latter study. The finding that LSECs are not independently capable of triggering a T cell–mediated immune response does not, however, exclude the possibility that LSECs, in concert with DCs or KCs, play an important role in antigen presentation in the liver.

Effector Cells

T Cells

As is the case for DCs, T cells are implicated in determining the liver's unique tolerogenicity. T cells are the primary effector cells of adaptive immunity. The nature of the interactions between APCs and T cells determines the overall character of the response to a particular antigen. It is difficult to know whether liver APCs or T cells are primarily responsible.

T cells are classified based on the types of antigen-recognition receptors present on their surface. Most of the T-cell subtypes in the body also have been identified in the liver. The broadest way to classify T cells is as either conventional or unconventional. *Conventional T cells* express the αβ T-cell receptor in association with either CD4 or CD8. These are the most prevalent T cells in the body and account for about one third of the murine liver T-cell population. In contrast, *unconventional T cells* expressing NK markers or the γδ T-cell receptor compose a greater proportion of liver T cells, about 50% and 10%, respectively. More recently, the discovery of the transcription factor FoxP3 has enabled the study of another family of T cells with immunosuppressive function. These $FoxP3^+$ or regulatory T cells coexpress either CD4 or CD8 and are present in the liver. Their relative contribution to liver tolerance remains to be defined.

The diversity of conventional T cells is based on their recognition of specific peptide antigen motifs within the context of MHC class I or II molecules on the surface of APCs. The αβ T-cell receptor is highly variable, and numerous T cells, each recognizing a different antigen presented by APC, are present in the immune system. $CD8^+$ T cells respond to peptides presented on MHC class I molecules, which are expressed by nearly every cell in the body, excluding erythrocytes. Activated $CD8^+$ T cells become cytolytic T lymphocytes. $CD4^+$ T cells also are called *helper T lymphocytes*; they recognize antigens presented on MHC class II molecules on the surface of professional APCs and are capable of regulating and further amplifying the immune response through the secretion of cytokines that act on nearby effector cells.

Liver T cells are divided into the same types of cells, as are the cells of lymphoid organs, however, evidence shows differences in the proportions of T-cell subtypes found within the liver. The interaction between $CD4^+$ and $CD8^+$ cells is clearly important, and more recent studies have suggested that the ratio between these two cell types—which is approximately 2:1 in the spleen, lymph nodes, and peripheral blood—is reversed in the liver (Crispe, 2003). Preliminary murine data from our laboratory, using more inclusive isolation techniques, have shown that the liver has a similar $CD4^+$ to $CD8^+$ T-cell ratio of approximately 1.5:1 as found in the spleen and node (Katz et al, 2005). Prior studies have shown that unconventional T cells are highly represented in the liver compared with the spleen or lymph nodes, and our data are in agreement with these findings.

γδ T cells

The γδ T-cell receptor is relatively invariant, but it can recognize multiple nonpeptide antigens without the need for MHC presentation. γδ T cells represent 10% of liver T cells, whereas they comprise only a small proportion (< 5%) of T cells in the blood or lymphoid organs. γδ T cells also are highly represented in the skin and at mucosal interfaces and are thought to play a regulatory role through their secretion of activating and modulatory cytokines as part of an early response to atypical bacterial and viral pathogens. They can influence the activation of γδ T cells and also have been shown to be crucial in tumor immunity through their early secretion of interferon γ (IFN-γ) (Gao et al, 2003). The high proportion of γδ T cells in the liver suggests that they have an important immunologic role, but further investigation is required. Similarly, both human and mouse livers are enriched with a large proportion of memory T cells. Although some investigators believe this is because the liver serves as a reservoir for activated T cells just before they die,

other theories include that the liver secretes chemokines that attract $CD8^+$ T cells.

Natural Killer T Cells

Natural killer (NK) T cells are a unique subset of lymphocytes that compose a small proportion of the total T-cell population throughout the body, but they are found in multiple organs. NK T cells share characteristics of conventional T cells and NK cells and are defined by the presence of several T-cell and NK-cell surface markers. Most NK T cells react against CD1d, which is a nonpolymorphic MHC class I–like glycoprotein that binds and presents glycolipid antigens. CD1d is expressed on APCs and hepatocytes. The synthetic glycolipid α-galactosylceramide, which binds CD1d and activates certain NK T cells, is the most well-studied glycolipid antigen. The complex of α-galactosylceramide bound to CD1d has been used to identify and isolate most NK T cells in mice and humans that express the invariant Vα14Jα28 T-cell receptor chain. The presence of such invariant T-cell receptor chains that are conserved across species suggests an important role for NK T cells in the innate immune response to pathogens. Activated NK T cells are capable of producing IFN-γ and interleukin-4 (IL-4), which are the prototypical helper T cell (Th1 and Th2) cytokines.

NK T cells constitute a relatively large proportion of T cells found in the liver compared with other organs. In addition, an expansion of NK T cells is seen in the liver in several models of liver injury, such as partial hepatectomy. NK T cells have been shown to play a role in the mechanisms of inflammatory diseases and clearance of infection in the liver. Depletion of NK T cells has been shown to abrogate the effects of an experimentally induced hepatitis in a mouse model, and mice lacking NK T cells are susceptible to a host of viral and bacterial infections. NK T cells are now also thought to play a part in tumor surveillance in the liver. Data from murine primary and metastatic tumor models have shown that NK T cells can mediate tumor rejection or suppression, in part because of their ability to secrete IFN-γ (Miyagawa et al, 2004).

Natural Killer Cells

NK cells are the primary respondents of innate immunity. Unlike T cells, NK cells do not possess clonotypic antigen receptors but still have the capability to respond to infected or transformed host cells. By expressing a variety of activating and inhibitory receptors, NK cells can bind ligands on their target cells. The resulting activation of NK cells causes the release of lytic granules, or cytokines such as IFN-γ, which kill the infected host of tumor cell in an MHC-unrestricted fashion. NK cells can also become activated by antibodies that are released B cells. The constant region of various antibodies bind Fc receptors on NK cells, causing antibody-dependent cytotoxicity of target cells.

NK cells have been shown to be a major component of murine and human liver lymphocytes (see Fig. 9.5) and are partially responsible for the inflammatory reactions seen in viral and autoimmune hepatitis. In addition, NK cells serve as the first line of defense against tumors in the liver. We recently discovered that bulk human liver NK cells possess weaker lytic capabilities when compared with autologous blood NK cells (Burt et al, 2009), because the liver has a greater proportion of NK cell subtypes, with weaker cytolytic function when compared with blood NK cells.

CYTOKINES

Cytokines (see also Chapter 10) are small signaling molecules produced by immune cells. They are proteins that typically act on nearby cells, but they also may have systemic effects. Cytokines can be roughly divided into two categories, those of *innate* and those of *adaptive* immunity (Table 9.1). Cytokines also can be distinguished based on whether they are *activating* or *inhibitory*, however, these distinctions are not always consistent. Additionally, the same cytokine can have different effects, depending on the setting and the particular cell on which it is acting. Although hundreds of cytokines have been described, we limit our discussion here to a select few that have been shown to be produced in, and have important effects on, the liver.

Tumor Necrosis Factor-α

Tumor necrosis factor (TNF)-α is one of the most important inflammatory cytokines. It directly regulates innate immunity; however, its effects are far reaching. TNF-α is primarily produced by macrophages in response to lipopolysaccharide present on the membranes of gram-negative bacteria. It also is secreted by T cells, mast cells, DCs, and NK cells. TNF-α was originally isolated from animals treated with lipopolysaccharide, and its name is derived from the fact that it was found to lyse tumors in vitro and in vivo. TNF-α has consistently been found to play a pathogenic role in acute liver failure in multiple animal models and in humans. TNF receptors are present on most cell types, and the TNF receptor family is a large group of proteins with myriad roles in inflammation and immunity.

Interleukin-6

Interleukin-6 (IL-6) is a pleiotropic cytokine that is highly expressed by the liver and has effects on innate and adaptive immunity. It is synthesized by DCs, macrophages, T cells, B cells, endothelial cells, fibroblasts, and keratinocytes. IL-6 is produced as an early response to TNF-α and is thought to amplify the inflammatory response in the liver through the induction of acute-phase protein production by hepatocytes. As part of its promotion of the early immune response, IL-6 also stimulates the differentiation of neutrophils from bone marrow precursors. Additionally, experimental models have shown that absence of IL-6 in cultures favors the differentiation of DCs; however, IL-6–knockout mice have normal numbers and types of DCs in their spleens and livers (Bleier et al, 2004). IL-6 also is known to play an important role in liver regeneration after trauma or hepatectomy.

Type I Interferons (Interferon-α and Interferon-β)

IFN-α refers to a family of structurally similar cytokines that are crucial in the immune system's defenses against viral infection. IFN-α is secreted by immune cells, whereas IFN-β is secreted by multiple cell types, such as fibroblasts, in response to their own viral infection. IFN-α was once thought to be produced by macrophages; however, more recent evidence has shown that plasmacytoid DCs are its primary producers (Siegal et al, 1999). Type I IFNs have direct antiviral action by triggering virally infected cells to produce enzymes that interfere with viral RNA or DNA replication. They also lead to the increased

Table 9.1

Cytokines Involved in Innate and Adaptive Immunity

Cytokine	Principal Source	Principal Target: Biologic Effects
Innate Immunity		
TNF-α	Macrophages, T cells, DCs	Endothelial cells: activation Neutrophils: activation Hypothalamus: fever Liver: synthesis of acute-phase proteins Muscle and fat: catabolism Multiple cell types: apoptosis
IL-1	Macrophages, endothelial cells	Endothelial cells: activation Hypothalamus: fever Liver: synthesis of acute-phase proteins
Chemokines	Macrophages, endothelial cells, T cells, fibroblasts, platelets	Leukocytes: chemotaxis, activation, migration into tissues
IL-12	Macrophages, DCs, NK DCs	T cells: Th1 differentiation NK DCs, NK cells, and T cells: IFN-γ synthesis, increased cytologic activity
IFN-α, IFN-β	IFN-α: macrophages, plasmacytoid DCs IFN-β: fibroblasts	All cells: antiviral state, increased inhibition of IL-12 production and expression of costimulatory and MHC class II molecules
IL-10	Macrophages, T cells (mainly Th2)	Macrophages, DCs: inhibition of IL-12 production and expression of costimulatory and MHC class II molecules
IL-6	Macrophages, DCs, endothelial cells, T cells	Liver: synthesis of acute-phase proteins
IL-15	Macrophages, others	NK cells: proliferation T cells: proliferation (memory $CD8^+$ cells)
IL-18	Macrophages	NK cells and T cells: IFN-γ synthesis
Adaptive Immunity		
IL-2	T cells	T cells; proliferation, increased cytokine synthesis; potentiates Fas-mediated apoptosis
IL-4	$CD4^+$ T cells (Th2), mast cells	B cells: isotype switching to IgE T cells: Th2 differentiation, proliferation NK DCs and NK cells: increased IFN-γ production
IL-5	$CD4^+$ T cells (Th2)	Eosinophils: activation, increased production
IFN-γ	$CD8^+$ T cells (Th1), NK DCs, NK cells	Macrophages: activation B cells: isotype switching to opsonizing and complement-fixing IgG subclasses T cells: Th1 differentiation Various cells: increased MHC class I and II expression, increased antigen processing and presentation to T cells
TGF-β	T cells (regulatory), macrophages, other cell types	T cells: inhibition of proliferation and effector functions B cells: inhibition of proliferation; IgA production Macrophages: inhibition
Lymphotoxin	T cells	Neutrophils: recruitment and activation Lymphoid organogenesis
IL-13	$CD4^+$ T cells (Th2)	B cells: isotype switching to IgE Epithelial cells: increased mucus production Macrophages: inhibition

TNF, Tumor necrosis factor; *DCs,* dendritic cells; *IL,* interleukin; *NK,* natural killer; *IFN,* interferon; *MHC,* major histocompatability complex; *Ig,* immunoglobulin.

expression of MHC class I molecules on the surface of virally infected cells, increasing their likelihood of being killed by cytolytic CD8+ T cells. Additionally, type I IFNs inhibit cellular proliferation. IFN-α has been used clinically in the treatment of viral hepatitis for decades.

Interferon-γ

IFN-γ is a type II IFN. It activates macrophages and plays a crucial role in bridging innate and adaptive immunity by increasing antigen presentation through the MHC class I and II pathways (Schroder et al, 2004). It is produced by T cells, B cells, NK T cells, DCs, and NK DCs. IFN-γ has many functions that are desirable for tumor immunotherapy, including a direct antiproliferative effect. Although not as crucial as the type I IFNs, the production of IFN-γ also is important in the clearance of viral infections within the liver.

IMMUNE SYSTEM IN LIVER DISEASES

The importance attached to understanding the cells that compose the immune system of the liver derives from the fact that many diseases that affect the liver are believed to have

immunologic origins. The following sections highlight the role of the hepatic immune system in a variety of diseases affecting the liver.

Transplantation

Transplant immunology has shed significant insight into the unique properties of the liver as an immunologic organ (see Chapter 96). Unlike other organs, the liver can be accepted across MHC barriers in animal models of transplantation (Qian et al, 1994). In addition, allograft recipients often develop systemic, donor-specific tolerance (Kamada et al, 1981). In humans, liver transplants confer protection from other organs from the same donor (Rasmussen et al, 1995), and recipients can often be weaned off immunosuppression altogether (Mazariegos et al, 1997). The comparative immune privilege of the liver highlights its role as a tolerogenic organ.

The development of mouse models of orthotopic liver transplantation have provided an opportunity to gain mechanistic insight into the regulation of immune responses in the liver (Qian et al, 1991). Of the factors that are thought contribute to hepatic tolerance (Table 9.2), microchimerism and induction of activated T-cell apoptosis have been the most intensively studied and widely accepted. Defined as the persistence of donor cells in recipients that accept their allografts, microchimerism has been postulated to be a prerequisite for organ allograft acceptance (Starzl et al, 1992, 1996). The high antigenic load derived from the donor liver coupled with persistence of donor APCs within lymphoid tissues of the recipient may provide a continuing source of allostimulation (Suzuki et al, 1988; Sriwatanawongsa et al, 1995). The persistent activation of alloreactive recipient T cells is thought to result in exhaustive deletion and induction of systemic tolerance. The role of specific donor-derived liver APCs, such as DCs and KCs, in contributing to chimerism-induced tolerance remains unclear. Although freshly isolated liver DCs have been shown to exhibit tolerogenic potential via the production of IL-10 (Bamboat et al, 2009a), others have shown that donor-derived liver DCs migrate into recipients' circulation and prime recipient T cells to differentiate into proinflammatory subtypes that promote rejection (Bosma et al, 2009).

The immunoregulatory role of KCs has also been extensively investigated. KCs have been implicated in the induction of oral tolerance and in lymphocyte apoptosis, which has been a proposed mechanism of immunosuppression in liver transplantation (Callery et al, 1989). More recently, KCs have been shown to play a crucial role in induction of antigen-specific T-cell tolerance (Breous et al, 2009) and are thought to suppress T-cell response via the production of prostaglandins (You et al, 2008). Despite evidence of the tolerogenic potential of KCs, the use of gadolinium chloride to suppress KC function has not been shown to impact survival of liver allografts in mouse models of liver transplantation. In addition, hepatocyte transplantation-induced liver inflammation has been shown to result in cytokines and chemokines associated with KCs (Krohn et al, 2009).

Activated T cells and their subsequent apoptosis within the liver are thought to be another critical component in the induction of hepatic tolerance and the acceptance of liver allografts. Donor-derived APCs deliver normal activating signals to recipient T cells in lymphoid tissues. These activated T cells subsequently migrate to the liver, secondary to inflammatory cytokines, where they encounter a large antigenic load that causes restimulation and apoptotic cell death (Huang et al, 1994; Crispe et al, 2000). The overall bias of intrahepatic T-cell responses toward tolerance and apoptosis might account for the survival of liver allografts (Crispe, 2003).

From a more clinical perspective, patients transplanted for end-stage liver disease secondary to hepatitis B or C often experience higher viral loads after transplantation secondary to the immunosuppressive regimen required to prevent rejection. Recurrent disease in the transplanted liver is inevitable and is therefore one of the most common reasons for allograft failure (Brown, 2005). Recent work using adoptive immunotherapy of donor lymphocytes provides some encouraging insight into dealing with recurrent viral disease in transplant recipients. Lymphocytes enriched in NK and NK T cells harvested from donor livers at the time of explanation were primed ex vivo for 2 days prior to reinjection into allograft recipients. Hepatitis C viral loads were found to be significantly lower at 1 month posttransplantation in patients treated with adoptive therapy versus noninjected controls (Ohira et al, 2009). Using human-hepatocyte chimeric mice, the authors showed that adoptive transfer of activated donor lymphocytes conferred protection via the production of IFN-γ. This makes sense, as the liver is enriched in cells capable of producing IFN-γ, such as NK, NK T, and $CD8^+$ T cells. Other groups have also shown that antigen-specific $CD8^+$ T cells are thought to be important in preventing recurrence of hepatitis in transplant recipients via the production of IFN-γ (Jo et al, 2009).

Although the hepatic immune system has been shown to clearly play an important role in liver and systemic tolerance, definitive mechanisms in humans remain elusive. Understanding the mechanisms controlling the tolerogenic propensity of the liver is of great significance in transplantation, as it will permit the design of novel approaches to reduce immunosuppressive-related morbidity and mortality.

Table 9.2

Factors Contributing to Hepatic Tolerance

1. Immunosuppression via release of soluble MHC class I antigens
2. Distinct lymphocyte population with distinct functions (KCs, DCs, NK and NK T cells, LSECs)
3. Constant antigen load from the portal circulation
4. Induction of activated T-cell apoptosis
5. Microchimerism
6. Immature phenotype and tolerogenic function of resident liver APCs (DCs, KCs, LSECs)
7. Altered Th1 versus Th2 profile within the liver (favoring Th2)

MHC, Major histocompatability complex; *KCs,* Kupffer cells; *DCs,* dendritic cells; *NK,* natural killer; *LSECs,* liver sinusoidal endothelial cells; *APCs,* antigen-presenting cells

Hepatitis

The viruses hepatitis B (HBV) and hepatitis C (HCV) are noncytopathic and hepatotropic, and they cause acute and chronic liver disease (see Chapter 64). The worldwide burden of disease is immense, with an estimated 500 million people infected with either of these two viruses (World Health Organization, http://www.who.int/mediacentre/factsheets). The cost to society is

magnified when the increased risk of developing cirrhosis and liver cancer in those infected with HBV and HCV are taken into account. Immune-mediated destruction of liver parenchymal cells is a common final pathway in viral hepatitis. The presence of large numbers of KCs and DCs in the liver, which produce TNF-α in response to viral antigens, leads to high local levels of inflammatory cytokines and untoward host cell damage. Similarly, T cells, NK T cells, and NK cells in the liver produce IFN-γ, which also serves to amplify the local immune response by activating KCs and DCs. Consistent with this, chronic active hepatitis is morphologically identified by piecemeal necrosis associated with a predominantly mononuclear cell infiltrate (Ferrari et al, 1999). Therefore to achieve successful viral control and limit collateral damage, a sustained, antigen-specific immune response is necessary (Gerlach et al, 1999; Maini et al, 2000).

The tolerogenic predisposition of the liver outlined in the transplantation section may account in part for the persistence of viral infection. A number of additional host parameters have been shown in experimental models to alter the immune response to viral hepatitis infection. Age can influence the outcome of infection, as vertical transmission to neonates generally results in persistent infection throughout life. The reason for persistent infection in younger hosts is thought to be related to neonatal tolerance and inability of the immune system to mount an effective immune response early in the course of infection, when these viruses are thought to be most vulnerable. In line with this hypothesis, chronic viral infection in animal models of hepatitis occurs more often when the initial insult fails to elicit an acute inflammatory response. In woodchucks, the absence of an acute infection following viral inoculation correlated with an indolent and chronic course of disease (Nakamura et al, 2001).

The precise mechanisms that account for persistent infection in hosts who are infected during adulthood are less clear. Immune-specific parameters that correlate with control of viral load include a coordinated helper and cytotoxic T-cell response against a number of viral antigens. Recognition of multiple viral epitopes by the host is also advantageous, as it theoretically minimizes the emergence of mutants that escape the immune system. Although significant strides have been made in understanding the immunopathogenesis of viral hepatitis over the past two decades, a cure remains elusive. Emerging research tools that will undoubtedly shed more light on the immune mechanisms underlying viral persistence and resistance to treatment include the development of chimeric mice that are reconstituted with human hepatocytes and immune cells (Manz & Di Santo, 2009). The transplantation of human hepatocytes into immunodeficient mice will allow for large-scale screening therapeutics against human hepatitis viruses. In addition, chimeric murine models will enable researchers to study the in vivo effects of human hepatotropic viruses on human immune responses to infection for the first time.

Cancer

The immune response to neoplastic cells has been shown to be a potential determinant of survival in several human malignancies including hepatocellular carcinoma (HCC) (Fu et al, 2007; Gao et al, 2007; Sasaki et al, 2008). In addition, recently published landmark studies revealed that the density, location, and functional capacity of intratumoral T cells can serve as a powerful predictor of outcome in primary colorectal cancer (Pages et al, 2005; Galon et al, 2006). The high prevalence of metastatic disease to the liver is likely due to multiple factors; however, evidence suggests that particular characteristics of the liver immune system may play an important role in this propensity. As delineated earlier, the primary mediators of innate and adaptive immunity found in the liver, DCs and T cells, are unique in their function and distribution of subtypes (Pillarisetty et al, 2004; Katz et al, 2005). In addition, freshly isolated liver DCs may promote the development of tolerance to antigens and have been found to be less immunogenic overall than their splenic and peripheral blood counterparts (Bosma et al, 2006; Bamboat et al, 2009a).

Although many investigators have attempted to manipulate the immune system for the treatment of cancer (Hunder et al, 2008), few attempts have been made to directly target intrahepatic immune cells. A report by Wagner and colleagues (2008) showed that intrahepatic T cells appear to be selectively activated in patients with colorectal liver metastases. Further evidence on the importance of the hepatic immune system in malignancy comes from recent data by our group, which reveal that 1) when compared with autologous blood, human liver specimens from patients with malignancy contain a disproportionately higher percentage of NK cells with reduced antitumor function (Burt et al, 2009), and 2) the hepatic T cell infiltrate predicts survival following surgery in patients with metastatic colorectal liver cancer (Katz et al, 2009). The hepatic immune system may therefore play an important role in explaining the liver's propensity for harboring metastatic disease.

The primary goal of cancer immunotherapy, particularly for liver tumors, is to reverse the tendency toward tolerance to tumor antigens. This reversal has been accomplished in animal models by activating DCs, T cells, NK cells, and monocytes. We previously showed the importance of IL-12 production by DCs in activating NK cells toward protection against tumor in a mouse melanoma liver metastasis model (Miller et al, 2002b). Since then, work by others has revealed that patients with low numbers of mature DCs within metastatic liver tumors have a worse prognosis (Miyagawa et al, 2004). Despite having less lytic potential than blood NK cells, we found that human liver NK cells do have the capacity to become potent antitumor cells when activated in the presence of KCs and TLR3 ligands (Burt et al, 2009).

In addition to DCs, recent work on the role of peritumoral monocytes in patients with HCC has garnered much attention among immunologists and hepatologists alike. Activated monocytes in the peritumoral stroma of HCC have been shown to foster a state of tolerance and promote tumor progression via the expression of an immunosuppressive antigen, programmed death ligand 1 (PDL-1) (Kuang et al, 2009). In addition, tumor expression of PDL-1 was recently shown to serve as a predictor of recurrence in patients with resected HCC (Gao et al, 2009). Blocking antibodies to molecules such as PDL-1 are currently in development for human use. Modulating the peritumoral interface may be a key step in harnessing the immune system to fight hepatic malignancies.

Autoimmune Hepatitis

Autoimmune hepatitis is an idiopathic disorder that leads to cirrhosis. In contrast to the preceding sections that highlighted disease states associated with hepatic tolerance, autoimmune

hepatitis is a manifestation of an overactive hepatic immune system. It has a female predominance and is characterized by elevated levels of immunoglobulin G (IgG) autoantibodies and increased responsiveness to immunosuppression (Obermayer-Straub et al, 2000). An experimental model of autoimmune hepatitis is based on the treatment of mice with concanavalin A (ConA), a plant lectin known to activate T cells in vitro. A single intravenous injection of ConA leads to severe liver damage and is associated with the activation of $CD4^+$ T cells and the production of TNF-α and IFN-γ. Further studies showed that NK T cells are the most important subset of $CD4^+$ T cells involved in mediating ConA hepatitis. The early activation of NK T cells also is associated with IL-4 production, which contributes to triggering autoimmune hepatitis. The importance of NK T cells in mediating autoimmune liver damage also is supported by the observation that injection of α-galactosylceramide, an activator of NK T cells through CD1d binding, leads to a similar form of injury as that seen in ConA hepatitis.

Primary Biliary Cirrhosis

Primary biliary cirrhosis is an autoimmune liver disease that leads to the destruction of intrahepatic bile ducts and subsequent cholestasis and cirrhosis (Bergasa et al, 2004; Lindor et al, 2009). Most cases of primary biliary cirrhosis (95%) are associated with antimitochondrial antibodies directed against specific enzymes located on the inner mitochondrial membrane. Antinuclear antibodies—usually associated with systemic lupus erythematosus, rheumatoid arthritis, and several other autoimmune diseases—are present in 50% of patients with primary biliary cirrhosis. Helper T cells and cytolytic T lymphocytes also are thought to be important in the pathogenesis of primary biliary cirrhosis. This is supported by the findings of lymphoid infiltration of the portal tracts and aberrant expression of MHC class II on biliary epithelial cells. Because biliary epithelial cells are the primary target of injury in primary biliary cirrhosis, their expression of MHC molecules and cytokines is likely to play an important role in the pathogenesis of this disease. In addition to increased MHC class II molecules, biliary epithelial cells from patients with primary biliary cirrhosis have elevated levels of intercellular adhesion molecule (ICAM) 1, and they attract mononuclear cells via the chemokine CX3CL-1 and overexpress the inflammatory cytokines IL-6 and TNF-α (Shimoda et al, 2009).

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) results from fibrosis of the intrahepatic and extrahepatic bile ducts (Lee & Jonas, 2007; see Chapter 41). The pathogenesis is thought to result from immune activation within the liver after bacteria gain access to the portal circulation via a diseased colon. The end result is biliary cirrhosis and a high risk of developing cholangiocarcinoma. Most cases of PSC are associated with underlying inflammatory bowel disease, specifically ulcerative colitis. In contrast to most autoimmune diseases, which predominantly affect women, PSC affects men twice as often as it does women. PSC is also associated with a particular MHC class II haplotype associated with other autoimmune disorders believed to be mediated by T cells. Although specific evidence that PSC is an autoimmune disorder remains to be elucidated, the disease is associated with T cells infiltrating the portal tracts. In addition, an increase in production of circulating proinflammatory cytokines has been shown to correlate with disease progression.

Ischemia/Reperfusion Injury

Liver ischemia/reperfusion (I/R) injury is a well-recognized consequence of trauma, circulatory shock, partial hepatectomy, and liver transplantation. It contributes to the shortage of organs available for transplantation and is a major determinant of postoperative allograft dysfunction and morbidity (Clavien et al, 1992). During liver I/R, the release of endogenous molecules signal danger to the host by activating innate immune cells through their interaction with TLRs (Lotze et al, 2007). Such "danger signals," or *danger-associated molecular patterns* (DAMPs), can be classified as intracellular proteins, nucleic acids, or components of the extracellular matrix that are released following host cell injury. The ensuing host immune response results in untoward collateral tissue damage that culminates in hepatocyte death and a systemic inflammatory response. The injury stems from the inability of TLRs on innate immune cells to distinguish infectious ligands from DAMPs released by autologous tissue. The need for effective approaches to manage patients with I/R-induced organ damage is highlighted by the fact that current treatment is merely supportive care.

Using a murine model of segmental liver I/R, we have recently discovered that hepatic DCs and TLR-9 play critical roles in modulating the host immune response during liver I/R (Bamboat et al, 2009b). Hepatocyte DNA released during ischemia binds TLR-9 on a variety of liver immune cells that cause liver damage. Using TLR-9–knockout mice, we found that the global absence of TLR-9 signaling confers protection from liver I/R injury (Fig. 9.8). Interestingly, the immune effects of TLR-9 activation appear to be cell specific. In neutrophils, host DNA binds TLR-9 and exacerbates injury through production of inflammatory cytokines and reactive oxygen species (ROS). In contrast, DCs respond to host DNA by curtailing injury via production of antiinflammatory IL-10, which confers protection by suppressing the function of inflammatory monocytes that migrate to the liver from the bone marrow (Fig 9.9).

Identifying mechanisms by which DCs and TLR-9 function as important regulators of the inflammatory response in liver I/R will enable development of novel strategies to limit untoward tissue injury. Extension of our murine I/R findings to humans have thus far revealed that freshly isolated human liver NPCs respond to ischemia- and hepatocyte-derived proteins by producing inflammatory cytokines (unpublished data). In addition, freshly isolated human liver DCs also have a propensity to secrete large amounts of IL-10 at baseline and after TLR activation (Bamboat et al, 2009a). Improved understanding of the complex interactions between DAMPs and PRRs on immune cells will promote the development of rational, more effective approaches to limit liver I/R injury.

Partial Hepatectomy

Unlike most other mammalian organs, the liver has the capacity to regenerate after resection or traumatic injury (see Chapter 90A). This unique property not only allows for partial liver transplantation from live donors but also enables surgeons to perform major hepatic resections for malignancy. The early response to hepatectomy involves the activation of NF-κB in liver NPCs and hepatocytes, which causes additional injury

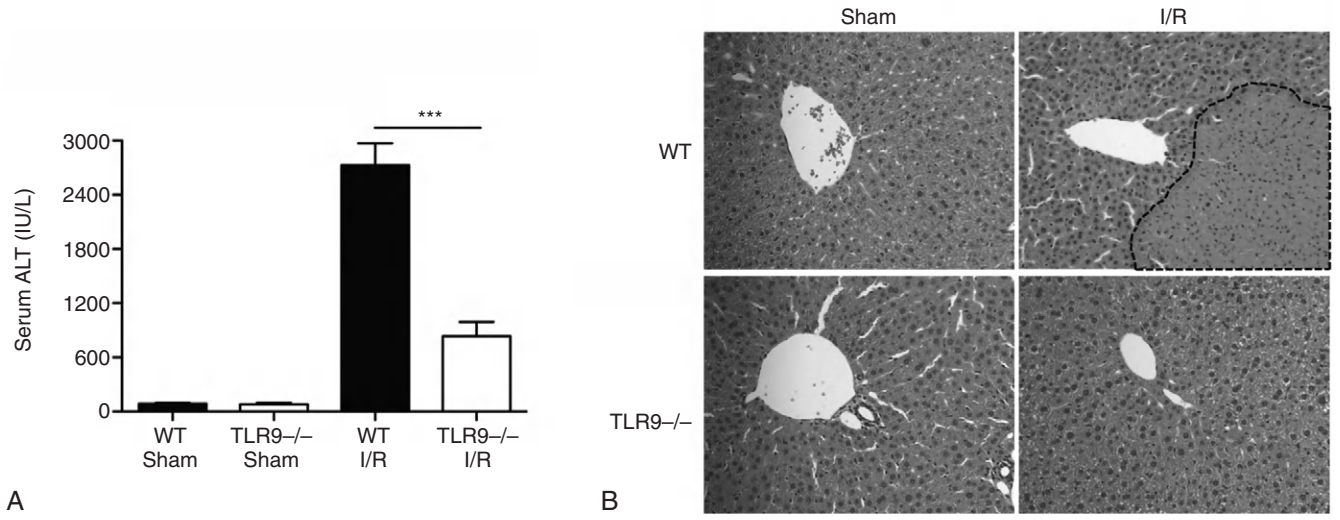

FIGURE 9.8. TLR9–/– mice are protected from liver I/R injury. **A,** Wild-type (WT) and TLR9–/– mice were subjected to sham laparotomy (Sham) or 1 hour of liver ischemia followed by 12 hours of reperfusion (I/R). Serum ALT was then measured. **B,** Hematoxylin and eosin–stained liver sections from the ischemic lobes of WT and TLR9–/– mice after sham procedure and 12 hours of liver I/R (original magnification ×200). Nonviable tissue is demarcated by the *dashed lines*. ***$P < .001$. *(From Wiley InterScience. Bamboat ZM, et al, 2009: Toll-like receptor 9 inhibition confers protection from liver ischemia-reperfusion injury. Hepatology 51[2]:621-632.)*

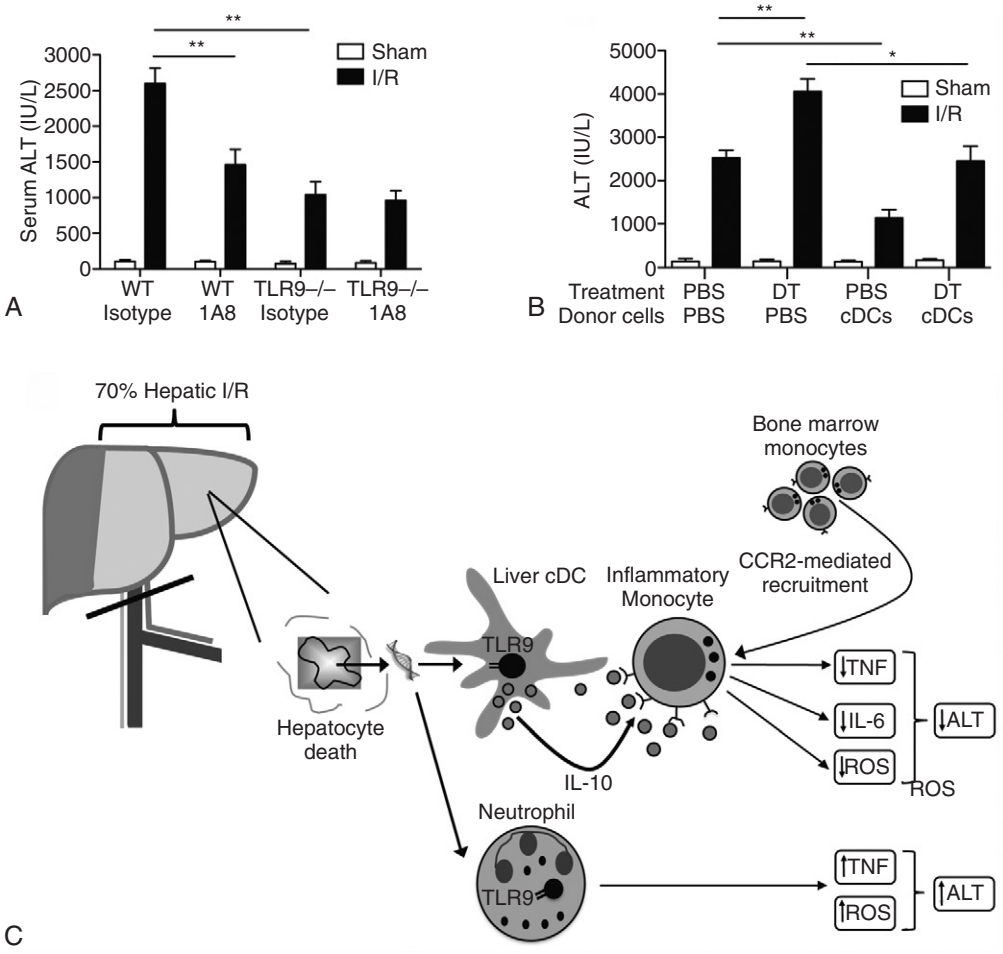

FIGURE 9.9. The role of Toll-like receptor 9 (*TLR9*) in neutrophils and dendritic cells (*DCs*) during liver ischemia/reperfusion (*I/R*). **A,** Wild-type (*WT*) and TLR9–/– mice were depleted of neutrophils using an antibody (*1A8*) or isotype control (*Isotype*). Mice then underwent sham laparotomy (*Sham*) or 1 hour of segmental ischemia followed by 12 hours of reperfusion (*I/R*). Serum alanine aminotransferase (*ALT*) was then measured. **B,** Conventional DCs (*cDCs*) were depleted selectively in transgenic mice via a single injection of diphtheria toxin (*DT*). Control mice were injected with saline (*PBS*). 12 hours later, mice were injected intravenously with cDCs or PBS just prior to sham or I/R. Serum ALT was measured 12 hours later. **C,** After segmental liver I/R (70% ischemia), the resultant hepatocyte death causes release of host DNA that activates cDCs and neutrophils via TLR9. cDCs produce interleukin-10 (*IL-10*), which suppresses the function of inflammatory monocytes. As a result, less inflammatory cytokines (tumor necrosis factor [*TNF*], IL-6) and reactive oxygen species (*ROS*) are produced, causing less liver injury. In contrast, neutrophil TLR9 activation causes an increase in TNF and ROS production, which increases ALT. *$P < .05$; **$P < .01$. *(**A,** From Wiley InterScience. Bamboat ZM, et al, 2009. Toll-like receptor 9 inhibition confers protection from liver ischemia-reperfusion injury. Hepatology 51[2]:621-632. **B** and **C,** Modified from the American Society for Clinical Investigation. Bamboat ZM, et al, 2010. Conventional dendritic cells reduce ischemia/reperfusion injury in mice via IL-10. J Clin Invest 120[2]:559-569.)*

through the production of ROS, TNF, and other inflammatory cytokines. Over time, IL-6 and IL-10 production increases, favoring a more antiinflammatory state that limits immune-mediated damage and promotes hepatocyte regeneration. Liver DCs have been reported to increase in number and function after partial hepatectomy in mouse models (Castellaneta et al, 2006). DCs produce more IL-10 and promote the development of antiinflammatory T cells from naïve precursors. In addition, increasing DC numbers via the administration of the growth factor fms-like tyrosine kinase 3 ligand (Flt3L) enhanced liver regeneration after partial hepatectomy. These data suggest that inherent tolerogenic properties of hepatic DCs may serve to promote hepatocyte regeneration after hepatectomy.

Like liver I/R, partial hepatectomy results in the release of a variety of danger signals that bind PRRs on innate immune cells, triggering a cascade of signaling events that modulate the rate of parenchymal regeneration. Deficiency in the intracellular signaling molecule, MyD88, which acts downstream of almost all TLRs (except TLR3), results in poorer outcome in mouse models of partial hepatectomy (Seki et al, 2005). In contrast, the absence of TLR3, which signals in a MyD88-independent manner, or blocking signaling of another PRR, the receptor for advanced glycation end products (RAGE), promotes liver regeneration and survival after massive hepatectomy (Cataldegirmen et al, 2005; Zorde-Khvalevsky et al, 2009). These data suggest that a balance exists between various TLRs and RAGE that governs the net effect of partial hepatectomy. Identification of mechanisms that limit regeneration after massive injury holds the key to expanding the limits of liver transplantation and salvaging livers and hosts overwhelmed by carcinoma and toxic insults.

Drug-Induced Liver Disease

The prevalence of liver failure as a result of drug-induced toxicity is increasing at an alarming rate and is the most common cause of acute liver failure in the developed world (Lee, 2007). The injury is characterized by toxin-induced hepatocyte death and activation of the innate immune system. This triggers a cascade of proinflammatory signals that result in further hepatocyte death and ultimately in liver failure. Through the use of mouse models of acetaminophen-induced liver injury, the roles of various components of the hepatic immune system have been well characterized. LSECs are thought to mediate liver injury by detecting hepatocyte DNA via TLR-9, resulting in production of pro–IL-1 and pro–IL-18, which are cleaved into their active forms by an intracellular protein complex called the *inflammasome* (Imaeda et al, 2009). Widespread inflammation ensues, resulting in additional parenchymal injury. The authors went on to show that administration of aspirin blocks inflammasome activation and the generation of active IL-1 and IL-18 and limits acetaminophen-induced liver injury.

In another set of elegant experiments using the same mouse model of liver injury, Chen and colleagues discovered how immune cells differentiate host danger signals from pathogenic ligands (Chen et al, 2009). An immune cell antigen, CD24, limits pathologic tissue damage by blocking PRR signaling from ligands released during sterile host cell damage. It fails, however, to block signaling from pathologic ligands that bind to the same PRR during infection. By understanding how immune cells distinguish between ligands released during infection and those encountered during sterile inflammation, researchers can develop approaches to curtail the progression of autoimmune diseases that are triggered by the release of host-derived danger signals.

Bacterial and Parasitic Liver Disease

Hepatic tolerance not only appears to be involved in the hyporesponsiveness to liver allografts but may also play a role in the vulnerability of the liver to various bacterial and parasitic infections (see Chapters 11, 66, 67, and 68). Pyogenic liver abscesses have increased in incidence as a result of more aggressive management of hepatobiliary diseases. The placement of stents for malignant biliary obstruction is the most common cause of hepatic abscesses. The host response to bacteria within the liver results in formation of an abscess in an effort to curtail the spread of infection. Neutrophils are recruited to the site of infection via chemoattractant signals released by the invading bacteria and activation of complement. Neutrophils then release cytokines and reactive oxygen species that promote inflammation and kill bacteria.

Helminthic infections of the liver such as schistosomiasis, echinococcus, and ascariasis have a hepatic phase in their life cycles. Animal models of schistosomiasis have helped in understanding the relationship between the hepatic immune system and the parasite. Eggs that are laid by adult worms in the portal vein get trapped within the hepatic sinusoids and trigger an immune response that results in granuloma formation. The early immune response mediated by eosinophils and neutrophils is proinflammatory. Later on, the cytokine profile within the liver becomes antiinflammatory and continues for the course of disease, ultimately resulting in liver fibrosis (Burke et al, 2009). KCs, IL-4, and IL-13 are thought to play a major role in shifting the cytokine profile during the course of schistosomiasis infection (Hayashi et al, 1999).

SUMMARY

The liver is an important immunologic organ with several unique features. It is constantly faced with the task of differentiating between nontoxic foreign antigens from the gut and those that may pose a significant threat to the host. Its propensity toward tolerogenicity in the setting of transplantation, infection, and malignancy is consistent with the finding that oral ingestion or portal vein injection can lead to antigen-specific tolerance. The liver contains a unique subset of immune cells that are, on the whole, less immunogenic than their counterparts found in lymphoid organs. Our understanding of the liver's immune system and how it relates to the immune system at large remains rudimentary, however, scientific investigation into this fascinating aspect of liver biology is rapidly accelerating, and it is hoped that this research will provide insight into how to modulate the immune system to treat the diverse array of liver diseases.

CHAPTER 10

Cytokines in liver, biliary, and pancreatic disease

Matthew J. Weiss

OVERVIEW

Cytokines are small, nonstructural proteins that are key regulators of the human response to noxious stimuli. Cytokines can be proinflammatory, antiinflammatory, or both depending on the timing and context in which they are secreted. Nearly all nucleated cells are capable of both synthesizing and responding to cytokines, but most cytokine genes are not expressed unless stimulated by a specific stressor. This chapter reviews the roles that specific stimuli—including endotoxin, microbial products, and cytokines—play in both the normal physiology and pathophysiology of liver, biliary, and pancreatic disease, with particular attention to surgical problems. Both a metabolic and immunologic organ, the liver has been the subject of extensive research, but cytokines undoubtedly play a role in pancreatic pathophysiology as well. The entire field of cytokine research has continued to grow exponentially since the last version of this text, with several key discoveries that are directly applicable to surgical practice. Exciting areas of therapeutics based on this new knowledge are also discussed.

MICROBIOLOGIC RECOGNITION AND TOLL-LIKE RECEPTORS

In mounting an immune response, the challenge to the host is to identify the presence of an infectious process early and to coordinate its considerable resources to eradicate the pathogen, while minimizing tissue damage and chronic inflammation. The recognition of microbial pathogens and the ability to distinguish self from nonself relies heavily on the innate immunity and cell surface receptors present on antigen-presenting cells in the liver (Akira & Hemmi, 2003). Antigen-rich blood from the portal circulation has the potential to activate either the innate and adaptive immune responses against infections or to maintain immunologic tolerance of harmless antigens (Tacke et al, 2009). In addition, the infiltration of monocytes during liver injury is an important adaptive mechanism leading to chronic infammation (Karlmark et al, 2009). The immune response to a biologic insult is a highly organized process that involves pattern-recognition receptors (PRRs) that identify preserved structures of different pathogens. Toll-like receptors (TLRs) are an important family of at least 10 PRRs that are ubiquitously expressed in humans (Akira & Takeda, 2004). Current evidence demonstrates crucial roles for TLRs in alcoholic liver disease, nonalcoholic steatoheaptitis, hepatitis B, hepatitis C, hepatic fibrosis and cirrhosis, hepatocellular carcinoma, primary biliary cirrhosis, acetaminophen-induced hepatotoxicity, and ischemia-reperfusion (I/R) liver injury, all of which are potential therapeutic targets (Pimental-Nunes et al, 2010; Table 10.1).

ENDOTOXIN STRUCTURE AND BIOLOGIC ACTIVITY

Lipopolysaccharides (LPSs) from gram-negative bacteria have a wide range of harmful biologic activities and are therefore also considered endotoxins (Dinarello, 2004). Research over the past decade has elucidated the mechanisms by which the host recognizes endotoxin and the innate immune response is initiated. Much more is known about the cell surface receptors and signaling pathways involved in the host response to endotoxin than is known about several other microbial products and TLRs. Although endotoxin has been implicated in the beneficial and injurious host responses to gram-negative infections, the exact role of endotoxin in the pathogenesis of human disease remains unclear. Similarities in host responses to various microbial products, including LPSs from gram-negative bacteria and the glycoconjugates of gram-positive bacterial and fungal infections, suggest that the host innate immune system has evolved to respond consistently to microbial invasion, regardless of its antigenic source (Fearon & Locksley, 1996).

Endotoxin is the major constituent of the outer cell wall of gram-negative bacteria and can comprise 65% by weight of the total bacterium. Endotoxin is shed spontaneously from the cell walls of living bacteria and is released in copious amounts upon cell death and cell lysis. Endotoxin comprises three major components: an inner lipid A, an intermediate R-core oligosaccharide, and an outer O-polysaccharide (Fig. 10.1). The inner lipid A portion and the R-core oligosaccharide generally are conserved, whereas the structure of the O-polysaccharide is unique for each strain of bacteria. The R-core oligosaccharide is exposed in rough forms of gram-negative bacteria. The internal lipid A moiety is poorly antigenic but seems to be a primary factor in inducing most of the biologic effects of LPS. Binding of endotoxin to serum proteins and its activation of host immunity through its cellular receptor are mediated predominantly via the lipid A moiety; the O-antigen is primarily immunogenic (Ulevitch & Tobias, 1999).

The host response to endotoxin is immediate (within minutes), is dose dependent, and affects all organ and tissue systems (Table 10.2). High-dose endotoxin exposure in rodents and primates reproduces the toxic effects of gram-negative bacteremia, characterized by hemodynamic collapse, shock, organ failure, and death (Beutler et al, 1985). Low-dose administration of endotoxin to human volunteers (Fong et al, 1990; Michie et al, 1988) produces a variety of constitutional

Table 10.1

Toll-like Receptors and Their Potential Targets for Gastrointestinal Diseases

Organ	Disease	Target
Stomach	*Helicobacter pylori* infection	2, 4, 9
	Adenocarcinoma	2, 4, 9
Pancreas	Acute pancreatitis	2, 4, 9
	Chronic pancreatitis	3
	Pancreatic cancer	2, 3, 6, 9
Liver	Alcoholic liver disease	4
	Nonalcoholic steatohepatitis	4
	Hepatitis B	3, 7, 8, 9
	Hepatitis C	3, 7, 9
	Fibrosis/cirrhosis	4, 9
	Hepatocellular carcinoma	3, 4
	Ischemia/reperfusion	2, 4
Colon	Inflammatory bowel disease	2, 4, 5, 9
	Adenocarcinoma	2, 4, 5, 9

symptoms consistent with a milder infectious process, including fever, myalgia, tachycardia, occasional hypotension, transient leukopenia followed by neutrophilia, and a hepatic acute-phase response (Table 10.3).

Although the host responses to endotoxin are likely to be dose dependent, there is now general acceptance that the clinical sequelae associated with systemic endotoxin administration are probably secondary to the host innate immune response rather than a result of direct interactions between endotoxin and cell membranes or secretory proteins (Fearon & Locksley, 1996; Ulevitch & Tobias, 1999). At high doses, endotoxin can produce direct endothelial injury, but most host responses to endotoxin are mediated by complement activation and the release of humoral factors, including proinflammatory cytokines, nitric oxide (NO), and prostaglandins.

IMMUNE REGULATION AND RESPONSE TO ENDOTOXIN (SEE CHAPTER 9)

The host defense against many gram-negative bacteria is dependent on the innate immune recognition of endotoxin, and this response must be highly sensitive and self-limited. The sensitivity of this system is crucial for prompt mobilization to combat infection, but a risk of severe immune-mediated pathology exists if this response not self-limited. Optimal sensitivity is achieved by the strictly ordered interactions of endotoxin with different extracellular and cell surface proteins, including lipopolysaccharide (LPS)-binding protein (LBP), cluster of differentiation (CD)14, MD-2, and Toll-like receptor 4 (TLR-4) (Gioannini & Weiss, 2007). The presence of endotoxin in the plasma and lymphatic system is initially recognized by serum proteins and lipoproteins, and this recognition initiates the activation of the innate immune response (Beutler et al, 2003). Redundancy is the hallmark of this activation process, as proteins, glycoproteins, lipids, and nucleic acids of prokaryotic origins are recognized by different TLRs and other components of innate immunity. For the most part, the innate immune system relies on cell surface receptors and hepatic secretory proteins, primarily opsonins, to recognize carbohydrate and lipid, protein, and DNA structures indicative of a microbial infection.

Different constituents of specific microbial products, including endotoxin, are recognized by different aspects of the innate immune system (Ulevitch & Tobias, 1999). The first step in the recognition of endotoxin by the innate immune system is its binding to a hepatic secretory protein, LBP, to form the LPS-LBP complex (Fig. 10.2). LBP is a member of a group of homologous lipid-binding proteins that function as lipid-transfer proteins (Tobias et al, 1986, 1989; Wright et al, 1989). Secreted by the liver and found in human blood in 2 to 20 mg/mL concentrations, LBP binds avidly to the lipid A moiety of endotoxin and mediates its transfer to the cell surface endotoxin receptor, CD14. Although CD14 functions as a ligand-binding protein for endotoxin-LBP complexes, CD14 is bound to the cell membrane through a glycosyl–phosphatidylinositol anchor, and it lacks an intracellular domain capable of transducing a

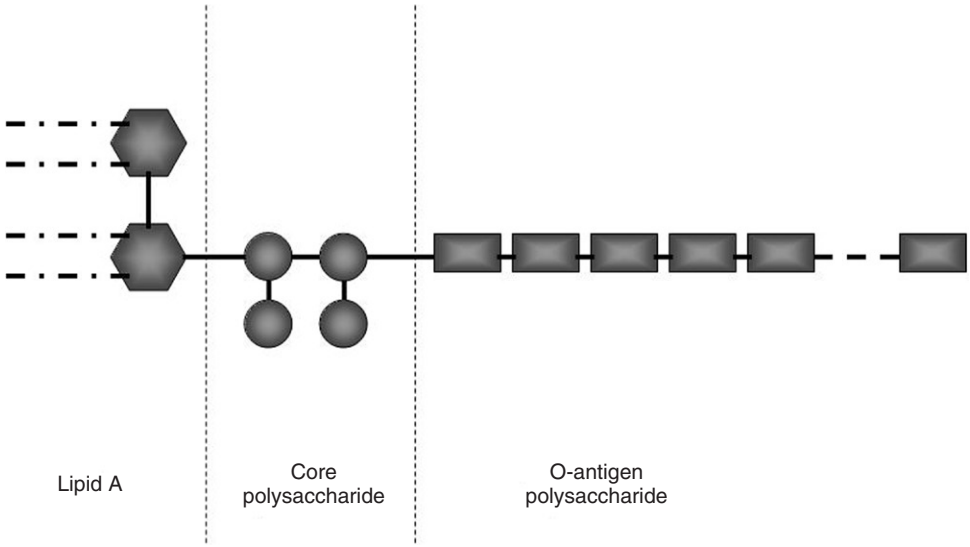

FIGURE 10.1. Schematic representation of the structure of endotoxin.

Table 10.2

Biologic Actions of Endotoxin

Fever

Direct effect on hypothalamus via prostaglandins
Indirect effect mediated by local interleukin production (IL-1, IL-6)

Hemodynamic Effects

Vasoconstriction
Direct effect
Secondary to sympathetic neurogenic activity
Indirectly caused by catecholamine and prostaglandin release
Vasodilation
Secondary to tissue hypoperfusion caused by vasoconstriction, endothelial injury, and reduced cardiac output
Indirectly caused by complement activation, neutrophil degranulation, prostacyclin and prostaglandin release, nitric oxide production
Produces pooling of blood in pulmonary and splanchnic vascular beds with hypotensive shock

Endothelial Cell Injury

Probable direct cell membrane damage by endotoxin at high concentrations
Prostaglandins, prostacyclin, procoagulants (e.g., tissue factor, factor V) and plasminogen activator inhibitor-1 release
Upregulation of adherence molecules with neutrophil adherence
Indirectly caused by TNF-α release

Intravascular Coagulation

Direct activation of the intrinsic and extrinsic pathways
Indirectly caused by release of tissue factor from monocytes and endothelial cells

Complement Activation (Antibody Independent)

Classical pathway activation (lipid A)
Alternative pathway activation (polysaccharide fraction)

White Blood Cell Effects

Transient leukocytopenia followed by leukocytosis, primarily a neutrophilia
Sustained monocytopenia and lymphopenia
Direct and indirect neutrophil activation and cytokine release, including TNF-α, IL-1α, IL-1β, IL-6, IL-8, CSF, PAF, procoagulants, prostanoids, and leukotrienes

Platelet Effects

Platelet aggregation and release of active constituents, direct effect of endotoxin and indirectly caused by release of PAF from monocytes/macrophages
Thrombocytopenia, probably secondary to platelet aggregation and intravascular coagulation

Activation of Reticuloendothelial System

Direct effect on tissue macrophages with release of secondary inflammatory mediators
Indirectly caused by proinflammatory cytokine release

Immunologic Effects

Specific B-cell antibody response to endotoxin antigens, especially potent O-antigen
Nonspecific polyclonal B-cell stimulation, indirectly caused by cytokines in response to IL-6 and IL-11 release
T-cell/macrophage regulation of antibody responses
B-cell release of CSF

Endocrine and Metabolic Responses

Increased resting energy expenditure
Increased plasma growth hormone, corticotropin, and cortisol
Increased lipolysis with raised plasma free fatty acid levels
Alterations in carbohydrate metabolism, increased gluconeogenesis, and glycogenolysis
Decreased albumin synthesis, increased acute-phase response protein production mediated by IL-6 and, to a lesser extent, TNF-α and IL-1

Organ-Specific Injury

Primarily lung, liver, and kidney
Secondary to microvascular effects and secondary cytokine release by infiltrating inflammatory cells

IL, interleukin; TNF, tumor necrosis factor; CSF, colony-stimulating factor; PAF, platelet activating factor

Table 10.3

Biologic Responses to Low-Dose Endotoxin in Human Volunteers

Constitutional Responses*

Fever (38° C to 39.8° C)
Headache
Chills
Myalgia
Photophobia
Nausea, vomiting

Cytokine/Hormone Responses

TNF-α (50 to 200 pg/mL)*
IL-6 (100 to 500 pg/mL)*
IL-1Ra (100 ng/mL)†
sTNFR (5 to 10 ng/mL)†
Corticotropin (80 to 120 pg/mL)*
Cortisol (350 to 500 ng/mL)‡
Epinephrine (50 to 60 pg/mL)*
Norepinephrine (375 to 450 pg/mL)*

Hemodynamic Responses

Tachycardia (90 to 105 beats/min)‡
Transient hypertension (increasing to 90 to 100 mm Hg)*

Leukocyte Responses

Transient neutropenia (<2000 cells/μL)*
Sustained delayed neutrophilia (>8000 cells/μL)†
Sustained lymphopenia and monocytopenia†

Metabolic Responses

Resting energy expenditure (20% increase)*
Increased free fatty acid concentration and appearance
Increased amino acid release and splanchnic uptake
Increased whole body and skeletal muscle protein breakdown
Increased gluconeogenesis and glucose oxidation

*≤4 hours' duration
†6 to 24 hours' duration
‡6 to 12 hours' duration
TNF-α, tumor necrosis factor α; IL, interleukin; s-TNFR, soluble TNF receptor

Data from Fong et al, 1990: The acute splanchnic and peripheral tissue metabolic response to endotoxin in humans. J Clin Invest 85:1896-1904.

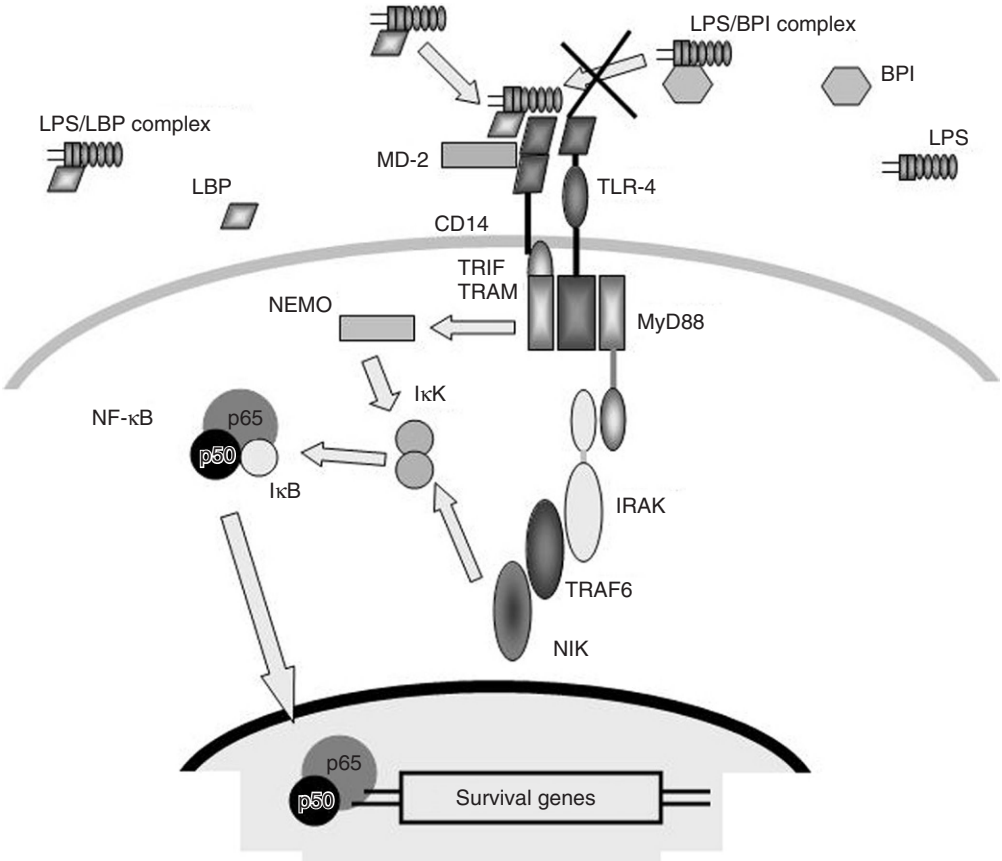

FIGURE 10.2. Endotoxin-binding proteins and signal transduction. Endotoxin in body fluids is rapidly recognized by endotoxin-binding proteins and lipoproteins. The balance between lipopolysaccharide binding protein (*LBP*) and bactericidal permeability–increasing protein (*BPI*) or high-density lipoprotein or both determines whether endotoxin in body fluids is detected by macrophages and other effector cells of the innate immune system. LBP-endotoxin complexes bind to CD14 and interact with Toll-like receptor-4 (*TLR-4*) and MD-2 membrane proteins, which activates intracellular myeloid differentiation response gene (88) (*MyD88*) dependent and independent pathways that ultimately lead to nuclear factor (NF)-κB activation and type I interferon production. IkB, inhibitor of NF-κB; IkK, inhibitor of NF-κB kinase; IRAK, interleukin-1 receptor–associated kinase; LPS, lipopolysaccharide; NIK, NF-κB–inducing kinase; NEMO, NF-κB essential modulator; TRAF, tumor necrosis factor receptor–associated factor; TRAM, Toll receptor–associated molecule; TRIF, Toll receptor–associated activator of interferon.

signal. LPS-LBP complex binding to CD14 alone is insufficient to transduce a signal.

The signal-transducing component of the CD14 bipartite complex protein has been identified as a member of the family of TLRs, specifically TLR-4 (Beutler, 2002). Although TLR-4 is expressed in several cells of healthy liver, signs of inflammation are absent because of low expression levels of TLR-4 and modulation of TLR-4 signaling. Mounting evidence suggests that altered LPS–TLR-4 signaling plays a role in the pathogenesis of chronic liver disease (Soares, 2010). TLR-4 seems to interact with CD14, the LBP-endotoxin complex, and a third protein, MD-2 (Viriyakosol et al, 2001).

Defining the complex role of CD14 in endotoxin-induced activation of TLR-4 is a challenge, and whether this role is obligatory remains unclear (Beutler et al, 2006; Jiang et al, 2005). However, the activation of TLR-4 by endotoxin does appear to require the simultaneous binding of endotoxin and TLR-4 by MD-2 (Gioannini et al, 2004). TLR-4 signaling can occur via a Toll-like and interleukin (IL)-1 receptor (TIR) domain and the formation of a scaffold composed of members of myeloid differentiation factor 88 (MyD88) adaptor proteins. At the same time, TLR-4 signaling also occurs through a MyD88-independent pathway that involves the adaptor protein TIR domain–containing adaptor inducing interferon-β (TRIF). This latter pathway seems to be more essential for the expression of type I interferons (IFNs) and IFN-dependent proteins in response to endotoxin exposure (Yamamoto et al, 2003). Although it is presently unknown how CD14-dependent signaling is integrated from the cell surface via TLR-4, the confirmation of TLR-4 as the signaling complex is important, because it identifies a signal transduction pathway and potential therapeutic targets.

The presence of LBP in the plasma increases the sensitivity of cells bearing CD14 to endotoxin by at least 1000-fold. From a teleologic standpoint, this has distinct advantages, because endotoxin can be detected, and innate immunity activated early, in response to gram-negative infection. However, increasing the sensitivity of the innate immune response to endotoxin can have devastating pathologic consequences, as may occur during sepsis or when gastrointestinal integrity is lost. These pathologic consequences include loss of vascular integrity, shock, organ failure, and death. Hosts have evolved several mechanisms to reduce the likelihood of an exaggerated endotoxin-induced signal.

High-density lipoproteins can bind endotoxin in serum and may play a role in protecting against endotoxemia (Cue et al, 1994). An additional endogenous mechanism to suppress

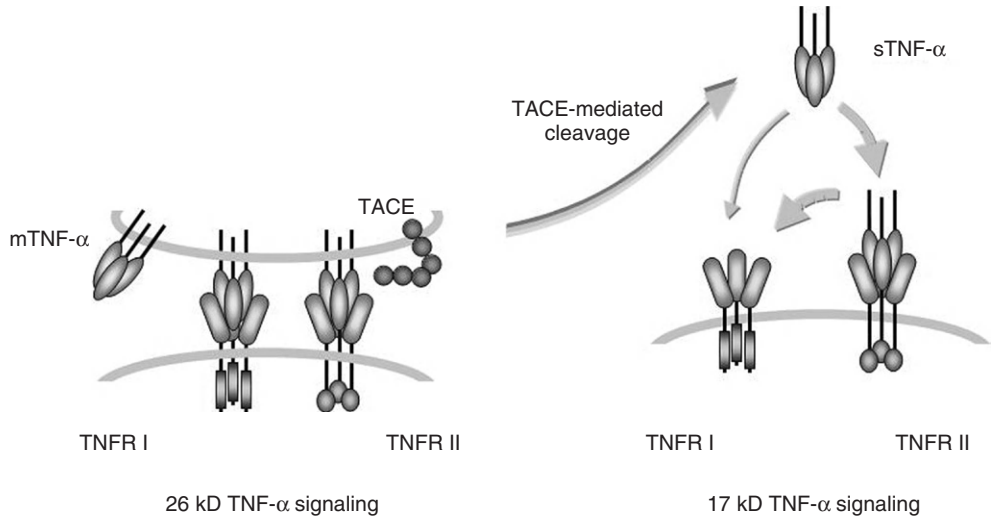

FIGURE 10.3. Processing of tumor necrosis factor (*TNF*)-α, which is initially synthesized as a 26-kD membrane-associated protein that is processed by TNF-α converting enzyme (*TACE*) to a secreted 17-kD homotrimer. Cell-associated and secreted molecules can bind and transduce a signal through two TNF receptors (*TNFRs*; p55 [type I] and p75 [type II]). mTNF, membrane TNF; sTNF, soluble TNF.

endotoxin responsiveness is through the release of an LBP-homologous protein, bactericidal/permeability-increasing protein (BPI; see Fig. 10.2). BPI is a 55- to 60-kD protein structurally similar to LBP, which binds endotoxin through its lipid A moiety. However, the resulting BPI-endotoxin complexes do not bind to CD14 or transduce a signal (Elsbach, 1998). BPI acts as an endogenous endotoxin inhibitor and has shown some modest beneficial effects in patients with meningococcal sepsis (Levin et al, 2000). In addition, BPI released from activated neutrophils can bind directly to endotoxin being expressed on the surface of gram-negative bacteria, and it is growth arresting and cytolytic for the bacteria (von der Mohlen et al, 1996).

BPI is stored in the granules of neutrophils and is released on neutrophil activation and degranulation. In a healthy adult, BPI levels in the serum are very low (15 to 50 ng/mL), but concentrations increase in response to an inflammatory or endotoxemic challenge (Calvano et al, 1994). In contrast, LBP concentrations are several logs higher in patients in the surgical ICU (2 to 20 mg/mL) and increase only modestly in response to inflammation. During infection, the ratio of LBP to BPI concentrations in the plasma approaches 1000:1, and this ratio favors endotoxin signaling. In closed-space infections infiltrated with neutrophils, however, BPI exceeds LBP concentrations, and BPI concentrations are directly proportional to neutrophil counts. These findings suggest that in the normal healthy adult and in patients with sepsis, the relationship between plasma LBP and BPI concentrations favors the recognition of endotoxin and activation of the innate immune response. In local infectious sites, where neutrophil and inflammatory cell recruitment has occurred, the increased BPI response is presumably compensatory and aimed at the continued activation of the immune system and reduction of bacterial growth.

Endotoxin signaling via the CD14 receptor and TLR-4 involves a novel IL-1 receptor-associated kinase, which activates a secondary kinase, NF-κB–inducing kinase (NIK) (Yang et al, 1999). Activation of this cascade rapidly induces the phosphorylation of additional kinases, which results in NF-κB translocation and the transcription of NF-κB–dependent genes (see Fig. 10.2). Genes containing NF-κB response elements are numerous and include most of the proinflammatory cytokines, including tumor necrosis factor (TNF)-α, IL-1, IL-6, IL-8, IL-12, IL-18, and IFN-γ (Blackwell & Christman, 1997).

Most of the systemic inflammatory responses to endotoxin are mediated by the release of proinflammatory cytokines and other humoral factors, predominantly TNF-α, IL-1, and IL-6 and, to a lesser extent, Fas ligand (FasL) (Suffredini et al, 1999). These proinflammatory cytokines not only globally regulate the inflammatory response to endotoxin, they also play a crucial role in reprogramming the metabolic and protein synthetic responses by the liver. As we will discuss in greater detail, TNF-α and IL-6 in particular play unique roles in regulating not only the hepatocyte acute-phase response to endotoxin but also hepatocyte proliferation versus apoptosis in liver regeneration (Michalopoulos & DeFrances, 1997; see Chapter 5), viral hepatitis (Hayashi & Mita, 1997; see Chapter 64), and toxic liver injury (Batey et al, 1999; Bradham et al, 1998; McClain et al, 1999). In contrast, FasL is a potent inducer of hepatocyte apoptosis and has been implicated in the pathogenesis of viral hepatitis (Kondo et al, 1997; Hayashi & Mita, 1997).

TUMOR NECROSIS FACTOR SUPERFAMILY

Since the discovery of TNF-α 35 years ago, the TNF superfamily has grown to comprise at least 20 related proteins that signal through greater than 30 receptors (Grewal, 2009). Members of the TNF superfamily are primarily homotrimeric proteins, with the exception of lymphotoxin, and they exist primarily in a membrane-associated form (Bazzoni & Beutler, 1996). As a general rule, members of the TNF family are primarily involved in the regulation of cell proliferation and apoptosis, although several of the members—including TNF-α, TNF-β, FasL, CD30L, and CD40L—also have proinflammatory properties.

TNF-α is synthesized as a bioactive cell-associated protein that is primarily involved in juxtacrine signaling of cytotoxicity. This 26-kD intermediate is enzymatically cleaved by a matrix metalloproteinase to a 17-kD secreted form that acts in a paracrine or endocrine fashion (Fig. 10.3). TNF-α originally was characterized as a factor that produced necrosis of solid tumors

Table 10.4

Biologic Activities of Tumor Necrosis Factor-α

Immune Cells	Nonimmune Cells	In Vivo
Monocytes-Macrophages	**Vascular Endothelial Cells**	**Central Nervous System**
Activate/autoinduce TNF	Modulate angiogenesis	Fever
Induce cytokines and prostaglandins	Increase permeability	Anorexia
Chemotaxis and transmigration	Prevent fibrinolysis	Altered pituitary hormone secretion
Stimulate metabolism	Increase coagulation	**Cardiovascular**
Inhibit differentiation	Suppress proliferation	Shock
Suppress proliferation	Rearrange cytoskeleton	Capillary leakage
Polymorphonuclear Leukocytes	Induce NO synthase	**Gastrointestinal**
Prime integrin response	Induce cytokines IL-1, IL-3R, G-CSF, GM-CSF	Ischemia
Increase phagocytic capacity	Induce prostacyclin	Colitis
Enhance production of superoxide	Induce E-selectin, ICAM, VCAM	Hepatic necrosis
Increase adherence to extracellular matrix	**Fibroblasts**	Inhibit albumin expression
Lymphocytes	Induce proliferation	Decrease hepatic catalase
Induce T-cell colony formation	Induce cytokines IL-1, IL-6, LIF	**Metabolic**
Induce superoxide in B cells	Induce metalloproteinases	Net lipid catabolism
Induce apoptosis in mature T cells	Suppress respiratory activity	Net protein catabolism
Activate cytotoxic T-cell invasiveness	Inhibit collagen synthesis	Release stress hormone
	Adipocytes	Insulin resistance
	Enhance release of free fatty acids	**Inflammatory**
	Suppress lipoprotein lipase	Activate cytotoxicity
	Endocrine System	Enhance natural killer cell function
	Stimulate corticotropin, prolactin	Mediate IL-2 tumor toxicity
	Inhibit TSH, FSH, GH	
	Enhance IL-1 inhibition of steroidogenesis	

FSH, follicle-stimulating hormone; G-CSF, granulocyte colony-stimulating factor; GH, growth hormone; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; IL, interleukin; LIF, leukemia inhibitory factor; TSH, thyroid-stimulating hormone; VCAM, vascular cell adhesion molecule

in vivo (Carswell et al, 1975). It subsequently was recognized that TNF-α modulates growth, differentiation, and metabolism in a variety of cell types; it can produce cachexia by stimulating lipolysis, inhibiting lipoprotein lipase activity in adipocytes, and stimulating hepatic lipogenesis; and it can initiate apoptosis in hepatocytes and lymphoid cells (Table 10.4; Ksontini et al, 1998).

TNF-α is a powerful inducer of the inflammatory response both directly and through stimulation of numerous downstream proinflammatory mediators. Secondary mediators that are known to be induced by systemically administered TNF-α include cytokines (IL-1, IL-2, IL-4, IL-6, IL-10, IL-12, IL-18, IL-23, type I and type II IFN, transforming growth factor-β, leukemia inhibitory factor [LIF], and macrophage migration inhibitory factor [MIF]), hormones (cortisol, epinephrine, glucagon, insulin, and norepinephrine), and assorted other molecules (acute-phase proteins, IL-1 receptor antagonist [IL-1Ra], leukotrienes, oxygen free radicals, NO, platelet-activating factor, and prostaglandins; Tracey & Cerami, 1994). Other principal biologic effects of TNF-α are listed in Table 10.4 (see Chapter 9).

Not only is TNF-α involved in tissue inflammation, but there is a growing recognition that it is also a prominent ligand for the activation of programmed cell death. Apoptosis occurs naturally during growth and development, but it may also result from certain pathologic conditions in which local and systemic production of TNF-α is increased. Hepatocytes are particularly sensitive to TNF-α–induced apoptosis, especially during simultaneous transcriptional inhibition (Leist et al, 1994).

TNF-α has been administered systemically in low doses to human volunteers and regionally in higher doses to sarcomas and melanomas. The physiologic responses to low-dose (50 mg/m^2) TNF-α administration were remarkably similar to the responses seen with low-dose endotoxin administration: fever and constitutional symptoms of pain, headache, myalgia, and nausea. Hematologically, the volunteers developed a rapid leukopenia, followed by neutrophilia with sustained lymphopenia and monocytopenia (van der Poll et al, 1992). Plasma IL-6 levels increased 40-fold, and the volunteers developed an acute-phase protein response. Prostaglandin (6-keto prostaglandin [PG] F_{1a}) production also was markedly increased. Metabolically, the patients exhibited increased lipolysis and glucose turnover (van der Poll et al, 1991b). There also were significant effects on the vascular endothelium. Within 1 hour, TNF-α administration induced activation of the fibrinolytic pathway, followed by activation of the coagulation cascade (van der Poll et al, 1991a).

At higher doses of TNF-α, as achieved with regional perfusion of limbs, the systemic release of large quantities of protein occasionally occurs, and the effects on the vascular endothelium are profound. Under these conditions, activation of the endothelium is evident by increased release of soluble selectins and integrins, and hemodynamic instability is common (Aderka et al, 1998; Zwaveling et al, 1996); therefore continuous monitoring for systemic leakage is required.

INTERLEUKIN-1 FAMILY

The IL-1 family of ligands and cytokines are similar to the TNF superfamily in that they are also primarily associated with inflammation. IL-1 possesses several biologic properties that result in increased expression of downstream proinflammatory genes. The most salient and relevant is the ability of

IL-1 to initiate and sustain the expression of cyclooxygenase type 2 and inducible NO synthase (Dinarello, 1996). This property accounts for the large amount of PGE_2 and NO produced by cells exposed to IL-1 or in subjects injected with IL-1. Other important proinflammatory properties of IL-1 are its ability to increase IL-8 synthesis and to express adhesion molecules on endothelial cell surfaces, which accounts for the infiltration of inflammatory cells into the extravascular space. IL-1 also potentiates the biologic activities of TNF-α, and modest doses of the two in combination can be lethal in experimental animals.

The original IL-1 superfamily consisted of two members: IL-1α and IL-1β. Currently, the IL-1 superfamily also contains IL-1Ra, IL-16, IL-17, IL-18, IL-33, and at least six other homologues in the IL-1 family (Schmitz et al, 2005). IL-1α and IL-1β are agonists, and IL-1Ra is a specific receptor antagonist for the IL-1 receptor family. The naturally occurring IL-1Ra seems to be unique in cytokine biology (Arend, 1993). The intron–exon organization of three primary IL-1 genes suggests the duplication of a common gene some 350 million years ago. Processing of IL-1α or IL-1β to "mature" forms requires specific cellular proteases. In contrast, IL-1Ra evolved with a signal peptide and is readily transported out of the cell and is termed *secreted IL-1Ra*.

Even under conditions of cell stimulation, human blood monocytes do not process or readily secrete mature IL-1α, which is probably only released by dying cells, as it is a key factor released by necrotic cells that promotes inflammation (Chen, 2007). The IL-1α precursor proIL-1α is synthesized in association with cytoskeletal structures (microtubules), which is in contrast to most proteins translated in the endoplasmic reticulum. ProIL-1α is fully active as a precursor and remains intracellular. The opposite is the case with the IL-1β precursor proIL-1β, which is not fully active, and a considerable amount is secreted after cleavage by a specific, intracellular cysteine protease, IL-1β–converting enzyme, or caspase-1. Caspase-1 plays a central role in the biology of IL-1β, IL-18, and IL-33 and has become a therapeutic target for modulating IL-1–based diseases (Martinon & Tschopp, 2004). IL-33 is an activator of Th2 cells and has recently been shown to play a protective role in the development of atherosclerosis (Miller et al, 2008; Sanada et al, 2007) and is thought to be released by cell death (Carriere et al, 2007).

Nearly all microbes and microbial products induce production of the three IL-1 family proteins, but stimulants of nonmicrobial origin also can elicit transcription and synthesis. Stimulants such as the complement component C5a, hypoxia, adherence to surfaces, and clotting of blood induce the synthesis of large amounts of IL-1 mRNA in monocytic cells without significant translation into the IL-1 protein.

Although animal experiments revealed that IL-1 was proinflammatory, a great deal of information has been gathered from studies in which humans have been injected with recombinant IL-1α or IL-1β. Humans have received IL-1α infusions as part of clinical trials following bone marrow transplantation because of its hematopoietic properties. Although the duration of leukopenia and thrombocytopenia were reduced, patients had serious signs of systemic inflammation that included fever, hypotension, and flulike symptoms, similar to endotoxemia (Smith et al, 1993). Interestingly, the exquisite sensitivity of humans to IL-1 given systemically was not appreciated from animal studies.

Table 10.5

Overlapping Biologic Activities of IL-1, TNF-α, and IL-6

	IL-1	TNF-α	IL-6
Endogenous pyrogen	Strong	Yes	Weak
Hepatic acute-phase inducer	Yes	Weak	Strong
Anorexia and cachexia	Yes	Yes	Yes
Induction of hypothalamic-pituitary-adrenal axis	Yes	Weak	Yes
Prostaglandin and NO synthesis induction	Strong	Strong	Weak
Shock producing	Yes*	Strong	No
NF-κB induction	Yes	Yes	No
Induction of hepatocyte apoptosis	Inhibitor	Yes†	No/inhibitor
Hepatic regeneration	Weak	Strong	Strong

The terms *weak* and *strong* are relative to the other two cytokines.
*Shock is not irreversible with IL-1.
†In the presence of transcriptional inhibition.
IL, interleukin, TNF, tumor necrosis factor; NO, nitric oxide; NF-κB, nuclear factor kappa B

INTERLEUKIN-6

IL-6 is another pleiotropic cytokine produced by a wide variety of cells, including T cells, B cells, endothelial cells, fibroblasts, monocytes, and macrophages. The biologic activities of IL-6 include immune regulation, hematopoiesis, inflammation, and oncogenesis (see Chapter 9). The IL-6 gene has been mapped to chromosome 7, and its product varies from 21 to 28 KD, depending on posttranslational modifications. IL-6 belongs to a much larger superfamily of related cytokines, including leukemia inhibitory factor, oncostatin M, ciliary neurotrophic factor, cardiotrophin-1, and IL-11. All members of this superfamily share a modest degree of structural homology, but more importantly, all these related cytokines use a common signal transduction pathway through heterocomplexes composed of gp130. Each ligand has its own receptor, which combines in a duplex to transduce its signal through the JAK/Stat signaling cascade.

Although microbial products are potent inducers of IL-6, the synthesis of IL-6 seems to depend on the release of more proximal cytokines, primarily TNF-α and IL-1. The biologic activities of IL-6 are numerous and can be divided into those involved in the regulation of the hematopoietic system and those involved in activation of the innate immunity. Recent studies have elucidated a crucial role for IL-6 in regulating the balance between T-regulatory cells and a new subset of T-helper cells that produce IL-17 (Kimura & Kishimoto, 2010). In the liver, IL-6 is secreted by Kupffer cells and is an important regulator of innate immune response and a stimulator of hepatocyte proliferation. Although IL-6 shares several biologic responses with TNF-α and IL-1, IL-6 is the predominant regulator of the hepatic acute-phase response and induces hepatocyte proliferation during liver regeneration (Table 10.5).

FAS LIGAND

FasL is another member of the TNF superfamily. Similar to TNF-α, FasL is synthesized and expressed first as a 40-kD membrane–associated protein and is then processed further by

matrix metalloproteinases to a homotrimeric 26-kD secreted form (Nagata & Golstein, 1995). Historically, FasL was presumed to have predominantly proapoptotic properties, especially for hepatocytes, and these were associated primarily with its membrane-associated form. Although it was noted that secreted FasL formed trimeric structures and retained its ability to ligate the Fas receptor, it was unclear whether soluble FasL could induce apoptosis (Schneider et al, 1998). A model of Fas activation has recently been proposed that distinguishes five separate stages (Lee et al, 2006). FasL occurs in a membrane-bound found and in a soluble form that is the result of splicing of the membrane-bound form. Studies in mice in particular suggested that the soluble forms of FasL may be receptor antagonists of Fas, which inhibit cell-associated FasL-mediated apoptosis.

The hypothesis that soluble FasL is strictly an inducer of apoptosis has been dispelled by several groups, who reported that soluble FasL also has proinflammatory properties. FasL can induce NF-κB through NF-κB–inducing kinase (NIK) signaling (Malanin et al, 1997). Ottonello and colleagues (1999) showed that soluble FasL in humans is endowed with potent chemotactic properties for neutrophils at concentrations incapable of producing apoptosis. FasL does not seem to activate neutrophils, only to recruit them; neutrophil calcium flux, superoxide production, and degranulation are not affected. Other investigators have come to similar conclusions (Chen et al, 1998; Seino et al, 1998). In addition, Park and colleagues (2003) suggested that FasL can activate blood monocytes. These authors showed that these inflammatory properties are separate and distinct from the proapoptotic properties of FasL. This observation is significant in part because it suggests that FasL, similar to TNF-α and other members of the TNF superfamily, may contribute to neutrophil and monocyte infiltration and recruitment as part of the host inflammatory response. This observation is particularly relevant in viral hepatitis, in which increased FasL expression and neutrophil infiltration have been observed.

Although FasL was originally thought to be expressed only by cells of the lymphoid or myeloid lineage—including predominantly T and B cells, phagocytes, and natural killer cells—it is now recognized that FasL frequently is expressed by nonlymphoid cells (Kiener et al, 1997; Liles et al, 1996). The Fas receptor, also called CD95 or Apo1, is widely expressed on a variety of cell types, including hepatocytes. The Fas receptor shares structural homology with the TNF receptor I (Fig. 10.4), and Fas signaling can also lead to proinflammatory events through the activation of NF-κB–dependent pathways, which may be responsible for some its chemotactic properties.

TRANSFORMING GROWTH FACTOR-β

TGF-β is another ubiquitously expressed cytokine that plays a role in several cellular functions, including apoptosis, cell cycle regulation, immune regulation, and inflammation (Massague, 2008; Bierie & Moses, 2006). TGF-β is produced in an inactive form that requires activation by proteases such as matrix metalloproteinase (MMP)2 and MMP9. Interestingly, TGF-β and its proteases are present at high levels in the periphery of certain tumors (Reiss & Barcellos-Hoff, 1997), and TGF-β also seems to be a potent inducer of fibrosis (see Chapter 6) and eventually of carcinogensis of the liver (see Chapter 8C). TGF-β signaling is via phosphorylation of Smad3, but the location of phosphorylation determines whether the effect will be oncogenic or tumor suppressive. Phosphorylation at the C-terminal region of Smad3 transmits a tumor-suppressor signal, and phosphorylation at the linker region initiates oncogenic sequelae. Therefore TGF-β signaling appears to play a role in chronic liver disease progressing to cancer. In addition, mutations in the genes encoding the receptors for TGF-β and decreased expression of downstream Smad proteins have been reported in pancreatic cancer (Derynck et al, 2001).

CYTOKINES IN THE LIVER AND PANCREAS

Regulation of Cytokine Expression in the Liver

Cytokine production by resident cell populations in the liver contributes significantly, not only to local cytokine appearance and organ homeostasis but also to the cytokines' emergence into the systemic circulation. Fong and colleagues (1990) cannulated the hepatic vein of human volunteers and examined the efflux of TNF-α and IL-6 from the splanchnic bed after intravenous endotoxin administration. Almost 40% of the TNF-α that appeared in the systemic circulation was derived from the splanchnic bed. Not only are Kupffer cells a potential source of proinflammatory cytokines in the liver, biliary epithelial cells and venous endothelial cells can also make significant quantities of cytokines, especially TNF-α, during liver regeneration (Bradham et al, 1998). In addition, resident and infiltrating T cells and natural killer cells can contribute significantly to TNF-α and FasL production, especially during viral-induced hepatic injury (Hayashi & Mita, 1997). There is some evidence that virally infected hepatocytes themselves can express TNF-α directly (Gonzalez-Amaro et al, 1994). TNF-α, IL-1, IL-6, and FasL expression is increased in the liver in response to intravenous endotoxin administration, generalized peritonitis, hepatic I/R injury, infected burn injury, and concanavalin A–induced hepatitis and during liver regeneration (Solorzano et al, 1997; Tannahill et al, 1999).

Cytokines and the Hepatic Acute-Phase Response

The local and systemic release of TNF-α, IL-1, and IL-6 provide anabolic signals to the liver that direct the increased synthesis of hepatic acute-phase reactant proteins (Table 10.6). IL-1 and IL-6 in particular act on the hypothalamic–pituitary axis to stimulate the release of corticotropin-releasing hormone, corticotropin, and cortisol, and these serve to facilitate the mobilization of free amino acids from skeletal muscle, connective tissue, and gut to the liver, where amino acid uptake is enhanced. These free amino acids become the precursors for increased protein synthesis and the altered protein synthetic pattern seen in patients with chronic inflammation and mediated directly by IL-6, IL-1, and to a lesser extent TNF-α.

These three cytokines transcriptionally suppress albumin synthesis, the primary protein secretory product of the liver in the healthy adult. Decreased albumin synthesis and hypoalbuminemia are well-described consequences of chronic liver disease, and the patient's plasma albumin concentration often has been predictive of adverse outcome in a variety of hospitalized patients. In addition, IL-6, IL-1, and TNF-α induce the transcription of a class of heavily glycosylated secretory proteins, termed *acute-phase reactants*. The number of acute-phase reactants synthesized by the liver in response to these cytokines

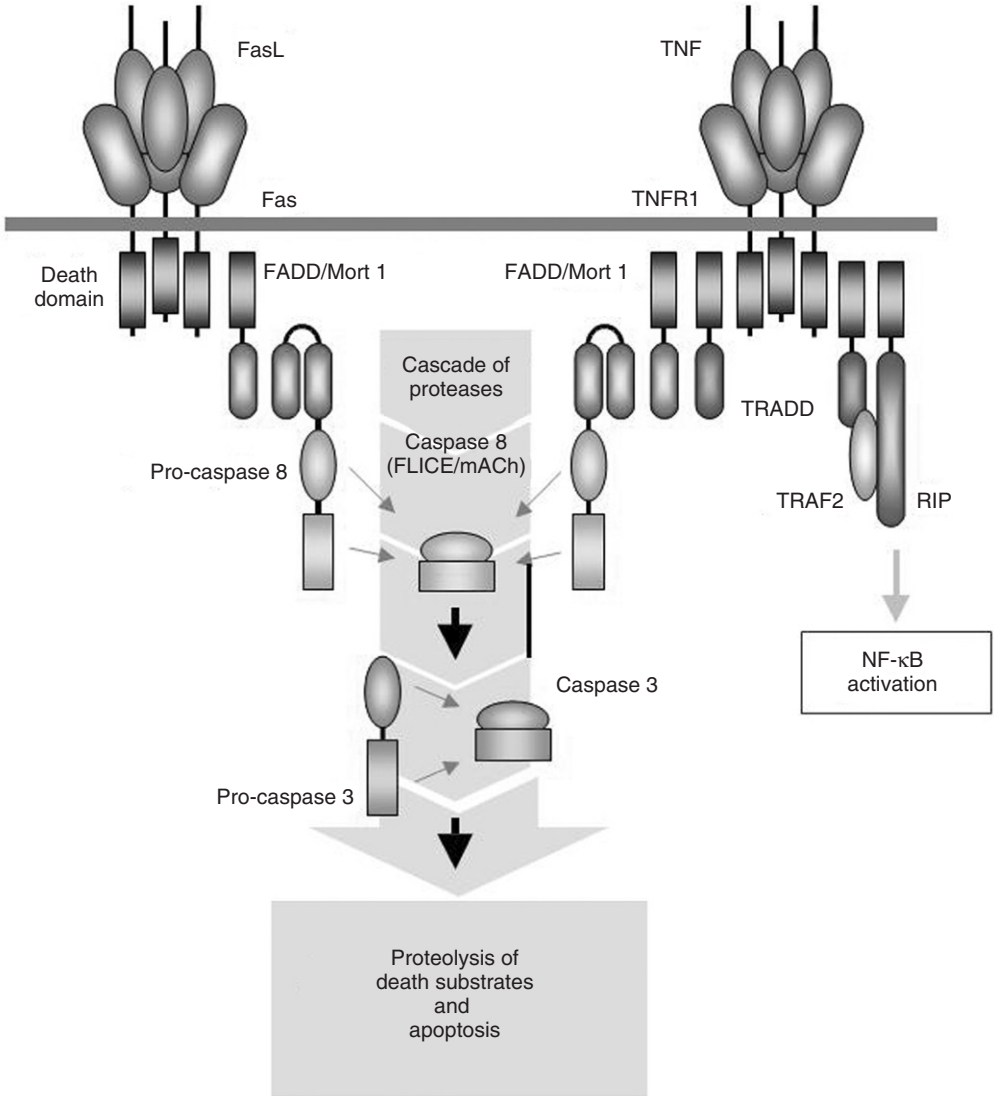

FIGURE 10.4. Tumor necrosis factor (TNF) receptor I and Fas signaling of apoptosis and nuclear factor (*NF*)-κB activation. TNF type I and Fas signaling share a common signal transduction pathway, leading to apoptosis through caspase-8 and caspase-3. TNF type I receptor signaling leads directly to NF-κB activation through a divergent tumor necrosis factor receptor–associated factor (*TRAF2*)-dependent pathway. Fas signaling also can induce NF-κB through NF-κB–inducing kinase (NIK) activation, but under in vivo conditions, Fas signaling is a weaker inducer of NF-κB than TNF type I receptor. FADD/Mort1, Fas-associated death domain; FLICE, FADD-like interleukin-1β–converting enzyme; mACh, muscarinic acetylcholine; RIP, receptor interacting protein; TNFR, TNF receptor; TRADD, TNFR type 1–associated death domain.

Table 10.6

Hepatic Acute-Phase Reactant and LPS Recognition Molecules

Molecule	Synthesis	Ligand	Function
C-reactive protein	Hepatic acute-phase reactant	Microbial polysaccharides	Complement activation, increased phagocytosis
Serum amyloid P	Hepatic acute-phase reactant	Microbial cell wall polysaccharides, extracellular matrix proteins	Increased phagocytosis, stabilizes extracellular matrix proteins and mannose binding
Hepatic secretory protein	Microbial cell wall polysaccharides	Binds collectin receptor and protein	Activates complement, increased phagocytosis
LPS-binding protein	Hepatic acute-phase reactant	Transfers LPS to CD14 and serum lipoproteins	Macrophage activation, enhances sensitivity to LPS
BPI	Neutrophil granules	Binds LPS and prevents transfer to LBP/CD14	Prevents LPS-induced actions
Soluble CD14	Plasma-protein derived, shed from monocytic cells	LPS and other microbial cell wall fragments	Enhances sensititvity to LPS, particularly in cells lacking CD14 but possessing TLRs
C3	Hepatic acute-phase reactant	Forms ester linkages with OH groups	Ligand attachment for CD21 and on proteins CD35

LPS, lipopolysaccharide; BPI, bactericidal permeability-inducing protein; LBP, lipopolysaccharide-bindng protein; TLRs, Toll-like receptors; CD, cluster of differentiation.

Table 10.7

Acute-Phase Reactants and Their Responses

Acute-Phase Proteins Whose Plasma Concentrations Increase

Complement System

C3
C4
C9
Factor B
C1 inhibitor
C4b-binding protein
Mannose-binding lectin

Coagulation and Fibrinolytic System

Fibrinogen
Plasminogen
Tissue plasminogen activator
Urokinase
Protein S
Vitronectin
Plasminogen activator inhibitor 1
Antiproteases
α_1-Protease inhibitor
α_1-Antichymotrypsin
Pancreatic secretory trypsin inhibitor
Inter-α-trypsin inhibitor

Transport Proteins

Ceruloplasmin
Haptoglobin
Hemopexin

Participants in Inflammatory Responses

Secreted phospholipase A_2
LPS-binding protein
IL-1–receptor antagonist
Granulocyte colony-stimulating factor

Others

C-reactive protein
Serum amyloid A
α_1-acid glycoprotein
Fibronectin
Ferritin
Angiotensinogen

Plasma Proteins Whose Plasma Concentrations Decrease

Albumin
Transferrin
Transthyretin
α_2-HS glycoprotein
α-Fetoprotein
Thyroxin-binding globulin
Insulin-like growth factor I
Factor XII

LPS, lipopolysaccharide; IL, interleukin.

Modified from Gabay C, Kushner I, 1999: Acute-phase proteins and other systemic responses to inflammation. N Engl J Med 340:448-454.

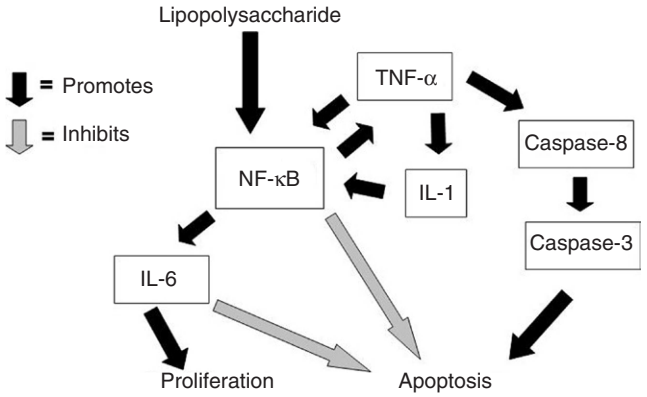

FIGURE 10.5. Hepatocyte fate is determined by the balance between tumor necrosis factor-α (*TNF-α*)–mediated nuclear factor (NF)-κB activation and apoptosis. TNF-α signaling simultaneously activates pathways that induce and antagonize capase-dependent apoptosis. Drugs or agents that inhibit NF-κB activation promote apoptosis, whereas cytokines that induce NF-κB protect against TNF-α–mediated apoptosis. IL, interleukin.

is quite large and has already been reviewed (Gabay & Kushner, 1999). As a class, the acute-phase proteins have diverse biologic functions (Table 10.7), but many of these proteins are recognition molecules of the innate immune system, including C-reactive protein, MBP (collectin), LBP, amyloid A, and amyloid P (Fearon & Locksley, 1996). These proteins bind microbial polysaccharides or LPS and either activate complement or enhance phagocytosis. Other acute-phase reactants—such as α_1-antitrypsin, α_1-antichymotrypsin, and tissue inhibitors of metalloproteinases—are protease inhibitors, whereas some, such as haptoglobin and hemopexin, are antioxidants. The function of these latter two groups of acute-phase reactants is to reduce local tissue damage secondary to activation of the innate immune response.

Cytokines and the Pancreas

Many pathways that regulate pancreatic development have already been identified and include TGF-β, Notch, Hedgehog, fibroblast growth factor, and epidermal growth factor (EGF) (Rane, 2006; see Chapter 1A). Dysregulation of these pathways appears to be important in many pancreatic disease states.

Much of the current data pertaining to the role of cytokines in the pancreas comes from the diabetes, pancreatitis, and adenocarcinoma literature. It is known that islet cells produce a variety of cytokines in response to both physiologic and pathologic exposure to nutrients (Donath et al, 2010). The inflammatory mediators of cytokine production are produced by α, β, endothelial, ductal, and immune cells. A chronic state of metabolic stress is believed to induce an inflammatory state that leads to islet cell dysfunction and insulin secretion failure. A significant role for TGF-β in the progression of type 1 diabetes has been demonstrated in mice (Baxter et al, 1995).

TGF-β proteins are regulators of pancreatic cell function and appear to have key roles in the development of nondiabetic pancreatic disease as well. The first model of pancreatic adenocarcinoma was generated with overexpression of TGF-β (Greten et al, 2001). These mice developed fibrosis and then pancreatic adenocarcinoma. Additionally, TGF-β2 subset levels appear to be associated with advanced tumor stage (Friess et al, 1993). Patients with long-standing pancreatitis are thought to be at increased risk of developing adenocarcinoma. TGF-β levels are elevated in patients with chronic pancreatitis, and this appears to correlate with both fibrosis and hyperglycemia (Fogar et al, 1998).

Cytokines and Apoptosis

TNF-α seems to be a prominent ligand for the activation of cellular apoptosis, but how TNF-α induces apoptosis in hepatocytes remains unclear. Although hepatocytes are particularly sensitive to TNF-α–mediated apoptosis, the cells first must be exposed to transcriptional inhibition. Incubating cultured hepatocytes with TNF-α or administering TNF-α does not produce hepatocyte apoptosis unless D-galactosamine or actinomycin D is coadministered. The requirement for transcriptional inhibition is likely explained by TNF-α simultaneously activating signaling pathways in hepatocytes that both induce and antagonize apoptosis, suggesting a delicate balance among TNF-α signaling pathways (Fig. 10.5; Beg & Baltimore, 1996; Van Antwerp et al, 1996). Induction of the proinflammatory properties of TNF-α, induced in part through activation of NF-κB–dependent "survival genes," seems to inhibit apoptosis directly (Baker & Reddy, 1998). NF-κB is a ubiquitous transcription factor that plays a crucial role in the cellular response to signal transduction by TNF-α and IL-6. All members of this family (NF-κB) share a conserved region of approximately 300 amino

acids important for their dimerization, nuclear translocation, and DNA binding (Baeuerle, 1998). These NF-κB proteins form homodimers and heterodimers, and their activity is modulated by interactions with inhibitory proteins of the I-κB family.

These findings have several clinical implications. The role of NF-κB in the development of type 1 diabetes and its effect on β cells is still unclear, but both antiapoptotic and proapoptotic effects have been described (Donath et al, 2008). Recent studies suggest that enhanced activation of the NF-κB pathway via NIK overexpression may exist in pancreatic adenocarcinoma (Nishina et al, 2009). Robin and colleagues (2005) showed that alcohol abuse increases the sensitivity of hepatocytes to TNF-α–mediated apoptosis and hepatotoxicity. This increased sensitivity seems to be secondary to the failure of TNF-α to induce NF-κB activation in the livers of animals after alcohol abuse. Similarly, radiation to hepatocytes prevents induction of survival genes and increases the apoptotic response to TNF-α (Christiansen et al, 2004). In contrast, ischemic preconditioning seems to protect livers from subsequent apoptotic cell death secondary to induction of NF-κB and IL-6 (Iwasaki et al, 2002). In contrast, activation of TNF-α signaling of caspase-8 and caspase-3 via tumor necrosis factor receptor type 1–associated death domin/Fas-associated death domain (TRADD/FADD) leads to apoptosis through pathways shared by FasL signaling. The balance between these two pathways ultimately determines whether a cell responds to TNF-α by proliferating or undergoing apoptosis (Beg & Baltimore, 1996;Van Antwerp et al, 1996).

The role that specific cytokines play in apoptotic liver injury secondary to endotoxin administration has been well characterized. Similar to high-dose TNF-α in the absence of transcriptional inhibitors, high-dose endotoxin administration results in significant liver injury secondary to hepatocyte necrosis, although hepatocyte apoptosis is minimal (Bohlinger et al, 1996). Simultaneous inhibition of transcription, either by depleting hepatocyte nucleotides with D-galactosamine or by blocking transcription with actinomycin D, results in a 1000-fold increased sensitivity to endotoxin-induced lethality, and the hepatic injury is characterized by massive liver apoptosis (Solorzano et al, 1997). The liver injury seems to depend primarily on TNF-α expression, although FasL, interferon-γ, IL-12, IL-18, and IL-23 probably also contribute. Mice lacking either TNF-α or the TNF type I receptor are completely protected from endotoxin and D-galactosamine–induced hepatocyte apoptosis and mortality, whereas they are still susceptible to high-dose endotoxin-induced lethality. Fas agonists differ from TNF-α in that they apparently can induce massive hepatocyte apoptosis in the absence of transcriptional inhibition. The differential response to apoptosis mediated by TNF-α and FasL seems to be related to the observation that FasL is a significantly weaker inducer of NF-κB than is TNF-α. IL-1 and NO protect hepatocytes from TNF-α–mediated apoptosis, presumably by stimulating NF-κB activation and inhibiting caspase activities (Bohlinger et al, 1996). Caspases play central roles as the "suicide effectors" of hepatocyte apoptosis, demonstrated by the treatment of mice with broad-acting caspase inhibitors to prevent apoptotic liver injury and mortality (Kunstle et al, 1997; Mignon et al, 1999).

Nitric Oxide

Oxidative stress has been implicated in the pathogenesis of apoptosis, cancer, diabetes, hypertension, and inflammation. This implies that it may be a final common pathway by which numerous diseases exert their harmful effects. The contribution of NO to liver injury and apoptosis is complex. NO is a lipophilic, short-lived molecule (with a half-life of seconds) that physiologically seems to have roles in vasodilation, immune response, apoptosis, and protection of cells from oxidative killing (Wink et al, 1999). NO derived from NO synthase originating in endothelial cells and other nonparenchymal liver cells seems to be hepatoprotective in most cases (Ou et al, 1997). NO from inducible NO synthase (iNOS) in hepatic parenchymal cells can either damage or protect hepatocytes. Upregulation of iNOS occurs after stimulation by endotoxin and by cytokines such as IL-1b (Kitade et al, 1996; Zamora et al, 2000). Depending on the level of redox stress, iNOS can cause detrimental effects, such as direct cytotoxicity and suppression of hepatic protein synthesis, in a manner similar to the septic state (Taylor et al, 1998; Chen et al, 2003). After resuscitation from profound hemorrhagic shock, iNOS can also mediate activation of NF-κB and increases in IL-6 expression, which leads to acute liver injury followed by recovery (Hierholzer et al, 1998).

Alternatively, with lower redox states, NO plays a cytoprotective role by suppressing apoptosis in hepatocytes and reducing mitochondrial dysfunction to limit liver injury (Brookes et al, 2000; Wang et al, 2002; Chen et al, 2003). NO exerts its cytoprotective effect during acute inflammation by suppressing caspase activation, inducing heat shock proteins (Kim et al, 1997), upregulating hemoxygenase-1 (Zamora et al, 2000), and activating the cyclic guanosine monophosphate signal pathway to interrupt apoptosis (Kim et al, 1997; Wang et al, 2002; Chen et al, 2003). NO can act as an electron acceptor for S-nitrosylation, which can alter the catalytic site of caspases and render them inactive (Li et al, 1997). NO also can induce the expression of heat shock proteins 70 and 32 (Kim et al, 1995; Li et al, 2000). These proteins may function by refolding damaged proteins in the liver, modulating caspase activation, and regulating expression of hemoxygenase-1, an inducible enzyme that catalyzes the degradation of heme into biliverdin, releasing carbon monoxide as a by product, which is thought to confer local antiinflammatory effects (Otterbein et al, 2000). NO also can bind soluble guanylyl cyclase, which can increase intracellular cyclic guanosine monophosphate, suppressing apoptosis and caspase activity (Lucas et al, 2000). Which particular mechanism predominates likely depends on the specific circumstances (Chen et al, 2003). To delineate further the effect of NO on hepatocytes, Wang and others (2002) are continuing to evaluate genetic changes using DNA microarray and large-scale proteomic analysis.

Liver Regeneration

The liver's ability to regenerate is a unique quality that is essential for its functions of controlling metabolism and detoxification (see Chapter 5). This capability to fully regenerate after insult differs significantly from other organs, which heal with scar (Fausto et al, 2006; Michalopoulos et al, 2007). However, in certain chronic liver injury states, the liver's regenerative capacity can be insufficient, leading to the replacement of functional epithelial tissue with connective tissue and to development of cirrhosis. A thorough understanding of the mechanisms and factors by which liver regeneration takes place is important in developing therapies to enhance regenerative capacity and prevent cirrhosis.

It has been shown that humoral factors are required, because hepatectomy in a rodent joined in parabiotic circulation results in proliferation and regeneration of the intact liver from the other member of the pair (Moolten & Bucher, 1967). This work provides convincing evidence that some mitogenic factor or factors are released into the peritoneal or systemic circulation during liver regeneration. Studies with recombinant proteins, cytokine inhibitors, and transgenic mice have convincingly shown that at least three cytokines—TNF-α, IL-6, and hepatocyte growth factor—play crucial roles in this regenerative process (Michalopoulos & DeFrances, 1997). The regenerative process of the liver can be divided into three phases: 1) initiation, 2) expansion, and 3) termination (Zimmermann et al, 2004) and is discussed elsewhere (Chapter 5). However, cytokines and growth factors play a significant role. The initiation phase is regulated by cytokines such as IL-6 and TNF-α, the expansion stage is regulated by mitogenic factors such as hepatocyte growth factor, and the termination phase is where mitosis stops, and sometimes apoptosis begins to control overgrowth. Additional cytokines, TGF-β and EGF, also may have roles. The TGF-β superfamily of cytokines appears to play a significant role in maintaining embryonic stem cell identity, and the differentiation of pancreas and liver progenitor cells is restricted by this pathway (Wandzioch & Zaret, 2009).

Several converging lines of evidence suggest that TNF-α, and particularly its signaling through the type I receptor, is essential for liver regeneration. Treatment of animals with neutralizing antibodies against TNF-α delays regeneration and decreases DNA synthesis (Yamada et al, 1997). DNA synthesis is also impaired after partial hepatectomy in TNF-receptor type I knockout mice. Whether these defects are due directly to the effects of TNF-α or are mediated through TNF-α–dependent expression of other mediators, including IL-6, is not fully understood, because treating TNF-receptor type I knockout mice with exogenous IL-6 corrects this delay in regeneration.

The role of IL-6 in hepatic regeneration also has been established (Drucker et al, 2010). Plasma IL-6 concentrations increase after partial hepatectomy, peaking within 24 to 48 hours (Matsunami et al, 1992; Rai et al, 1996). Although it is controversial whether IL-6 is directly mitogenic for hepatocytes in culture, it is clear that IL-6 is mitogenic for biliary epithelial cells (Matsumoto et al, 1994), and the absence of IL-6 delays regeneration in vivo (Cressman et al, 1996). Hepatocyte DNA synthesis after a partial hepatectomy is suppressed in IL-6 knockout mice. A recent randomized trial suggested a beneficial effect of pentoxifylline, a TNF-α inhibitor, on liver regeneration that seems to be IL-6 mediated (Petrowsky et al, 2010). IL-6 expression required for a normal regenerative response seems to depend on NF-κB translocation. NF-κB–dependent pathways are required to protect hepatocytes from TNF-α–mediated apoptosis. Studies from several groups have shown that inhibition of TNF-α–mediated NF-κB activation exaggerates apoptotic pathways initiated by TNF-α and FasL. Xu and colleagues (1998) noted that blocking NF-κB in RALA hepatocytes resulted in TNF-α–mediated apoptosis. Actinomycin D pretreatment of the same cells also promoted TNF-α apoptosis but did not prevent NF-κB translocation. Actinomycin D prevented the transcription of NF-κB–induced genes in response to TNF-α. In addition, inhibition of NF-κB using an inhibitory adenoviral vector in the livers of mice after hepatic resection produces massive apoptosis and liver failure (Iimuro et al, 1998). Taken together, these findings suggest that blockade of NF-κB–dependent transcription of certain genes in hepatocytes during liver regeneration results in TNF-α–mediated apoptosis.

PATHOGENESIS OF ENDOTOXIN AND CYTOKINES IN LIVER, BILIARY, AND PANCREATIC DISEASE

Endotoxemia and Bacterial Translocation

Bacterial translocation has been defined as the process by which viable enteric bacteria cross the intestinal mucosal barrier to mesenteric lymph nodes and remote organs and tissues (Lemaire et al, 1997; MacFie, 1997). Because the bowel contains massive amounts of viable, pathogenic bacteria and endotoxin, several physiologic mechanisms must be disrupted for bacterial translocation to occur.

The exact mechanisms by which bacterial translocation occurs through the intestinal mucosa are not fully known. Electron microscopy has revealed bacteria penetrating epithelial cells. Most of the bacteria are phagocytosed by macrophages, but free bacteria can be recovered from the portal circulation and the lymphatics. Nonpathogenic obligate anaerobic organisms, the mucosal barrier, and an efficient reticuloendothelial system all act in concert to reduce the frequency of pathogenic bacterial translocation.

For bacterial translocation to occur, several perturbations must take place simultaneously. Alterations in the composition of the gut flora as a result of malnutrition, antibiotic use, changes in bile production, or intestinal stasis all predispose the patient to bacterial translocation. Similarly, drugs or diseases that alter the integrity of the mucosal barrier increase the risk of bacterial translocation. Chemotherapeutic agents can reduce secretory IgA levels by inhibiting the antimicrobial function of immune cells. Total parenteral nutrition, chemotherapeutic agents, direct injury secondary to shock, and reperfusion injury can all increase bacterial translocation.

Endotoxemia itself can further promote bacterial translocation, possibly suggesting an amplification cascade. Endotoxemia frequently produces hypoperfusion of the splanchnic bed, leading to decreased perfusion of the distal ileum and cecum and increased intestinal permeability. In mice, administration of endotoxin induced bacterial translocation, which could be blocked by inhibitors of xanthine oxidase activity (Deitch et al, 1989a, 1989b, 1989c). In humans, low-dose endotoxin administration increases urinary excretion of orally administered D-mannitol, suggesting a reduction in gut barrier function (O'Dwyer et al, 1988).

Bacterial translocation has been proposed to occur in acute necrotizing pancreatitis (Fritz et al, 2010) and numerous biliary diseases, including obstructive jaundice, cirrhosis, portal hypertension, and alcoholic hepatitis (Nehez & Andersson, 2002; Wiest & Garcia-Tsao, 2005). Although the measurement of endotoxin in the blood of patients using current assays is problematic, increased appearance of endotoxin in the systemic circulation is a reproducible event. Several investigators have postulated that endotoxemia and bacterial translocation are the "engines" that drive the systemic inflammatory response syndrome in liver disease (Szabo et al, 2002).

Systemic endotoxemia rarely occurs in patients without liver disease or sepsis. In patients with cirrhosis, alcoholic hepatitis,

or obstructive jaundice, systemic appearance of endotoxin has been reported in as many as 70% of patients. Increased levels are also associated with adverse outcomes (Hanck et al, 1998; Kimmings et al, 1995). One hypothesis for obstructive jaundice is that the absence of bile secretion leads to endotoxemia, because enteric biliary drainage of bile salts reduces the absorption of endotoxin (Kimmings et al, 1995, 2000).

The liver is the primary site of endotoxin uptake and detoxification from the blood. Clearance of endotoxin by the liver is greater from the portal enteric drainage than from the hepatic artery. Considerable experimental and clinical evidence suggests that the increased systemic appearance of endotoxin seen in patients with liver and biliary tract disease is the result of increased enteric absorption and reduced clearance from the hepatic reticuloendothelial system (Kimmings et al, 1995). Increased endotoxemia has been reported in patients with cirrhosis, acute hepatic failure, severe hepatitis B and C infections, and obstructive jaundice. In many cases, the appearance of endotoxemia in fulminant hepatic failure correlates strongly with liver disease severity, coexisting renal failure, and mortality. Endotoxin is detected at a higher frequency in the circulation of patients with cirrhosis who exhibit ascites, renal dysfunction, and portocaval shunting, and endotoxemia is a predictor of adverse outcome (Kimmings et al, 1995), although endotoxin can bypass the liver directly via the lymphatics. In rats subjected to a cecal ligation and puncture, endotoxin appearance in the thoracic lymph duct was higher by a factor of several hundred than in the portal blood, suggesting that lymphatic flow may represent a significant source for the systemic circulation (Olofsson et al, 1986).

Pathogenesis of Proinflammatory Cytokines

Convincing circumstantial evidence shows that increased TNF-α–mediated and FasL-mediated apoptosis contributes to hepatocyte injury in chronic hepatitis C infections and in alcoholic hepatitis. Increased TNF-α and FasL expression has been detected in liver biopsy specimens from patients with hepatitis C infections (Fukuda et al, 1995; Larrea et al, 1996), presumably localized to infiltrating inflammatory cells (Kupffer, T, and natural killer cells). In addition, patients with chronic hepatitis B and C often have elevated plasma TNF-α concentrations and occasionally have increased soluble Fas and FasL concentrations. Plasma concentrations of the shed TNF receptors are commonly elevated in chronic hepatitis B and C infections, and levels frequently correlate with the extent of inflammation and hepatocyte death.

Increased hepatocyte apoptosis also has been detected in livers from patients with chronic hepatitis C (Bantel et al, 2004; McPartland et al, 2005). Anti–TNF-α agents administered to mice infected with chronic hepatitis C appear to be antiviral by promoting apoptosis and preventing regeneration of hepatocytes (Brenndorfer et al, 2010). Similarly to plasma TNF-α levels, IL-6 and endotoxin levels are both increased in patients with alcoholic hepatitis, and concentrations often correlate with mortality (Bird et al, 1990; Khoruts et al, 1991; Naveau et al, 1998; Sheron et al, 1991). Peripheral blood monocytes from patients with alcoholic cirrhosis spontaneously release more TNF-α and IL-6 than monocytes from healthy adults, and they do so in response to ex vivo endotoxin stimulation (Schafer et al, 1995). One explanation for this increased endotoxemia and TNF-α expression is that ethanol consumption increases the permeability of the gut to bacterial products such as endotoxin, potentially inducing TNF-α and FasL expression in the liver.

Several reports have shown elevated levels of TNF-α, its shed receptors, and IL-6 in animals and patients with obstructive jaundice (Kimmings et al, 1995). In animal models of experimental biliary obstruction, TNF mRNA expression in the liver is increased, and plasma concentrations rise (Beierle et al, 1996). These animals produce more TNF-α after a surgical injury than do healthy mice, and the increased production correlates with an adverse outcome (Bemelmans et al, 1992, 1993). In patients with obstructive jaundice, elevated TNF-α production by peripheral blood mononuclear cells also has been detected (Kimura et al, 1998; Puntis & Jiang, 1996).

There is considerable controversy regarding the increased level of circulating TNF-α and whether it is biologically active, because many assays only detect total TNF-α. The shed receptors of TNF-α are natural inhibitors of TNF-α bioactivity, and their concentrations also increase in patients with obstructive jaundice. Shedding of the TNF receptors may represent a protective mechanism to reduce the pathologic responses to TNF-α by binding and blocking their interaction with cellular receptors, and binding of TNF-α to its shed receptor may facilitate its clearance by the kidneys. In mice with jaundice, the concentrations of the shed receptors are increased (Bemelmans et al, 1996), and similar findings are seen in patients with obstructive liver disease (Kimmings et al, 1995).

Serum IL-6 levels are significantly higher in patients with biliary obstruction compared with control subjects (Akiyama et al, 1998; Kimura et al, 1999; Puntis & Jiang, 1996; Yamashiki et al, 1998). In one study, serum IL-6 levels decreased significantly after drainage (Akiyama et al, 1998). Patients with elevated serum IL-6 levels had lower serum levels of total protein and albumin, higher mean age, and more frequent positive cultures of bile compared with patients with lower serum IL-6 levels.

Cytokines in Ischemia-Reperfusion Injury

Visceral ischemia and reperfusion are frequent occurrences during hepatobiliary surgery, liver transplantation, trauma surgery, aortic surgery, and mesenteric vascular surgery and can lead to pulmonary and hepatic injury and multiorgan failure. Elective hepatic resection in particular is often performed using portal inflow occlusion with intermittent periods of reperfusion, which potentially reduces blood loss during the resection but can result in hepatocellular damage. I/R injury is associated with release of TNF-α and other proinflammatory cytokines (Colletti et al, 1996; Liu et al, 2000). In rats, intestinal ischemia of 120 minutes followed by reperfusion for 30 minutes was associated with 10-fold increases in circulating TNF-α over controls, which were transient and cleared by 60 minutes of reperfusion (Caty et al, 1990). Blocking TNF-α or IL-1 could mitigate the degree of organ damage (Welborn et al, 1996). After ischemia, gut-derived endotoxin was detected in the portal vein, which preceded the appearance of TNF-α in systemic plasma (Caty et al, 1990). I/R injury is also associated with activation of the oxidant-sensitive TNF transcription factor, NF-κB (Donnahoo et al, 2000; Yoshidome et al, 1999). Studies in mice demonstrate that reperfusion of ischemic liver tissue causes a series of events that include superoxide anion generation and NF-κB–mediated expression of injurious and

protective mediators that favor injury (Abe et al, 2009). IL-10 seems to protect against acute lung injury that can occur after hepatic I/R injury (Huber et al, 2000; Welborn et al, 2003; Yoshidome et al, 1999). Hemoxygenase-1 also has been shown to reduce I/R injury in an ex vivo liver transplant model in rats (Amersi et al, 1999), and low-dose carbon monoxide has been shown to be hepatoprotective (Amersi et al, 2002).

In humans, thoracoabdominal aortic aneurysm repair necessitates complete occlusion of the thoracic aorta above the celiac artery for 20 minutes to more than 1 hour, which is associated with pulmonary and renal dysfunction, consumptive coagulopathies, and mortality of 15% (Derrow et al, 2001; Rectenwald et al, 2002). For patients undergoing thoracoabdominal aortic aneurysm repair, visceral I/R is also associated with proinflammatory cytokine release (Welborn et al, 2000). Compared with patients undergoing infrarenal abdominal aortic aneurysm repair, in which the viscera remain perfused, patients undergoing thoracoabdominal aortic aneurysm repair had elevated levels of TNF-α, IL-6, IL-8, and IL-10 and the TNF receptors p55 and p75 (Welborn et al, 2000). The postoperative cytokine response was associated with the duration of visceral ischemia, and when left atrial femoral bypass was used to reduce ischemia time, the systemic TNF-α, p75, and IL-10 responses were attenuated. Patients with early and sustained peaks of IL-6 and TNF-α were more likely to develop multisystem organ failure.

Microarray technology and multiplex protein analyses were used on blood leukocytes and plasma in 10 patients to identify adverse clinical outcomes after thoracoabdominal aortic aneurysm repair with its requisite I/R injury (Feezor et al, 2004). From roughly 30,000 genes, changes in 146 correlated with an adverse clinical outcome. Several—such as monocyte-to-macrophage differentiation-associated factor, matrix metalloproteinase-8, and platelet factor 4—are involved in the innate immune response. Others are associated with a general stress response and cytoprotection, such as the upregulation of heat shock proteins; several genes involved with major histocompatability complex (MHC) class I were downregulated. Many of the differences seen in patients who eventually would develop multiorgan dysfunction were evident preoperatively, suggesting a preexisting proinflammatory state in these patients with diseased vasculature (Feezor et al, 2004).

Cytokines in Ablation of Hepatic Tumors (See Chapters 83 and 85)

For resectable primary and metastatic tumors, resection remains the standard of care (Blumgart & Fong, 1995; DeMatteo et al, 1999). However, several ablative techniques have been described, which by definition leave tumor debris in situ and can elicit a complex immunologic response. Cryoablation entails the use of metallic probes cooled with liquid nitrogen and placed into the tumor or on the liver surface (Chapman et al, 2000). Freezing of the tumor tissue results in obliteration of small vessels and disruption of hepatocyte plasma membranes (Chapman et al, 2000). In early clinical series, approximately 1% of patients treated with cryoablation developed "cryoshock," a syndrome characterized by acute respiratory distress syndrome, multiorgan failure, and disseminated intravascular coagulation; it results in death in nearly 20% of patients who develop it (Seifert & Morris, 1999). This complication, now rarely seen, was noted to be dose dependent, such that the risk increases proportionately with the volume of treated liver, and especially when more than 30% of the total hepatic volume is cryoablated (Chapman et al, 2000; Sarantou et al, 1998). This process seems to be mediated by NF-κB, which becomes activated, and transcription of TNF-α and other cytokines is increased (Barnes & Karin, 1997; Blackwell et al, 1999; Chapman et al, 2000; Seifert et al, 2002).

Radiofrequency ablation (RFA) involves the dispersal of heat around a needle passed into a tumor to cause coagulative necrosis. The technology behind this technique is limited by a smaller zone of ablation, which prevents its use in larger tumors (Chapman et al, 2000). In contrast to cryoablation, after treatment with RFA, liver cell organelles undergo thermal coagulative destruction, but the plasma membrane stays intact (Chapman et al, 2000). In rodent models in which the size of the ablation was controlled, rats treated with RFA had markedly diminished lung inflammation and lower TNF-α and macrophage inhibitory protein-2 levels (analogous to human IL-8) compared with rats treated with cryoablation (Chapman et al, 2000; Ng et al, 2004). In a study of 17 patients undergoing RFA, production of cytokines (TNF-α, IL-1b, IL-1Ra, IL-6, IL-8, and IL-10) and the TNF cytokine receptors (p55 and p75) was not altered at any time within the first 48 hours after the procedure (Schell et al, 2002). When stimulated with endotoxin (LPS), blood samples from the same patients showed normal ability to elaborate cytokines, suggesting that the absence of cytokine production after RFA was not related to the patients' underlying disease or inability to produce cytokines but rather was due to thermal coagulation of hepatocytes (Schell et al, 2002).

Microwave ablation is a more recently developed technology that is being used with increasing frequency to treat liver tumors. Microwave ablation involves application of microwaves directly to liver tissue to produce rapid temperature elevations and cause coagulative necrosis. Zhang and colleagues (2002) demonstrated a significant increase in T cells, NK cells, and monocytes in microwave-ablated hepatocellular patients. This response was maximal at day 3 but persisted to day 30. Interestingly, patients with a higher degree of immune cell infiltration had lower recurrence rates, similar to RFA patients (Hansler et al, 2006).

FUTURE DIRECTIONS

Over the past two decades, cytokines have been the subject of intense research, particularly from pharmaceutical companies. As a result of both academic and industrial interest, several agents are currently available that either stimulate cytokine activity or block their effects to treat cancer, infectious disease, inflammatory disorders, and autoimmunity.

Although it is clearly premature to celebrate the widespread use of cytokine or anticytokine therapies for patients with liver, biliary, or pancreatic disease, research is certainly heading in that direction. Several treatment modalities that offer the opportunity to interrupt endotoxin and the proinflammatory cytokine responses in liver disease remain of considerable interest. Antiendotoxin therapies are of particular interest in obstructive jaundice and acute alcoholic hepatitis. In chronic viral hepatitis, in which increased TNF-α–mediated and FasL-mediated apoptosis are presumed to occur, enthusiasm remains for the opportunity to intervene with either immunoadhesins or antibodies. The clinical use of antiinflammatory cytokines, such

as IL-10, is likely to occur at some point in the near future, although the risk of added immunosuppression remains a concern. The pegylated form of IFN-α, which has greater stability and in vivo activity than IFN-α alone, has substantially improved viral response rates in hepatitis C patients (see Chapter 64). As a result, it is now considered the standard of care for treatment of hepatitis C and may also have some efficacy in hepatitis B patients.

The greatest excitement, however, has been focused on the availability of antiendotoxin and cytokine therapies currently being used for other disease states that may eventually be utilized for diseases of the liver, biliary system, or pancreas.

Antiendotoxin antibodies have been evaluated in patients with sepsis, generally with disappointing results. Although concerns have been raised about the neutralizing capacity and specificity of some of these antibodies, the lack of efficacy could be explained in part by the inadequate selection of patients and the timing of administration. Only a fraction of the patients receiving antiendotoxin therapies were actually endotoxemic, and the administration of the antibody usually occurred 12 to 24 hours after the onset of symptoms. Recently, focus has been placed on the development of antiendotoxin vaccines, which likely will be tested in Phase I human trials soon (Cross, 2010). An alternative approach is recombinant BPI. In human volunteers treated with low-dose endotoxin, recombinant BPI administration reduced the proinflammatory cytokine responses and activation of the fibrinolytic and coagulation pathways (von der Mohlen et al, 1995). Recombinant BPI continues to be under U.S. Food and Drug Administration (FDA) investigation for its potential use in children with meningococcal sepsis (Levin et al, 2000). Although the results of this trial indicated a trend toward a survival benefit, this study was underpowered to detect significant differences in mortality. In rats subjected to a partial hepatectomy, recombinant BPI reduced liver injury and the magnitude of the inflammatory response (Kimmings et al, 1999).

Another group of cytokine modulators being utilized to treat other diseases are TNF-α blockers. Three TNF-α blocking agents—etanercept (Enbrel), adalimumab (Humira), and infliximab (Remicade)—have received FDA approval for rheumatoid arthritis. TNF-α blockers are also currently the cornerstone of therapy for inflammatory bowel disorders, particularly infliximab and adalimumab. Recombinant human IL-1Ra, anakinra (Kineret), a potent inhibitor of IL-1, is currently approved for the treatment of rheumatoid arthritis.

Although most of the cytokine and anticytokine therapies currently in use are not specifically indicated for liver, biliary, or pancreatic disease, much information about their effects will be learned in the coming years, and some of these therapies may well emerge as effective therapies in patients with inflammatory, neoplastic, or other hepatopancreatobiliary disorders. A recent phase I/II trial of intratumoral injections of TLR-2 and TLR-6 antagonists for R2 resected pancreatic adenocarcinoma shows a possible increased survival, but larger trials will be needed (Schmidt et al, 2007). Preclinical studies indicate that TLR-3 antagonists may delay the development of pancreatic cancer (Schwartz et al, 2009). The now common use of TNF-α and pegylated IFN demonstrate the potential application of cytokine therapy to liver disease. The liver's complex interplay of metabolism, immunology, cytokine productivity, and regenerative capacity make it ideally suited for the development of cytokine-directed therapies.

CHAPTER 11

Infections in liver, biliary, and pancreatic surgery

Chad G. Ball, C. Max Schmidt, and Keith D. Lillemoe

INFECTION

Infection is defined as a pathologic state resulting from invasion of the body by pathogenic microorganisms—bacteria, yeast, parasites, or viruses. These agents can challenge host defense mechanisms because of either an infectious organism's virulence or a weakness in host defenses. In most instances, infection results when normal host defense mechanisms fail to prevent tissue penetration and the subsequent local propagation and/or systemic dissemination of the injurious agent. All infections can be complicated by sepsis, which is the invasion of a micoorganism or its toxins into the bloodstream, coupled with the host response to that invasion. More specifically, *sepsis* is a systemic inflammatory response syndrome caused by infection (American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference Committee, 1992). When sepsis remains untreated, altered host inflammatory and coagulation cascades—intracellular homeostasis, cellular hypoxia, endothelial dysfunction, apoptosis, and eventually cardiovascular collapse—lead to multiorgan failure and death. Despite recent advances in treatment (Rivers et al, 2001), the incidence of sepsis and septic shock has been increasing (Angus et al, 2001). Furthermore, the associated mortality rate remains at 30% among all septic patients, with rates increasing to 85% in the setting of multiple organ failure (Angus et al, 2001).

Patients undergoing hepatopancreatobiliary surgery are at particular risk for infection and sepsis because of the severity of their disease process, often complicated by comorbid medical conditions and exacerbated by the stress of the surgical treatment itself. Hepatopancreatobiliary diseases that place patients at particular risk include infected necrotizing pancreatitis and sepsis associated with uncontrolled leakage from pancreatic–enteric anastamosis following pancreatoduodenectomy (Howard et al, 2007; Adams, 2009). This chapter reviews the applicable host defense mechanisms as well as their alteration by hepatopancreatobiliary diseases and operations.

HOST DEFENSES

The host defense mechanisms preventing the entry of infectious organisms into the liver, biliary tract, and pancreas can be organized into three broad categories (Krige & Bornman, 2000): *physical, chemical,* and *immunologic* (Table 11.1). Although these mechanisms are distinct, significant overlap occurs. Furthermore, optimal defense often requires coordination of all three systems.

Infectious microorganisms can enter the liver either hematogenously or retrograde via the biliary ductal system. The most common hematogenous route of infectious entry is the portal venous system. Under normal circumstances, the portal system drains all abdominal gastrointestinal venous blood directly into the liver before it enters the systemic circulation. As a result, portal venous blood typically contains enteric pathogens and toxins, which are cleared and neutralized by the liver (see Chapter 9). This activity is primarily regulated by Kupffer cells, which act as the resident hepatic macrophages. Consequently, Kupffer cells are not only important determinants of normal hepatic physiology and hemostasis but also of any inflammatory response. The liver therefore acts as the ultimate barrier to infection for all gastrointestinal tract and peritoneal cavity microorganisms attempting to access the systemic circulation. Perturbation of this flow, in particular portal venous obstruction, may occur from causes that are *presinusoidal* (portal vein thrombosis, surgery, trauma, cancer), *sinusoidal* (hepatitis, cirrhosis), or *postsinusoidal* (Budd-Chiari syndrome, right heart failure). Such obstructions often lead to portal hypertension with subsequent portosystemic shunting (see Chapter 70A). This new access to the systemic circulation allows a bypass of the liver's defenses against enteric pathogens and toxins, thereby increasing the risk of bacteremia and sepsis. Although less common, direct hematogenous spread of microorganisms to the liver may also occur via the hepatic arterial system (e.g., bacterial endocarditis, intravenous drug use).

Under normal circumstances, an intact sphincter of Oddi provides an effective mechanical barrier that prevents bacteria and other enteric organisms from entering the liver (retrograde) via the biliary system (see Chapter 1B). Ascending infection from the intestine can access the biliary tree when the sphincter mechanism is destroyed, endoscopically or surgically; bypassed, as in a biliary-enteric anastomosis; or violated, such as via a transsphincteric stent. The biliary system can also be directly contaminated by percutaneous access via either the transhepatic route or with operatively placed drains (e.g., T-tubes). Fortunately, the presence of bacteria within bile does not uniformly result in an ascending biliary infection, because the main physical barrier to biliary sepsis remains: intrahepatic tight junctions (Fig. 11.1), which form a barrier between bile canaliculi and hepatic sinusoids and act to keep bile separated from the bloodstream. Under pathologic conditions, mixing of these two compartments can result in seeding of biliary organisms into the hepatic blood supply. Another physical hepatic defense mechanism is the flow of bile itself. Bile is produced by hepatocytes and excreted into bile canaliculi, which then coalesce to form larger ductules, major sectoral ducts, and ultimately extrahepatic biliary ducts. Bile flow out of the liver helps prevent ascending infection by its mechanical flushing action; however, interruption of flow via obstruction or stasis reduces this protective mechanism (see Chapter 43).

Table 11.1

Hepatobiliary and Pancreatic Host Defense Mechanisms

	Hepatobiliary	Pancreatic
Physical	Biliary sphincter	Pancreatic sphincter
	Hepatic tight junctions	Pancreatic tight junctions
	Bile flow	Pancreatic juice flow
	Mucus	Mucus
	Cilia	Cilia
Chemical	Bile salts	Pancreatic fluid
Immunologic	Kupffer cells	—
	Immunoglobulin A	Immunoglobulin A
	Fibronectin	—
	Complement	Complement
	CD40 receptor	CD40 receptor
	Blood supply	Blood supply

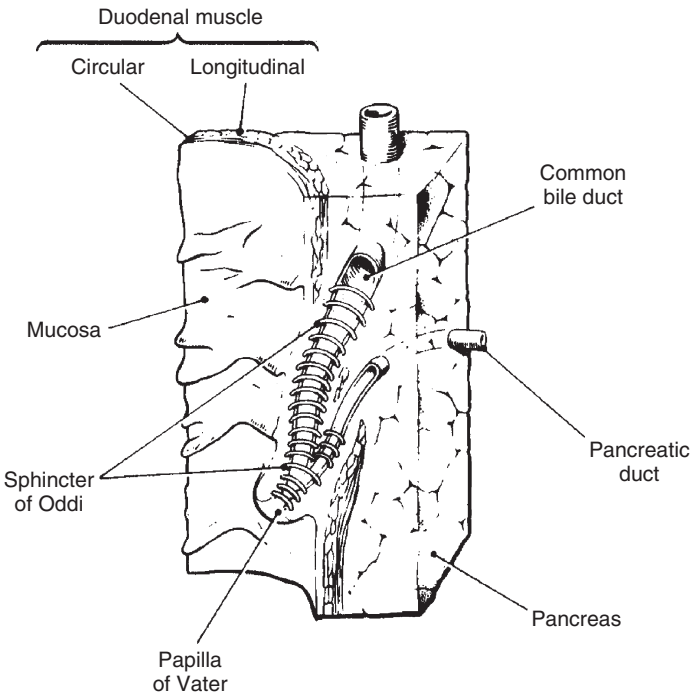

FIGURE 11.2. Schematic representation of the sphincter of Oddi in the human, showing the circular muscle (sphincter) that surrounds the termination of the common bile duct and pancreatic duct. The pancreatic duct has a shorter sphincter than the bile duct; most of the sphincter lies within the wall of the duodenum. *(From Touli J, 1984: Sphincter of Oddi Motility. Br J Surg 71:251.)*

As previously discussed, the main physical host defense against the reflux of enteric contents, and adherent bacteria, into the biliary system is the biliary sphincter within the sphincter of Oddi (Fig. 11.2; see Chapter 1). Similar to the liver, bile flow also assists the biliary system by flushing and helping prevent free reflux of duodenal contents into the extrahepatic ducts. The bile duct epithelium within the ductules has a single cilium, which facilitates propulsion of bile toward the extrahepatic biliary ducts (Gilroy et al, 1995; Itoshima et al, 1977). Bile flow is further propelled toward the duodenum by gallbladder contraction. A final physical barrier within the biliary tract is mucus produced by the epithelial cells throughout the extrahepatic bile ducts. Mucus promotes distal flow by preventing adherence of bacteria and debris to the epithelial cell membrane (see Chapter 7).

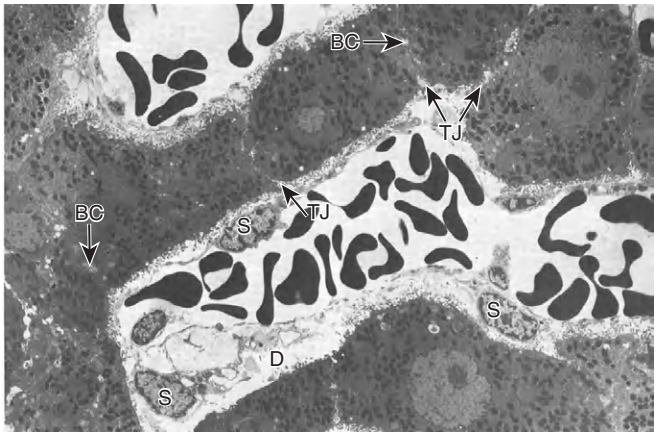

FIGURE 11.1. Electron micrograph shows the main ultrastructural features of the liver. Each hepatocyte is bathed on at least two sides by blood in the sinusoids, which are lined by a discontinuous layer of sinusoid lining cells (*S*) supported by the fine reticular framework of the liver such that a space, *the space of Disse* (*D*), remains between the lining cells and the hepatocyte surface. Because the sinusoid lining cells form a discontinuous layer, the space of Disse is continuous with the sinusoid lumen, and numerous irregular microvilli extend into it from the hepatocyte surface, greatly increasing the plasma membrane surface available for bidirectional exchange of metabolites between liver and blood. Bile canaliculi (*BC*) are formed from the plasma membranes of adjacent hepatocytes; these membranes are bound by tight junctions *(TJ)*; small microvilli project into the canaliculi. *(From Wheater PR, et al, 1985: Functional Histology. New York, Churchill Livingstone, p 206.)*

Similar to the biliary system, the main physical host defense mechanism for the pancreas is the pancreatic sphincter within the sphincter of Oddi. Although a true anatomic pancreatic sphincter is present in only one third of patients, all normal glands have a pressure zone at the end of the pancreatic duct that relaxes in response to secretin (Carr-Locke et al, 1985). This pressure zone prevents reflux of enteric contents into the pancreatic ductal system. Similar to the liver, the pancreas also contains paracellular seals or tight junctions between acinar and intralobular ductal epithelial cells. The integrity of the pancreatic tight junctions can be compromised, however, in experimental states of inflammation or pancreatitis, and possibly when ductal pressures are elevated (Fallon et al, 1995; Schmitt et al, 2004). The pancreatic ductal system is also aided by the flow of pancreatic duct fluid (flushing) to prevent reflux of duodenal contents. To facilitate this flow, the epithelium in the secondary ducts has a single cilium (Fig. 11.3) that propels secretion into the main pancreatic ductal system. Similar to the biliary system, the pancreatic ductal epithelium also secretes mucus, which acts as a barrier to the adherence of bacteria and debris (Moniaux et al, 2004; Trede & Carter, 1997).

Chemical host defense mechanisms also exist in the hepatic and pancreatobiliary systems. Bile salts within the biliary ducts have been shown to have bacteriostatic and bactericidal properties (Stewart et al, 1986; Sung et al, 1993). The maintenance of intestinal flora by bile salts is also crucial to host defenses,

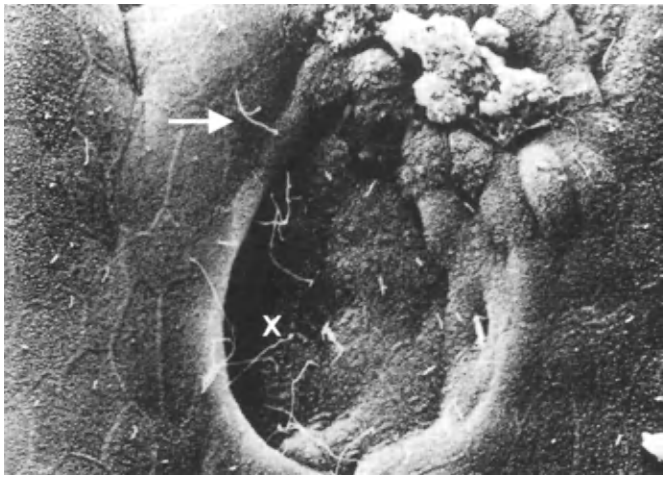

FIGURE 11.3. Electron micrograph of cat pancreatic duct showing surface contours of individual epithelial cells, some of which possess a solitary cilium (*arrow*) that protrudes into the lemen of the duct. The point of entry (*X*) of a tributary duct is shown. *(From Trede M, Carter DC, 1997: Surgery of the Pancreas, 2nd ed. New York, Churchill Livingstone.)*

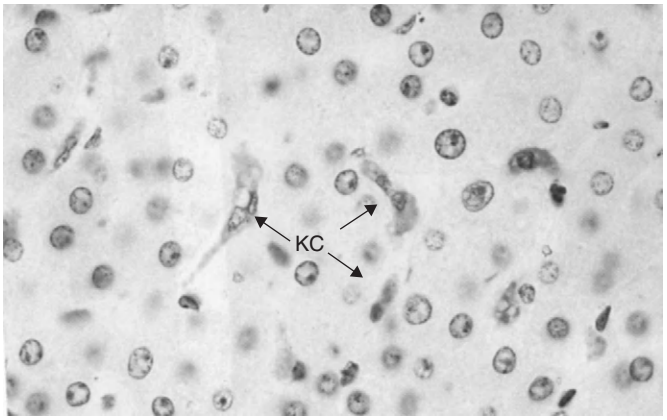

FIGURE 11.4. The sinusoidal macrophages can be distinguished from endothelial cells by the presence of histiocyte markers. This immunostain for lysozyme shows the positive Kupffer cells (*KC*). *(From Ishak KG, et al [eds], 2001: Tumors of the Liver and Intrahepatic Bile Ducts. Washington, DC, Armed Forces Institute of Pathology, p 4.)*

because bile salts have the ability to suppress pathogenic bacteria that threaten the integrity of the mucosal barrier, and they promote translocation of bacteria into the portal circulation (Bradfield, 1974; Clements et al, 1993; Deitch et al, 1990). Conditions of either bile salt loss or administration of prolonged courses of antibiotics may interfere with the balance of the intestinal flora and weaken this important host defense. Bile salts have also been shown to have antifungal effects, particularly against *Candida albicans* (Marshall et al, 1987). Furthermore, their trophic impact on epithelial cells increases both their integrity and ability to withstand insult from infectious pathogens (Stewart et al, 1986). Finally, bile salts posses an antiendotoxin effect (Stewart et al, 1986).

Pancreatic ductal fluid also contains inherent antibacterial properties (Rubinstein et al, 1985) independent of its enzymatic activity. Data suggest this fluid is bactericidal against multiple bacteria, including *Escherichia coli, Shigella* and *Salmonella* species, and *Klebsiella pneumoniae* (Kruszewska et al, 2004). Pancreatic fluid is also bacteriostatic against *Staphylococcus aureus, S. epidermidis,* and *Pseudomonas aeruginosa;* however, *Bacteroides fragilis* and *Streptococcus faecalis* are resistant to effects of pancreatic ductal fluid (Rubinstein et al, 1985). According to studies in swine, the antibacterial activity of pancreatic fluid appears to be independent of digestive enzymes. It is highest before eating and lowest during digestion of food, suggesting regulation through alternative signaling pathways (Holowachuk et al, 2004). By virtue of its antibacterial properties, pancreatic ductal fluid also regulates the colonization of enteric bacteria throughout the intestine by allowing the flora to maintain a normal homeostatic balance (Kruszewska et al, 2004).

In addition to its antibacterial effects, pancreatic ductal fluid appears to enhance the inherent action of certain bactericidal antibiotics (e.g., quinolones, trimethoprim, chloramphenicol, tetracycline) in studies comparing microbiologic media with those containing pancreatic ductal fluid (Mett et al, 1984). This enhanced activity has been shown toward many species of bacteria, including *E. coli, Salmonella, Serratia, Proteus,* and *Staphylococcus.* An unidentified, low-molecular-weight factor (independent of complement or lysozyme) in the pancreatic ductal fluid has been implicated (Mett et al, 1984). Although this factor is unknown, reproducible data show enhanced antibacterial activity in combination with commonly employed antibiotics, such as mezlocillin, ceftriaxone, gentamicin, ciprofloxacin, ofloxacin, and imipenem (Minelli et al, 1996). The relative degree of enhanced activity from pancreatic juice also depends on the specific bacteria (Minelli et al, 1996). Pancreatic ductal fluid contains fungistatic properties, in particular toward *C. albicans* (Kruszewska et al, 2004; Rubinstein et al, 1985), as well as growth factors (e.g., epidermal growth factor) that have a trophic effect on pancreatic epithelial cells. This helps preserve their integrity to pathogens (Alvarez et al, 1997). It is unknown whether pancreatic ductal fluid offers any antiendotoxin effects.

Immunologic host defense mechanisms also exist in the hepatic and pancreatobiliary systems. Hepatic cellular defense is provided by a large phagocyte population termed *Kupffer cells* (Fig. 11.4) as well as a plethora of other immunologically active cells (see Chapters 9 and 10). Kupffer cells are strategically located in the sinusoids of the liver, where they filter endotoxins from the gut, phagocytose bacteria, regulate sinusoidal vascular responsiveness, process and present antigens to T cells, and secrete cytokines, such as interleukins (ILs), interferons (INFs), and tumor necrosis factor (TNF) (Laskin, 1990). Kupffer cells represent one third of all nonparenchymal liver cells and 85% of all mononuclear phagocytes in the body (Kimmings et al, 1995; Wang et al, 1993). With the exception of circulating mononuclear cells, there is no evidence of a functionally equivalent resident phagocyte population in the pancreas.

Humoral defenses also exist within the hepatic and pancreatobiliary systems. Immunoglobulin (IG) A is secreted into the bile from the gallbladder and intrahepatic/extrahepatic biliary epithelium and plays an important role in barrier protection from infectious pathogens (Emmrich et al, 1998; Scott-Conner & Grogan, 1994) and is also present in pancreatic ductal fluid. The concentration of IgA is inversely related to pancreatic ductal fluid volume (Ohshio et al, 2001). In disease states characterized by exocrine insufficiency (e.g., chronic pancreatitis), a

higher concentration of IgA is also observed in the remaining human pancreatic ductal fluid (Emmrich et al, 1998).

Other immunologic molecules in the bile include fibronectin, which opsonizes pathogens and facilitates biliary epithelial defense against bacteria (Wilton et al, 1987). Complement—in particular, C3, C4, and factor B—is also present and functionally active in the bile at levels similar to serum (Sumiyoshi et al, 1997). As expected, clinical conditions of C3 deficiency are associated with increased susceptibility to infection in the biliary system and elsewhere (Homann et al, 1997). Complement is also present in pancreatic ductal fluid (Andoh et al, 1996; Sumiyoshi et al, 1997). Specifically, C3, C4, and factor B are synthesized in the pancreatic ductal epithelium and secreted in response to proinflammatory cytokines IL-1β, TNF-α, and INF-γ (Andoh et al, 1996; Sumiyoshi et al, 1997). These cytokines act as the primary drivers for sepsis (Cohen, 2002).

The biliary and pancreatic epithelium also may have some inherent immunologic ability. Normally, the CD40 receptor is expressed on regenerating or inflamed bile duct epithelium. CD40-CD40 ligand interactions may be responsible for immunity to certain pathogens. CD40 is also expressed on pancreatic ductal epithelial cells and may play a similar role (Vosters et al, 2004). Patients with deficient CD40 ligand (X-linked immunodeficiency with hyper-IgM) show a higher incidence of hepatopancreatobiliary infections, inflammation, and carcinoma (Hayward et al, 1997).

A final common immunologic host defense to liver, biliary, and pancreatic systems is the rich blood supply. An efficient and uninterrupted blood supply prevents tissue ischemia and allows for a microorganism challenge to be fully mounted by all elements of the host's immune system.

Host Defenses Challenged by Underlying Hepatopancreatobiliary Conditions in Surgical Patients

Numerous conditions—those both generalized and specific to the liver, biliary tree, and pancreas—may interfere with the host defenses in patients with hepatopancreatobiliary disease. Patients can be systemically immunosuppressed secondary to either exogenous medications or autoimmune diseases. Underlying hepatopancreatobiliary cancers themselves also have depressive effects on host defense. Malnutrition, obesity, smoking, age, and major organ system dysfunction are further important risk factors in this population.

Liver

Underlying hepatic conditions that may challenge host defenses in a surgical patient include hepatitis, cirrhosis, liver failure, portal hypertension, and hepatocellular toxin–induced dysfunction (see Chapters 64 and 70A). Hepatitis, cirrhosis, and liver failure all represent relative degrees of hepatic dysfunction, insufficiency, and compromise. As hepatic function deteriorates and ultimately leads to liver failure, physical, chemical, and immunologic hepatic host defenses also become compromised. With decreased bile production capacity, the physical defense of flushing bile flow is less efficient. The effect of primary liver cell dysfunction on hepatic tight junction integrity is unknown, but these junctions are altered in biliary obstructive causes of liver dysfunction. Bile salt deficiency associated with liver dysfunction leads to inadequate chemical defenses of bile salt–mediated antibacterial and antiendotoxin effects, as well as epithelial tropism, which results in reduced integrity of the epithelial barrier. The bacteriologic flora of the intestine is also altered, which may increase the quantity and change the type of bacteria that translocate into the portal system (Clements et al, 1993; Deitch et al, 1990). Liver dysfunction also leads to primary and secondary decreases in Kupffer cell function and to depressed synthesis of immunologically active proteins, which impairs cellular and humoral immunologic defense. Finally, cellular immunity may also be affected by the altered number and type of T cells present within the liver in hepatitis and cirrhosis (Deignan et al, 2002).

Portal hypertension is responsible for secondary decreases in Kupffer cell function. Resultant portosystemic shunting in patients with cirrhosis may compromise reticuloendothelial cell function by allowing enteric pathogens to be moved away from Kupffer cells. Portal hypertension therefore contributes to an increased risk of infection in animals with liver dysfunction (Basista et al, 1994). Local blood flow is also substantially altered in portal hypertension and cirrhosis, as intrahepatic sinusoidal resistance is increased. Sinusoidal responsiveness to endogenous vasodilators is depressed, whereas responsiveness to endogenous vasoconstrictors is increased (Birney et al, 2003). Endothelin and nitric oxide are two significant endogenous mediators of stellate cell contractility that modulate the local intrahepatic resistance in portal hypertension (Rockey, 2001).

Biliary System

The most well-studied underlying biliary condition that can interfere with host defenses in a surgical patient is biliary obstruction (see Chapter 7). This condition may occur from causes that are *intrinsic* (tumors, stones, strictures), *extrinsic* (pancreatitis, tumors), or *functional* (sphincter of Oddi dysfunction). The increased pressure within the biliary system as a consequence of biliary obstruction leads to weakened hepatic tight junctions. This effect is even more dramatic when pressure increases rapidly, such as with biliary tract manipulation (Raper et al, 1989). Leaky tight junctions result in bile reflux into the hepatic sinusoids (i.e., cholangiovenous reflux). Other studies suggest that cholangiovenous reflux may occur directly from bile ductules, through the spaces of Mall and Disse (see Fig. 11.1), into the hepatic sinusoids. This pathway measures 1.7 to 10 μm and offers less resistance to bacteria and toxins than higher resistance pathways such as hepatic tight junctions, biliary canaliculi, or hepatocytes (Stewart et al, 1988). During states of biliary obstruction, the reduced flow of bile also diminishes the physical barrier of the flushing action of bile. Obstruction causes decreased bile salt delivery to the intestine, resulting in reduced bile salt–mediated bacteriostatic and bactericidal activity and therefore colonic bacterial overgrowth. This overgrowth disturbs the protective bacterial flora and promotes local inflammation, injury, and subsequent increased rates of translocation into the portal circulation (Clements et al, 1993; Deitch et al, 1990). The increased bacterial load is not adequately cleared in the liver, allowing entry into the systemic circulation (Bradfield, 1974).

In addition to the direct local effect, jaundice associated with biliary obstruction can substantially alter host defenses. It causes depressed Kupffer cell function by reducing clearance capacity. This results in an increased bacterial load, which overwhelms the hepatic sinusoids and increases bacterial entry into the bloodstream (Clements et al, 1993; Ding et al, 1992; Katz et al, 1991; Megison et al, 1991; Pain et al, 1987).

The cause of Kupffer cell dysfunction in biliary obstruction and jaundice is unclear. One plausible theory relates increased bacterial translocation from the ileum and colon into the portal venous system, thereby directly overwhelming Kupffer cell clearance. Other theories include direct effects of bile salts on Kupffer cell membranes (Takiguchi & Koga, 1988), ineffective opsonins (e.g., fibronectin), decreased sinusoidal size and blood flow, and reduced major histocompatibility complex expression (Clements et al, 1994a, 1994b; Ding et al, 1992; Takiguchi & Koga, 1988).

The role of endotoxins on Kupffer cell function is also poorly understood, and animal studies suggest that biliary obstruction and portal vein endotoxinemia may generate oxygen free radicals in the liver that reduce the ability of Kupffer cells to clear toxins (Ogura et al, 1996; Takahashi et al, 1996). The use of oxygen free-radical scavengers, such as coenzyme Q10 or styrene-co-maleic acid superoxide dismutase in animal models, has been shown to interrupt the detrimental effects of endotoxin on Kupffer cell clearance and hepatic immunologic reserve (Ogura et al, 1996; Takahashi et al, 1996). Biliary obstruction results in less IgA production by the liver and lowers bile IgA levels. Endoscopic drainage of patients with biliary obstruction resolves this IgA deficiency in the bile (Sung et al, 1995); however, prolonged biliary obstruction eventually leads to hepatocyte dysfunction and necrosis, impairing liver synthetic function. Many proteins with immunologic importance are produced less efficiently, resulting in an increased susceptibility to infection.

Clinical relevance of the host challenge associated with biliary obstruction is evident in the higher probability of morbidity and mortality in patients with obstructive jaundice who undergo invasive procedures (Blamey et al, 1983; Pitt et al, 1981; Povoski et al, 1999; Schmidt et al, 2004).

Numerous controlled studies have suggested that preoperative external biliary drainage is associated with increased infectious morbidity. This is likely related to bile loss and the risk of infection and inflammation with catheterization of the biliary tree (Hatfield et al, 1982; Hochwald et al, 1999; Kimmings et al, 2000; McPherson et al, 1984; Pitt et al, 1985; Povoski et al, 1999; Smith et al, 1984; Sohn et al, 2000; van der Gaag et al, 2009). Internal stenting offers a theoretic benefit, with avoidance of external catheters and a return of bile to the gastrointestinal tract (eneterohepatic cycle). Unfortunately, multiple retrospective studies have reported mixed results (Trede & Schwall, 1988; Sohn et al, 2000; Schmidt et al, 2004), and four prospective randomized controlled trials provide conflicting data. These trials typically include patients undergoing pancreaticoduodenectomy (periampullary or pancreatic head adenocarcinoma), randomized to either preoperative endoscopic biliary drainage or surgery without drainage (see Chapters 50B, 50C, 62A, 90B, and 90C). Because of varied findings, however, the authors' conclusions have ranged from recommending routine preoperative endoscopic biliary drainage for patients with biliary obstruction (Lygidakis et al, 1987) to suggesting that although liver function improves with internal stenting, there is no difference in infectious outcomes (Lai et al, 1994). The most recent and methodologically sound trial reports that routine preoperative biliary drainage actually increases the rate of complications related to surgery (van der Gaag et al, 2010). Finally, a Cochrane review, as well as a meta-analysis, concluded no positive effect was seen from preoperative endoscopic biliary stenting in obstructed patients (Saleh et al, 2002; Wang et al, 2008).

Differences in the perioperative risk of pancreatectomy and major partial hepatectomy in jaundiced patients must be recognized. Contrary to the results in pancreas, some evidence shows improved outcome with decompressing the future liver remnant in patients with proximal biliary tumors (see Chapters 50C and 90C).

Theoretically, internal biliary stenting is advantageous over externalized stents, because it avoids the loss of bile and may reduce bacterial contamination. In animal models of obstructive jaundice, biliary decompression via internal stenting promotes Kupffer cell recovery (Clements et al, 1996), as evidenced by increased cell clearance capacity and normalization of endotoxin and anti–core glycolipid antibody concentrations (Greve et al, 1992). It has been suggested that the inconsistent results of clinical trials may be due to inadequate time allowed for liver recovery. The duration of biliary decompression needed to affect these parameters is unknown (van der Gaag et al, 2009). Some animal studies suggest several weeks (Katz et al, 1991; Megison et al, 1991; Parks et al, 1996; Roughneen et al, 1986; Scott-Conner & Grogan, 1994; Thompson et al, 1990), which may not be feasible in the clinical setting for cancer patients. In contrast, studies of limited duration in bile duct ligation models suggest Kupffer cell clearance recovers within days (Ding et al, 1992).

In addition to the effects of biliary obstruction on hepatic tight junctions, bile salt loss, bacterial overgrowth, and Kupffer cell dysfunction as described earlier, it may also be associated with the development of cholangitis. Although bacteria may colonize the biliary tract without producing clinically significant cholangitis, the risk of subsequent infection is directly related to the pressure within the biliary system. More specifically, greater degrees of obstruction lead to higher pressures (Pitt et al, 1990). This increase has a more dramatic effect when pressure increases quickly, as with biliary tract manipulation or common bile duct stone obstruction (Raper et al, 1989). In addition, specific virulence factors may explain how some bacteria species colonize and others cause sepsis. Slime production, for example, is necessary for some bacteria to colonize, but too much prevents cholangiovenous reflux and sepsis (Stewart et al, 2003). Bacteria that create complement are thought to induce an enhanced cholangiovenous reflux from resulting TNF-α production (Stewart et al, 2002). P1 fimbriae, α-galactosyl residues, and the absence of mannose-specific fimbriae also have been cited as distinguishing pathogenic bacteria from colonizing bacteria (Wetter et al, 1994). As a result, the degree and rapidity of obstruction and bacterial virulence play important roles in determining whether biliary pathogens will promote cholangitis.

Pancreas

The underlying pancreatic conditions that interfere with host defenses in surgical patients are pancreatic ductal obstruction, pancreatitis, and chronic pancreatic insufficiency. Ductal obstruction can be due to pancreatitis, tumor, a stone, or mucus (intraductal papillary mucinous neoplasm). This obstruction results in the loss of pancreatic ductal flow with its associated flushing, antibacterial, and immunologic actions. The treatment of some pancreatic diseases involves pancreatic duct stenting, but this leads to subsequent disruption of the pancreatic sphincter/pressure zone barrier between the intestine and

pancreas, which makes the pancreas susceptible to bacterial colonization, infection, and scarring. Stenting can also cause subsequent pancreatitis or can exacerbate previously existing pancreatitis.

In acute and chronic pancreatitis, host defenses can also be affected by obstruction of the biliary duct, duodenum, or mesenteric vasculature. Obstruction of bile flow to the intestine can depress host defense, as previously discussed. Duodenal obstruction can ultimately lead to poor nutrition with subsequent effects on patient immunologic reserve. Mesenteric vascular obstruction can result in liver or intestinal ischemia, insufficiency, or failure, which depresses the host's functional reserve. Ultimately, patients with chronic pancreatitis may develop pancreatic failure manifested as exocrine and endocrine insufficiency. Exocrine insufficiency can lead to poor absorption of fats, protein, and carbohydrates. If undertreated, this may cause malnutrition, weight loss, and decreased functional and immunologic reserve. Endocrine insufficiency (diabetes) has well-established risks to host defenses that include glycosylation of tissues and a general predisposition to infections.

Patients who present with acute necrotizing pancreatitis are at significant risk of developing a pancreatic infection. Translocation of bacteria and endotoxin is thought to play a major role in the cause of these infectious complications, both before and after operative debridements. This theory is based on experimental (Foitzik et al, 1995; Medich et al, 1993; Widdison et al, 1994) and clinical data (Buchler et al, 1992). Interestingly, the bacteriology of infected pancreatic tissue has changed substantially in recent years from predominantly gut flora to a greater emphasis on gram-positive microorganisms as well as on fungus (Kochhar et al, 2009; Besselink et al, 2009). This is presumed to be a consequence of improved therapies with a resultant increase in the microorganisms (gram-positive and fungal) associated with advanced/prolonged critical care treatments (central line infections). Finally, bacteria may exist within pancreatic pseudocysts, which if drained ineffectively can result in pancreatic abscess that may progress to systemic infection.

Numerous prospective randomized controlled trials have attempted to address the role of prophylactic antibiotics in preventing pancreatic infection during acute pancreatitis. The methodologic heterogeneity in these studies is striking, given their variations in patient numbers (underpowered), entry criteria, antibiotic selection, outcome measures, and lack of appropriate controls. They have also often ignored patients with significant necrosis, who are at greatest risk for infection. Although older trials employing prophylactic antibiotics (Foitzik et al, 1995; Luiten et al, 1995; Pederzoli et al, 1993; Sainio et al, 1995) reported reductions in the incidence of infectious complications, subsequent operations, and mortality, two larger contemporary trials found no significant benefit to the early use of prophylactic antibiotics in patients with severe acute pancreatitis (Dillinger et al, 2007; Isenmann et al, 2004). These data highlight the impact of proinflammatory mediators (cytokines) in inducing a systemic inflammatory response syndrome during the early phase (onset to 2 weeks) of pancreatitis and therefore a shift in philosophy from previous reviews and meta-analyses (Bassi et al, 2003; Nathens et al, 2008). As a result, currently no compelling evidence supports the use of early prophylactic antibiotics in these patients (Howard, 2007).

Host Defenses Challenged by Hepatopancreatobiliary Surgery

Any invasive or surgical procedure on the hepatopancreatobiliary system affects the host defense mechanisms. These include the introduction of foreign bodies, removal of functional tissue mass, rerouting of normal flow of fluids (bile, pancreatic fluid, succus entericus), mixing of normal barriers (sphincters), reduction of blood supply (ischemia, necrosis, shock), blood transfusion (immunosuppression), and microbiologic contamination of sterile fluid and tissue.

Liver

SURGERY. The main surgical procedures of the liver involve resections of various extents in patients with variable degrees of hepatic reserve. Liver resection may be accompanied by biliary–enteric reconstructive procedures, such as with proximal cholangiocarcinomas (see Chapter 50B). Various hepatic ablative techniques are also being increasingly utilized, such as radiofrequency ablation, cryoablation, and microwave ablation (see Chapter 85).

HOST DEFENSE. The main effect of liver resection on host defense is the removal of functional liver mass, which results in hepatocyte loss, disruption of the biliary drainage system, and reduced portal venous drainage (increased portal pressure, reduced portal outflow). Loss of functional liver mass has a direct and proportional effect on the capacity of the reticuloendothelial system to respond to infection. Bacterial and endotoxin clearance is also suppressed after hepatectomy. Normally, the existing reserve of a healthy liver can accommodate this loss, however, a patient with impaired liver function may not be able to compensate. In recent years, the role of preoperative portal vein embolization (PVE) of the hepatic lobe to be resected has been increasing (see Chapter 93). This allows preoperative hypertrophy of the remaining lobe, which can be beneficial in patients with limited hepatic reserve.

Despite the overall loss of Kupffer cell quantity, function of the remaining liver is not depressed (Andersson & Foss, 1991; Gross et al, 1985; Vo & Chi, 1988). Loss of functional liver mass also results in less overall production of bile and bile salts with their trophic (Borghi et al, 1991), antibacterial, antiendotoxin, and immunologic effects (Cahill et al, 1987; Dahlgren et al, 1986). Loss of reticuloendothelial system capacity, portal venous drainage, and protective effects of bile salts presents significant challenges to host defenses. Preexisting liver dysfunction and postoperative liver failure further exacerbate these challenges.

Although ablative procedures may preserve more hepatic mass than formal resections, the loss of functional volume remains important. More specifically, ablative techniques can result in two distinct challenges to host defenses: First, they create necrotic tissue, which is not surgically removed. Cryoablation causes hepatocellular necrosis by inducing formation of ice crystals, whereas radiofrequency and microwave ablation result in necrosis via heat-induced coagulation. Necrotic tissue from either source can act as a nidus for infection. Second, ablative techniques may have systemic effects, as cryotherapy has been shown to induce "cryoshock" in 1% of patients (Seifert & Morris, 1999). This can result in a systemic inflammatory response, coagulopathy, and multiorgan dysfunction or failure, particularly of the renal and pulmonary systems. More recent

studies have suggested that patients undergoing radiofrequency ablation do not display the systemic inflammatory responses with Kupffer cell–mediated cytokine release of proinflammatory cytokines (TNF-α, IL-1) characteristic of cryoablation (Schell et al, 2002; Jansen et al, 2010). Other authors have confirmed a reduced cytokine response after radiofrequency ablation but suggest that it still has a significant response compared with resection alone. This group also reported that the renal and lung dysfunction characteristic of cryoablation does not occur in swine treated with radiofrequency ablation (Ng et al, 2004). In contrast, other authors have suggested the systemic inflammatory response characteristic of cryoablation is not detrimental but rather leads to inhibition of tumor growth (Joosten et al, 2001, 2003).

Although the acceptance of laparoscopic techniques for hepatic resection is rapidly increasing, data outlining the immune host response to this approach are minimal. Porcine models suggest that open procedures may be associated with more immune suppression than laparoscopic approaches (Burpee et al, 2002), but to date no studies have evaluated differences in relevant clinical end points, such as postoperative infection.

INFECTIONS. Septic complications represent the most frequent cause of morbidity after liver resection (D'Amico & Cillo, 1999; Melendez et al, 1998) with the most common issue being intraabdominal abscesses (D'Amico & Cillo, 1999; Melendez et al, 1998). Intraabdominal infection can lead to sepsis and organ failure. Mortality from infectious complications after liver resection is significant and depends on age, comorbidities, hepatic reserve, and extent of liver resection (Garwood et al, 2004).

Pathophysiology of Infection. Translocation of bacteria and endotoxin is thought to play a major role in the cause of sepsis after liver resection. Bacteria are present in the mesenteric lymph nodes, portal venous system, and systemic vasculature after resection, regardless of whether a biliary–enteric drainage is constructed (Wang et al, 1992, 1994, 1995; Yeh et al, 2003). Decreased bile flow through the intestine, bacterial overgrowth with preference for *E. coli* (Wang et al, 1993), and postoperative ileus associated stasis, overgrowth, and bacterial adherence to the intestine appear to be important factors. Finally, experimental evidence indicates that decreased blood flow to the intestine results in enterocyte protein loss, mucosal atrophy, and loss of villous height (Wang et al, 1993). This combination is thought to promote bacterial and endotoxin translocation in the setting of decreased functional Kupffer cell mass. As noted earlier, ablative therapies may also promote infection through the formation of necrotic liver tissue and its effects on systemic immunity and end-organ function. All of these factors combine to promote infection in patients following liver surgery.

Risk Factors. One of the risk factors for infection in patients undergoing hepatic resection may relate to the amount of ischemic/necrotic liver at the resection margin (Yanaga et al, 1986) or ablation site. Intraperitoneal blood and bile, which accumulate in the surgical field, also inhibit peritoneal macrophage function (Andersson et al, 1989, 1990a, 1990b). Other risk factors relate to the extent of hepatic resection—specifically, the loss of functional liver mass—patient functional reserve, preoperative liver sepsis, iatrogenic introduction of bacteria (stenting, biliary-enteric anastomosis), blood transfusion, and shock (Andersson et al, 1990a, 1990b; Hochwald et al, 1999; Pace et al, 1989; Yanaga et al, 1986).

Causative Organisms. Most organisms isolated from intraabdominal sepsis after liver resection are enteric gram-negative aerobes, most commonly *E. coli*, and *Enterococcus*. Multiple bacterial isolates are present in 50% to 75% of cases (Pace et al, 1989; Wang et al, 1992). Common isolates associated with higher mortality in current studies also include fungus and gram-positive organisms, particularly methicillin-resistant *S. aureus* (Garwood et al, 2004).

Prevention and Treatment. Prophylactic antibiotics that cover enteric organisms—gram-negative aerobes, anaerobes, and enterococci—should be administered prior to any hepatobiliary manipulation. In addition, prophylactic antibiotics to cover skin flora should be included. Minimizing the amount of necrotic tissue at the margin of resection is optimal, and methods of sparing functional liver mass (parenchymal-sparing segmental resections) can be preventive (Jarnagin et al, 2002). Techniques using low central venous pressure and intermittent Pringle maneuvers reduce blood loss and thereby decrease the subsequent need for transfusion. Meticulous hemostasis, intraoperative identification of bile leaks, and judicious use of saline irrigation to remove bile, blood, and succus entericus from the peritoneal cavity and wound at the time of surgery are also essential.

After liver resection, early enteral feeding has been shown to reduce the rate of all infectious complications (Shirabe et al, 1997). It is thought to preserve and promote the gut mucosal integrity by maintaining nutrition and normal microbiologic flora. Animal studies have also shown that ethylhydroxyethyl cellulose (Wang et al, 1993, 1995), dextran 70 (Wang et al, 1997), and probiotics (Seehofer et al, 2004) can reduce bacterial translocation after liver resection. Ethylhydroxyethyl cellulose and dextran 70 act as cellular surfactants that may enhance endothelial cell resistance (Wang et al, 1995, 1997). Probiotics are bacterial cultures (e.g., lactic acid bacteria) that promote the normal microbiologic flora (Seehofer et al, 2004). Proper validation of these interventions still await human trials (Rayes et al, 2009).

Abdominal drains after liver resection do not prevent infection and may be associated with greater infectious complications based on randomized prospective studies (Belghiti et al, 1993; Burt et al, 2002; Fong et al, 1996; Liu et al, 2004). Techniques of preoperative PVE and hepatic arterial embolization may be employed to promote hypertrophy of the existing functional liver mass before resection. A prospective trial in 55 patients undergoing right hepatectomy showed that PVE significantly decreased postoperative complications in patients with chronic liver disease. Notably, a trend was seen ($P < .08$) toward decreased septic complications (Farges et al, 2003).

By creating a greater functional liver volume, the remaining mass after resection may better support any infectious challenge to host defenses. A study comprising 181 patients in whom mesenteric lymph nodes were cultured before and after liver resection showed that the only factor associated with bacterial translocation and subsequent postoperative infection was intraoperative blood transfusion (Yeh et al, 2003). Avoidance of blood-product transfusion during liver resection deserves strong consideration based on data indicating higher complication

rates, longer hospital stays, and early mortality (Kooby et al, 2003; Dixon et al, 2009).

Biliary System

SURGERY. Surgery on the biliary system typically involves resection (gallbladder, biliary tree) and/or biliary drainage. The most common biliary procedure is laparoscopic cholecystectomy.

HOST DEFENSE. With resection of the gallbladder, the patient loses the protective effects of gallbladder contraction and therefore the propulsion of bile toward the duodenum. As previously noted, bile flow helps prevent ascending infection by its flushing action. Resection, bypass, manipulation, and disruption of the biliary sphincter may also interfere with its ability to prevent reflux of enteric contents and adherent bacteria from the duodenum into the common bile duct. Resection of the extrahepatic biliary tract with a hepaticojejunostomy eliminates protective mechanisms of the biliary epithelium. Mucus, IgA, and complement produced by the biliary epithelium are also lost with resection.

In comparison to laparoscopic techniques, data suggest that open procedures may be associated with significant suppression of cell-mediated immune response, such as delayed-type hypersensitivity (Altamura et al, 2002; Whelan et al, 2003; Boo YJ et al, 2007). Additionally, the degree of intraabdominal pressure during laparoscopic cholecystectomy may regulate interleukin release (Basgul et al, 2004). To date, few trials have shown differences in immunologic parameters and relevant clinical end points, such as postoperative infection (Jacobi et al, 2002; Kooby, 2006).

INFECTIONS. The most common significant postoperative infection is the intraabdominal abscess; however, cholangitis may also occur when indwelling stents are introduced into the biliary ductal system. Wound infection may comprise skin flora, but more commonly, it involves enteric organisms when bile is infected, or when a biliary-enteric anastomosis has been performed (Lewis et al, 1987; Wells et al, 1989).

Pathophysiology of Infection. Infection occurs from two main sources: First, bacteria invade the biliary tract and liver locally by ascending from the duodenum. This invasion is facilitated by indwelling stents, sludge, or various degrees of biliary obstruction. Second, enteric bacteria translocate from the intestine and are introduced hematogenously into the liver through the hepatic portal vein. If the bacterial or endotoxin load exceeds the liver's clearance capacity, bacteremia and sepsis result.

Risk Factors. Bactibilia is an important risk factor for infectious complications in biliary surgery. The presence of bacteria in the bile does not predict a patient's risk of infection; however, evidence of bactibilia was found in 10% to 15% of patients at low risk for positive gallbladder bile cultures, for example, patients undergoing elective open cholecystectomy (Lewis et al, 1987; Reiss et al, 1982; Wells et al, 1989). Bactibilia is present in more than 80% of patients at high risk for positive cultures, such as those with acute cholecystitis (Claesson, 1986).

In patients undergoing laparoscopic cholecystectomy with positive gallbladder bile cultures, no significant difference in postoperative infectious complications were seen when a several-day course of preoperative antibiotics was employed for those at high risk (Al-Abassi et al, 2001). In contrast, the presence of bactibilia in the setting of common bile duct disease, and specifically increased biliary pressure and biliary obstruction, does predispose patients to postoperative infectious complications (Cox et al, 1978; Pitt & Couse, 1990). The greater the concentration of bacteria and the higher the degree and rapidity of obstruction, the more severe the septic complications (Pitt & Couse, 1990; Raper et al, 1989). As expected, in patients with acute suppurative cholangitis, bactibilia is present in nearly 100% of cases. This translates into a high risk of postoperative infection (Lee & Chung, 1997). Other risk factors for infection include the patient's functional reserve, preoperative sepsis, introduction of foreign bodies (stents, drains), disruption of efficient blood supply, blood transfusion, and shock.

Causative Organisms. Bile is normally sterile, so the type and concentration of biliary bacteria depend on the degree of obstruction or stasis, the presence of foreign bodies, and whether the obstruction is related to malignant or benign causes. The most common biliary pathogens are enteric gram-negative aerobes (Lee & Chung, 1997). Polymicrobial cultures are present in 67% of infected bile cultures (Leung et al, 1994). In patients with previous biliary instrumentation, and particularly after long-term antibiotic treatment, *Pseudomonas, Serratia, Streptococcus, Enterococcus,* and *Enterobacter* species may be present (Lipsett & Pitt, 1990; Nomura et al, 2000; Thompson et al, 1994). Gram-positive organisms, especially *Enterococcus faecalis,* are more common in patients who have undergone percutaneous instrumentation of the biliary tree. Anaerobes are present only occasionally but typically are found in patients with poor functional reserve, complex biliary problems, or long-term biliary stenting (Doty & Pitt, 1986; Krige et al, 1992; van den Hazel et al, 1994a, 1994b). Bile cultures in patients with malignant causes of biliary obstruction more commonly display *Klebsiella, Enterobacter, Streptococcus, Enterococcus,* and *Candida* species compared with benign biliary obstruction (Nomura et al, 2000; Thompson et al, 1994). Whether *E. faecalis* is truly a biliary pathogen is unclear. Antibiotic use is known to destabilize *E. faecalis* in the enteric flora by killing susceptible strains. Multiple antibiotic-resistant enterococcal strains, such as *E. faecalis* strain V583, are able to colonize the gut (Gilmore & Ferretti, 2003). In a study of patients with biliary malignancy undergoing preoperative biliary decompression, only the incidence of enterococcal bactibilia increased after antibiotic use (16% before and 63% after antibiotic use). When analyzing the correlation between preoperative bile bacteria and postoperative complications, only *Enterococcus* species were associated with the occurrence of complications (Nomura et al, 2000). Whether *E. faecalis* works independently or synergistically with other biliary bacteria as a primary pathogenic mechanism is unknown.

Prevention and Treatment. In patients undergoing biliary surgery, preoperative obstruction and jaundice—with their physical, chemical, and immunologic consequences—increase the risk of perioperative infectious complications. Prophylactic antibiotics treating enteric gram-negative aerobes, anaerobes, and skin flora should be used. If the patient has an indwelling biliary catheter, bile cultures should be taken, and antibiotics should be tailored to the particular bacteria and their

corresponding sensitivities. Oral bile salts may be employed to replenish stores in patients with obstructive jaundice.

The role of biliary stenting is controversial. External stenting to relieve biliary obstruction has been shown consistently to increase the complication rate in patients undergoing pancreatobiliary surgery, secondary to the introduction of bacteria directly into the biliary tree. External stenting is reserved for cases of cholangitis that cannot be relieved by internal stenting and for nonsurgical palliation of high biliary obstruction. Preoperative internal stenting to relieve biliary obstruction in patients undergoing pancreatobiliary surgery is more controversial. Theoretically, internal stenting avoids the introduction of exogenous bacteria characteristic of external stenting and corrects the detrimental effects of biliary obstruction and reduced bile salt delivery into the gut. Clinical trials have yet to establish the role of internal stenting in this setting.

Pancreas

SURGERY. Surgery on the pancreas typically involves resection (distal pancreatectomy, pancreaticoduodenectomy, debridement) and/or drainage (pancreaticoenteric) procedures.

HOST DEFENSE. The main effect of resection on host defense is the removal of functional pancreatic tissue mass. Pancreatectomy results in less production of pancreatic ductal fluid with its trophic, antibacterial, and immunologic effects. Pancreatic exocrine insufficiency following resection can also cause malnutrition and result in long-term depressed immunity without sufficient supplementation of exogenous pancreatic enzymes. In patients with preexisting pancreatic exocrine insufficiency, these host defenses are suppressed even further. Pancreatectomy may also result in pancreatic endocrine dysfunction secondary to loss of islet cell mass or in patients with inadequate islet cell function. Although the precise target range is somewhat controversial, uncontrolled perioperative hyperglycemia is a significant predisposing factor for postoperative infection and mortality (Capes et al, 2000; Grey & Perdrizet, 2004; Lipshutz & Gropper, 2009). Also, when pancreatic surgery involves enteric drainage, the effect on host defense results from exposure to enteric pathogens via biliary–enteric or pancreaticoenteric anastomoses. Finally, the impact of laparoscopic techniques for pancreatic resection on host immune status is unclear. In dog models, however, laparoscopic distal pancreatectomy results in significantly less stress as measured by both IL-1 and serum cortisol levels, when compared with conventional open procedures (Naitoh et al, 2002).

INFECTIONS. The most common cause of intraabdominal sepsis in pancreatic surgery is intraabdominal abscess with or without pancreatic fistula or pancreaticoenteric anastomotic leak. Wound infection may occur with skin flora or enteric flora when bile is infected, or when an enteric anastomosis is performed (Lewis et al, 1987; Wells et al, 1989). Surgical procedures to address the complications of acute necrotizing pancreatitis, infected pancreatic necrosis, or pancreatic abscess are frequently accompanied by sepsis and the systemic inflammatory response syndrome.

Pathophysiology of Infection. The pathophysiology of infection in pancreatic resection without enteric drainage is due to pancreatic fistula and bacteria in the pancreatic ductal fluid. Intraabdominal abscess occurs in these patients when the pancreatic duct leaks fluid that is contaminated with bacteria. Preexisting bacteria in the pancreatic duct are typically a result of endoscopic, radiologic, or surgical instrumentation of the duct itself.

The pathophysiology of pancreatic resection with enteric drainage is similar. In this scenario, the direct communication of the duct with the intestine allows for enteric bacteria to invade the pancreatic ducts and contaminate the ductal fluid because of the absence of a functional sphincter. If an anastomotic leak occurs after pancreaticoenteric anastomosis, the pancreatic ductal fluid contains enteric bacteria. With adequate drainage, the patient may avoid local or systemic signs of sepsis, unless bacterial antibiotic resistance develops. Translocation of bacteria and endotoxin is thought to play a major role in the cause of infectious complications in necrotizing pancreatitis.

Risk Factors. Risk factors include the extent of the pancreatic resection and corresponding loss of functional mass, general functional reserve of the patient, underlying sepsis, pancreatitis, ischemic necrosis, disruption of efficient blood supply, blood transfusion, shock, and use of stenting, instrumentation, and drains. Biliary obstruction, as seen in many patients undergoing pancreaticoduodenectomy, is also a significant risk factor.

Causative Organisms. Enteric gram-negative aerobes arising in the pancreatic ductal fluid, either from instrumentation or via biliary-enteric or pancreaticoenteric drainage, are the main source of bacterial contamination. In acute necrotizing pancreatitis, gram-negative organisms are more commonly isolated in patients with biliary pancreatitis, whereas gram-positive organisms are more frequent in those with alcoholic pancreatitis (Raty et al, 1998). The incidence of gram-positive organisms may also be higher in necrotizing cases, when sampling of fluid collections or necrosis is performed. *Candida* and *Pseudomonas*, as in biliary bacteriology, occur during long hospital and intensive care unit stays and are typically associated with prolonged courses of antibiotics and subsequent increased mortality (Bittner et al, 1987; Kochhar et al, 2009; Agvald-Ohman C, 2008).

Prevention and Treatment. Prevention of the infectious risks associated with pancreatic surgery entails counteracting the loss of functional pancreatic tissue. For pancreatic exocrine insufficiency, adequate exogenous pancreatic enzyme supplementation should begin postoperatively with initiation of diet. Early feeding prevents the breakdown of gut integrity (Kimmings et al, 1995), and for pancreatic endocrine insufficiency (diabetes), reasonable perioperative control of hyperglycemia with insulin should be routine. Appropriate prophylactic antibiotics must be employed that address enteric gram-negative aerobes, anaerobes, and skin flora. Prophylactic antibiotics that address translocation flora and penetrate pancreatic tissue (e.g., imipenem, cilastatin, piperacillin/tazobactam) remain important preventive measures, particularly in patients with underlying pancreatic necrosis.

CONCLUSION

This chapter provides a basic understanding of the pathophysiology of sepsis and the host defense mechanism's ability to

mount an effective response following hepatopancreatobiliary surgery. Physical, chemical, and immunologic host defense mechanisms in the liver, biliary, and pancreatic systems can be profoundly altered by the patient's underlying health status (comorbid conditions), hepatic or pancreatobiliary disease, and specific surgical therapy. Important preventive measures should be instituted to minimize the risk of infectious complications from hepatopancreatobiliary surgery.

CHAPTER 12

Clinical investigation of hepatopancreaticobiliary disease

Ali W. Majeed and William E.G. Thomas

Despite the rapid increase in diagnostic modalities available to the clinician dealing with hepatobiliary disease, a detailed history and clinical examination are crucial if an accurate overall assessment is to be made. With advances in technology, an array of diagnostic modalities is at the disposal of the physician. These include better availability of tumor markers and more sensitive and specific imaging. A systematic approach is important to rationalize the use of these techniques. Multidisciplinary assessment allows more accurate diagnosis and disease staging, while avoiding unnecessary and expensive investigations. This chapter addresses the specific features in the history and clinical examination that are of particular importance in hepatobiliary and pancreatic disease.

CLINICAL HISTORY AND PHYSICAL EXAMINATION

The clinical investigation of patients with hepatobiliary and pancreatic disease begins with a detailed history and physical examination that will direct the sequence of subsequent investigations. The history should begin with the presenting complaint and then proceed with a systematic inquiry into hepatopancreatobiliary symptoms. The history should include details of gastrointestinal symptoms including anorexia, nausea, vomiting, and any alteration of bowel habit, because this may indicate the source of a liver mass (e.g., colorectal metastasis to the liver). The history also should include a careful assessment of pain, itching, or jaundice and a comprehensive past medical history, family history, foreign travel history, and drug history, including alcohol intake and smoking. The general symptoms of liver dysfunction include weakness, fatigue, anorexia, nausea and vomiting, weight loss or gain (related to ascites), disordered taste and smell, muscle cramps, and impotence. Specific symptoms of liver dysfunction relate to ascites (abdominal distension and oliguria), coagulopathy (excessive bruising or bleeding), cholestasis (itching), and jaundice.

Examination should assess the presence or absence of the stigmata of chronic liver and biliary disease (see Chapter 7), including jaundice, pruritus, spider nevi (Fig. 12.1), hepatosplenomegaly (Fig. 12.2), ascites (Fig. 12.3), and caput medusae. Abnormal abdominal masses should also be noted. The circulation in patients with liver failure is hyperdynamic with flushed extremities and a bounding pulse, and peripheral cyanosis may be evident. Fetor hepaticus—a sweet, musty odor of the breath—is associated with hepatocellular failure and is thought to be related to changes in the gut flora (Challenger & Walsh, 1995). Spider nevi are angiomata that occur in the vasculature of the superior vena cava, and their disappearance and reappearance vary with liver function and are thought to be associated with estrogen excess (Bean, 1959). Palmar erythema (Fig. 12.4) affects the thenar and hypothenar eminences and is associated with the hyperdynamic state. Other changes include loss of axillary and pubic hair and whitening of the nails (Lloyd & Williams, 1948). Gynecomastia (Fig. 12.5) and testicular atrophy can also occur.

Chronic encephalopathy associated with portal hypertension and portosystemic shunting varies in severity, producing symptoms that range from mild confusion and a shortened attention span to marked intellectual deterioration that may end in coma. Psychomotor tests have been devised to quantify the intellectual deterioration and allow monitoring (Sherlock & Dooley, 2002). A flapping tremor of the extended wrist ("liver flap") and later cogwheel rigidity and ankle clonus may be present. Acute liver failure is associated with jaundice, confusion, delirium, and renal failure. These features may occur on a background of cirrhosis, and the precipitating cause may be treatable (e.g., infection).

Patients also may be seen with acute abdominal pain or jaundice. Examination may reveal localized peritonism in the right upper quadrant or epigastrium with a tender mass or generalized peritonitis in cases of gallbladder perforation or severe pancreatitis. A Murphy sign is a "catch" in the breath elicited by gently pressing on the right upper quadrant and asking the patient to take a deep breath. A Boas sign is hyperesthesia of the skin over the lower right ribs posteriorly. One or both of these signs may be found in acute cholecystitis. Erythema ab igne is caused by prolonged local application of heat and may be evident in the right upper quadrant in patients with chronic gallbladder disease or, more commonly, on the back in patients with chronic pancreatitis (Fig. 12.6). In Asia, bleeding from a ruptured hepatocellular carcinoma is a common acute presentation. Patients with severe acute pancreatitis may develop a bluish discoloration of the flanks as a result of retroperitoneal bleeding (Turner sign) or in the periumbilical area (Cullen sign; Fig. 12.7).

EXAMINATION OF THE LIVER

The liver is examined using a combination of palpation and percussion from above and below to delineate its borders. Dullness to percussion of the upper border extends as far as the fifth intercostal space. Auscultation is also important, because a venous hum may be heard with portal hypertension, and a bruit may be heard in association with hepatocellular carcinomas.

FIGURE 12.1. Spider nevus in a patient with cirrhosis.

FIGURE 12.2. Hepatomegaly and Dupuytren contracture in a patient with extensive cirrhosis.

FIGURE 12.4. Palmar erythema affecting the thenar and hypothenar eminences.

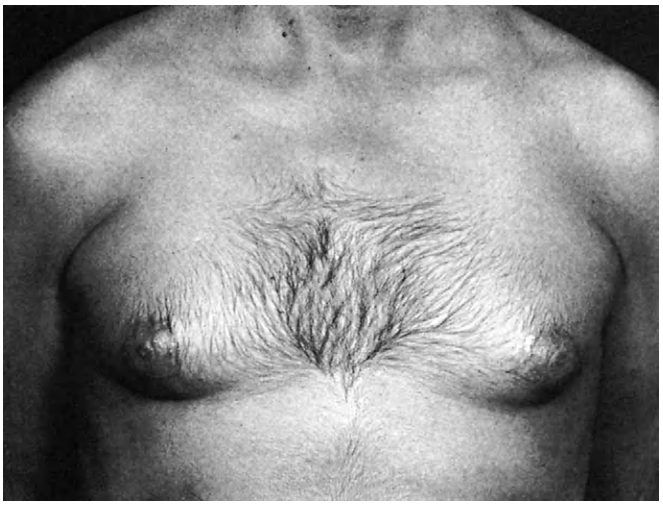

FIGURE 12.5. Bilateral gynecomastia in a patient with alcoholic liver disease.

FIGURE 12.6. This patient has long-standing chronic pancreatitis that affects the entire length of the pancreas with severe flank and back pain on the left side. Prolonged application of local heat has resulted in marked rash of erythema ab igne.

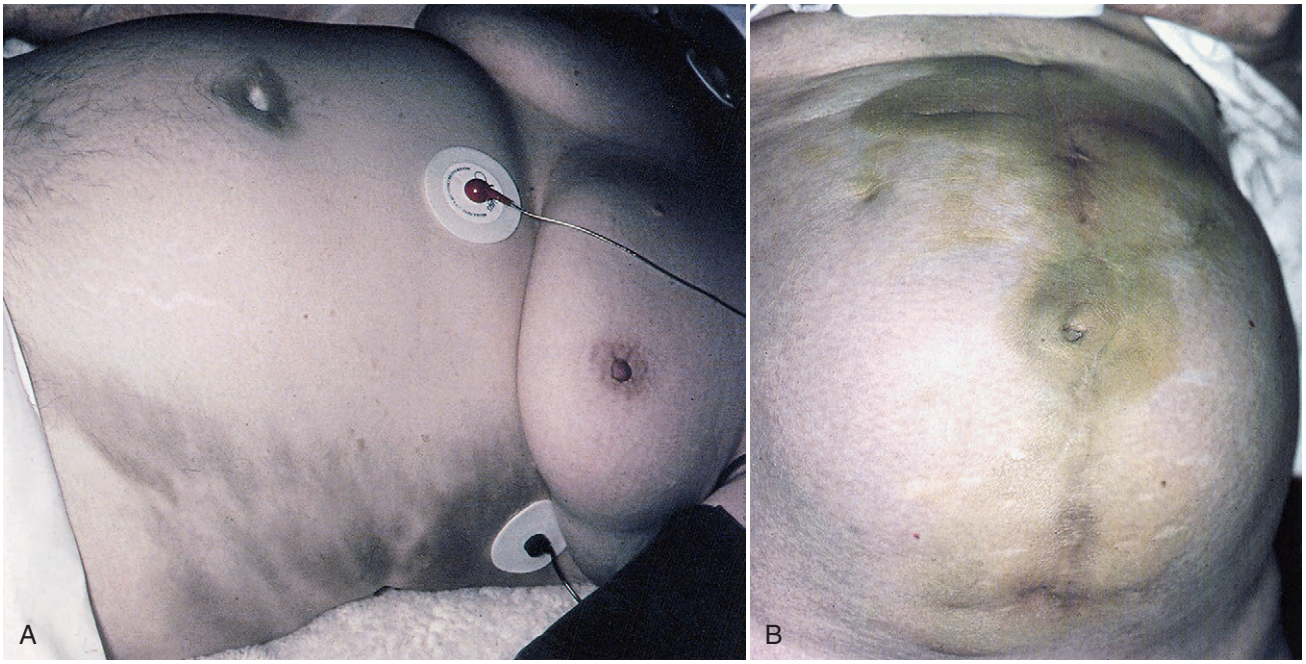

FIGURE 12.7. Turner sign (**A**) and Cullen sign (**B**) in patients with acute pancreatitis.

The normal liver is usually impalpable; however, in asthenic individuals, the anterior edge may be palpable. Enlargement of the liver occurs in many pathologic states, although a tonguelike extension from the right lobe—a *Riedel lobe*, which is of no pathologic significance—may be mistaken for a tumor (Fig. 12.8). Causes of hepatomegaly are listed in Table 12.1. A lobe may undergo hypertrophy and become palpable, and this may occur in the presence of liver atrophy or after liver resection. Reduction in liver size also is important, because this may occur in cirrhosis and certain types of hepatitis. Consistency also is relevant; a hard, knobbly liver often represents the presence of metastases, whereas smooth enlargement may be due to cirrhosis.

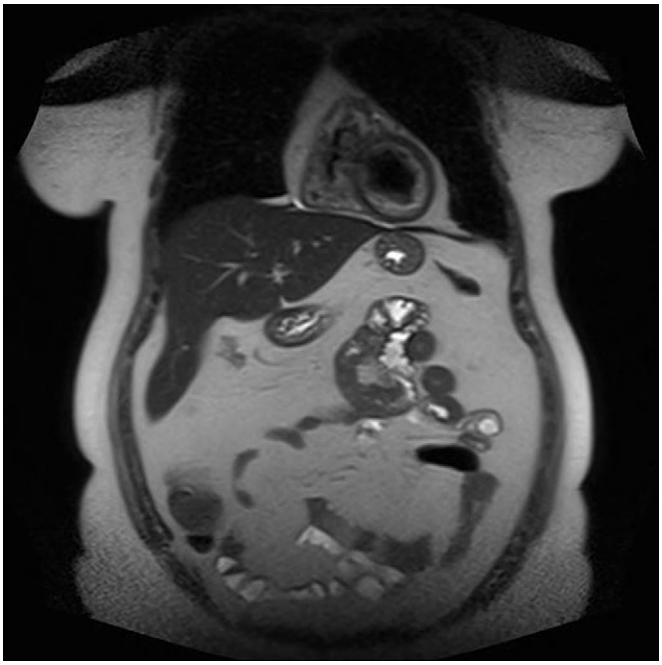

FIGURE 12.8. Coronal magnetic resonance image of a Riedel lobe of liver. This normal variant, a tonguelike extension from the right lobe, may be mistaken for a mass or an enlarged liver on physical examination.

EXAMINATION OF THE SPLEEN

Examination of the spleen should begin in the right iliac fossa and proceed toward the left subcostal region, because this is the direction in which splenomegaly occurs. Rotation of the patient 45 degrees to the right may aid palpation, because the spleen then falls onto the examining right hand. During this maneuver,

the left hand should support the rib cage and relax the skin and abdominal musculature by drawing these down to the right. Percussion may be useful, and if ascites is present, the spleen may be ballotable. If the spleen is sufficiently enlarged, the notch on its anterior border may become palpable. Causes of splenomegaly are listed in Table 12.2.

SIGNS OF PORTAL HYPERTENSION

Portal hypertension (see Chapter 70A and 74) is due to either intrahepatic or extrahepatic portal venous obstruction. Intrahepatic portal hypertension usually is associated with hepatomegaly and may be accompanied by splenomegaly and ascites. Dilated abdominal wall veins also may be found secondary to portosystemic anastomosis, giving rise to a caput medusae. The more common clinical site of portosystemic anastomosis is at the gastroesophageal junction, leading to esophageal varices; any evidence of upper gastrointestinal blood loss, whether hematemesis or melena, should be investigated with urgent endoscopy (see Chapter 75A). Rarely, these patients may develop hemorrhoidal varices around the anus as a result of portosystemic anastomosis.

Extrahepatic portal hypertension is usually due to portal vein thrombosis, and as such it is important to identify any history of neonatal infection around the umbilicus, major intraabdominal sepsis, pancreatic cancer, or a blood disorder that might lead to hypercoagulability. These patients almost invariably have splenomegaly, often associated with pancytopenia. In such cases, the liver is normal, but ascites may be present. A palpable spleen in the upper left abdomen associated with portal hypertension may be found in the event of splenic occlusion caused by tumor or chronic pancreatitis.

CLINICAL FEATURES OF ALCOHOLIC LIVER DISEASE

The symptoms and signs of alcoholic liver disease may be related directly to alcoholism or to secondary hepatocellular dysfunction. Patients commonly experience repeated falls while inebriated and may have signs of trauma and bruising. Multiple "old" rib fractures are common findings on chest radiographs and are related to such behavior. Alcoholic neuropathy also may be present, especially given the malnourished state of many patients. Acute alcoholic hepatitis usually occurs after a bout of drinking and may be associated with liver tenderness, jaundice, pyrexia, and leukocytosis. Advanced alcoholic liver disease may be associated with other manifestations of hepatic impairment (e.g., portal hypertension, ascites, hepatomegaly, liver failure).

CLINICAL FEATURES OF OTHER TYPES OF LIVER DISEASE

Primary Biliary Cirrhosis

Primary biliary cirrhosis, or *chronic nonsuppurative destructive cholangitis*, usually affects middle-aged women. Asymptomatic individuals may be diagnosed during routine examination, where they are found to have hepatomegaly, elevated autoantibodies, or elevated plasma alkaline phosphatase. The earliest symptom is usually pruritus, even before clinical jaundice is apparent, but later the patient may develop overt jaundice; hepatosplenomegaly; xanthelasma, especially in the palms and around the eyes; vitiligo; and arthritis. Primary biliary cirrhosis often is found in association with connective tissue disease.

Ulcerative Colitis and Crohn Disease

Ulcerative colitis and Crohn disease are associated with hepatobiliary disorders, especially primary sclerosing cholangitis (see Chapter 41). It is important to include a detailed gastrointestinal systems review and investigations in any patient with unexplained liver disease.

Budd-Chiari Syndrome

This syndrome is characterized by venous outflow obstruction to the liver, which could be intrahepatic or extrahepatic (see Chapter 77). Acute venous obstruction is usually secondary to another pathologic process and presents with abdominal pain, vomiting, hepatomegaly, ascites, and jaundice, which may be mild. Hepatocellular failure leading to death is usually rapid. Chronic venous obstruction of the liver usually presents with ascites and hepatomegaly. If the inferior vena cava (IVC) is blocked with tumor or thrombus, gross edema of the legs and superficial venous distension of the abdominal veins is apparent. Diagnosis is made on imaging.

Hemochromatosis

Hemachromatosis is an iron overload state in which the liver is usually affected. Excess iron deposition leads to fibrosis and cirrhosis with an increased risk of developing hepatocellular carcinoma. Clinically, hemochromatosis usually presents between the ages of 40 and 60 years. Symptoms are usually nonspecific with lethargy, increased pigmentation, loss of body hair, loss of libido, arthralgia, and diabetes, usually due to the involvement of the pancreas. Clinical examination may show hepatomegaly and hyperpigmentation in the axillae, groins, and genitalia as well as testicular atrophy. Diagnosis is made by hematologic tests including serum iron, serum ferritin, and serum transferrin; liver damage can be assessed with a liver biopsy.

Polycystic Disease

Symptoms of polycystic disease are usually caused by the mass effect of the enlarged liver (see Chapter 69A). Abdominal

distention and breathlessness are common. Early satiety and vomiting can occur because of pressure on the stomach. Acute abdominal pain is usually due to infection or bleeding into a cyst.

Acute Liver Failure

Acute liver failure (ALF) is characterized by massive cellular injury to a previously healthy liver, and it is associated with the development of hepatic encephalopathy (see Chapter 72). This can occur as a result of paracetamol (acetaminophen) toxicity, usually caused by overdosage, or from a massive viral infection. ALF is associated with a high mortality and requires careful monitoring. Orthotopic liver transplantation is the only effective treatment for this condition, although some cases of ALF can recover spontaneously. Donor organ shortage has dictated the development of criteria that can help to predict whether a patient with ALF has a potential to recover or whether a liver transplant is required. More recently, these criteria have also been used to predict the prognosis of patients with cirrhosis undergoing surgery for hepatocellular carcinoma (Kuang et al, 2009). Various sets of criteria have been proposed, of which the Model for End-Stage Liver Disease (MELD) and the King's College Hospital (KCH) criteria are the best known. Most criteria utilize prothrombin time/INR, serum bilirubin, serum creatinine, arterial blood pH, and hepatic encephalopathy in categorizing patients' disease severity.

Liver Masses

Patients with large liver masses may be seen initially with right upper quadrant discomfort or a palpable mass in the upper abdomen. More often, liver masses are discovered during imaging as part of the investigation of jaundice, nonspecific abdominal symptoms, or follow-up of malignancy. If the liver mass is discovered incidentally, a full clinical history should be obtained with particular attention to gastrointestinal and respiratory symptoms. Details and duration of oral contraceptive and anabolic steroid use should be recorded. Relevant past history, especially of other malignancies, should be obtained, and the possibility of viral hepatitis should be considered. A thorough abdominal examination should be performed, especially for abnormal masses and ascites, and a digital rectal examination is mandatory at the initial assessment. Signs of jaundice, liver insufficiency, and development of collateral circulation should be sought. A comprehensive hematologic and biochemical screening (Table 12.3) should include an assessment of coagulation factors and of common tumor markers (α-fetoprotein, carcinoembryonic antigen (CEA), CA 19-9, CA 125). Cross-sectional imaging evaluation of liver masses is discussed later in this chapter (see Investigation of Hepatobiliary Disease; see also Chapters 16 and 17).

Table 12.3

Laboratory Investigations in Hepatopancreatobiliary Disease

Hematologic Tests

Complete blood count: erythrocyte sedimentation rate, reticulocyte count, haptoglobulin levels, Coombs test
Coagulation profile (prothrombin time)

Liver Function Tests

Conjugated and unconjugated bilirubin levels, aspartate aminotransferase, alanine aminotransferase, γ-glutamyltransferase, alkaline phosphatase
Proteins (albumin, globulin)

Immunologic and Serologic Tests

Mitochondrial antibodies
Smooth muscle and antinuclear antibody
Immunoglobulins
Hepatitis B surface antigens
Immunoglobulin M antibody to hepatitis A
Hepatitis C antibodies
Cytomegalovirus antibodies
Epstein-Barr virus antibody
Leptospiral agglutinins
Fasciola complement fixation test
Amebic complement fixation test
Hydatid complement fixation test
Wasserman reaction and other serologic tests for syphilis

Tumor Markers

Carcinoembryonic antigen
α-Fetoprotein
CA 19-9
α_1-Antitrypsin levels

Other Tests

Serum amylase
Plasma ceruloplasmin levels
Iron and iron-binding capacity
Spot blood alcohol
Urine (urobilinogen, hemosiderin)
Stools (ova and parasites)

GALLBLADDER AND BILIARY TRACT DISEASE

Gallbladder

Tenderness and guarding in the right hypochondrium exacerbated by inspiration (Murphy sign) suggests cholecystitis. If the gallbladder is palpable in the presence of obstructive jaundice, this suggests malignant obstruction of the biliary tree (Couvoisier's law), which is commonly due to carcinoma in the head of the pancreas. Failure to palpate the gallbladder does not exclude malignant disease, however, and a nonpalpable gallbladder is the rule in malignant obstruction at the hilus of the liver. A gallbladder that is intermittently palpable suggests the presence of a periampullary carcinoma (Kennedy & Blumgart, 1971). Gallbladder distension and signs of sepsis in the presence of gallstones may indicate empyema of the gallbladder. In such instances, initial treatment consists of percutaneous aspiration and drainage, with a cholecystectomy delayed for some time.

Acute Cholecystitis

Acute cholecystitis may begin with a constant dull ache that slowly increases in severity over time, usually a couple of days, and may be associated with anorexia, nausea and vomiting, and pyrexia. It arises as the result of acute inflammation of a distended, obstructed, and usually infected gallbladder (see Chapter 31). Patients may be more comfortable lying still because of the associated localized peritonitis, and coughing or sneezing may exacerbate the pain. Acute cholecystitis is often associated with tenderness (peritoneal irritation) in the right upper quadrant and signs of systemic infection (pyrexia, raised leukocyte count,

raised C-reactive protein), and it requires antibiotic therapy to settle the infection. An infected, obstructed gallbladder sometimes ruptures and causes generalized peritonitis or a liver abscess. It is important to examine patients with acute cholecystitis regularly, and if the pain and tenderness do not settle rapidly with antibiotic therapy, percutaneous drainage of the gallbladder or an emergency cholecystectomy may be required.

Biliary *colic*, which is a clinical entity distinct from acute cholecystitis, usually has a crescendo-decrescendo pattern, with the pain slowly building up to a peak over a few hours; this peak is often associated with vomiting, and the pain then gradually subsides over the ensuing few hours. Often the pain radiates to the back (Berhane et al, 2006), and this pattern of gallbladder pain is thought to arise from gallbladder nociceptors, in response to a rise in intracholecystic pressure caused by strong contraction of the gallbladder against an obstructed neck. Biliary colic usually settles spontaneously, leaving some residual soreness in the right upper quadrant. These attacks of pain can be widely variable in their occurrence, and some patients may have an interval of many years between attacks; others may have almost constant discomfort. Some patients report that the pain is triggered by certain foods, usually fatty foods, and some patients are afraid of eating for fear of triggering an attack of pain (sitophobia).

Cholelithiasis

Symptomatic cholelithiasis is the commonest indication for cholecystectomy. Unfortunately, the symptomatology of gallbladder stone disease has been hard to define despite research spanning decades (Johnson & Jenkins, 1975; see Chapter 30). A large epidemiologic investigation in Denmark into the relationship between abdominal symptoms and gallstones concluded that the predictive values of various abdominal symptoms for gallstones were very low. In patients with gallstones, the prevalence of right upper quadrant abdominal pain was similar to patients without gallstones but was higher in patients who had previously undergone cholecystectomy (Jorgensen, 1989). A larger, multicenter Italian study, MICOL, showed that in an Italian population, the presence of epigastric or right upper quadrant pain radiating to the right shoulder that forced the patient to rest and intolerance to fried or fatty food were good predictors of gallstones (Corazziari et al, 2008). A recent Swedish study that followed up 503 patients without gallstones for 5 years reported that the incidence of gallstone formation was 1.39 per 100 person-years, and that no change was seen in the symptoms of these patients before and after development of gallstones (Halldestam et al, 2009).

Studies examining the relief of symptoms after cholecystectomy suggest that approximately one quarter of patients undergoing cholecystectomy will not experience relief of symptoms, and that dyspeptic symptoms are least likely to be cured by cholecystectomy (Weinert et al, 2000; Jorgensen et al, 1991). A study comparing the symptomatic outcomes after cholecystectomy for functioning and nonfunctioning gallbladders showed no difference in outcome (Larsen et al, 2007). An important study outlined the variation in perceptions of what was considered a valid indication for cholecystectomy (Scott & Black, 1991). These authors showed the case histories of 252 patients to two panels, one comprising surgeons and the other a mixed panel of doctors. The mixed panel considered 41% of the operations appropriate for the indications and 30% inappropriate, but the surgeons considered 52% appropriate and 2% inappropriate but could not agree on the other 46%. It is therefore important that an accurate documentation of dyspeptic or atypical symptoms be made, and patients should be counseled that cholecystectomy may not relieve any of their symptoms.

Biliary Obstruction

Classically, pain is a discriminating feature in jaundiced patients. Patients with biliary tract obstruction resulting from tumor usually have painless jaundice (see Chapters 50A through 50D and Chapter 58B), whereas patients with an acute attack of pain or a long history of intermittent episodes of jaundice accompanied by pain frequently have gallstone disease (see Chapter 35). In the event of cholangitis, rigors and fever also are present. Jaundice unaccompanied by pain, and especially if the gallbladder is palpable, almost always indicates malignancy. Back pain usually indicates a pancreatic lesion; chronic pancreatitis and tumors of the pancreas can manifest in this manner. Patients with chronic pancreatitis occasionally are seen with jaundice, especially during an acute-on-chronic attack, and the jaundice may be accompanied by symptoms of endocrine and exocrine deficiency (diabetes, steatorrhea, malabsorption; see Chapter 55A).

Malignant disease affecting the hepatic ducts at the biliary confluence in the hilus of the liver often presents with jaundice (Fig. 12.9), but in such instances, the gallbladder is not palpable (see Chapter 50B). Itching can be an initial feature of biliary obstruction (Fig. 12.10), but in prolonged cholestasis, itching may occur in association with partial biliary obstruction and significantly in primary biliary cirrhosis. Alkaline phosphatase often is markedly increased in partial biliary obstruction, even though the bilirubin may be only marginally elevated. A markedly increased or increasing alkaline phosphatase level may be the only sign of an early malignant or benign biliary stricture.

The distinction between obstructive (surgical) jaundice and hepatocellular (medical) jaundice is seldom the problem it was in the past. Hematologic and biochemical tests of liver function (Table 12.4) usually indicate whether the jaundice is obstructive, but this is not always the case. Identification of the cause and level of biliary obstruction is essential. Ultrasound (Chapter 13) is the preferred initial imaging test for diagnosis of biliary obstruction and to determine the etiology and level of obstruction. Computed tomography (CT) and magnetic resonance cholangiopancreatography (MRCP; see Chapters 16 and 17) are also extremely useful for evaluation of biliary obstruction.

Bile Duct Stones

The human bile duct is sensitive to acute distension, and obstruction of the lower end of the bile duct by a gallstone may cause epigastric pain that may radiate to the chest and back. Cholesterol bile duct stones are lighter than bile, and any distension of the bile duct may cause these stones to float proximally, releasing the obstruction. The symptoms of bile duct stones are typically intermittent jaundice associated with upper abdominal pain.

Acalculous Biliary Pain

Acalculous biliary pain is considered to be the result of a "functional" motor disorder of the gallbladder and/or sphincter of Oddi (Behar et al, 2006). Gallbladder motor dysfunction giving

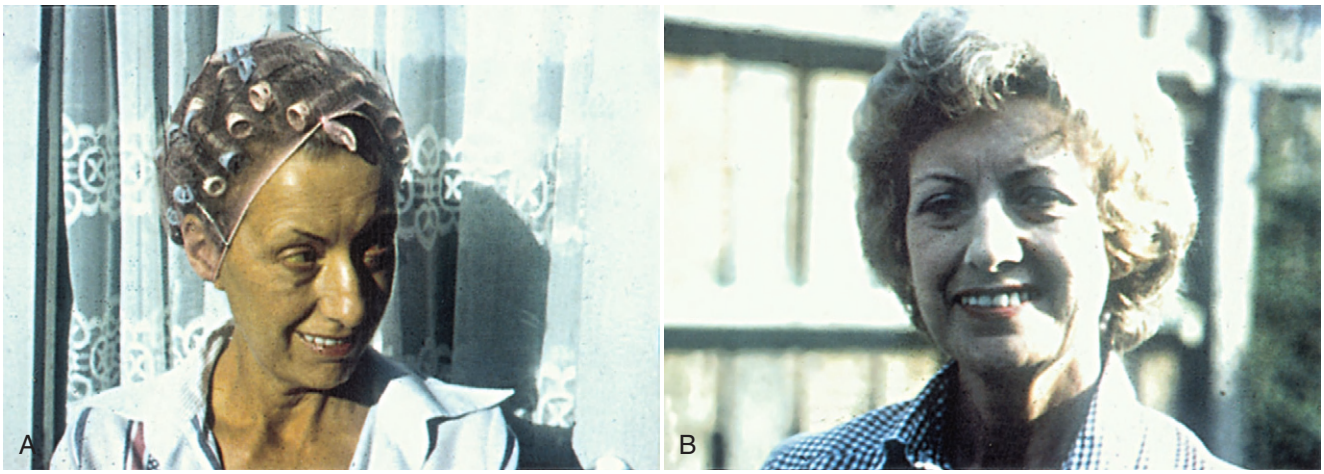

FIGURE 12.9. This patient initially presented with obstructive jaundice resulting from hilar cholangiocarcinoma. She had lost a great deal of weight and was anorexic and had intermittent attacks of cholangitis. Treatment was extended right hepatic lobectomy with excision of the biliary confluence and hepaticojejunostomy with Roux-en-Y to the left hepatic ducts. Four years later, she shows an excellent result: no tumor recurrence, normal liver function tests, and the patient has gained weight.

Table 12.4

Liver Function Aberrations in Obstructive and Hepatocellular Jaundice*

Parameter	Value	Obstructive Jaundice	Hepatocellular Jaundice
Bilirubin	Assesses severity; unconjugated bilirubin increases in hemolysis	↑↑↑↑	↑↑
Alkaline phosphatase	Marker of cholestasis	↑↑↑↑	↑↑
Alanine aminotransferase	Marker of hepatocellular damage	↑↑	↑↑↑↑
Aspartate aminotransferase	Marker of hepatocellular damage	↑↑↑	↑↑↑↑
γ-Glutamyltransferase	Marker of alcohol abuse and biliary stasis	↑	↑↑↑
Albumin	Marker of synthetic function	↓ or normal	Usually ↓↓
Prothrombin time†	Marker of synthetic function	↑↑↑	↑↑↑↑

*Prolonged biliary obstruction causes hepatocellular damage.
†Coagulopathy associated with biliary obstruction can be rapidly reversed with vitamin K, but not so in hepatocellular damage.

rise to abdominal pain has been defined by the Rome II Committee on Functional Biliary and Pancreatic Disorders as episodes of severe, steady pain located in the epigastrium and right upper quadrant and all of the following: episodes last 30 minutes or more, symptoms have occurred on one or more occasions in the previous 12 months, the pain is steady and interrupts daily activities or requires consultation with a physician, no evidence of structural abnormalities explains the symptoms, and gallbladder function is abnormal with regard to emptying. To eliminate calculous disease from the differential diagnosis, the Rome II Committee recommendations in the evaluation of these patients includes screening tests: upper gastrointestinal endoscopy, liver biochemisty, pancreatic function tests, and ultrasound of the gallbladder should be normal, and microlithiasis of bile should be excluded by endoscopic aspiration at endoscopic retrograde cholangiopancreatography (ERCP) or by aspiration of bile from the duodenum after stimulation by cholecystokinin (CCK) or magnesium sulfate. The recommended tests for gallbladder function are CCK cholescintigraphy assessment of gallbladder emptying, CCK- or meal-stimulated ultrasonographic volumetry of the gallbladder, and CCK-induced pain provocation tests. The Committee recommended that abnormal gallbladder emptying after CCK stimulation (<40% ejection) is an acceptable indication for cholecystectomy, as medical therapies are usually not effective (Corazziari et al, 1999).

Unfortunately, no consensus exists regarding the infusion rate of CCK that in turn can directly influence gallbladder emptying. Delgado-Aros and colleagues (2003) and DiBaise and Oleynikov and colleagues (2003) reported meta-anlayses of studies examining the symptomatic benefit from cholecystectomy based on abnormal CCK-stimulated gallbladder emptying. They found no good evidence to support the use of CCK-stimulated gallbladder ejection fraction to select patients for cholecystectomy. Similar findings were reported by Rastogi and colleagues (2005). Smythe and colleagues (1998) conducted a critical evaluation of CCK-provoked gallbladder pain and concluded that this test was not a predictor of symptomatic relief after cholecystectomy. It is interesting to note that in a prospective randomized study examining the development of symptoms in patients with uncomplicated gallbladder stones, a CCK-stimulated ejection fraction greater than 60% was independently associated with the development of symptoms.

The etiology and pathogenesis of calculous and acalculous gallbladder pain are poorly understood despite some recent insights by mathematical modeling (Li et al, 2007, 2008; Bird et al, 2006; Wegstapel et al, 1999; Ooi et al, 2004; Ahmed et al, 2000). We would therefore currently recommend that patients experiencing recurrent and severe symptoms as defined by the Rome II criteria should be offered cholecystectomy but should be carefully counseled regarding the uncertainty of its outcome, and this counseling should be clearly documented.

Sphincter of Oddi Dysfunction

Sphincter of Oddi (SO) dysfunction may be present in patients with an intact biliary tree, but it usually comes to light as a potential diagnosis when symptoms continue after a cholecystectomy. SO dysfunction has been subclassified into a biliary or pancreatic type. *Biliary type* SO dysfunction in postcholecystectomy patients has been arbitrarily subclassified into types I, II, and III. *Type I SO dysfunction* is defined as pain, elevated liver function tests documented on two or more occasions, delayed contrast drainage, and a dilated common bile duct with a corrected diameter of 12 mm or more at endoscopic retrograde cholangiopancreatography (ERCP). *Type II SO dysfunction* is characterized as pain only with one or two of the criteria in Type I. *Type III SO dysfunction* is defined as recurrent biliary-type pain with none of the criteria from type I. Toouli (2009) concluded that accurate sphincter manometric data is crucial to establish a diagnosis of SO dysfunction. Invasive investigation of sphincter dysfunction and/or sphincterotomy is associated with a risk of pancreatitis in up to 30% of patients. Insertion of prophylactic pancreatic stents are advocated as a means of reducing this risk, and some evidence exists to support this practice. Injection of botulinum toxin into the sphincter also has been advocated as a "therapeutic test" before a sphincterotomy is performed. In a literature review, Sgouros and Pereira (2006) concluded that biliary sphincterotomy reliably treats symptoms in 85%, 69%, and 37% of patients with types I, II, and III SO dysfunction, and pancreatic sphincterotomy may benefit up to 75% of patients. They state that sphincter manometry is the gold standard in the investigation. *Pancreatic type* SO dysfunction is also subclassified into types I, II, and III according to whether pancreatic enzymes are elevated soon after an attack of pain and whether the pancreatic duct is dilated greater than 5 mm.

Iatrogenic Biliary Injury

Patients with iatrogenic damage to the biliary tract (see Chapter 102) may not only present with jaundice because of biliary stricture but also may present with biliary leakage, resulting in biliary peritonitis or fistula. In such patients it is important to obtain a good history that includes a copy of the original operative report, which may offer an indication as to the level and nature of the injury and may provide a baseline for comparison with further investigations. Many patients may present with biliary and abdominal sepsis, and blood and bile cultures should be obtained. If a biliary fistula is present, or if the patient is deeply jaundiced, coagulation may be deranged. Liver function tests may show biochemical evidence of biliary obstruction or of liver damage, and patients are often nutritionally depleted and may be anemic. Ongoing liver damage may be present, resulting from a combination of sepsis and biliary obstruction.

Imaging with CT and MRCP may yield valuable information in these patients. MRCP can accurately depict areas of stricture and fistula formation, and CT can be used to guide intervention and drainage. The key question is whether the biliary tract is intact and in continuity. In patients with a biliary fistula, fistulography may outline the problem; but ERCP and percutaneous transhepatic cholangiography are more useful, because they provide a dynamic view of the site and show the severity of leakage, which may allow a stent to be placed across the site of the leak. Associated vascular injuries should be suspected and may be suggested at imaging. Extensive bleeding at the time of cholecystectomy should lead to a high index of suspicion for vascular injury. Hepatic arterial injury is usually well compensated, and portal venous injury may be revealed by the presence of liver atrophy, usually best seen on CT. Occasionally, long-standing biliary strictures result in secondary biliary cirrhosis, and liver biopsy may be necessary.

PANCREAS

Acute Pancreatitis

Acute pancreatitis is usually accompanied with severe upper abdominal pain that develops rapidly, becomes constant, and persists for several hours (see Chapter 53). The pain typically starts in the epigastrium but may soon spread throughout the abdomen and radiate into the back. Sometimes the patient may find relief by sitting forward, but usually they lie still and curled up in bed. The pain can be so sudden in onset that at times, it can simulate a perforated peptic ulcer, and indeed acute pancreatitis can mimic almost every cause of acute abdominal pain and may even produce chest pain that simulates myocardial infarction, pneumonia, or pleurisy. Frequent vomiting and sequestered fluid in the small bowel may lead to rapid and severe dehydration. Even keeping the stomach empty with a nasogastric tube may not prevent the patient from retching, and marked nausea is almost a constant feature. Hiccoughs can also occur due to diaphragmatic irritation secondary to extension of the inflammatory process tracking up via the retroperitoneum.

Patients with acute pancreatitis may exhibit signs of profound shock with tachycardia, tachypnea, hypotension, and confusion. At the other extreme, patients may appear well, with little in the way of physical signs. The patient may be afebrile on admission, but progression of the inflammatory process leads to fever, facial flushing, and mild jaundice. Abdominal examination usually reveals marked tenderness in the epigastrium with guarding, but marked rigidity as seen in a perforated ulcer is often lacking. The presence of a paralytic ileus may result in abdominal distension with a tympanitic percussion note and diminished bowel sounds. Later features may include a discoloration around the umbilicus (Cullen sign) or in the flanks (Grey-Turner sign) as a result of bruising within the fascial planes, pancreatic ascites, and a pleural effusion. A mass is rarely present, unless the inflammatory process has resulted in a pancreatic abscess or sizeable pseudocyst. General features of acute pancreatitis may include confusion, disorientation, hypoxemia, and even adult respiratory distress syndrome. The associated hypocalcemia rarely results in clinical signs of neuromuscular irritability.

Rarely, acute pancreatitis can occur without severe pain, and in these cases, the diagnosis can be missed, and such failure may be associated with a poor prognosis (Lankisch et al, 1991). It is important to be aware of the condition and consider it in any patient who develops sudden shock or anuria, especially if it follows biliary surgery, ERCP, coronary artery bypass, or trauma. A detailed history is therefore vital, particularly inquiring as to the past medical history and family history, especially in children. Any history of alcohol abuse, bilary colic, jaundice, recent surgery, or ERCP should be actively sought.

Most cases of acute pancreatitis are associated with alcohol abuse or biliary disease but can also follow ERCP; abdominal surgery, especially to the stomach, duodenum, and biliary tree; coronary artery bypass surgery; trauma; and certain viral illnesses, especially mumps. The association with alcohol abuse varies according to country and urbanization, being as high as 65% in parts of urban America. Biliary disease is responsible for over 30% of cases in a general population, and sieving the feces of patients with gallstone-associated pancreatitis shows gallstones present in a high proportion of them (Kelly, 1976), prompting many to speculate that the pancreatitis resulted from the temporary lodging of a stone in the ampulla of Vater. Postoperative pancreatitis accounts for 5% to 10% of cases (Thompson et al, 1988), and hyperamylasemia can occur in about 10% of patients undergoing ERCP, although only 1% will develop severe acute pancreatitis. The cause of traumatic pancreatitis is again subject to geographical variation (Jones, 1985); penetrating trauma is more common in the United States and blunt trauma and injury as a result of traffic accidents are more common in the United Kingdom. Other rare causes include hyperparathyroidism, hyperlipidemia, and certain drugs including steroids, azothiaprine, and diuretics (Nakashima & Howard, 1977). However, once all these causes have been excluded, for about 25% of patients, no clear etiology is identified. The sex ratio for acute pancreatitis is virtually equal but tends to have a higher peak age incidence in women, reflecting the higher incidence of gallstones; in men the lower peak age reflects their propensity to alcohol abuse.

Chronic Pancreatitis

There are few pathognomonic or diagnostic signs for chronic pancreatitis, and diagnosis usually depends on the history and special investigations (see Chapter 55A). The patient may appear malnourished with signs of weight loss, they may be icteric as a result of compression of the common bile duct by the fibrotic process in the head of the pancreas, and erythema

ab igne may be present on the back or abdomen. Uncommonly, a palpable mass, pseudocyst, or splenomegaly may be evident, and occasionally pancreatic ascites, if there has been rupture of a pseudocyst or of the duct system.

Chronic pancreatitis is a difficult condition both to diagnose and to treat. It is crucial to exclude other associated conditions, such as pancreatic cancer; but once the diagnosis is established, it is important to 1) identify any predisposing cause, 2) stage the severity of the disease, and 3) document any morphologic and functional changes against which any progression can be assessed. One of the commonest predisposing factors is alcohol abuse, although chronic pancreatitis is also associated with biliary disease, congenital abnormalities such as an annular pancreas (Dowsett et al, 1989), ductal abnormalities, and rarely with hyperparathyroidism. An autosomal dominant hereditary form of the condition may also be a factor, so a family history is crucial (Teich, 2008). Rarely is any specific drug or dietary factor implicated.

Pain is the commonest presenting symptom of chronic pancreatitis and is often the most difficult to control. The pain is usually situated in the epigastrium and subcostal regions and commonly radiates through to the back. Pain can be severe and penetrating in nature, and often the patient will lean forward or curl up to relieve the discomfort. In severe cases, the patient may even kneel on all fours to gain relief. Occasionally, the pain may radiate to the left shoulder tip. Variation in the pattern of pain in these patients is enormous, and some are never free of discomfort, but others may simply complain of intermittent attacks. In some, these severe bouts may be brought on by eating or ingesting alcohol, although often no clear association is made between attacks and oral intake. In many the pain is so debilitating that it interferes with the patient's domestic, social, and occupational activities and can have a devastating impact on the quality of life. Indeed, in many it results in a change in personality with a manipulative tendency often associated with an addiction to opiates. These patients can be particularly difficult to assess, especially if they are already addicted to alcohol.

Other presenting symptoms include marked steatorrhoea resulting from diminished lipase production and inadequate fat absorption (Di Magno, 1982). The stool frequency may be increased up to six times a day, and the stools themselves become pale and bulky with an offensive odor, and they float, making them difficult to flush away. However, this is not a constant feature of chronic pancreatitis; some patients may even suffer from constipation as a result of the increased use of opiate analgesia.

The incidence of diabetes mellitus is a variable and often late feature. As chronic pancreatitis progresses, there may be loss of endocrine function, initially requiring dietary control and subsequently oral hypoglycemic agents or even insulin. Other more general features of chronic pancreatitis may include weight loss, nausea and vomiting, jaundice, and even gastrointestinal bleeding as a result of splenic vein thrombosis, although this is rare.

Pancreatic Cancer

Regretfully, physical signs of pancreatic cancer are often absent or infrequent, until the lesion is unresectable (see Chapter 58B). The patient may be symptomatic with weight loss, but unless the lesion is situated in the head of the pancreas such that it obstructs the common bile duct early, causing obstructive jaundice, few other signs may be evident. With distal bile duct obstruction, the gallbladder may become distended (Courvoisier gallbladder). An abdominal mass and ascites are late signs and usually herald inoperability. Systemic signs such as flitting thrombophlebitis migrans may be apparent, but this is uncommon and nonspecific. All too often cachexia is the only physical finding.

Later clinical features of pancreatic cancer are pain, weight loss, and jaundice. The pain is often severe and gnawing and radiates to the back. It is often worse at night, when the patient is lying flat, which usually indicates tumor extension to the retroperitoneum, often signifying irresectability. Weight loss may be marked, and in many cases of tumors in the body of the pancreas, weight loss may be the only symptom, until pain indicates invasion of the peripancreatic tissue. The more rapid the weight loss, the less likely the lesion is to be resectable (Bakkevold et al, 1992). Jaundice can be associated with severe pruritus, but this classical presentation only occurs when the lesion is in the head of the pancreas; when jaundice occurs with tumors of the body or tail of the pancreas, it usually signifies hilar liver or nodal metastases.

About 5% of patients with pancreatic cancer will have developed diabetes mellitus within the 2 years prior to diagnosis (Pannala et al, 2009). Other signs such as ascites, an epigastric mass, or enlarged supraclavicular nodes (Virchow sign) are indications of inoperability. Because of the lack of specific signs and symptoms, very commonly a diagnostic dilemma arises as to whether a lesion is chronic pancreatitis or pancreatic cancer. Frequently, diagnostic imaging cannot provide the answer, and even at operation it may not be apparent which condition the surgeon is facing; this occured in up to 15% of cases in some series (Mao et al, 1995).

INVESTIGATION OF HEPATOBILIARY DISEASE

All patients with suspected hepatobiliary and pancreatic disease should undergo a comprehensive hematologic and biochemical screening, including an assessment of clotting capability. The history may dictate additional serologic tests—tumor markers such as α-fetoprotein, CA 19-9, CEA—and immunologic tests, such as a viral hepatitis screening. Particular attention needs to be paid to the platelet count, coagulation profile, and liver function tests (see Tables 12.3 and 12.4).

Imaging of incidentally discovered liver masses should be directed toward characterizing the liver lesions. Magnetic resonance imaging (MRI) is usually highly specific in characterizing liver masses (Seneterre et al, 1996), and it can be used to differentiate between benign and malignant lesions (see Chapter 17). Contrast-enhanced CT scan of the chest, abdomen, and pelvis is mandatory in patients with suspected malignancy of the liver to exclude extrahepatic disease and to determine resectability (see Chapter 16). In the presence of resectable disease, liver biopsy is seldom indicated, because many lesions can be characterized by imaging and clinical features; biopsy is generally reserved for patients with nonresectable tumors that require histopathologic confirmation prior to instituting therapy (Thompson et al, 1985).

It is important to assess the patient in terms of fitness for surgery, nutritional status, cardiorespiratory and renal function, and parenchymal liver disease. It is vital to be aware of the Child-Pugh stage of the liver disease before planning any

treatment of hepatocellular cancer (see Chapter 80). An array of autoantibodies is used to diagnose autoimmune hepatobiliary disorders, and some of these are listed in Table 12.3.

Cardiorespiratory disease and fitness for surgery are assessed during history taking and may indicate the need for further detailed study. These additional investigations are often conducted with advice from anesthesiologists, in the event a major surgical procedure is contemplated. Nutritional status can be determined crudely by hemoglobin, protein, and albumin levels and is often abnormal, especially if liver function has been compromised for a long time. Continuous fine-bore enteral tube feeding may be instituted in these patients to try to optimize nutritional status before surgery (Allison, 2004; Lidder & Lewis, 2004). If renal function is abnormal, creatinine clearance quantifies the problem and may indicate the need for renal support in the perioperative period (Thompson et al, 1987).

Many patients with hepatobiliary and pancreatic disease may have undergone instrumentation of the biliary tract. ERCP or percutaneous transhepatic cholangiography may have been employed. Biliary sepsis is extremely common after these procedures (Brody et al, 1998; Heslin et al, 1998; Povoski et al, 1999). If external biliary drainage has been used, it is important to culture the biliary output, even if no evidence of systemic sepsis is present. In such cases, no immediate indication for antimicrobial therapy is apparent, but culture and sensitivity will guide future therapy. In particular, perioperative antibiotic therapy is indicated in these patients. Systemic sepsis requires urgent broad-spectrum antibiotic therapy, subsequently guided by the results of blood culture and sensitivity tests. Patients with long-standing partial biliary obstruction and sepsis have a high likelihood of fungal infections.

Colorectal Liver Metastases

Liver metastases from primary colorectal cancer are frequently discovered at the time of diagnosis on the staging CT scan (see Chapter 81A). Metastases may occasionally be detected during operation on the primary tumor, especially if this is done as an emergency procedure. They are also frequently discovered as metachronous tumors during follow-up after resection of primary colorectal cancer. Follow-up strategies in patients with colorectal cancer are a subject of much debate, and no clear consensus exists. In patients with no perioperatively detected metastatic disease and an R_0 colonic resection, it is advisable to image the chest, abdomen, and pelvis with contrast-enhanced CT scan at 9 months and 2 years postresection. If metachronous liver metastases are detected, resectability is determined by the patient's ability to undergo potentially major liver surgery by the location and segmental distribution of the hepatic metastases and by the presence of extrahepatic disease. Positron emission tomography (PET) and CT scan can be most useful in this regard (see Chapter 15). Recent reports have shown added benefit of contrast-enhanced MRI scan to determine resectability (Blyth et al, 2008; Hekimoglu et al, 2009). Synchronously detected liver metastases may be resected at the time of the resection of the primary lesion or as a second procedure, sometimes after the administration of neoadjuvant chemotherapy.

It is important to note that metastatic disease in the liver, especially in its early stages, may not give rise to symptoms and can only be detected by screening these patients. Regular serum CEA levels are useful in the follow-up of these patients, and combined with interval CT scanning, this should detect the majority of colorectal liver metastases.

INVESTIGATION OF PATIENTS WITH PANCREATIC DISEASE

In patients with acute pancreatitis (see Chapters 53 and 54), diagnosis usually is made based on the history and the serum amylase and lipase levels. An elevated serum amylase can fall quite rapidly, and it may be normal if measured 2 to 3 days after the onset of the attack. Urinary amylase may be elevated in these patients, however, a contrast-enhanced CT scan often confirms the diagnosis but is particularly poor at identifying gallstones. An ultrasound scan is usually the first investigation of choice, because it detects gallstones and allows the patient to proceed to endoscopy and endoscopic sphincterotomy when appropriate. In patients with acute pancreatitis, the duodenum and small bowel often are filled with gas, and detection of common bile duct stones is less reliable.

Serum amylase is of no value in predicting the severity of an attack, and scoring systems have been developed, such as the Ranson and Glasgow scores. Scoring systems are accurate in predicting outcome only after 48 hours. Inflammatory markers such as C-reactive protein are also are valuable, but similarly to the Ranson and Glasgow scores, such markers may not assess severity accurately until 48 hours after onset. The Acute Physiology, Age, and Chronic Health Evaluation (APACHE II) is a more accurate predictor of severity at admission, but its complexity limits its routine clinical use.

In patients who remain unwell 1 week after onset, or in those who deteriorate after initial improvement, pancreatic necrosis should be suspected, and a contrast-enhanced CT scan should be performed (British Society of Gastroenterology, 2005). Patients judged to have a severe attack of pancreatitis at onset are at high risk of developing a systemic inflammatory response syndrome and require very careful and repeated observation with attention to fluid balance, nutrition, and sepsis. Prophylactic antibiotic therapy in this group of patients is useful and may prevent the development of infected pancreatic necrosis. Patients with clinically and biochemically severe pancreatitis should be managed in conjunction with critical care physicians in a suitable environment. Patients may go on to develop pancreatic pseudocysts that may cause pain or other effects as a result of pressure on neighboring organs, especially the stomach. Nausea, vomiting, or early satiety should alert the physician, as these pseudocysts are easily detectable on CT scanning. Continuing evidence of systemic sepsis usually indicates the presence of infected pancreatic necrosis, which can be confirmed by fine needle aspiration.

In patients with chronic pancreatitis, serologic blood tests such as amylase, lipase, and elastase are not helpful, but C-reactive protein may indicate active inflammation. Fecal elastase may indicate exocrine deficiency, whereas routine hematologic and biochemical tests, including glycosylated hemoglobin, are important to provide a baseline for endocrine assessment.

It may be difficult to differentiate between pancreatic carcinoma and some cases of chronic pancreatitis, as there are no clear-cut markers for this, although lymphoplasmacytic sclerosing pancreatitis is usually accompanied by an elevated serum IgG. The tumor marker CA 19-9 has a sensitivity of 80% and a specificity of 75% for pancreatic cancer (Kim et al, 1999), but

as the level tends to correspond with tumor volume, potentially curative tumors may be associated with normal levels (Eloubeidi et al, 2004; Schlieman et al, 2003), which limits its use as a screening tool. Very high levels of CA 19-9 are associated with a higher incidence of metastatic disease (Maithel et al, 2008), and laparoscopy is advocated to determine the presence of subradiological metastatic disease in patients with a CA 19-9 level above 150 kU/L (nonjaundiced patients) and above 300 kU/L in jaundiced patients (Halloran et al, 2008).

A contrast-enhanced spiral CT scan using thin (3 to 5 mm) slices provides information as to the extent and nature of any mass and in particular helps differentiate solid from cystic lesions, vascular involvement or encasement, and lymph node metastases. No significant advantage of gadolinium-enhanced MRI over multidetector CT has been seen in the staging of pancreatic cancer (Park et al, 2009), but multidetector CT has a better diagnostic yield (Satoi et al, 2009). MRCP can be useful in the differential diagnosis of pancreatic cystic masses and duct delineation, and endoscopic ultrasound may contribute substantially to the assessment of ampullary tumors (Kahaleh et al, 2004), for image-guided aspiration of pancreatic cysts, and to obtain biopsies of intrapancreatic tumors.

CHAPTER 13

Ultrasound of the liver, biliary tract, and pancreas

Terry S. Desser and Lucy E. Hann

ULTRASOUND TECHNOLOGY

Ultrasound is a high-resolution, low-cost imaging technique that uses no ionizing radiation. Its versatility and real-time imaging capability are also major advantages. Another unique advantage is Doppler ultrasound, which allows visualization of blood flow and assessment of flow dynamics. Ultrasound units are now smaller and more portable, so they are widely used in multiple medical settings, including the bedside, operative suite, emergency room, and in diagnostic and interventional radiology suites. Miniaturized high-resolution transducers also facilitate laparoscopic and endoscopic procedures (Berber et al, 2004; Machi et al, 2004).

Despite these broad applications for ultrasound, certain limitations influence its applicability. Ultrasound is not transmitted past bone or air interfaces with soft tissue, so some areas may be obscured or imaging access limited. Another factor is that ultrasound has a limited field of view compared to computed tomography (CT) or magnetic resonance (MR) imaging; this may pose some difficulty for localization and follow-up of lesions. Lastly, ultrasound is very operator dependent; quality of ultrasound imaging and diagnosis is influenced greatly by the experience of the examiner.

Principles of Ultrasound Interpretation

Gray-scale sonography employs a pulse-echo technique to generate a two-dimensional display of the backscattered signal from insonated tissue. The intensity of the received echoes is recorded as brightness in the image. The strength of the echo at a tissue boundary is determined by *acoustic impedence*, defined as the product of tissue density and the speed of sound in the tissue. Sonographic scanners assume a uniform velocity of sound (1540 m/s) to compute the depth from which the received echo originated. Higher frequency sound has a shorter wavelength and therefore better spatial resolution, but a high-frequency sound beam attenuates more and has less tissue penetration. For this reason, lower frequency transducers are used to image structures deep within the abdomen, and higher frequencies are used to image more superficial structures (Zagzebski, 1996).

Gray-Scale Ultrasound Terminology and Artifacts

Lesions that appear dark relative to the background tissue are termed *hypoechoic*; those that are brighter than background are *hyperechoic* or *echogenic* (Fig. 13.1). Spaces that contain fluid do not contain internal interfaces, so no sound is reflected from within them; they appear uniformly black or *anechoic*. The ultrasound scanner normally compensates for the attenuation of sound that occurs with increasing depth within the tissue by amplifying echoes that return later from the far field. This is called *time-gain compensation* (TGC) or *depth-gain compensation*. TGC results in needless amplification of echoes from areas deep to pure fluid structures, because the acoustic pulse is attenuated to a lesser extent by fluid than by tissue. Such artificially bright areas beyond the fluid represent *increased through transmission*, or *acoustic enhancement* (Fig. 13.2). Although technically an artifact, acoustic enhancement is useful to characterize structures as cystic if they also lack internal flow on color Doppler.

Several other ultrasound artifacts also are used for diagnosis. At boundaries with large acoustic impedance mismatches, such as between tissue and air or tissue and bone, nearly all the energy in the incident beam is reflected; because none is transmitted, areas beyond the interface will not be visualized. A black *acoustic shadow* is thereby produced behind the object in the image (Fig. 13.3). Shadowing is characteristic of virtually all gallstones and greatly aids in distinction of gallstones from gallbladder polyps.

Within fluid-filled structures such as the gallbladder, faint echoes are often seen paralleling the anterior surface. These echoes represent *reverberation* artifact, which occurs as the sound is repeatedly reflected between the highly echogenic anterior gallbladder wall and the transducer. Reverberation also accounts for *comet tail artifact*, a streak of tiny, bright, parallel bands tapering behind a punctate crystalline reflector, generated by sound echoing within the crystal itself. Comet tail artifact is a feature of adenomyomatosis of the gallbladder and emanates from cholesterol crystals trapped in dilated Rokitansky-Aschoff sinuses in the gallbladder wall (Fig. 13.4). Fluid-filled structures may also have artifactual echoes along the dependent wall that originate from off-axis portions of the ultrasound beam. This is termed *side lobe artifact* and may be distinguished from true debris by changing the angle of insonation or repositioning the patient (Feldman et al, 2009; Zagzebski, 1996).

Doppler Ultrasound

Doppler techniques offer unique capability for imaging blood flow. When transmitted sound strikes a moving object, the reflected signal changes frequency; this phenomenon is defined by the Doppler equation. Doppler imaging allows assessment of 1) vessel patency, 2) direction of blood flow, 3) flow velocity, and 4) spectral waveforms.

Three different Doppler displays are available (Fig. 13.5). Color Doppler displays show flow velocity and direction of flow

FIGURE 13.1. Transverse gray-scale ultrasound image of the liver shows the right hepatic vein (*hv*) as a black (anechoic) fluid-containing structure. Note that the walls of the veins are bright (echogenic). The echogenic *curved line* posteriorly represents the diaphragm.

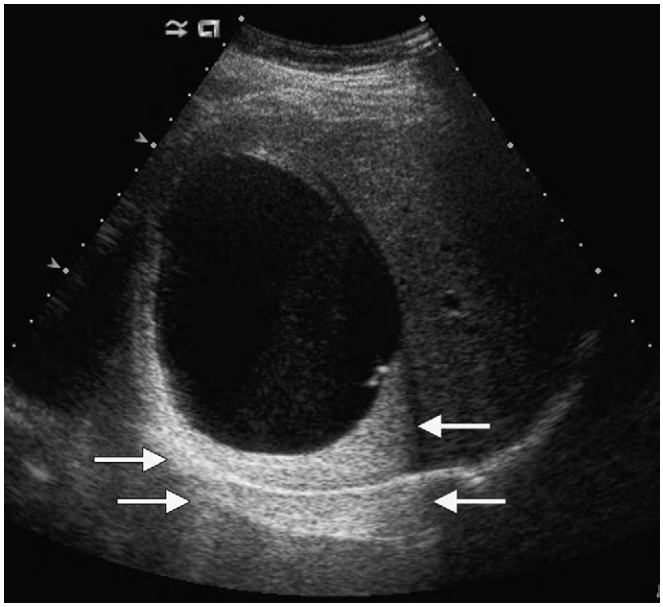

FIGURE 13.2. Simple hepatic cyst has no internal echoes and a thin smooth wall. Note the bright posterior acoustic enhancement (*arrows*) that is a characteristic feature of a cystic lesion.

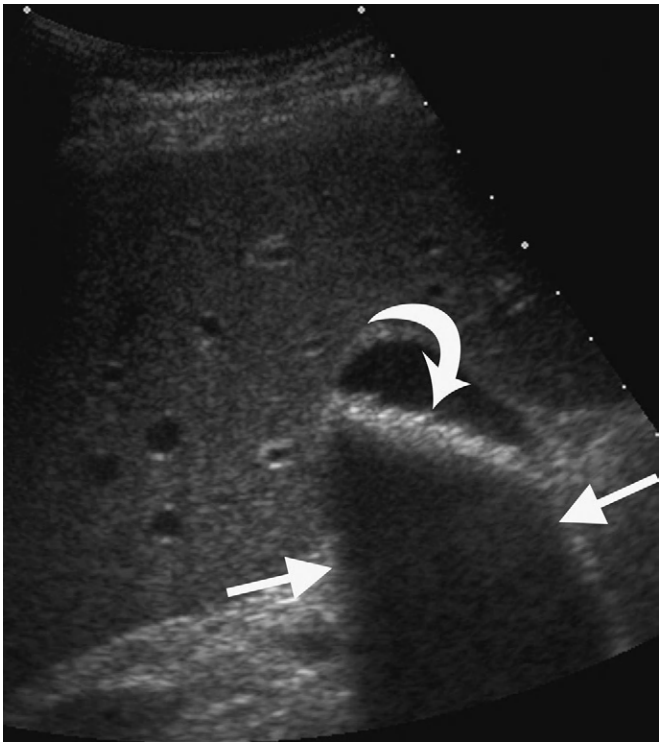

FIGURE 13.3. Gallstones (*curved arrow*) layering in the gallbladder produce an acoustic shadow (*straight arrows*).

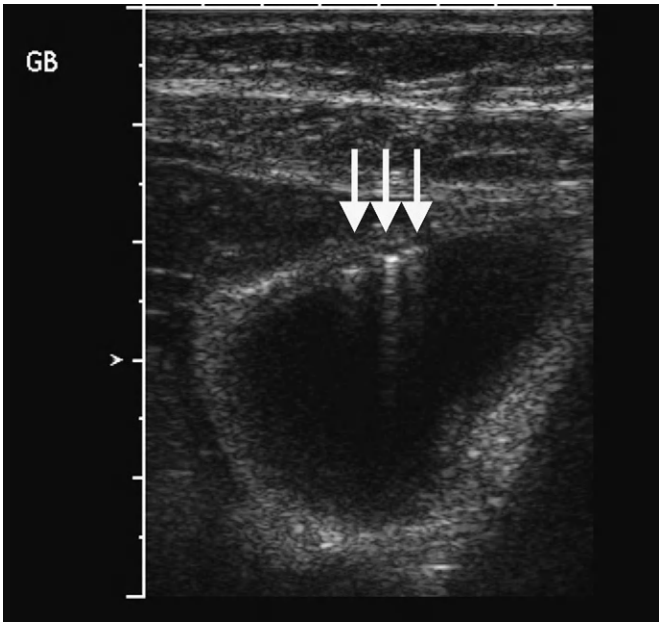

FIGURE 13.4. Bright reflectors in the gallbladder wall (*arrows*) produce comet tail, or ring-down, artifacts secondary to sound reverberation. This appearance is characteristic of gallbladder adenomyomatosis.

toward or away from the transducer. A graphic or bar on the color Doppler image indicates the colors designated for flow toward and away from the transducer and the range of displayed velocities. Focal areas of high velocity that exceed the highest value on the Doppler setting produce a disorganized color signal; this is an artifact termed *color aliasing* that is useful to identify high-velocity flow, which may indicate vascular stenosis or encasement. Power Doppler displays amplitude of flow but not flow direction, and the signal is not dependent on the angle of insonation. Power Doppler is most useful to show areas of low flow and to demonstrate intralesional vascular patterns.

Spectral Doppler displays a graph of the entire range of velocities over time, rather than the mean velocity, as in a color Doppler image. When combined with gray-scale and/or color

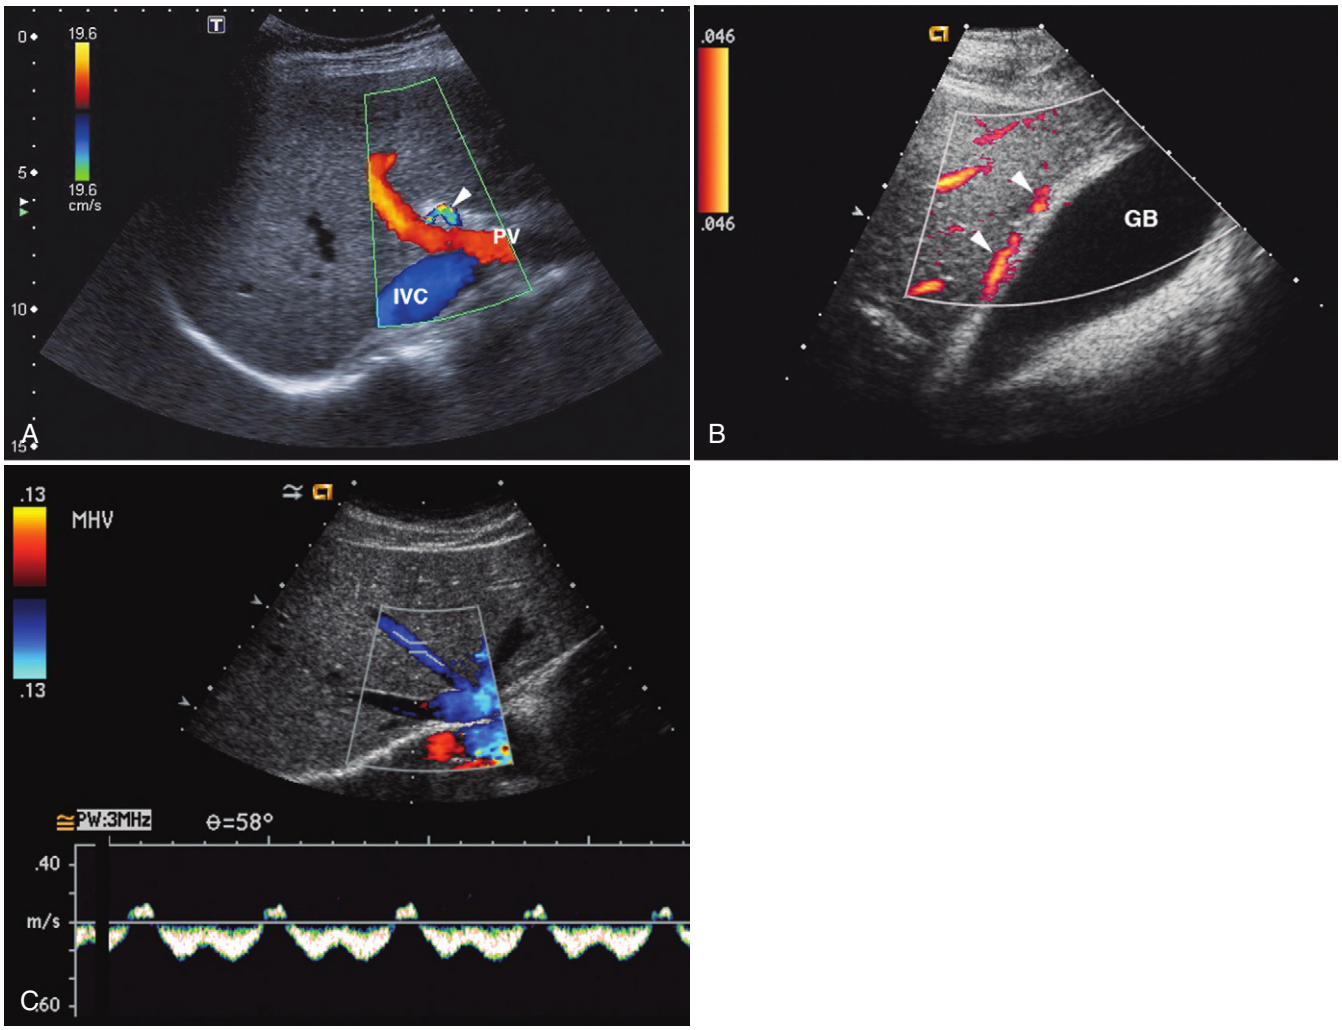

FIGURE 13.5. Doppler ultrasound of the liver. **A,** Color Doppler mode shows mean flow velocity and direction of flow toward or away from the transducer, as indicated in the *bar display at left* of the image. The portal vein (*PV*) indicates hepatopetal flow. The inferior vena cava (*IVC*) shows flow away from the transducer. The hepatic artery (*arrowhead*) has mixed signals due to high-velocity flow and aliasing. **B,** Power Doppler shows amplitude flow but not direction. It is useful for small vessels and low flow, as shown in this image of vessels in the gallbladder (*GB*) wall (*arrowheads*). **C,** Spectral Doppler shows flow pattern over time; when angle corrected, it can measure true velocity. A sample cursor is placed within the vessel, as shown in this transverse image of the middle hepatic vein. Flow variations are due to changes in right atrial pressure.

Doppler imaging in real time, it is possible to sample flow in specific blood vessels. For arterial flow, the peak systolic velocity and end-diastolic velocity indicate the strength of the inflow pressure and the downstream resistance. A useful metric for arterial waveform evaluation is the *resistive index*, defined as the difference between the peak systolic and end-diastolic velocities divided by the peak systolic velocity. A resistive index close to 1 implies nearly absent diastolic flow and high-resistance downstream. A lower than normal resistive index generally results from decreased systolic velocity and indicates impaired inflow to the region of interest. Hepatic venous waveform is usually phasic, with transmitted cardiac pulsation (see Fig. 13.5). When the hepatic veins or inferior vena cava (IVC) are narrowed, the waveform becomes flattened; this is a sensitive sign for venous compromise. Normal portal venous flow also has a phasic pattern that is decreased in conditions such cirrhosis and fatty infiltration (Colli et al, 1994).

Recent Technologic Advances

New techniques have been developed to coregister ultrasound, CT, and MRI images to facilitate lesion localization and to guide intervention or biopsy. Electromagnetic sensors placed near the scanning area and sensors attached to the ultrasound probe allow tracking of transducer position and orientation. Anatomic landmarks are identified on initial scanning and with navigation software, and these landmarks are coregistered with CT or MR images that have been downloaded into the ultrasound unit (Ewertsen et al, 2008). As the ultrasound scan is being performed in real time, the CT or MR images are reconstructed into a similar orientation plane (Fig. 13.6). Images may be displayed side by side or in a blended, overlapped format. In a study of contrast-enhanced ultrasound fused real time with CT, Jung and colleagues found that more lesions were identified with image fusion than with CT alone (Jung et al, 2009). Similar instrumentation allows global positioning system (GPS)

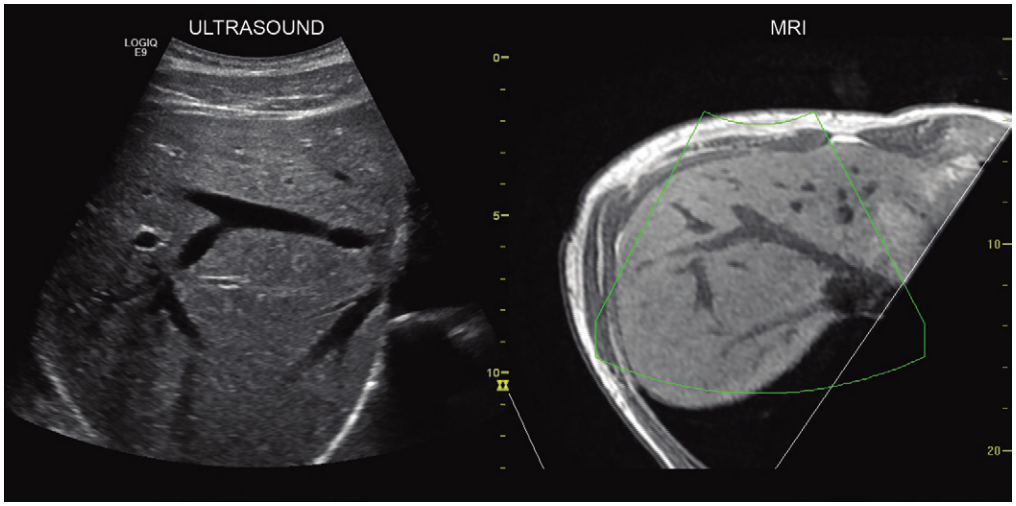

FIGURE 13.6. Coregistration technology shows a transverse ultrasound image of the liver and a magnetic resonance image that have been coregistered to display identical orientation and plane of section. *(Courtesy GE Healthcare, Little Chalfont, United Kingdom.)*

navigation for needle tracking and volume acquisition. Acoustic force imaging to assess liver stiffness is another recent advance in development (see Songraphy of Diffuse Liver Disease below), and contrast-enhanced ultrasound is discussed in various sections on liver masses, detection, and characterization that follow.

LIVER ULTRASOUND

Normal Liver Anatomy

The normal liver (see Chapter 1B) has a smooth surface and is uniform in echogenicity. Compared to adjacent organs, the liver is similar to or more echogenic than the kidneys and less echogenic than the spleen and pancreas. The superior aspect of the liver may have thin, linear indentations from diaphragmatic leaflets. Hepatic shape is variable. For example, a Riedel lobe may cause tonguelike inferior extension of the right lobe that may present as a palpable mass. Estimates of hepatic volume may be done with volumetric analysis (Treece et al, 2001; Wilson et al, 2009), but liver size is most commonly determined by a longitudinal image in the right midaxillary line. Normal liver length is reported to be less than 15.5 cm (Gosink et al, 1981). Others have used the right midclavicular longitudinal measurement with normal mean length of 10 cm (Niederau et al, 1983).

The Couinaud segmental anatomy of the liver is shown in Figures 13.7 and 13.8 (Couinaud, 1957; see Chapter 1B). Ultrasound images are obtained through available acoustic windows that avoid bone and air; this may vary the appearance of the liver compared with the standard axial, sagittal, and coronal planes of CT and MR, but the vascular landmarks that define the Couinaud segmental anatomy are well seen by ultrasound (Lafortune et al, 1991; Soyer et al, 1994). The hepatic veins and portal vein bifurcation are visualized with a subcostal transverse view; longitudinal images of the main portal vein, portal bifurcation, and hepatic artery are obtained best by intercostal approach, with the patient in the left lateral decubitus position. Transverse images of the portal confluence show the right portal vein and its bifurcation. The left portal vein in this plane courses transversely in the hilar plate for 3 to 4 cm before it extends into the umbilical fissure and gives off branches to the left hepatic segments. It is important to note that the horizontal portion of the left portal vein is extrahepatic and more readily available to the surgeon than the right portal vein.

Detection and Characterization of Focal Liver Masses

Gray-Scale Ultrasound of Focal Liver Masses

Conspicuity of liver lesions by gray-scale ultrasound is determined by lesion echogenicity relative to the liver. Small, markedly hypoechoic or hyperechoic lesions may be readily detected and characterized by ultrasound (Eberhardt et al, 2003), but masses that have echogenicity similar to adjacent liver may be more difficult to appreciate. On gray-scale ultrasound, liver masses are differentiated by internal architecture and are described as cystic, hypoechoic, and hyperechoic relative to the liver. Table 13.1 shows the common differential diagnoses within each of these categories (Charboneau, 2002; Middleton, 2002). The majority of cystic masses are benign, whereas most hypoechoic masses, with the exception of focal fatty sparing, are suspicious for neoplasm and require further evaluation, as they are clinically significant. Focal sparing often has geographic margins, typically is located in segment IV anterior to the portal bifurcation or adjacent to the gallbladder, and vessels are undisturbed. These distinctive features allow confident diagnosis (Fig. 13.9).

Hyperechoic masses include benign hemangioma, focal fat, and hepatic neoplasms such as hepatocellular carcinoma (HCC), adenoma, and metastases. Hemangiomas are brightly echogenic in the majority of cases and are sharply circumscribed. This appearance differs from malignant hyperechoic masses, which often have a hypoechoic halo. Any liver mass with a hypoechoic halo is suspicious for malignancy, and this sign has 86% positive predictive value and 89% negative predictive value for diagnosis of malignancy (Wernecke et al, 1992b).

Ultrasound Microbubble Contrast Agents for Evaluation of Liver Masses

Ultrasound microbubble contrast agents improve both detection and characterization of focal liver masses (Albrecht et al,

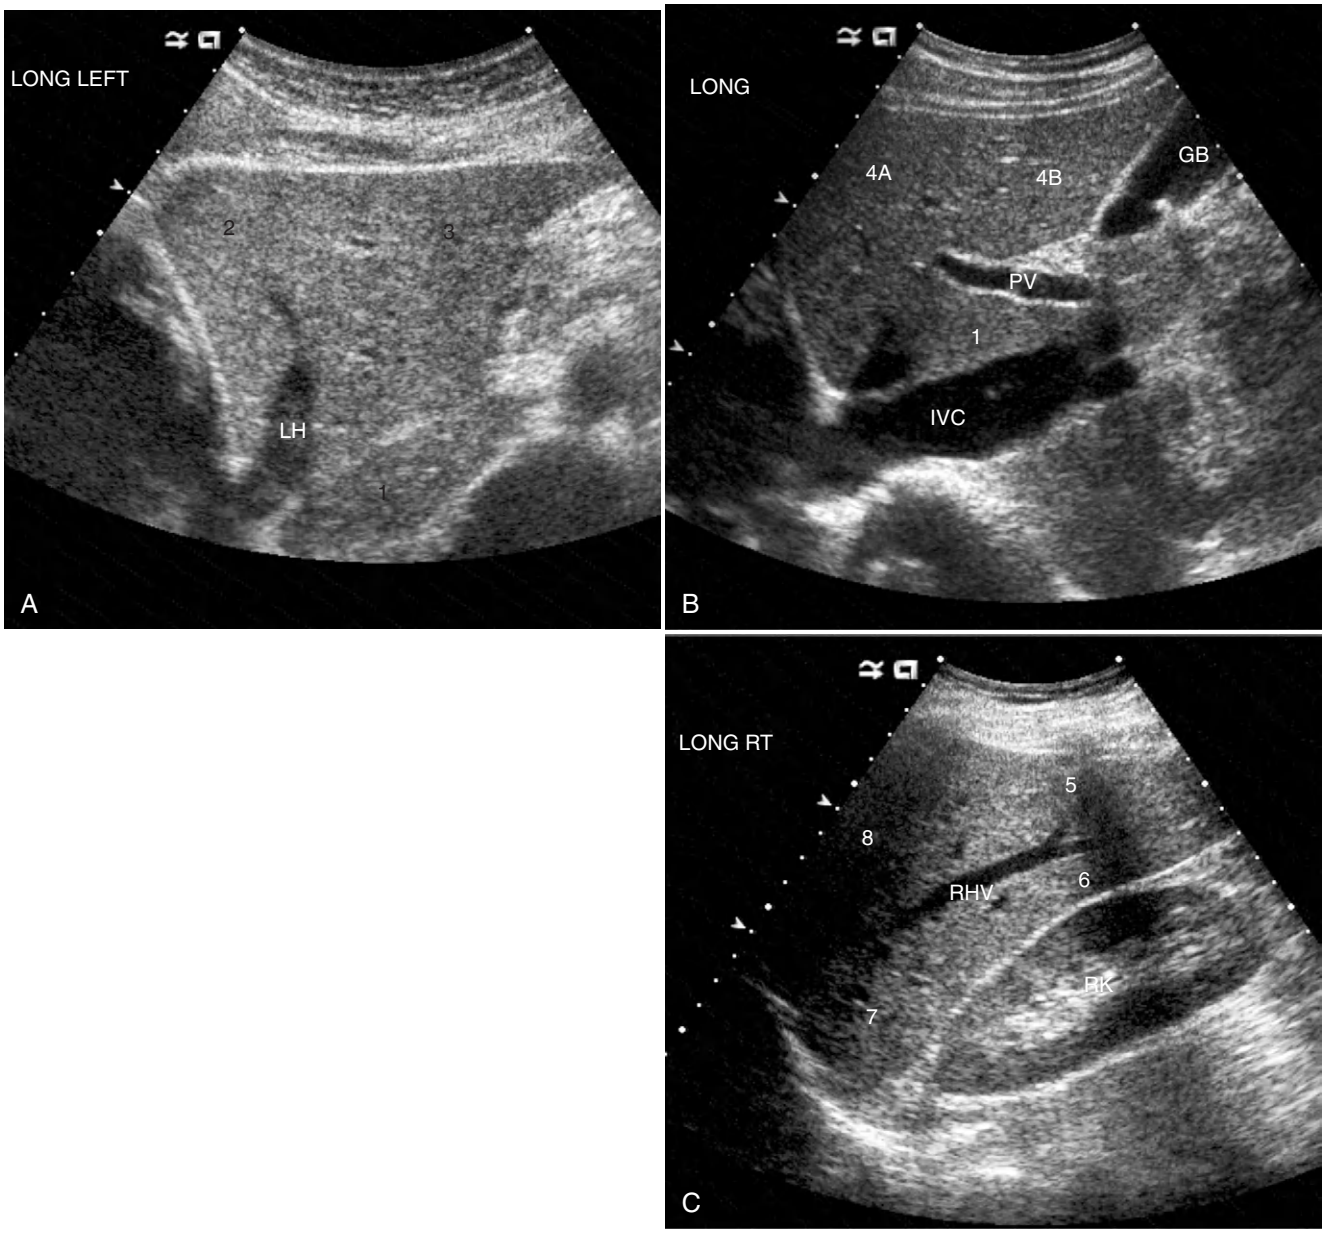

FIGURE 13.7. Normal liver longitudinal ultrasound images. **A,** Left hepatic lobe. Segments are numbered. LH, Left hepatic vein. **B,** Left lobe segment IV. PV, portal vein; GB, gallbladder; IVC, inferior vena cava. **C,** Right lobe. Segments are numbered. RHV, right hepatic vein; RK, right kidney.

2003, 2004; Blomley et al, 1999; Bryant et al, 2004; Harvey et al, 2000; Quaia et al, 2004). First-generation contrast agents, such as SHU 508A (Levovist; Schering, Berlin), remain within the Kupffer cells after the vascular phase; when high mechanical index is applied to burst the bubbles, the liver enhances brightly, but metastases and other lesions without Kupffer cells appear dark. A multicenter study showed improved detection of individual metastases from 71% to 87%, and in seven of 80 patients, contrast-enhanced ultrasound showed more metastases than CT (Albrecht et al, 2003).

More recently, second-generation contrast agents and low mechanical index (LMI) scanning techniques have become available. At LMI settings, the microbubbles emit acoustic signals as they expand and contract in response to the ultrasound pulse, but they do not burst. Because the microbubbles stay in circulation, it is possible to image throughout arterial and portal phases. With LMI scanning, hypervascular tumors that enhance in the arterial phase are more easily detected. Lesion detection is also improved in the portal phase, because hepatic malignancies are hypoechoic during this phase (Wilson et al, 2006).

Contrast-enhanced ultrasound with second-generation contrast agents and LMI techniques allow assessment of vascular morphology, arterial enhancement relative to the liver, and duration of enhancement or "washout" during the portal venous phase (Wilson et al, 2006). These patterns of enhancement can be used to differentiate benign from malignant focal hepatic lesions as shown in the algorithm presented

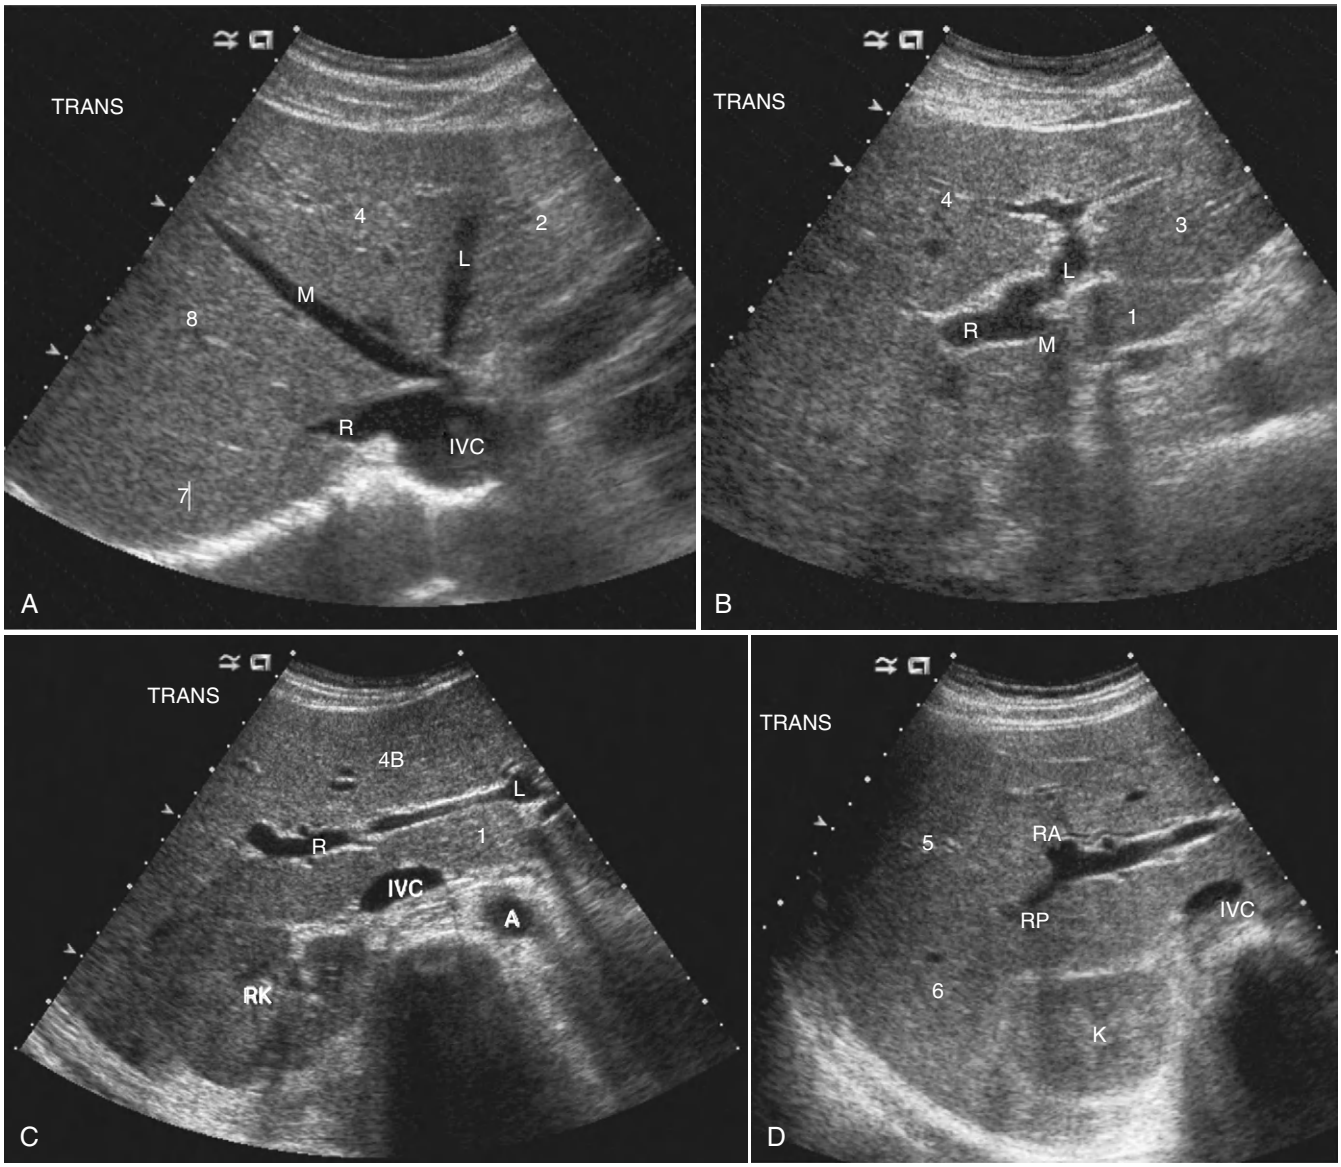

FIGURE 13.8. Transverse images of the liver. **A,** Transverse sonogram at the level of the hepatic veins. Segments are numbered. R, right hepatic vein; M, middle hepatic vein; L, left hepatic vein; IVC, inferior vena cava. **B,** Transverse section of the left lobe at the level of the portal vein bifurcation. M, uppermost main portal vein; R, right portal vein; L, left portal vein. **C,** Transverse image of the left portal vein (*LPV*) and right portal vein (RPV) at the bifurcation. Segments IVB and I are indicated. RK, right kidney; A, aorta. **D,** Transverse image of the inferior right lobe segments V and VI. K, right kidney; RA, anterior right portal vein; RP, posterior right portal vein.

in Figure 13.10 (Brannigan et al, 2004; Ding et al, 2005; Wilson et al, 2006). Washout during the portal venous phase is highly correlated with malignant histology (von Herbay et al, 2009). In the portal phase, metastases and HCC are unenhanced relative to the liver, whereas benign hemangiomas and focal nodular hyperplasia (FNH) have sustained enhancement equal to or greater than the liver (Wilson et al, 2009; Quaia et al, 2004; Brannigan et al, 2004).

In a study of 452 liver lesions, contrast-enhanced ultrasound improved diagnostic accuracy for two readers from 49% to 85% and from 51% to 88%, and diagnostic confidence was increased from 0.82 to 0.97 and from 0.83 to 0.98, respectively (Quaia et al, 2004). A multiinstitutional study of 1349 patients with hepatic masses found that contrast-enhanced ultrasound had a diagnostic accuracy of 83% for all benign lesions, 82% for hemangiomas, and 87% for FNH. Diagnostic accuracy for malignant lesions was 96% overall, 91% for hepatic metastases, and 85% for HCC (Strobel et al, 2009).

Diagnostic performance of contrast-enhanced ultrasound has been compared to that of CT and MRI in several studies. There is high concordance for appearance in arterial phase imaging but less so in the portal phase, probably due to the fact the ultrasound contrast remains intravascular, but CT and MR contrast agents diffuse into the interstitium (Wilson et al, 2006). A multicenter study of 134 patients found that in comparison to CT and MRI, contrast-enhanced ultrasound was 30% more sensitive in recognition of malignancy, 16% more specific in exclusion of malignancy, and 23% more accurate (Trillaud et al, 2009).

Table 13.1

Differential Diagnosis of Focal Liver Lesions by Gray-Scale Ultrasound Appearance

Cystic	Isoechoic	Hyperechoic	Hypoechoic
Benign			
Cyst	FNH	Hemangioma	Focal fatty sparing
Hematoma		Focal fat	
Abscess			
Clinically Significant			
		HCC	HCC
		Adenoma	Adenoma
		Metastases	Metastases
			Lymphoma

FNH, Focal nodular hyperplasia; *HCC*, hepatocellular carcinoma.

Am J Roentgenol 186:1401-1412.)*

Benign Liver Lesions

Cystic Masses

Benign hepatic cysts have smooth, thin walls, posterior acoustic enhancement, and no internal echoes (see Fig. 13.2). A partial, thin septum or puckered wall may be present. A confident diagnosis of simple hepatic cyst can be made on gray-scale ultrasound, and no further evaluation is required. Blood vessels and arteriovenous fistulas or aneurysms may appear cystic on gray-scale ultrasound, but these can be differentiated from simple cysts, because they will have internal flow on Doppler imaging. Lymphoma, which is very hypoechoic, may mimic a

cyst rarely, but internal vascularity will be present on Doppler imaging. When cysts are innumerable and also present in the kidneys or pancreas, polycystic disease should be considered (see Chapter 69B).

Complex masses that contain fluid have internal echoes within the fluid, irregular or thickened walls, mural nodularity, and solid areas or calcification (Middleton, 2002). Hemorrhage, infection, and neoplasm should be considered in the differential diagnosis. Hemorrhagic cysts may have internal solid components, septations, and or debris layering in the dependent portion of the cyst, but on Doppler imaging, no internal vascularity is evident. Hepatic hematomas from trauma have variable appearance in the acute phase but become hypoechoic and cystic as they evolve (Korner et al, 2008; McGahan et al, 2006).

Abscess may be solid in appearance initially, but it then becomes cystic with debris; the wall is usually vascular (Fig. 13.11). Echinococcal cysts have variable appearance; they may be simple fluid-filled cysts, they may have undulated membranes from a rupture and detached endocyst, they may contain daughter cysts and/or echogenic material, and they may show calcification (Lewall et al, 1985). When hydatid cysts are infected, they lose their characteristic sonographic appearance and become diffusely hyperechoic.

Cystic neoplasms, such as biliary cystadenoma and cystadenocarcinoma, may be multiloculated or may have a nodular wall. Cystic metastases from sarcomas undergo necrosis and have a thick wall as a result of central liquefaction within a solid mass. Ovarian cystic metastases characteristically are located peripherally, secondary to tumor implants on the hepatic surface.

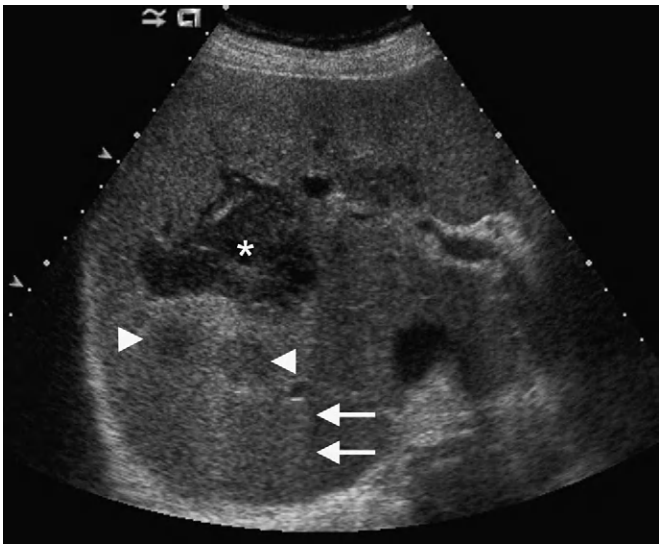

FIGURE 13.11. Hepatic abscess in a patient after embolization for hepatic neuroendocrine metastases (*arrowheads*). The abscess (*asterisk*) contains complex fluid and has posterior acoustic enhancement (*arrows*).

Cavernous Hemangioma

Typical cavernous hemangioma, seen in 80% of cases, is a brightly echogenic homogeneous mass with a sharp margin (Fig. 13.12). Approximately 10% to 20% of hemangiomas are multiple (Charboneau, 2002). Multiple vascular interfaces within hemangiomas cause the increased echogenicity; the

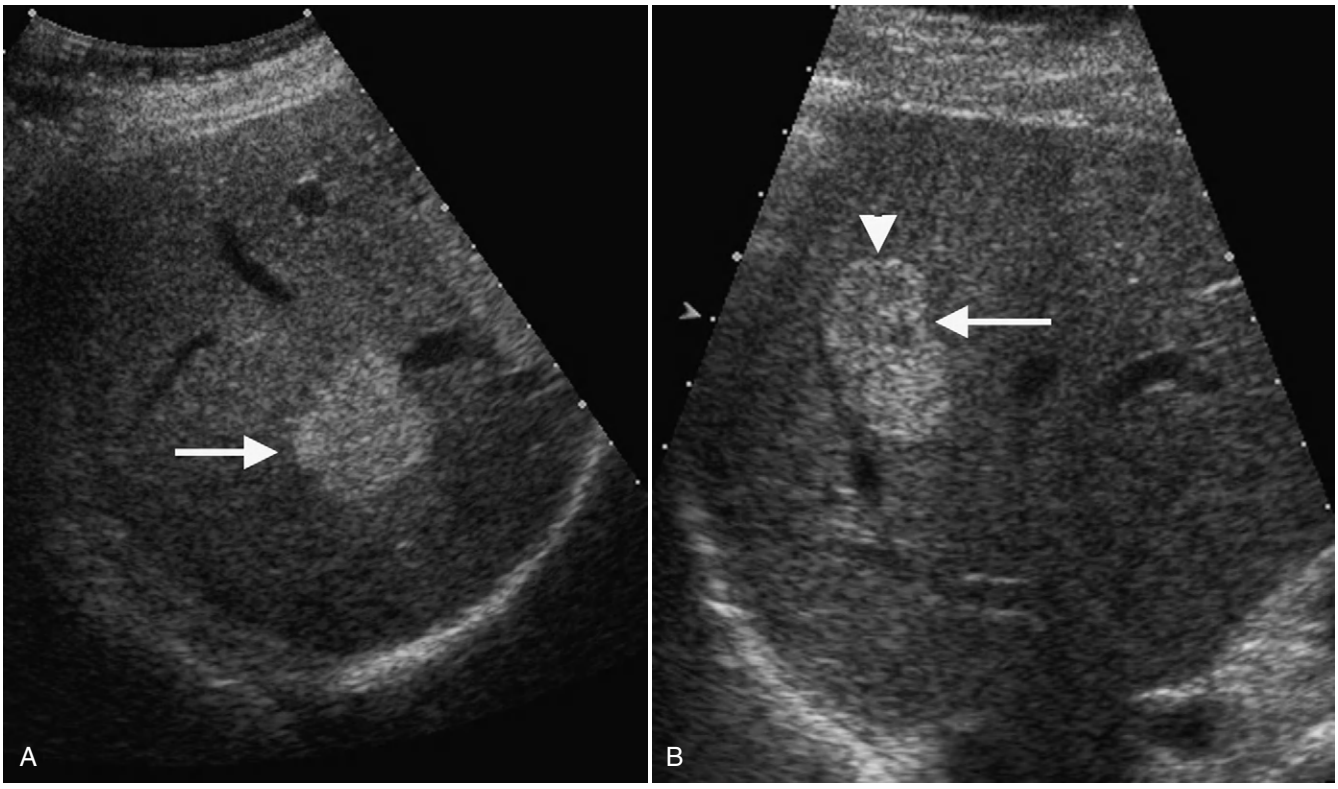

FIGURE 13.12. Hemangiomas. **A,** Longitudinal sonogram of the right lobe shows a brightly echogenic hemangioma (*arrow*) with a sharp border. **B,** Atypical hemangioma (*arrow*) seen in 20% of patients may have areas of internal heterogeneity, a result of fibrosis or myxomatous degeneration, and may demonstrate a thin echogenic rim (*arrowhead*).

margins are well demarcated because histopathologically, only one cell layer is present at the junction with adjacent liver (Charboneau, 2002). Although hemangiomas are vascular, flow is extremely slow, and usually no Doppler signals are evident. Atypical hemangiomas, seen in 20% of cases, may have a thin echogenic rim and a lacy or granular central appearance from foci of collagen (see Fig. 13.12). Hemangiomas are often smaller than 3 cm, but some are giant hemangiomas that become symptomatic as a result of mass effect. Giant hemangiomas, those greater than 5 cm, often lack the characteristic ultrasound features because of central fibrosis, necrosis, and myxomatous degeneration. When the background liver becomes hyperechoic as a result of fatty infiltration, hemangiomas also may appear atypical and less echogenic than the liver. In such cases, contrast-enhanced ultrasound or CT may be useful (Bartolotta et al, 2007; Liu et al, 2009; see Chapter 79A).

With ultrasound contrast imaging at LMI settings, hemangiomas have sustained enhancement in the portal phase and on the arterial phase, enhancement intensity is usually less than the liver, and the pattern of enhancement is peripheral and nodular with puddling of contrast and centripetal progression, similar to CT (Wilson et al, 2006; Quaia et al, 2004; Brannigan et al, 2004; Fig. 13.13).

If the ultrasound shows the classic appearance of hemangioma, and the patient has no history of underlying liver disease or malignancy, then no further investigation is required (Leifer et al, 2000). A study of 213 patients with ultrasounds that showed a typical hemangioma appearance and without risk for hepatic malignancy found only one patient with malignancy on long-term follow-up and concluded that typical hemangiomas in low-risk patients do not require follow-up. This rule does not apply to patients with cirrhosis, hepatitis, or chronic liver disease who are at increased risk for HCC, nor does it apply to patients who already have malignancies. In a study of 2000 patients with cirrhosis, 44 had hemangioma-like lesions; on follow-up, half of these proved to be HCCs, and half were hemangiomas (Caturelli et al, 2001). Thus, in patients at risk for HCC, any echogenic lesion merits further evaluation and follow-up.

Focal Nodular Hyperplasia

The second most common benign hepatic neoplasm, FNH may be difficult to detect on gray-scale ultrasound, because it often has similar echogenicity to the liver, but subtle vascular displacement or contour abnormalities may draw attention to the lesion (Buetow et al, 1996; Hussain et al, 2004; Wilson et al, 2005; Fig. 13.14). FNH typically occurs in asymptomatic patients and is more common in women. Approximately 20% are multiple, and they may occur in association with hemangiomas (Nguyen et al, 1999; see Chapter 79A). FNH contains Kupffer cells, hepatocytes, and biliary structures but without portal triads and central veins found in normal hepatic lobules (Hussain et al, 2004). FNH is considered to be secondary to vascular malformation; fibrous septa radiate from a central scar, and tortuous feeding arteries are present.

On gray-scale ultrasound, FNH has variable echogenicity and lobulated smooth contour (see Fig. 13.14). A central scar may be evident, but it is usually better depicted on CT, MRI, or contrast-enhanced ultrasound. A key to ultrasound diagnosis of FNH is the characteristic power Doppler appearance of the tortuous feeding artery and spoke-wheel vascularity within the lesion. With ultrasound contrast imaging, the central scar is better seen, and the vascular pattern can be diagnostic. FNH is hypervascular on early arterial phase imaging with diffuse enhancement that is sustained into the early portal phase (Wilson et al, 2006; Kamaya et al, 2009; Dietrich et al, 2005; Ungermann et al, 2007; Brannigan et al, 2004; Quaia et al, 2004). Persistent portal phase enhancement differentiates FNH from malignant liver lesions (Kim et al, 2009; von Herbay et al, 2009; Fig. 13.15)

Hepatic Adenoma

Hepatic adenomas are rare benign tumors that usually occur in young women with a history of oral contraceptive use, but they can also be seen in men using anabolic steroids (see Chapter 79A). They are usually solitary (80%) but can be multiple in patients with type 1 glycogen storage disease or liver adenomatosis. Adenomas lack portal venous supply and bile ductules; they have disorganized plates of cells separated by dilated sinusoids that are perfused by arterial pressure, which predisposes to hemorrhage (Grazioli et al, 2001). On gray-scale ultrasound, adenomas appear echogenic, because adenoma cells have a high lipid content. Internal hemorrhage within adenomas may produce cystic areas, and calcification may also be present (Grazioli et al, 2001). Spectral Doppler flow may have a continuous waveform (Golli et al, 1994; Bartolozzi et al, 1997). Contrast ultrasound of hepatic adenomas more often shows centripetal or mixed filling during the arterial phase; this pattern differs from FNH, which has spoke-wheel vascularity. On portal phase imaging, adenomas are variable, but most commonly they are isoechoic or slightly hypoechoic relative to the liver (Bartolotta et al, 2007; Kim et al, 2006, 2008; Ricci et al, 2008).

Malignant Liver Neoplasms

Hepatocellular Carcinoma

HCC (see Chapter 80), one of the most common malignancies worldwide, usually arises in the background of cirrhosis and has poor survival (Collier et al, 1998; El-Serag et al, 1999). Chronic hepatitis B and C infection accounts for the high prevalence of HCC in Southeast Asia, sub-Saharan Africa, and the Mediterranean, and the increased prevalence of these viral infections has contributed to rising incidence of HCC in the United States (Caturelli et al, 2003; El-Serag et al, 1999).

Ultrasound in combination with serum α-fetoprotein (AFP) is used to screen for HCC in high-risk patients, and ultrasound-guided biopsy can be used for diagnosis with 90% accuracy (Caturelli et al, 2004; Collier et al, 1998; Sato et al, 2009; Tong et al, 2001). In patients with elevated AFP, ultrasound was found to have 86% sensitivity, 82% specificity, 55% positive predictive value, and a false-negative rate of only 4% (Mok et al, 2004). A study comparing screened versus unscreened patients with cirrhosis showed improved median survival (17 months vs. 12 months) and improved survival rates at 1, 3, and 5 years for HCC arising in the screened Child-Pugh class B patients, but not in the class C patients (Trevisani et al, 2007). Chan and colleagues (2008) compared survival of HCC arising in screened versus unscreened groups during two different 7-year time periods ending in 1997 and 2004. Long-term survival was better in the screened group and, as a result of improved surgical treatment, the proportion of patients undergoing curative resection increased from 51% to 68% in those two time periods.

On gray-scale ultrasound, HCC may be solitary, multiple, or diffuse, and it has a propensity for venous and bile duct

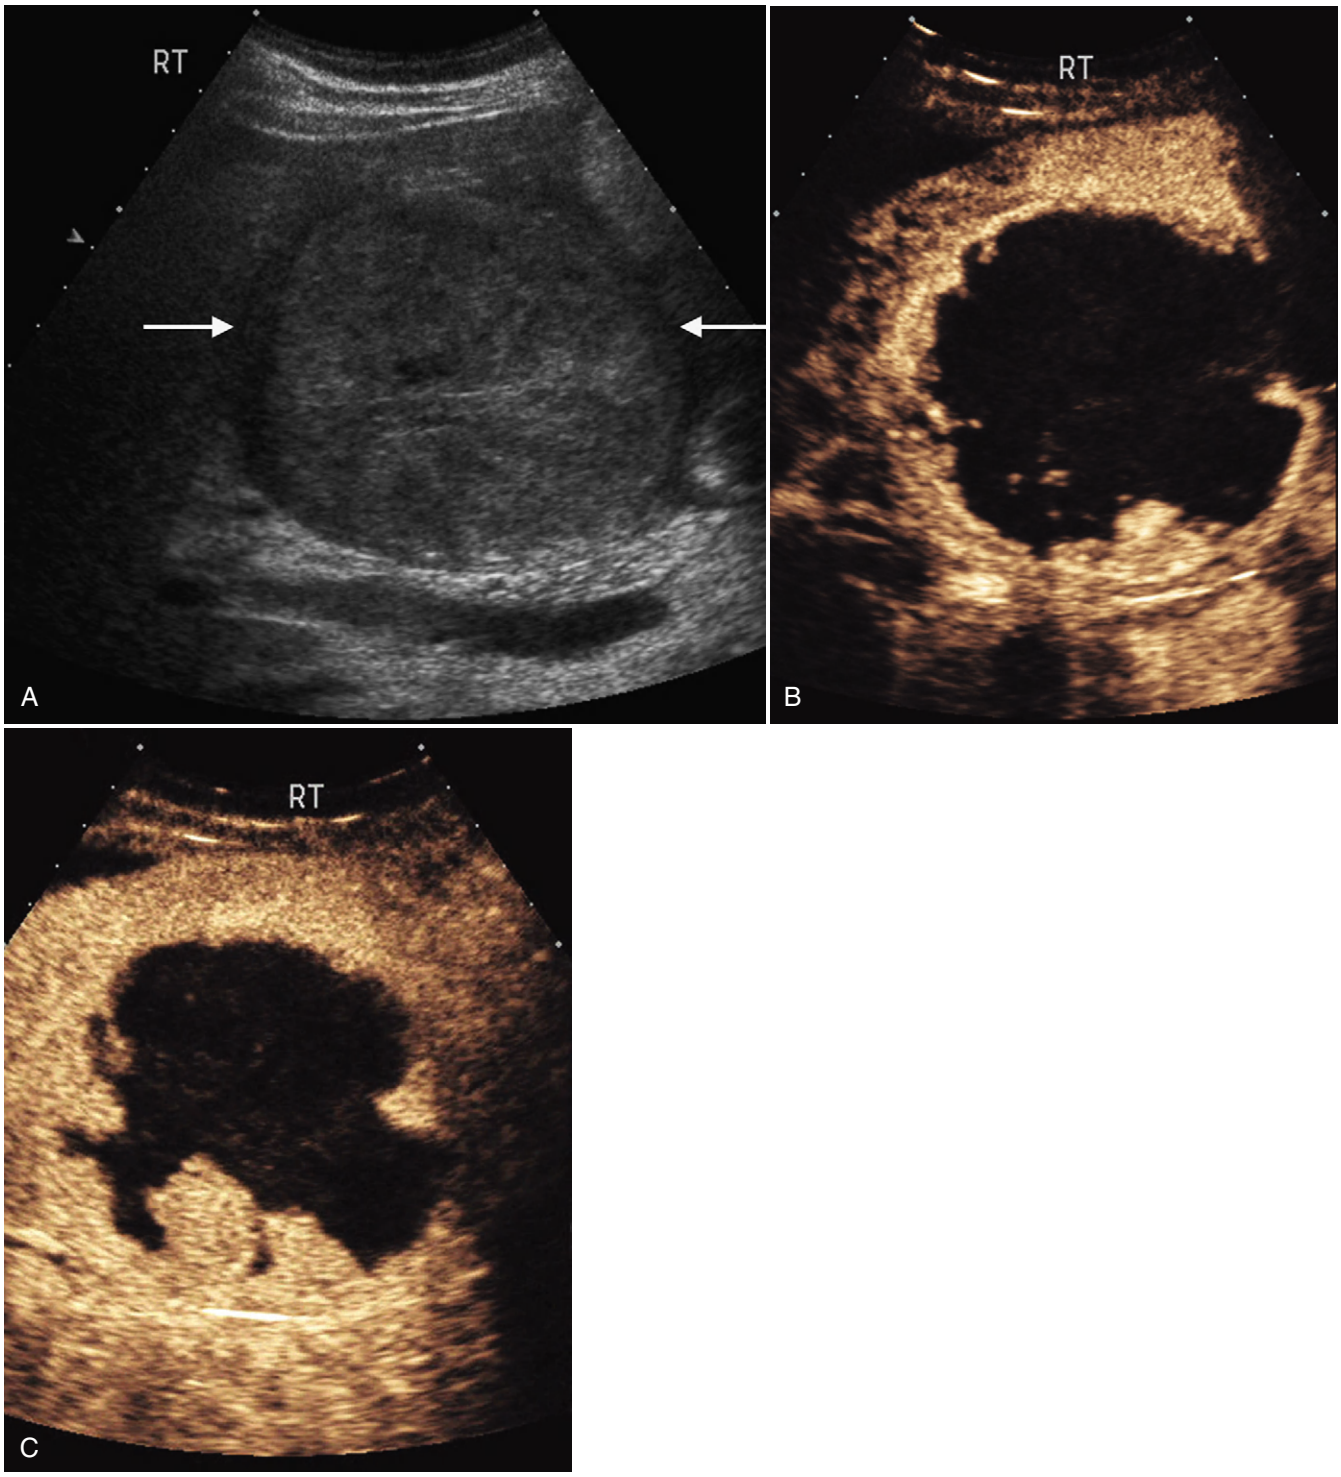

FIGURE 13.13. Giant atypical hemangioma. **A,** Baseline gray-scale image demonstrates a large, mainly isoechoic left lobe mass (*arrows*) found in a patient with abdominal pain. **B,** Contrast-enhanced ultrasound in early arterial phase (19 seconds) demonstrates that the mass has globular peripheral enhancement but no central enhancement. **C,** In the portal venous phase (56 seconds), the mass demonstrates more marked peripheral globular enhancement consistent with hemangioma. *(Courtesy Paul S. Sidhu, King's College Hospital, London.)*

involvement (Wilson et al, 2005). Small HCC tumors (<5 cm) are often hypoechoic but may be hyperechoic from fatty metamorphosis (Choi et al, 1993; Caturelli et al, 2001). Larger HCC tumors are often inhomogeneous because of liquefaction necrosis and fibrosis (Tanaka et al, 1983), and sonographic depiction of HCC may be limited in the setting of severe cirrhosis (Bennett et al, 2002). Thrombosis of portal and/or hepatic veins is frequent, seen in 30% to 60% of patients (Wilson et al, 2005; Fig. 13.16). Tumor thrombus usually expands the vein, and Doppler interrogation may reveal hepatofugal arterial flow within the

FIGURE 13.14. Focal nodular hyperplasia (FNH). As shown in this longitudinal gray-scale image of the right lobe, FNH (*crosses*) has similar echogenicity to the liver, and lesions are often subtle.

thrombus, a pathognomonic finding (Shah et al, 2007; Lencioni et al, 1995; Giorgio et al, 2004; Tanaka et al, 1993). HCC may also extend into the bile ducts and cause biliary obstruction or hemobilia (Kojiro et al, 1982).

HCC is hypervascular with dysmorphic arteries and high-velocity flow on Doppler imaging (Koito et al, 1998; Tanaka et al, 1990). Microbubble ultrasound contrast imaging improves HCC characterization and is highly concordant with CT findings, but contrast-enhanced ultrasound is best at identifying lesions greater than 2 cm (Quaia et al, 2007; Giorgio et al, 2004; Inoue et al, 2009; Jang et al, 2008). Moderately differentiated HCC is hypervascular in the arterial phase, whereas well-differentiated and poorly differentiated HCC may have a more variable appearance. Observation during the portal phase should be extended, as many HCCs have delayed washout for up to 300 seconds (Jang et al, 2007; Fig. 13.17)

Fibrolamellar Carcinoma

Fibrolamellar HCC, a variant of HCC with better prognosis, characteristically presents as a large solitary mass in an adolescent or young adult without liver disease, and AFP levels are usually normal. On ultrasound, fibrolamellar HCC is well defined, lobulated, and has variable echogenicity. Calcification may also be present (Chung et al, 2009). A central scar may be visible on gray-scale ultrasound in a third to two thirds of patients, but scars are better seen with contrast-enhanced ultrasound (Smith et al, 2008; McLarney et al, 1999). Regional lymphadenopathy is common.

Liver Metastases

Liver metastases (see Chapter 81C) are multiple in 98% of patients and are found in up to 50% of cancer patients at autopsy (Wilson et al, 2005; Middleton, 2002). Liver metastases are frequently detected by gray-scale ultrasound, but CT is the preferred modality to determine extent of disease, number of hepatic lesions, and extrahepatic disease. Response to therapy is also better evaluated by CT, because treatment-related fatty infiltration may obscure lesions that have diminished in size or changed echogenicity as a result of chemotherapy.

On ultrasound, hepatic metastases frequently have a hypoechoic halo that corresponds to fibrosis, compressed sinusoids, and tumor neovascularity surrounding the metastatic deposit (Wernecke et al, 1992a; Kruskal et al, 2000; Fig. 13.18). Uniformly hypoechoic lesions are the second most frequent sonographic appearance of metastases (Middleton, 2002; Fig. 13.19) Hypoechoic appearance and hypoechoic halo are highly suggestive of malignancy. In addition to metastases, lymphoma and HCC should be considered in the differential diagnosis. Contrast-enhanced ultrasound improves detection of individual metastases compared with gray-scale ultrasound, and in some cases, contrast-enhanced ultrasound may reveal more lesions than are evident on CT (Albrecht et al, 2003; see Fig. 13.19).

The ultrasound appearance of metastases may vary according to the primary origin. Echogenic lesions tend to arise from HCC or gastrointestinal primaries. Vascular metastases, such as those from renal cell carcinoma, islet cell tumors, carcinoids, and choriocarcinoma, also are typically hyperechoic (Tanaka et al, 1990; Marchal et al, 1985; Rubaltelli et al, 1980). Hypoechoic metastases are commonly due to untreated metastatic breast, lung, pancreatic, gastric, and esophageal carcinoma. Lymphoma, which is also hypoechoic because of its uniform cellularity, may be diffusely infiltrative or may have multiple masses; this latter pattern is more common in non-Hodgkin lymphoma or AIDS-related lymphoma (Townsend et al, 1989). Calcified metastases may be found with mucinous adenocarcinoma of the colon as well as other primaries. Cystic hepatic metastases are seen in ovarian and pancreatic cystadenocarcinomas and mucinous colon carcinomas. Metastases undergoing central necrosis, such as sarcomas, also may appear cystic, but the thick surrounding tumor wall is usually evident. When metastases are diffusely infiltrative, such as in breast or lung carcinoma, it can be difficult to detect individual lesions, and the liver may have a pseudocirrhotic appearance (Fennessy et al, 2004; Young et al, 1994).

Sonography of Diffuse Liver Disease

Steatohepatitis

Fatty liver (see Chapter 65) is commonly encountered incidentally on sonograms of the liver and in patients referred for imaging evaluation of abnormal values on liver function tests. The fat deposition within hepatocytes results in increased echogenicity of the liver relative to the kidney and in decreased acoustic penetration (Fig. 13.20). Because echogenicity is not a quantitative measure, one useful objective sign of fatty infiltration is loss of the echogenic borders of the portal vessels. To reduce subjectivity in fatty liver diagnosis, some investigators advocate comparing the relative echogenicity between the liver and right kidney to that between the spleen and left kidney. Because the normal spleen is more echogenic than liver, if the difference in echogenicity between the liver and right kidney is greater than the difference between the left kidney and spleen, then the liver is abnormally echogenic (Tchelepi et al, 2002).

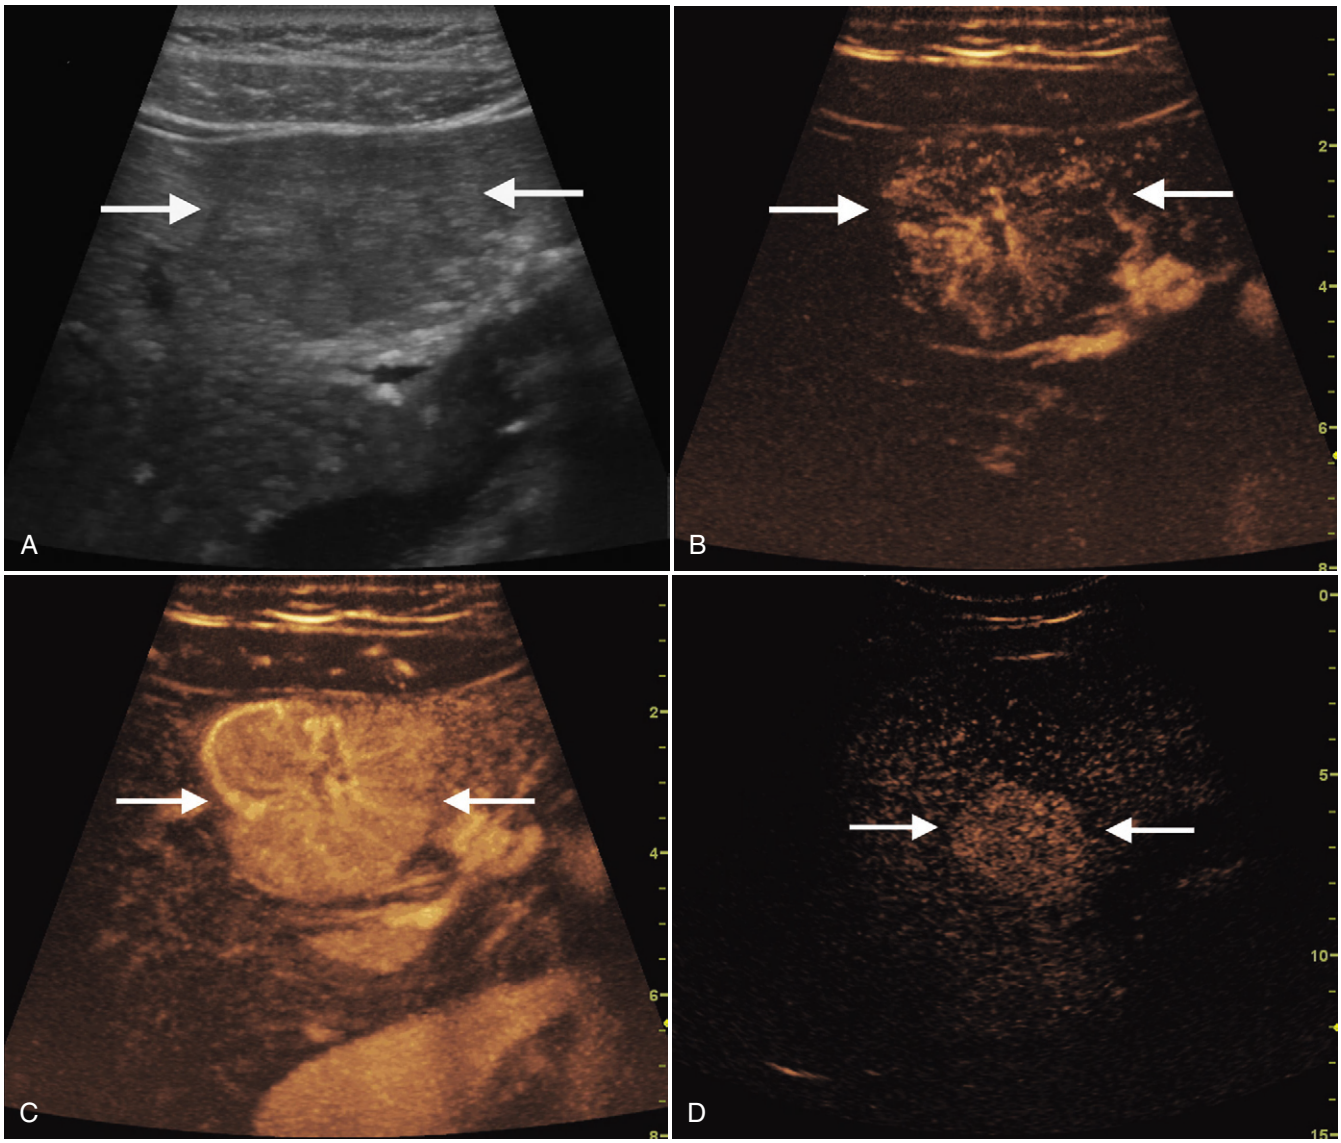

FIGURE 13.15. Focal nodular hyperplasia (FNH) on contrast-enhanced ultrasound. **A,** An isoechoic mass (*arrows*) is seen in the left hepatic lobe on gray-scale imaging. **B,** Twelve seconds after contrast injection, the FNH (*arrows*) shows enhancement in a central scar and a characteristic spoke-wheel vascular pattern. **C,** The FNH (*arrows*) enhances brightly at 18 seconds. **D,** Five minutes after contrast injection, the FNH (*arrows*) is still enhanced and is echogenic relative to the liver. *(Courtesy GE Healthcare, Little Chalfont, United Kingdom.)*

In fatty liver disease, the liver edge remains smooth. In severe cases, hepatomegaly may be present. The presence of a fatty liver degrades the quality of sonographic evaluation of the hepatic parenchyma because of decreased acoustic penetration, and focal lesions may escape detection. In addition, lesions that typically appear echogenic against a background of normal liver, such as hemangiomas, may appear hypoechoic in the fatty liver.

A fatty liver may be diffuse and uniform, patchy, or focal. Areas of focal fat deposition are commonly wedge-shaped and echogenic and occur in characteristic locations, such as along the ventral surface of segment IV and adjacent to the falciform ligament. Focal fat deposition may also be lobar, rounded, and masslike or perivascular in distribution. In the latter two cases, magnetic resonance imaging (MRI) with in-phase and opposed-phase sequences is highly useful to confirm that the focal abnormality truly represents intracellular fat deposition and not a mass lesion. Focal fat deposition should not have mass effect, and therefore intrahepatic vessels should traverse these areas of increased echogenicity without displacement. However, this finding is not entirely specific, as occasionally some mass lesions may likewise fail to displace vessels. Finally, within the diffusely fatty liver, certain regions may be spared (see Fig. 13.9). These are typically areas of nonportal venous inflow, such as around the gallbladder (cystic veins) and in the region of the porta hepatis.

Acute Hepatitis

Most imaging modalities, including sonography, are neither sensitive nor specific for the diagnosis of acute hepatitis. Definitive diagnosis of hepatitis is usually made based on clinical and laboratory grounds, with imaging useful for excluding other diagnoses, such as biliary obstruction or hepatic mass lesions

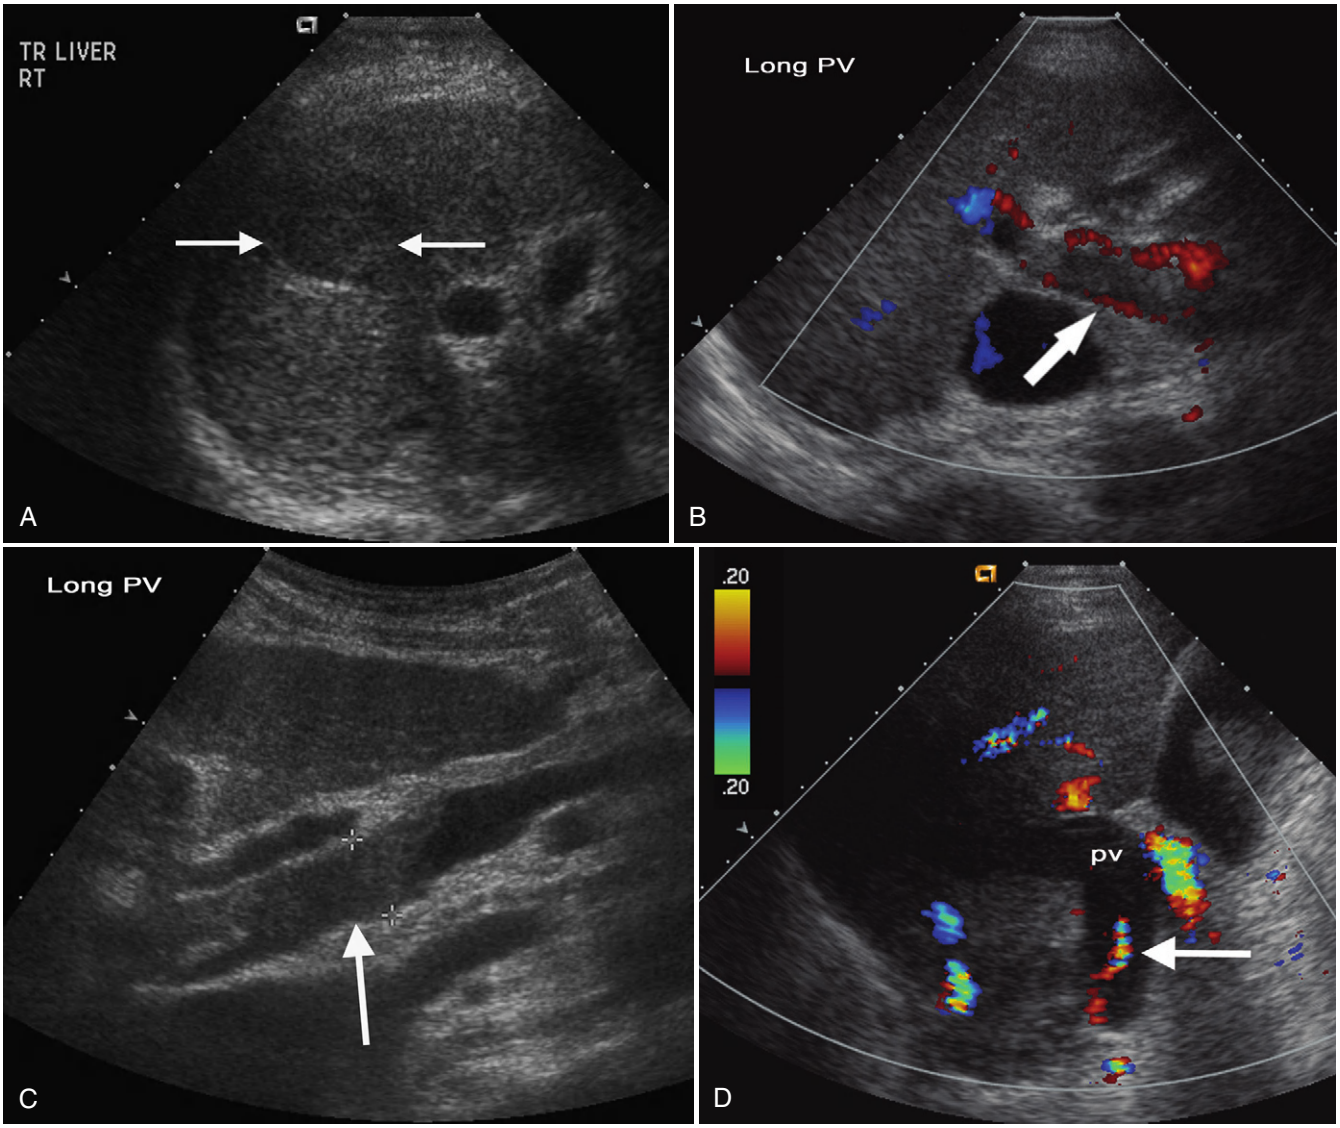

FIGURE 13.16. Hepatocellular carcinoma with portal vein thrombosis. **A,** Transverse image shows a hypoechoic right hepatic hepatocellular carcinoma (*arrows*). **B,** Transverse image of the main portal vein reveals only a trickle of blood flow (*arrow*), and the lumen is filled with echogenic thrombus. **C,** Longitudinal image of the main portal vein shows the long area of thrombus (*arrow*). **D,** Color Doppler image of the main portal vein confirms arterial flow (*arrow*) within the hypoechoic thrombus; this is pathognomonic for tumor thrombus. *pv*, Portal vein.

(Mortele et al, 2001). The most common sonographic abnormality in hepatitis is hepatomegaly. Periportal edema may be appreciated sonographically, but it is better seen on CT or MRI. Occasionally, sonography may demonstrate very low hepatic parenchymal echogenicity, producing an appearance known as the "starry night" liver for the striking prominence of the periportal echoes against the abnormally dark background liver (Mortele et al, 2001; Tchelepi et al, 2002). Hepatitis may also produce secondary changes in the gallbladder, with irregular lamellated thickening of the gallbladder wall noted, especially in hepatitis A (Tchelepi et al, 2002).

Cirrhosis

Cirrhosis (see Chapter 70A) is a diagnosed histologically by the presence of bridging fibrosis and regenerative nodule formation. Although sonographic findings are neither sensitive nor specific for the diagnosis, certain findings may suggest that cirrhosis is present (Tchelepi et al, 2002). Surface nodularity is the most reliable sign of cirrhosis, and nodularity along the deep surfaces of the liver has been found to be a more sensitive sign of cirrhosis than superficial nodularity (Filly et al, 2002; Fig. 13.20). Surface nodularity may be better appreciated in the presence of ascites. Other sonographic features of cirrhosis include coarsening and inhomogeneity of the parenchymal echo texture and volume loss in the right lobe with relative hypertrophy of the left lobe and caudate.

Stigmata of portal hypertension—such as splenomegaly, ascites, reversal of portal venous flow direction, and varices—indicate that severe parenchymal disease is present. The portal vein diameter may exceed 13 mm, although this is not invariably the case. Enlarged, tortuous hepatic arteries are often present in cirrhotic livers and should not be mistaken for dilated

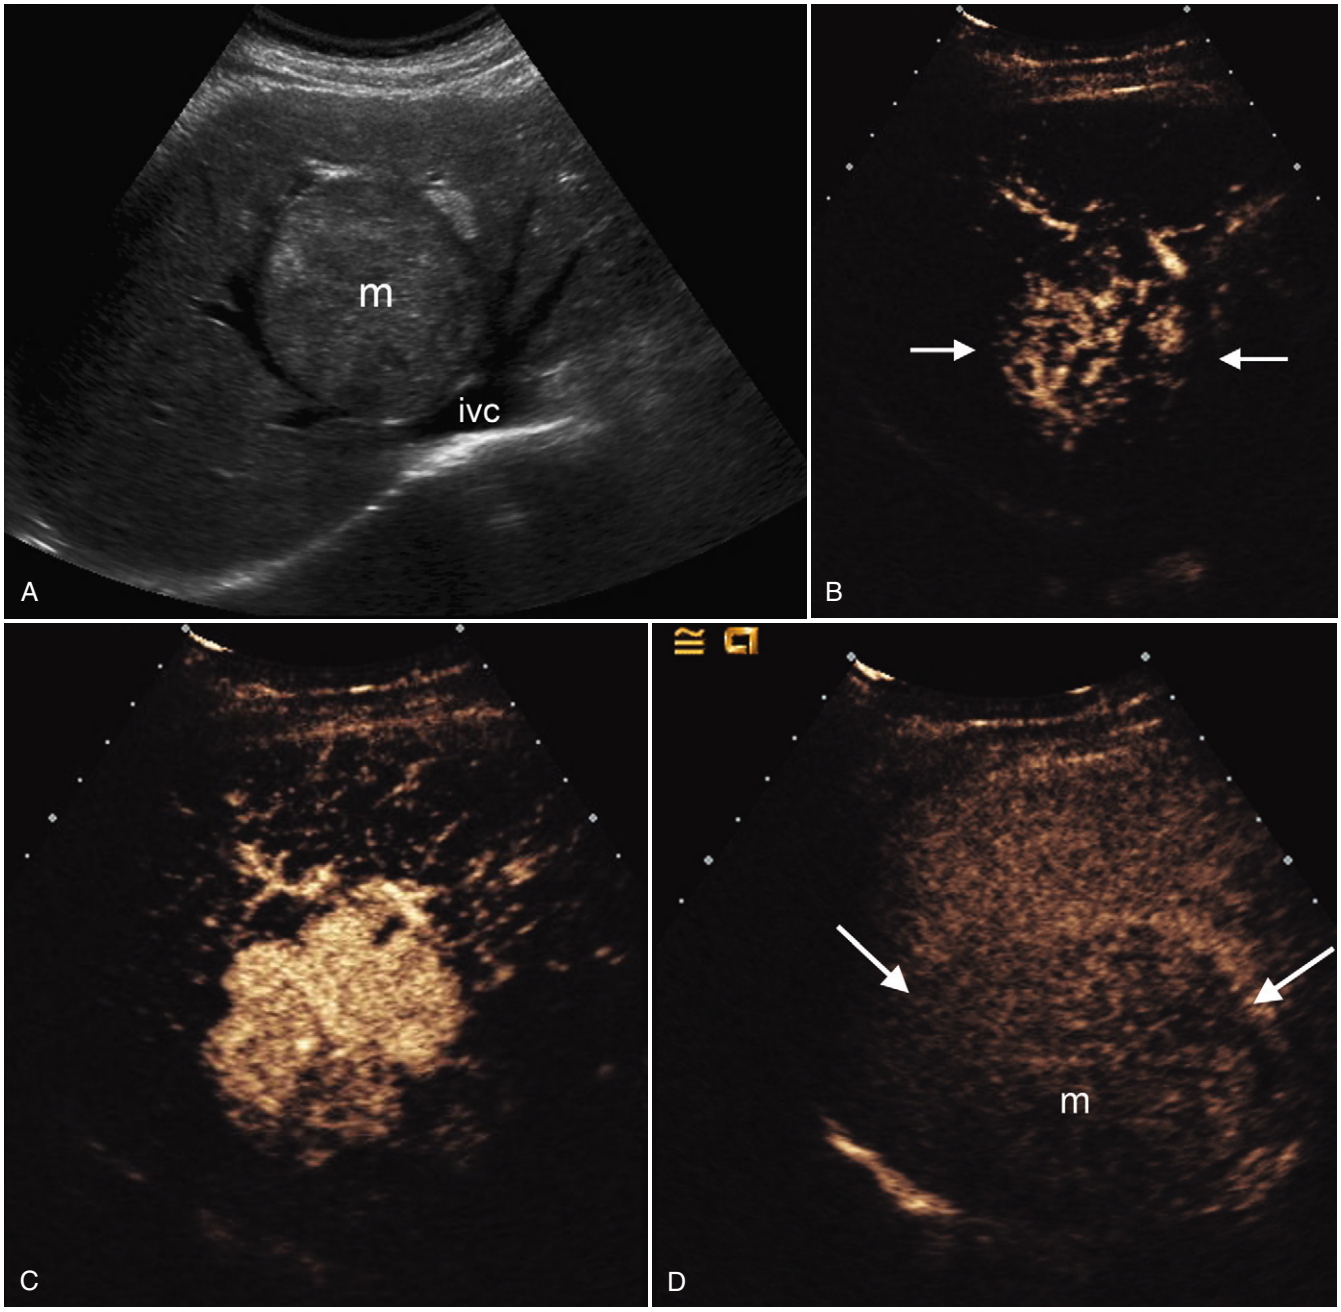

FIGURE 13.17. Hepatocellular carcinoma. **A,** Transverse gray-scale image reveals a large hepatocellular carcinoma (HCC); the mass (*m*) splays the hepatic veins. ivc, inferior vena cava. **B,** Contrast-enhanced ultrasound, early arterial portal venous phase, shows dysmorphic vessels in the hypervascular hepatocellular carcinoma (HCC) (*arrows*). **C,** Peak arterial portal phase image shows brightly enhancing HCC. **D,** The HCC (*arrows*) has very slow and weak washout, not shown until more than 4 minutes from the end of the saline flush. *(Courtesy Stephanie R. Wilson.)*

bile ducts or venous collaterals; color and spectral Doppler are useful for making this distinction. Although not widely used, a scoring system has been developed for cirrhosis based on four ultrasound criteria: 1) *surface appearance*, either normal, irregular, undulated; 2) *parenchymal echo texture*, either normal, heterogeneous, or coarse; 3) *intrahepatic vessel caliber*, either normal, obscure, or narrowed; and 4) *spleen size*, which has been proposed with scores above 7 or 8 having relatively high sensitivity and specificity (Lin et al, 1993).

Elastography is a relative new sonographic technique that has shown great promise for noninvasive quantification of hepatic fibrosis in patients with cirrhosis or chronic hepatitis. Two primary methods for performing elastography with ultrasound have been devised. Transient elastography (TE, FibroScan) uses an ultrasound transducer mounted on the axis of a vibrator. A vibration sent into the tissue induces an elastic shear wave, the velocity of which is directly related to tissue stiffness. The harder the tissue, the faster the shear wave

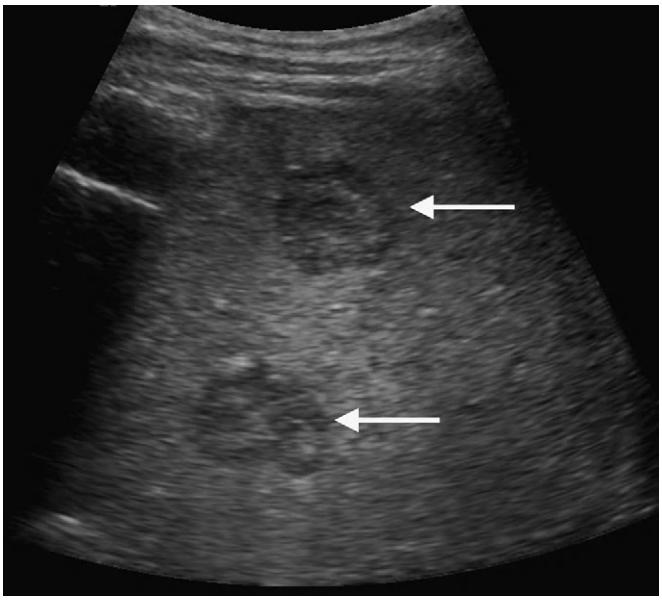

FIGURE 13.18. Liver metastases with hypoechoic halo. Metastatic neuroendocrine tumors (*arrows*) in the liver have a hypoechoic halo peripherally and a target appearance. A hypoechoic halo usually indicates malignant lesion or, less commonly, an infectious etiology.

propagates. The TE technique is rapid, operator independent, feasible with nonfasting patients, and it yields results that are reproducible and immediately available (Goyal et al, 2009). A recent trial of the technique in 711 patients with chronic liver disease found that a cutoff value of 17.6 kPa for liver stiffness had 90% positive and negative predictive values for the presence of cirrhosis (Foucher et al, 2006). More recently, the technique of real-time elastography was studied in 79 patients with chronic viral hepatitis and known fibrosis and in 20 healthy, normal volunteers. Unlike TE, real-time elastography uses conventional ultrasound probes and can be performed with modified conventional real-time sonography equipment. Results were promising, with areas under the receiver operating characteristic curve 0.75 for significant fibrosis, 0.73 for severe fibrosis, and 0.69 for cirrhosis (Friedrich-Rust et al, 2007).

Liver Transplantation (see Chapter 100)

Ultrasound is the modality of choice for the evaluation of the postoperative liver transplant recipient. Both gray-scale and Doppler imaging modes are required—the former for evaluation of the biliary tree and posttransplant fluid collections and the latter for evaluation of the status of the hepatic vasculature. Early detection of transplant complications is essential for preservation of graft function; therefore sonographic expertise must be readily available in any transplant setting (see Chapter 100). The frequency of sonographic surveillance varies by institution, although initial assessment of vascular patency is generally performed in the immediate (<24 hours) posttransplant period.

The overall incidence of vascular complications following liver transplantation is approximately 9% (Caiado et al, 2007; Quiroga et al, 2001), and Doppler ultrasound is the mainstay of evaluation. Among vascular complications, hepatic arterial thrombosis is the most feared, because it impairs the viability of the transplant bile ducts. In the native liver, arterial collaterals, primarily from the phrenic arteries, can sustain bile ducts following hepatic artery ligation (Bekker et al, 2009), but in the transplanted liver, such collaterals are initially absent, requiring at least 2 weeks to develop. Therefore in the early posttransplant period, bile ducts are supplied solely by the hepatic artery.

The frequency of early hepatic arterial thrombosis is higher in children (see Chapter 98C) than adults and has been decreasing over the past two decades with improvements in perioperative care. A recent review of 71 clinical studies of early hepatic arterial thrombosis published between 1990 and 2007 found an overall incidence of 4.4%, with a rate of 8.3% in children and 2.9% in adults (Bekker et al, 2009). Causes of hepatic arterial thrombosis include technical surgical problems (kinking, stenotic anastomosis) and nonsurgical causes such as immunologic factors, clotting abnormalities, and infections, especially cytomegalovirus (Pastacaldi et al, 2001). The median time to detection of hepatic arterial thrombosis is approximately 7 days (Bekker et al, 2009). Most cases of hepatic artery thrombosis are identified through routine sonographic surveillance, when patients are either asymptomatic or have only mild elevation of values on liver function tests. Fulminant hepatic necrosis is decidedly unusual. More commonly, undiagnosed bile duct ischemia as a result of hepatic artery thrombosis results in recurrent cholangitis, intrahepatic abscess, bile duct stenosis, or bile leak (Garcia-Criado et al, 2002).

On sonographic evaluation, the normal hepatic artery waveform shows a brisk upstroke in systole and continuous forward flow in diastole, with a resistive index between 0.5 and 0.8. The normal acceleration time, measured from end diastole to the first systolic peak, should be less than 0.08 seconds. Hepatic artery thrombosis is diagnosed on ultrasound when flow is absent in the proper hepatic artery and intrahepatic arteries on color and spectral Doppler.

Stenosis of the hepatic artery occurs in an estimated 5% to 11% of transplant recipients and usually develops at the anastomotic site within 3 months of transplantation (Caiado et al, 2007). If the anastomotic site can be visualized directly, color Doppler may show focal aliasing, and spectral Doppler will demonstrate elevated velocities. More commonly, though, the hepatic artery can only be visualized in the porta hepatis downstream of the anastomosis. With anastomotic stenosis, there will be a tardus-parvus waveform in the downstream proper hepatic and intrahepatic arteries (Fig. 13.21). This waveform is characterized by a blunted, delayed peak systolic velocity with resistive index below 0.5 and a prolonged acceleration time in excess of 0.08 seconds (Caiado et al, 2007; Tamsel et al, 2007). Occasionally a tardus-parvus waveform may be present in the intrahepatic arteries in the setting of chronic hepatic artery thrombosis. This implies that a collateral arterial supply has developed, and its dampened flow resembles the waveform seen in hepatic artery stenosis (Caiado et al, 2007). Therefore both the main hepatic artery in the porta hepatis and the intrahepatic right and left hepatic arteries must be interrogated on all Doppler studies of transplanted livers. In the early postoperative period, the hepatic artery resistive index may be elevated, but this finding is generally of no clinical consequence and is often associated with an older donor age or prolonged cold ischemia time (Caiado et al, 2007; Shaw et al, 2003).

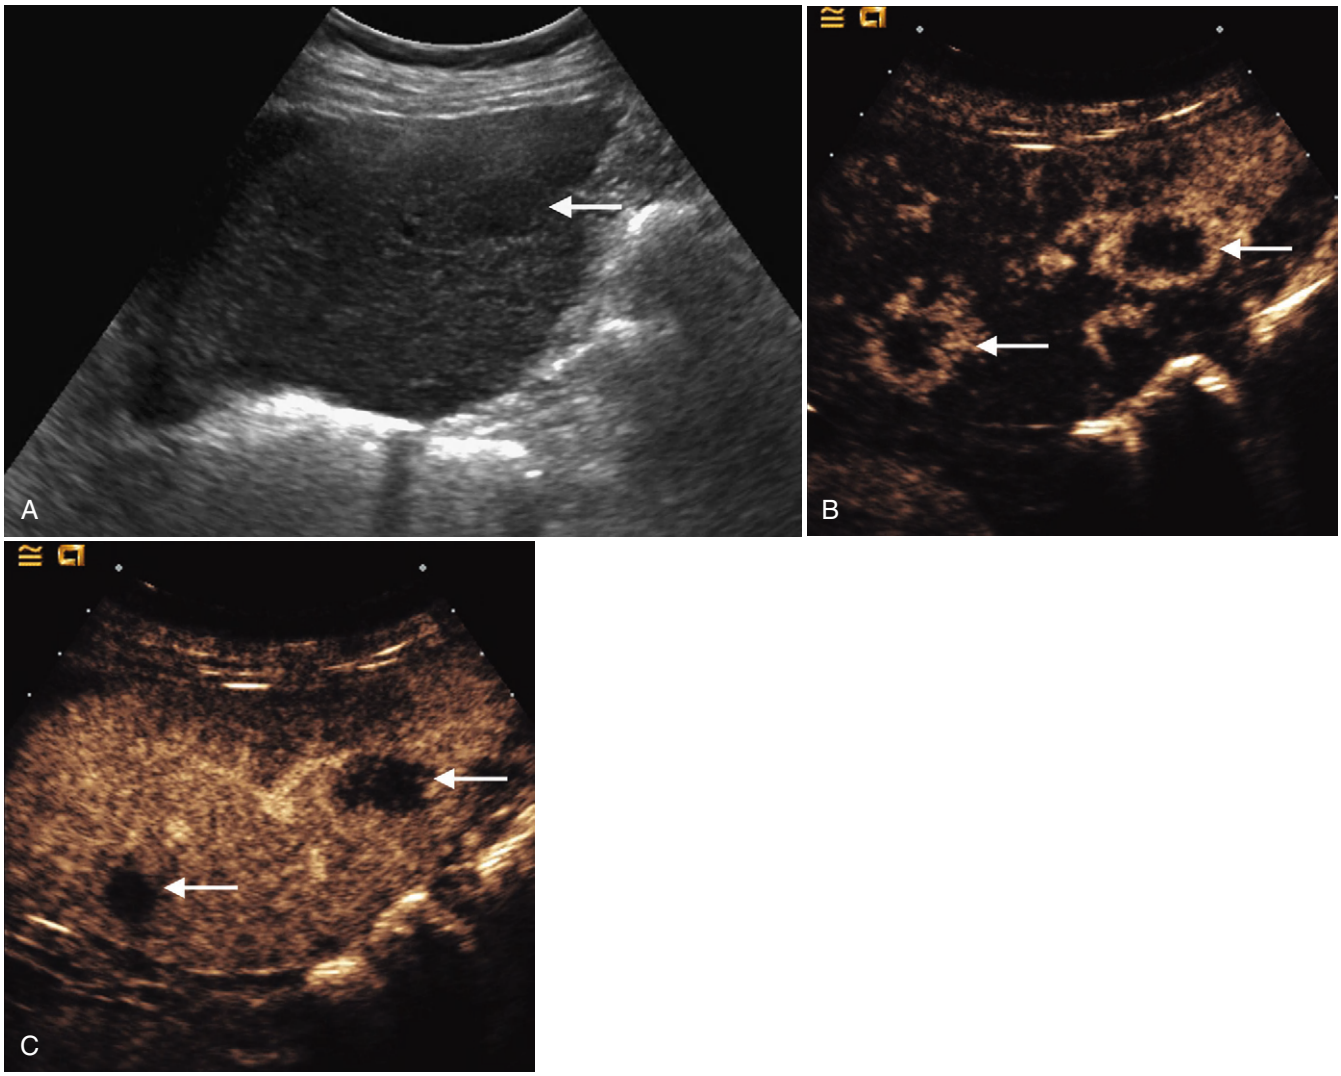

FIGURE 13.19. Hepatic metastases evaluated with contrast-enhanced ultrasound. **A,** Gray-scale image reveals a hypoechoic mass (*arrow*) consistent with metastasis. **B,** In the arterial portal phase after contrast injection, the liver metastases (*arrows*) have peripheral rim enhancement, and an additional lesion is now evident. **C,** The metastases show complete washout of contrast in less than a minute; image taken at 54 seconds. *(Courtesy Stephanie R. Wilson.)*

On the venous side, portal and hepatic vein transplant complications are relatively rare (see Fig. 13.21). Portal vein stenosis and thrombosis each have an incidence of approximately 1% to 2% (Caiado et al, 2007; Tamsel et al, 2007). Portal vein thrombosis may result from technical problems at surgery, previous portal vein thrombosis, increased downstream resistance from hepatic venous outflow impairment, sluggish portal vein inflow, or hypercoagulable states. Diagnosis is made when flow is absent in the various Doppler modes, or an echogenic thrombus is visualized on gray-scale ultrasound. Very slow flow may be undetected by sonography; so, suspected thrombosis should be confirmed with another modality, such as CT or MRI.

Vascular Disorders of the Liver

Portal Vein Thrombosis and Cavernous Transformation

Portal vein thrombosis may be caused by hypercoagulable states; inflammatory diseases; sepsis; myeloproliferative disorders; neoplasms, especially HCC; and most commonly, portal hypertension (Rossi et al, 2006; Wilson, 2005). Gray-scale findings include solid material within the portal vein lumen that may be anechoic, hypoechoic, isoechoic, or hyperechoic. The portal vein diameter may be normal, or it may be expanded. Doppler imaging may show absent color flow or areas in the vessel that do not fill with color completely. Tumor thrombus may be distinguished from bland thrombus by the presence of arterial waveforms within the thrombus, a finding that is specific but not very sensitive (Rossi et al, 2006; see Fig. 13.16). Recent work with microbubble sonographic contrast media suggests that contrast administration improves both detection and characterization of thrombi in the portal system (Rossi et al, 2006). Very slow flow in the portal venous system may result in a false-positive sonographic diagnosis; therefore CT or MRI can be useful for confirmation, especially in the evaluation of patients prior to liver transplantation.

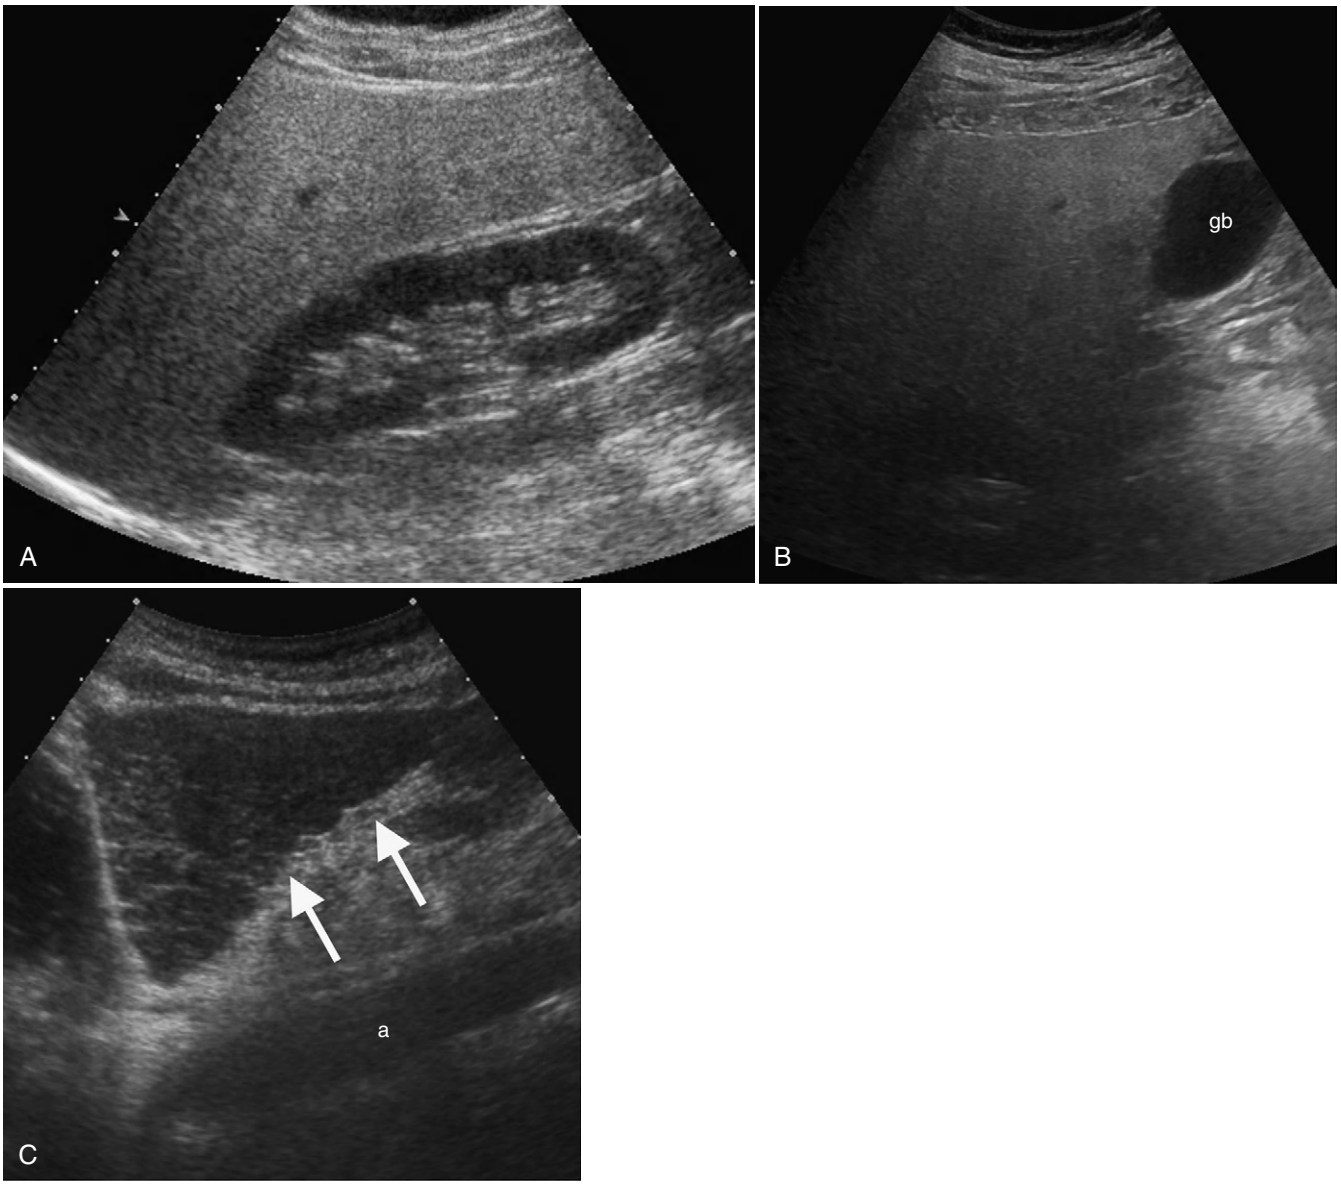

FIGURE 13.20. Diffuse liver disease. **A,** Hepatic steatosis, longitudinal right lobe. Fatty liver is very echogenic relative to the right kidney. **B,** Severe fatty infiltration. There is such marked attenuation of sound that the posterior liver is not visualized. gb, gallbladder. **C,** Cirrhosis. The left lobe is small, with coarsened echogenicity and a nodular surface (*arrows*). a, aorta.

In the setting of long-standing portal vein thrombosis, a collateral hepatopetal venous circulation develops in the hepatic hilum through recanalization of the thrombus and enlargement of collateral veins (de Groen et al, 1999). This phenomenon is known as *cavernous transformation* of the portal vein, and it manifests on sonography as numerous serpiginous vessels in the periportal region and nonvisualization of the main portal trunk (Wilson, 2005; Fig. 13.22) In patients with cirrhosis, spectral Doppler should be used to confirm the venous character of the varicosities, because enlarged and tortuous hepatic arteries may have a similar appearance on color Doppler. In chronic portal vein thrombosis and cavernous transformation, the morphology of the liver may become distorted, with enlargement of the caudate lobe and segment IV and atrophy of the left lateral segment and/or periphery of the liver (Vilgrain, 2001; Vilgrain et al, 2006; Tublin et al, 2008).

Transjugular Intrahepatic Portosystemic Shunt Evaluation

Transjugular intrahepatic portosystemic shunts (TIPS; see Chapter 76E) are often placed for management of the complications of portal hypertension, such as variceal bleeding, or as a bridge to liver transplantation. Color and spectral Doppler ultrasound is essential for evaluation of these shunts, which typically extend from the right portal vein to the right hepatic vein. In normally functioning TIPS, flow in the portal veins should be directed toward the TIPS rather than antegrade into the liver parenchyma. Color Doppler should therefore show reversed flow direction in the left and right portal veins. The

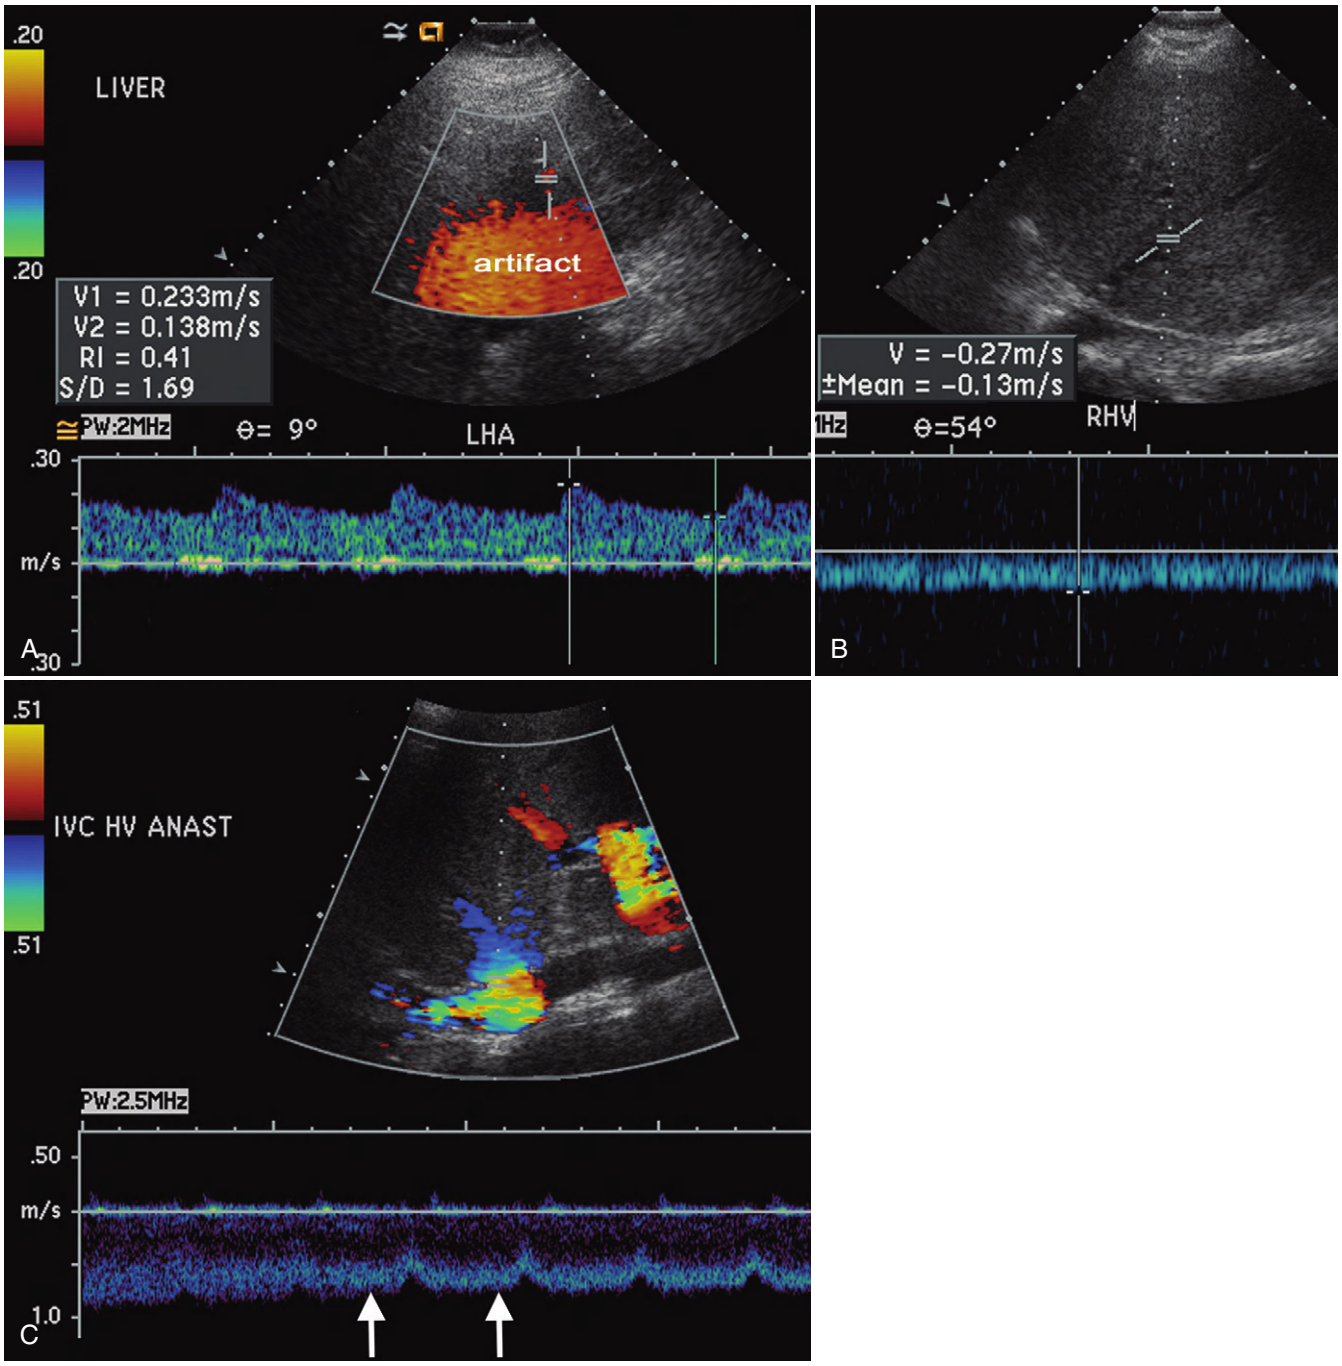

FIGURE 13.21. Vascular complications after liver transplantation. **A,** Left hepatic artery (*LHA*) tardus-parvus waveform indicates hepatic artery stenosis or thrombosis. The waveform has blunted arterial upstroke and high diastolic flow with resistive index <0.5. **B,** Duplex spectral Doppler image of the right hepatic vein (*RHV*) in a patient after orthotopic liver transplant with piggyback anastomosis (*ANAST*) shows monophasic flattened flow, indicating anastomotic stricture. **C,** Duplex Doppler with the sample placed over the area of flow aliasing shows high-velocity turbulent flow (*arrows*) at the stenotic venous anastomosis, localizing the area of focal narrowing. IVC, inferior vena cava.

flow velocity within the mid and distal segments of the shunt should range from 90 to 200 cm/s (Abbitt, 2002; Tchelepi et al, 2002). TIPS evaluation with ultrasound is usually performed immediately after shunt placement to obtain baseline velocity values and at 3-month intervals thereafter to monitor for dysfunction that could indicate developing stenosis. Absent flow on color and spectral Doppler is 100% sensitive and 96% specific for shunt thrombosis (Abbitt, 2002). Doppler sonography can also detect stenosis of the hepatic vein receiving the shunt. An angle-corrected peak velocity below 50 cm/s or reversal of flow in the proximal portion of the hepatic vein suggests stenosis (Abbitt, 2002; Dodd et al, 1995). Other authors have found that an increase or decrease in peak stent velocity of more than 50 cm/s compared with baseline is

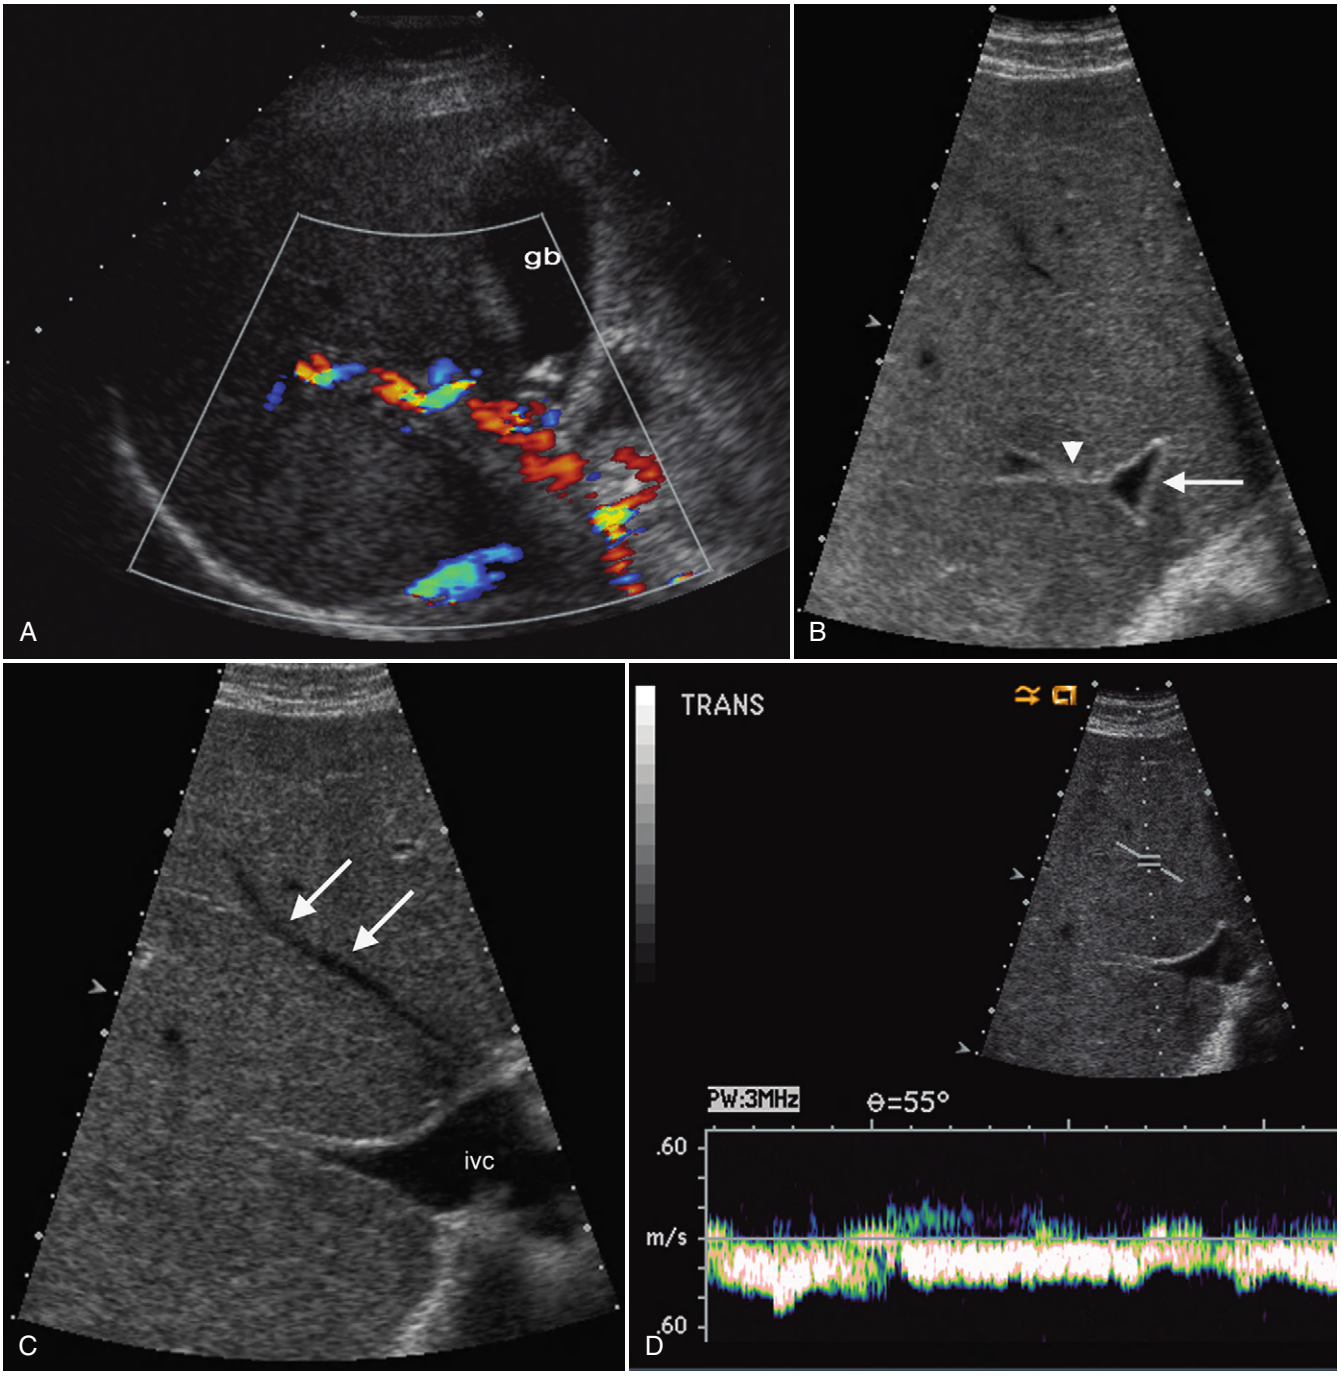

FIGURE 13.22. Vascular disorders of the liver. **A,** Cavernous transformation of the portal vein. The portal supply has a serpiginous appearance because of numerous collaterals. gb, gallbladder. **B,** Outflow obstruction in a patient with venoocclusive disease. On transverse view, the intrahepatic inferior vena cava (*arrow*) is markedly narrowed, and portions of the right hepatic vein (*arrowhead*) are obliterated. **C,** The middle hepatic vein (*arrows*) is narrowed. ivc, inferior vena cava. **D,** The middle hepatic vein shows flattened Doppler flow consistent with partial venous obstruction.

93% sensitive and 77% specific for shunt stenosis (Dodd et al, 1995).

Budd-Chiari Syndrome and Venoocclusive Disease (See Chapter 77)

Hepatic venous outflow obstruction may be secondary to obstruction of the inferior vena cava, hepatic veins, or hepatic venules. Etiologies include venous thrombosis, venous webs, venous obstruction by intrahepatic tumor, or injury to hepatic venules from irradiation and chemotherapy (Cura et al, 2009). The liver becomes enlarged and heterogeneous in echogenicity, but the caudate is typically spared and hypertrophied because of its unique venous drainage (Bargallo et al, 2003). Venous obstruction and ascites are key features of Budd-Chiari

syndrome in the acute phase; in the more chronic phase, intrahepatic venous collaterals and regenerating nodules are also present (Brancatelli et al, 2002, 2007).

Ultrasound is a primary imaging method for evaluation of Budd-Chiari syndrome (Kane & Eustace, 1995). Gray-scale imaging of the hepatic vein confluence may show narrowed hepatic veins, tumor encasement, or intraluminal thrombus. On color Doppler imaging the hepatic vein flow alterations and venous collaterals are readily evident, and spectral Doppler analysis shows flattened waveforms or areas of high velocity flow because of the more central venous obstruction (Grant et al, 1989; Ralls et al, 1992; see Fig. 13.22).

ULTRASOUND OF THE GALLBLADDER AND BILE DUCTS

Normal Anatomy of the Gallbladder and Bile Ducts (See Chapter 1B)

The gallbladder lies on the undersurface of the liver in the plane between the right and left lobes as defined by the middle hepatic vein superiorly and inferiorly by the interlobar fissure, which extends from the right portal vein to the gallbladder fossa. The fundus, body, and neck of the gallbladder are best visualized sonographically from the right intercostal approach with the patient in the left posterior oblique position (Fig. 13.23). At the junction with the cystic duct, the spiral valves of Heister are often visualized. The gallbladder may fold upon itself or may have a phrygian cap appearance at the fundus.

The main bile duct is demarcated into two sections defined by the cystic duct insertion: the common hepatic duct is above; the common bile duct, which traverses the pancreas and enters the duodenum via the sphincter of Oddi, is below the cystic duct insertion. The common bile duct, best seen from the right intercostal approach, normally measures 6 mm in diameter or less. There may be no change or only a slight increase in diameter after cholecystectomy (Mueller et al, 1981; Abbitt, 2002; Feng et al, 1995). The effect of age is controversial, but even in the elderly, the common duct diameter usually does not exceed 7 mm. (Bachar et al, 2003; Horrow et al, 2001; Perret et al, 2000). The right and left main bile ducts are anterior to the portal vein confluence and are best visualized on transverse subcostal ultrasound images. Second order branches may also be seen adjacent to the segmental portal vein branches. The several variant patterns of biliary branching are described in Chapter 1B.

Gallbladder

Cholelithiasis (See Chapter 30)

Ultrasound is the procedure of choice for detection of gallstones, which are highly echogenic and have posterior acoustic shadowing because of the difference in the acoustic impedance between stones and bile (Fig. 13.24; also see Fig. 13.3). It is important to scan patients in different positions, as gallstones are mobile, whereas polyps are fixed. Tumefactive sludge or thick bile may also change with positional variation, but sludge is thick and moves slowly, whereas gallstones roll quickly on real-time ultrasound. Stones in the gallbladder neck may be difficult to visualize, but when the patient is examined in the left lateral decubitus position, they may roll into the gallbladder body or fundus. Fixed stones impacted in the gallbladder neck are frequently associated with cholecystitis. There may be little surrounding bile if large stones or multiple stones fill the entire gallbladder lumen; when this occurs, gallstones are diagnosed by the "wall echo shadow" sign produced by echoes from the anterior gallbladder wall, anterior surface of the stone, and posterior acoustic shadowing.

Cholecystitis (See Chapter 31)

Acute cholecystitis is associated with cystic duct or gallbladder neck obstruction from cholelithiasis in approximately 90% to 95% of cases (Bennett et al, 2003). Ultrasound has 80% to 100% sensitivity, 60% to 100% specificity, and positive predictive value of 94% for the diagnosis (Harvey et al, 1999; Ralls et al, 1985; van Breda Vriesman et al, 2007). Ultrasound findings include gallstones, gallbladder wall thickening greater than 3 mm, pericholecystic fluid, and a positive sonographic Murphy sign (Smith et al, 2009; Teefey et al, 1991; Fig. 13.25).

Gangrenous cholecystitis occurs more often in patients with diabetes mellitus or a white blood cell count greater than 15,000 cells/mL (Fagan et al, 2003). Ultrasound features include floating intraluminal membranes from sloughed mucosa, shadowing foci from air in the gallbladder wall, disrupted gallbladder wall, and pericholecystic abscess formation (Jeffrey et al, 1983). When emphysematous cholecystitis is present, air in the gallbladder wall produces acoustic shadowing and reverberation artifact. This may be diagnosed sonographically, but CT is more sensitive for the presence of air in the gallbladder wall (Gill et al, 1997).

Gallbladder wall thickening may be seen in acalculous cholecystitis and in other conditions that cause edema in the pericholecystic space such as hypoalbuminemia, congestive heart failure, hepatitis, and pancreatitis.

Gallbladder Polyps and Adenomyomatosis (See Chapter 48)

The spectrum of hyperplastic cholecystosis includes benign cholesterol polyps and adenomyomatosis. Cholesterol polyps are usually numerous, small (2 to 10 mm), nonshadowing, and fixed in position (see Fig. 13.23). These are benign with no malignant potential (Ito et al, 2009; Levy et al, 2002). Adenomyomatosis results from hypertrophy of the smooth muscle in the gallbladder wall with prominent Rokitansky-Aschoff sinuses, which may appear as cystic spaces in the gallbladder wall with a characteristic ring-down or comet tail artifact (see Fig. 13.4). The gallbladder wall thickening may be focal, segmental, or diffuse. Focal thickening is most often seen in the fundus, but when it occurs in the middle region, it produces an hourglass-shaped gallbladder.

Gallbladder Carcinoma

Carcinoma of the gallbladder (see Chapter 49) may appear as a focal mass, thickened gallbladder wall, or infiltrative mass that fills the gallbladder lumen and extends into the adjacent liver and bile ducts (Wibbenmeyer et al, 1995; see Fig. 13.24). When the mass occupies the gallbladder lumen, it can result in a displaced or "trapped" stone that is fixed in position because of an intraluminal tumor (Khalili & Wilson, 2005). Mucosal plaque and wall irregularity of gallbladder carcinoma can be differentiated from other causes of gallbladder wall thickening when tumor vessels are demonstrated on Doppler imaging. Contiguous hepatic involvement in segments IV and V is common. Gallbladder carcinoma also frequently extends into the hepatic hilus and causes biliary obstruction secondary to direct involvement

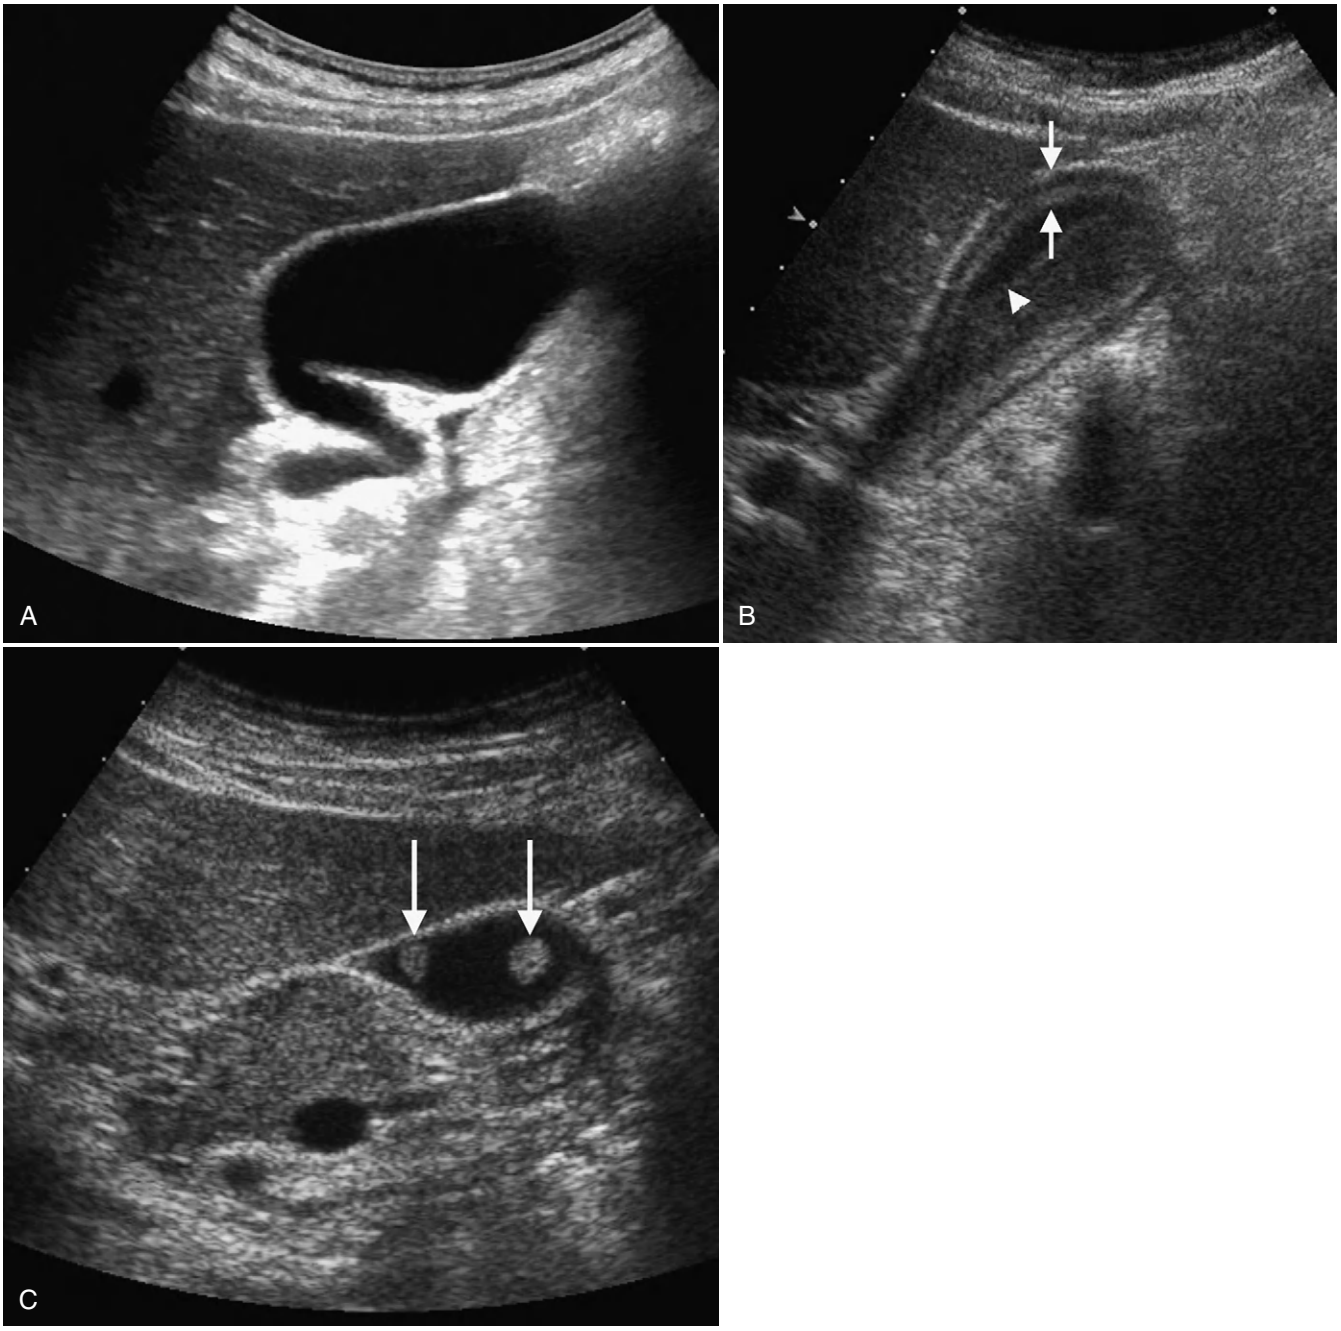

FIGURE 13.23. Gallbladder. **A,** Normal longitudinal gallbladder image with visualization of the gallbladder neck. **B,** Thickened gallbladder wall resulting from inflammation. Sludge (*arrowheads*) layers posteriorly. **C,** Gallbladder polyps (*arrows*). Note the lack of acoustic shadowing.

of the common hepatic duct. Adjacent adenopathy may also be present. Ultrasound performs well for detection of the gallbladder primary and local tumor spread, but CT is necessary to more accurately determine resectability, distant disease spread, and peritoneal metastases (Bach et al, 1998).

In the era of laparoscopic surgery for gallstone disease, it is especially important to assess the gallbladder carefully on preoperative ultrasound to exclude occult gallbladder cancer and to plan an appropriate surgical approach. Unfortunately, approximately 47% of gallbladder carcinomas are detected incidentally at laparoscopic cholecystectomy (Duffy et al, 2008). For these patients, reexploration with definitive resection to clear disease and reexcision of laparoscopic port sites is required (D'Angelica et al, 2009; Duffy et al, 2008; Winston et al, 1999).

Biliary Ducts

Congenital Anomalies

Choledochal cysts (see Chapter 46) are classified according to the location of the dilated ductal segment: *type 1* is fusiform common duct dilation, *type II* is diverticulum of the duct, *type*

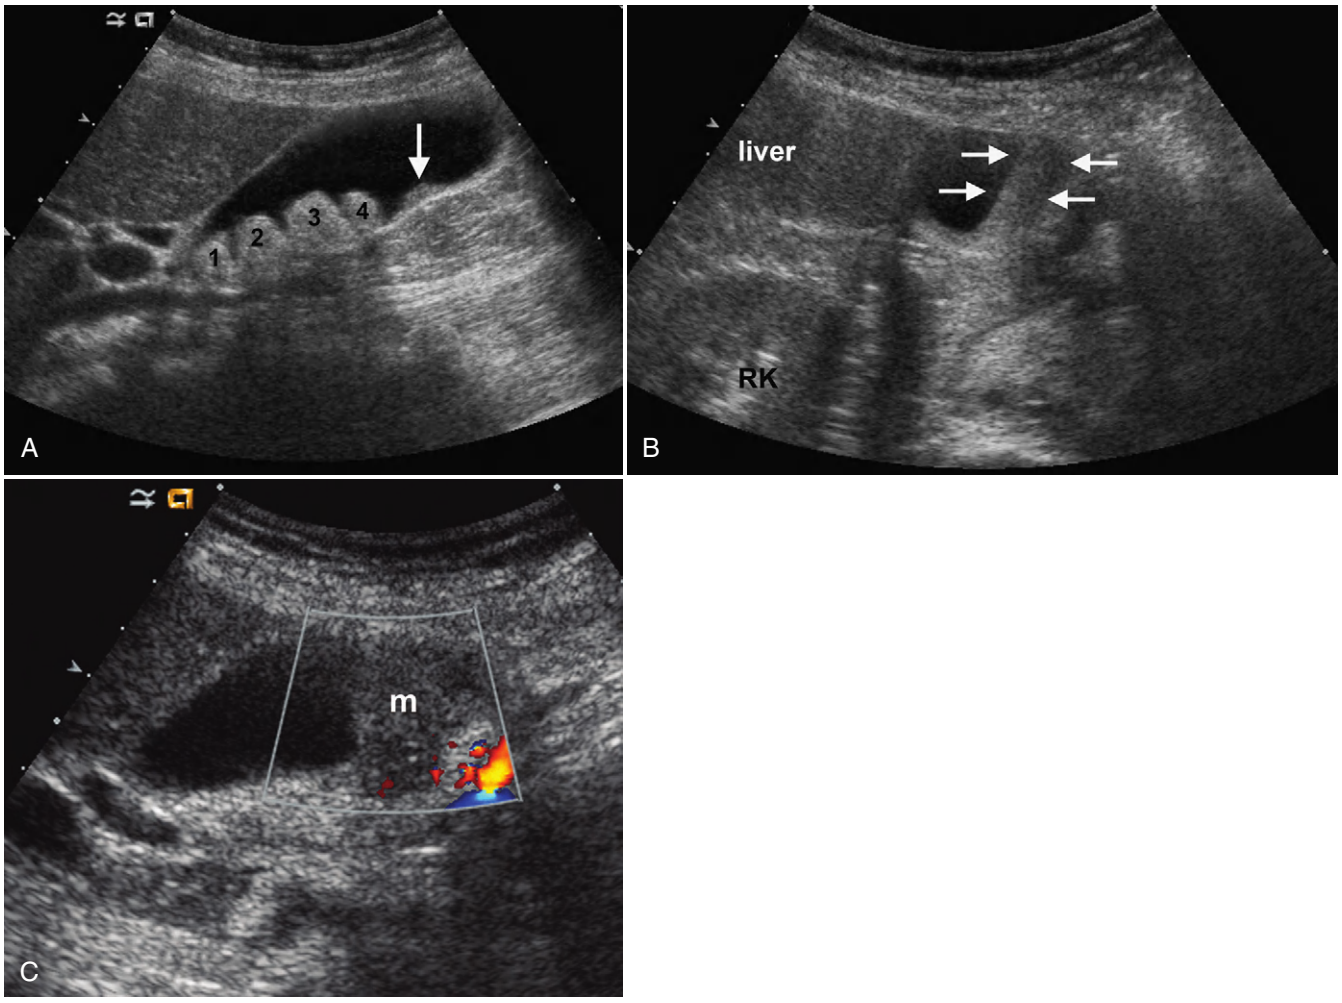

FIGURE 13.24. Gallstones and gallbladder carcinoma. **A,** Longitudinal view of the gallbladder shows layering stones (*numbered*) with acoustic shadow. A small amount of sludge (*arrow*) is also seen in the dependent portion of the gallbladder. **B,** Views of the fundus show focal mural thickening (*arrows*) suspicious for tumor. RK, right kidney. **C,** Flow is seen within the mass (*m*) on color Doppler imaging.

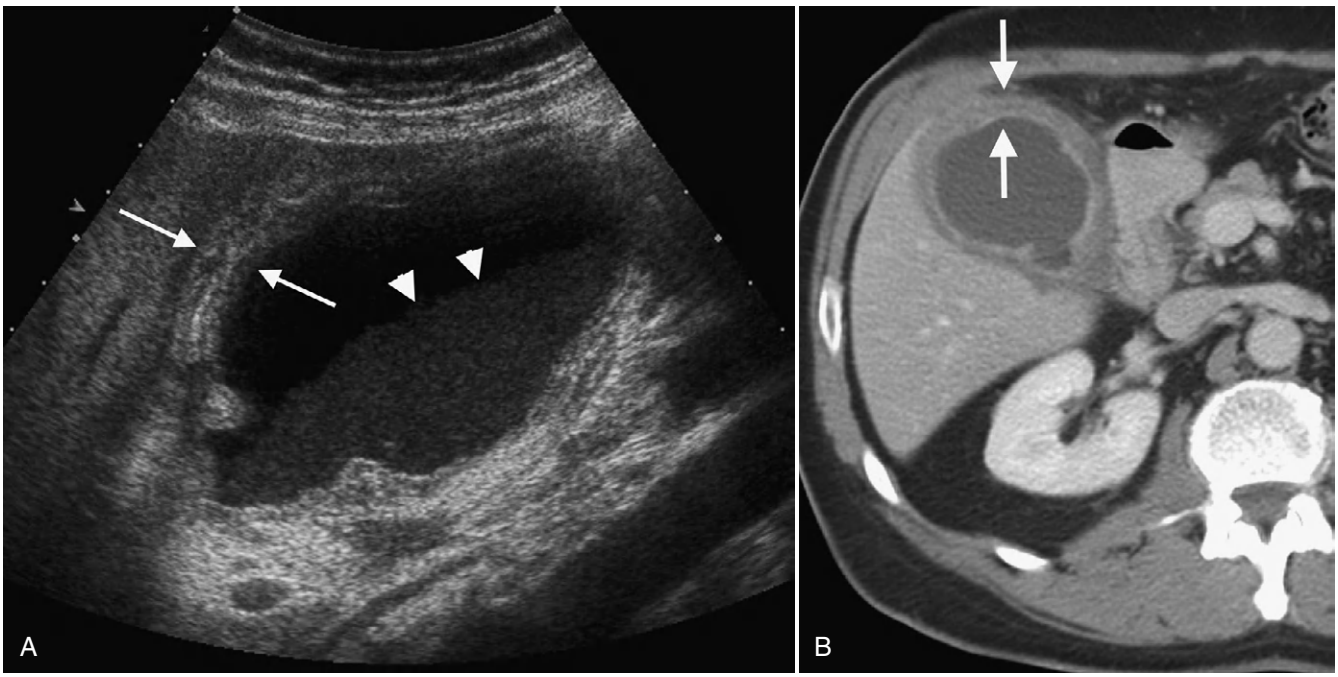

FIGURE 13.25. Acute cholecystitis. **A,** Longitudinal sonogram shows a distended gallbladder with thickened irregular wall (*arrows*) and layering sludge (*arrowheads*). **B,** Computed tomographic scan shows gallbladder wall thickening (*arrows*).

III is a choledochocele from a dilated terminal portion of the common bile duct, and *type IV* is multifocal dilation (Todani et al, 1977). The cysts may be large, and the connection with the bile duct is not always evident sonographically (Khalili & Wilson, 2005). Caroli disease is cystic bile duct malformation that results in multiple diverticulum-like outpouchings from the intrahepatic ducts. On imaging, it is important to demonstrate the connection with the bile ducts to differentiate this condition from polycystic disease. Arterial signals from the fibrovascular bundle at the margin of the saccules may also aid in diagnosis (Miller et al, 1995).

Biliary Obstruction

Ultrasound is the preferred initial imaging study to diagnose biliary obstruction and to determine the level of obstruction (Gibson et al, 1986). Signs of intrahepatic biliary obstruction include the "double track" sign and the "too many tubes" sign caused by dilated bile ducts parallel to the portal vein branches (Fig. 13.26). Bile duct dilation is best appreciated in transverse images of the left hepatic lobe. The pattern of bile duct dilation should be assessed to determine whether it is symmetric in both lobes or localized to one portion of the liver. To determine the level of obstruction, the left and right main ducts are followed transversely to their junction, and transverse views of the common hepatic and common bile ducts are obtained. With this approach it is possible to differentiate intrahepatic from extrahepatic obstruction, and usually the etiology of the obstruction can be determined (Fig. 13.27).

Bile duct calculi (see Chapters 35 and 39) appear as intraluminal filling defects (see Fig. 13.26). Because there is little bile surrounding the ductal calculi, acoustic shadowing may not always be elicited. Debris or thick bile within the ducts may cause internal echoes within ducts and fluid levels, but debris does not shadow, and it shifts with positional variation. Hemobilia (see Chapter 105) may layer or appear echogenic and masslike if the clot is organized. Intraductal tumor from colorectal metastases or HCC may also appear as an intraductal mass, but tumor often expands the duct, and it does not produce acoustic shadowing (Ghittoni et al, 2009; Jhaveri et al, 2009). Obstruction as a result of biliary ascariasis is associated with tubular structures within the bile duct, and movement of the worms is pathognomonic (Lim, 1990; see Chapter 45).

The pattern of biliary obstruction and the appearance of the duct wall are also useful for diagnosis. Recurrent pyogenic cholangitis (see Chapter 44) is evidenced by dilated ducts with intraductal calculi, but dilation is often segmental, frequently in the left lobe. Lobar atrophy may also be present. Primary sclerosing cholangitis (see Chapter 41) causes a beaded appearance of the ducts with wall thickening, strictures, and discontinuous areas of dilation. Mural thickening of the ducts also is seen with AIDS-associated cholangitis. For tumors adjacent to the umbilical portion of the left portal vein, subtle bile duct dilation or wall thickening may be a clue to biliary ductal involvement.

In patients with biliary obstruction who are being considered for surgical resection or palliative biliary drainage, the distribution of biliary ductal dilation should be carefully evaluated to determine management. For example, if surgery is being considered for a mass or vascular or biliary ductal involvement in one lobe, and main biliary duct obstruction is in a contralateral lobe, the disease is not resectable (Jarnagin et al, 2001). Any isolated biliary ductal segments that do not communicate with the main ducts should be noted, as isolated segments may alter surgical approach, and biliary drainage may require placement of multiple catheters.

Primary Bile Duct Neoplasms

INTRAHEPATIC CHOLANGIOCARCINOMA. Cholangiocarcinoma is the second most common primary hepatic neoplasm after HCC. The peripheral intrahepatic form arises from the intralobular ducts and presents as a focal hepatic mass that is usually solitary, but satellites may occur. Intrahepatic cholangiocarcinoma (see Chapter 50A) has associated peripheral biliary ductal dilation in 25%, may have capsular retraction, and lacks venous thrombosis; these features help differentiate

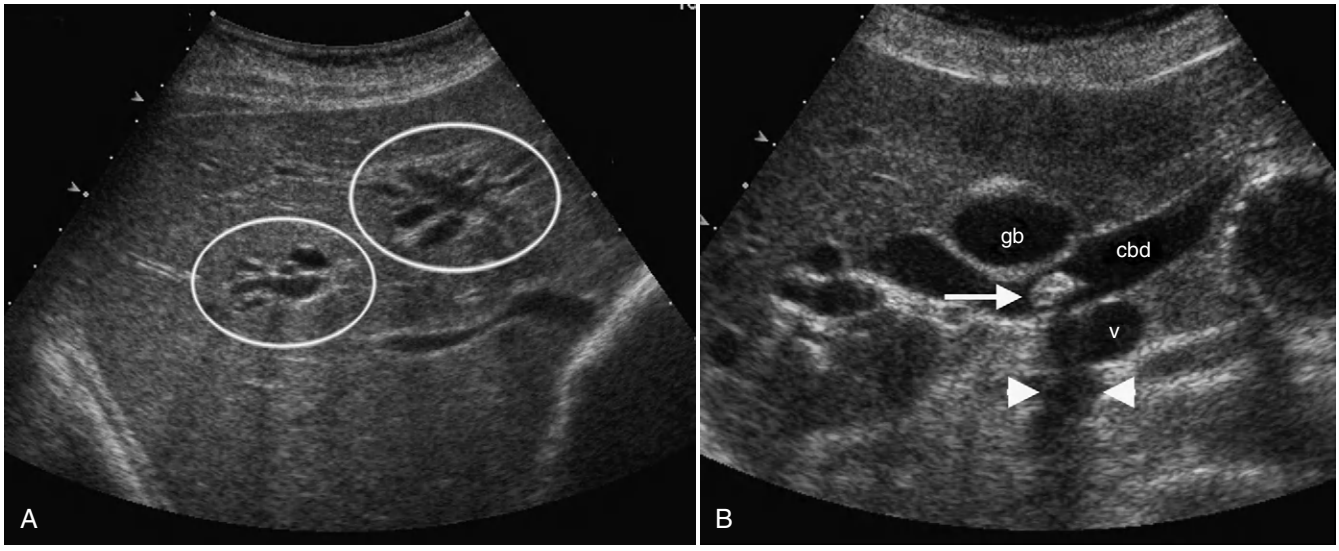

FIGURE 13.26. Biliary obstruction from choledocholithiasis. **A,** Transverse sonogram of the liver reveals "too many tubes" (*circled areas*), consistent with intrahepatic biliary dilation. **B,** Longitudinal view of the common bile duct (*cbd*) shows an echogenic stone (*arrow*) that produces acoustic shadowing (*arrowheads*). gb, gallbladder; v, portal vein.

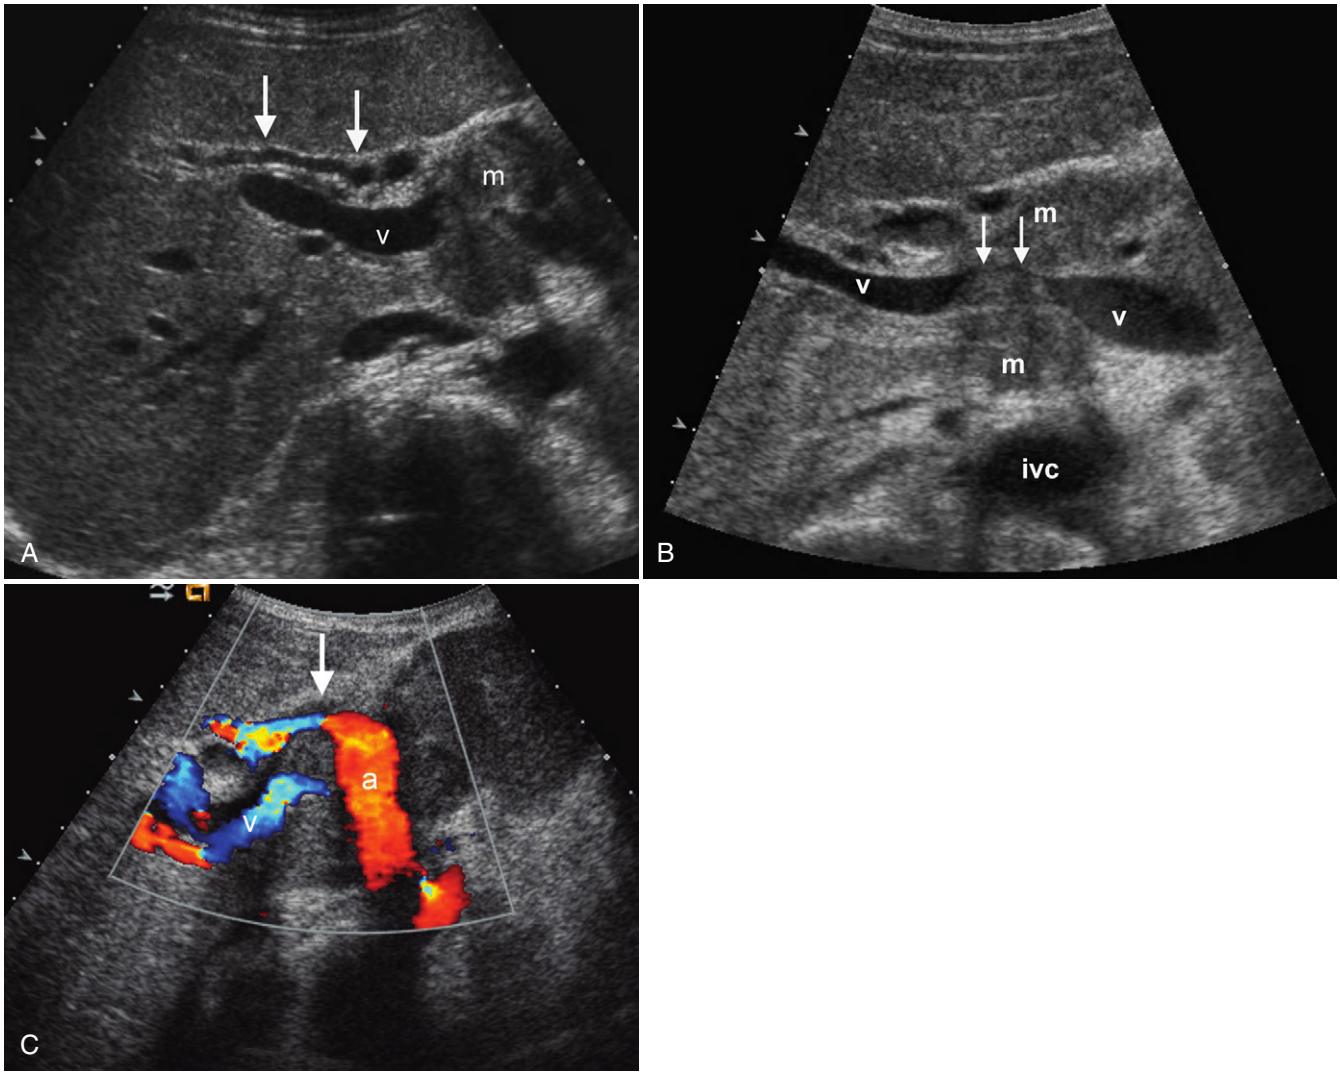

FIGURE 13.27. Biliary obstruction and vascular encasement from adenopathy at the porta hepatis. **A,** Mass (*m*) obstructs a mildly dilated common bile duct (*arrows*) and involves the main portal vein (*v*). **B,** Nodal masses (*m*) encase the portal vein (*v*) that is markedly narrowed (*arrows*). ivc, inferior vena cava. **C,** Color Doppler image shows narrowed hepatic artery (*a*; *arrow*) with dilation proximal to the encased segment.

peripheral cholangiocarcinoma from HCC (Soyer et al, 1995; Chung et al, 2009).

HILAR AND DISTAL CHOLANGIOCARCINOMA. Hilar cholangiocarcinoma or Klatskin tumor (see Chapter 50C), occurs at the biliary confluence. It is best evaluated by ultrasound prior to placement of biliary drainage catheters, as pneumobilia or stent artifact may obscure tumor margins, and the pattern of biliary obstruction may not be evident after decompression. Hilar cholangiocarcinoma is classified by extent of tumor along the duct, and some staging systems also include the status of the portal vein, because direct encasement of the adjacent vessels is common; surgical approach is determined by both portal vein status and ductal spread (de Groen et al, 1999; Jarnagin et al, 2001; Fig. 13.28).

On ultrasound, extrahepatic cholangiocarcinoma (see Chapter 50B) may be infiltrating, nodular, or papillary (Hann et al, 1997). The papillary form, which is expansile, has a better prognosis and surgical outcome (Jarnagin et al, 2005). With experienced operators, ultrasound can correctly identify 96% of extrahepatic cholangiocarcinomas and can demonstrate tumor infiltration along the duct wall (Lim, 2003; Robledo et al, 1996). Ultrasound contrast agents aid diagnosis and staging (Lim et al, 2006). Khalili and colleagues (2003) reported that correct prediction of resectability improved from 69% on noncontrast ultrasound to 96% after contrast.

ULTRASOUND OF THE PANCREAS

Anatomy and Technique

The pancreas is oriented transversely in the epigastrium (see Chapter 1) and is situated immediately ventral to the splenic vein (Fig. 13.29). The latter serves as a useful landmark for locating the pancreas because the organ may sometimes appear isoechoic with the surrounding fat. The splenic vein unites with the superior mesenteric vein (SMV) just posterior to the neck of the pancreas, so that the SMV is a useful anatomic landmark

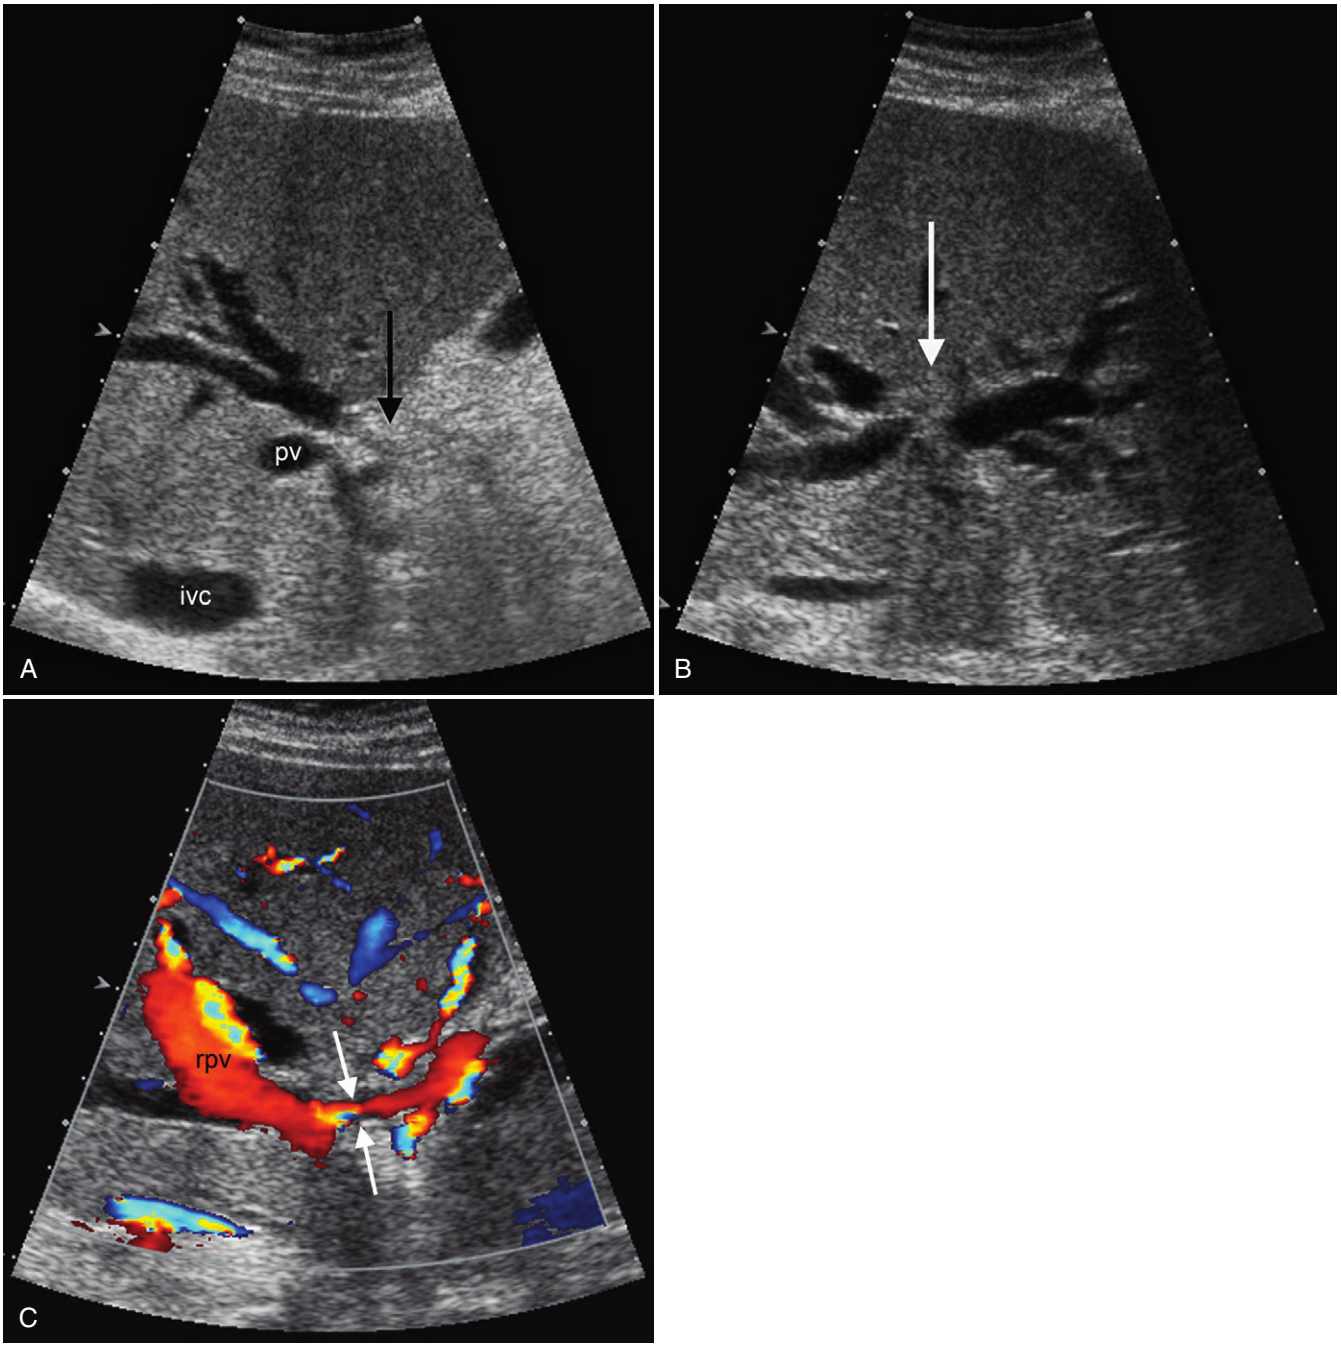

FIGURE 13.28. Klatskin tumor. **A,** Longitudinal view of the common hepatic duct shows a tapered segment (*arrow*) consistent with tumor stricture. pv, portal vein; ivc, inferior vena cava. **B,** Transverse image at the biliary confluence reveals an echogenic mass (*arrow*) at the bifurcation and dilated bile ducts in both lobes. **C,** The left portal vein is narrowed and encased (*arrows*), as shown on color Doppler transverse image. rpv, right portal vein.

that separates the head from the neck of the pancreas. Normal pancreas is homogeneously echogenic and generally of higher echogenicity than the normal liver. In thin patients, the normal pancreatic duct may be visible as an anechoic tubular structure oriented along the long axis of the pancreas. The normal pancreatic duct in young patients should measure no larger than 2 mm in diameter. On transverse images, the common bile duct can usually be visualized in cross section in the posterior aspect of the head of the pancreas (see Fig. 13.29). The gastroduodenal artery can often be seen in cross section along the right anterior aspect of the pancreatic head.

Because of its midline and posterior location, the pancreas is often partially obscured by overlying gas in the stomach. Therefore when primary pancreatic pathology is suspected, CT is the preferred imaging modality (see Chapter 16). Nevertheless, routine abdominal sonograms should include the pancreas, and when sonography is performed for biliary colic or suspected biliary dilation, every attempt must be made to

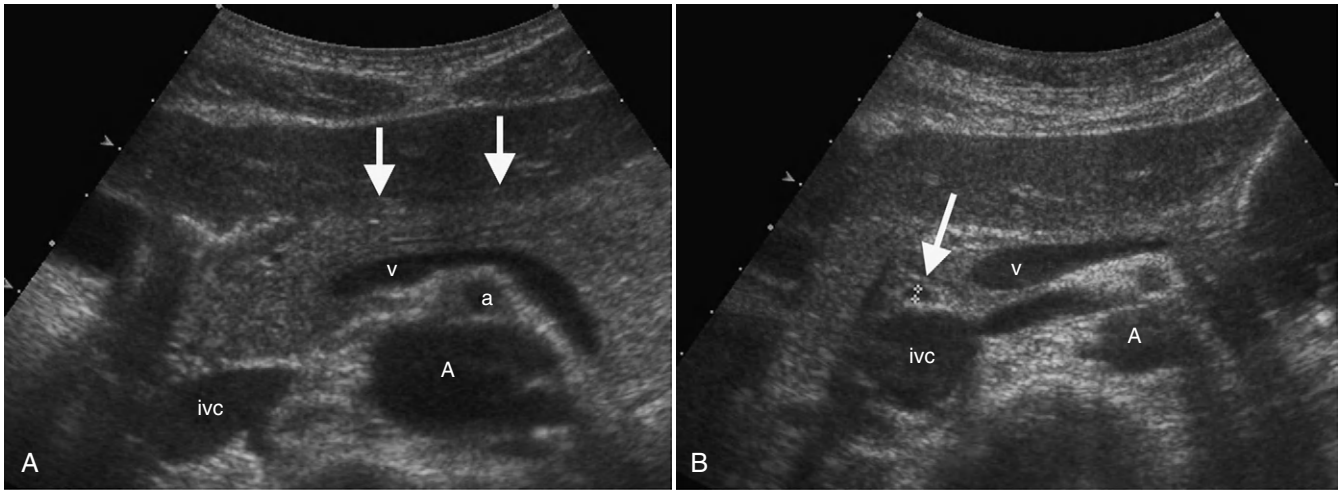

FIGURE 13.29. Normal pancreas. **A,** Transverse image of the normal pancreas and adjacent vascular anatomy. Pancreatic body (*arrows*) is shown. v, splenic vein; a, superior mesenteric artery; A, aorta; ivc, inferior vena cava. **B,** Common bile duct (*cursors; arrow*) in the head of the pancreas.

visualize at least the pancreatic head. It is usually best to begin scans of the abdomen by obtaining images of the pancreas, because the deep inspiratory scans used to image the liver lead to aerophagia and diminish the likelihood of pancreatic visualization. Positional maneuvers, such as sitting the patient upright to displace the stomach gas into the fundus, may help with pancreatic visualization if overlying gas is present in the supine position.

Pancreatitis

Acute pancreatitis (see Chapters 52 and 53) is a common cause of abdominal pain and is usually diagnosed clinically and with laboratory examination findings. Although CT is the preferred technique for gauging the severity and extent of acute pancreatitis, sonography in this setting is useful to determine whether the disease was triggered by gallstones, because the sensitivity of CT for detection of gallstones has been reported to be as low as 25% (Chan et al, 2006). Direct visualization of the pancreas itself on ultrasound may be impaired by gas from an overlying paralytic ileus at initial presentation. In mild pancreatitis, no sonographic abnormalities may be appreciable. If the inflammation is diffuse and more severe, the pancreas may be uniformly hypoechoic. The presence of pancreatic necrosis or hemorrhage cannot be determined reliably with ultrasound; CT is therefore necessary for accurate evaluation.

Other complications of acute pancreatitis, such as extrapancreatic and intrapancreatic fluid collections and pseudocysts, may be readily seen with sonography (see Chapter 54). Pseudocysts form in approximately 10% to 20% of patients with acute pancreatitis (Atri & Finnegan, 2005). They are loculated fluid collections contained within a wall of collagen and granulation tissue, and they generally take 4 to 6 weeks to form following an acute episode of pancreatitis (Atri & Finnegan, 2005; Balthazar, 2002). On sonography, pseudocysts are typically well-marginated ovoid or spherical anechoic masses with posterior acoustic enhancement (Fig. 13.30). Internal echoes representing hemorrhage or debris may be present in the early stages, and

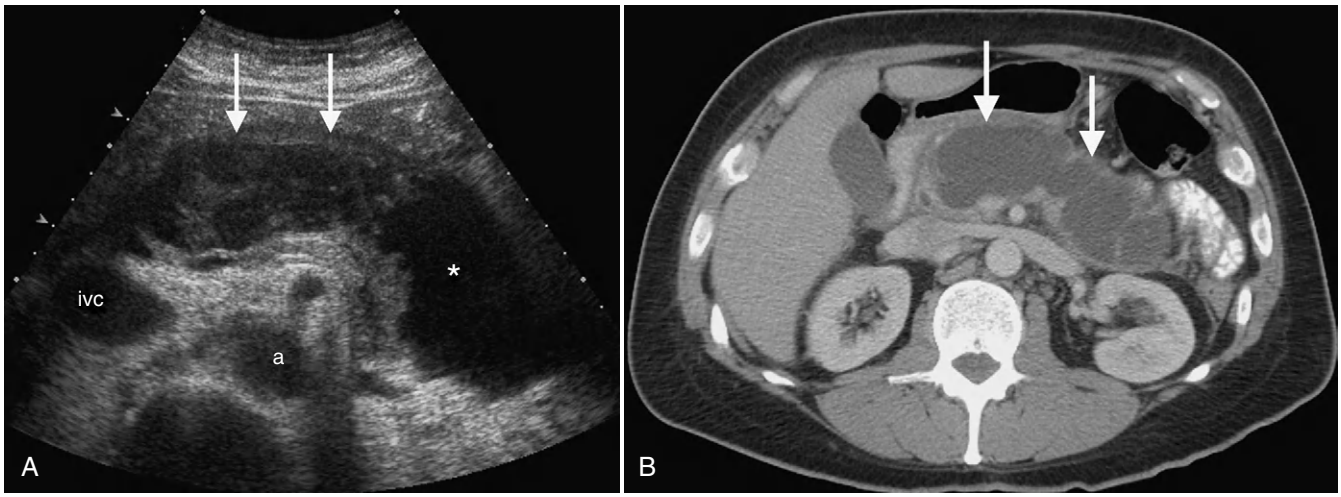

FIGURE 13.30. Pancreatic pseudocyst. **A,** Transverse sonogram of the pancreas reveals a cyst (*asterisk*) in the tail and extension into the body (*arrows*). ivc, inferior vena cava; a, aorta. **B,** Computed tomographic scan confirms extensive pseudocyst (*arrows*).

calcification of the pseudocyst wall may occur. Color Doppler should always be used to evaluate any epigastric cystic mass, including those seen in the setting of pancreatitis, to distinguish these fluid collections from other complications of pancreatitis such as pseudoaneurysms. Color Doppler will also enable detection of splenic vein thrombosis, which occurs in 1% to 3% of patients following acute pancreatitis (Balthazar, 2002).

With repeated episodes of mild acute or subclinical pancreatitis, chronic inflammation with scarring and destruction of pancreatic parenchyma occurs. The changes of chronic pancreatitis seen on sonography include dilation and irregularity of the main pancreatic duct, intraductal calcifications, and focal inflammatory masses (Atri & Finnegan, 2005; see Chapter 55A). The latter may be especially problematic, because these hypoechoic focal regions mimic the ultrasound appearance of pancreatic carcinoma. The finding of calcifications within a hypoechoic focal mass is helpful for differentiating the two entities and suggests chronic pancreatitis, rather than carcinoma, as the etiology. Common duct dilation can be seen in 5% to 10% of patients with chronic pancreatitis (Bolondi et al, 1989), although again, other etiologies—including a downstream obstructing adenocarcinoma or intraductal papillary mucinous neoplasm—should also be considered in the differential diagnosis of main pancreatic duct dilation. Again, calcification visible within the pancreas makes chronic pancreatitis more likely.

Autoimmune lymphoplasmacytic pancreatitis is an unusual type of chronic pancreatitis characterized by fibrotic change with lymphocytic infiltration (Fig. 13.31). On imaging studies, the gland is diffusely or focally swollen, and the main duct is irregularly narrowed (Araki et al, 2006; Sahani et al, 2004). This type of pancreatitis is highly responsive to steroids, and recent studies of contrast-enhanced sonography suggest that the degree of vascularity evident following contrast injection correlates directly with the pathologic grade of inflammation and inversely with the grade of fibrosis (Numata et al, 2004).

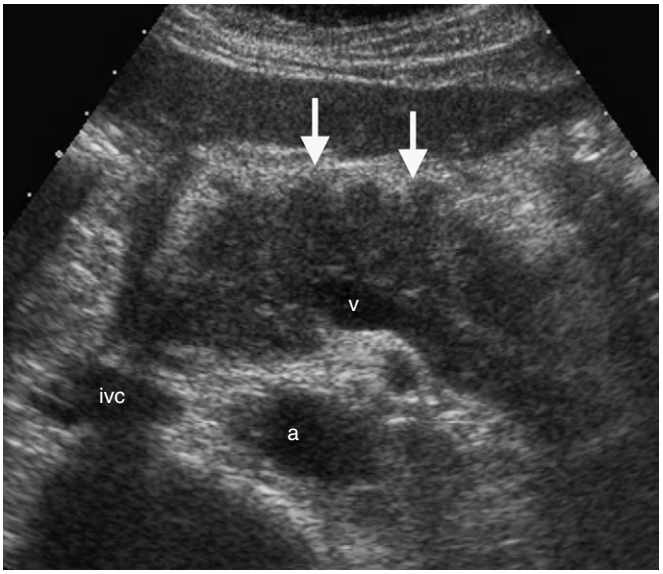

FIGURE 13.31. Lymphoplasmacytic pancreatitis. Transverse image of the pancreas shows diffuse pancreatic enlargement, well-defined margins, and lobulated appearance (*arrows*). ivc, inferior vena cava; a, aorta; v, splenic vein.

Pancreatic Neoplasms

Solid Neoplasms of the Pancreas

Although best staged by CT, adenocarcinoma of the pancreatic head is often detected on sonography, because ultrasound is typically the initial imaging study for evaluation of jaundice, right upper quadrant pain, and epigastric pain (see Chapter 58B). The typical pancreatic adenocarcinoma is an ill-defined hypoechoic mass associated with abrupt dilation of the upstream pancreatic duct and atrophy of the more distal pancreas (Fig. 13.32). Carcinomas of the pancreatic head typically also cause biliary dilation and a "Courvoisier gallbladder." Dilation of both the pancreatic duct and common bile duct, the "double-duct sign," is always a suspicious imaging finding for pancreatic adenocarcinoma, with any imaging modality. Adenocarcinoma in the body or tail of the pancreas is inconsistently visualized on sonography because of variables such as patient body habitus and overlying gastric or bowel gas. Color Doppler sonography typically does not show increased vascularity within pancreatic adenocarcinoma. Nevertheless, this mode can be useful to

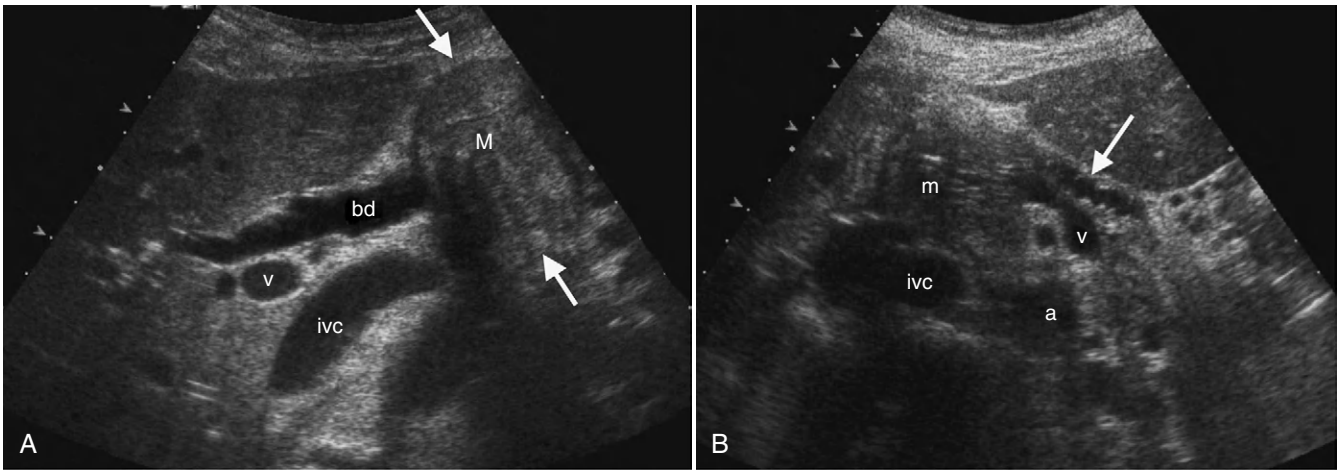

FIGURE 13.32. Pancreatic adenocarcinoma. **A,** Longitudinal view reveals a mildly dilated common bile duct that terminates in a pancreatic head mass (*M; arrows*). v, Portal vein; ivc, inferior vena cava; bd, bile duct. **B,** On transverse view, the pancreatic duct (*arrow*) is dilated. m, Pancreatic head mass; v, splenic vein; a, aorta.

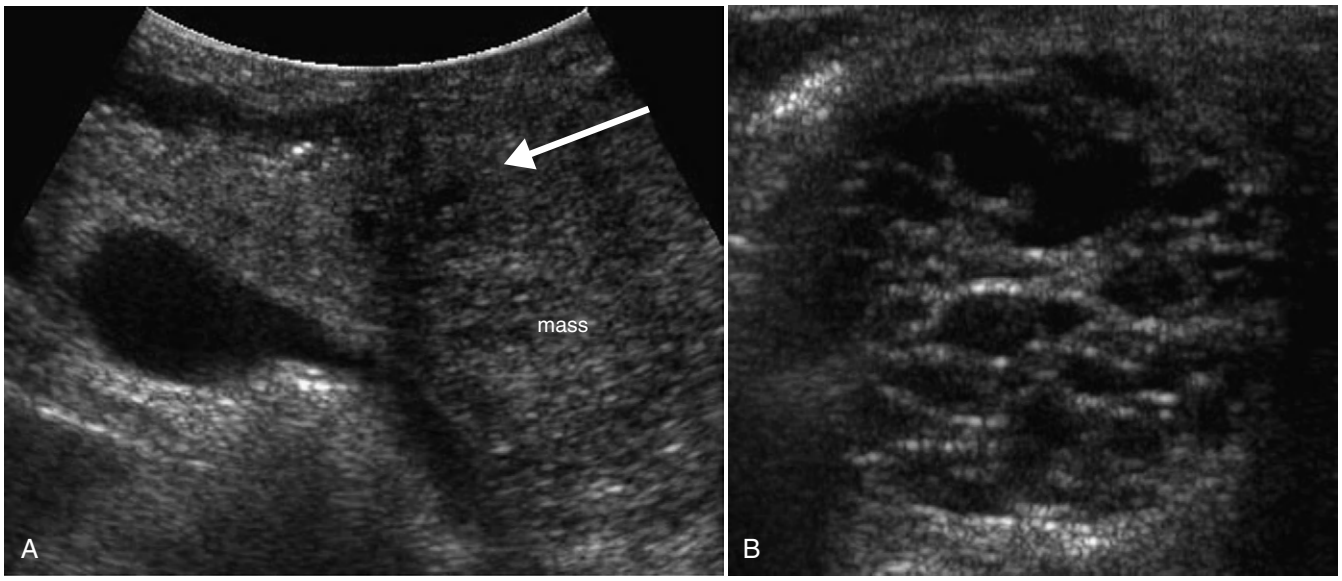

FIGURE 13.33. Serous (microcystic adenoma) of the pancreas. Transverse intraoperative ultrasound images of the pancreas. **A,** Mass in the pancreatic tail has a small cyst (*arrow*). **B,** On magnified higher frequency images, the mass has honeycomb architecture.

visualize the peripancreatic vasculature, such as the celiac axis and superior mesenteric vessels, which are often encased in locally advanced disease (Atri & Finnegan, 2005).

In contrast to adenocarcinomas, neuroendocrine tumors of the pancreas are commonly hypervascular masses (see Chapter 61). They are typically more hypoechoic than adenocarcinomas and may be well defined and smoothly marginated. Intraoperative ultrasound is often a useful adjunct to surgery for pancreatic neuroendocrine tumors, because many are localized and can be safely enucleated. In patients with multiple endocrine neoplasia type I (MEN-I), real-time intraoperative scanning can also help identify additional subcentimeter neuroendocrine tumors that may escape CT detection (Shin et al, 2009).

Cystic Neoplasms of the Pancreas

Cystic pancreatic neoplasms (see Chapter 57) fall into two major categories: *serous* (microcystic) neoplasms and *mucinous* (macrocystic) neoplasms. The two should be distinguished on imaging, because serous tumors are always benign, but mucinous tumors have malignant potential. Differentiation can be made on imaging studies based on the internal architecture and size of the cysts. Serous tumors have cysts ranging in size from less than 1 mm to 2 cm in size, and the internal architecture is often described as having a honeycomb appearance (Fig. 13.33). However, these tumors can vary considerably in sonographic appearance based on the sizes of the internal cysts they comprise. Serous tumors composed of relatively larger cysts will appear as partially solid cystic masses on sonography. As the cysts in a serous tumor get smaller, the less likely it is that the individual cyst cavities and walls will be resolvable on ultrasound; instead, the numerous interfaces created by the walls of the cysts will confer an overall echogenic appearance to the mass. A central stellate scar is a characteristic feature of many serous cystadenomas and may be visible as an echogenic or frankly calcified focus with shadowing (Atri & Finnegan, 2005; Hutchins et al, 2009).

Mucinous neoplasms, by contrast, are typically unilocular or multilocular cystic masses. The cysts within these tumors are larger than 2 cm, and a solid mural nodule within any of the cyst cavities is suspicious for malignancy in these lesions. Intraductal papillary mucinous tumors (IPMTs) arise from the epithelium of the main pancreatic duct or side branches. Side-branch type IPMTs commonly appear as small unilocular cysts or multilocular cystic masses within the pancreatic parenchyma. Main-duct type IPMTs show up as focal or diffuse dilation of the main pancreatic duct. Again, any internal mural nodularity is concerning for malignancy in these tumors.

Endoscopic ultrasound is very useful in evaluation of cystic pancreatic neoplasms, because the internal architecture of the lesions is much better demonstrated. The lesions can also be aspirated under endoscopic ultrasound, and the fluid can be evaluated for the presence of glycogen (serous tumors), mucin (mucinous tumors), and tumor markers such as carcinoembryonic antigen (Hutchins et al, 2009).

CHAPTER 14

Endoscopic ultrasound of the biliary tract and pancreas

Mark Schattner, Paul Belletrutti, and Hans Gerdes

IMAGING AND DIAGNOSIS

The diagnosis of benign and malignant diseases of the pancreas and biliary tree has traditionally relied on a detailed history and complete physical examination, with correlation of the results of clinical chemistries. Imaging of the hepatic and pancreatic parenchyma and ductal anatomy has, however, evolved as critical for accurate diagnosis and for guiding therapy. Routine radiography does not provide the soft-tissue resolution required, but ultrasonography (US; see Chapter 13), computed tomography (CT; see Chapter 16), and magnetic resonance imaging (MRI; see Chapter 17) have become important noninvasive modalities in the routine investigation of almost any symptom, physical sign, or laboratory abnormality potentially relating to pathologic conditions of the liver or pancreas.

Invasive procedures for imaging the biliary and pancreatic ductal systems, primarily percutaneous cholangiography (PTC) or endoscopic retrograde cholangiopancreatography (ERCP) remain important therapeutically, but with respect to diagnosis, these have been almost entirely replaced by noninvasive modalities. Endoscopic ultrasonography (EUS) has also become an important tool for diagnosis and treatment. Its high-resolution images complement the more general findings of cross-sectional imaging and result in a higher sensitivity for diagnosis of early-stage disease. The new-generation EUS instruments (Figs. 14.1 and 14.2) permit guided passage of needles and devices through the endoscope, allowing biopsies to be obtained and permitting therapeutic interventions. This chapter discusses the techniques of radial and linear endosonography in the diagnosis, staging, and treatment of benign and malignant disease of the pancreas and biliary tree.

ENDOSCOPIC ULTRASOUND TECHNIQUE

Because the normal pancreas is located posterior to the stomach, the entire gland is readily seen by EUS imaging through the wall of the stomach and duodenum. With the transducer in the duodenum, the pancreatic head and uncinate process, ampulla of Vater, pancreatic ducts, common bile ducts (CBDs), and the surrounding vascular and nodal structures can be visualized. With the transducer in the stomach, the pancreatic body and tail and the celiac, splenic, hepatic, and superior mesenteric arteries and the splenic, superior mesenteric, and portal veins are all seen in detail.

The normal pancreatic parenchyma has a homogeneous echogenic appearance (Fig. 14.3), and tumors usually appear hypoechoic, often with irregular borders, in sharp distinction from normal tissue (Fig. 14.4). Large tumors of the pancreas may be difficult to evaluate completely because of limited penetration of the tumor by US. Conversely, small tumors of the pancreas that are often missed by CT or MRI are readily imaged by EUS. For example, islet cell tumors, which are often encapsulated and small, are frequently detected on EUS and appear as well-demarcated hypoechoic lesions (Fig. 14.5). Other neuroendocrine tumors, such as gastrinomas, may be isoechoic within the pancreatic parenchyma and difficult to identify without careful, tedious, real-time imaging. Ampullary tumors are also often seen and staged on EUS because of their relation to the duodenal wall, CBD, and pancreatic duct (Fig. 14.6). Extrahepatic bile duct tumors can also be detected and described in detail with EUS imaging (Fig. 14.7).

Cysts of the pancreas are generally anechoic and well demarcated and thus easily identified even when small. Some cysts may have internal echoes or solid areas, which raise concern for a mucinous lesion or associated tumor (Fig. 14.8). If the cysts are complex with septa (Fig. 14.9), they are best distinguished from vascular structures using the Doppler flow feature of the linear array echoendoscopes. Serous cystadenomas may also appear isoechoic with the pancreas and require careful imaging for proper identification (Fig. 14.10). Pseudocysts can vary in size and sonographic features but usually lack a discrete wall and septa, particularly if acute. However, internal echoes often are seen as a result of necrotic debris (Fig. 14.11).

Endoscopic Ultrasound-Guided Fine Needle Aspiration

The development of linear array echoendoscopes, which scan an area orthogonally in line with the endoscope (thus in line with the biopsy channel), has allowed the development of endoscopic ultrasound-guided fine needle aspiration (EUS-FNA). The indications for EUS-FNA include pathologic confirmation of a suspected pancreatic or periampullary cancer prior to nonoperative therapy, evaluation of pancreatic masses or lymph nodes of unclear etiology, and aspiration of pancreatic cysts to help distinguish mucinous from inflammatory or serous lesions. EUS-FNA has also provided the framework for investigations into novel therapies (see EUS-Guided Therapy and Novel Therapeutics below).

Endoscopic Ultrasound Fine Needle Aspiration Technique

Within the duodenum or stomach, the US probe is positioned in close proximity to the target lesion, typically less than 3 cm away. The area is then interrogated with Doppler flow US to ensure the absence of significant vascular structures in the needle path. A 25-, 22-, or 19-gauge needle can then be directed into the target lesion. The tip and shaft of the needles used for FNA are manufactured to produce a bright, hyperechoic image.

FIGURE 14.1. Radial echoendoscope.

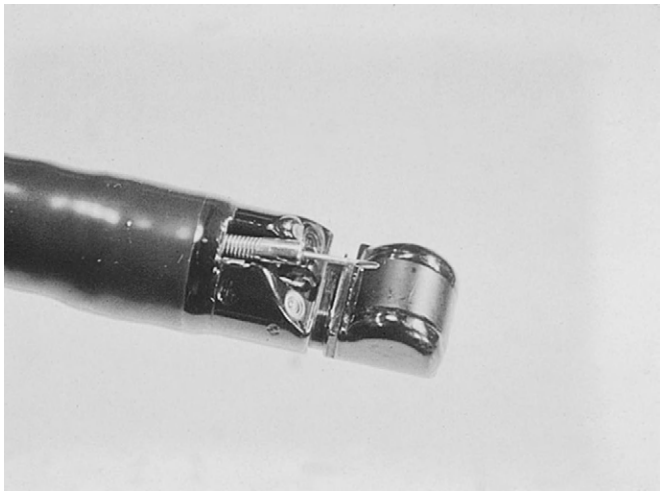

FIGURE 14.2. Linear array echoendocope.

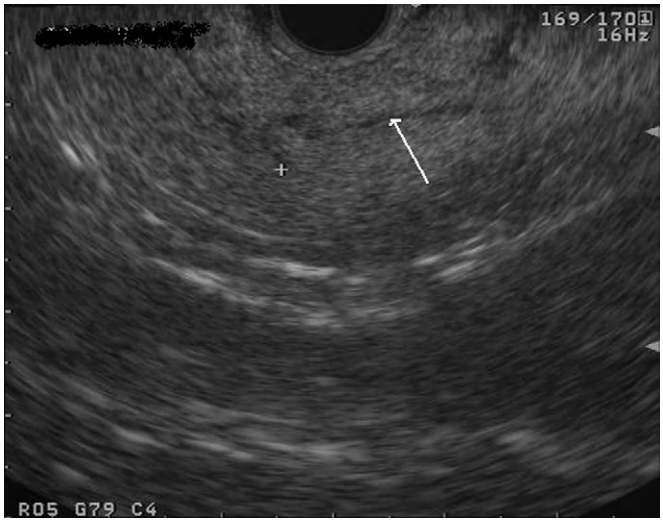

FIGURE 14.3. Normal endoscopic ultrasound image of the body of the pancreas with thin main pancreatic duct (*arrow*).

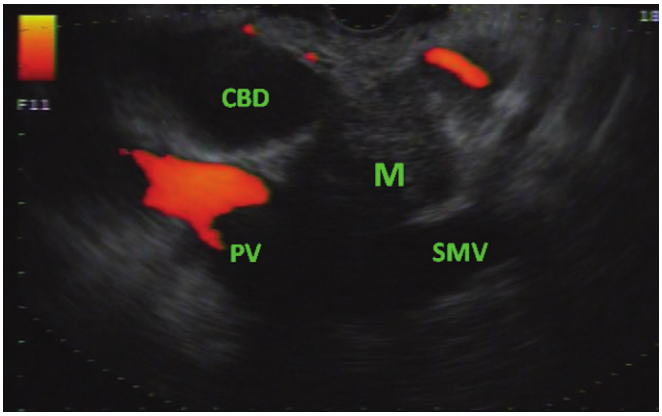

FIGURE 14.4. Solid, irregular, hypoechoic mass (*M*) in the pancreatic head seen with abrupt termination of a dilated common bile duct (*CBD*) and contact with the portal confluence (portal vein [*PV*] and superior mesenteric vein [*SMV*]). Cytology obtained by endoscopic ultrasound–guided fine needle aspiration proved to be adenocarcinoma.

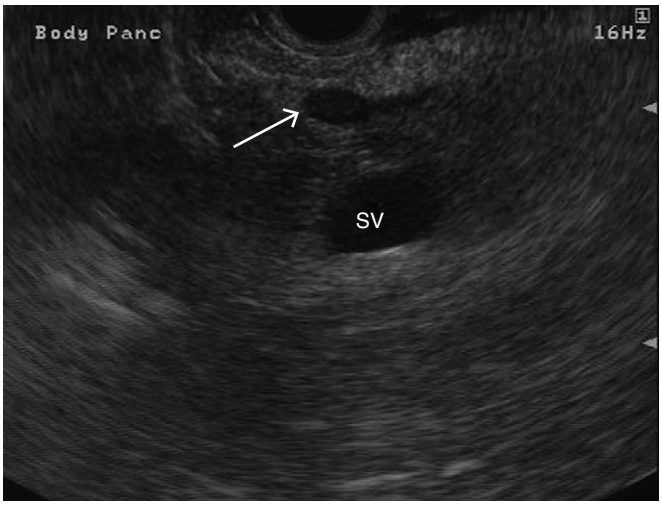

FIGURE 14.5. Small, well-circumscribed, hypoechoic appearance of an insulinoma (*arrow*) in the body of the pancreas with splenic vein below (*SV*).

This allows the needle to be followed in real time to ensure precise positioning within the target lesion (Fig. 14.12). Ideally, a cytopathologist or cytotechnologist should be present at the time of the FNA to determine the cellular adequacy of the specimen. Alternatively, multiple punctures (up to seven) should be performed to ensure an adequate cytologic specimen (LeBlanc et al, 2004). Cyst fluid can also be aspirated and sent for cytology, tumor markers, and chemical analysis (Fig. 14.13).

DIAGNOSIS OF PANCREATIC CANCER

Endoscopic Ultrasound Fine Needle Aspiration of Solid Pancreatic Lesions

Solid masses of the pancreas may represent a primary pancreatic cancer, neuroendocrine tumor, metastatic lesion, or focal pancreatitis. These masses may be difficult to visualize and are often indistinguishable on noninvasive imaging. Percutaneous CT-guided biopsy has a pooled sensitivity of 87% and negative

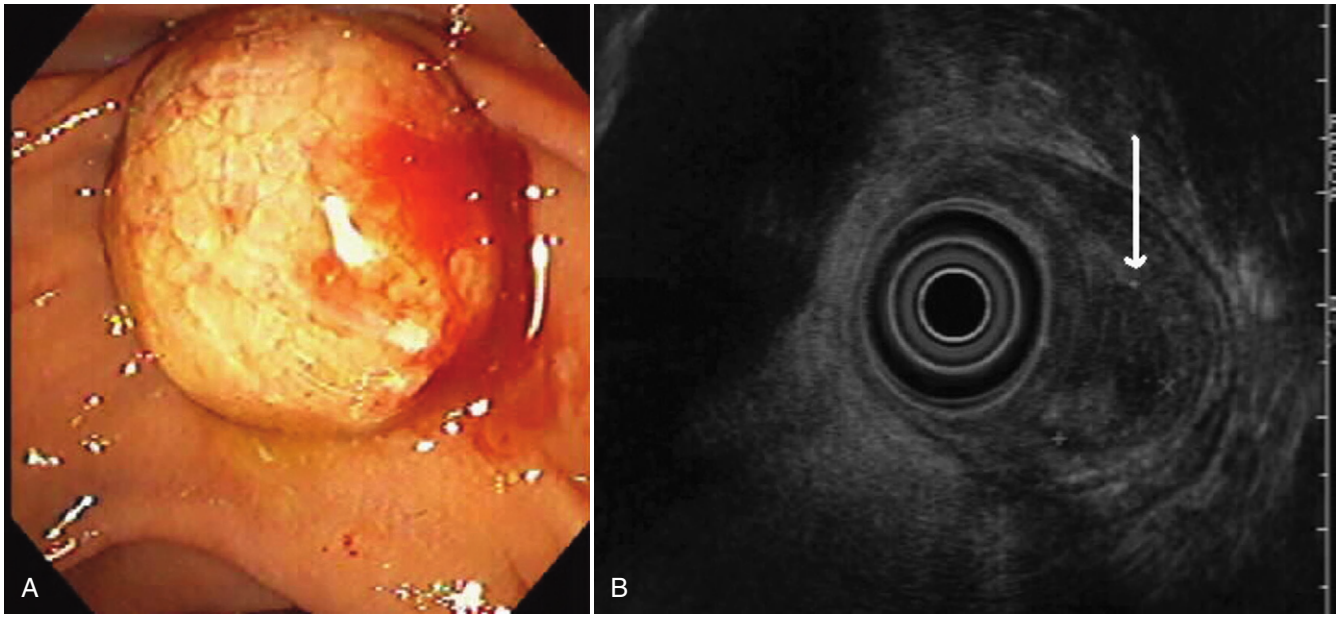

FIGURE 14.6. Endoscopic (**A**) and endoscopic ultrasound (**B**) imaging of an ampullary tumor (*arrow*).

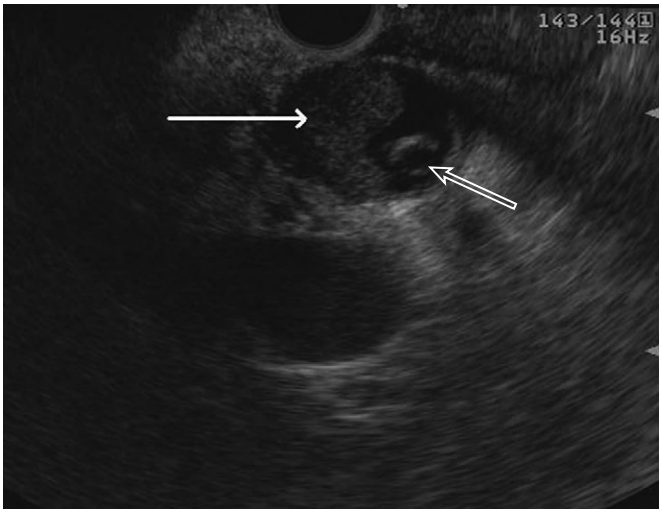

FIGURE 14.7. Hypoechoic mass appearance of cholangiocarcinoma of the common bile duct (*solid arrow*) with biliary stent visible (*open arrow*).

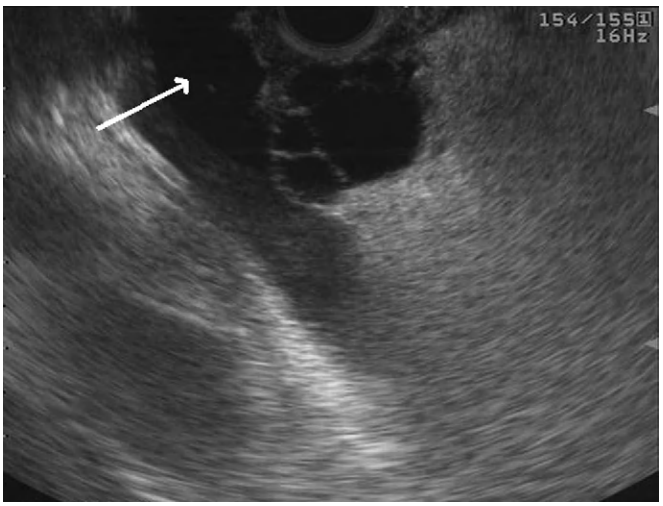

FIGURE 14.9. Multiseptated mucinous cystic lesion in the head of the pancreas (*arrow*).

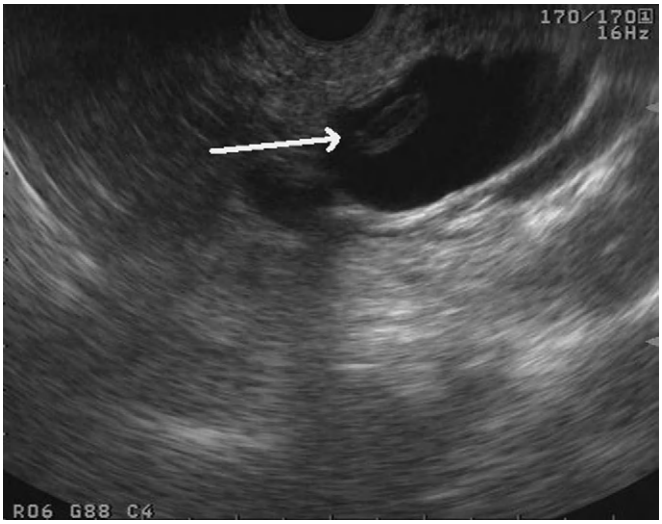

FIGURE 14.8. Mucinous cystic lesion in the head of the pancreas with mural nodule (*arrow*).

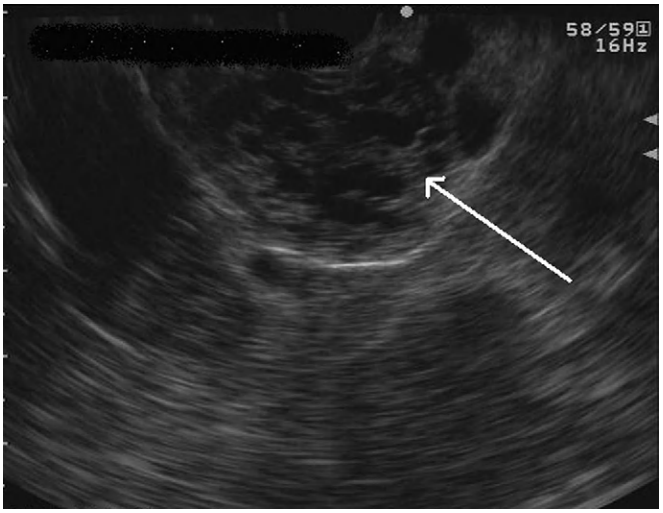

FIGURE 14.10. Typical microcystic appearance of a serous cystadenoma in the head of the pancreas (*arrow*).

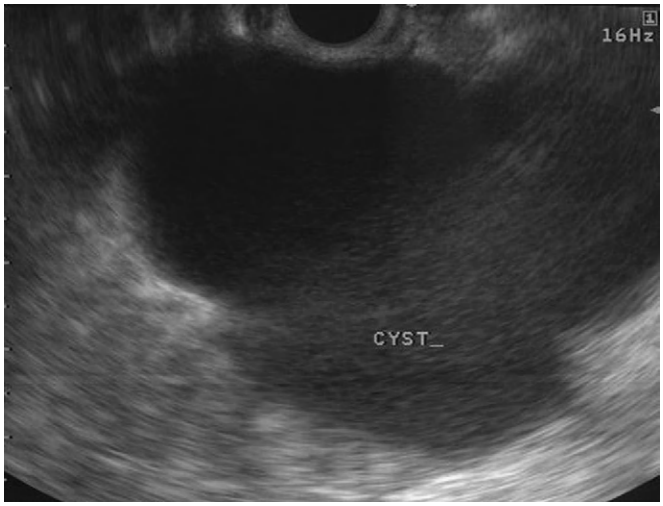

FIGURE 14.11. Large debris-filled pseudocyst adjacent to the tail of the pancreas.

FIGURE 14.12. Bright appearance of fine needle aspiration of a solid mass in the head of the pancreas.

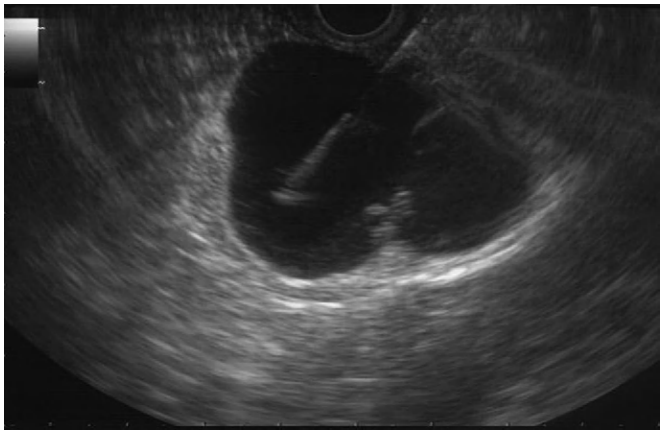

FIGURE 14.13. Fine needle aspiratin of cyst fluid.

predictive value of only 58% (Hartwig et al, 2009), and it carries the risk of cutaneous or peritoneal tumor seeding. Therefore a percutaneous biopsy is best indicated in patients with unresectable disease to help establish a diagnosis and plan palliative care. Similarly, the sensitivity of cytology obtained from brushings during cholangiography is poor (approximately 40%) and cannot adequately exclude cancer (Wakatsuki et al, 2005).

EUS-FNA is highly accurate in diagnosing patients with suspected pancreatic cancer with a sensitivity of 77% to 95%, specificity of 94% to 99%, positive predictive value (PPV) of 98% to 100%, and a negative predictive value (NPV) of 86% to 92% (Wiersema et al, 1997; Yusuf et al, 2009; Turner et al, 2010; Table 14.1). EUS-FNA should be considered as the initial approach to lesions in or adjacent to the pancreas. In a prospective study of 102 patients with suspected pancreatic cancer who had a negative CT-guided biopsy, EUS-FNA had a sensitivity of 95%, specificity of 100%, PPV of 100%, and a NPV of 92% (Gress et al, 2001). With EUS, the issue of needle-tract tumor seeding is minimized, as the FNA is generally performed through a segment of duodenal or stomach wall that will be removed as part of a resection, should the patient be an appropriate surgical candidate. The utility of preoperative EUS-FNA was further demonstrated in a prospective study of 44 patients with resectable pancreatic mass lesions by cross-sectional imaging. EUS with or without FNA precluded surgery in 27% of patients by determining vascular invasion and nodal involvement or by diagnosing lymphoma of the pancreas (Chang et al, 1997).

Endoscopic Ultrasound Fine Needle Aspiration of Pancreatic Cystic Lesions

Cystic lesions of the pancreas remain a diagnostic and therapeutic challenge. The differential diagnosis includes retention/simple cysts, pseudocysts, cystic neoplasms, and cystic degeneration of solid masses (Table 14.2). EUS provides detailed

Table 14.1

Performance Characteristics for EUS in the Diagnosis and Staging of Pancreatic, Ampullary, and Extrahepatic Biliary Tumors

	Sensitivity	Specificity	Accuracy
Pancreatic Tumors			
Diagnosis*			
Tumor >3 cm	86%-95%	94%-99%	86%-94%
Tumor <3 cm	85%-95%	87%-100%	93%-100%
Tumor staging	—	—	72%-98%
Nodal staging	—	—	44%-66%
Resectablity	33%-50%	78%-100%	79%-95%
Ampullary Tumors			
Diagnosis	—	—	93%-100%
Resectability	—	—	61%-88%
Bile Duct Tumors			
Diagnosis*	—	—	43%-86%
TN staging	—	—	60%-80%

*Includes the use of fine needle aspiration to obtain cytology.
EUS, endoscopic ultrasound; TN, tumor node.

Table 14.2

Imaging Characteristics and Fluid Analysis of Pancreatic Cystic Lesions

	EUS Morphology	Communication with Pancreatic Duct	Fluid Amylase	Fluid CEA	Fluid Cytology
Retention cysts	Unilocular, thin walled	No	Variable	Low	Normal duct or centroacinar cells
Pseudocyst	Unilocular, thick walled with debris	Yes	Very high	Low	Inflammatory cells, no epithelial cells
Serous cystadenoma	Microcystic with central calcification	No	Low	Low	Small cuboidal cells, positive glycogen stain
Mucinous cystadenoma	Macrocystic with thick septations	Occasionally	Low	High	Atypical ductal cells, positive mucin stain
IPMN	Dilated, tortuous pancreatic duct and/or side branches	Yes	High	High	Atypical ductal cells, positive mucin stain

EUS, endoscopic ultrasound; CEA, carcinoembryonic antigen; IPMN, intraductal papillary mucinous neoplasm.

information about the entire pancreas—location and number of cysts, size, ductal dilation or communication, signs of chronic pancreatitis, cyst wall thickness, mural nodules, papillary projections, and intracystic structures such as septations, debris, and mass component. Retention cysts are generally small, thin-walled, and unilocular; they carry no malignant potential and can be left untreated. Pseudocysts develop as a result of acute inflammation. On EUS, they are thick-walled as they become chronic and may have debris within the cyst cavity (see Fig. 14.11). They can be seen in or adjacent to the pancreas and often communicate with the pancreatic duct. FNA will yield thick fluid with inflammatory cells but no epithelial cells, and tumor marker levels (carcinoembryonic antigen [CEA], CA19-9) in the cyst fluid are low or undetectable; by contrast, fluid amylase is usually markedly elevated.

Regarding cystic neoplasms, it is important to distinguish mucinous and papillary tumors from serous lesions (see Chapter 57). Serous tumors have little or no malignant potential and do not require resection unless symptoms occur. Typically, serous cystadenomas are composed of a honeycomb of microcysts with no communication with the pancreatic duct (see Fig. 14.10). They can be large and exhibit central stellate calcification on imaging studies. Papillary lesions, solid and pseudopapillary tumors, carry the risk of malignant transformation and usually should be referred for resection. Mucinous lesions—mucinous cystic neoplasm (MCN) and intraductal papillary mucinous neoplasm (IPMN)—also harbor malignant potential that appears to correlate with size; however, universally accepted management criteria are lacking, and treatment recommendations often vary. Mucinous cysts are generally composed of one or more large cystic spaces with thickened walls or septa (see Fig. 14.9). In the case of IPMNs, distinguishing main-duct from side-branch types is important clinically, because the former are associated with a much higher risk of malignant change. Cross-sectional imaging may help in this regard by demonstrating a dilated pancreatic duct characteristic of main-duct IPMN. However, diagnostic uncertainty is not uncommon, and communication with the main pancreatic duct may be demonstrated on EUS.

Although these anatomic characteristics are helpful, EUS cyst morphology alone is insufficient to characterize the lesion (Ahmad et al, 2003; Brugge et al, 2004). Aspiration of cyst fluid via EUS-FNA can further aid in the diagnosis. Cyst fluid can be analyzed for tumor markers, amylase, and molecular markers, and it provides material for cytopathologic assessment. Because of the low cellularity of cyst fluid, the sensitivity and negative predictive value of cytology is low (Centeno et al, 1997; Sedlack et al, 2002). The presence of thick, viscous fluid and a positive mucin stain is suggestive of a mucinous lesion. The concentration of several tumor markers in pancreatic cyst fluid has been examined, and CEA has been found to be the most useful. A cyst-fluid CEA concentration of more than 192 ng/mL predicts a mucinous lesion with a sensitivity of 73%, specificity of 84%, and an accuracy of 79% (Brugge et al, 2004).

Although helpful for diagnosing mucinous lesions, cyst-fluid CEA levels do not correlate with the presence of malignancy. Another limitation of cyst-fluid CEA analysis is that it requires aspiration of at least 1 mL of fluid, which can be difficult if the cavity is small or the fluid is very viscous, making it difficult to pull through a fine needle. More recently, cyst-fluid DNA analysis has shown promise in differentiating mucinous from nonmucinous cysts. This analysis can be done on as little as 200 µL of fluid. The presence of a *KRAS* mutation, high DNA content, and loss of polymorphic alleles are indicators of mucinous cysts. In a large validation study, early *KRAS* mutation followed by allelic loss was 96% specific and 37% sensitive for a malignant cyst (Khalid et al, 2009); however, a reliable and sufficiently sensitive marker for malignancy is still lacking.

Complications of Endoscopic Ultrasound Fine Needle Aspiration

EUS-FNA of the pancreas is a safe procedure. The reported rate of pancreatitis is 0% to 2% (Eloubeidi et al, 2004b; Gress et al, 2002a; O'Toole et al, 2001; Williams et al, 1999). In a multicenter analysis of almost 5000 EUS-FNAs of solid pancreatic masses, the incidence of pancreatitis was 0.3%, and the majority of cases were clinically mild (Eloubeidi et al, 2004b). EUS-guided aspiration of pancreatic cysts is similarly safe, with a pancreatitis rate of less than 1% and an overall complication rate of about 2% (Lee et al, 2005). Bacteremia is uncommon following EUS-FNA of solid lesions, with a rate similar to that for diagnostic upper endoscopy; thus prophylactic antibiotic administration is unwarranted (Levy et al, 2003; Janssen

et al, 2004). However, early data evaluating EUS-guided cyst aspiration showed increased infectious complications, leading to the recommendation of routine antibiotic prophylaxis for all patients undergoing this procedure (Adler et al, 2005). Major extraluminal hemorrhage is a rare complication and occurs at a rate of less than 1% (Affi et al, 2001).

STAGING OF PANCREATIC CANCER (SEE CHAPTER 58B)

The method of staging generally practiced in the United States is that published by the American Joint Committee on Cancer (AJCC). It follows the tumor, node, and metastasis (TNM) staging system and is outlined in Table 14.3.

Endoscopic Ultrasound TNM Staging

Some of the first reports of EUS imaging of the pancreas described its ability to detect and diagnose pancreatic and periampullary tumors (Yasuda et al, 1988; Kaufman & Sivak, 1989). However, subsequent studies evaluated the ability of EUS to stage tumors and assess resectability (Tio & Tytgat, 1986; Rosch et al, 1992). Although the general approach to the preoperative evaluation of pancreatic cancer has focused on the TNM stage, the usefulness of such staging is questionable, particularly because T stage does not necessarily correlate with resectability. Initial studies favored EUS over CT in terms of staging accuracy. However, with the development of high-resolution, multidetector technology, CT has equaled if not surpassed the accuracy of EUS and is once again the preferred staging modality. The same can be said for determining vascular invasion and resectability of large pancreatic tumors (>3 cm).

The performance characteristics of EUS for the diagnosis and staging of pancreatic tumors is summarized in Table 14.1. For example, using the TNM system of cancer staging, Muller and colleagues (1994) showed that EUS has an accuracy of 75% for staging pancreatic cancer, as compared with 56% for CT and 57% for MRI. Recently, a prospective study comparing EUS with multidetector CT for diagnosis and staging of pancreatic cancer also found EUS to be more accurate for diagnosis and tumor staging (DeWitt et al, 2004). Of the 80 evaluated patients, the sensitivity for detecting a pancreatic mass was 98% for EUS and 86% for CT (P = .012). Both modalities were equivalent for nodal staging (44% vs. 47%) and for predicting resectability (88% vs. 92%). In contrast, another recent study favored CT, with an accuracy of 74% for tumor staging, 62% for node staging, and 83% for resectability compared with 62%, 65%, and 72%, respectively for EUS (Soriano et al, 2004).

Perhaps the most useful application of EUS is the diagnosis of small pancreatic tumors (<3 cm) in patients with equivocal radiologic imaging (see Table 14.1). Several studies have demonstrated that EUS is superior to CT scanning for evaluation of pancreatic lesions smaller than 3 cm. For example, Muller and colleagues (1994) reported sensitivities of 93% for EUS, 67% for MRI, and 53% for CT using surgical pathology as the gold standard. In addition, EUS far exceeds CT and MRI in the diagnosis and staging of tumors of the ampulla of Vater to determine whether local or radical resection may be appropriate (see Table 14.1). Other reports, as well as our own experience, have shown the usefulness of EUS in evaluating patients with dilated pancreatic and/or bile ducts but no demonstrable cause. EUS in this setting has been useful in the identification of small tumors of the ampulla, pancreas, or bile duct and nonneoplastic causes such as stone disease, chronic pancreatitis, or abnormal anatomy as may be found in patients with chronic narcotic use (Zylberberg et al, 2000). Therefore, when a pancreatic mass is suspected but cannot be identified by standard imaging modalities, EUS should be considered if further clarification is clinically warranted. A recent, large retrospective series reported a high specificity for EUS in the diagnosis of pancreatic cancer, with a negative predictive value of 100%, when the results of EUS showed a normal pancreas (Klapman et al, 2005).

Endoscopic Ultrasound Determination of Vascular Involvement

Some of the earlier descriptions of EUS in assessing pancreatic cancer focused on its accuracy in identifying vascular involvement. In this regard, Yasuda and colleagues (1993) reported an accuracy of 79% for EUS compared with 41% for CT and 72% for angiography. Rosch and colleagues (1992) showed that EUS

AJCC Staging of Pancreatic Cancer

TNM Definitions	
Primary tumor (T)	
TX	Cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor confined to pancreas, ≤2 cm in diameter
T2	Tumor confined to pancreas, >2 cm in diameter
T3	Extrapancreatic extension, no celiac axis or SMA involvement
T4	Involvement of celiac axis or SMA
Regional lymph nodes (N)	
NX	Cannot be assessed
N0	Regional lymph node metastases absent
N1	Regional lymph node metastases present
Distant metastases (M)	
MX	Cannot be assessed
M0	Distant metastases absent
M1	Distant metastases present
AJCC TNM	
Stage 0	Tis, N0, M0
Stage I	
IA	T1, N0, M0
IB	T2, N0, M0
Stage II	
IIA	T3, N0, M0
IIB	T1-T3, N1, M0
Stage III	T4, N0-N1, M0
Stage IV	T1-T4, N0-N1, M1

From American Joint Commitee on Cancer, 2010: AJCC Cancer Staging Handbook, 7th ed. New York, Springer.

correctly identified portal vein invasion in 95% of 40 patients undergoing operation for ampullary and pancreatic cancer, compared to 85% for angiography, 73% for CT, and 55% for transcutaneous US. These authors also showed that arterial encasement was less reliably detected by EUS.

Some of these earlier studies were criticized, because the EUS findings were compared with the surgical findings based on manual assessment by the surgeon rather than by pathologic confirmation of vascular invasion. Aslanian and others (2005) carefully studied this issue by retrospectively comparing preoperative EUS findings with the surgical pathology of specimens, including tumors adherent to the vasculature. In this series, the reported sensitivity, specificity, PPV, and NPV of EUS for vascular invasion was 50%, 58%, 28%, and 82%, respectively, but the results were better when only the portal, superior mesenteric, and splenic veins were considered. Another recent report compared EUS and MRI staging of resectability based on arterial invasion or encasement. The sensitivity, specificity, NPV, PPV, and accuracy of MRI were 78%, 96%, 92%, 88%, and 91%, respectively, compared with 33%, 100%, 81%, 100%, and 82% for EUS, but these differences were not statistically significant ($P = .13$) (Borbath et al, 2005).

Preoperative Reassessment after Neoadjuvant Chemoradiotherapy

Studies on the treatment of pancreatic cancer have recently focused on neoadjuvant treatment with chemotherapy and radiation therapy, followed by attempted radical resection. Several studies have investigated the ability of EUS to reassess patients who have completed neoadjuvant therapy, with most suggesting that EUS is no better than CT for determining resectability. In one report, EUS correctly assessed residual tumor stage in 40% and node status in 90%, but it incorrectly suggested venous invasion in 43% (Bettini et al, 2005). These results suggest that inflammatory changes in the tumor bed, pancreas, and lymph nodes alter the anatomy and blur the distinction between normal tissue planes and between tumor and normal tissue.

DIAGNOSIS AND STAGING OF CHOLANGIOCARCINOMA

Primary bile duct cancers (see Chapters 50A through 50D) usually present with painless jaundice. Although transcutaneous US and CT scanning reliably show biliary dilation, they are less accurate for delineating tumors, especially if tumors are less than 2 cm. ERCP is the dominant invasive modality employed to evaluate extrahepatic bile duct strictures. Diagnostic specimens can be obtained by rubbing a cytology brush against the stricture, but the sensitivity is low, with a yield of only 40% to 50% (Wakatsuki et al, 2005; Ponchon et al, 1995). EUS has now emerged as a useful diagnostic and staging technique in this regard through the use of linear and radial echoendoscopes, as well as high-frequency radial miniprobes (passed into the bile duct over a guidewire through the working channel of an ERCP scope), to perform intraductal US.

For detecting benign causes of biliary obstruction, such as common bile duct stones, EUS, with a sensitivity of 89% to 94% and specificity of 94% to 100%, is more accurate than transcutaneous US, CT, MRCP, ERCP, or intraoperative cholangiography (Garrow et al, 2007; Tse et al, 2008). If a biliary stricture is visualized, malignancy is suggested by the presence of an irregular, thickened (>3 mm) bile duct wall (see Fig. 14.7). Hypoechoic infiltration invading through the biliary wall layers or an adjacent pancreatic mass can also be seen. Limited studies have reported on the accuracy of EUS-FNA in the diagnosis of bile duct strictures, but the reported sensitivity is 43% to 86% (DeWitt et al, 2006; Eloubeidi et al, 2004a; Rosch et al, 2004; see Table 14.1). For example, in a study of 24 patients with negative cytology brushings, EUS-FNA of the biliary stricture yielded a diagnosis in 19 patients, or 80% (DeWitt et al, 2006).

Intraductal US can also provide staging information with respect to depth of invasion, the maximal longitudinal extent of the lesion, and the presence of invasion into other organs and major blood vessels, particularly portal vein invasion, with a reported accuracy of 60% to 80% (Tamada et al, 1995, 1998; Inui & Miyoshi, 2005). Standard echoendoscopes are less accurate for tumor staging but can detect regional lymphadenopathy and allow for tissue acquisition via FNA.

ENDOSCOPIC ULTRASOUND–GUIDED THERAPY

Celiac Plexus Neurolysis

In patients with pain as a result of pancreatic cancer, EUS-guided celiac plexus neurolysis has been shown to be a safe and effective alternative to surgical or percutaneous approaches. The celiac axis is easily identified using a linear-array echoendoscope positioned in the stomach (Fig. 14.14), and it provides a quick method of palliating cancer-related pain in patients undergoing staging and diagnosis of pancreas cancer. A recent meta-analysis demonstrated pain relief in 80% of patients at a follow-up range of 1 to 6 months (Puli et al, 2009). In addition, decreased analgesic requirements and fewer opioid-induced side effects can be expected after EUS-guided neurolysis. Recent studies have suggested that bilateral ethanol injection to the right and left of the celiac axis is more effective than

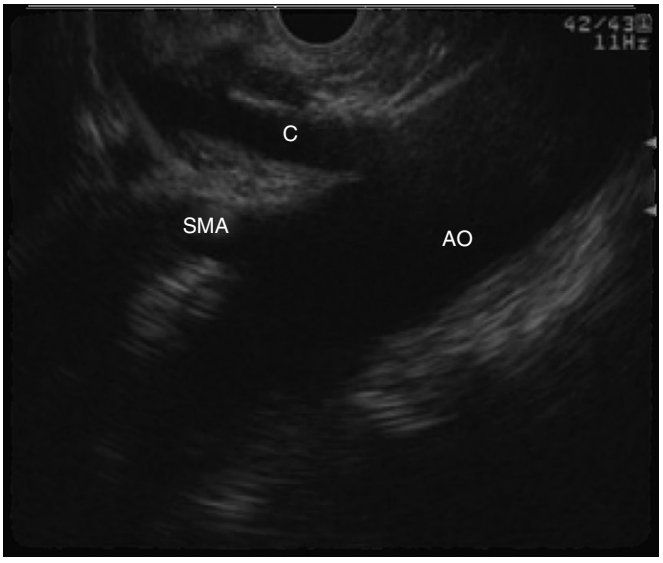

FIGURE 14.14. Endoscopic ultrasound appearance of the longitudinal course of the aorta (*AO*) with celiac (*C*) and superior mesenteric artery (*SMA*) origins.

unilateral or central injection (Puli et al, 2009; Sahai et al, 2009), and no reports of neurologic complications or pancreatitis have been reported with this technique (Puli et al 2009; O'Toole & Schmulewitz, 2009).

Drainage of Pseudocysts and Peripancreatic Collections

The role for EUS as a minimally invasive and effective technique for guiding drainage of peripancreatic fluid collections after acute pancreatitis (see Chapter 54; Varadarajulu et al, 2007; Lopes et al, 2007) or after pancreatic resection has been established. A fine needle is used to puncture the fluid collection, and one or more plastic catheters are inserted over a guidewire to establish transluminal drainage. Using real-time imaging and Doppler flow, intervening organs and vascular structures can be avoided. Thus there are fewer complications, such as bleeding and perforation, compared with the traditional percutaneous approach. True pseudocysts often contain a large amount of necrotic debris that typically requires debridement and is not effectively drained simply by placing drains. This technique has also been applied to the drainage of peripancreatic fluid collections after distal pancreatectomy (Varadarajulu et al, 2009).

Tumor Localization

Preoperative localization of small pancreatic tumors by fine needle tattooing can be performed safely using EUS (Gress et al, 2002b; Farrell et al, 2009). This precludes the need for intraoperative US and may allow the surgeon to perform a more limited pancreatic resection. A role for EUS-guided intratumoral placement of gold fiducials in localizing pancreatic tumors for targeted radiation therapy has also been demonstrated (Pishvaian et al, 2006; Yan & Van Dam, 2008). This modality of radiotherapy minimizes toxicity to the surrounding tissue by allowing delivery of highly conformal radiation treatments.

NOVEL THERAPEUTICS

EUS-guided ethanol ablation of cysts has been recently reported (Gan et al, 2005; DeWitt et al, 2009). Patients with asymptomatic, unilocular pancreatic cysts were treated by injection and lavage of the cyst with ethanol through an FNA needle. Compared to saline lavage, a significant decrease in mean cyst size was seen on follow-up imaging. Those that underwent resection showed histologic evidence of epithelial ablation, and 30% to 35% of patients had complete cyst resolution. Acute pancreatitis was observed at a rate of 0% to 4% with no instances of intracystic hemorrhage.

In patients with advanced abdominal malignancies, simultaneous duodenal and biliary obstruction can occur. Traditionally, these patients have required percutaneous or surgical biliary drainage, because transpapillary decompression via ERCP is often not possible. EUS-guided transduodenal or transgastric biliary drainage is a technique in development that may offer an alternate mode of internal decompression. Similar to pseudocyst drainage, the target—in this case, a dilated CBD or left hepatic duct—is localized with EUS and punctured with an FNA needle. A cholangiogram is performed (Fig. 14.15A) followed by guidewire insertion, dilation of the tract, and deployment of a plastic or self-expanding metal stent across the choledochoduodenostomy or hepaticogastrostomy tract (Fig. 14.15B). High technical and clinical success has been reported, with prompt relief of pruritus and jaundice and no major procedural complications (Park et al, 2009; Yamao et al, 2008; Will et al, 2007).

EUS-guided intratumoral therapy of solid masses is being actively investigated. Several therapeutic agents have been evaluated, including activated lymphocyte cultures, viral vectors,

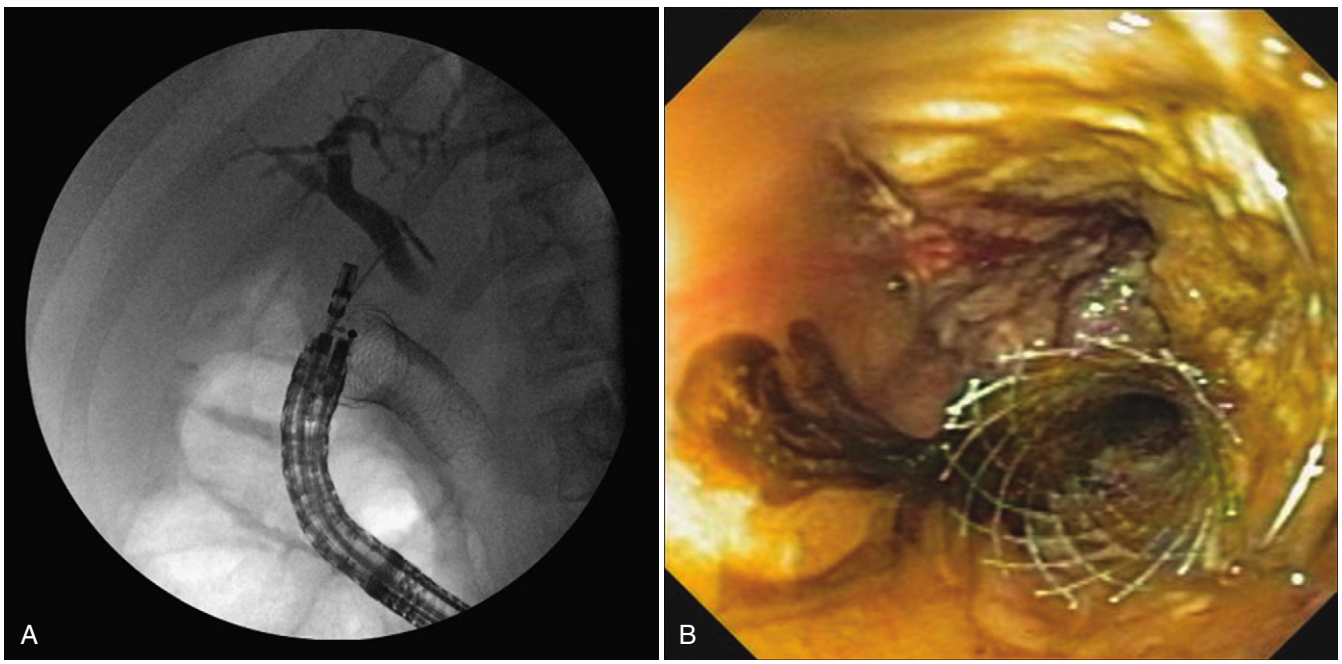

FIGURE 14.15. A, Cholangiogram obtained by endoscopic ultrasound (EUS)-guided puncture of the common bile duct by fine needle aspiration in preparation for EUS-guided biliary drainage. **B,** EUS image after deployment of self-expanding metal stent.

oncolytic viruses, and radioactive seeds (Chang et al, 2000; Senzer et al, 2004; Hecht et al, 2003; Jin et al, 2008). Early studies have established safety and demonstrated partial response or disease stabilization in most patients. The feasibility and safety of performing radiofrequency ablation and cryotherapy of the pancreas using an EUS platform has been established in animal models (Goldberg et al, 1999; Carrara et al, 2008).

SUMMARY

EUS is an important tool in the preoperative evaluation of patients with abnormalities that involve the pancreas and the biliary tree. It provides detailed images of the pancreas and bile ducts and complements the findings of noninvasive radiographic imaging. For patients seen initially with suspected pancreatic or bile duct cancer, multidetector CT scanning assists in identifying those with obvious masses, metastatic disease, and vascular involvement. The usefulness of EUS in this setting is limited, except to provide tissue diagnosis through the use of EUS-guided fine needle aspiration. For patients with small tumors, ampullary lesions, or equivocal findings detected by CT or MRI, the high sensitivity of EUS helps provide a diagnosis, with a high accuracy for tumor staging and determining resectability. Because EUS has poor sensitivity for identifying distant metastatic disease, CT scanning and laparoscopy will remain important tools in the evaluation of patients with pancreatic and bile duct cancer who are being considered for surgery. EUS-FNA is a safe and valuable tool in the evaluation of patients with a suspected solid or cystic mass of the pancreas or extrahepatic bile ducts. It has a higher diagnostic sensitivity and specificity than noninvasive imaging and allows tissue sampling as part of the same procedure. As molecular testing improves, the utility of EUS-FNA as a diagnostic modality is likely to grow. Similarly, the evolution of EUS-FNA from a diagnostic to a therapeutic procedure for pancreatic tumors is in its earliest stages but seems promising.

CHAPTER 15

Nuclear medicine techniques in hepatobiliary and pancreatic disease

Timothy Akhurst

OVERVIEW

The care of patients with hepatobiliary disease has been improving continually. Although much of this improvement is due to innovative surgical techniques and improved anesthesia, diagnostic imaging also has made major contributions to better care. Advances in cross-sectional imaging have led to improved presurgical planning so that there are fewer "surprises" found at operation. Modern nuclear medicine contributes to presurgical diagnosis with a vital role in the differential diagnosis of right upper quadrant pain and presurgical staging of malignant neoplasms involving liver.

Nuclear medicine should be regarded as the study of human pathophysiology, because the uptake of radiotracers used for nuclear imaging depends on the function or molecular composition of normal or neoplastic tissues. Computed tomography (CT), ultrasound (US), magnetic resonance imaging (MRI), and plain radiography excel at showing anatomy. The addition of pathophysiologic information to high-quality cross-sectional imaging improves patient care by characterizing the processes that led to a structural change. The power of nuclear medicine lies in its ability to perform dynamic studies to document physiologic processes quantitatively and to show the presence or absence of malignancy in normal-sized structures.

The workhorse of nuclear medicine has been the γ-camera, which is capable of planar, tomographic, and dynamic acquisitions. The increasing availability of machines capable of acquiring positron emission data of the whole body has revolutionized the practice of nuclear medicine, particularly in the field of nuclear oncology; this is due to the improved physics of imaging positron-emitting radionuclides and to the fact that positron emitters are available for the most important biologic elements (i.e., carbon-11 [^{11}C], fluorine-18 [^{18}F], and oxygen-15 [^{15}O]). The development of positron emission tomography (PET) CT has removed the anatomic uncertainty from PET imaging, improving the specificity of interpretation. In addition, new radiopharmaceuticals have been developed that offer more selective targeting to alterations in molecular structure of tissues. One example is indium 111 (^{111}In) octreotide, which targets tumors that express somatostatin receptor; this particular agent has a variety of PET analogues that permit exquisite anatomic and biologic resolution.

Fluorodeoxyglucose (FDG) PET is now an established area of nuclear medicine practice that is changing the management of patients with colorectal cancer metastatic to the liver. FDG PET also is being investigated in the management of other hepatobiliary malignancies. Hepatobiliary scintigraphy remains a powerful tool in the assessment of the functional status of the biliary tract and is the gold standard noninvasive test for the exclusion of cystic duct obstruction and, by inference, acute cholecystitis. Using planar γ-camera imaging and single-photon emission computed tomography (SPECT) with a variety of technetium-99m (^{99m}Tc)-labeled and ^{111}In-labeled compounds, general nuclear medicine imaging continues to play an important role in preoperative assessment and postoperative care of patients with hepatobiliary disease.

NEW DEVELOPMENTS IN SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY

Hybrid SPECT imaging systems enable the same coregistration techniques that have been embraced by clinicians with regard to PET CT. In part, the difficulties in developing and commercializing new radiopharmaceuticals from a regulatory perspective have left a market niche for SPECT systems capable of showing the anatomic localization of SPECT tracers already in the marketplace. There has been an evolution in these machines, with initial models that used low-dose, low-resolution CT being gradually replaced in the marketplace by SPECT systems coupled to high-resolution spiral CT devices.

POSITRON EMISSION TOMOGRAPHY

Physics

Some elements undergo radioactive decay by ejecting a positron from their nucleus (Table 15.1). A positron is a nuclear particle that has the same mass as an electron, but it has a positive charge. When ejected, the positron moves through surrounding tissues for 1 mm or so, until it eventually combines with a nearby electron, and the mass of both particles is converted to two photons of energy (γ-rays) of 511 keV, which are emitted 180 degrees apart. The PET camera detects these two photons.

Camera Issues

Dedicated Positron Emission Tomography Systems

PET machines are constructed using multiple rings of circularly arranged detectors comprising scintillator crystals, such as bismuth germanium oxide crystals, lutetium oxyorthosilicate, or gadolinium orthosilicate, usually without associated collimators. These cameras all work in coincidence, meaning that a true count is generated only when the two 511 keV γ-rays emitted during positron decay simultaneously strike a set of paired

Table 15.1

Positron Emission Tomography Isotopes in Clinical Use

Isotope	Maximal Range (mm)	FWHM (mm)	Half-life (min)	Products/Use
Fluorine-18	2.6	0.22	110	FDG, F-MISO, FLT, fluorocholine
Carbon-11	4.2	0.28	20	Methionine and other amino acids; colchicine
Nitrogen-13	5.4	0.35	10	Ammonia
Oxygen-15	8.4	1.22	2	Water
Rubidium-82	17.1	2.6	1.3	Myocardial perfusion
Gallium-86	9	1.35	68.3	Antibodies, peptides
Iodine-124	10	8	6048 (4.2 days)	Antibodies, peptides

FWHM, full width at half maximum; FDG, fluorodeoxyglucose; F-MISO, fluoromisonidazole; FLT, fluorothimidine.

From Cho ZH, et al, 1975: Positron ranges obtained from biomedically important positron-emitting radionuclides. J Nucl Med 16:1174-1176.

detectors (Fig. 15.1). These types of PET imaging devices have high sensitivity. A large amount of usable data is obtained from a given amount of material injected into a patient so that the camera is able to detect small accumulations of injected tracer. The resolution of these machines is defined as the smallest distance between two sources of radiation, whereby the imaging instrument is able to show two sources of radiation rather than one. This distance is currently around 5 mm for most clinical systems; animal imaging devices are now available that have 1-mm resolution (for ^{18}F).

Computed Tomography/Positron Emission Tomography Hybrid Systems

γ-Rays originating in the center of the body have to pass through tissue for a considerable distance to reach the detector, and if one or more of the paired annihilation photons are absorbed, that decay is not recorded as a true count. An anatomically central source would be underrepresented if no attempt were made to correct for differing body tissue density and the depth of the origin of the γ-rays. One of the major advantages of PET imaging is that an accurate correction can be made for this process of attenuation, or loss of counts. Combination machines have been developed (Beyer, 2000) that contain a CT and a PET device in the same imaging gantry. Attenuation correction maps extrapolated from the CT acquisition overcome the attenuation of activity originating in the center of the body. In this way, the PET image becomes quantitative so that the process of computerized data reconstruction ultimately generates a map of the three-dimensional distribution of radioactivity. It is essential that attenuation be performed to obtain quality information from areas such as the porta hepatis, particularly if quantification of radioactivity content in the lesion is to be attempted.

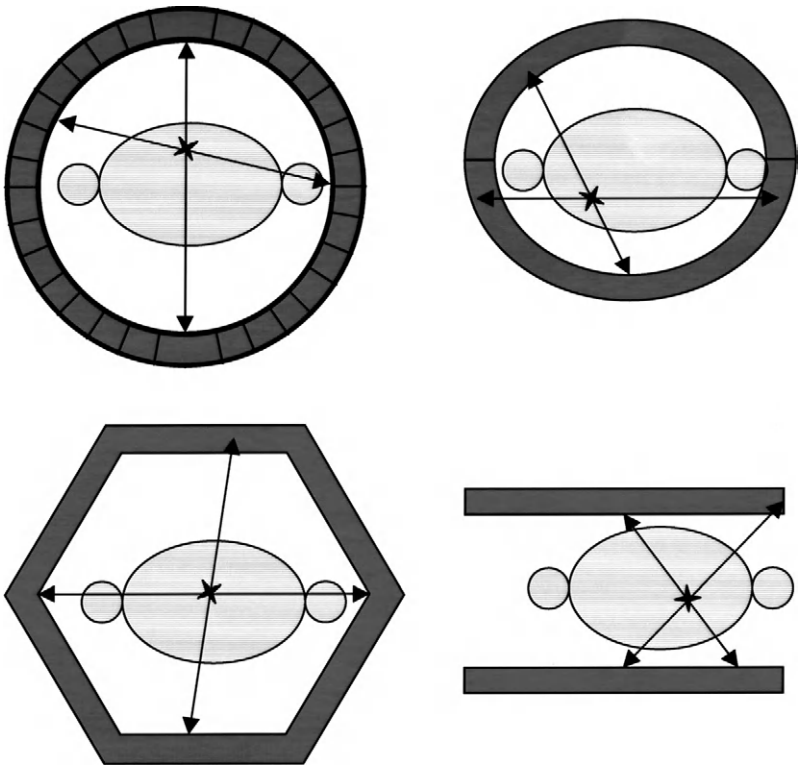

FIGURE 15.1. Stylized representation of the end-on geometry of types of cameras used for positron emission tomography in medicine, arranged in decreasing detector performance. The *top left image* is of a dedicated bismuth germanium oxide–based system, showing one detector ring of many with a single crystal represented by one of the gray segments. The *star* represents the site of positron decay in the patient. *Arrows* represent two photon pairs emitted as a result of positron decay. The *top right image* represents a dedicated curved sodium iodide (NaI) detector system. These systems usually have six large, curved NaI crystals. The *bottom left image* is of a hexagonally arranged system with six large, flat NaI crystals. The *bottom right image* is of a hybrid γ-camera system.

Using PET CT enables coregistration of structural and functional information; this promises near-perfect anatomic localization of areas of functional changes. Some drawbacks with these machines are related to misregistration of the CT data used for attenuation correction in the region of the diaphragm and around the heart, related to cardiorespiratory motion (Beyer et al, 2003). At present there are multiple approaches to this issue but no universally accepted methodology of addressing it.

Biochemistry

The most common radiopharmaceutical used in PET imaging is FDG, a glucose analogue that crosses cell membranes, sharing the glucose transporter molecules used by glucose. Similar to glucose, it undergoes phosphorylation by the enzyme hexokinase. The resulting molecule, FDG-6-phosphate, is polar; it cannot cross cell membranes and is not a substrate for glucose-6-phosphate isomerase, which converts glucose-6-phosphate to fructose-6-phosphate. FDG-6-phosphate is not a substrate for glucose-6-phosphatase in any tissue except the normal hepatocyte. The net effect is a continuous accumulation and retention of FDG in cells (Fig. 15.2).

Warburg (1930) reported that cancer cells show increased rates of glycolysis compared with normal cells. This discovery has stood the test of time and now underpins the utility of FDG PET imaging in cancer. Glucose metabolism is the most efficient form of energy transfer, and all normal tissues have characteristic glucose metabolic rates. The brain has a high rate of glucose metabolism, and the lung and white fat have low rates. A clump of tumor cells is easier to detect in the lung or in fat than in the brain, because the target-to-background ratio is high in these tissues. The liver has an intermediate glucose metabolic rate. Active inflammatory cells exhibit an increased rate of glycolysis, and sites of active inflammation exhibit increased FDG uptake, although in general the rate of glucose metabolism is lower in inflammatory sites than in most tumors. Sarcoidosis in particular can be quite FDG avid and may have similar patterns and degrees of uptake as some malignancies, such as lymphoma and small cell lung cancer. In such cases, clinical judgment is called into play just as it is in the interpretation of opaque masses in the lung on CT scan.

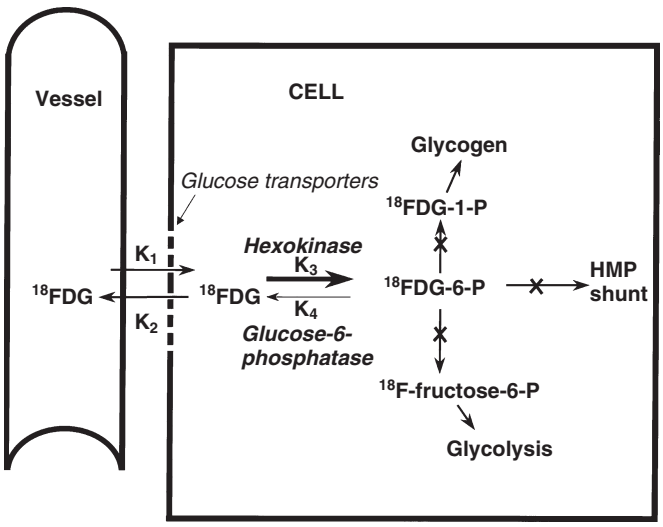

FIGURE 15.2. The metabolic fate of ^{18}F fluorodeoxyglucose (*FDG*) after injection. The curved diagram at *left* represents the blood vessel; the gap represents the extracellular space, and the cell is on the right. ^{18}F-FDG is phosphorylated by hexokinase and thereafter is not effectively metabolized further. HMP, hexose monophosphate.

The process of ^{18}F and ^{18}F-FDG production and distribution is now routine, and most major cities have intracity distribution of unit doses, as they do for many other radiopharmaceuticals. Most tertiary hospitals are likely to have some form of positron imaging–capable camera in the near future, and many will install dedicated high-end systems, as clinicians realize the advantage of high-resolution PET CT in their practices.

FDG PET Imaging in Patients with Colorectal Cancer Metastatic to Liver (See Chapter 81A)

Historical Review

The earliest human study of FDG PET in colorectal cancer was performed by Yonekura and colleagues in 1982; this study of large hepatic metastases in three patients with colorectal cancer was successful and showed that these tumors were highly glucose avid. Numerous publications from multiple centers have established that colorectal cancer is readily detected on FDG PET, and colorectal cancer is a common reason for referral of patients for a scan. The value of FDG PET in colorectal cancer patients is based on the consistently accelerated levels of glycolysis seen in colorectal cancer, which results in high FDG uptakes on PET scanning.

Technique

FDG PET studies (Figs. 15.3 to 15.13) are typically performed as a screening procedure that obtains a whole-body image in an attempt to find as many sites of disease as possible. The usual FDG PET CT study of the whole body takes between 7 and 20 minutes, depending on the machine used. The amount of time spent imaging the liver alone is 2 to 4 minutes. If an acquisition of the liver were performed for 1 hour, the accuracy of PET would improve over the values reported in the literature. Nevertheless, FDG PET imaging performs remarkably well with an extraordinary safety profile, with no adverse effects reported in more than 81,000 doses administered over a 4-year period in 22 centers (Silberstein, 1998).

Staging

Preoperative imaging identifies sites of disease in relation to the vascular anatomy of the liver and excludes disease that renders the patient inoperable. Cross-sectional imaging with CT, MRI, and US are the methods of choice to elucidate the vascular anatomy of the liver (see Chapters 13, 16, and 17); nuclear medicine plays no direct role. A secondary role of preoperative imaging is in the demonstration of disease that renders the patient nonresectable. In the best of centers, many patients who are scheduled for hepatic resection are found intraoperatively to have disease that if shown initially would have led to a nonoperative treatment plan (Jarnagin et al, 1999). In a series reported by Scheele and colleagues in 1995, the rates of resection with curative intent steadily increased from 1960 to 1992. Among the many reasons for this increase are improved treatment options and better preoperative imaging that allows more accurate selection of patients with potentially resectable disease.

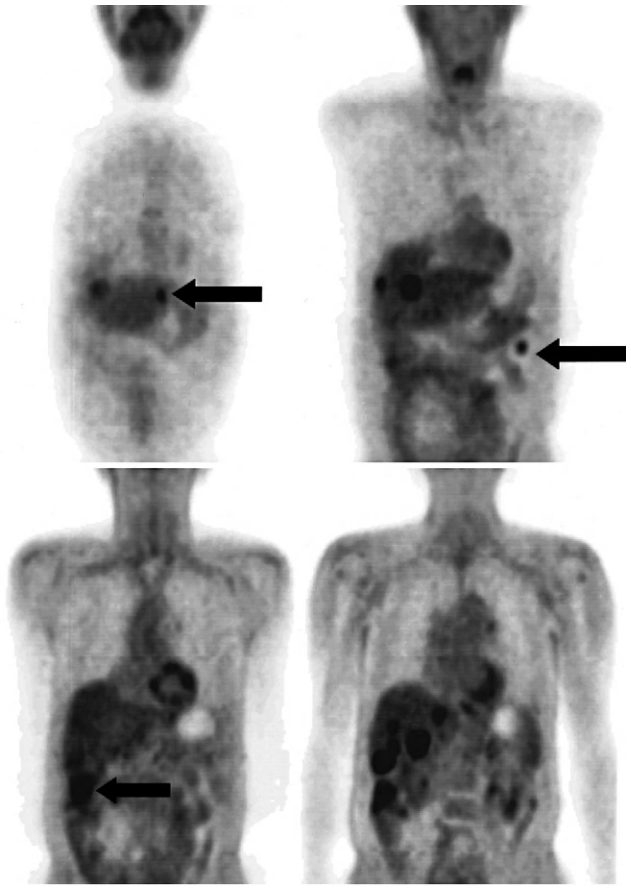

FIGURE 15.3. A 74-year-old man with colorectal cancer synchronously metastatic to the liver was referred for fluorodeoxyglucose (FDG) positron emission tomography to assess for possible localized treatment to the liver. Increased FDG metabolism was seen in at least eight sites within both lobes of the liver, consistent with multiple liver metastases (*arrow, upper left panel*). A further focus of abnormal FDG metabolism is seen in the left upper quadrant (*arrow, upper right panel*), consistent with an omental deposit, and at the hepatic flexure (*arrow, lower left panel*), consistent with a probable anastomotic recurrence. A prior computed tomographic scan revealed liver disease only. As a result of this scan, the patient underwent systemic chemotherapy.

Conventional cross-sectional imaging with helical CT in arterial and portal phases is the standard study for detection of colorectal metastases, and MRI may also be used in conjunction for preoperative evaluation. The previous standard, CT arterial portography, has been supplanted by helical CT, which has equivalent sensitivity for detection of hepatic metastases and results in fewer false positives (Valls et al, 1998).

Fluorodeoxyglucose Positron Emission Tomography for Detection of Hepatic Metastases

A head-to-head retrospective comparison of CT versus FDG PET clinical readings showed an advantage of FDG PET over CT (Table 15.2). The values reported were 23 with disease (n = 58) and FDG PET sensitivity of 95% and specificity of 100% compared with CT sensitivity of 74% and specificity of 85% (Ogunbiyi et al, 1997). The limitations of this study are its retrospective nature and the lack of information regarding the use of intravenous contrast material; in addition, the FDG PET scans were read with knowledge of the CT, whereas the converse may not have been true.

Another report of 34 patients with colorectal cancer that was potentially resectable, comparing CT with contrast and FDG PET, revealed FDG PET had a sensitivity of 89% and specificity of 67% compared with CT, with a sensitivity of 100% and specificity of 14%, giving an overall accuracy of 85% for FDG PET versus 82% for CT (Lai et al, 1996). A further series of 24 patients, 19 of whom had liver metastases, compared CT, computed tomography in arterial portography (CTAP), and FDG PET on a lesion-by-lesion basis. In terms of accuracy, FDG PET performed better than the radiologic methods: 93% compared with 76% for CT and CTAP. The reason the more sensitive CTAP performed worse than FDG PET is because the specificity of CTAP was only 9%. A separate group reported similar findings; FDG PET accuracy was 92% compared with CT arterial portography (CTAP) and CT accuracy of 80% and 78%, respectively. The low specificity of CTAP (5%) worked to its detriment (Delbeke et al, 1997). Many centers now combine a dedicated CT of the liver as part of the PET CT examination.

Fluorodeoxyglucose Positron Emission Tomography for Detection of Extrahepatic Disease

There has been a remarkable consistency in the rate that FDG PET alters the preoperative stage of a patient after standard-of-care preoperative diagnostic imaging (Table 15.3). In a wide variety of tumors, including colorectal cancers, about 30% of patients conventionally staged have their treatment plans altered as a result of FDG PET. The National Oncology PET Registry (NOPR) study of nearly 23,000 patients revealed a management rate of change of 36% (Hillner et al, 2008). A report of 34 patients with potentially resectable hepatic disease (Lai et al, 1996) found retroperitoneal nodal metastases in six patients, pulmonary metastases in three patients, and locoregional recurrences in two patients. One patient had unexpected disease in two sites, and FDG PET had an influence on clinical management in 10 of 34 patients (29%). The experience at Memorial Sloan-Kettering Cancer Center in the preoperative assessment of patients at high risk of recurrence after hepatic resection of colorectal cancer is similar. We found nine (23%) of 40 patients had their management radically altered owing to FDG PET findings of extensive unresectable disease, with management in another seven patients being influenced by the FDG PET findings confirming isolated, resectable extrahepatic disease, giving a total of 40% of patients in whom management was influenced.

A real strength of FDG PET is its ability to detect extrahepatic disease and alter the surgical plan for the patient. Most if not all lesions detected with FDG PET are within the resolution of conventional imaging modalities and theoretically should be detectable, but lesions either are not recognized as being abnormal ("missed"), or they appear normal. One reason why FDG PET performs so well is that the accelerated glucose metabolism of the tumors makes the tumor stand out against the background of normal tissue, just as the light of a match is easily discerned, even at a distance, on a dark night. The effectiveness of FDG PET is due to its ability to show lesions that mimic a normal structure, particularly intraperitoneal disease (see Figs. 15.4, 15.7, and 15.10), which mimics unopacified loops of bowel and normal-sized lymph nodes replaced by tumor. The influence of a finding of extrahepatic disease depends on the aggressiveness of the approach to disease the treating clinician and the patient wish to undertake. Local pelvic recurrence, if completely resectable, should not prevent a

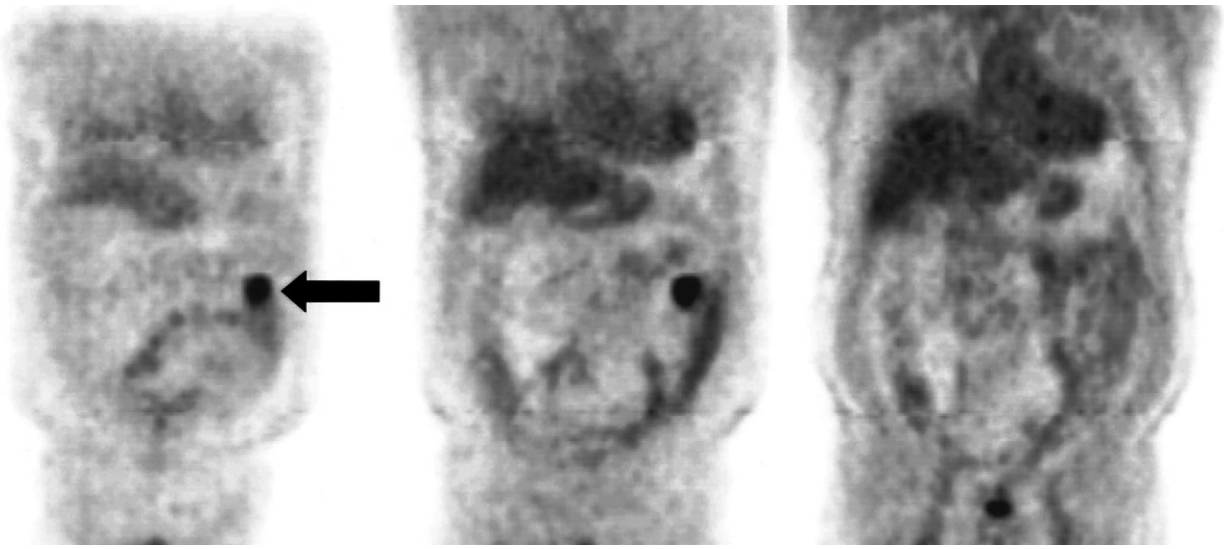

FIGURE 15.4. A 49-year-old man with colon carcinoma was sent for evaluation of rising carcinoembryonic antigen after resection of his primary tumor. Two coronal views of the fluorodeoxyglucose positron emission tomography scan are shown. Workup, including computed tomography of the abdomen and pelvis, was negative. At operation performed 6 weeks later, a solitary metastasis was found in the jejunal mesentery, 4.5 × 4 × 2 cm in size. The arrow shows the jejunal mesenteric metastasis.

patient from undergoing hepatic resection. FDG PET is not a panacea, however, because an imaging study does not change the biology of a disease, and the fact that disease cannot be detected with FDG PET does not rule out micrometastatic disease. It is important in terms of informed consent that patients appreciate that a workup including FDG PET does not rule out the later appearance of a distant metastasis.

Evaluation of Patients After Treatment

There is a dearth of literature on the relative sensitivities of FDG PET and conventional imaging in the detection of recurrent intrahepatic disease after liver surgery (see Figs. 15.11 to 15.13). Some patients develop subphrenic abscesses after resection, which are difficult to differentiate from recurrent tumor; however, even in this situation, FDG PET seems to perform well. In an initial report of seven patients who had undergone resection previously, PET correctly differentiated recurrent disease from postsurgical change in all; CT misdiagnosed two of six, with one false-positive result and one false-negative result; CTAP misdiagnosed three of five patients, all false-positive results (Vitola et al, 1996b). In the assessment of the effectiveness of chemoembolization (see Chapter 83), FDG PET has been shown to be useful (Vitola et al, 1996a), although an increment over CT and tumor markers has yet to be shown.

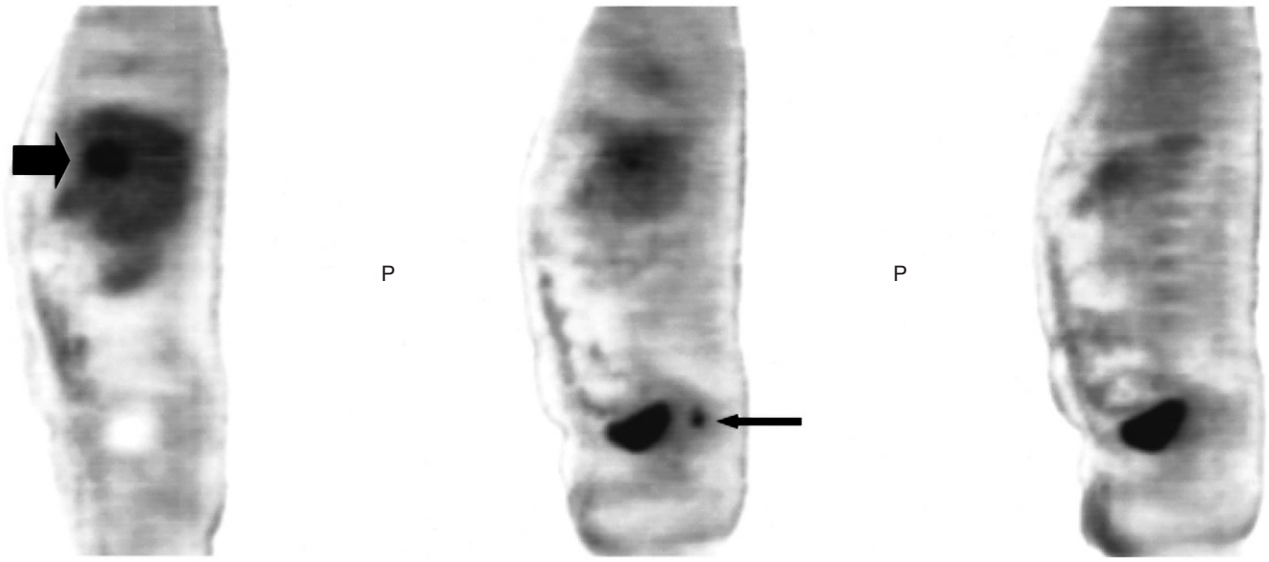

FIGURE 15.5. A 66-year-old man underwent a low anterior resection and at the time of surgery was found to have synchronous liver metastases. He underwent 5-fluorouracil and leucovorin chemotherapy for 1 year and pelvic radiotherapy. His carcinoembryonic antigen level had been progressively rising, and he was found to have liver metastasis. He was referred with a view to hepatic cryotherapy. The fluorodeoxyglucose positron emission tomography scan reveals a presacral pelvic recurrence (biopsy proven; *arrow, middle panel*) and the known liver metastasis (*arrow, left panel*).

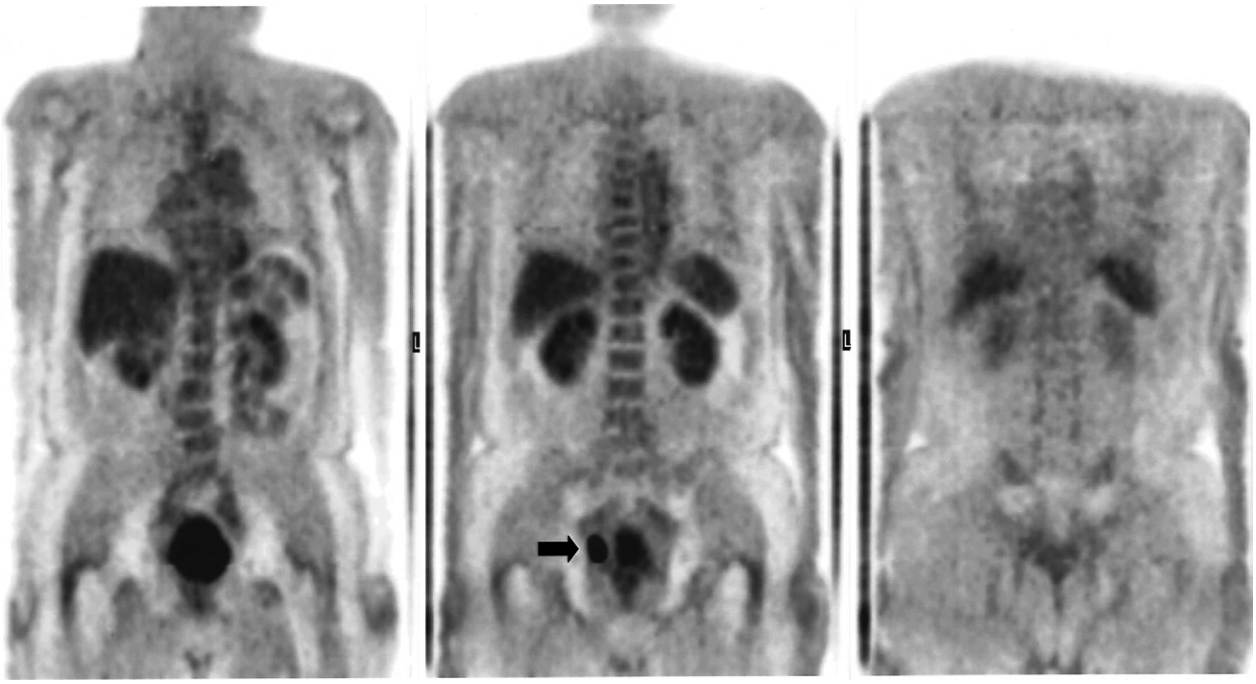

FIGURE 15.6. A 57-year-old man was referred with a rising carcinoembryonic antigen level. The patient underwent anteroposterior resection and treatment with 5-fluorouracil and leucovorin. An exploratory laparotomy 1 year later was negative, but a positron emission tomography scan performed 2 months after the negative exploratory procedure showed an abnormal area in the posterior pelvis, beside the bladder (*arrow*).

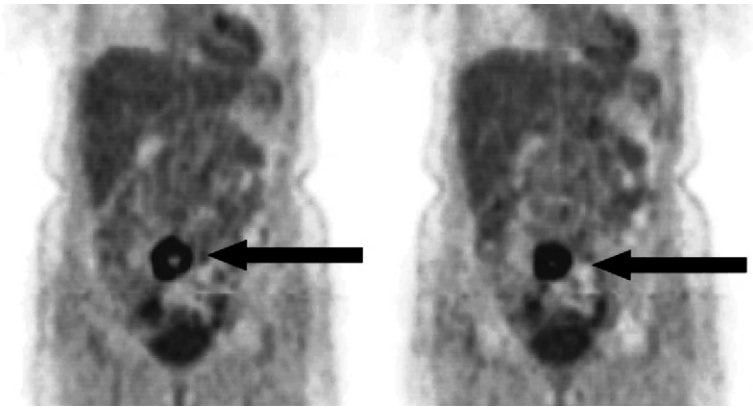

FIGURE 15.7. A 59-year-old woman was referred for assessment of fluorodeoxyglucose metabolism in the setting of recurrent rectal cancer after surgery, radiation, and chemotherapy. The scan reveals a large mass with partial necrosis within the peritoneum (*arrows*).

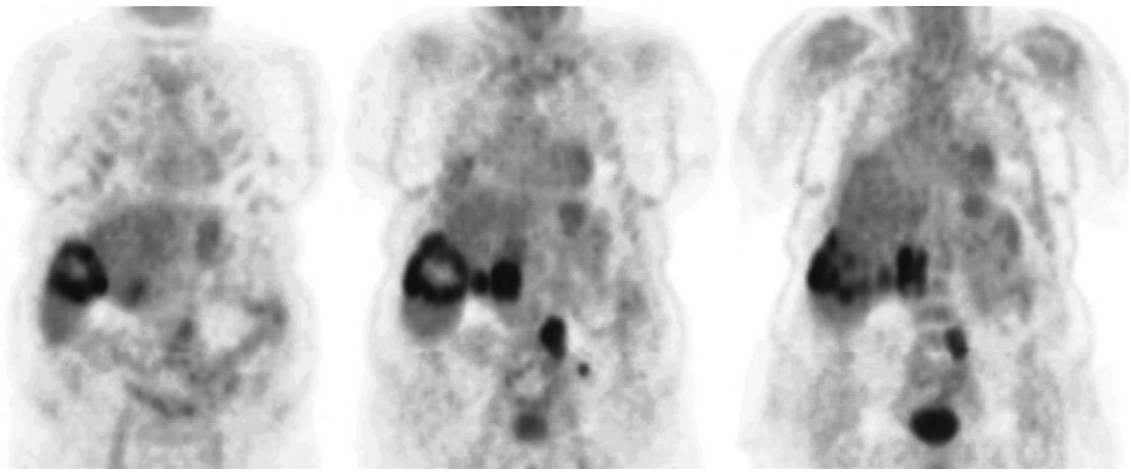

FIGURE 15.8. A 74-year-old man presented with a T3N1 right colon cancer invading the psoas muscle; he was treated with 5-fluorouracil and leucovorin. Computed tomography showed a caudate lesion, one lesion in segment IV, and questionable lesions elsewhere within the liver. Fluorodeoxyglucose positron emission tomography images show liver metastases with associated omental metastases.

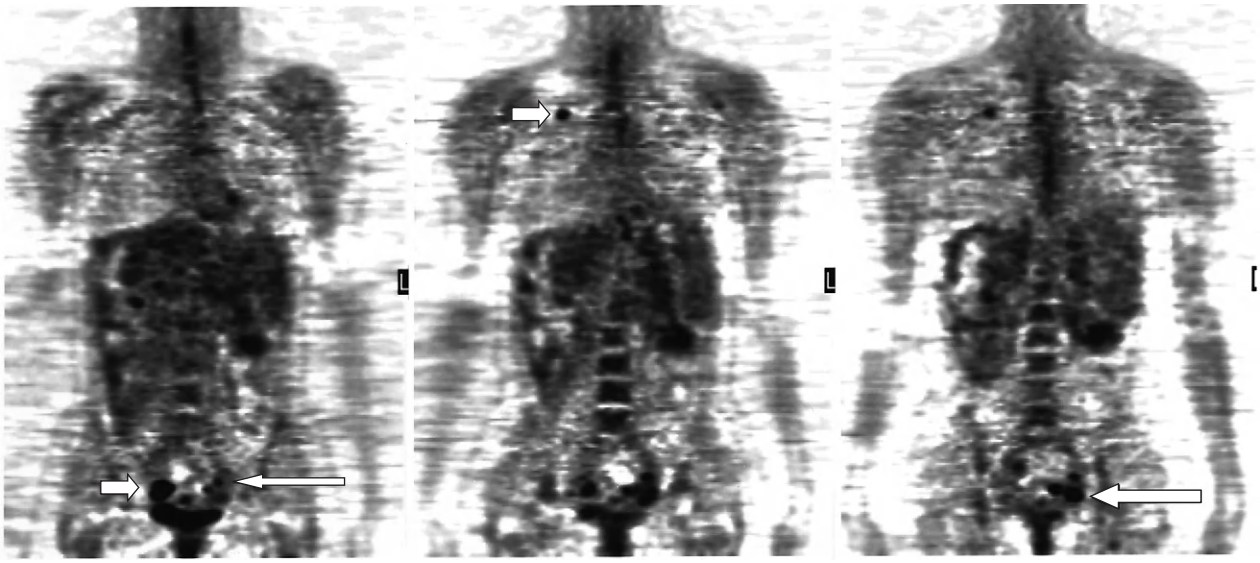

FIGURE 15.9. A 31-year-old woman with colon cancer after colon resection and right hepatectomy, recently treated with systemic and intraarterial pump chemotherapy with a known pulmonary nodule, was referred for evaluation for possible resection of the right pulmonary nodule. The images show the right pulmonary nodule (*arrow, middle panel*) and pelvic recurrence of disease (*arrows, right and left panels*) that subsequently was surgically confirmed. The liver reveals right lobe hypertrophy; the activity to the left of the liver is due to large bowel ptosed into the potential space left by the liver resection.

Preliminary investigations suggest FDG PET performed within 24 hours after hepatic cryotherapy (see Chapter 85B) can predict sites of recurrent disease based on the pattern of FDG uptake (Akhurst et al, 1999). This is an exciting development, because it helps clinicians identify patients in whom cryotherapy has been unsuccessful (see Fig. 15.13). The early demonstration of potential treatment failure can assist in further treatment planning. We also have been using FDG PET to follow patients who are being treated with hepatic artery pump therapy (see Chapter 6). In two cases, the information derived from FDG PET would not have been obtainable from conventional imaging, because the effects of cryotherapy persist on CT and US, leading to an inability to differentiate posttreatment change from residual tumor.

Management of Patients with Hepatocellular Carcinoma (See Chapter 80)

Diagnosis

In general, the ease of lesion detection on imaging depends on the target/background ratio. The higher the target-to-background ratio, the easier it is to detect a lesion. A low-grade lesion is likely to have a metabolic profile similar to the surrounding normal tissues. From an imaging standpoint, the liver is a relatively homogeneous solid structure. Because hepatomas are derived from liver tissue, they share many imaging characteristics with a normal liver and are therefore difficult to detect (Schroder et al, 1998). A study aiming to evaluate FDG PET in the diagnosis of liver masses found all primary sarcomas and adenocarcinoma metastases and all cholangiocarcinomas had increased

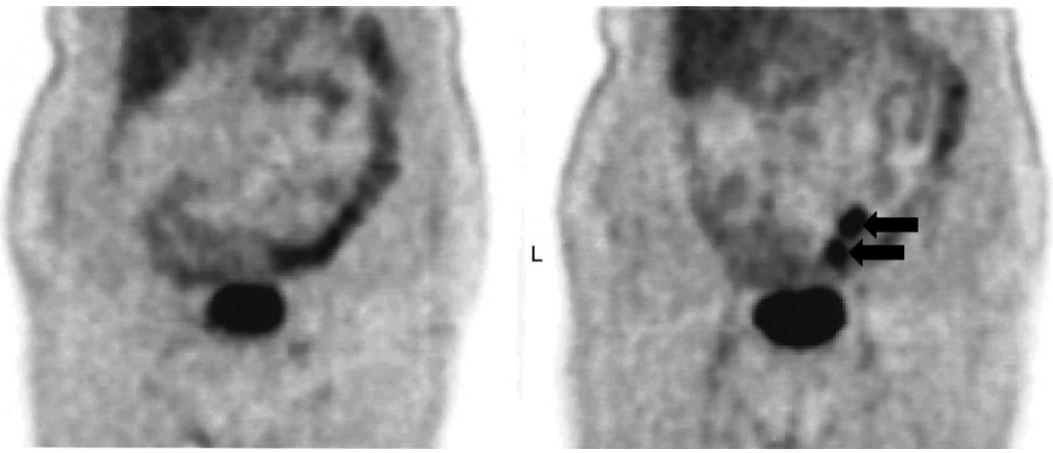

FIGURE 15.10. A 68-year-old woman with colon cancer, rising carcinoembryonic antigen level, and an equivocal CT scan for hepatic metastasis but no other disease. She had no postoperative chemotherapy and felt well. Fluorodeoxyglucose positron emission tomography scan reveals two intraperitoneal lesions (*arrows*) that were confirmed at operation.

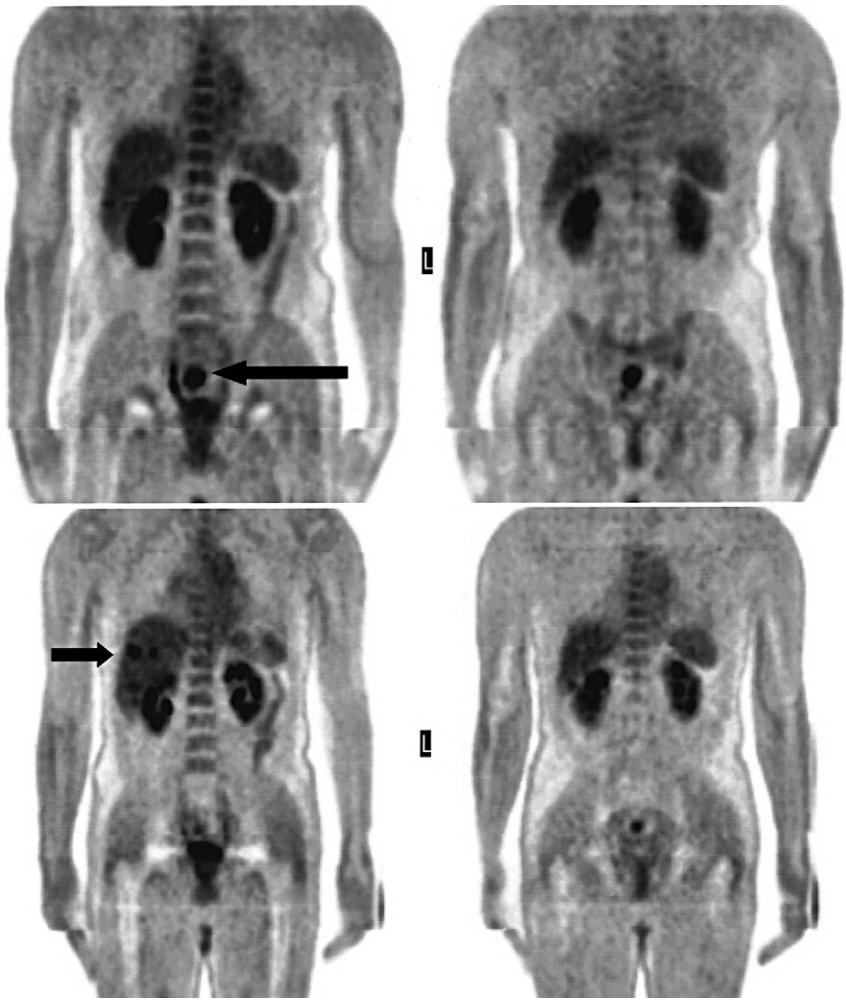

FIGURE 15.11. A 59-year-old man with primary rectal cancer underwent two fluorodeoxyglucose positron emission tomography scans separated by chemotherapy with 5-fluorouracil and leucovorin and pelvic radiotherapy. The top panels are the pretreatment images and show the primary tumor (*arrow, top left panel*) with a local nodal metastasis (*top right panel*) and a liver metastasis seen lateral to the right kidney. The bottom panels show involution of the primary lesion but progression of the liver metastases (*arrow, bottom left panel*).

FDG uptake values, but that seven of 23 patients with hepatocellular carcinoma (HCC) had poor FDG uptake (Delbeke et al, 1998). A sound pathophysiologic basis underlies this reduced efficacy, as shown by Torizuka and colleagues (1995) in a study of HCC greater than 3 cm in size. They showed that undifferentiated HCC had a pattern of continual FDG uptake shared by most solid tumors, whereas a moderately differentiated HCC showed a pattern of uptake similar to the normal liver, with an initial rise and then a slow fall. The difference in pattern was due to marked differences in the activity of transporters carrying glucose into the cell and in hexokinase activity, but it may also be due to a similarity between normal liver and HCC in terms of the rate of dephosphorylation of FDG-6-phosphate.

Treatment Planning and Assessment of Prognosis

The survival rate of HCC patients seems to correlate with the degree of FDG uptake into the tumor, with patients with low FDG uptake showing a longer survival than patients with high FDG uptake (Enomoto et al, 1991). FDG uptake may correlate with the degree of expression of p53 (Schroder et al, 1998; Yoon et al, 1998), a known factor in hepatocellular carcinogenesis (Hui et al, 1998). In a similar fashion to other tumors, FDG PET has been shown to be effective in monitoring lipiodol chemoembolization in HCC (Torizuka et al, 1994).

FDG PET is valuable in the management of patients with HCC. Its greatest utility is likely in cases in which the tumor is technically unresectable. In these cases, a pretreatment scan determines whether FDG PET can detect the tumor, and then FDG PET can be used in therapeutic monitoring. If the primary is known to be FDG avid, or tissue specimens show high levels of hexokinase activity, a follow-up FDG scan may be useful in determining a site of recurrence or metastatic disease.

Cholangiocarcinoma (See Chapter 50)

The detection of cholangiocarcinoma in patients with primary sclerosing cholangitis can be difficult, because imaging findings of the underlying disease may mimic those of tumor. Preliminary reports indicate a potential role of FDG PET, because cholangiocarcinoma seems to be FDG avid (Delbeke et al, 1998; Keiding et al, 1998), although this may be limited to follow-up assessment (Berr et al, 1999). If active cholangitis is present, the mucosal inflammation may obscure small sites of carcinoma in situ. If strictures are stented, the resultant mucosal irritation also may make the diagnosis of malignancy more difficult. Screening for cholangiocarcinoma may require interrogation of a different metabolic pathway, such as that of protein synthesis or proliferation.

In an analysis of data at Memorial Sloan-Kettering Cancer Center, 82 patients with cholangiocarcinoma were studied; 24% of the 62 newly diagnosed patients had their management changed as a result of the detection of occult metastases. FDG PET detected 95% of the intrahepatic tumors and 69% of the extrahepatic tumors; this is not surprising, because central cholangiocarcinomas are more often clinically silent and present later in terms of size than extrahepatic tumors. In terms of the detection of metastases, 100% of metastases from intrahepatic tumors and 93% from the extrahepatic group were detected (Corvera et al, 2004). An example of a cholangiocarcinoma detected with FDG PET is shown in Figure 15.14.

Focal Liver Lesions

A focal liver lesion in a patient with a recent history of colorectal cancer and increasing carcinoembryonic antigen (CEA) is likely due to a metastasis; this partly explains the high success rates in detecting malignant disease reported by some groups (Delbeke et al, 1998). In a separate group, FDG PET was not found to be useful in the characterization of liver masses in patients with chronic hepatitis C infection (Schroder et al, 1998).

Diagnosis and Follow-up of Pancreatic Diseases

Pancreatic Cancer (See Chapter 58)

The clinical presentation of painless jaundice in a middle-aged individual should immediately raise the clinical suspicion of the presence of a cancer obstructing the common bile duct; this is most commonly due to a cancer of the head of the pancreas. Classic approaches to imaging of masses of the head of the pancreas still have validity, with US being the least invasive test available. If surgical resection is to be considered, MRI is likely to give the best possible local soft-tissue discrimination, allowing for planning of a surgical approach and the best assessment of the pancreatic and biliary ducts. Most solid pancreatic adenocarcinomas are FDG avid (Fig. 15.15), allowing for the screening of patients for unexpected distant disease and for the possibility of assessment of the response of the pancreatic mass to induction therapy, if that is considered appropriate. The implementation of PET CT allows much greater confidence in the localization of focal epigastric FDG uptake to a particular anatomic structure; previously epigastric FDG uptake was described as a regional, rather than an organ-specific, phenomenon.

The mechanism of FDG uptake into cells is exactly the same as for unlabeled glucose, so according to the laws of mass action, a high serum concentration of unlabeled glucose (as seen in diabetics with insulin resistance) reduces the amount of FDG uptake into cancer cells, leading to a reduction in sensitivity. In a study of 106 patients with pancreatic masses, of which 32 were benign, PET showed an overall sensitivity of 85%, a specificity of 84%, a negative predictive value of 71%, and a positive predictive value of 93%. In a subgroup of patients with normal serum glucose levels (n = 72), the results were 98%, 84%, 96%, and 93%, respectively (Zimny et al, 1997). Insulin-sensitive

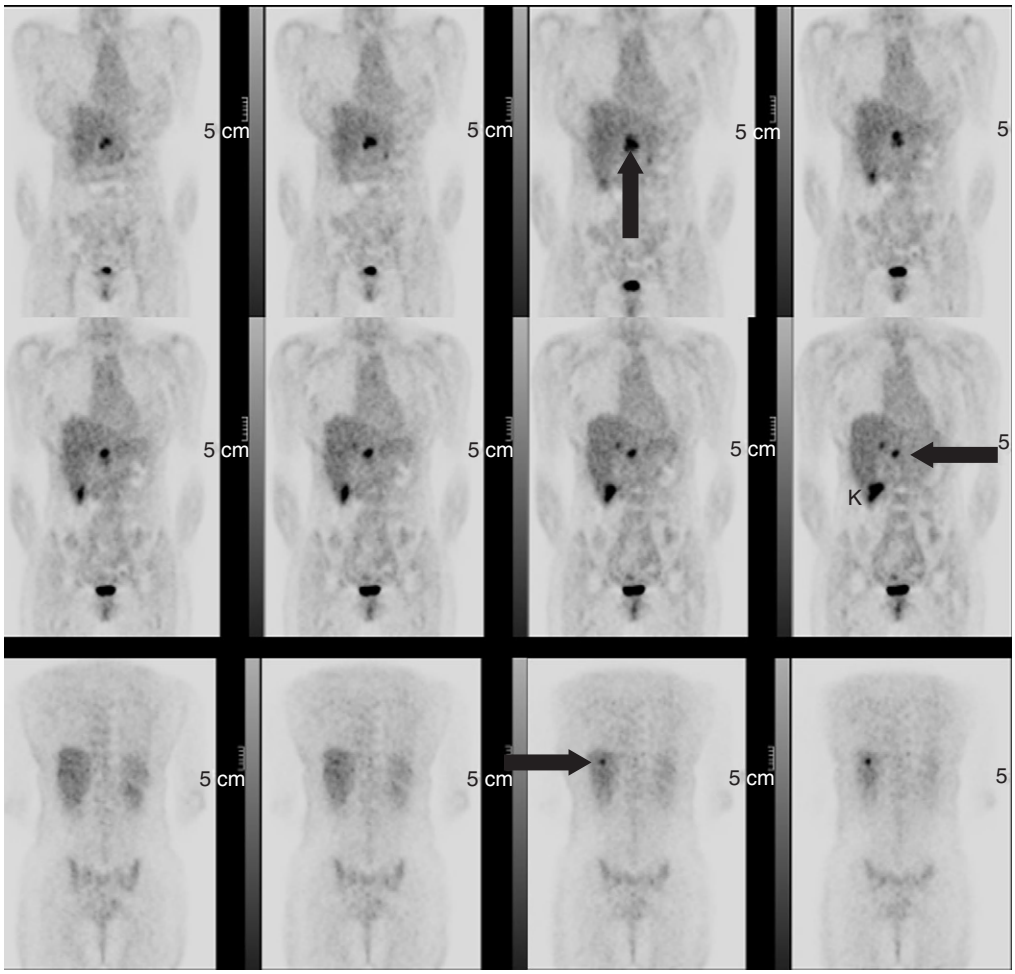

FIGURE 15.14. A 38-year-old woman with bile duct cancer referred for staging. Computed tomography and magnetic resonance imaging failed to show the segment VII lesion seen on fluorodeoxyglucose positron emission tomography. The patient had an exploratory laparotomy, at which time a bile duct cancer (*up arrow*) and metastases in the common hepatic artery lymph node chain (*right arrow*) and segment VII of the liver (*left arrow*) were confirmed.

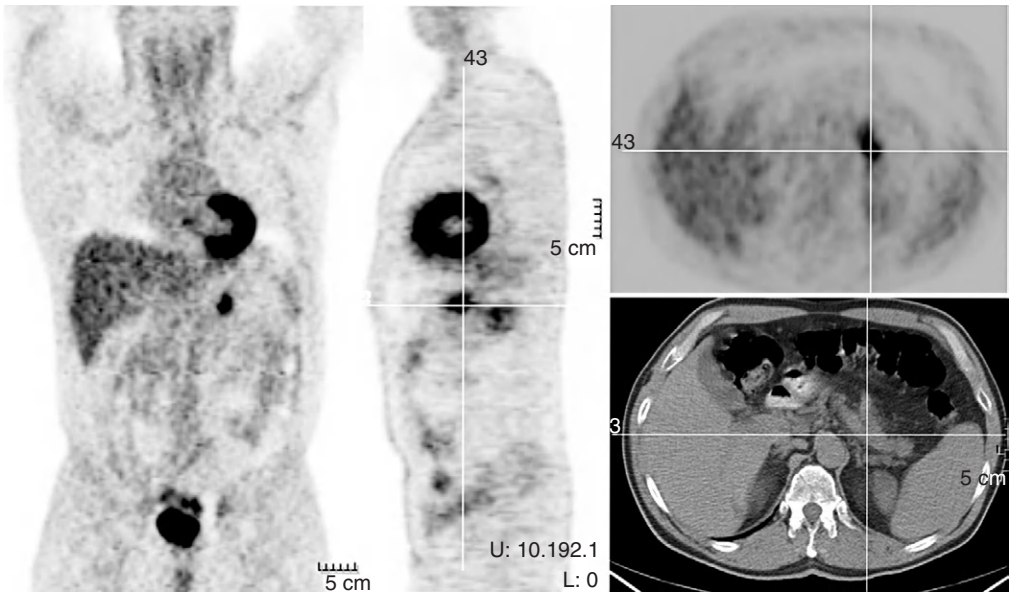

FIGURE 15.15. Axial and coronal slices of a pancreatic adenocarcinoma with corresponding transaxial positron emission computed tomography (PET CT) images shown without intravenous contrast material. Notice how the integrated PET CT device allows exact localization of the metabolic activity to the pancreas, rather than "the epigastrium."

patients also present an interesting problem because incorrect timing of the FDG injection in relation to the insulin injection may lead to much of the injected FDG being driven into muscle, reducing tumor sensitivity.

Cystic pancreatic masses (see Chapter 57) present a difficult imaging problem, because they consist of a thin layer of cells surrounding a large void (Fig. 15.16). A large report of 599 patients with cystic masses of the pancreas found 280 (46.8%) were pseudocysts, 102 (17%) were intraductal papillary mucinous tumors, 100 (16.7%) were serous tumors, 62 (10.4%) were mucinous tumors, 39 (6.5%) were mucinous cystadenocarcinoma, and 16 (2.7%) were solid papillary cystic tumors (Bassi et al, 2003). Clues that a cystic mass of the pancreas may be neoplastic, rather than due to a pseudocyst, include the absence of symptoms (Fernandez-del Castillo et al, 2003) and the presence of calcification in the wall of the cyst, rather than the entire pancreas, as is seen in chronic pancreatitis. Multiloculated cystic lesions favor a neoplastic origin, rather than the single cyst seen in a pseudocyst.

In lung and esophageal cancers, the standardized uptake value (SUV) predicts prognosis in surgically resected patients. The underlying assumption is that the rate of glycolysis reflects the degree of differentiation of the tumor. The use of the SUV is proposed by some authors to differentiate benign and malignant lesions of the pancreas.

Because of the relatively low resolution of all nuclear medicine techniques and partial volume averaging, it is extremely problematic to attempt to characterize a cystic pancreatic mass. Two tumors with the same metabolic rate may have different standardized uptake value measures related solely to the thickness of the cyst wall (Fig. 15.17). If a portion of the mass is thick, characterization can be attempted, but most often this portion of a lesion is adjacent to normal tissues, making accurate characterization difficult. In addition, if inflammation or infection of the pancreatic mass is suspected, the specificity of focal FDG uptake as a predictor of malignancy is reduced dramatically. For this reason, a single FDG PET scan is unlikely to be completely successful in characterizing cystic pancreatic masses.

Follow-up of patients after resection typically is performed with CT or MRI, because these two modalities are very sensitive in the detection of small liver lesions. FDG PET usually is reserved as a modality to document unexplained increases in CEA or other tumor markers or to characterize indeterminate masses seen on other cross-sectional imaging. Novel tracers targeting the pancreas include radioiodinated phenylalanine derivatives, which seem to have preclinical promise in that they show higher affinity for pancreatic tumor xenografts in murine models than FDG with less uptake in inflammatory lesions. These compounds may lead to improved specificity in the diagnosis of pancreatic malignancy in patients with coexistent chronic pancreatitis (Hellwig et al, 2005).

Assessment of Pancreatic Reserve

EXOCRINE PANCREATIC FUNCTION. An experimental approach to the assessment of pancreatic exocrine function illustrates the wide-ranging potential of PET. ^{11}C-methionine is a PET radiopharmaceutical that is taken up into normal pancreas and liver. Initial studies of pancreas involved the use of selenium 75-methionine in the 1960s; the production of ^{11}C-methionine was described in 1976 (Comar et al, 1976). Good correlations of secretin-induced duodenal amylase and

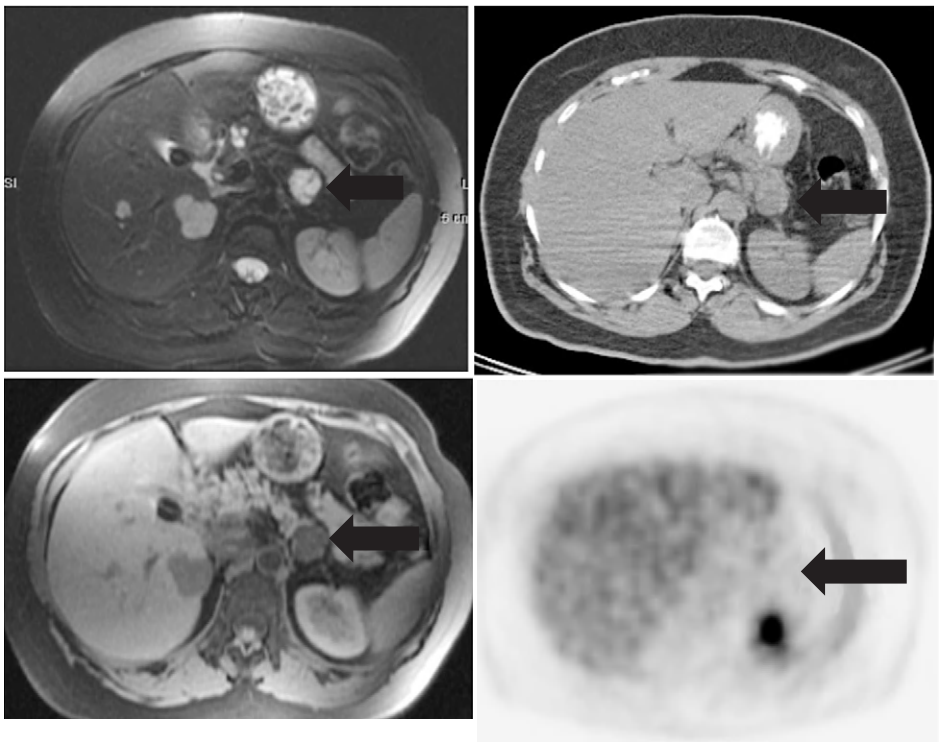

FIGURE 15.16. A 56-year-old woman presented with a multicystic pancreatic mass (*arrows in all images*) for evaluation. The positron emission computed tomography (PET CT) images are in the right panels. The CT shows the lesion, and the corresponding FDG PET slices reveal no evidence of accelerated metabolism in the same anatomic position. Left panels are corresponding magnetic resonance images.

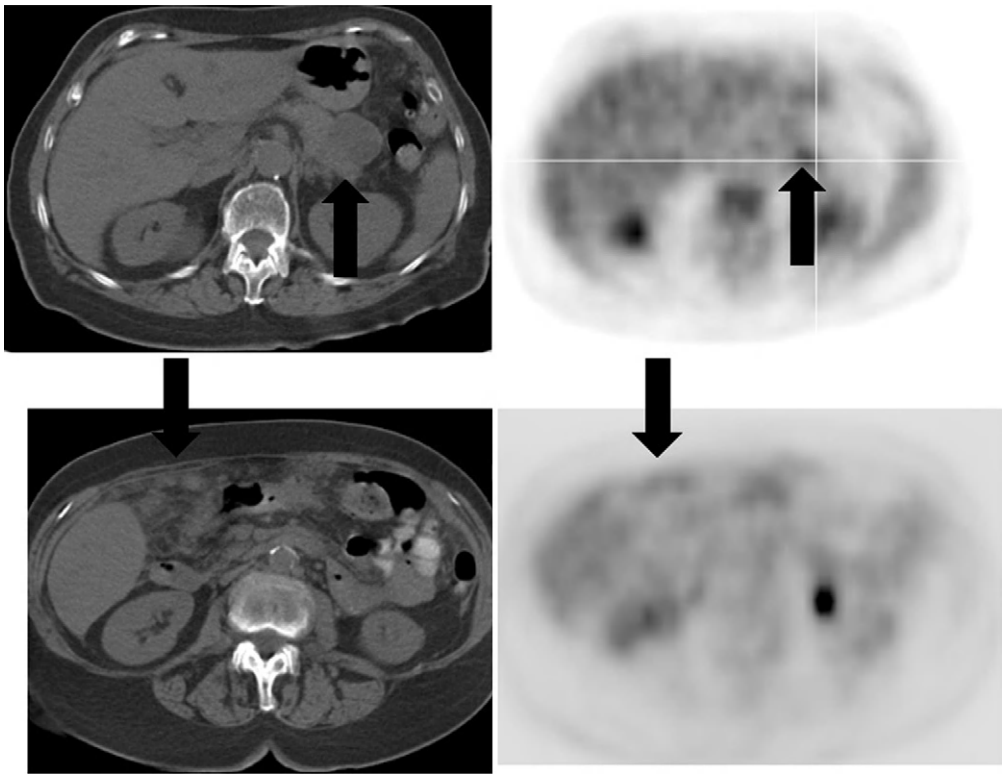

FIGURE 15.17. Cystic pancreatic mass with fluorodeoxyglucose (FDG) uptake only in the thickest portion of the cyst wall. Note the relatively low-grade FDG activity in the mass within the primary lesion (*arrows in top panels*) and the peritoneal metastases (*arrows in lower panels*).

bicarbonate concentrations with the pancreas-to-liver ^{11}C-methionine ratios 4.5 minutes after injection of the methionine have been reported (Takasu et al, 2001). The investigators found that a pancreas-to-liver ^{11}C-methionine ratio at 4.5 minutes after injection of greater than 1.25 had 100% sensitivity and 86% specificity for the detection of chronic pancreatic impairment.

ENDOCRINE PANCREATIC IMAGING. Because of the 100-fold fewer β cells compared with exocrine cells, β cell imaging poses additional problems over and above imaging of exocrine pancreatic cells. It has been suggested that a successful β-cell imaging agent must have a β/exocrine cell affinity ratio of greater than 1000:1 (Sweet et al, 2004). Realization of this problem has focused efforts on specific β-cell surface markers. The use of the monoclonal antibody to image β cells successfully in mice has been described (Moore et al, 2001). Such approaches represent a proof of principle of one method of following up patients in experimental programs aimed at preserving β-cell function in the setting of diabetes and pancreatic transplantation.

GASTROENTEROPANCREATIC NEUROENDOCRINE TUMORS (SEE CHAPTER 81B)

Gastroenteropancreatic neuroendocrine tumor imaging and therapy is a developing field. The standard bearer of somatostatin imaging, ^{111}In octreotide, which will be discussed later in this chapter, is increasingly being substituted with gallium 68 (^{68}Ga) somatostatin receptor imaging. ^{68}Ga, a generator-derived, 68-minute half-life positron emitter, has been coupled to a variety of somatostatin analogues; the only difference between the somatostatin analogue [DTPA^0,Tyr^3] *octreotate* and [DTPA^0,Tyr^3] *octreotide* is that the C-terminal threoninol is replaced with threonine. Octreotate binds with greater affinity to somatostatin receptor subtype II than octreotide, making this tracer particularly suitable for tumors of pancreatic origin. The advantages of using a PET camera over a SPECT camera are significant because of improved quantification and resolution. A parallel development in radiopeptide therapy has occurred, whereby the same somatostatin analogues have been bound using the same chelators to lutetium-177, a 6.71-day half-life radioisotope that has both a 208 keV γ-emission suitable for imaging and a β-emission with an average energy of 0.13 MeV, which provides therapeutic efficacy. Lutetium radiopeptide therapy has proved to be less nephrotoxic than yttrium-90 (^{90}Y) radiopeptide therapy, particularly when administered under the cover of renoprotective amino acid infusions using lysine and arginine. Administration of 5-fluorouracil (5-FU) at a starting dose of 200mg/m^2 for a 3-week period around the time of the lutetium-177 (^{177}Lu) is well tolerated and has the radiosensitizing potential to increase the tumoricidal effects of the ^{177}Lu (Hubble et al, 2010).

^{68}Ga octreotate imaging is complementary to the use of FDG PET and cross-sectional imaging. Growing neuroendocrine tumors that are moderately to intensely FDG avid but ^{68}Ga octreotate negative will not respond to radiopeptide therapy, and either local ablative or other systemic approaches should be evaluated. Growing neuroendocrine tumors that are concordantly ^{68}Ga octreotate and FDG avid are quite likely

to respond to radiopeptide therapy, and following radiopeptide therapy reassessment with imaging at 6 to 12 months after treatment, such tumors will often demonstrate an FDG-avid component of the tumor that has diminished with preservation of the ^{68}Ga octreotate–avid component, reflecting the relative sensitivity of the clones of cells to the radiation treatment (Figs. 15.18 and 15.19). Retreatment leads to long-term tumor control (Kwekkeboom et al, 2008), but caution must be exercised, as cumulative doses greater than 100 GBq have been associated with preleukemic states.

HEPATOBILIARY SCINTIGRAPHY

Scintigraphic imaging of the hepatobiliary system aims to mimic the extraction of the precursor of bile from the blood, the formation of bile, and the excretion of bile into the bile ducts and gut. Iminodiacetic acid derivatives can be labeled with ^{99m}Tc. These compounds are extracted rapidly from the circulation by hepatocytes and are excreted into the biliary system without undergoing conjugation. The hepatic half-clearance time varies with the agent used (Table 15.4), and some renal excretion of iminodiacetic acid derivatives occurs with proportionally increased renal excretion in hepatocellular dysfunction (Fig. 15.20).

Patient preparation is important in the performance and interpretation of hepatobiliary scintigraphy. Detailed clinical information is required for the proper interpretation of the studies. To image the gallbladder, the patient should be fasted for 2 to 24 hours. If a study is performed immediately postprandially, the gallbladder is contracted, leading to nonvisualization (Klingensmith et al, 1981). An overdistended gallbladder leads to nonvisualization in patients fasted for more than 24 hours (Larsen et al, 1982).

Normal Scan

A hepatobiliary study usually is acquired in many dynamic acquisitions; the immediate postinjection sequence is performed with rapid frame times (2 to 5 seconds) to assess perfusion (Fig. 15.21). The later images are acquired for a longer duration (2 to 5 min/frame) to assess the uptake and excretory phases (Fig. 15.22). Right lateral or oblique images often are needed to distinguish gallbladder activity from underlying renal pelvis or duodenal activity (Fig. 15.23).

After injection of the radiopharmaceutical tracer, a biphasic influx of the tracer to the liver is seen (see Fig. 15.21) that reflects delivery of tracer from the hepatic arterial and then the portal circulation. The hepatocytes are efficient at extracting the tracer, so uptake is rapid and leads to hepatic uptake quickly

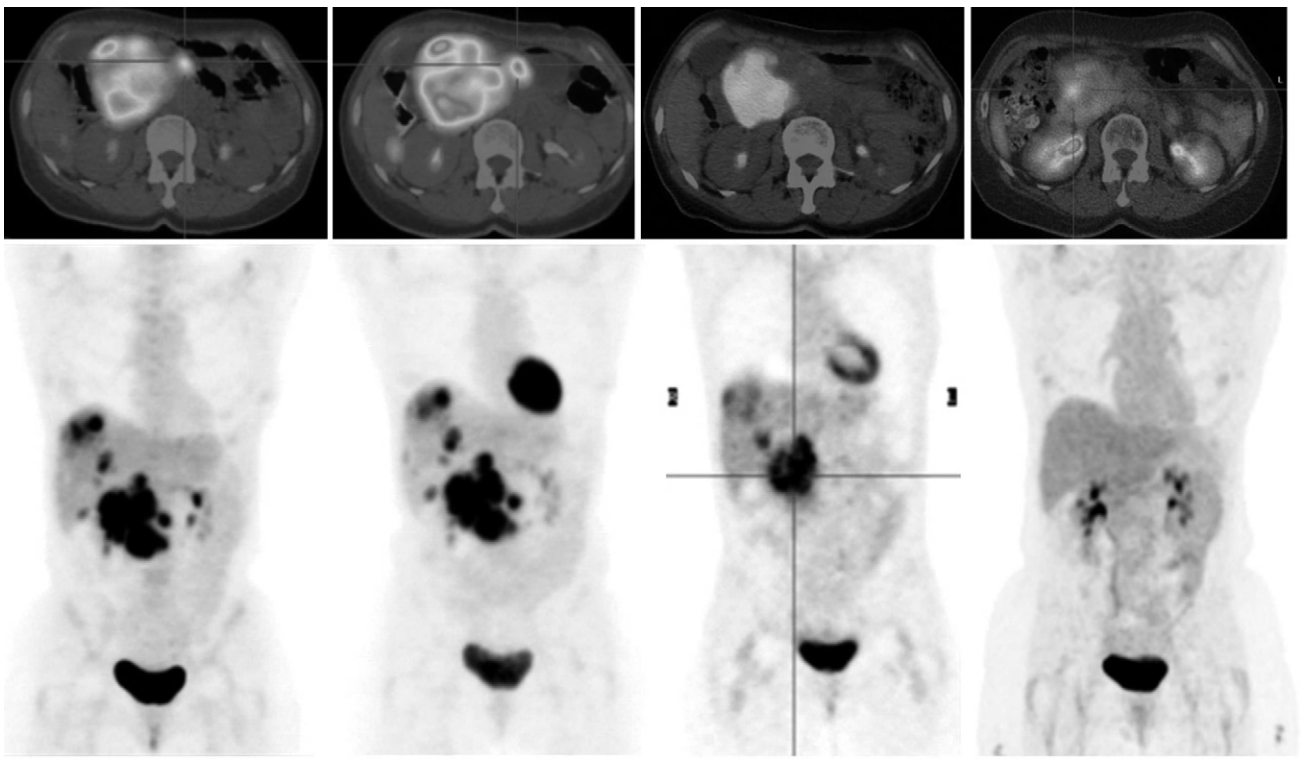

FIGURE 15.18. This 60-year-old female with a pancreatic neuroendocrine tumor underwent a series of fluorodeoxyglucose positron emission computed tomography (FDG PET CT) scans prior to and following her radiopeptide therapy with and 5-fluorouracil as a radiosensitizer. The figure comprised the fused PET CT images in the top row with FDG images in the lower row. The leftmost column of images is the baseline study, and the second column is after 3 cycles of conventional chemotherapy with carboplatin and etoposide; it demonstrates an increase in the degree of FDG uptake, best seen in the top row. One month after the images in the second column were taken, the patient commenced radiopeptide therapy, which was repeated three times over a 12-week period. The third column is a scan performed 25 weeks after the first radiopeptide therapy and demonstrates a significant reduction in the amount of FDG uptake into the tumors. The final column reveals an almost complete metabolic response 24 months later, after two additional radiopeptide treatments.

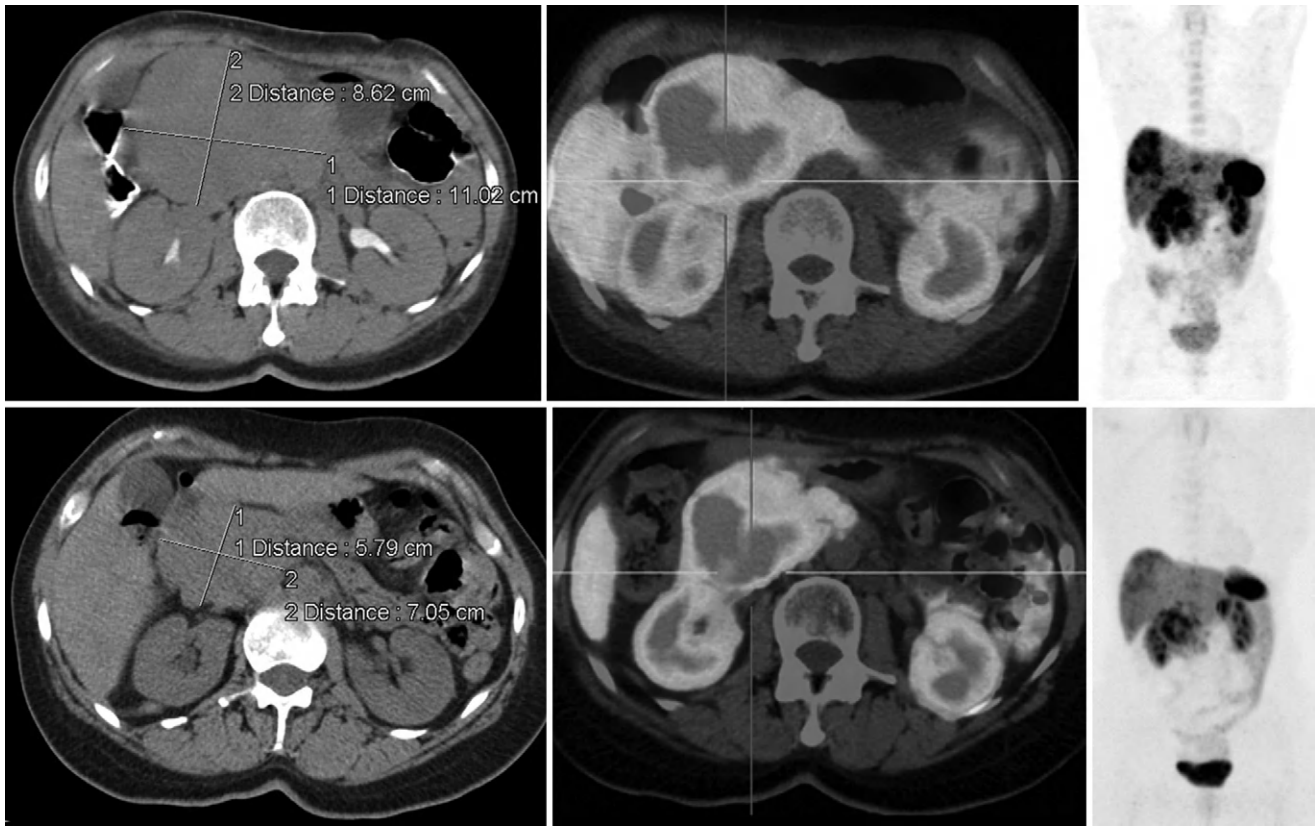

FIGURE 15.19. The same patient as in Figure 15.18, comprising in the top row a pretreatment computed tomography (CT) through the pancreatic mass, a fused ^{68}Ga octreotate positron emission tomography (PET) CT image, and the whole-body ^{68}Ga octreotate PET image performed at baseline. The same sequence is seen in the bottom row after nearly 3 years and five treatments of a total of 41 GBq of ^{177}Lu octreotate therapy with concomitant 5-fluorouracil chemotherapy (200 mg/m^2 given as a radiosensitizer). Note the reduction in size of the pancreatic mass that retains somatostatin receptor 2 expression, in spite of the near-complete resolution of FDG activity in the pancreatic mass shown in Figure 15.18.

exceeding that of the cardiac blood pool. The hepatic activity reaches a peak at about 10 minutes after injection. The hepatocytes clear the tracer into the biliary canaliculi, and within 30 minutes, the right and left hepatic ducts and the common hepatic duct can be seen, although such detail may not be seen in very small infants. The gallbladder is seen in 90% of normal individuals within 30 minutes after injection, and 100% are seen within 1 hour. The bowel is seen in 80% of normal individuals within 60 minutes, and the remaining 20% eventually drain to the gut, with delayed drainage as a result of mild dehydration or mildly increased sphincter of Oddi dysfunction.

Table 15.4

Iminodiacetic Acid Derivatives

Name	Liver Half-Clearance Time (min)	Hepatic Uptake (%)
Mebrofenin	17	98
Disofenin	19	88
o-Diethyl	37	82
o-Dimethyl	42	84
p-Isopropyl	59	85
p-n-Butyl	107	94

In patients who have had a cholecystectomy, the gut usually can be seen by 20 minutes (Fig. 15.24; Sostre et al, 1992b), and bile reflux into the stomach often can be seen (Fig. 15.25; also see Fig. 15.22). If a patient has a contracted gallbladder, as is often seen in chronic cholecystitis, gallbladder filling may be delayed (Fig. 15.26).

Augmented Hepatobiliary Scintigraphy

Numerous drugs affect the function of the hepatobiliary tree and are used to improve the diagnostic efficacy of hepatobiliary scintigraphy. Phenobarbital is used to increase the production of bile in infants to improve the diagnostic accuracy of the test in cases of neonatal jaundice. Cholecystokinin infusion leads to increased bile flow, contraction of the gallbladder, and relaxation of the sphincter of Oddi. Nitroglycerin relaxes the sphincter of Oddi (Staritz, 1988), and morphine contracts it; this effect is promptly relieved by cholecystokinin or naloxone (Helm et al, 1988; Patch et al, 1991). The duration of increase of pancreatic cholecystokinin levels secreted in response to a fatty meal is much longer than the effects of infusion. A repeat dose of cholecystokinin given after a cholecystokinin infusion as premedication leads to an equivalent gallbladder ejection of bile. Patients who have had a prolonged fast can have one injection to empty the gallbladder to enable subsequent filling and a later injection to assess gallbladder ejection fraction in

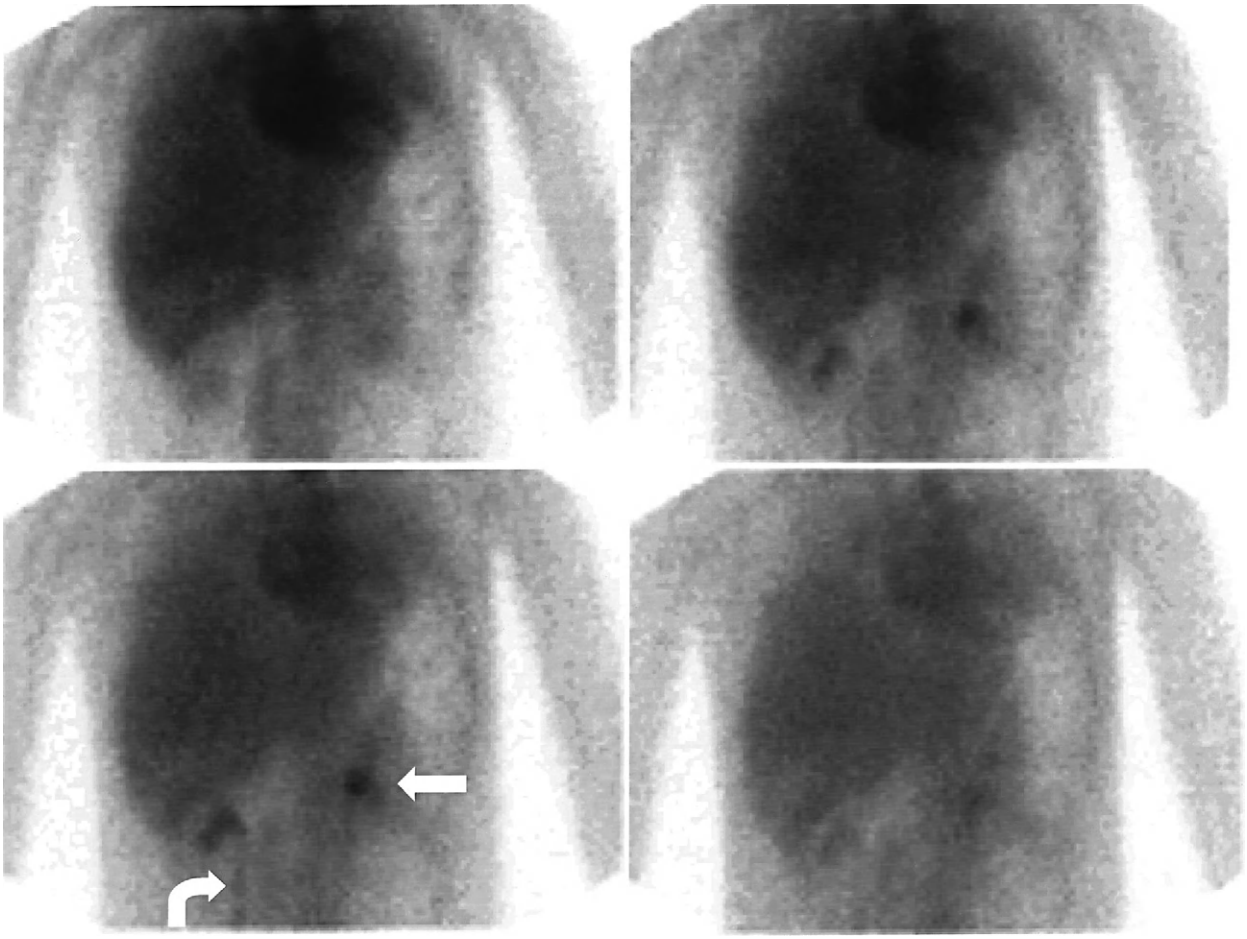

FIGURE 15.20. This study shows severe hepatocellular dysfunction, with the kidneys exhibiting increased clearance of the tracer. Note the parallel reduction in activity in the cardiac blood pool and the liver. The two bright foci beneath the liver are due to activity in the pelvis of the right and left kidneys. The straight arrow points to the left renal pelvis; the curved arrow points to the right ureter. Images were acquired at 2, 15, 25, and 60 minutes after injection.

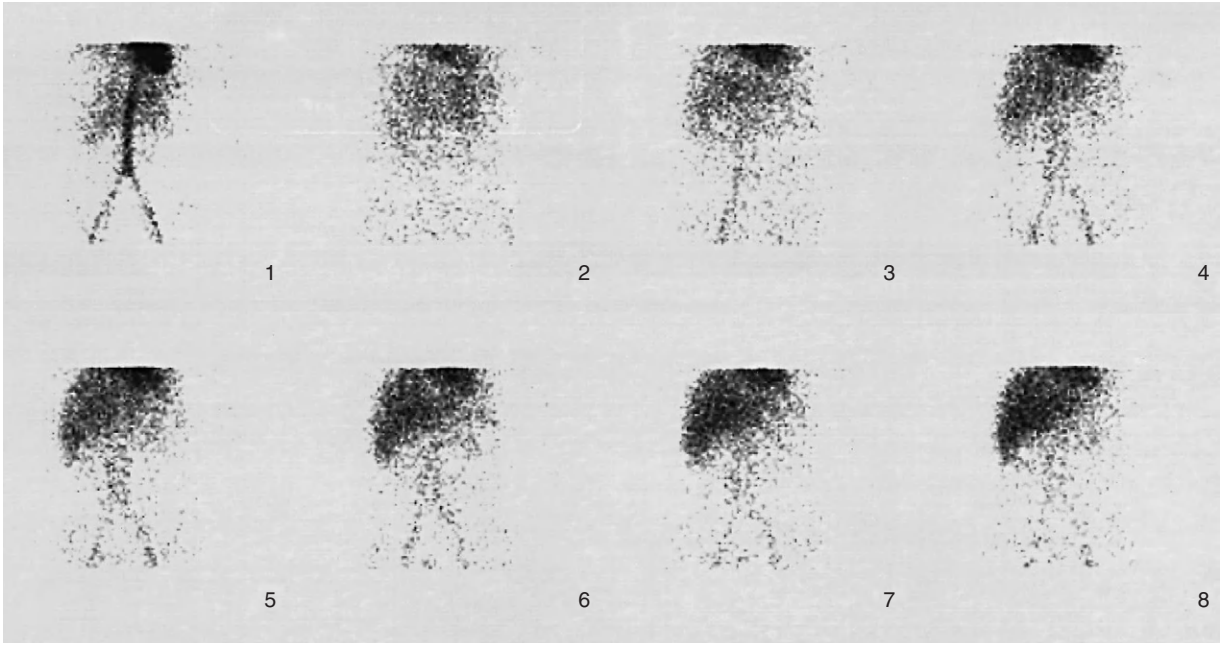

FIGURE 15.21. Normal hepatobiliary iminodiacetic acid perfusion study shows the biphasic influx of tracer into the liver, reflecting the dual blood supply. The relatively reduced uptake coincides with aortic activity.

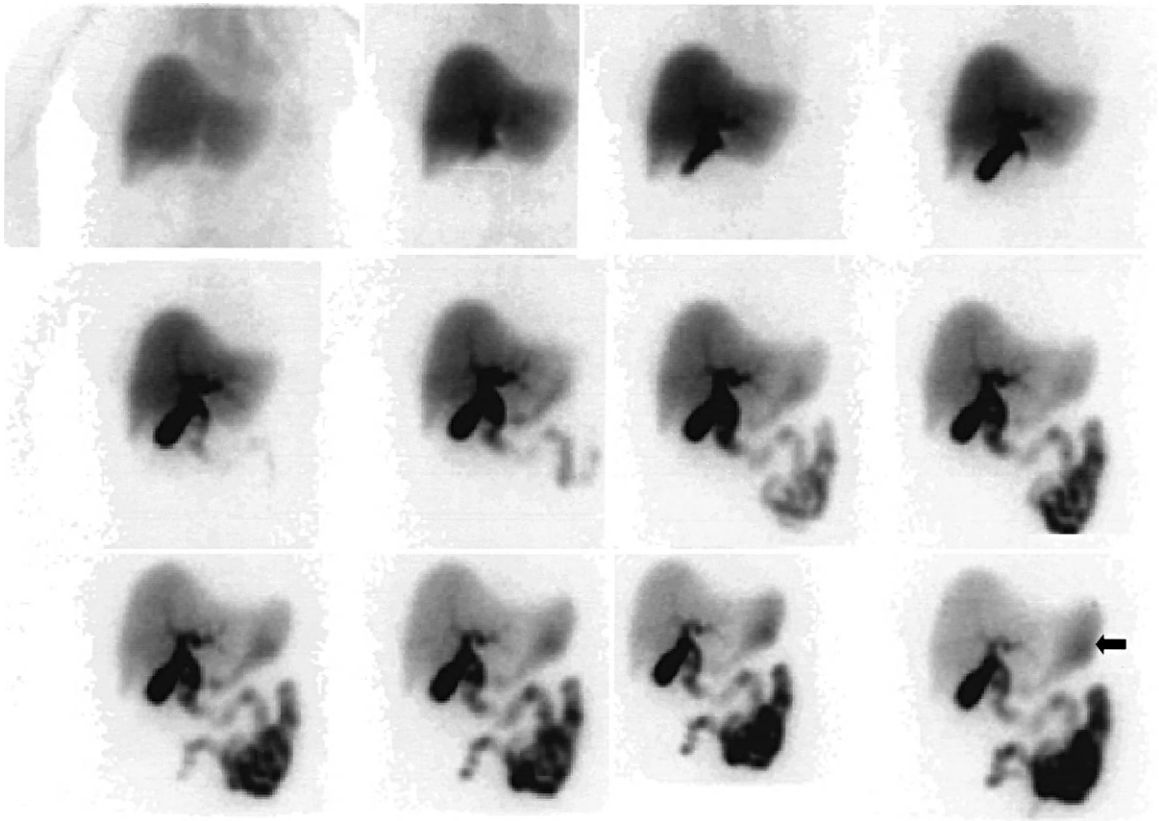

FIGURE 15.22. Normal hepatobiliary iminodiacetic acid study shows free passage of the tracer into the proximal bile ducts and gallbladder with subsequent free drainage into the gut. The images were acquired in the anterior projection 5 minutes apart for 1 hour. Note the reflux of bile into the stomach (*arrow*) seen after 30 minutes, reaching a peak at 55 minutes.

the same sitting, with no loss of diagnostic accuracy (Sostre et al, 1992a).

Right Upper Quadrant Pain

The differential diagnosis of right upper quadrant pain is beyond the scope of this chapter, but hepatobiliary scintigraphy has a role in the assessment of acute and chronic right upper quadrant pain (see Chapter 31). A 30% increase has been seen in the number of cholecystectomies performed since the 1990s. Another phenomenon is the change in the indications, with rates of operations for biliary dyskinesia, acute acalculous cholecystitis, and chronic acalculous cholecystitis increasing 348%, 139%, and 138%, respectively, in the same time frame (Johanning & Gruenberg, 1998). This study was a review of the *International Classification of Diseases* (9th revision) discharge codes,

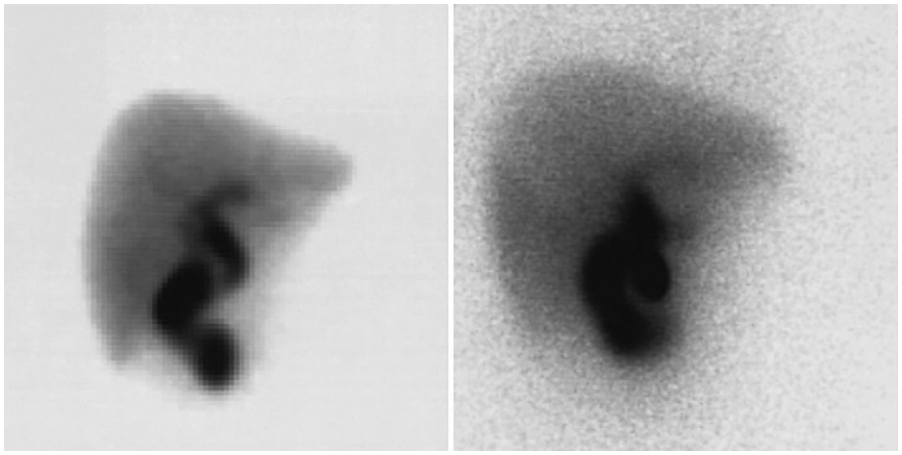

FIGURE 15.23. This study shows the benefit of a right anterior oblique view in separating the gallbladder and renal pelvis. Images were acquired 60 minutes after injection.

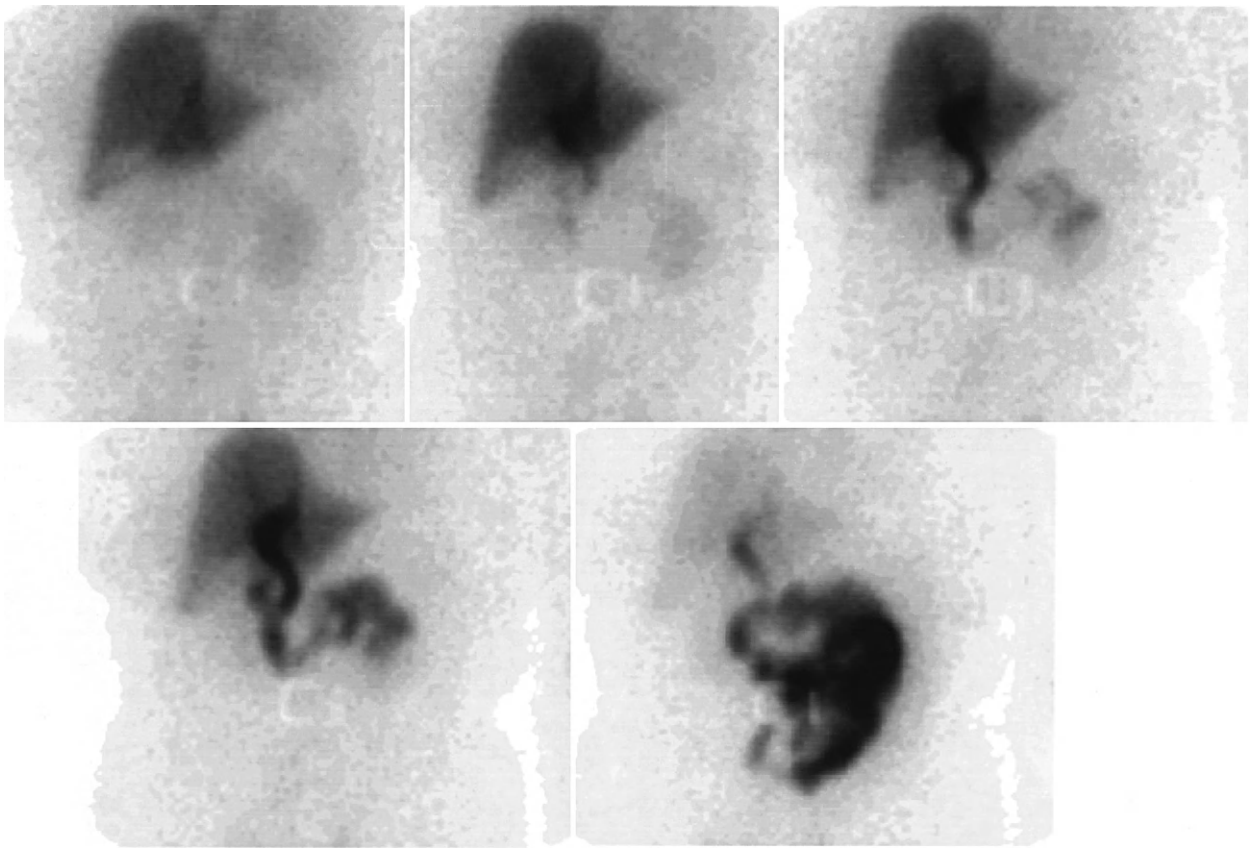

FIGURE 15.24. This study shows rapid transit into the gut after cholecystectomy; the intestines are seen 10 minutes after injection. Images were acquired 2, 5, 10, 15, and 60 minutes after injection.

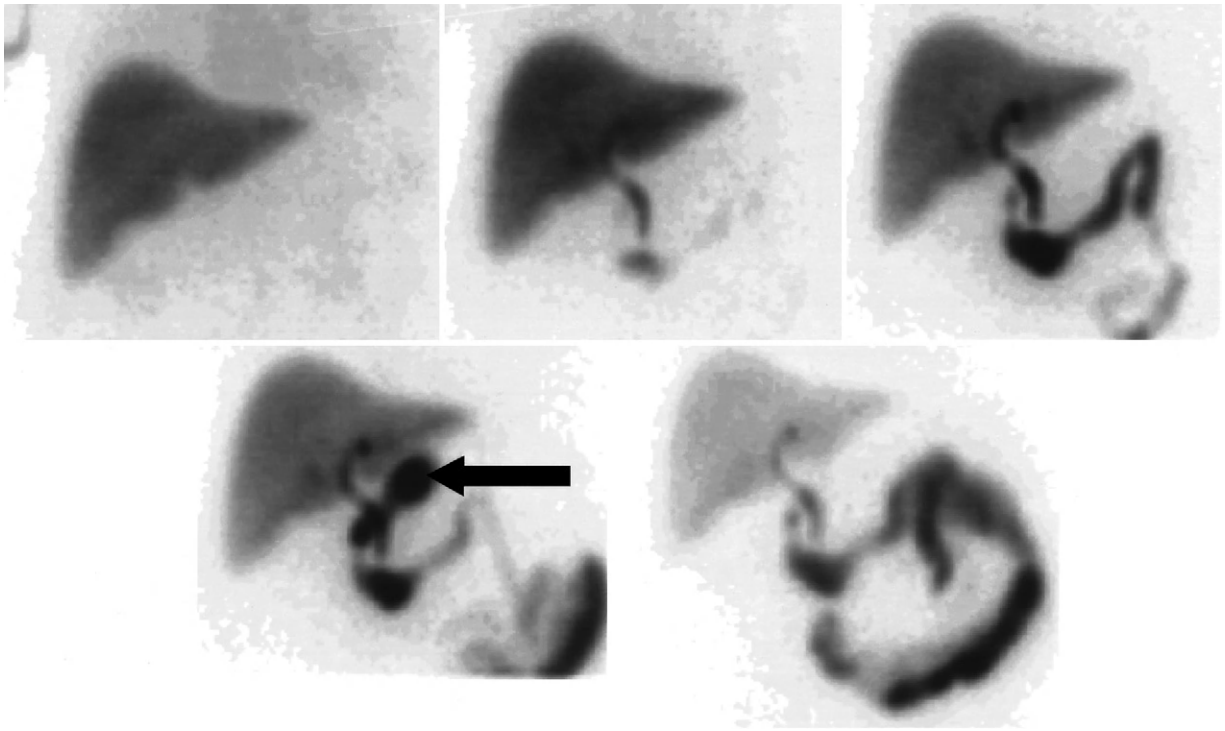

FIGURE 15.25. This study reveals nonvisualization of the gallbladder even after administration of morphine. Pathology revealed acute cholecystitis. Images were acquired 10, 30, 40, and 60 minutes after injection of tracer and 20 minutes after morphine injection. The 60-minute image reveals refluxed activity in the stomach (*arrow*).

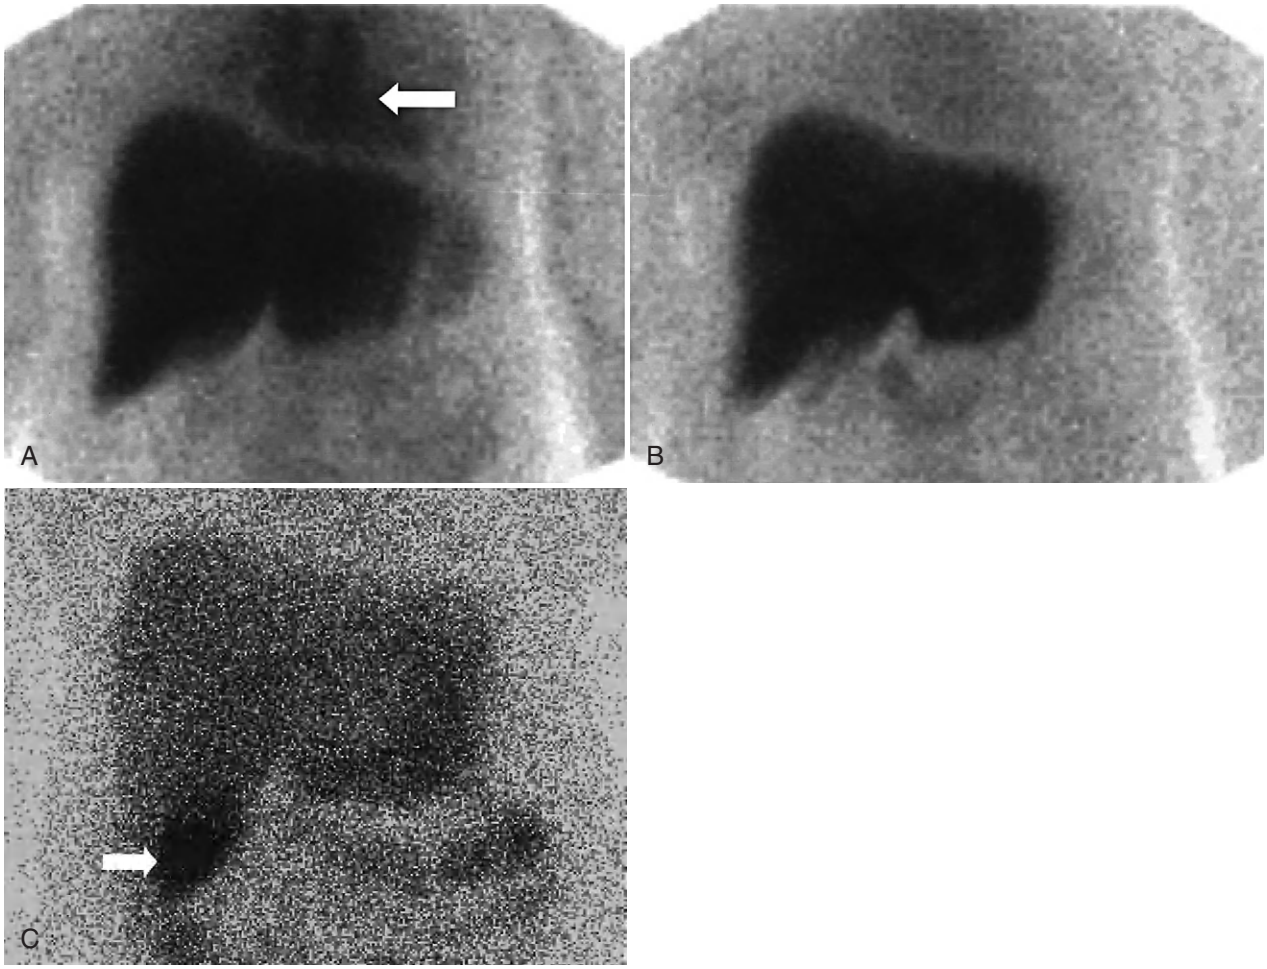

FIGURE 15.26. Delayed gallbladder demonstration. **A,** The *left arrow* outlines blood pool activity at 10 minutes after injection. **B,** Nonvisualization of the gallbladder at 60 minutes after injection. **C,** The 4-hour image shows the gallbladder (*right arrow*). The 6-hour half-life of ^{99m}Tc and biologic clearance of the tracer lead to a reduction in counts acquired in time, producing a grainy image at 4 hours.

and the results may be due in part to a reporting bias, as these disease states become more widely appreciated; but they are more likely due to the reduced morbidity of the laparoscopic operative procedure. Preoperative testing with biliary scintigraphy predicts patients with acalculous biliary pain who are likely to benefit from cholecystectomy (Goncalves et al, 1998; Reed et al, 1993), and it should be performed in this patient group (Barron & Rubio, 1995).

Cholecystitis (See Chapter 30)

The diagnosis of acute cholecystitis is largely clinical, although ancillary tests are often performed to increase clinical confidence before surgery. The two competing imaging tests are US and hepatobiliary scintigraphy. The key finding on hepatobiliary imaging is nonvisualization of the gallbladder (see Fig. 15.25). Sensitivity rates of greater than 96% have been reported consistently by many groups (Freitas et al, 1982; Suarez et al, 1980; Szlabick et al, 1980; Velasco et al, 1982). An additional finding of a hot rim around the gallbladder fossa is strongly associated with a diagnosis of acute cholecystitis (Cawthon et al, 1984), but it is not 100% specific, as had previously been thought (Oates et al, 1996). The specificity of unaugmented hepatobiliary scintigraphy is lower, however, because prolonged fasting may lead to nonvisualization of the gallbladder. This finding has led to many investigators routinely using morphine augmentation (Choy et al, 1984) or cholecystokinin pretreatment (Eikman et al, 1975) to increase biliary tree pressure and show cystic duct patency. The addition of this step increases the specificity of hepatobiliary scintigraphy (Cabana et al, 1995; Chen et al, 1997; Choy et al, 1984; Fink-Bennett et al, 1991a) over and above delayed imaging (Kim et al, 1993). Morphine-augmented hepatobiliary scintigraphy in the detection of acute cholecystitis has sensitivity, specificity, positive predictive value, and negative predictive value of 95%, 99%, 97%, and 98%, respectively (Fink-Bennett et al, 1991a). These figures compare favorably with US, and hepatobiliary scintigraphy seems to be the diagnostic test of choice in the diagnosis of acute cholecystitis (Shea et al, 1994). US relies on a combination of sonographic findings, including the presence of stones, gallbladder wall thickening, perigallbladder fluid, and a positive Murphy sign over the gallbladder fossa rather than demonstration of cystic duct obstruction itself (Dykes et al, 1986; Lauritsen et al, 1988; Samuels et al, 1983; Soiva et al, 1986; van Weelde et al, 1986).

Chronic Cholecystitis

In patients with chronic cholecystitis, the crucial imaging finding is the presence of cholelithiasis, and this is best shown with US (Shea et al, 1994). Most patients with chronic cholecystitis show cystic duct patency. Delayed filling of the gallbladder is associated with chronic cholecystitis, but this is a nonspecific finding, because fasting may give the same appearance (see Fig. 15.26). US remains the diagnostic test of choice in the detection of chronic cholecystitis.

Chronic Acalculous Right Upper Quadrant Pain

Chronic acalculous disorders of the biliary tree comprise acalculous cholecystitis, cystic duct syndrome, sphincter of Oddi dysfunction, and gallbladder dyskinesia.

ACALCULOUS CHOLECYSTITIS AND THE CYSTIC DUCT SYNDROME. *Cystic duct syndrome* is defined as fibrotic narrowing of the cystic duct lumen by 60%, kinking or adhesions of the duct seen at surgery, or both. *Chronic cholecystitis* is defined pathologically as hypertrophy of the gallbladder wall (>1.5 to 2 mm thick) and the presence of Rokitansky-Aschoff sinuses, a mononuclear infiltrate, foamy macrophages, diffuse muscularis hypertrophy, and yellow papillary nodules (Fink-Bennett et al, 1991b). Using a standardized protocol of cholecystokinin infusion (0.2 μg/kg administered over 3 minutes), a normal range for the ejection of bile from the gallbladder has been established. Fink-Bennett and colleagues (1991b) studied this group in detail. Patients with reduced gallbladder ejection fraction (<35% ejected in the first 20 minutes after cholecystokinin infusion) were considered abnormal. Of patients with an abnormal gallbladder ejection fraction, 108 (94%) of 115 had either cystic duct narrowing or chronic cholecystitis on pathology, with only 1 of 106 who had follow-up reporting no amelioration of symptoms; 69 of 78 (89%) who were medically managed had continued symptoms suggesting biliary colic. This study suggests the finding of reduced gallbladder ejection fraction in response to cholecystokinin is a strong indicator of the need for surgical intervention. Only seven (6%) of the 115 patients with histopathologic confirmation of disease had a gallbladder ejection fraction greater than 35%, a false-negative result. The negative predictive value of a normal gallbladder ejection fraction is 91%, with 130 of 143 patients with improvement after treatment for nongallbladder pathology having a gallbladder ejection fraction greater than 35% (Fink-Bennett et al, 1991b).

POSTCHOLECYSTECTOMY SYNDROME AND SPHINCTER OF ODDI DYSFUNCTION (SEE CHAPTER 38). A significant proportion of patients subjected to cholecystectomy have continued pain postoperatively. Many are diagnosed as having irritable bowel syndrome, pancreatitis, gastritis, and esophagitis, but about 6% have unexplained pain. Sphincter manometry is considered one of the main objective tests for the presence of sphincter of Oddi dysfunction (SOD).

The overall incidence of pancreatitis in patients undergoing endoscopic retrograde cholangiopancreatography (ERCP) manometry alone has been reported as 9.3%, with a 26% incidence if sphincterotomy is combined with manometry (Maldonado et al, 1999). The high rate of this side effect serves as a continued stimulus to investigate noninvasive methods for diagnosing SOD. Augmented hepatobiliary scintigraphy is a promising method in the noninvasive diagnosis of SOD. The most common abnormal finding with hepatobiliary scintigraphy is an obstructive pattern of biliary drainage, but some patients who have no symptoms at the time of the examination have a normal study. A variety of criteria for analysis have been developed using quantitative hepatobiliary scintigraphy (Roberts-Thomson et al, 1986). Augmentation techniques include an improvement in biliary drainage after amyl nitrate therapy (Madacsy et al, 1994) to exclude a fixed stenosis that would not respond to drug therapy and the development of an obstructive pattern with prostigmine-morphine administration observed by Madacsy and colleagues (1995), who suggested that only patients with prostigmine-morphine–induced obstruction should undergo manometry.

Biliary Tract Complications after Surgery (See Chapter 42)

The complication rates of laparoscopic cholecystectomy decrease as the number of cases performed by a particular surgical group increases (Walker et al, 1993). Hepatobiliary scintigraphy is a powerful, noninvasive tool to detect bile leak and iatrogenic biliary obstruction (Reichelt, 1978). When there is clinical suspicion of bile duct injury after surgery, hepatobiliary imaging should be one of the first tests considered (Figs. 15.27 to 15.32). The degree of leak can be assessed, and this can assist in the triaging of patients with bile leak to conservative or operative repair. After bile drainage has been achieved, a follow-up scan can assist in the triaging of patients who require further intervention (Walker et al, 1992). Improved disease-free survival after hepatic resection of metastases has led to an increase in the complexity and aggressiveness of hepatic resection, including complex operations involving the biliary tree. Hepatobiliary scintigraphy can assess the efficacy of biliary drainage after these complex procedures.

Liver Transplantation (See Chapter 97)

The major role of hepatobiliary imaging in liver transplant patients is in the postoperative assessment of the presence or absence of bile duct injury (Mochizuki et al, 1991; see Chapter 100). The noninvasive assessment of the integrity of a bile duct anastomosis is best done by hepatobiliary scintigraphy, because conventional imaging cannot characterize the nature of ascitic fluid. Bile duct stenoses do occur, and these are well shown with scintigraphy. Acute vascular rejection is an uncommon event in liver transplantation, and scintigraphy allows the assessment of perfusion noninvasively (Williams et al, 1985). Preservation injury or peritransplantation infarction is demonstrable on scintigraphy and may give the clinician a clue for the level of function expected from the graft (Karademir et al, 1994), but such information is unlikely to change posttransplant treatment. Cholestasis and rejection are two common posttransplantation problems, and the two overlap in terms of their scintigraphic appearance (Engeler et al, 1992). This problem had led to many units not including scintigraphy in the postoperative assessment. Attempts to further analyze the information within the hepatobiliary scan to assess transplant viability more accurately have been promoted by some authors but have not become widely used (Brown et al, 1988; Shah et al, 1995; Tagge et al, 1987). A normal study effectively excludes rejection or severe cholestasis, but this information is unlikely to be additive to other simpler tests. Nuclear medicine studies are useful in the assessment of immunosuppressed patients with pyrexia of unknown origin.

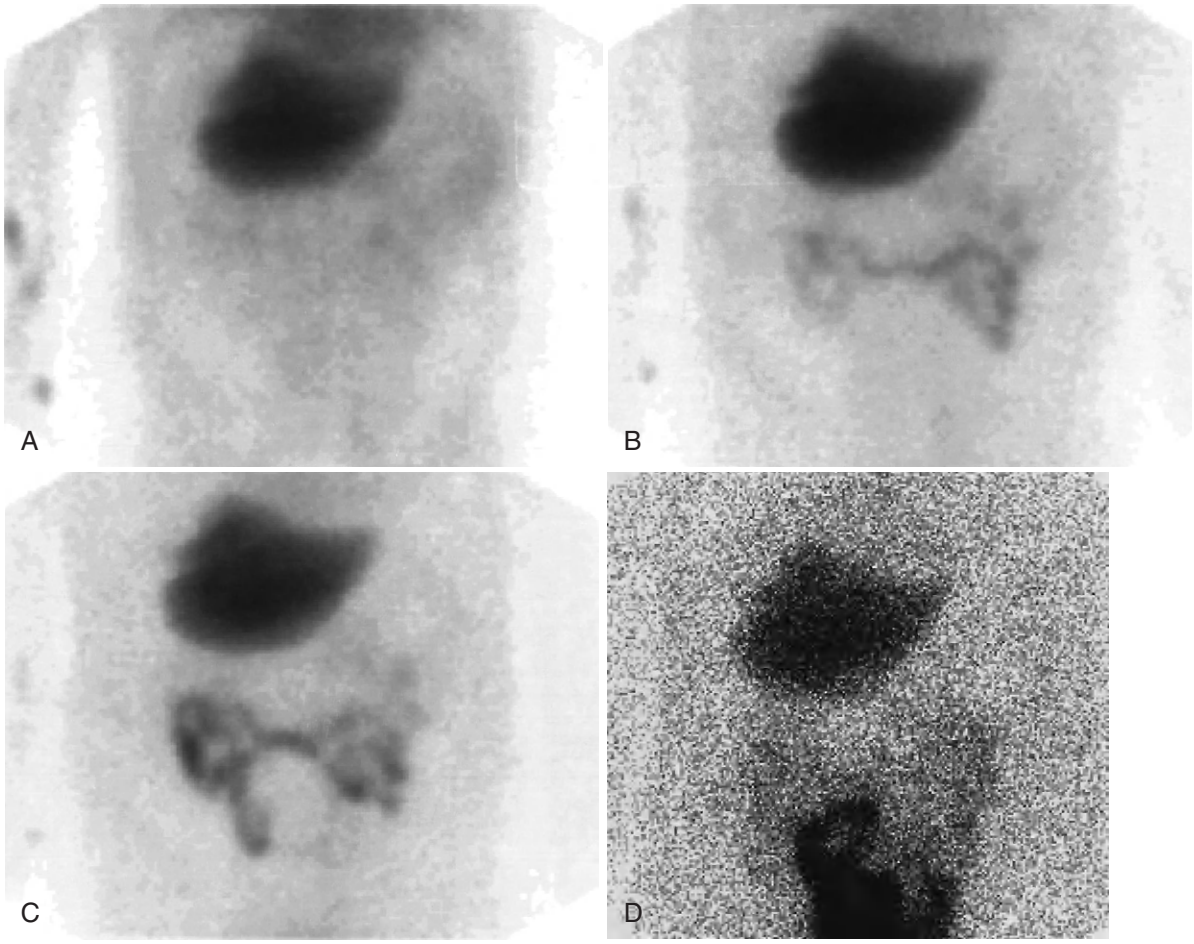

FIGURE 15.27. Normal scan 12 days after right trisegmentectomy. Images were acquired at 0, 30, and 60 minutes and at 3.5 hours after injection.

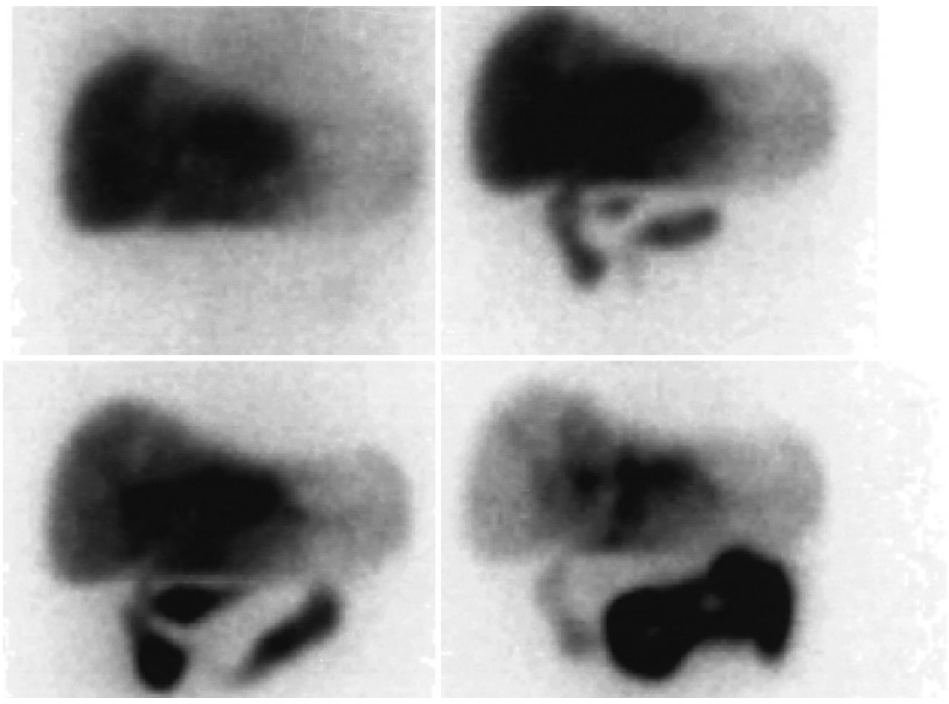

FIGURE 15.28. A 47-year-old man with hypereosinophilic syndrome after right liver lobectomy for liver abscess was referred to rule out biliary obstruction and to evaluate the segmental drainage 0, 10, 20, and 60 minutes after injection. The images show impaired drainage of the left ductal system with bile duct retention. Ultrasound showed bile duct stones, and the patient required percutaneous drainage.

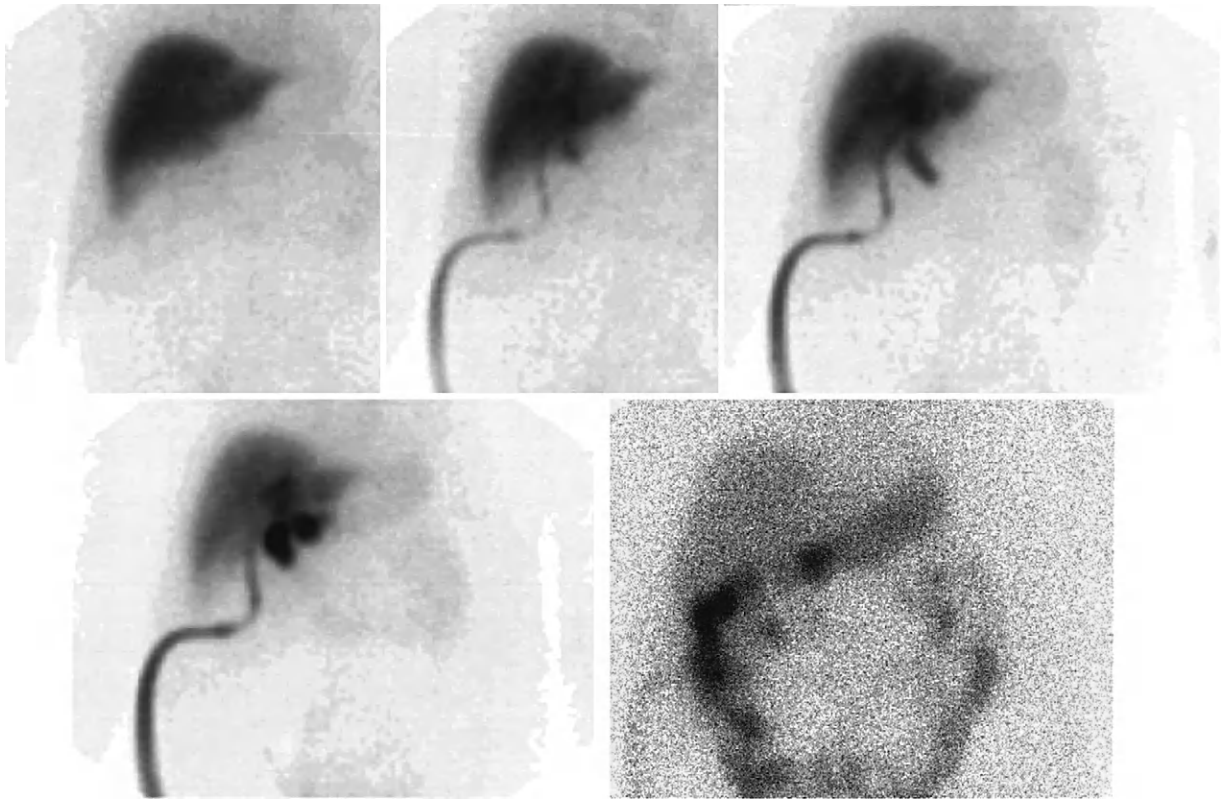

FIGURE 15.29. A 70-year-old man with inoperable duodenal carcinoma had persistent bile drainage into the intraperitoneal drain tube inserted intraoperatively. The study revealed free passage of bile from the drain tube with some drainage into the bowel. Images were acquired 20, 30, 40, and 60 minutes and at 3.5 hours after injection.

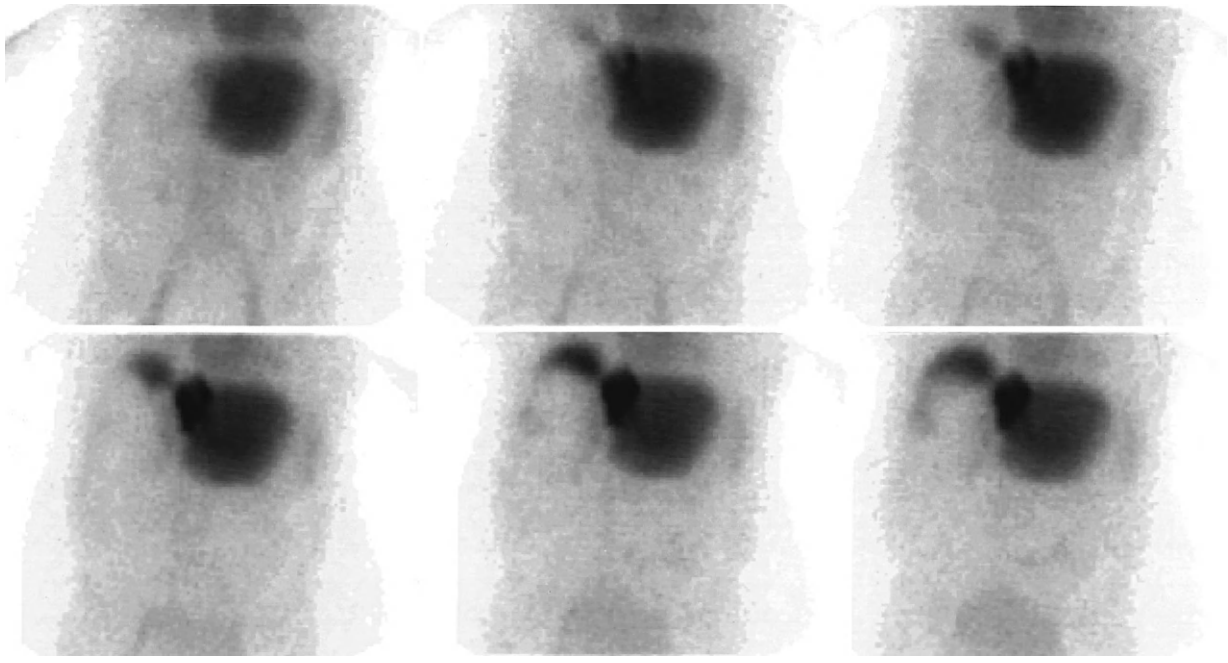

FIGURE 15.30. A 63-year-old woman with a history of colon carcinoma metastatic to the liver was referred after right trisegmentectomy for assessment of bile leak. The images show leakage from the anastomosis with tracking of the isotope into the right subphrenic space. The images shown are 10 minutes apart, acquired over 1 hour.

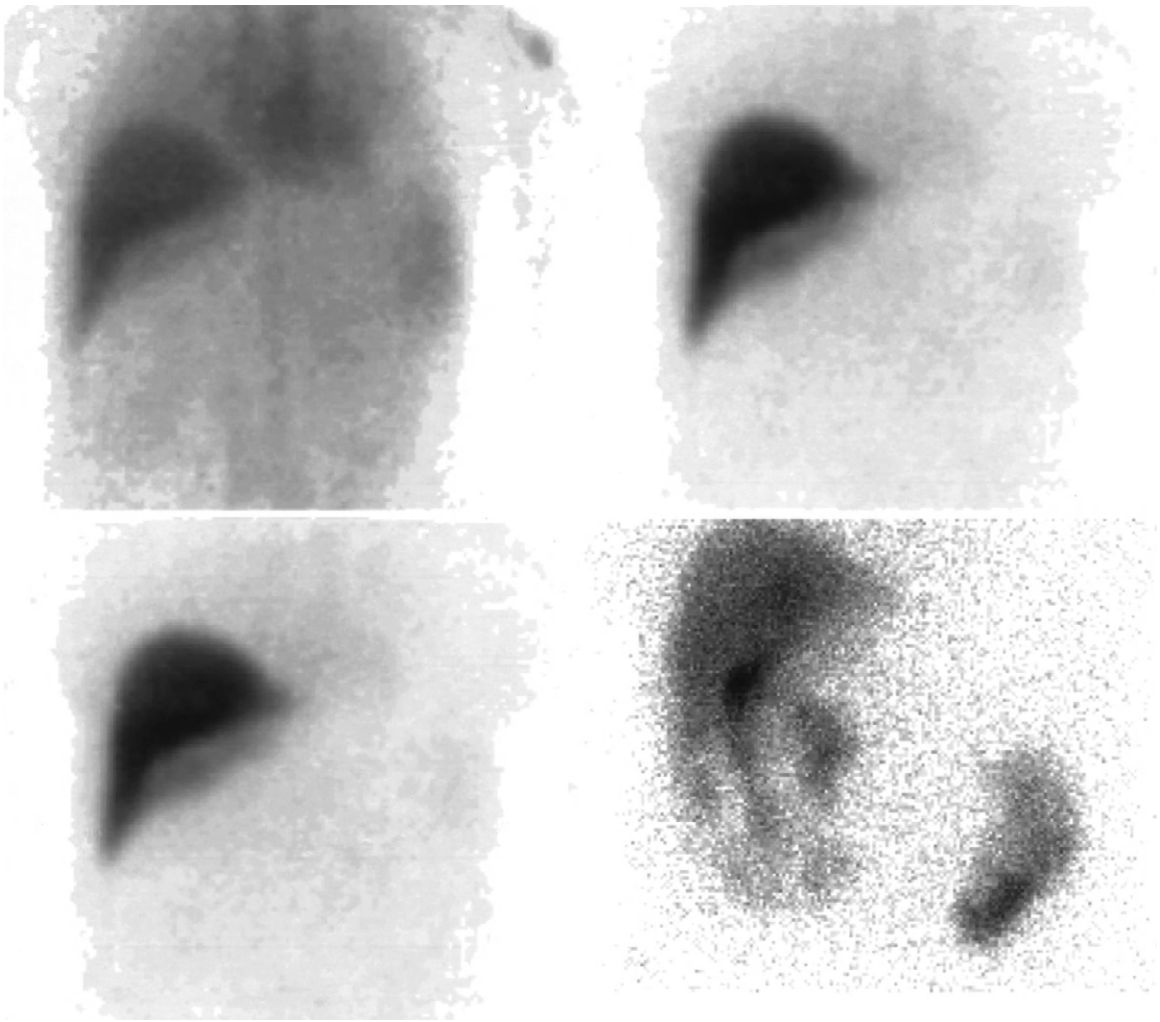

FIGURE 15.31. A 40-year-old woman with repeated cholangitis after a Whipple procedure is referred for assessment of possible biliary obstruction. After this study, an 8.5-Fr biliary drainage catheter was placed across a 1.5-cm high-grade biliary-enteric obstruction. Images were acquired at 0, 30, and 60 minutes and at 3 hours after injection.

Hepatocellular Carcinoma

HCC has a variable pattern of uptake, seen with hepatobiliary tracers. Poorly differentiated HCC appears as a cold lesion; well-differentiated HCC typically exhibits retention of the tracer on delayed images, performed 2 to 3 hours after injection, that a normal liver would have cleared. Sequential studies can be used to follow well-differentiated HCC, if the clinician and patient wish to undertake such a course. Focal nodular hyperplasia (FNH) is the differential diagnosis of focal retention of tracer, but an image at 5 to 10 minutes after injection should differentiate between FNH (isointense with normal liver) and HCC (usually hypointense).

Pediatric Imaging

Neonatal Jaundice

The task of the physician faced with a newborn who is jaundiced is to determine the cause to decide whether intervention is required. Most cases of neonatal jaundice are due to physiologic causes, breast milk jaundice, and, less commonly, erythroblastosis fetalis. Idiopathic neonatal hepatitis is rare, as is biliary atresia (see Chapter 40). Both of these conditions result in either mixed or conjugated prolonged hyperbilirubinemia (direct bilirubin of >15%). Early diagnosis of biliary atresia is important, because it leads to the development of cirrhosis and liver failure with an average survival of 12 months if untreated (Emblem et al, 1994). The differentiation of neonatal hepatitis and biliary atresia is difficult on clinical grounds and occasionally at liver biopsy (Manolaki et al, 1983).

Biliary Atresia (See Chapter 40)

Differentiation of biliary atresia and neonatal hepatitis on histopathology depends on the presence of ductal proliferation and portal fibrosis, both of which may take some time to develop; this may reduce the accuracy of a biopsy performed too soon after birth. The diagnosis of biliary atresia using hepatobiliary scintigraphy is based primarily on nonvisualization of the gut at

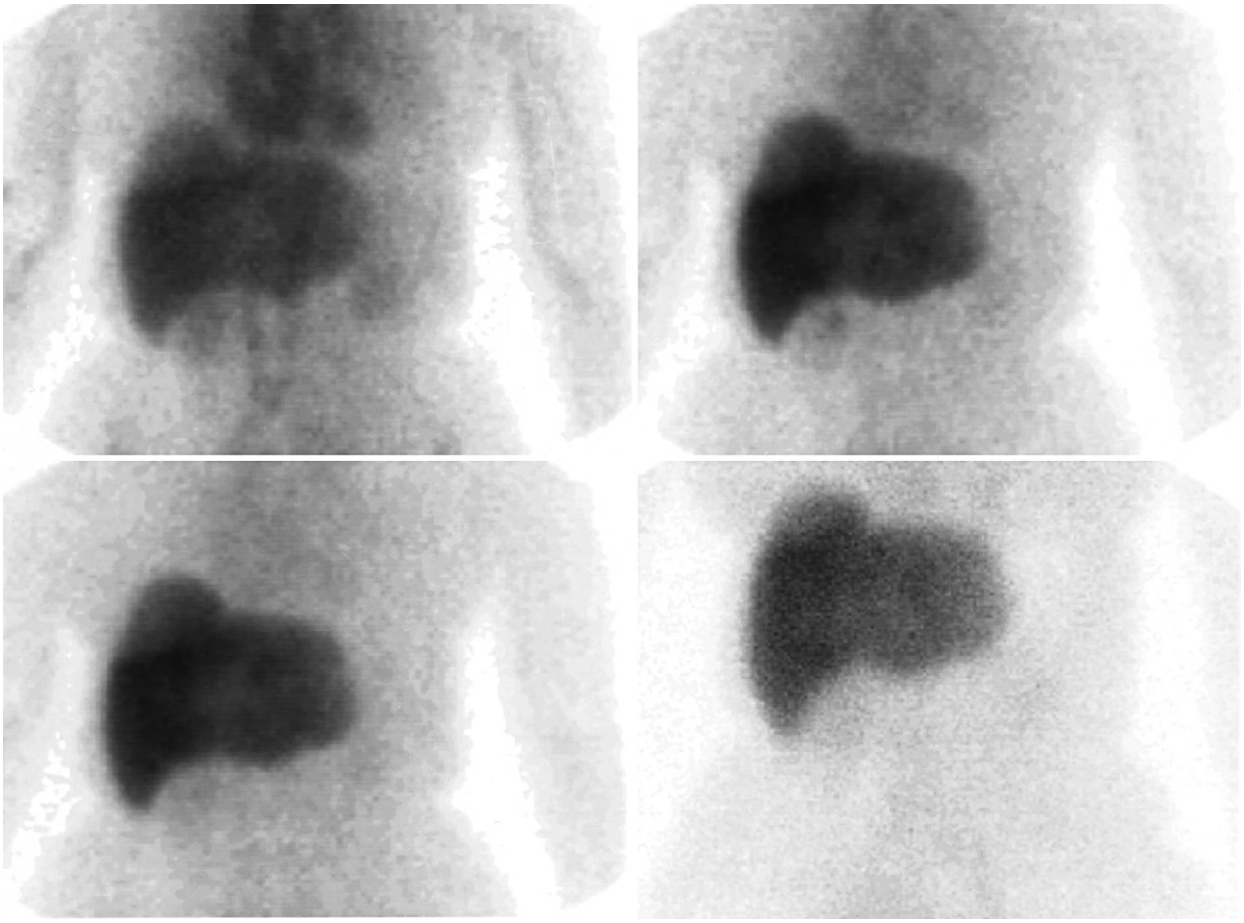

FIGURE 15.32. Complete biliary obstruction. Images are immediately postinjection, and at 30 minutes, 60 minutes, and 3 hours. Note the lack of biliary excretion and the breast shadow over the right lobe of the liver.

24 hours, but a secondary criterion of rapid uptake of the tracer into the liver without biliary excretion also suggests the presence of biliary atresia. Idiopathic neonatal hepatitis is characterized by impaired uptake of the tracer by the liver with slow hepatic clearance of the tracer, which occurs in parallel to cardiac blood pool, owing to renal excretion (this finding is mimicked by biliary atresia as cirrhosis develops, leading to impaired hepatocyte extraction of the tracer). It is advisable to perform hepatobiliary imaging before 3 months of age to reduce the likelihood of the development of cirrhosis. Premedication with phenobarbital (5 mg/kg/day for 5 days) leads to increased bile flow and improved specificity of the test, as it reduces the number of cases in which the gut is not visualized. The differential diagnosis of nonvisualization of the gut at 24 hours includes biliary atresia, bile plug syndrome, cystic fibrosis, or severe hepatocellular dysfunction secondary to idiopathic neonatal hepatitis, total parenteral nutrition (Cooper et al, 1985), infectious hepatitis, and septooptic dysplasia (Kumura et al, 1987). Bile plug syndrome is seen in dehydrated, septic infants. The characteristic scintigraphic features of this syndrome are excretion of the tracer into a dilated proximal biliary tract without gut excretion.

The diagnosis of biliary atresia on US is based on numerous features, including inability to see a gallbladder, a hypoplastic gallbladder, no change in gallbladder size with food, and a new feature known as the *triangular cord sign.* Recently reported in many publications by a single group of researchers, the triangular cord sign appears to have high sensitivity, specificity, and accuracy (85%, 100%, and 95%, respectively) (Choi et al, 1996, 1998; Park et al, 1997). The reported efficacy of diisopropylacetanilido-iminodiacetic acid scanning (sensitivity 96%, specificity 35%, accuracy 56%) by this group is less than reported in most other literature; however, using these criteria alone, US sensitivity of 85% translates into 15% of infants with biliary atresia having a delayed surgical procedure; a combined approach would therefore seem appropriate as the authors suggest. US is a good initial test, and it is useful in ruling out the presence of a choledochal cyst, which also may manifest with neonatal jaundice. Hepatobiliary scintigraphy in such a case is useful, if it shows filling of the cyst with bile (Fig. 15.33).

Lin and colleagues (1997) directly compared US with hepatobiliary scintigraphy using premedication with phenobarbital and cholestyramine premedication in a group of 66 patients with neonatal jaundice. The diagnostic sensitivity, specificity, and accuracy of scintigraphy in differentiating biliary atresia from other forms of neonatal jaundice were 100%, 87.5%, and 90.5%, respectively, compared with US results of 86.7%, 77.1%, and 79.4%, respectively (Lin et al, 1997). Premedication with oral phenobarbital increases test accuracy by accelerating biliary excretion (Majd et al, 1981a, 1981b). Reduced specificity of

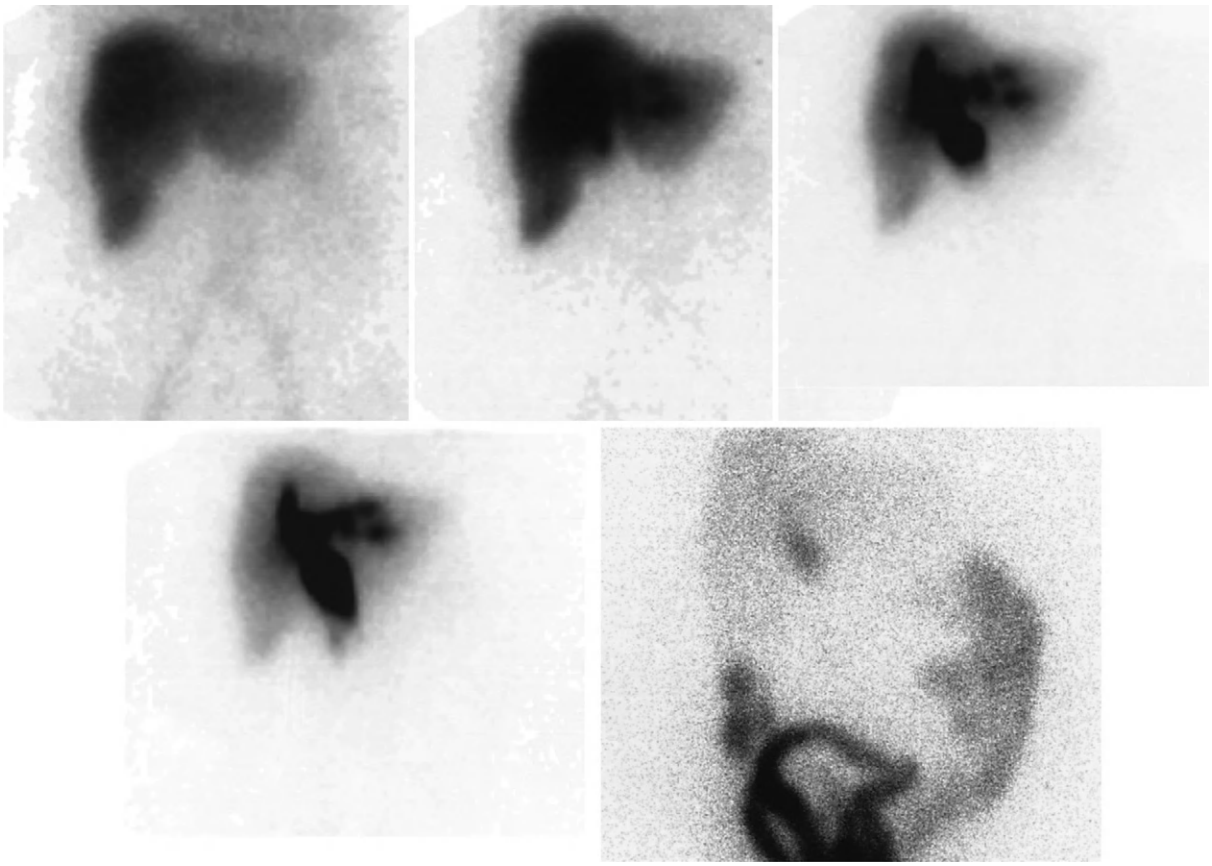

FIGURE 15.33. A 70-year-old woman who previously had undergone a cholecystectomy was referred for assessment of a possible choledochal cyst. The study reveals a large bile-filled structure beneath the hepatic hilum consistent with a choledochal cyst. Images were acquired at 0, 20, 40, and 60 minutes and at 4 hours after injection.

hepatobiliary scintigraphy is seen if the infant's birth weight is less than 2,200 g (Spivak et al, 1987). Hepatobiliary scintigraphy is the diagnostic test of choice in the diagnosis of cystic duct obstruction; it predicts response to cholecystectomy in patients with acalculous biliary pain and plays a vital role in the assessment of patients with biliary tract injury and neonatal jaundice.

ROLE OF GENERAL NUCLEAR MEDICINE IN ASSESSMENT OF ADULTS WITH MALIGNANT INVOLVEMENT OF THE LIVER AND HEPATOBILIARY TREE

Cardiac Preoperative Risk Assessment (See Chapter 22)

It is prudent to perform preoperative testing to attempt to risk-stratify patients before major surgery when risk of coronary disease is significant. Patients who have been recommended to undergo preoperative testing include those with two or more of the following: diabetes, prior congestive cardiac failure, prior myocardial infarction, Canadian class 1 or 2 angina, poor functional capacity (<4 metabolic equivalents on a treadmill exercise test), or a planned prolonged surgical procedure with large fluid shifts, blood loss, or both (Leppo & Dahlberg, 1998). Preoperative testing with myocardial perfusion scintigraphy with either thallium-201 (^{201}Tl)- or ^{99m}Tc-based perfusion agents is a powerful predictor of perioperative events. The initial reports of thallium scintigraphy showed a high positive predictive value of the test on the order of 20%, but the positive predictive value has declined slowly over time (Leppo & Dahlberg, 1998). In part, this decline may be due to changes in scanning protocols (SPECT versus planar acquisition) or to physicians overreading the scans to avoid possible litigation, as the biology of the disease is unlikely to have changed significantly. A negative test remains highly predictive (>99%) of a cardiac event–free perioperative period.

Sulfur Colloid Imaging

Historical Background

Before high-resolution CT, US, and MRI were developed, the initial imaging investigation to evaluate potential hepatic involvement with tumor was colloidal scintigraphy. The initial work was done with radiolabeled gold, but this was supplanted by ^{99m}Tc-labeled colloids. Injected colloids undergo phagocytosis by reticuloendothelial cells found in liver, spleen, and bone marrow.

In a normal patient, approximately 90% of the injected dose of ^{99m}Tc–sulfur colloid is taken up by the liver, with the spleen and bone marrow each accounting for 5% (Fig. 15.34). Sulfur colloid imaging has been used in the assessment of diffuse

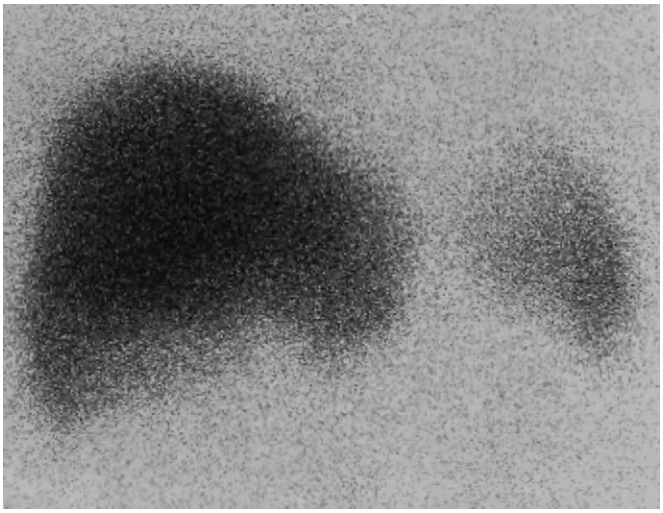

FIGURE 15.34. Anterior delayed view of a normal liver and spleen scan after injection of ^{99m}Tc–sulfur colloid.

parenchymal disease of the liver, with ratios of liver to spleen and bone marrow, the *colloid shift,* being used to assess the degree of hepatocellular dysfunction. The finding of a hypertrophied caudate lobe raises strong suspicions of the presence of Budd-Chiari syndrome. The advent of high-speed CT and color Doppler US has reduced the demand for liver and spleen imaging for the establishment of this diagnosis.

Diagnosis of Malignancy

The typical appearance of a malignant deposit is a focal cold defect on ^{99m}Tc–sulfur colloid imaging, because metastases do not contain the phagocytic cells necessary for uptake of the radiopharmaceutical. "Cold spots" on colloid imaging are nonspecific findings; hepatic cysts, hemangioma, and hepatic adenoma all may appear cold, because they do not contain Kupffer cells (Table 15.5). A solid lesion identified on cross-sectional imaging that is not accompanied by a photopenic defect on sulfur colloid imaging is likely to be FNH (Sandler et al, 1980) or the rare hepatoblastoma, usually only seen in children (Tanasescu et al, 1991). Hepatic adenomas that take up sulfur colloid are quite rare (Low & Khangure, 1990) and usually are gallium avid.

Table 15.5

Cold Defects and Hot Lesions on Technetium 99m–Sulfur Colloid Imaging

Lesion	Explanation
Cold Defects	
Hepatic pseudotumor	Hepatic regeneration or scar in cirrhotic patients, may or may not be hot
Acute radiation injury	Radiosensitive reticuloendothelial cells
Extrahepatic masses	Deformation of normal liver
Simple cysts	No target cells in lesion
Polycystic liver disease	No target cells in lesion
Hemangioma	No target cells in lesion
Adenoma	Usually cold; rare cases with uptake present have been reported
Hamartoma	No target cells in lesion
Hydatid cyst	No target cells in lesion
FNH	Variably hot or cold because it may contain reticuloendothelial cells
Hot Lesions	
Budd-Chiari syndrome	Typically caudate lobe hypertrophy
Cirrhosis	
Hepatoma	
Hemangioma	
Hamartoma	
Abscess	
FNH	

FNH, focal nodular hyperplasia

Dual-Tracer Studies

The relatively low specificity of sulfur colloid imaging led to the development of a variety of dual-tracer studies involving gallium 67 (^{67}Ga) citrate (Beihn et al, 1974; Rovekamp et al, 1983), ^{99m}Tc-labeled red blood cells, ^{111}In-labeled white blood cells (Fawcett et al, 1985), and more recently ^{201}Tl (Mochizuki et al, 1994). The principle of the dual-tracer studies was to use tracers of known physiologic processes to add specificity to the colloid findings. ^{201}Tl acts as a potassium analogue when injected intravenously, and it accumulates in viable cells. It has been used for many years for myocardial scintigraphy, and after serendipitous uptake in a tumor, it was investigated as a tumor-seeking agent. Subtraction imaging with ^{201}Tl-labeled and ^{99m}Tc-labeled colloids has been used in the assessment of HCC (Mochizuki et al, 1994). ^{67}Ga citrate is a nonspecific tumor-seeking agent whose efficacy probably is related to shared metabolic pathways with iron. A lesion negative on colloidal imaging but positive on labeled white blood cell scan suggests abscess; a lesion positive on ^{67}Ga and negative with colloid imaging is more likely to be a hepatoma (given the absence of fever and other signs of infection). Serial ^{67}Ga studies can be a useful follow-up tool in patients after resection of HCC (Serafini et al, 1988). The improvements in the image achievable with US, CT, and MRI and the limits of resolution (1.5 to 2 cm) of the tracer techniques have led to the gradual replacement of colloid imaging with conventional radiologic investigations. If there are contraindications to biopsy or equivocal lesions, combined tracer studies remain a useful noninvasive technique.

Hemangioma Studies (See Chapter 79A)

A hepatic hemangioma is almost always negative on sulfur colloid imaging (Fig. 15.35). If a lesion suspicious for a hemangioma can be identified as a cold spot with sulfur colloid, a red blood cell study can add weight to the diagnosis of hemangioma. A red blood cell study involves the labeling of the patient's red blood cells with ^{99m}Tc using a stannous chloride chelate, which bonds the ^{99m}Tc to the red blood cells (Royal et al, 1981). Because hemangiomas have an increased blood volume compared with normal tissues, they appear as a hot spot on a blood pool scan and may be visualized when other imaging modalities are negative (Krausz et al, 1997). Lesions 1.5 to 2 cm can be reliably detected with sensitivities of 89%

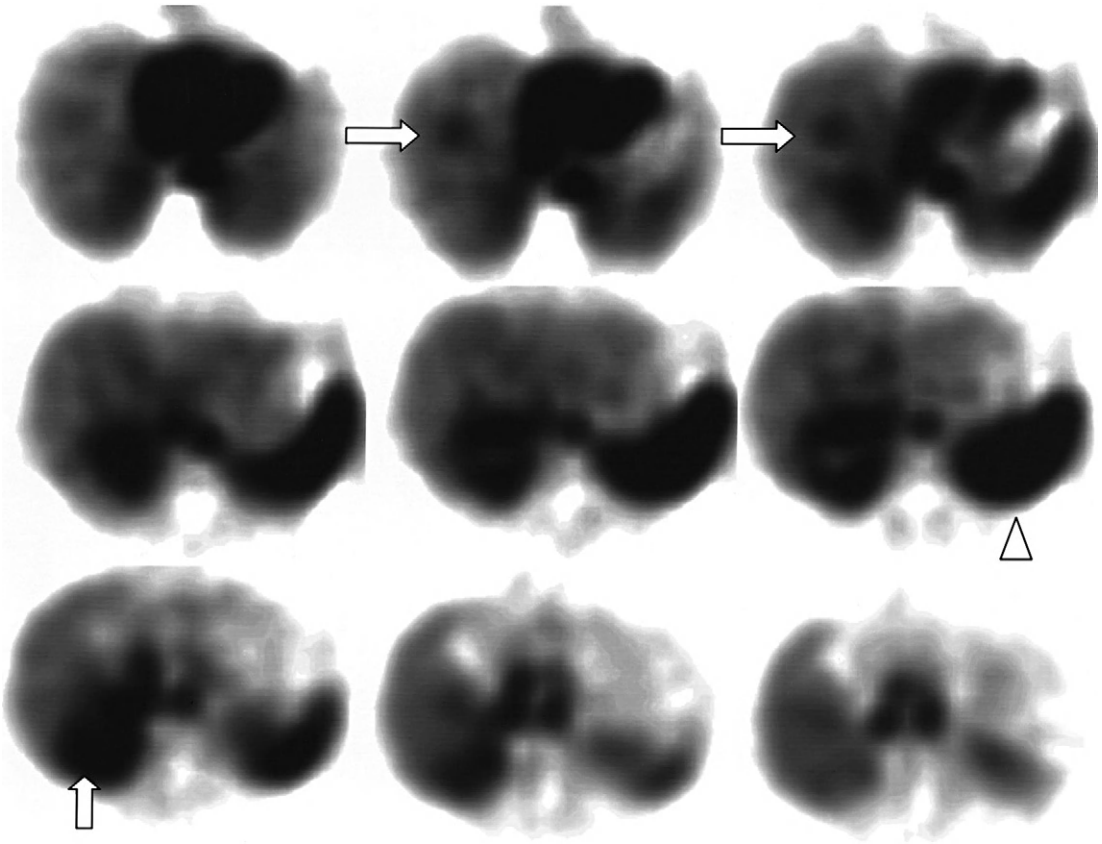

FIGURE 15.35. A 52-year-old woman with breast cancer was found to have lesions suggesting hemangioma in her liver and was referred for assessment. The images are sequential transaxial sections through the lower chest and upper abdomen. The study shows the right and left ventricles in the top right image; the right arrows point to a small hemangioma in the upper liver. The *arrowhead* points to the spleen; the up arrow points to the larger hemangioma in the posterior right lobe of the liver.

(Guze & Hawkins, 1989; Siegel & Mazurek, 1997; Ziessman et al, 1991). Hypervascular metastases do occur but are rare (Farlow et al, 1993; Ginsberg et al, 1986; Shih et al, 1996; Swayne et al, 1991).

Neuroendocrine Receptor Imaging (See Chapters 61 and 81B)

Many neuroendorine tumors can be imaged using ^{111}In-labeled octreotide, a somatostatin analogue, including carcinoids, gastrinomas, insulinomas, glucagonomas, medullary carcinoma of the thyroid, meningiomas, small cell lung cancer, and other tumors such as Hodgkin and non-Hodgkin lymphomas (Krenning et al, 1992). These agents can be used to characterize liver lesions in patients with the aforementioned underlying conditions. Uptake in the normal liver may obscure small lesions, so unless a lesion can be seen as a cold spot or a hot spot, there is limited diagnostic information in a scan showing homogeneous liver uptake of octreotide. The real advantage of somatostatin receptor imaging is in the demonstration of extrahepatic metastases that may not have been shown with the conventional imaging modalities, altering the stage of the patient. Most patients with neuroendocrine tumors should have an octreotide scan before an attempted curative resection for metastatic disease (Fig. 15.36). If available, ^{68}Ga somatostatin receptor imaging should be performed in place of ^{111}In octreotide because of the time savings to the patient and the improved imaging characteristics of the PET agent over the γ-camera agent (Fig. 15.37).

Hepatic Arterial Perfusion Studies (See Chapter 86)

Technetium-99m Macroaggregated Albumin

The radiopharmaceutical ^{99m}Tc–macroaggregated albumin (MAA) is available in kit form and is commonly used for pulmonary perfusion scintigraphy. A heating process makes an aggregate of the albumin, resulting in MAA particles, 90% of which are between 10 and 90 μm in diameter. The net effect is that this pharmaceutical embolizes into the first capillary bed it meets and does not pass on through the remainder of the circulation when injected. This preparation has been used to assess the perfusion of the liver by direct injection into the hepatic artery (Yang et al, 1982). The addition of ^{99m}Tc–sulfur colloid imaging provides information regarding the relative perfusion of the liver via the hepatic artery as assessed by ^{99m}Tc–MAA and the intrahepatic distribution of the hepatic metastases as shown by ^{99m}Tc–sulfur colloid imaging (Figs. 15.38 to 15.41; Ridge et al, 1987). Direct injection of chemotherapeutic agents into the hepatic artery has been shown to deliver 10 times the

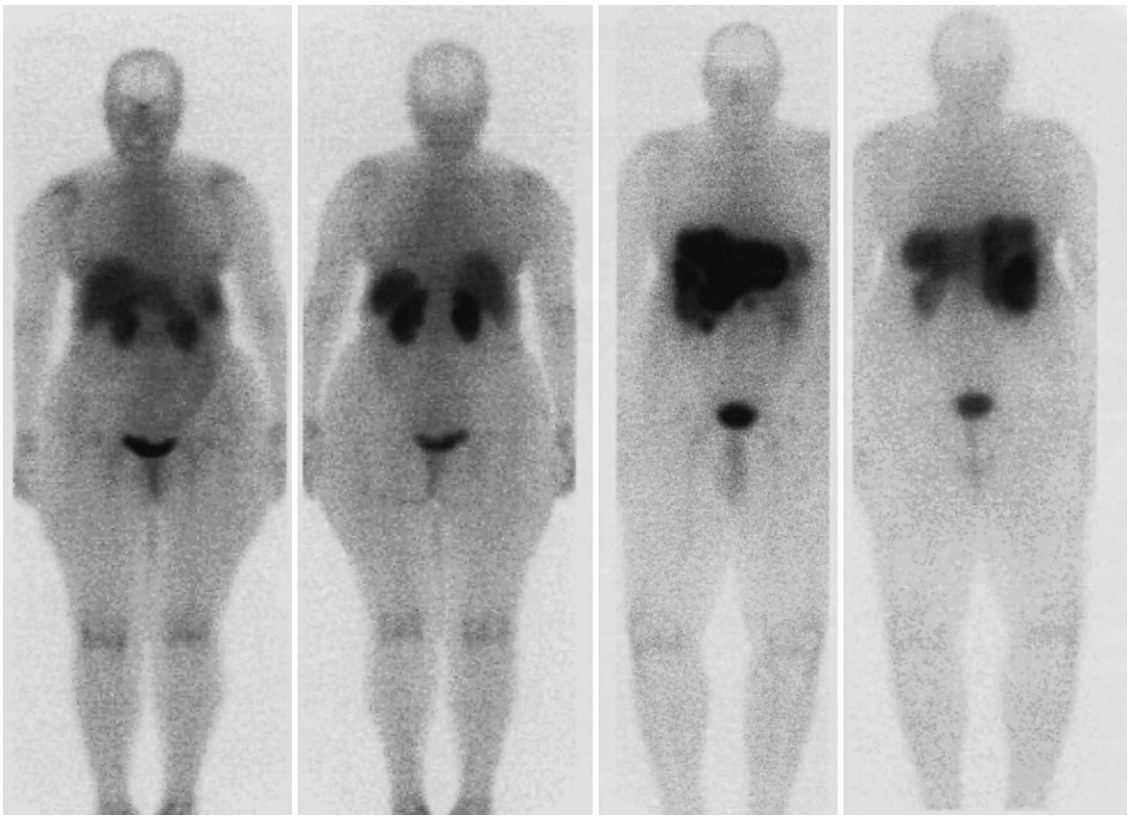

FIGURE 15.36. A normal octreotide study in a woman is shown on the left. On the right are images of a 53-year-old man who presented with confusion and was found to be hypoglycemic. Abdominal examination revealed hepatomegaly, and computed tomography revealed metastases. Fine needle aspiration revealed small round cells, suggesting a neuroendocrine origin. There is normally low-grade uptake of the tracer in the liver, spleen, and kidneys. The images on the right reveal extensive hepatic metastases and an epigastric mass.

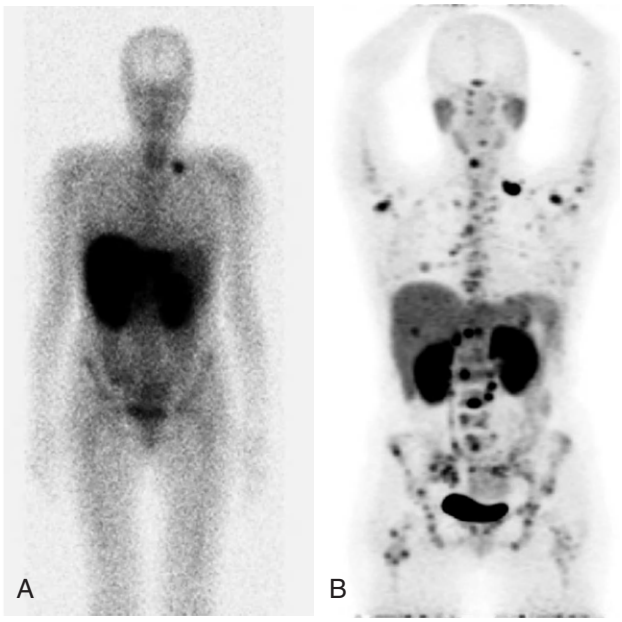

FIGURE 15.37. An abnormal indium 111 octreotide scan. **A,** A left supraclavicular node in a woman with a known neuroendocrine tumor. **B,** The gallium 68 (^{68}Ga) octreotate positron emission tomography scan was performed less than 1 week later and revealed abormalites in multiple bones and intraabdominal nodes in addition to the same supraclavicular node that was seen on the octreotide study. The greater sensitivity of the ^{68}Ga octreotate scan is well demonstrated. *(Images courtesy Dr. Michael Hofman.)*

concentration of 5-fluorouracil (5-FU) into liver metastases than delivery via the intravenous route (Hohenberger et al, 1993).

The advent of intrahepatic arterial drug therapy has led to increasing use of combined ^{99m}Tc–MAA and ^{99m}Tc–sulfur colloid imaging to exclude extrahepatic delivery of the radiopharmaceutical, which may necessitate catheter revision (Habbe et al, 1998). Inadvertent direct perfusion of the stomach, small intestine, or pancreas can cause local chemotoxicity, leading to localized inflammation that is often symptomatic (Figs. 15.42 and 15.43; Choplin et al, 1983; Chuang et al, 1981; Ku et al, 1998; Ottery et al, 1986). In some cases, the distribution of the tracer on scintigraphy has predicted the pattern of response of the metastases to the therapy (Borzutzky & Turbiner, 1985) and is a useful adjunct in the assessment of response to therapy (Savolaine et al, 1989). Hepatic artery scintigraphy also has been used to show the presence of arteriovenous shunting in hepatic tumors, which can modify therapy in an attempt to limit pulmonary toxicity (see Fig. 15.41; Leung et al, 1994).

Hepatic Arterial Therapy using Radiopharmaceuticals (See Chapter 84A)

An adaptation of the chemotherapy approach has been made by many groups, using therapeutic doses of unsealed radiotherapy. MAA imaging is also integral to the workup of a patient being considered for hepatic arterial embolization with radioactive microspheres, another approach to the palliation of liver tumors that share similar toxicity profiles when administered

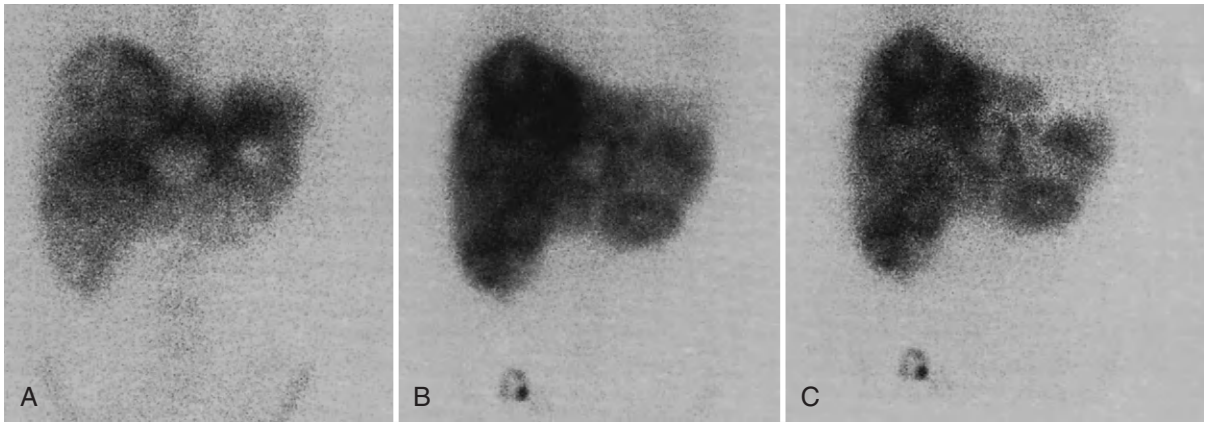

FIGURE 15.38. The methodology of subtraction scintigraphy with ^{99m}Tc–sulfur colloid and ^{99m}Tc macroaggregated albumin (MAA). The tracer requiring in vivo processing is injected first in a dose of 1 mCi (37 MBq). The second tracer, MAA, is injected through the hepatic catheter in a dose of 5 mCi (185 MBq). **A,** Sulfur colloid image. **B,** MAA image. **C,** MAA minus the sulfur colloid image. Multiple hepatic metastases are seen showing a hot rim of the MAA in the hypervascular rim of tumor. The activity in the right lower portion of the image is retained activity in the catheter.

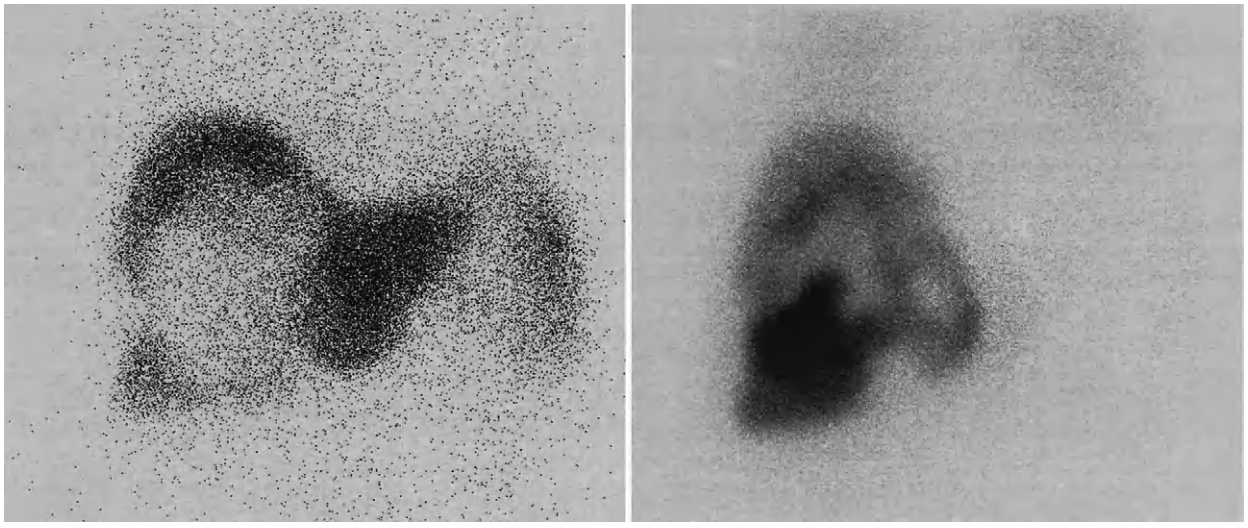

FIGURE 15.39. Image of a patient with a lesion in the lower right liver shows reduced uptake of sulfur colloid (*left*) but relative hyperperfusion (*right)* taken after injection of macroaggregated albumin intraarterially. This case shows the principle of metastases being supplied by the hepatic artery rather than by the portal vein.

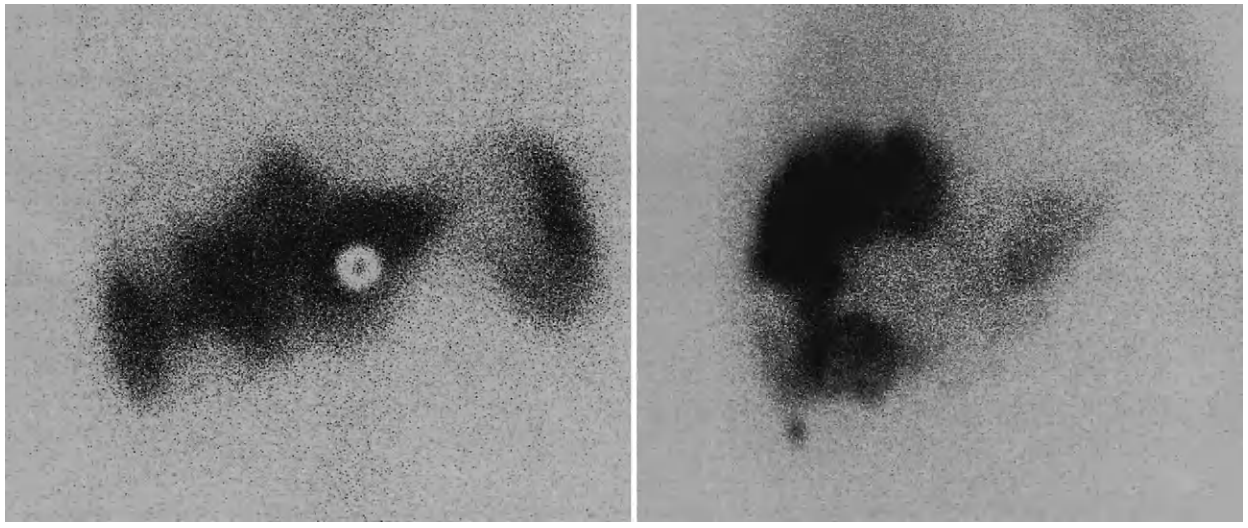

FIGURE 15.40. Image of a patient with a lesion in the upper right liver shows reduced uptake of sulfur colloid (*left*) but relative hyperperfusion (*right*) taken after injection of macroaggregated intraarterially. This case shows the principle of metastases being supplied by the hepatic artery rather than by the portal vein. The *inferior black dot* is an umbilical marker; the upper "cold" dot is an epigastric marker.

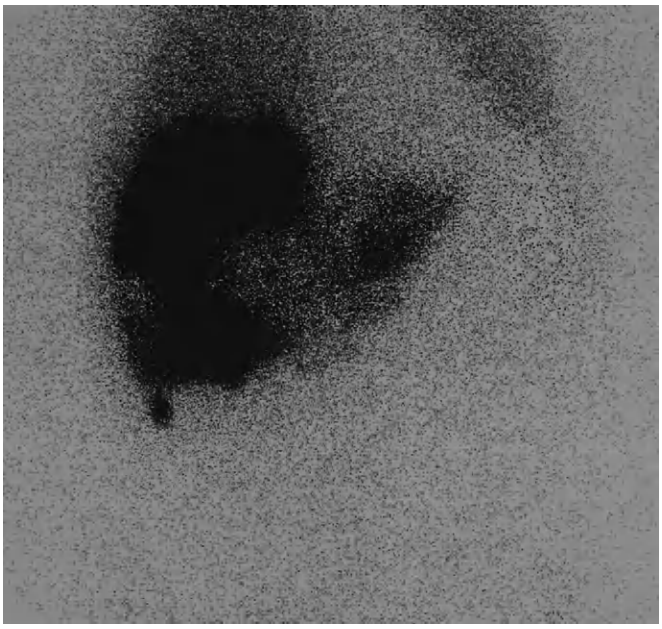

FIGURE 15.41. Same patient as in Figure 15.40. The window and level of display are "wound up," showing hepatopulmonary shunting.

inaccurately. Hepatic delivery of β-particle–emitting radiopharmaceuticals, such as ^{90}Yt- or ^{131}In-labeled microspheres, has been associated with improved median survival and reductions in tumor markers (Lau et al, 1994).

SUMMARY

Nuclear medicine is a diverse specialty. The tracer principle has been adapted to provide diagnostic information in the preoperative and postoperative setting and toward the therapeutic administration of radiopharmaceuticals. Hepatobiliary scintigraphy plays a vital role in the noninvasive assessment of patients with acute and chronic right upper quadrant pain and in the assessment of biliary dynamics in patients after biliary tract intervention. FDG PET-CT has become a mainstream tool in the diagnosis of metastatic disease in patients with cancer, and it shows great promise in the assessment of response to treatment. The integration of FDG PET-CT information into treatment assessment is currently occurring and should lead to more appropriate management, as treatment algorithms become more refined over time. Other nuclear medicine techniques, such as receptor imaging and therapy, have a niche in the planning and follow-up of patients with gastroenteropancreatic neuroendocrine tumors.

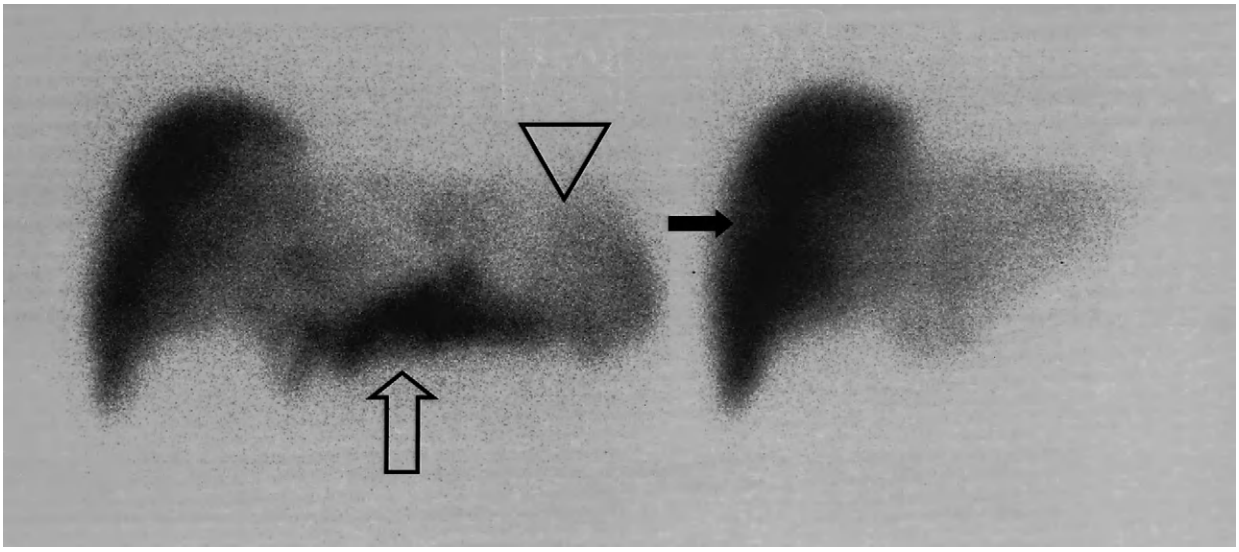

FIGURE 15.42. This study shows perfusion of the pancreas and spleen that was corrected with repositioning of the hepatic arterial catheter. The images to the right were acquired after the injection of ^{99m}Tc–macroaggregated albumin into the hepatic artery catheter, and they show aberrant perfusion of the pancreas (*open arrow*) and the spleen (*arrowhead*). After repositioning of the catheter, the metastasis can be seen in the right lobe of the liver (*solid arrow*) with no extrahepatic perfusion.

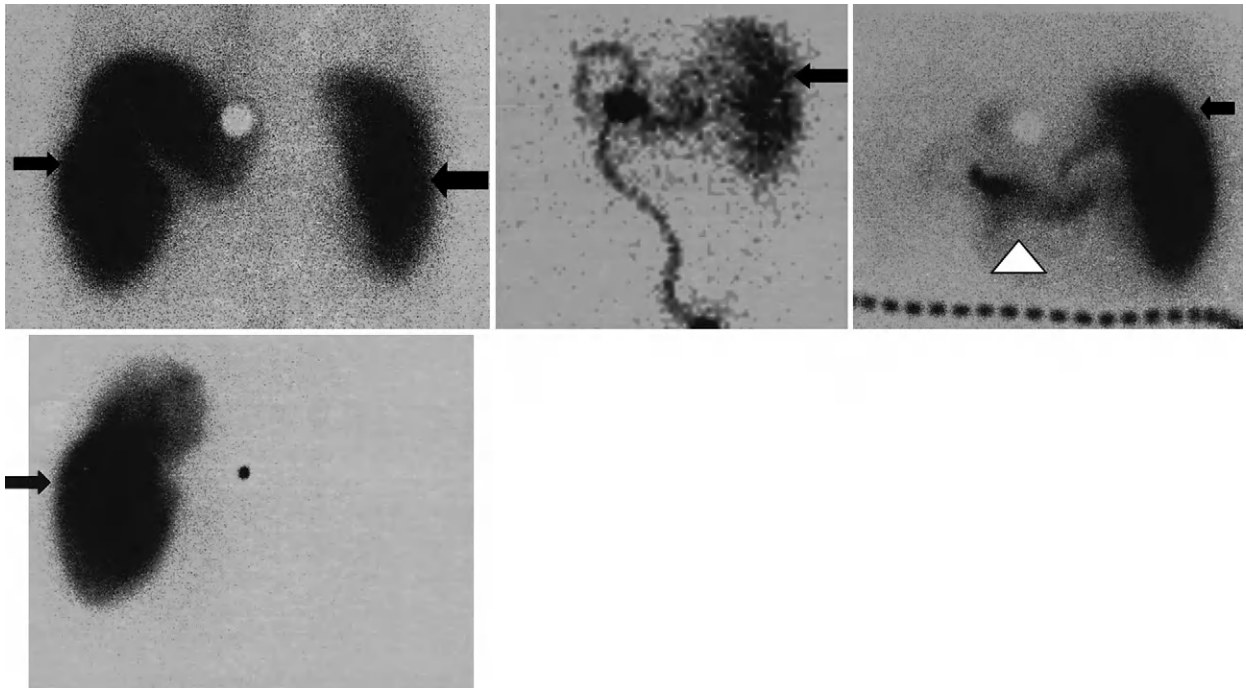

FIGURE 15.43. Composite anterior projection images. ^{99m}Tc–sulfur colloid images (*top left panel*) and perfusion phase of hepatic pump study with ^{99m}Tc–macroaggregated albumin (*top center panel*) are shown. Top right panel shows delayed pump study showing perfusion of pancreas and spleen, and the bottom left panel shows perfusion of the liver after repositioning of the arterial catheter.

CHAPTER 16

Computed tomography of the liver, biliary tract, and pancreas

Corinne Winston and Jerrold Teitcher

IMAGING OVERVIEW

Technologic advances have dramatically expanded the role of computed tomography (CT) in hepatobiliary and pancreatic imaging. New developments in CT technology, image display, and three-dimensional postprocessing have broadened the role of CT in patients with hepatobiliary and pancreatic disease. The role of imaging has extended beyond lesion detection to vascular mapping, assessment of tumor vascularity, and surgical planning (see Chapter 90). As technology continues to be refined, CT remains the main imaging modality for evaluating the liver and pancreas.

TECHNICAL ADVANCES

Major innovations have occurred in image acquisition (CT scanning), image viewing (picture archiving and communication system [PACS]), and three-dimensional post processing. Helical (spiral) CT, developed in the late 1980s, uses continuous tube rotation to acquire volumetric imaging data, while the patient moves through the gantry in a single breath hold. The data can be reconstructed into standard axial images or manipulated further to display two-dimensional or three-dimensional reconstructions of the area of interest. An important advantage of helical CT is the ability to reconstruct the data acquired on the initial scan at small intervals; this improves diagnostic accuracy by reducing partial volume artifact. Another important advantage of helical CT is reduced scan time, which reduces respiratory misregistration and allows imaging to be performed during the different phases of parenchymal enhancement after intravenous administration of a contrast agent. Helical CT makes it possible to image the liver in the hepatic arterial, portal venous, and delayed phases of enhancement, improving the detection and characterization of focal hepatic lesions.

Helical CT has undergone another major advance with the development of a new class of multidetector array scanners (MDCTs), which use a substantially greater percentage of the x-rays emitted from the tube cathode. This improves tube efficiency and permits even faster scanning. Multiple acquisitions through the liver may be obtained in a single breath hold to obtain images in the early and late arterial phases. Early arterial phase images are useful to identify variant vascular anatomy before hepatic arterial embolization, prior to placement of a hepatic arterial chemoinfusion pump, or before hepatic resection. Late arterial phase images are useful in the detection of hypervascular hepatic lesions. MDCT also allows thinner collimation (submillimeter), which improves resolution and increases detection of small hepatic lesions by 46% (Weg et al, 1998).

High-resolution images are particularly useful for CT angiography, which is used not only to determine the arterial supply to a tumor but also to assess tumor involvement along the major arteries and to delineate variant arterial anatomy. Another major advantage of MDCT is the ability to change the slice thickness of an image after it is taken. As long as the raw data are stored, the technician can retrospectively create a thinner slice and improve resolution in the craniocaudad plane.

Since the initial introduction of MDCT, technologic advances have been made to increase the number of detectors. Early MDCT scanners had four detectors accruing information per tube rotation, but more recent MDCT scanners have 64 detectors, and images now can be acquired with unprecedented speed. The increase in the number of detectors also results in a decrease in the minimum slice thickness and improved resolution in the craniocaudad plane, referred to as the *z-axis*. The improved resolution in the *z*-axis allows for the creation of isotropic *voxels*, volumes of imaging data that are equal in all dimensions, for more accurate three-dimensional images.

The introduction of PACS technology also has revolutionized CT image display. PACS permits storage, rapid retrieval, and display of CT data and provides a convenient venue for electronic distribution and review of images. PACS workstations have improved markedly the radiologist's ability to interpret the multiple images acquired for each examination. It is now possible to view images by scrolling rapidly through areas of interest. Interactive image viewing in the cine mode facilitates tracing tubular structures that course through different planes, such as the dilated biliary tree and hepatic arteries. The ability to magnify images and alter image contrast also greatly facilitates image interpretation. Ready access to recent and prior CT images is provided when PACS workstations are placed throughout the hospital, in clinical offices, and in the operating room.

CT data are acquired in volumetric data sets that can be postprocessed on a three-dimensional workstation. The generation of 16-slice MDCT scanners acquires isotropic voxels that are essentially perfect cubes of information, resulting in three-dimensional models without image distortion. Several different types of postprocessing techniques are available (Salgado et al, 2003). Maximum intensity projection (MIP) images depict only the brightest structures within the volume of data (Johnson et al, 1996, 2003; Magnusson et al, 1991; Rubin, 2003; Salgado et al, 2003; Zeman et al, 1994). When focusing on the liver in the portal venous phase of contrast enhancement, MIP images produce a concise depiction of portal venous and hepatic venous anatomy (Fig. 16.1). Volume-rendered reconstructions provide a lifelike three-dimensional model of complex anatomy that can be rotated in any direction (Fig. 16.2; Johnson et al, 1996, 2003; Rubin, 2003; Zeman et al, 1994). This type of

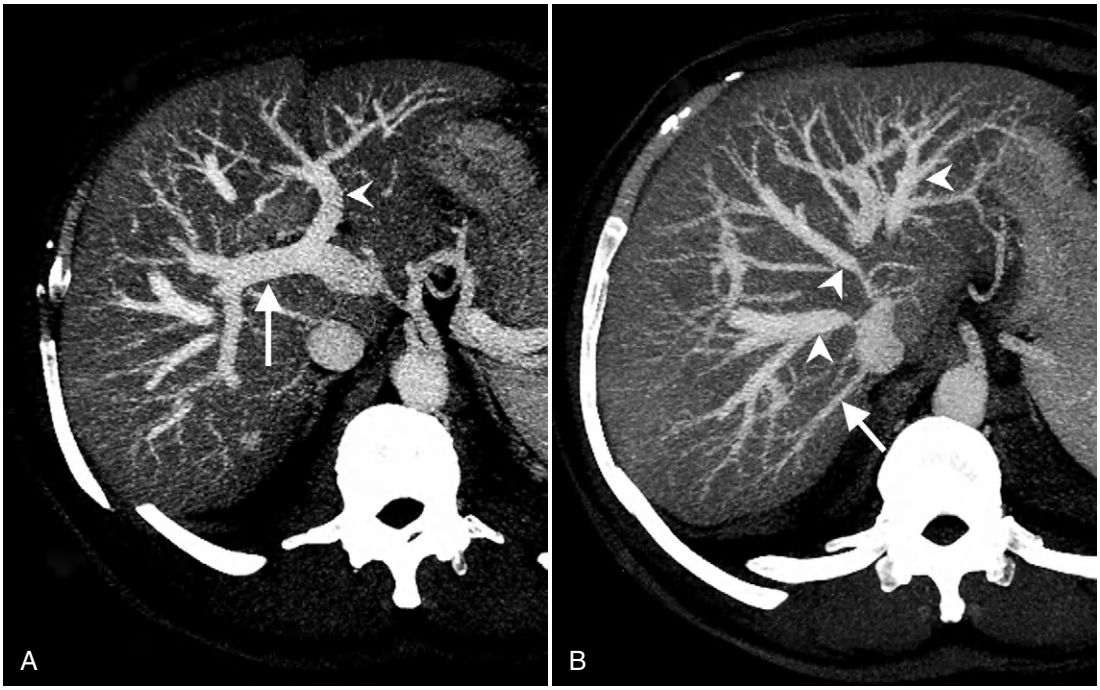

FIGURE 16.1. **A,** Thick-slab maximum intensity projection (MIP) through the portal veins reveals standard bifurcation of the main portal vein into the right (*arrow*) and left (*arrowhead*) portal veins. The anterior and posterior sectoral branches of the right portal vein are evident, as are the medial and lateral sectoral branches of the left portal vein. **B,** Thick-slab MIP image through the hepatic veins reveals the three major hepatic veins (*arrowheads*) and an accessory hepatic vein (*arrow*) draining into the inferior vena cava.

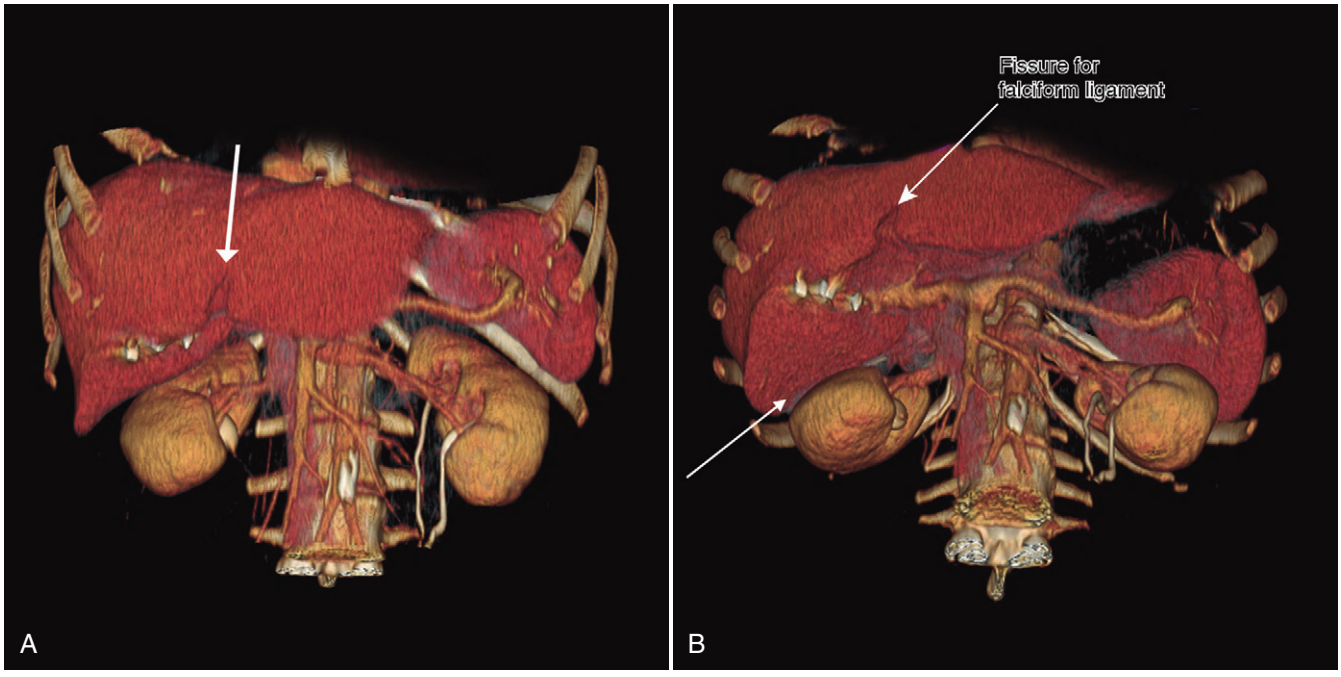

FIGURE 16.2. **A,** Volume-rendered three-dimensional (3D) image of the external contour of the liver created from contrast-enhanced axial computed tomographic data. Note the fissure for the falciform ligament seen en face (*arrow*). **B,** Volume-rendered 3D image of the same patient rotated upward reveals the undersurface of the liver. Note the surgical clips in the gallbladder fossa and the bare area of the liver (*short arrow*).

reformatting transforms the numerous axial images into an interactive three-dimensional model. Hepatic arterial anatomy can be displayed with a three-dimensional model composed of reconstructed axial images (Fig. 16.3). The relationship of tortuous vessels to the hepatic parenchyma and lobar anatomy can be depicted clearly (Fig. 16.4). It is also possible to view a rotating model that depicts the relationship of a mass to the adjacent vessels from any angle to help the surgeon conceptualize preoperatively what would be encountered at surgery (Fig. 16.5; see Chapters 90 and 92).

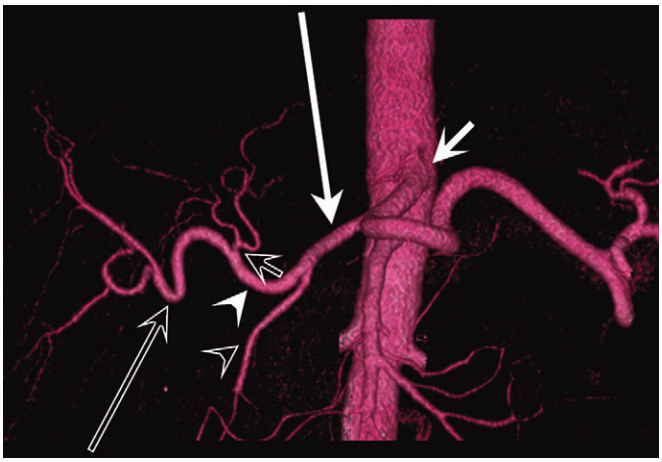

FIGURE 16.3. Classic arterial anatomy. Volume-rendered three-dimensional image created from axial contrast-enhanced computed tomographic data reveals classic branching arterial anatomy. The celiac axis (*small solid arrow*) trifurcates into the splenic artery, common hepatic artery (CHA; *long solid arrow*), and left gastric artery. The CHA gives rise to the gastroduodenal artery (*open arrowhead*) and the proper hepatic artery (*solid arrowhead*). The right hepatic artery (*long open arrow*) and the left hepatic artery (*small open arrow*) originate from the proper hepatic artery.

FIGURE 16.4. Three-dimensional reformatted image reveals the course of the left portal vein, which ascends in the umbilical fissure before looping anteriorly and inferiorly (*short arrow*) to branch into the medial (*arrowhead*) and lateral (*long arrow*) sectoral branches.

ROLE OF COMPUTED TOMOGRAPHY IN LIVER AND BILIARY IMAGING

Detailed knowledge of anatomy, patterns of disease spread, and an understanding of the surgical relevance of imaging findings are essential to the interpretation of hepatobiliary imaging studies. Although the primary goal of CT imaging is lesion detection and characterization, CT also plays a vital role in the triage of patients with malignant disease to different treatment options. Determination of the local extent of tumor, lymphadenopathy, carcinomatosis, and extraabdominal disease is crucial in staging malignant disease.

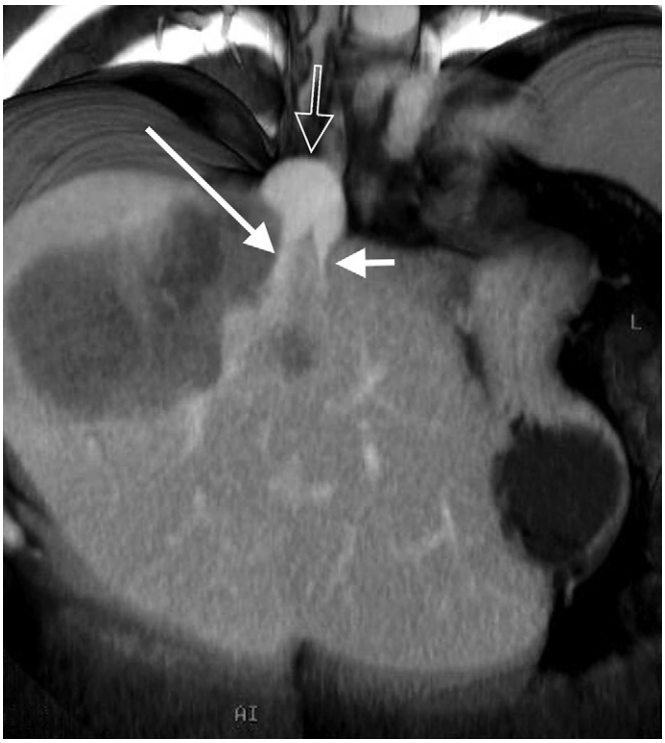

FIGURE 16.5. Volume-rendered three-dimensional image of the liver from above reveals a large colorectal metastasis involving the right lobe with extension into the medial sector of the left lobe. The mass is in continuity with the middle hepatic vein (*long arrow*) at its confluence with the inferior vena cava (IVC; *open arrow*). The middle hepatic vein and left hepatic vein (*short arrow*) drain separately into the IVC.

CT is particularly valuable in planning for hepatic resection. Using the contrast-enhanced portal and hepatic veins as anatomic landmarks, the radiologist can localize tumors into the specific hepatic segments (Fig. 16.6). The proximity of tumor to the major portal pedicles, hepatic veins, and inferior vena cava (IVC) is evident, and this information determines the extent of hepatic resection required to achieve clear surgical margins (Figs 16.7 and 16.8). CT can also help predict whether sufficient hepatic reserve will exist after hepatic resection (see Chapters 90 and 92). Hepatic atrophy (Fig. 16.9), resulting from biliary obstruction with or without portal venous occlusion, and compensatory hypertrophy can be identified on CT. Fatty infiltration and hepatic cirrhosis, processes that affect the remnant liver's ability to regenerate, are apparent. CT angiography can identify the arterial supply to tumor and can delineate the extent of tumor involvement along the arteries.

An important additional role of CT angiography for evaluating patients with hepatobiliary malignancy is the delineation of variant arterial anatomy, which occurs in more than half of the population (Michels, 1955). Visualization of the surgical field often can be limited in patients with hepatobiliary malignancy, especially with prior surgery, if the patient is obese, or when local inflammation is present, such as that accompanying a biliary stent. Preoperative knowledge of variant anatomy can assist in surgical planning (see Chapter 90 and 92), facilitate surgical dissection, and help avoid iatrogenic injury (Winston et al, 2007). CT angiography is a noninvasive alternative to direct catheter angiography for preoperative planning before

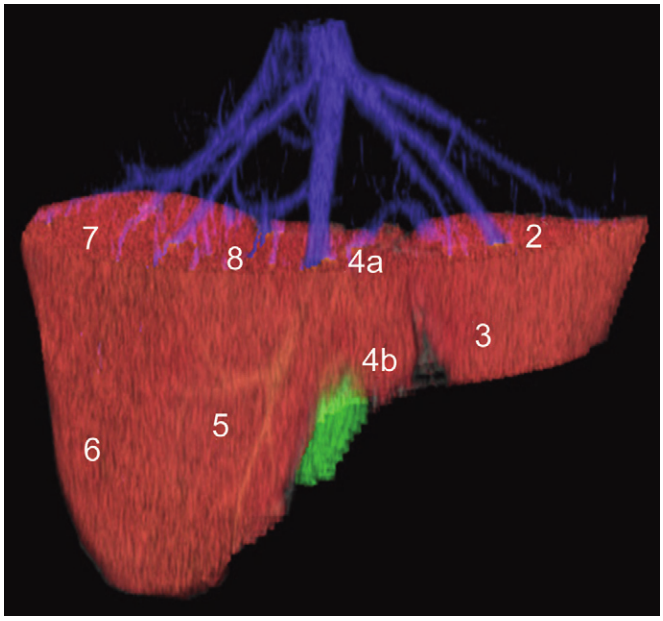

FIGURE 16.6. Volume-rendered three-dimensional model of the liver created from axially acquired computed tomographic data. The superior portion of the hepatic parenchyma has been removed to reveal the course of the hepatic veins through the liver substance as they drain into the inferior vena cava. The gallbladder is depicted in green, and hepatic segments are indicated.

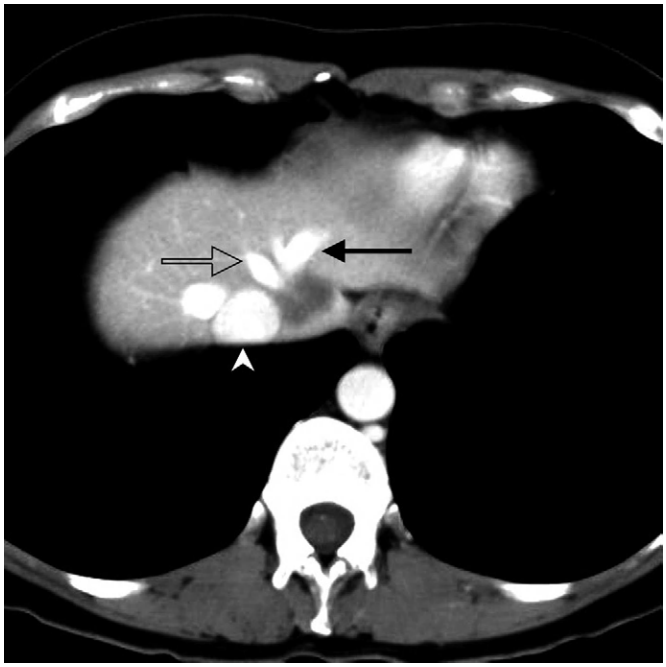

FIGURE 16.7. Contrast-enhanced computed tomography reveals a small malignant lesion in segment I abutting the middle hepatic vein (*open arrow*) and left hepatic vein (*solid arrow*) at their confluence with the inferior vena cava (*arrowhead*). The location of this small mass mandates a large hepatic resection to achieve clear surgical margins.

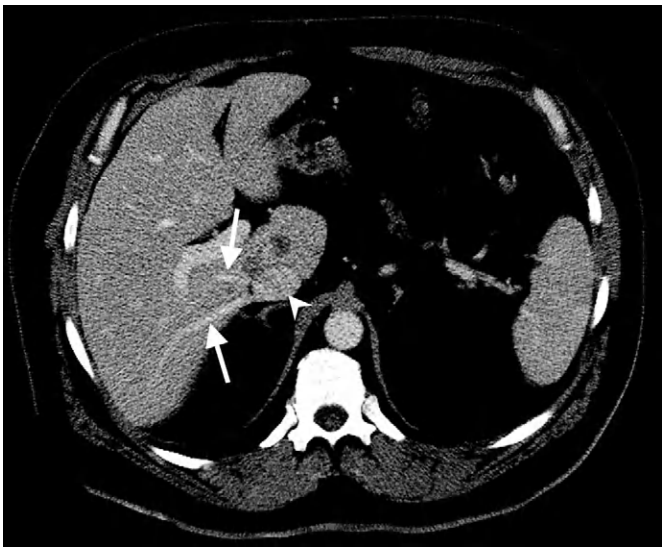

FIGURE 16.8. Contrast-enhanced computed tomography reveals a segment I mass that abuts the inferior vena cava (IVC; *arrowhead*). Two accessory hepatic veins (*arrows*) are draining into the IVC.

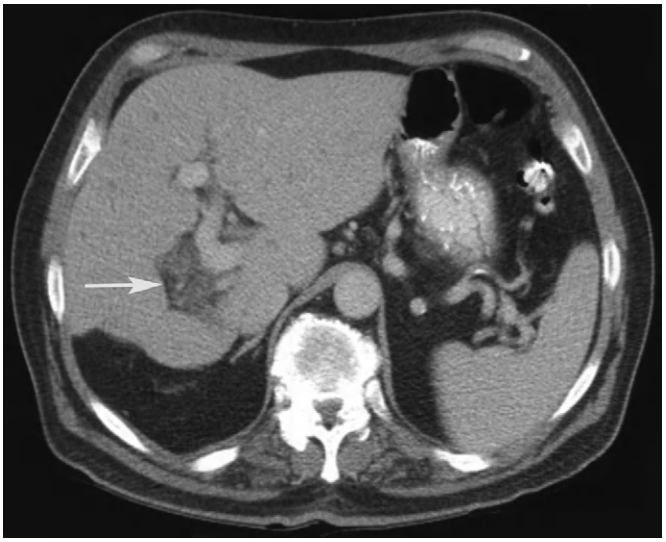

FIGURE 16.9. Right lobe atrophy as a result of an infiltrative tumor involving the right portal pedicle (*arrow*). Note the counterclockwise rotation of the porta hepatis.

placement of an intraarterial chemoinfusion pump (Kapoor et al, 2003; see Chapter 86).

The trend in surgery is toward minimally invasive procedures, and diagnostic radiology has evolved accordingly. Vascular mapping, now performed with CT, was previously possible only using invasive procedures. Continued advances in imaging and three-dimensional postprocessing undoubtedly will broaden the role of radiology in the diagnosis and treatment of patients with hepatobiliary disease.

Technique

State-of-the-art CT evaluation of the liver for hepatic resection includes contrast-enhanced CT and CT angiography. The

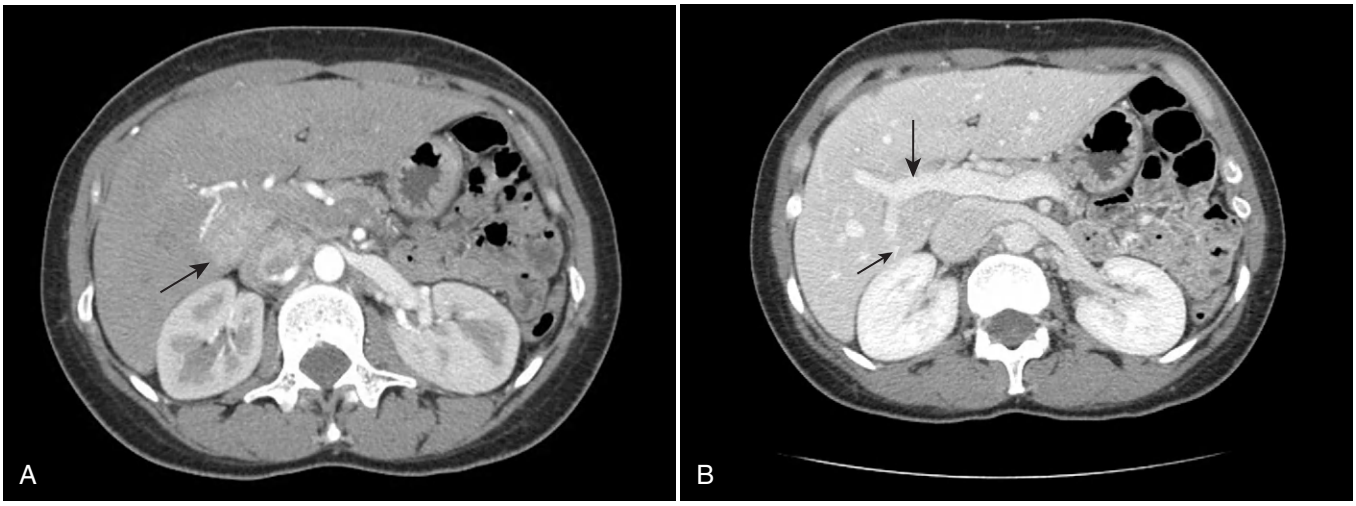

FIGURE 16.10. A, Arterial phase image through the inferior right hepatic lobe reveals branches of the right hepatic artery. Faint enhancement of a hypervascular mass is seen in segment VI, which proved to be focal nodular hyperplasia (*arrow*). **B,** Portal venous phase image through the same level reveals enhancement of the right portal vein (*long arrow*) and the sectoral branches. The mass (*short arrow*) is nearly hypointense to the liver.

specific protocols vary with the specific tumor type being evaluated, but most hepatic neoplasms are low attenuation on contrast-enhanced CT and are evaluated best during the portal venous phase of imaging. Hypervascular neoplasms, such as hepatocellular carcinoma (HCC) and metastatic neuroendocrine tumors, are evaluated using a triphasic protocol including non–contrast-enhanced CT, hepatic arterial phase images, and portal venous phase images (Fig. 16.10). Oral contrast medium is administered routinely for CT, but water is substituted when CT angiography is performed. Routine hepatic parenchymal imaging generally is performed using 5-mm slices.

Non–Contrast-Enhanced Computed Tomography of the Liver

The attenuation value of the normal liver typically varies between 54 and 60 Hounsfield units (HU), which is approximately 8 HU greater than that of the spleen, owing to glycogen and iron stores in the liver. Increased density may be seen in hemochromatosis, glycogen storage disease, Wilson disease, β-thalassemia, sickle cell disease, and with certain drugs (amiodarone, cisplatin). A false appearance of increased hepatic density may occur in anemia, in which the decreased attenuation of the blood pool gives the impression of increased hepatic density relative to the intrahepatic vessels. Decreased hepatic density most frequently is related to fatty infiltration of the liver or occasionally secondary to hepatic edema. Noncontrast CT is useful for detecting diffuse abnormalities, such as hemochromatosis or fatty infiltration (Figs. 16.11 and 16.12), in which the attenuation of the liver is increased (hemochromatosis) or decreased (fatty infiltration). Both of these processes may be obscured by the administration of intravascular contrast

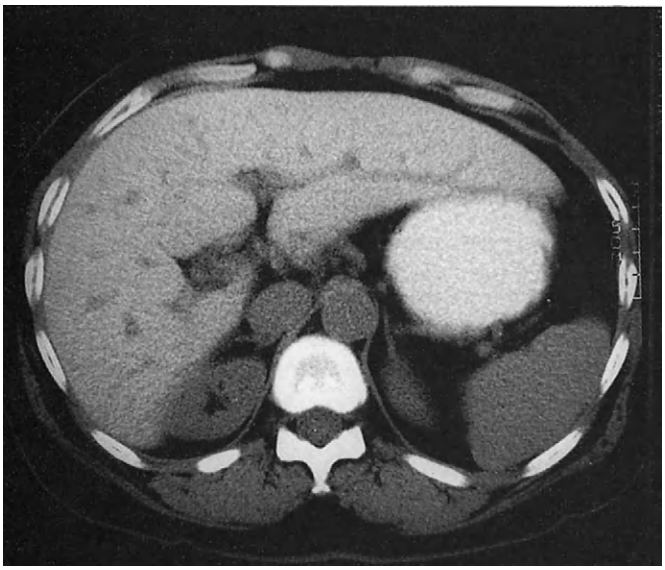

FIGURE 16.11. Nonenhanced computed tomography through the liver of a patient with hemochromatosis shows diffuse increased attenuation of the liver compared with the spleen.

FIGURE 16.12. Nonenhanced computed tomography through the liver of a patient with fatty infiltration shows low attenuation of the hepatic parenchyma compared with the hepatic blood vessels and liver capsule.

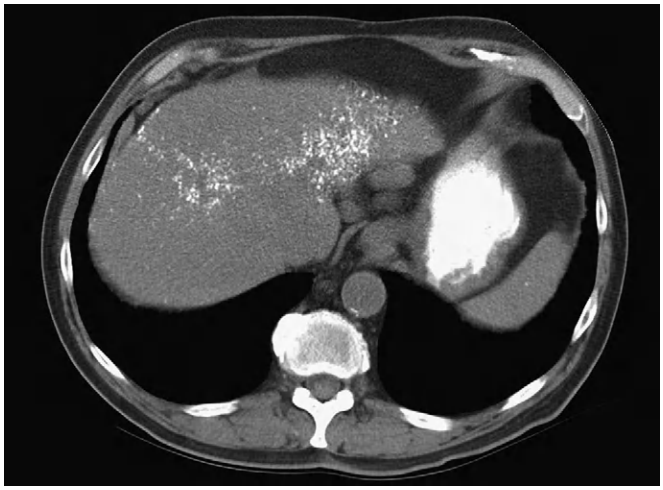

FIGURE 16.13. Unenhanced computed tomography reveals numerous calcifications in a patient with amyloid.

medium. Hemorrhage or faint calcifications also are better visualized on unenhanced CT (Fig. 16.13).

Hepatic neoplasms usually have a high water content, resulting in relative hypoattenuation compared with liver parenchyma. The portal veins and bile ducts also are of lower attenuation than liver parenchyma, and a vessel running vertically through a section may mimic a small tumor, leading to errors in diagnosis. On unenhanced studies, the attenuation difference between liver and tumor may be subtle and may require viewing at very narrow window widths to allow focal lesion detection, but much higher lesion-to-liver attenuation difference can be achieved by the administration of intravenous contrast medium (Tidebrant et al, 1990).

Contrast-Enhanced Computed Tomography of the Liver

The administration of an iodinated contrast agent serves many purposes in hepatic CT imaging, including improved lesion detection and characterization and better vascular mapping. Because a precise rate of injection is essential to image quality, a dedicated power injector is required. Different methods are commercially available to determine the time of maximal arterial enhancement for each patient, depending on factors such as cardiac function and state of hydration (Sica et al, 2000).

Lesion conspicuity is enhanced when there is maximal contrast between a lesion and the surrounding parenchyma. The liver receives 75% to 80% of its blood supply from the portal venous system and only 20% to 25% from the hepatic artery; however, the majority of liver tumors receive most of their blood supply from the hepatic arterial system (Honda et al, 1992). The noncirrhotic liver displays maximal contrast enhancement at approximately 70 seconds from the start of the intravenous administration of contrast medium. At this time, referred to as the *portal venous phase* of enhancement, maximal contrast between a liver lesion and the surrounding parenchyma is seen with clear delineation of the portal and hepatic veins. Routine evaluation of the liver should be performed using portal venous phase imaging.

The pattern of contrast enhancement also is important for lesion characterization. Certain lesions, such as focal nodular hyperplasia (FNH) and hemangiomata (discussed in greater detail later in this chapter), have specific patterns of enhancement on arterial phase and portal venous phase images. Hypervascular malignant neoplasms, such as HCC and metastatic neuroendocrine carcinoma, display prominent contrast enhancement and increased lesion conspicuity on the arterial phase images, but these lesions may become isodense to the remaining liver and and may be invisible on the portal venous phase images (Fig. 16.14). When HCC or neuroendocrine mestastases are suspected, arterial phase images should be acquired in addition to the routine portal venous phase images.

Computed Tomographic Angiographic of the Liver

MDCT scanners can acquire high-resolution images (<1-mm slice thickness) of the aorta and hepatic arterial anatomy, referred to as *early arterial phase images*. The intravenous administration of contrast material is performed using a high injection rate of 4 to 5 mL/s to provide maximal contrast enhancement of the arteries, before opacification of the veins or abdominal organs. The same volume of intravenous contrast material is

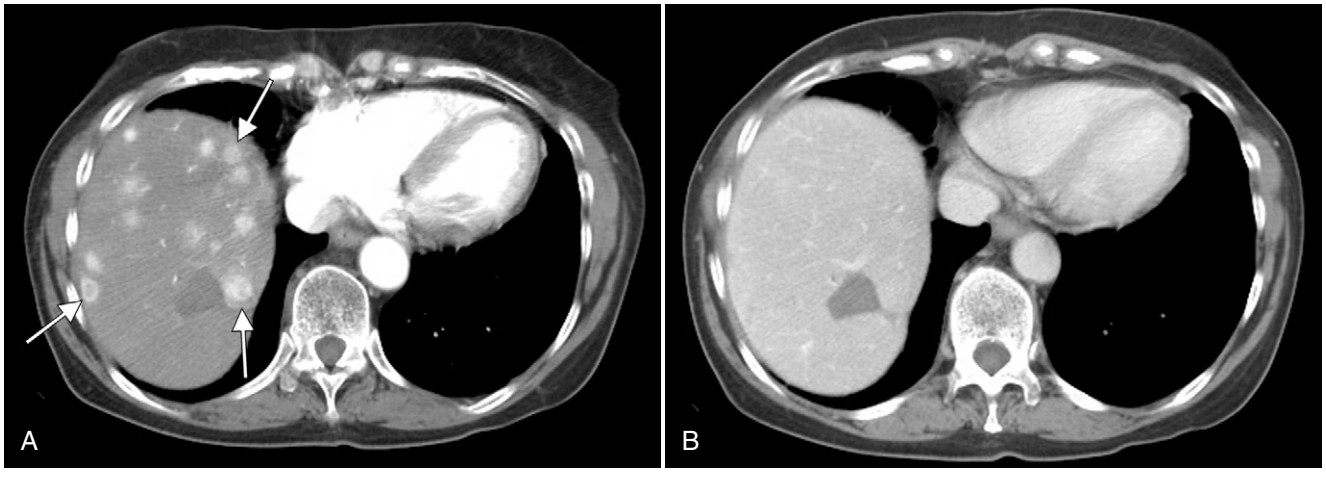

FIGURE 16.14. Arterial and portal venous phase images as part of a triphasic examination in a patient with metastatic renal cell carcinoma. **A,** Late arterial phase image reveals multiple hypervascular enhancing foci of metastatic renal cell carcinoma (*arrows*). **B,** Portal venous phase image at the same level does not reveal the numerous masses. The low-attenuation lesion represents a partially treated hypoattenuating metastasis.

administered as that for routine abdominal CT. Water is administered as a negative contrast agent to facilitate three-dimensional postprocessing. Additional late arterial phase images can be obtained through the hepatic parenchyma in the same breath hold in patients with suspected hypervascular lesions. A major attribute of CT angiography is that it is performed as an adjunct to a routine CT scan. CT of the chest, abdomen, and pelvis can be performed during the same examination to allow for a staging examination in addition to vascular mapping.

Lesion Evaluation

In a patient with multiple hepatic lesions, each lesion should be evaluated independently, because benign and malignant lesions may coexist (Fig. 16.15). Mistaking an incidental benign lesion for a malignant mass has clear and potentially important implications in patient management, perhaps leading to unnecessary invasive procedures or resulting in a diagnosis of metastatic disease that alters treatment recommendations. When assessing lesion size for treatment response on serial CT scans, it is important to compare serial, unenhanced CT scans with unenhanced CT scans and to also compare contrast-enhanced scans with contrast-enhanced scans. Nazarian and colleagues (1999) showed that colorectal metastases appeared different in size on pre–contrast-enhanced and post–contrast-enhanced CT scans obtained as part of the same examination. On average, hepatic metastases from colorectal carcinoma appeared significantly smaller after contrast media administration (Nazarian et al, 1999).

Anatomy

Gross Morphology

Three scissurae interrupt the surface of the liver and help define its segmentation (see Chapter 1B). The interlobar fissure is an incomplete structure that defines the inferior separation between the right and the left liver; the scissura here is generally difficult to identify on axial CT, but its position may be estimated, because it is orientated in a vertical plane defined by the gallbladder fossa inferiorly (Fig. 16.16) and the middle hepatic vein superiorly. The gallbladder lies in the main interlobar scissura on the inferior surface of the liver. Three-dimensional reformatting of axial CT data provides a clear depiction of the interlobar scissura and its relationship to the hepatic segments (see Fig. 16.6).

Slightly to the right of midline, toward the patient's left side, the anteroinferior portion of the diaphragmatic surface of the liver is notched by the fissure for the ligamentum teres, or *umbilical fissure,* which defines the inferior border between the medial and lateral segments of the left liver. The ligamentum teres passes through this fissure and usually is surrounded by a small amount of fat. When the ligamentum teres passes out of the liver ventrally, it is located in the free edge of the falciform ligament. The third fissure is present at the point of contact between the lateral segments of the left hepatic lobe and the caudate lobe. This is the fissure for the ligamentum venosum, which is in continuity with the umbilical fissure.

Segmental Anatomy

The segmental anatomy of the liver is based on both the hepatic venous outflow and the inflow pedicles. A functional scheme that corresponds to the liver anatomy and is useful surgically has been described (Bismuth, 1982). The three main hepatic veins divide the liver into four sectors, each of which is independent in that it receives a separate portal venous and hepatic arterial supply and is drained by a separate bile duct. The middle hepatic vein divides the liver into a right and left liver. The right liver is divided into two sectors by the right hepatic vein, and the left liver is divided similarly by the left hepatic vein. Because axial CT readily shows the course of all three major hepatic veins on contrast-enhanced scans obtained near the diaphragm, the major hepatic sectors are easy to identify at this level. The inferior boundary between the anterior and posterior sectors of the right lobe has to be estimated by extrapolating the line of the right hepatic vein onto lower sections. An imaginary line drawn between the IVC and the gallbladder divides the right and left liver on caudal sections and corresponds to the line of the middle hepatic vein. Three-dimensional reformatting can assist in localization of the hepatic segments (see Fig. 16.6). The fissure for the ligamentum teres divides the medial and lateral segments of the left liver and corresponds to the line of the left hepatic vein. The anterior and posterior sectors of the right lobe are subdivided into inferior (V and VI) and superior (VIII and VII) segments. The right portal vein runs horizontally as it enters the right liver, and this level demarcates the anterior and posterior sectors.

Vascular Anatomy

In classic arterial anatomy (see Chapter 1B), the celiac axis gives rise to the common hepatic artery, which bifurcates into the proper hepatic artery and the gastroduodenal artery (see Fig. 16.3). The proper hepatic artery divides into the right and left branches before entering the liver, but the point at which the proper hepatic artery gives rise to the left and right hepatic arteries varies. Although classic arterial anatomy is the most common pattern seen, variant hepatic and celiac arterial anatomy has been reported in 55% of patients based on initial cadaveric dissections by Michels (1955). Many of these variants have significance for preoperative planning and surgical management. Preoperative knowledge of variant anatomy can assist in selection of treatment options and in surgical planning, and

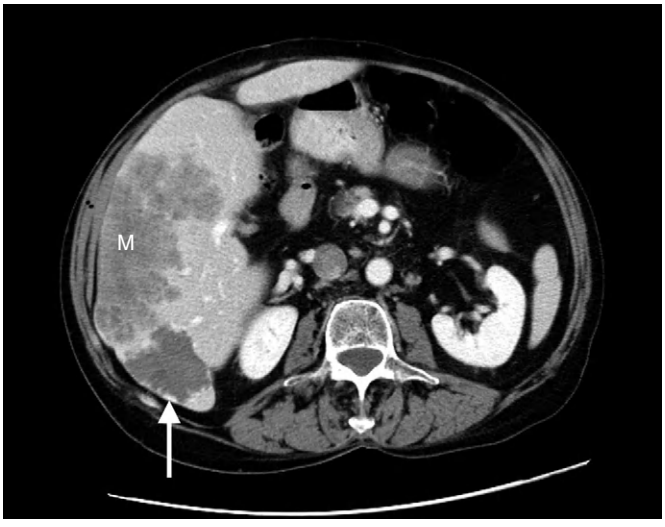

FIGURE 16.15. Metastatic disease (*M*) adjacent to a hemangioma. Note the peripheral nodular, clumplike enhancement (*arrow*) within the hemangioma.

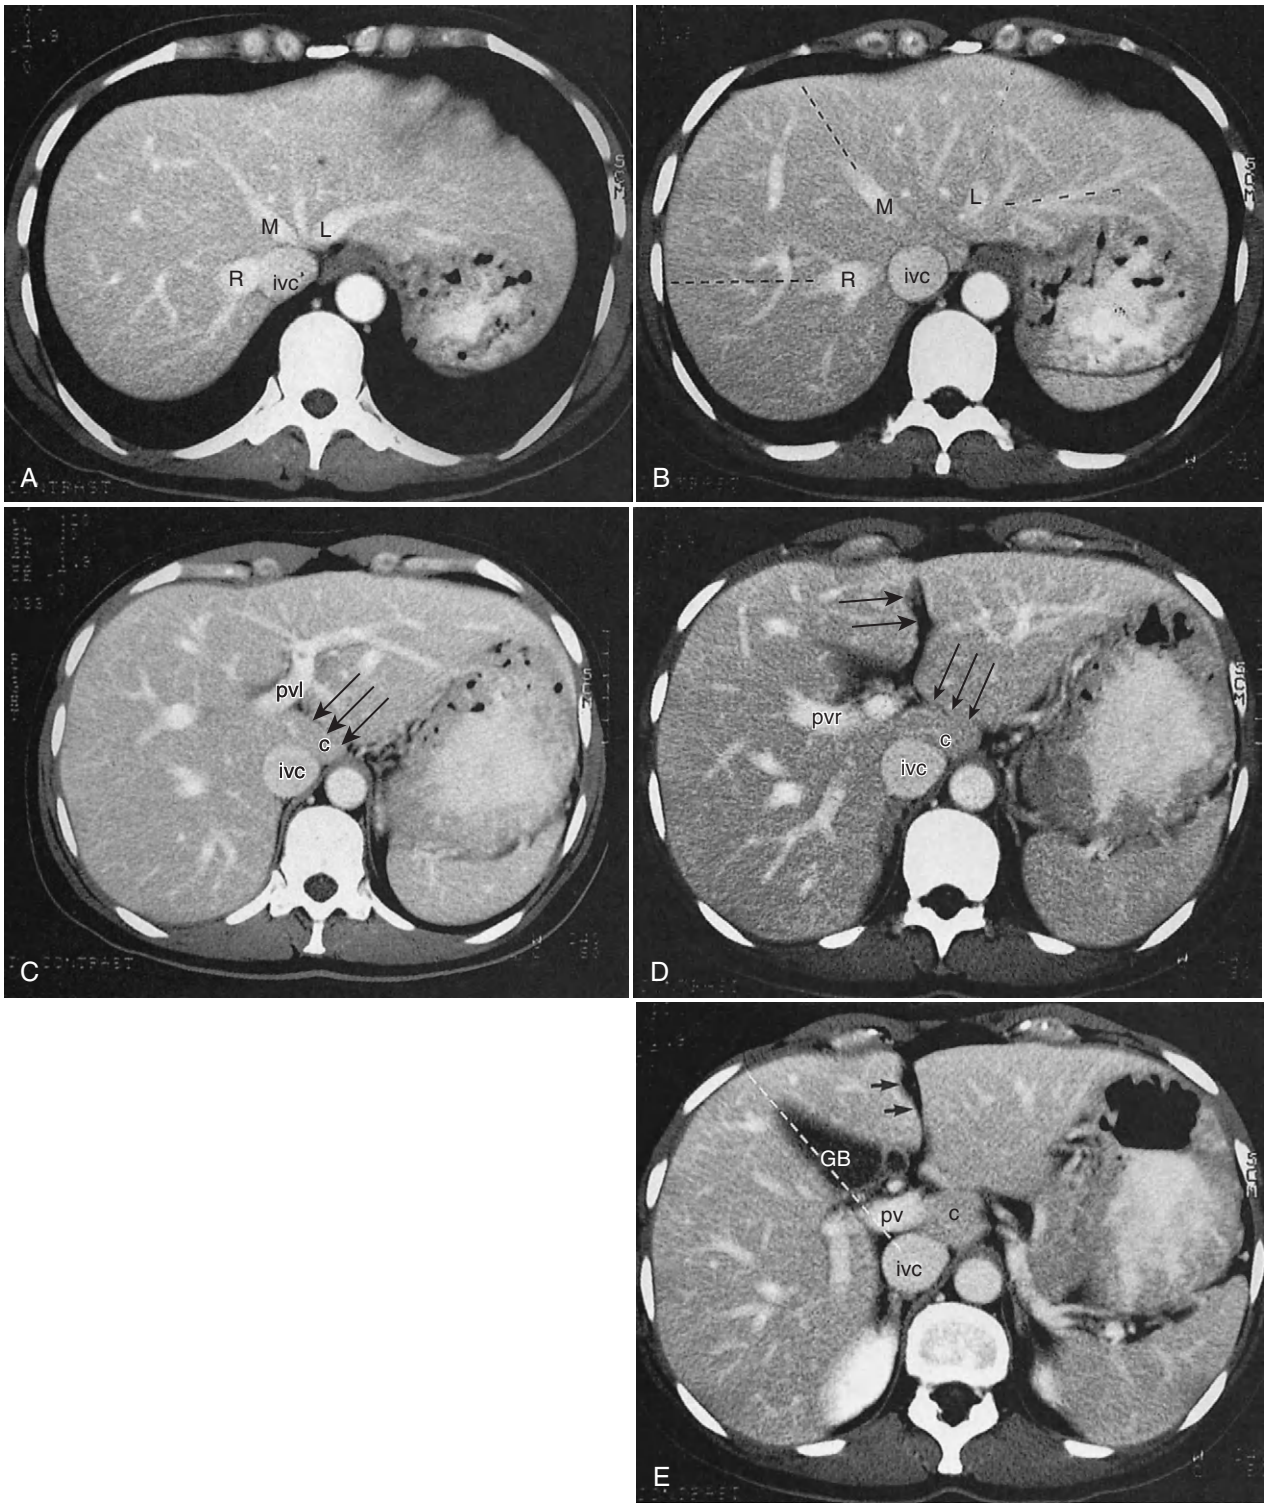

FIGURE 16.16. Normal hepatic segmental and vascular anatomy on computed tomography. **A,** On cephalad sections, the three hepatic veins are seen to enter the inferior vena cava (*ivc*). **B,** The lines of the hepatic veins divide the liver into sectors. The right hepatic vein divides the right liver into anterior and posterior sectors; the middle hepatic vein separates the right from the left liver and represents the line of the interlobar scissura; the left hepatic vein separates segments II and III of the left lobe. **C,** Approaching the midpoint of the liver, the left portal vein (*pvl*) is seen. The fissure for the ligamentum venosum (*arrows*) divides the caudate lobe (*c*) from the left lateral segments. **D,** The next section shows the horizontal portion of the right portal vein (*pvr*). The fissure for the ligamentum teres is now seen (*large arrows*); this structure divides the lateral segments of the left liver from the caudate lobe (*c*), segment IV. **E,** On the last section, the gallbladder (*GB*) has come into view; a line drawn along the axis of the gallbladder to the IVC represents the inferior extent of the interlobar scissura. *R,* right hepatic vein; *M,* middle hepatic vein; *L,* left hepatic vein.

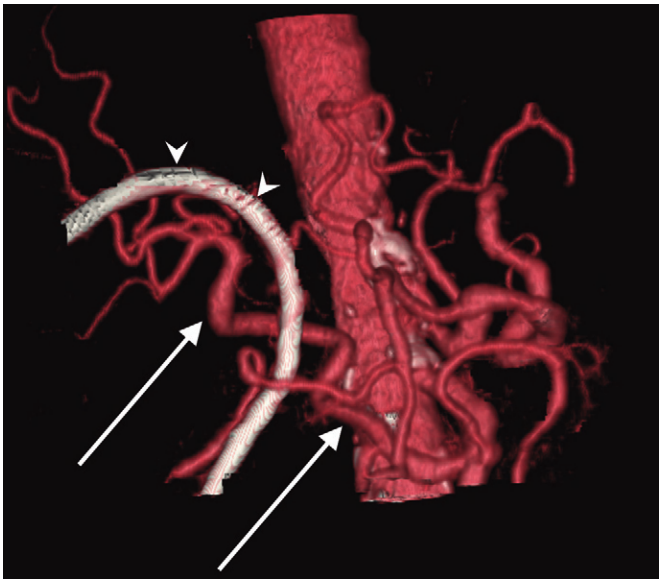

FIGURE 16.17. Three-dimensional volume-rendered computed tomographic angiogram reveals a replaced right hepatic artery (*arrows*) originating from the superior mesenteric artery. The right hepatic artery courses posterior to a stent in the common bile duct (*arrowheads*).

it facilitates surgical dissection and may help avoid iatrogenic injury (Figs. 16.17 and 16.18).

The portal vein originates at the junction of the splenic vein (SV) and superior mesenteric vein (SMV), immediately posterior to the neck of the pancreas. It courses toward the right and cephalad, as it enters the hepatoduodenal ligament. Within this ligament, the portal vein courses parallel to the proper hepatic artery, which lies on its anteromedial surface, and the common bile duct, which lies on its anterolateral surface. After entering the hepatic parenchyma, the portal vein branches to supply each portal sector (see Fig. 16.1A) and subsequently each segment. A spectrum of portal venous variants has been described, many of which have major implications for safe and efficacious hepatic resection and percutaneous hepatobiliary intervention. Covey and colleagues (2004) reported the presence of variant portal venous anatomy in 35% of a group of 200 patients studied. CT is ideally suited to display these variants, an awareness of which may help avoid iatrogenic injury (Fig. 16.19).

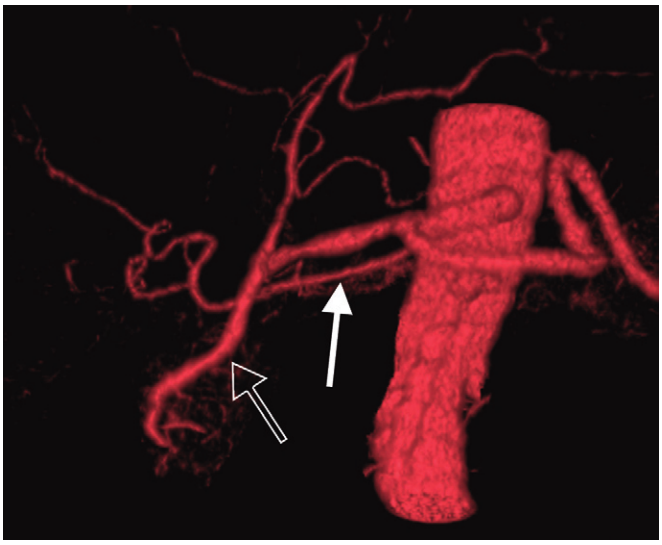

FIGURE 16.18. Three-dimensional volume-rendered computed tomographic angiogram reveals the right hepatic artery (*solid arrow*) originates from the celiac axis and courses posterior to the gastroduodenal artery (*open arrow*).

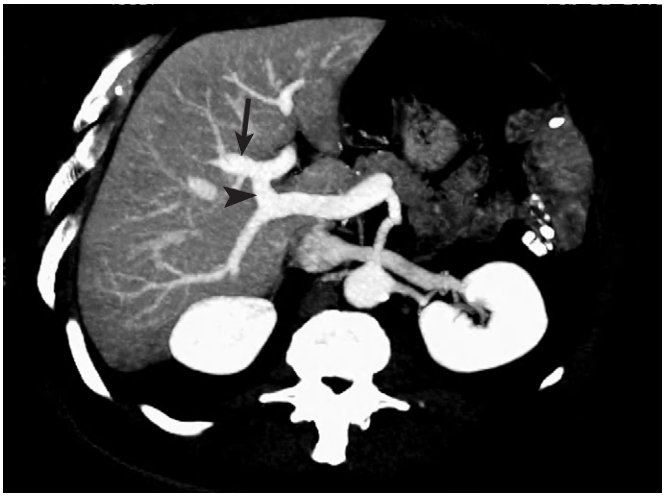

FIGURE 16.19. Variant portal venous anatomy. Thick-slab maximum intensity projection reveals that the portal venous branch perfusing the anterior sector of the right hepatic lobe (*arrow*) shares a common trunk with the left portal vein (*arrowhead*).

The hepatic veins course between the hepatic sectors and have a short extrahepatic course before joining the IVC (Blumgart et al, 2001). The right hepatic vein drains directly into the IVC, and the middle hepatic vein and left hepatic vein usually join before draining into the IVC. A variable number of retrohepatic veins drain from the posterior aspect of the liver into the IVC, and a large inferior right hepatic vein, referred to as an *accessory right hepatic vein,* may be present in some patients (see Fig. 16.1B).

Biliary Anatomy

The intrahepatic biliary tree branches in a fashion nearly identical to the portal system (Fig. 16.20; see Chapter 1B). The left and right hepatic ducts form the common hepatic duct, near the lateral margin of the main portal vein, near its junction with the right portal vein. The common hepatic duct continues inferiorly toward the left and posteriorly, and it maintains its anterolateral position with respect to the portal vein throughout its course within the hepatoduodenal ligament. It becomes retroperitoneal at the level of the head of the pancreas and occupies a position on the posterolateral surface of the pancreas, until it joins the pancreatic duct immediately before entering the ampulla of Vater. The confluence of the right and left hepatic ducts is often seen lying anterior to the portal venous confluence.

Visualization of the intrahepatic bile ducts with CT originally was considered to be evidence of biliary obstruction; but with newer scanners and thin collimation, peripheral bile ducts measuring 1 to 3 mm may be seen in normal subjects (Liddell et al, 1990). The common duct, which measures 3 to 6 mm in cross-sectional diameter, is seen as a circular structure of near-water density posterolateral to the head of the pancreas on a

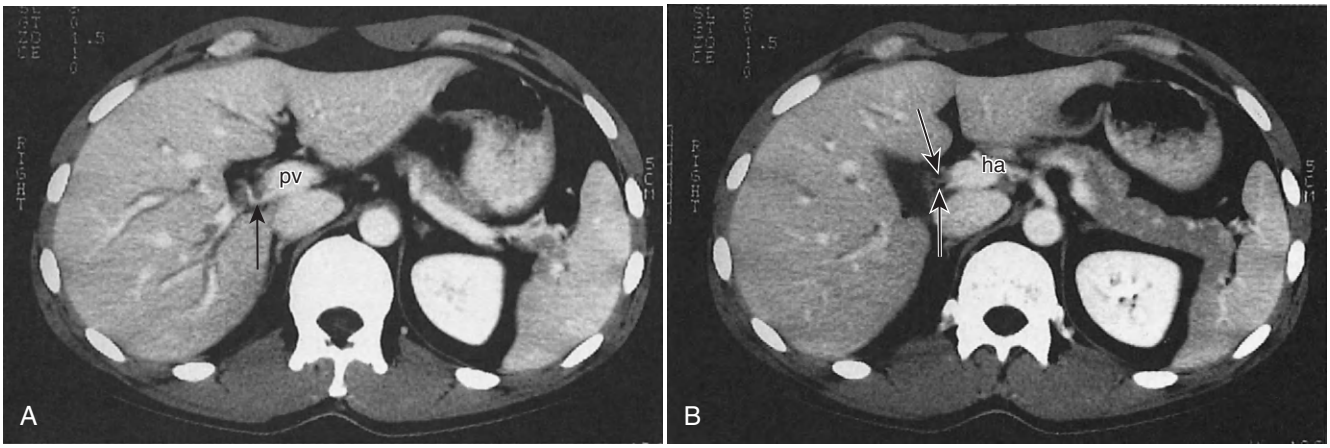

FIGURE 16.20. Contrast-enhanced computed tomography in a patient with a minimally dilated biliary system. **A,** The intrahepatic bile ducts are seen as branching, low-attenuation structures adjacent to the portal veins. At the porta hepatis, the hepatic artery (*arrow*) is seen to pass between the main portal vein (*pv*) and the common hepatic duct. **B,** A scan caudal to the porta hepatis shows the common hepatic duct and the cystic duct running adjacent to each other in the hepatoduodenal ligament (*arrows*). The hepatic artery (*ha*) is in a more medial position.

postcontrast scan. The CT diagnosis of biliary obstruction is based on the demonstration of dilated intrahepatic or extrahepatic bile ducts. Dilated intrahepatic ducts appear on CT as linear branching or circular structures of near-water density that enlarge as they approach the junction of the left and right hepatic ducts in the porta hepatis. The extrahepatic bile duct is considered unequivocally dilated if it is 9 mm or more in diameter; less than 7 mm is considered normal. High-resolution images and reformatting techniques allow for depiction of the biliary tree on CT that was once impossible (Fig. 16.21).

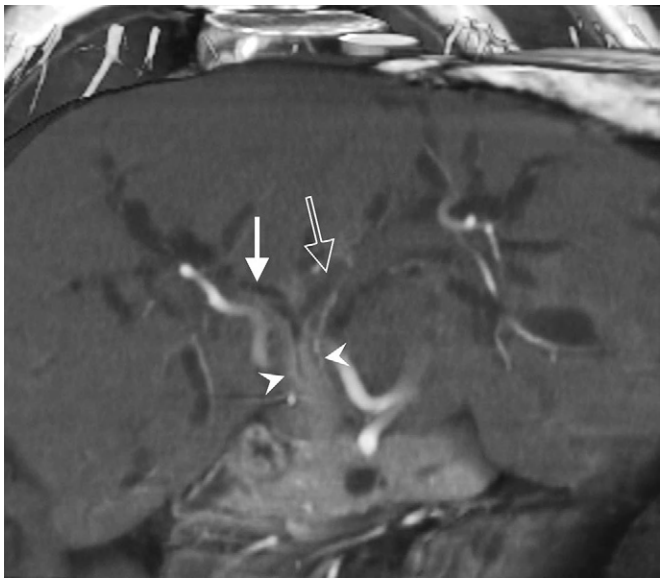

FIGURE 16.21. Coronal reformatted image of the confluence of the right (*solid arrow*) and left (*open arrow*) hepatic ducts reveals soft tissue thickening and enhancement along the common bile duct (*arrowheads*), reflecting recurrent gallbladder carcinoma in a patient after cholecystectomy. Note the bilobar intrahepatic biliary ductal dilation.

Although CT has proved to be accurate in establishing a diagnosis of biliary obstruction, a direct correlation between the caliber of the biliary tree and the presence of clinically significant obstruction has not been found. In patients with significant dilation of the biliary tree, in whom the obstruction is later relieved surgically or by spontaneous passage of a calculus, the bile duct may remain more dilated than normal for the remainder of the patient's life. In such patients, the CT findings may falsely suggest the presence of biliary obstruction. Likewise, a normal-caliber bile duct can be observed in the presence of a surgically correctable cause of jaundice. Intermittently obstructing calculi and subtle strictures of the extrahepatic duct may be present when the overall duct caliber is normal. When a discrepancy exists between clinical or biochemical evidence and the CT findings, magnetic resonance cholangiopancreatography (MRCP) or direct cholangiography by the percutaneous or endoscopic route should be performed to resolve the problem.

CT can also help ascertain the cause of obstruction in many cases. Although abrupt termination of the extrahepatic duct suggests a malignant process, smooth and gradual tapering of bile ducts favors benign disease. The use of water as a negative oral contrast agent aids in identification of small distal bile duct calculi.

Benign Tumors and Tumorlike Conditions of the Liver

Cyst (See Chapters 69 and 79)

Hepatic cysts are common and occurr in 2% to 7% of the population (Horton et al, 1999). Hepatic cysts may be either *congenital* or *acquired.* Congenital cysts are more common and are thought to be caused by a malformation of a bile duct that has lost its communication with the remainder of the biliary tree. Lined by a single layer of cuboidal or columnar epithelium that secretes fluid, the cyst fills with serous fluid (Blumgart et al, 2001). The acquired type of hepatic cyst is usually secondary to inflammation, trauma, or parasitic disease. Hepatic cysts typically are discovered incidentally and have no malignant potential.

FIGURE 16.22. Multiple simple hepatic cysts in a patient with polycystic kidneys.

At CT, a hepatic cyst is round or ovoid and sharply defined with an imperceptible wall; it shows water attenuation and does not enhance after administration of an intravenous contrast agent. Although small cysts do not affect the adjacent hepatic parenchyma, very large cysts may result in lobar atrophy with contralateral compensatory hypertrophy (Blumgart et al, 2001).

Multiple hepatic cysts may be associated with polycystic renal disease (Fig. 16.22) but may occur in the absence of renal cysts. Occasionally, patients may present with discomfort or biliary obstruction secondary to a large cyst (Fig. 16.23). In such cases, therapeutic intervention may be indicated.

FIGURE 16.23. Giant simple cyst arising in right lobe of liver. It is well circumscribed and has homogeneous, near-water attenuation.

Hemangioma

Hemangiomas (see Chapter 79) are the most benign solid tumors of the liver (Blumgart et al, 2001). The incidence of cavernous hemangiomata has been reported as 7% in an autopsy series (Karhunen, 1986). Cavernous hemangiomata may range in size from less than 1 cm to greater than 40 cm, referred to as *giant hemangiomata* (Blumgart et al, 2001). Hemangiomata usually are incidentally detected lesions seen in women (Horton et al, 1999).

Hemangiomata are composed of endothelium-lined vascular spaces separated by fibrous septa, and they derive their blood supply from the hepatic artery (Horton et al, 1999). On unenhanced CT, a hemangioma has low attenuation compared with the adjacent hepatic parenchyma. After the intravenous administration of contrast material, peripheral globular enhancement is seen on the arterial phase images. The attenuation of the peripheral nodules equals that of the aorta (Quinn & Benjamin, 1992), and venous phase images reveal centripetal enhancement to the center of the lesion (Leslie et al, 1995; Nelson & Chezmar, 1990). Because the peripheral, nodular, clumplike enhancement is seen best on arterial phase images, it is important to acquire images during this phase (Fig. 16.24).

Giant hemangiomata (>6 to 10 cm; Bouras et al, 1996; Mitsudo et al, 1995; Ros et al, 1987) have a heterogeneous appearance with a low-attenuation central scar on unenhanced CT. The low attenuation is attributed to thrombosis, hyalinization, and fibrosis (Ros et al, 1987). The typical early, peripheral, nodular, clumplike enhancement is observed on the arterial phase images, but giant hemangiomata often do not completely fill in with contrast material on delayed images (Fig. 16.25; Vilgrain et al, 2000).

Most hemangiomata do not cause clinical symptoms. However, larger tumors are more likely to cause symptoms such as abdominal pain, increasing abdominal girth, early satiety, and nausea and vomiting (Blumgart et al, 2001). These symptoms are attributed to the rapid expansion of the tumor or thrombosis and infarction resulting in stretching or inflammation of the Glisson capsule (Blumgart et al, 2001). Large hemangiomata can lead to complications such as an inflammatory process manifested by low-grade fever, weight loss, abdominal pain, and elevated erythrocyte sedimentation rate (Takayasu et al, 1990). Other complications include Kasabach-Merritt syndrome, a coagulopathy with systemic fibrinolysis and thrombocytopenia (Maceyko & Camisa, 1991), intratumoral hemorrhage, spontaneous rupture resulting in hemoperitoneum (Vilgrain et al, 2000), and volvulus of a pedunculated hemangioma (Tran-Minh et al, 1991). Pain or secondary complications may necessitate surgical intervention. CT angiography can play an important role in delineating the arterial supply to these tumors, facilitating surgical enucleation or hepatic resection.

Focal Nodular Hyperplasia

FNH (see Chapter 79) is the second most common benign liver tumor, with a reported prevalence ranging from 0.9% (Nguyen et al, 1999) to 3% (Karhunen, 1986). FNH usually is incidentally detected when patients are scanned for other reasons (Carlson et al, 2000). With the increased use of CT and faster scan protocols, FNH is being detected more frequently (Carlson et al, 2000). FNH is more commonly seen in women, and it occurs in relatively young patients (Nguyen et al, 1999). At histopathologic analysis, classic FNH contains nodular

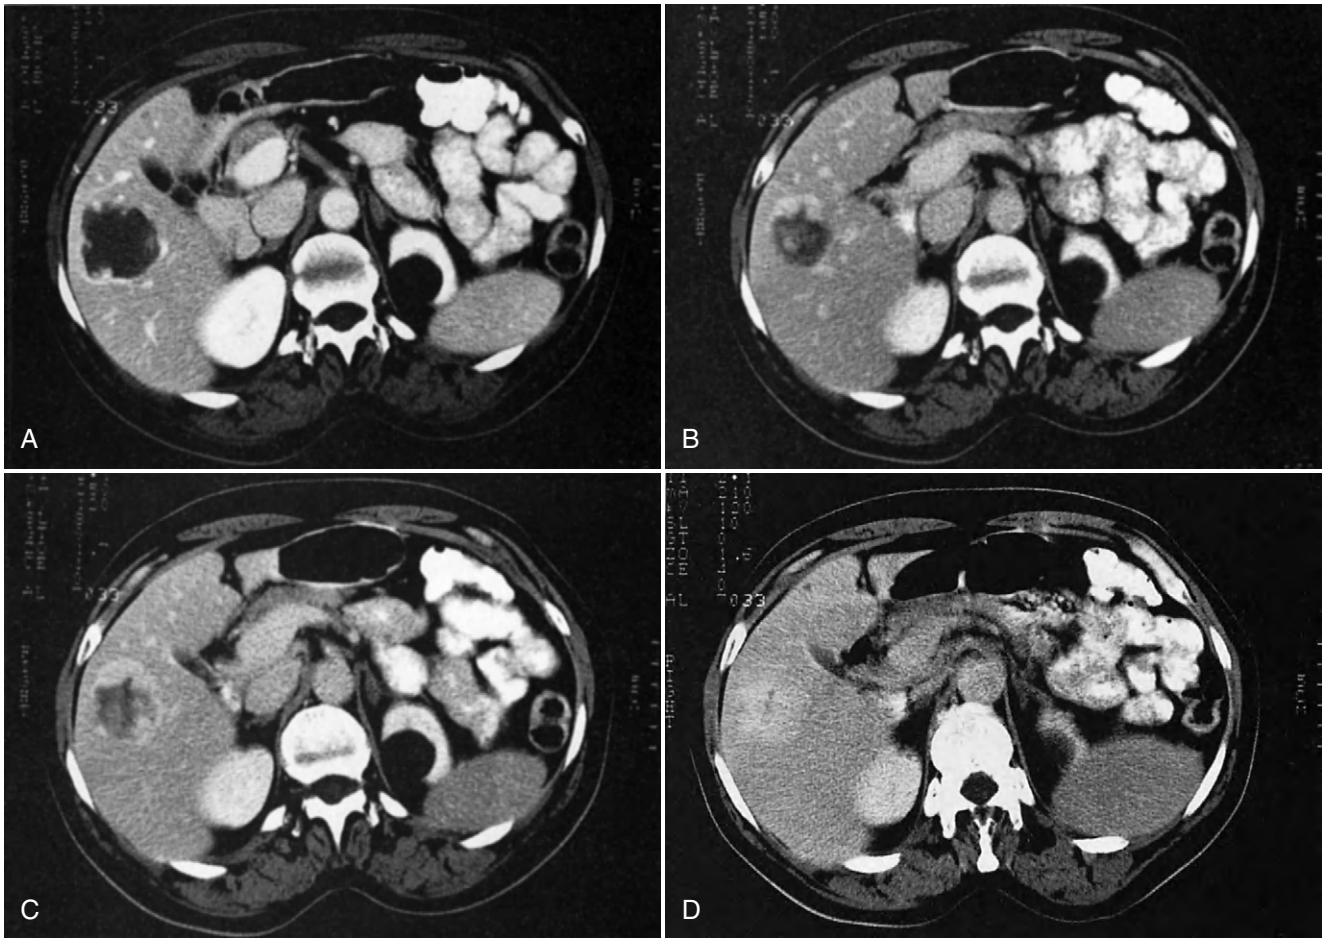

FIGURE 16.24. Cavernous hemangioma of the right liver showing typical enhancement starting at the periphery of the lesion (**A** to **C**) and finally showing complete opacification (**D**).

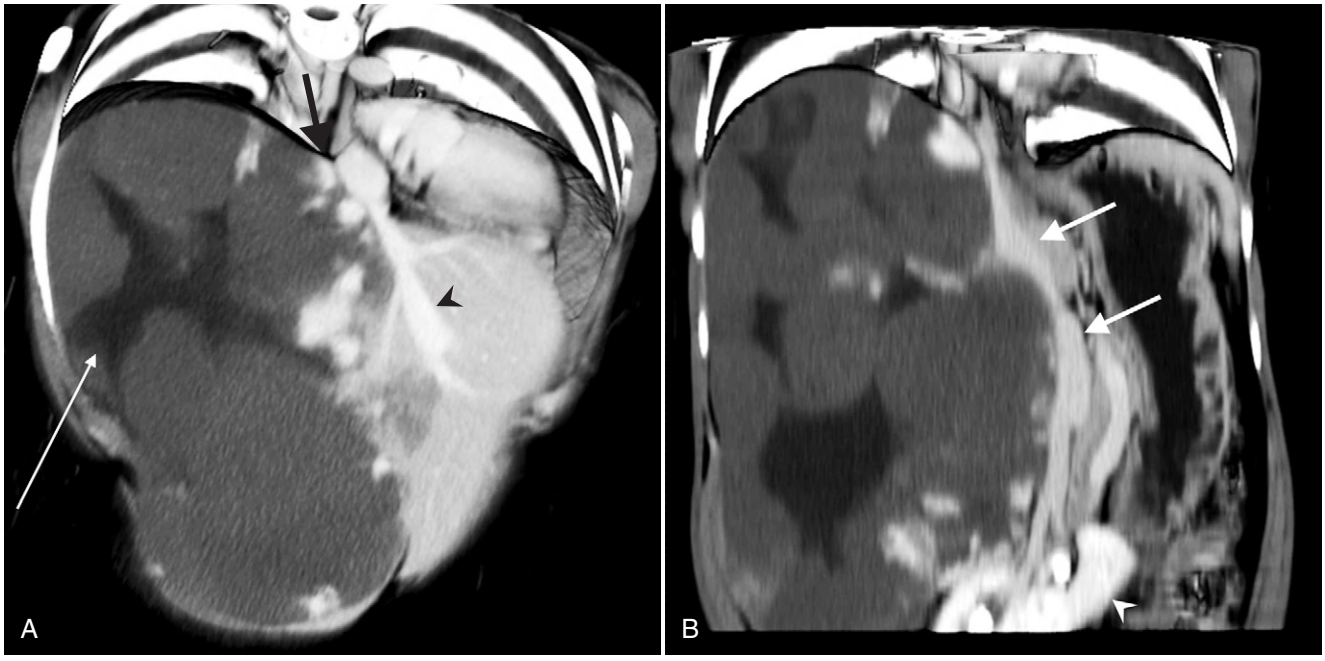

FIGURE 16.25. A, Volume-rendered three-dimensional image of a giant hemangioma. The image is oriented such that the patient is facing forward, with the observer looking down from above. Note the peripheral nodular, clumplike enhancement (*black arrow*) and the central low-attenuation scar (*white arrow*). The hemangioma is in contact with the left hepatic vein (*arrowhead*) and with the inferior vena cava (IVC). **B,** Volume-rendered coronal image of the same patient. The giant hemangioma exerts mass effect on a long segment of the IVC (*arrows*), which is displaced to the left of midline. The right kidney (*arrowhead*) is displaced inferomedially by the mass. Resection was performed with a good result. *(Courtesy L.H. Blumgart, MD.)*

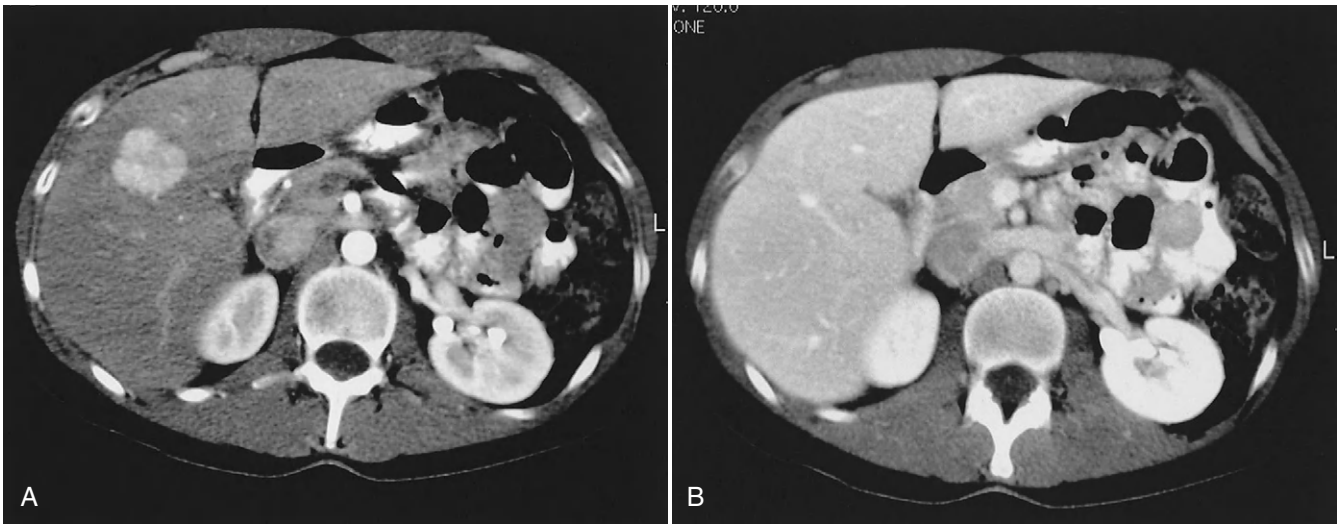

FIGURE 16.26. Focal nodular hyperplasia. **A,** Arterial phase image shows a well-circumscribed, brightly enhancing lesion in segment IV/V. **B,** During the portal phase, the lesion is isodense with liver parenchyma and cannot be identified.

hyperplastic parenchyma that is at least partially surrounded by fibrous septa and a central scar. The central scar contains fibrous connective tissue, cholangiolar proliferation with surrounding inflammatory infiltrates, and malformed vessels (Nguyen et al, 1999; Wanless et al, 1985).

On unenhanced CT, FNH has the same or slightly lower attenuation than the liver. When FNH has the same attenuation as the liver, the lesion may be invisible or may be detectable only because of the central, low-attenuation scar or mass effect on the adjacent structures (Carlson et al, 2000). The value of unenhanced images is to ensure the absence of intralesional hemorrhage, intratumoral fat, and calcifications, findings atypical of FNH (Carlson et al, 2000). During the early phases (arterial, early portal venous), the typical pattern of FNH is diffuse, immediate, homogeneous, hyperdense contrast enhancement. The prompt, diffuse arterial enhancement is due to the rich arterial supply. Rapid washout of contrast material is seen in the late portal venous phase and on delayed images, as lesions tend to become isodense to the liver on these views (Figs. 16.26 and 16.27; Carlson et al, 2000).

A central scar is thought to be present at histopathology in almost all cases of FNH, but on CT, scars are less frequently

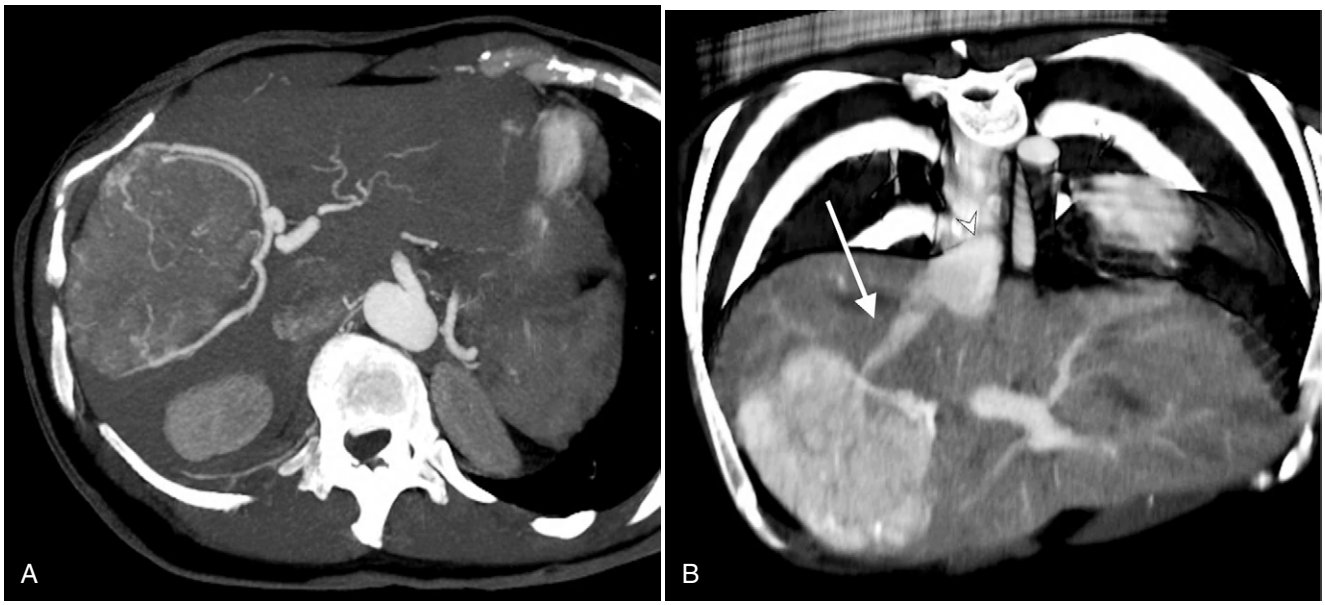

FIGURE 16.27. Focal nodular hyperplasia. **A,** Contrast-enhanced computed tomographic image acquired in the late arterial phase reveals the arterial supply to a well-circumscribed hypervascular mass in the right hepatic lobe. **B,** Oblique coronal, volume-rendered three-dimensional reformatted image of the same patient reveals early venous drainage from the mass via a large vein (*arrow*) into the inferior vena cava (*arrowhead*). The major hepatic veins have not yet opacified with contrast material.

visualized, seen in approximately one third of patients (Shamsi et al, 1993; Welch et al, 1985). The central scar is usually hypodense to the liver on unenhanced and early contrast-enhanced images, and it displays gradual fill-in on the portal venous phase and delayed images owing to diffusion of contrast material into the myxomatous stroma.

Adenoma

Hepatic adenoma (see Chapter 79) is an uncommon benign neoplasm usually discovered in women. A causative link has been described between the use of oral contraceptives and the development of hepatic adenomas (Blumgart et al, 2001). Other risk factors for the development of this neoplasm are androgen-containing steroids (Soe et al, 1992) and type I glycogen storage disease (Labrune et al, 1997). Adenomas are usually solitary but may be multiple in 30% of patients (Foster & Berman, 1977). A distinct entity referred to as *liver adenomatosis*, a term coined in 1985, refers to multiple (>10) adenomas in a patient without other known risk factors (Flejou et al, 1985).

Adenomas contain large plates of hepatocytes separated by dilated sinusoids perfused solely by peripheral arterial feeding vessels (adenomas lack a portal venous supply) under arterial pressure. Adenomas have poor connective tissue support, and the combination of poor connective tissue support and arterial pressure predisposes to hemorrhage. Multiple and large adenomas are more prone to spontaneous hemorrhage (Leese et al, 1988). Intracellular and intercellular lipids manifest as macroscopic fat within the tumor (Ichikawa et al, 2000).

The imaging appearance of adenomas parallels the histopathologic appearance. Unenhanced CT may be valuable in detecting the presence of intralesional hemorrhage or fat. Calcifications have been reported in 10% of lesions (Grazioli et al, 2000, 2001). Adenomas tend to be isoattenuating relative to normal liver on unenhanced CT and on portal venous phase images. Small adenomas usually enhance homogeneously in the arterial phase and are hyperattenuating to the liver (Grazioli et al, 2001). Larger adenomas are more heterogeneous in appearance than smaller lesions (Grazioli et al, 2001), presumably because of the presence of acute or prior hemorrhage. Peripheral enhancement reflects the presence of large subcapsular feeding vessels, with a resultant centripetal pattern of enhancement.

Biliary Hamartoma

Bile duct hamartoma (see Chapter 79), also known as *von Meyenburg complex,* is a common benign tumor composed of disorganized bile ducts and ductules with a fibrocollagenous stroma (Horton et al, 1999). The tumors usually range from 1 to 15 mm, do not communicate with the biliary tree, and are scattered throughout the liver (Wei et al, 1997). Bile duct hamartomas may be single, although they are often multiple (Blumgart et al, 2001), and they have a nonspecific imaging appearance such that they may be mistaken for metastases or microabscesses (Eisenberg et al, 1986; Lev-Toaff et al, 1995; Sada & Ramakrishna, 1994).

Bile Duct Adenoma

Bile duct adenomas are usually incidentally detected, benign, asymptomatic lesions (Welch et al, 1985). Bile duct adenomas are usually solitary and subcapsular, ranging in size from 1 mm to 1 cm. On unenhanced CT, a bile duct adenoma appears as a well-defined hypoattenuating or isoattenuating mass. Usually, little or no enhancement is seen after contrast administration. There is no specific imaging finding, however, and definitive diagnosis can be made only at histologic analysis (Horton et al, 1999).

Inflammatory Conditions

Pyogenic Abscess

Recent surgery, biliary disease, diverticulitis, Crohn disease, and alcoholism all predispose to pyogenic hepatic abscess (see Chapter 66), commonly caused by *Clostridium* species and gram-negative bacteria such as *Escherichia coli* and *Bacteroides*, which enter the liver via the biliary tree or portal venous system (Mergo & Ros, 1997). Ascending cholangitis and portal phlebitis are the most common causes of pyogenic hepatic abscesses (Murphy et al, 1989).

As a result of the widespread use of broad-spectrum antibiotics, the clinical presentation and CT appearance vary widely (Halvorsen et al, 1984). Pyogenic hepatic abscesses may be classified as either *microabscesses* (<2 cm) or *macroabscesses*, larger confluent lesions. Microabscesses appear as small, well-defined, hypodense lesions on contrast-enhanced CT. They may be widely scattered or clustered with a tendency to coalesce (Jeffrey et al, 1988). Larger pyogenic abscesses range in appearance from unilocular cavities with smooth outer margins to highly complex and septated structures with internal debris and irregular contours. Most large pyogenic abscesses appear as a well-defined mass of low attenuation on unenhanced CT. The attenuation value of the abscess cavity depends on the age of the abscess; it becomes lower as the abscess matures. Gas bubbles may be seen if anaerobic bacteria are present, and the periphery and internal septa may enhance after contrast agent administration. Abscesses often have a thick wall, which enhances with contrast administration (Fig. 16.28). In addition, there may be hepatic enhancement peripheral to the enhancing wall, secondary to increased capillary permeability. This is referred to as the *double-target sign* (Mendez et al, 1994; Murphy et al, 1989).

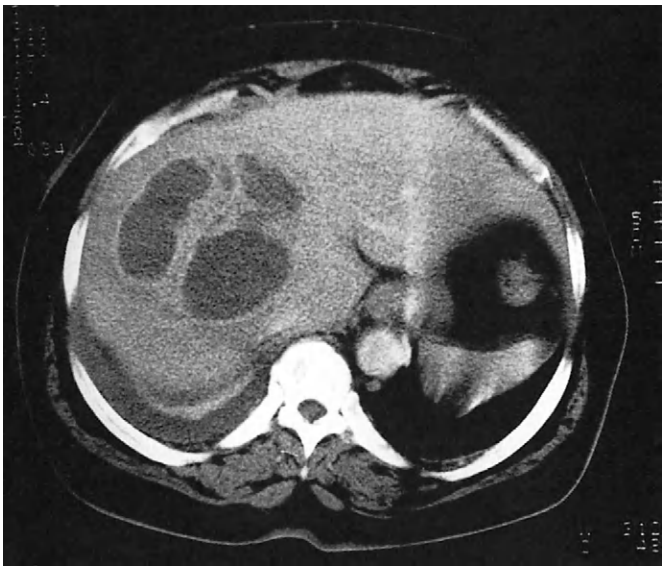

FIGURE 16.28. Contrast-enhanced computed tomography of a pyogenic liver abscess shows enhancement of the walls and internal septa. A sympathetic right-sided pleural effusion is seen.

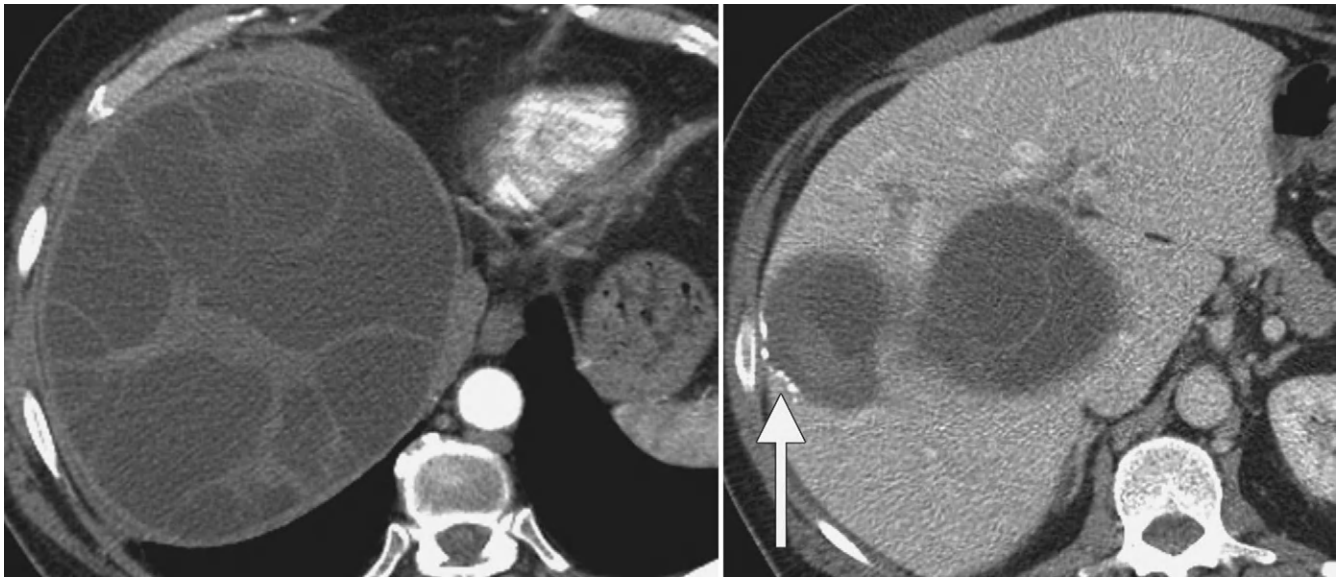

FIGURE 16.29. Contrast-enhanced axial computed tomography reveals a multiseptated echinococcal cyst in the right hepatic lobe. Note eccentric calcifications along the wall of one of the cysts (*arrow*).

Fungal Abscesses

Fungal hepatic abscesses generally are disseminated microabscesses that occur in immunosuppressed patients. The most common fungal organism implicated is *Candida albicans*. Other fungal infections that cause microabscesses include cryptococcus, histoplasmosis, and mucormycosis. With contrast-enhanced CT, hepatic microabscesses appear as small, hypodense lesions ranging from several millimeters to 1.5 cm in size. A bull's-eye appearance may be identified, with a small, high-attenuation focus centrally surrounded by a low-attenuation zone. Authors have reported significant increase in the sensitivity and lesion conspicuity using arterial phase CT, compared with portal venous phase CT, when evaluating liver lesions in immunocompromised patients suspected to have hepatosplenic fungal infections (Metser et al, 2005).

Echinococcus

In endemic areas, involvement of the liver by hydatid disease is a common finding. *Echinococcus granulosus* (see Chapter 68) presents with a large solitary mass or multiple well-defined cystic lesions, which often contain internal "daughter" cysts (Fig. 16.29). Coarse calcifications of the wall are present in 50% of patients (Fig. 16.30), and daughter cysts are identified in approximately 75% (de Diego Choliz et al, 1982; Murphy et al, 1989). Communication between the cysts and the biliary tree is found in approximately 25% of patients (de Diego Choliz et al, 1982), and frank rupture of cyst contents into the bile ducts occurs in 5% to 10%, accompanied by clinical features of cholangitis. In contrast, *Echinococcus alveolaris* infection resembles an infiltrating hepatic tumor clinically and radiographically with its irregular margins and heterogeneous density (Didier et al, 1985).

Amebic Abscess (See Chapter 67)

The protozoan *Entamoeba histolytica* infects 10% of the world's population. Hepatic abscess is the most common extraintestinal complication of amebiasis and occurs in approximately 8.5% of all patients with amebic infection (Ralls, 1998). On CT, amebic abscesses appear as well-defined masses of near-water attenuation with a thick enhancing rim. One or more internal septations may be present. A feature of amebic liver abscess that may aid in distinguishing it from other focal hepatic lesions is its tendency to extend beyond the surface of the liver (Radin et al, 1988). The CT findings are not specific, however, and serologic tests are necessary to confirm the diagnosis.

Diffuse Hepatocellular Diseases

Fatty Infiltration

Fatty infiltration (see Chapter 65), as seen in patients on chemotherapy or in patients with systemic disorders, such as diabetes mellitus, cystic fibrosis, or malnourishment, results in

FIGURE 16.30. Unenhanced computed tomography reveals a calcified rim of echinococcal cyst (*arrow*). Air within the cyst was from recent instrumentation.

FIGURE 16.31. Numerous foci of fatty infiltration. Contrast-enhanced computed tomography reveals numerous low-attenuation lesions in a patient with breast cancer. Note lack of mass effect or distortion of the hepatic vessels. Lesions were stable over time and were shown to represent focal fatty deposition on magnetic resonance imaging.

a decrease in hepatic density. Mild degrees of fatty change may be subtle, unless liver density is compared carefully with the density of the spleen. The liver is normally 6 to 12 HU higher in attenuation than the spleen, and reversal of this relationship is the earliest CT indication of fatty infiltration. With more advanced changes, the hepatic parenchyma becomes less dense than the intrahepatic vessels. In most instances, fatty infiltration is diffuse and uniform (see Fig. 16.12), but a nonuniform, focal distribution also can occur and occasionally may mimic a mass (Fig. 16.31). Fatty infiltration should be suspected if blood vessels can be seen passing through the focal area in a normal pattern (Fig. 16.32).

An awareness of the common locations of focal fatty infiltration and focal fatty sparing is important, so as not to mistake these for tumor. Common locations for focal fatty infiltration include segment IV adjacent to the falciform ligament (Ohashi et al, 1995; Paulson et al, 1993) and around the gallbladder (Yoshimitsu et al, 1997). A common location for focal fatty sparing is in the posterior aspect of segment IV (Matsui et al, 1995; White et al, 1987) or along the gallbladder fossa. It has been suggested that areas of focal fatty sparing are due to aberrant venous drainage to the liver, because these areas do not receive portal venous flow from the main portal trunk (Gabata et al, 1997; Marchal et al, 1986; Matsui et al, 1995).

It has been shown that focal fatty sparing in a fatty infiltrated liver may occur secondary to a mass. This occurrence is presumably due to regionally decreased portal blood flow caused by compression of the adjacent portal venous branch distal to a mass. This fatty sparing can appear as wedge shaped, peripheral, segmental, or lobar, depending on the site of the portal venous compression (Grossholz et al, 1998).

Assessment for fatty infiltration is better performed with unenhanced CT than with contrast-enhanced CT, because factors such as the rate of contrast injection and timing of measurements significantly influence the optimal liver-to-spleen ratio threshold for diagnosing fatty liver. The required ratios are

FIGURE 16.32. Focal fatty infiltration. A wedge-shaped area of low attenuation is visible in the right liver. The hepatic vessels pass through the area normally with no deviation.

protocol specific, which limits the clinical usefulness of such measurements (Jacobs et al, 1998; Johnston et al, 1998). If it is unclear based on the CT findings whether an area of focal low attenuation represents a mass, magnetic resonance imaging (MRI) using opposed-phase gradient echo images may make a definitive diagnosis.

Cirrhosis (See Chapter 70)

CT is capable of showing morphologic changes associated with advanced hepatic cirrhosis. Typical CT features are a nodular hepatic outline (in macronodular cirrhosis) caused by regenerative nodules of variable size, bands or regions of confluent fibrosis, relative atrophy of the right hepatic and quadrate lobes, and hypertrophy of the left lateral segment and caudate lobe (Fig. 16.33; Torres et al, 1986). Measurement of the transverse dimension of the caudate lobe compared with the adjacent right lobe provides an index of right hepatic lobe shrinkage and a relatively specific morphologic measurement of hepatic cirrhosis (Harbin et al, 1980). A caudate/right lobe ratio greater than 0.65, using the bifurcation of the main portal vein to divide the lobes provides 96% confidence in the diagnosis of cirrhosis. An MRI study suggested that using the right portal vein to set the lateral boundary of the caudate lobe when assessing the caudate/right lobe ratio was more accurate for diagnosing cirrhosis than using the main portal vein (Awaya et al, 2002). Evidence of coexistent portal hypertension is found with ascites, splenomegaly, and portal-systemic varices. MDCT combined with three-dimensional reformatting can help determine the extent of portosystemic collateral vessels, such as the left gastric vein, short gastric vein, esophageal and paraesophageal varices, splenorenal and gastrorenal shunts, and paraumbilical and abdominal wall veins (Kang et al, 2002).

Budd-Chiari Syndrome

Budd-Chiari syndrome (see Chapter 77) is caused by chronic hepatic venous congestion secondary to obstruction to hepatic venous outflow. The CT appearance is characterized by hepatomegaly and ascites; the hepatic veins are either obliterated and not seen, or they contain thrombus (Fig. 16.34). Precontrast scans show decreased attenuation of hepatic parenchyma because of congestion; postcontrast scans show normal enhancement of the caudate lobe, which is hypertrophied in chronic cases, and patchy enhancement of the remainder of the liver (Vogelzang et al, 1987). Concomitant portal vein thrombosis is present in 20% of patients with Budd-Chiari syndrome. A similar CT appearance of the liver, with patchy enhancement, is seen in patients with congestive heart failure; in contrast to patients with true Budd-Chiari syndrome, these patients have patent and enlarged hepatic veins (Moulton et al, 1988).

Hepatic Infarction

Hepatic infarction is rare and implies compromise to the arterial and portal venous supply to a segment or lobe of the liver. CT findings include a well-defined, wedge-shaped area of low attenuation in segmental or subsegmental distribution, extending to the liver surface. After contrast administration, the affected zone is enhanced minimally; a peripheral, thin, subcapsular rim often contains enhancing hepatic tissue. Gas formation within sterile infarcts is a recognized finding and does not imply superimposed infection. A late complication of hepatic infarction is formation of bile lakes in the affected segments as a result of disruption of biliary radicles.

Malignant Lesions of the Liver

Hepatocellular Carcinoma

HCC (see Chapter 80) is the most common primary hepatic malignancy worldwide, with the highest incidence in Asia, Southeast Asia, and sub-Saharan Africa. Although less common in the West, the incidence of HCC in the United States has been increasing (Arakawa et al, 1986). The most significant risk factors include cirrhosis and hepatitis B and C viruses. Approximately 70% of HCCs develop in cirrhotic livers (Blumgart et al, 2001), and detection of HCC in the cirrhotic liver poses a great diagnostic challenge, because the hepatic parenchyma is distorted by nodular regeneration and fibrosis. In addition, there are alterations in arterial and portal venous blood flow. These

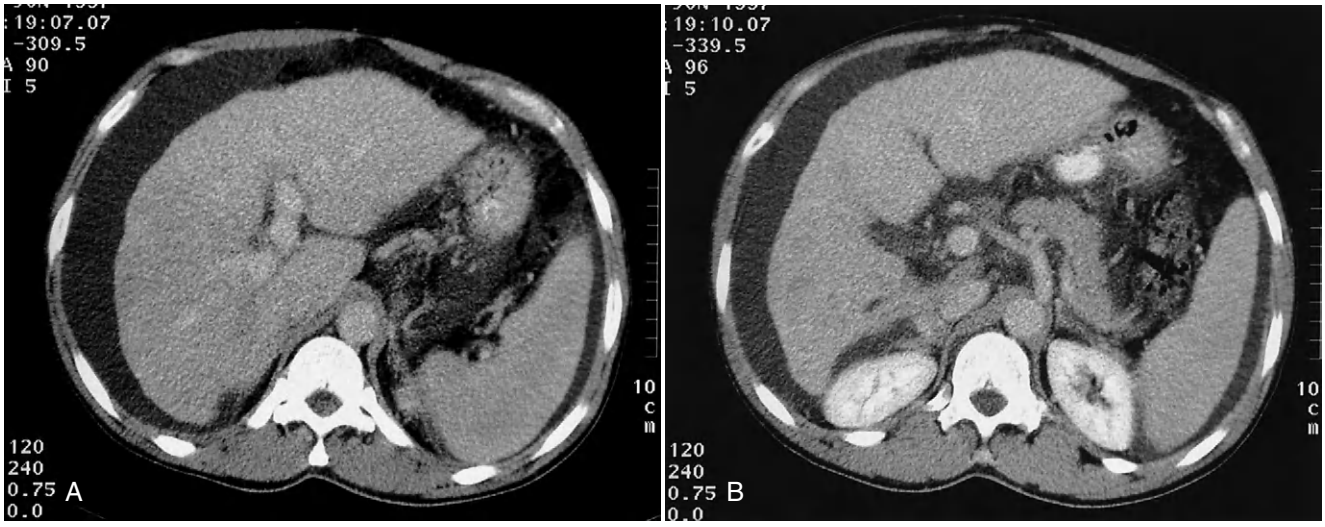

FIGURE 16.33. Cirrhosis. **A,** The liver has an irregular outline. **B,** The interlobar fissure, delineated by the gallbladder, is deviated toward the right as a result of atrophy of the right liver with hypertrophy of the left liver and the caudate lobe.

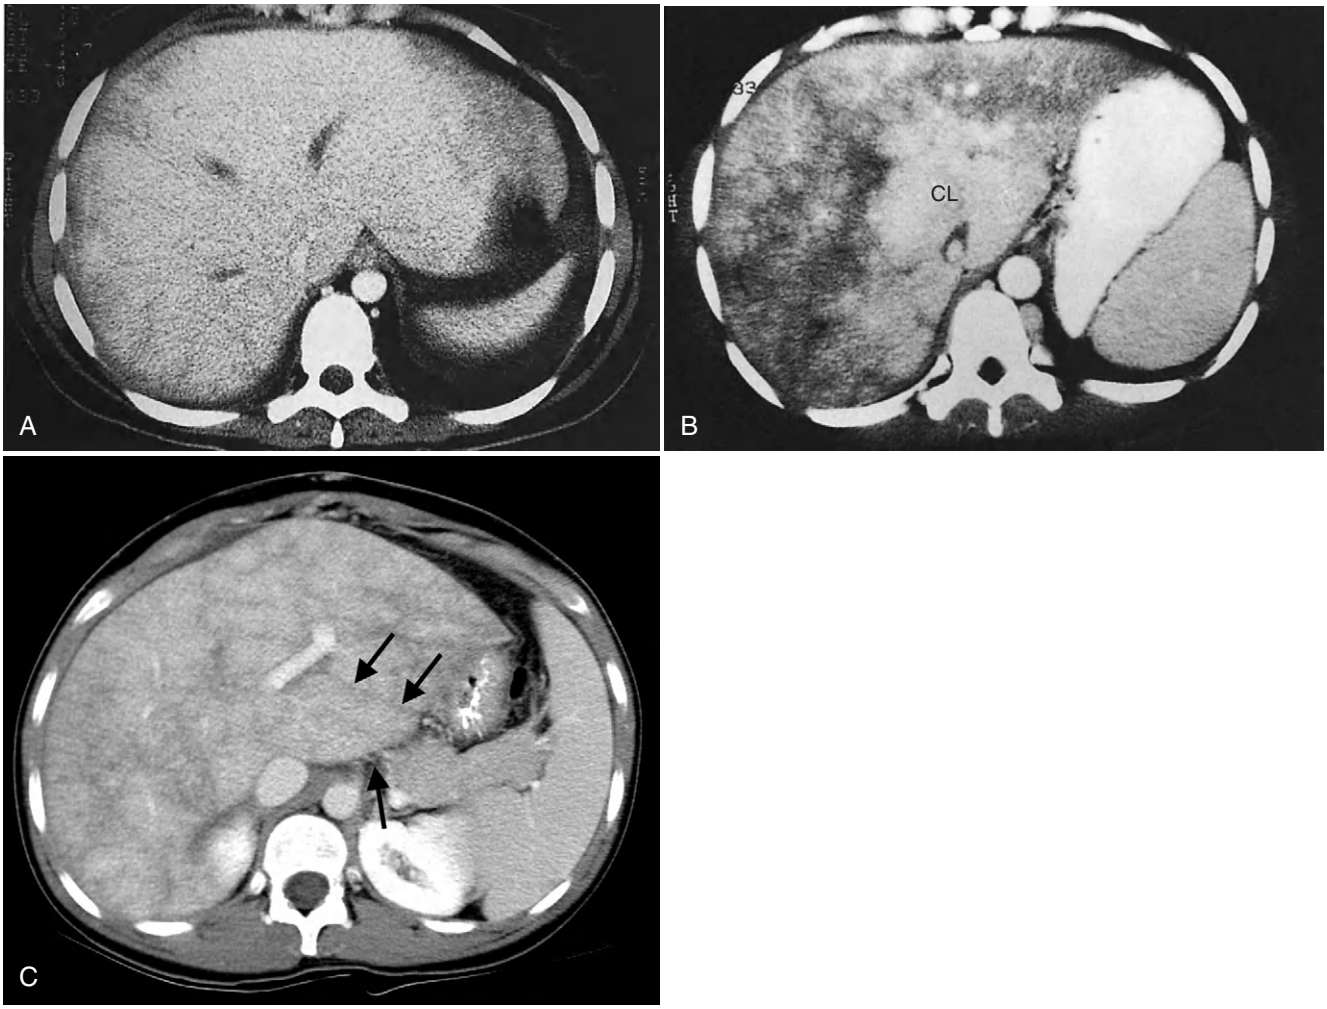

FIGURE 16.34. **A,** Contrast-enhanced computed tomography (CT) in a patient with acute hepatic venous thrombosis leading to Budd-Chiari syndrome shows nonenhancement of the thrombosed hepatic veins. There also is patchy peripheral parenchymal enhancement. **B,** In a patient with chronic Budd-Chiari syndrome resulting from a congenital stricture of the intrahepatic inferior vena cava, enlargement of the caudate lobe (*CL*) and marked homogeneity of parenchymal enhancement are seen. Splenomegaly also is seen. **C,** Contrast-enhanced CT reveals mottled parenchymal enhancement and enlargement of the caudate lobe (*arrows*) in a patient with occlusion of the hepatic veins secondary to paroxysmal nocturnal hemoglobinuria.

changes can obscure malignant lesions and conversely can simulate disease (Baron & Peterson, 2001).

Regenerative nodules within the cirrhotic liver, especially large nodules (8 to 10 mm), are readily identifiable at CT, because they distort the hepatic contour. When these nodules contain iron, referred to as *siderotic nodules,* they have high attenuation on unenhanced CT. These nodules typically do not enhance during the arterial phase, and this is an important characteristic that differentiates regenerating nodules from dysplastic nodules and HCC. Regenerative nodules enhance homogeneously during the portal venous phase to the same degree that surrounding fibrotic tissue does and thus are not visible as distinct from the adjacent parenchyma (Baron & Peterson, 2001).

Dysplastic nodules contain cellular atypia and are precursors to frank HCC in some cases. Dysplastic nodules may contain nontriadal arterial flow pathologically, which distinguishes them from regenerative nodules. Dysplastic nodules typically do not display vivid arterial enhancement on CT but occasionally do enhance in this phase and may mimic HCC (Baron & Peterson, 2001).

The appearance of HCC on CT varies. Most small HCC nodules enhance on arterial phase images and display a washout of contrast material during the portal venous phase (Fig. 16.35). A few are hypovascular and are best seen in portal venous phase or equilibrium phase imaging. Larger lesions (>5 cm) tend to be heterogeneous with a mosaic pattern of enhancement (Stevens et al, 1996); they may be surrounded by a tumor capsule and may contain necrosis and fatty metamorphosis. Tumor can invade the portal or hepatic veins directly (Freeny et al, 1992), with enhancing tumor thrombus evident on CT (Figs. 16.36 and 16.37). Tumor extension into the bile duct, resulting in biliary obstruction, also can be seen on CT.

Distortion of the liver related to the underlying cirrhosis can lead to abnormalities at CT that may be misinterpreted as HCC. A false-positive diagnosis of HCC was made on CT in 8% of 1329 patients with cirrhosis who were referred for hepatic transplantation in an experienced liver transplant center

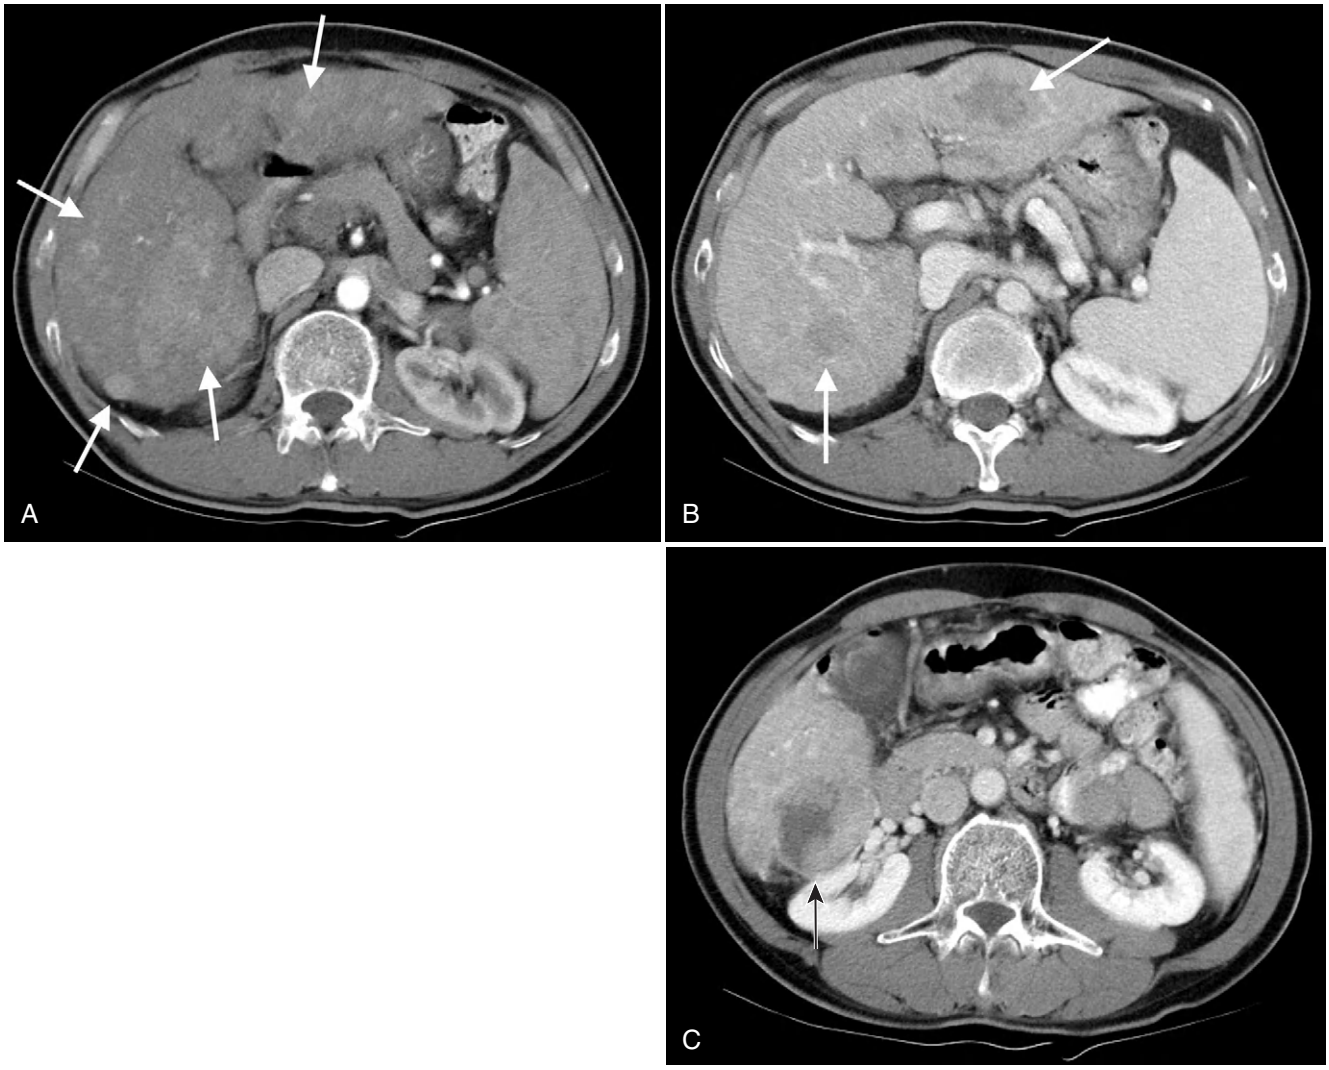

FIGURE 16.35. Arterial phase and portal venous phase images in a patient with multifocal hepatocellular carcinoma (HCC). **A,** Arterial phase images reveal numerous hypervascular masses (*arrows*) in a patient with multifocal HCC. **B,** Portal venous phase image reveals low-attenuation masses (*arrows*). **C,** Portal venous phase image reveals an exophytic heterogeneous mass reflecting an additional focus of HCC (*arrow*).

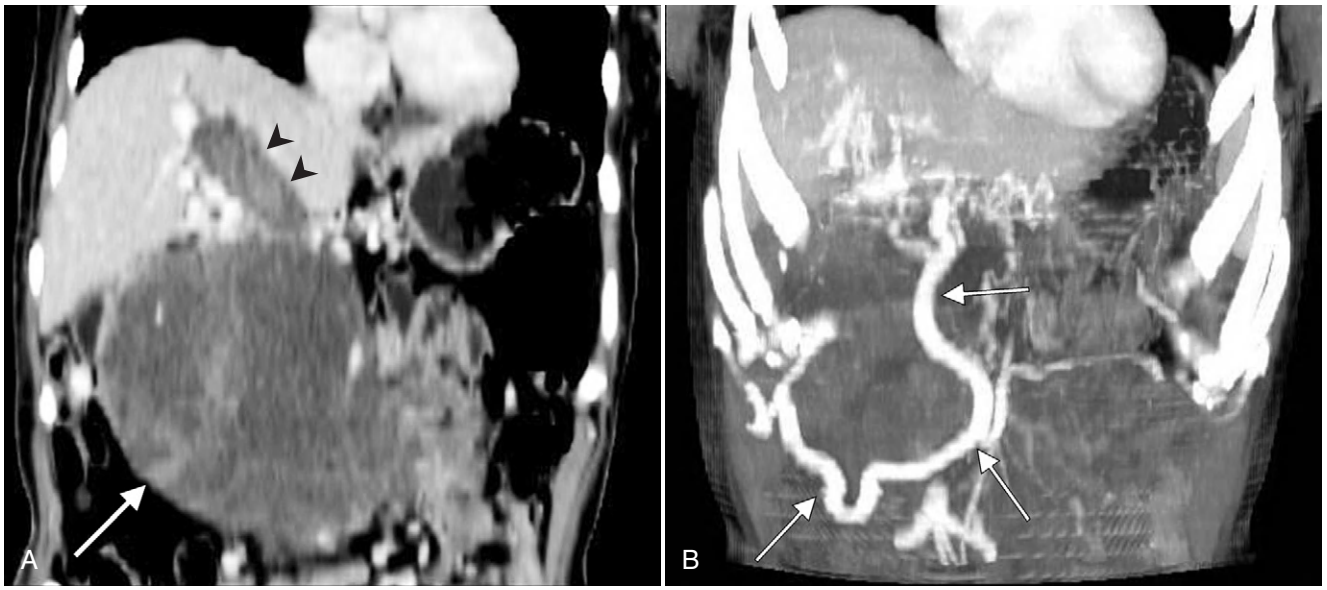

FIGURE 16.36. **A,** Contrast-enhanced computed tomography reveals an exophytic hepatocellular carcinoma (*arrow*) with tumor thrombus extending up the main portal vein (*arrowheads*). **B,** Coronal maximum intensity projection image in the same patient reveals extensive collateral venous flow (*arrows*) about the mass.

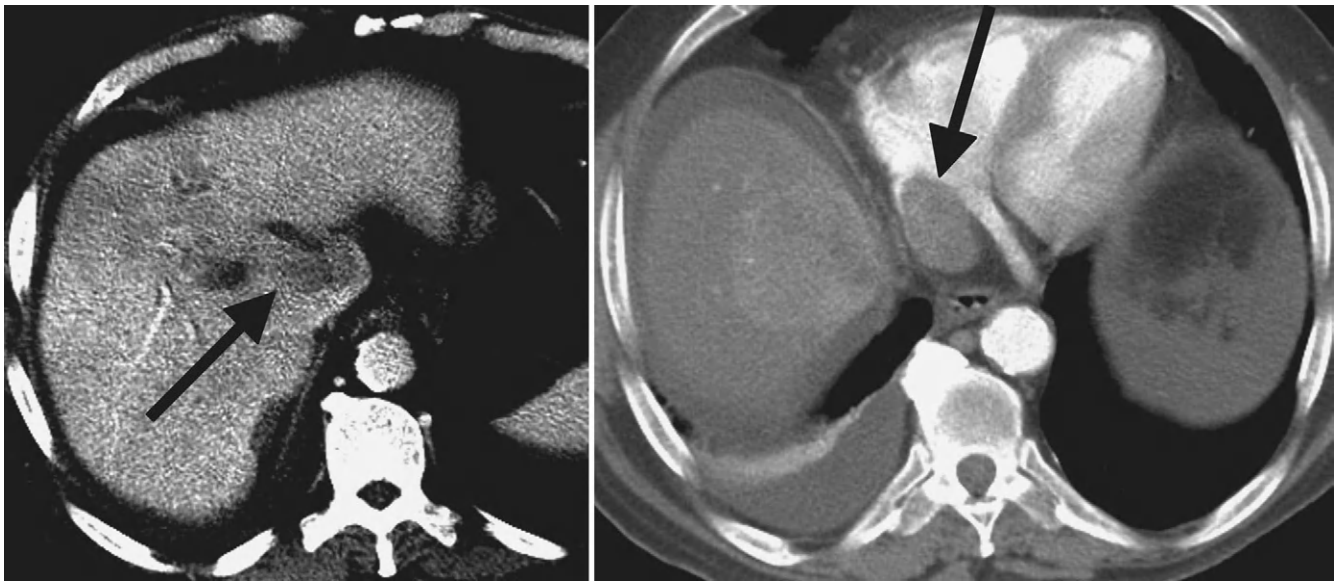

FIGURE 16.37. Hepatocellular carcinoma (HCC). Contrast-enhanced computed tomography reveals HCC involving segment I of the liver (*arrow*). Tumor thrombus extends into the inferior vena cava and right atrium (*arrow*).

(Brancatelli et al, 2003). Benign lesions mistaken for HCC include focal confluent fibrosis, transient hepatic attenuation difference, flash-filling hemangiomata, peliosis, and benign regenerative nodules showing dysplastic change.

HCC may be predominantly intrahepatic or pedunculated, with a large exophytic component "hanging" off the liver (see Fig. 16.36A). This finding is evident on cross-sectional imaging and has implications for surgical resectability (Vauthey et al, 1995). Approximately 5% of HCCs are seen with spontaneous rupture and hemoperitoneum (Blumgart et al, 2001).

The appearance of HCC differs in cirrhotic and noncirrhotic livers. HCC in a cirrhotic liver commonly appears as multifocal small lesions, whereas HCC in a noncirrhotic liver is more typically a large, hypervascular solitary or dominant mass with small satellite nodules and central necrosis (Fig. 16.38; Brancatelli et al, 2002; Winston et al, 1999b). The pathogenesis of HCC differs in these two patient groups. HCC may arise de novo in an otherwise normal liver, whereas a multistep sequence of carcinogenesis has been described in patients with cirrhosis (Okuda et al, 1982). It has been shown that venous invasion by tumor is more common in cirrhotic patients than in patients without underlying liver disease (Smalley et al, 1988). Patients with minimal or no cirrhosis have a better prognosis after resection than patients with cirrhosis (Fong et al, 1999).

Fibrolamellar Hepatocellular Carcinoma

Fibrolamellar HCC is a malignant hepatocellular tumor with distinct clinical, pathologic, and radiologic differences from HCC. Fibrolamellar carcinoma typically manifests as a large hepatic mass in adolescents or young adults with no evidence of cirrhosis, and it accounts for 1% to 9% of all HCCs (Berman et al, 1980; Craig et al, 1980; Goodman et al, 1985; Pinna et al, 1985). There are no known risk factors for the development of this lesion. The main diagnostic challenge is to distinguish it from FNH, a benign lesion occurring in the same age group.

On unenhanced CT scans, fibrolamellar carcinoma usually appears as a hypoattenuating, solitary mass with well-defined lobular margins (McLarney et al, 1999) and a central scar. Calcification, a finding used to help differentiate this lesion from FNH, has been reported in 35% to 55% of tumors (Brandt et al, 1988; Friedman et al, 1985; Soyer et al, 1991). During the arterial and portal phases of enhancement, the nonscar portion of the tumor enhances heterogeneously (McLarney et al, 1999). This heterogeneous enhancement is also an important imaging finding used to differentiate fibrolamellar HCC from FNH, which should display homogeneous arterial enhancement around a central scar. On delayed images, increasing homogeneity of the mass and occasional scar enhancement may simulate the appearance of FNH, underscoring the need to

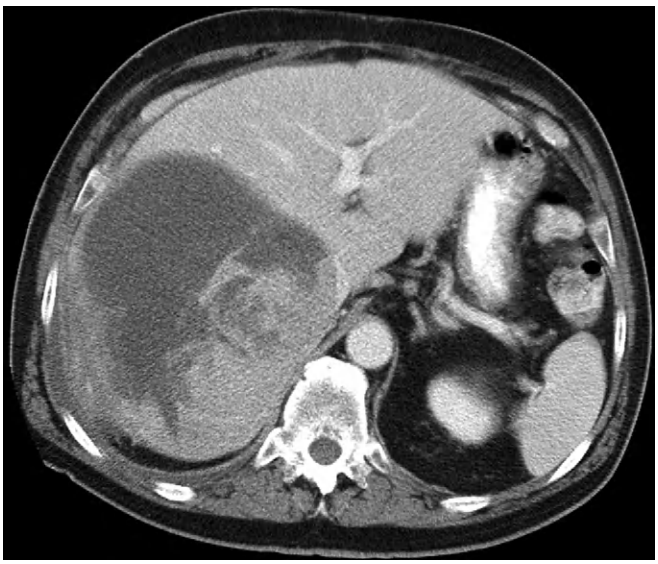

FIGURE 16.38. Hepatocellular carcinoma in a noncirrhotic liver.

scan the liver during the arterial and portal venous phases. Although fibrolamellar HCC does not typically have a true capsule, the liver surrounding the mass may be compressed and may form a pseudocapsule (McLarney et al, 1999). Associated findings of vascular invasion, lymphadenopathy, or peritoneal implants strongly suggest fibrolamellar HCC.

Angiosarcoma

Risk factors for angiosarcoma of the liver include hemochromatosis, radiotherapy, and exposure to compounds such as polyvinyl chloride (PVC), arsenic, or Thorotrast. Angiosarcoma is a vascular hepatic neoplasm that appears as an infiltrating, brightly enhancing mass on CT (Silverman et al, 1983). High-attenuation thorium deposition may be seen in a patchy distribution in the liver, perihepatic lymph nodes, and spleen. Histologic "cavernous" angiosarcoma may enhance in a way similar to that of hemangioma, with the tumor becoming wholly or partly isodense with liver on delayed scanning (Itai & Teraoka, 1989; White et al, 1993).

Hepatic Lymphoma

Primary lymphoma of the liver is rare, but the liver is a common secondary site of lymphomatous involvement in patients with Hodgkin disease and non-Hodgkin lymphoma. At autopsy, hepatic involvement is seen in 50% of patients with non-Hodgkin lymphoma and in 60% of patients with Hodgkin disease. Approximately 6% to 20% of patients with Hodgkin disease have hepatic involvement at presentation (Castellino, 1982; Fishman et al, 1991; Sandrasegaran et al, 1994). Liver involvement usually is associated with lymph node disease and almost invariably is associated with splenic disease. The more extensive the splenic involvement, the greater the likelihood of hepatic involvement (Figs. 16.39 and 16.40).

On CT, hepatic involvement usually appears diffuse; discrete nodular lesions are seen in only 10% of cases. The sensitivity of CT in the detection of hepatic disease is low, presumably because liver involvement is diffuse. It is thought that extensive disease must be present before becoming apparent at imaging, and CT may reveal only hepatomegaly with no focal lesion. Diffuse or infiltrative forms of the disease result in irregular infiltration in the portal areas.

Hepatic Metastases (See Chapter 81)

The liver provides a fertile soil for metastases, not only because of its dual blood supply from systemic and portal systems, but also because of humoral factors that promote cell growth. The liver is second only to regional lymph nodes as a site of metastatic disease. The CT appearance of metastases varies and depends on the size and vascularity of the tumor, the degree of necrosis, and the CT technique used (see Technique section). Borders may be sharp, poorly defined, or nodular; the shape may be round, ovoid, or irregular. Attenuation is usually lower than that of surrounding hepatic parenchyma on unenhanced CT. Intravenous contrast enhancement increases the sensitivity of lesion detection.

Scanning during the appropriate phase of enhancement (arterial, portal, delayed) increases detection even further (see Technique section). Peripheral ring enhancement occurs in metastases, but this is usually not appreciated in hypovascular metastases, which have low attenuation compared with surrounding, intensely enhancing hepatic parenchyma during portal phase scanning. Hypervascular metastases may be obscured during the portal phase and are most clearly visualized during the arterial phase (see Fig. 16.14). Metastases from mucinous carcinomas tend to contain punctate or amorphous calcification. Cystic metastases can be distinguished from benign simple cysts, because the former often contain mural nodules, fluid-fluid levels, or septations. Differentiation of multiple hepatic metastases from multifocal HCC may be difficult, but metastases rarely protrude prominently from the liver surface, a feature that is commonly seen with HCC.

The appearance of metastases may change in response to treatment. Lesions may appear of lower attenuation as they undergo necrosis (Figs. 16.41 and 16.42). Hepatic metastases from gastrointestinal stromal tumors (GISTs) that respond to

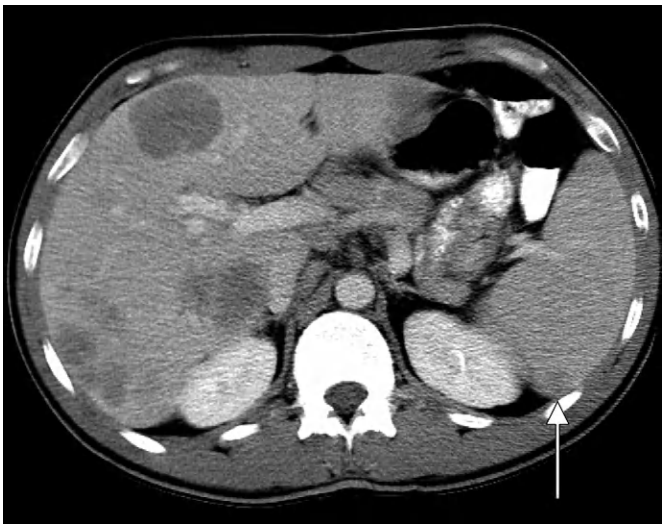

FIGURE 16.39. Contrast-enhanced computed tomography reveals multiple hepatic masses in a patient with lymphomatous involvement of the liver and spleen. Note the low-attenuation mass in the spleen (*arrow*).

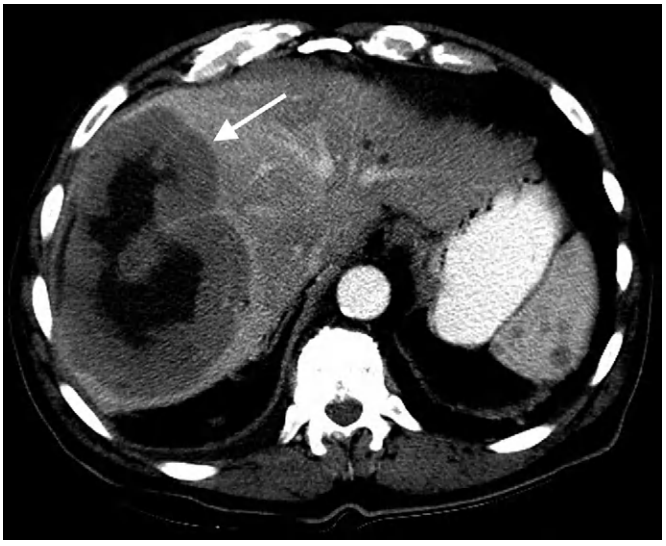

FIGURE 16.40. Large unifocal lymphomatous mass in the right hepatic lobe (*arrow*). Small splenic lesions are also seen.

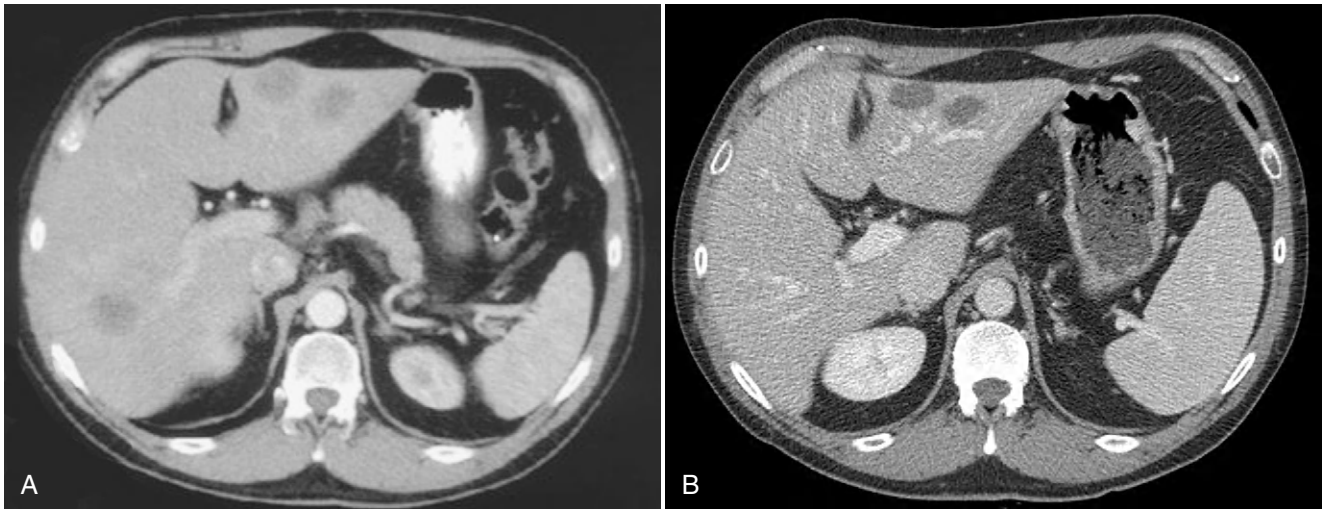

FIGURE 16.41. Metastatic colon cancer. **A,** Before treatment. **B,** After treatment.

imatinib mesylate become near cystic on contrast-enhanced CT. These metastases may resemble cyts, but they display a slightly higher HU (Chen et al, 2002). Therefore when evaluating the liver at CT in a patient with a history of GIST, it is very important to know whether the patient has undergone treatment; comparison with pretreatment images becomes essential. Metastases may result in focal biliary ductal dilation secondary to compression or invasion of the adjacent bile duct (Fig. 16.43).

Biliary System

Advances in technology have expanded the role of CT in evaluating the biliary tree. The ability to obtain high-resolution, thin-slice images in a single breath hold and the ability to view these images in cine mode are ideal for tracing the dilated bile ducts to the point of obstruction. Delineation of variant biliary anatomy is possible if the biliary tree is dilated (Fig. 16.44). Additionally, the relationship of arteries to the bile ducts can be identified, which is valuable information for surgical planning (Fig. 16.45; see Chapter 90).

Gallstones

CT is inferior to ultrasound for detection of gallstones, but it may reveal unsuspected gallstones during studies performed for other reasons. Visualized gallstones are calcified or of lower attenuation than the surrounding bile because of a high cholesterol content. Stones that are missed on CT are mixed cholesterol stones that are isodense with bile.

Cholecystitis (See Chapter 31)

CT should not be used as a screening technique for the detection of acute cholecystitis, but occasionally, patients with cholecystitis who display a confusing clinical picture may undergo

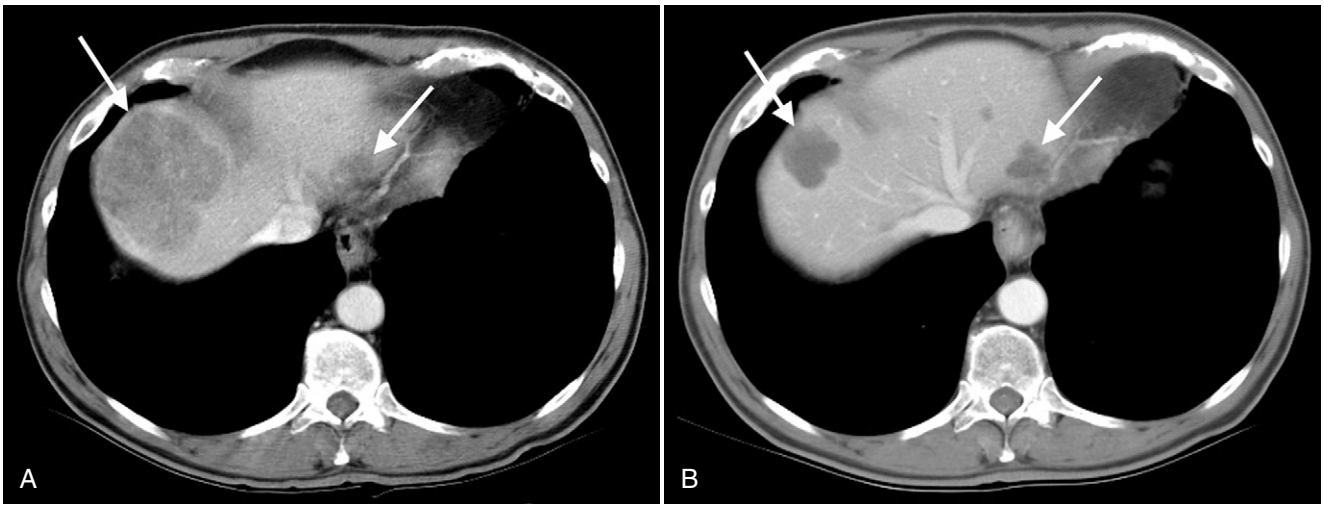

FIGURE 16.42. Contrast-enhanced computed tomography in a patient with metastatic gastrointestinal stromal tumor. **A,** Before treatment, heterogeneous solid enhancing masses are seen in the right and left hepatic lobes (*arrows*). **B,** After treatment, lesions have lower attenuation and appear more cystic (*arrows*).

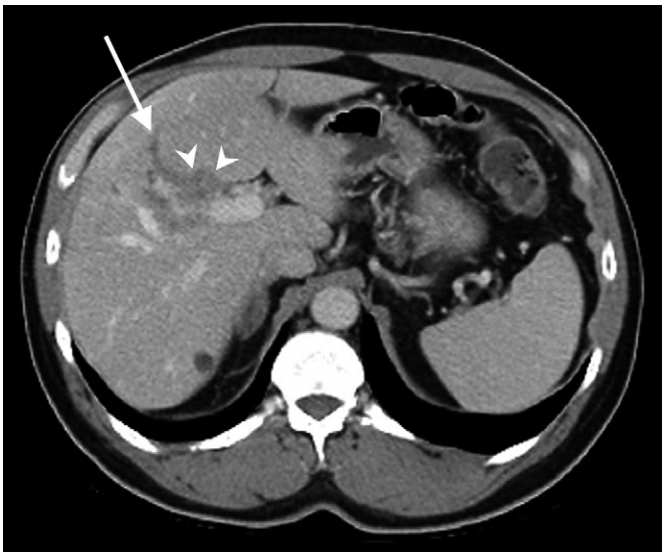

FIGURE 16.43. Contrast-enhanced computed tomography in a patient with metastatic colorectal cancer reveals infiltrative tumor invading the bile duct (*arrowheads*). Note the resultant biliary dilation (*long arrow*).

CT examination before the precise nature of the disease is clear. Gallbladder distension, wall thickening, and gallstones are often present in acute cholecystitis, but these are nonspecific signs that occur in most patients with chronic cholecystitis. The presence of ill-defined pericholecystic lucency within the hepatic parenchyma adjacent to the gallbladder suggests gallbladder inflammation (Fig. 16.46). Intramural edema within the gallbladder wall may be seen in acute cholecystitis and is a useful sign in an appropriate clinical setting, but it also can be seen in patients with ascites or hypoalbuminemia. The attenuation of the gallbladder bile is usually increased, and extremely high attenuation is seen in patients with hemorrhagic cholecystitis, a rare complication.

Although many of the CT findings in uncomplicated acute cholecystitis are nonspecific, CT is valuable when

FIGURE 16.44. Coronal reformatted image created from axial computed tomographic data acquired after intravenous administration of contrast medium. Bile is displayed as *bright areas* with marked dilation of the intrahepatic bile ducts and the common bile duct (*CBD*). Note the distended gallbladder (*asterisk*) and the aberrant biliary drainage of segment VI (*arrowheads*) directly into the common bile duct.

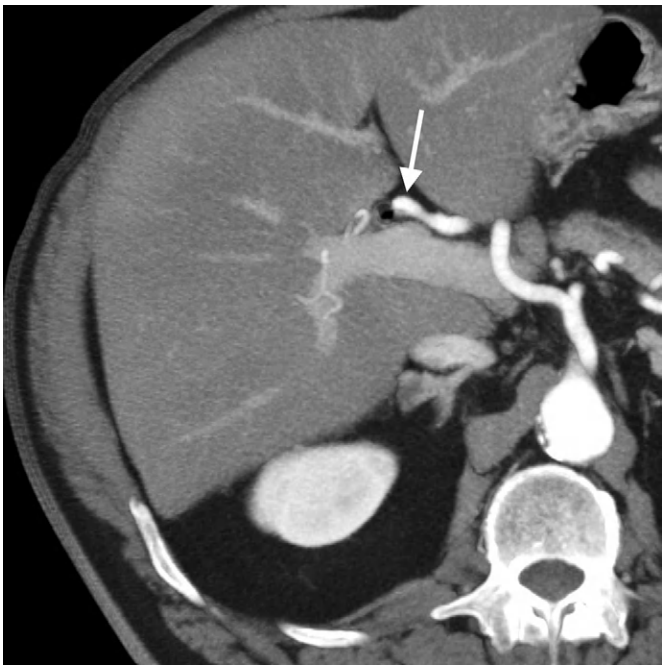

FIGURE 16.45. Arterial phase image reveals the right hepatic artery (*arrow*) coursing anterior to the common hepatic duct, which contains air from a papillotomy.

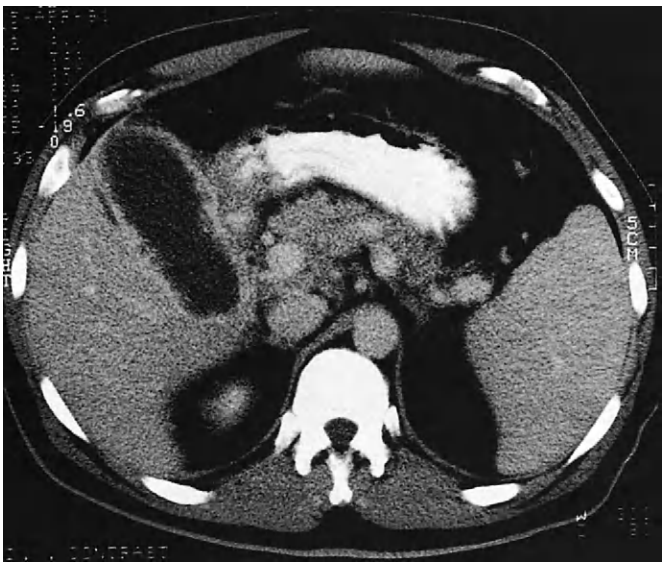

FIGURE 16.46. Acute cholecystitis. computed tomography shows a distended, thick-walled gallbladder with pericholecystic fluid. No gallstones are seen.

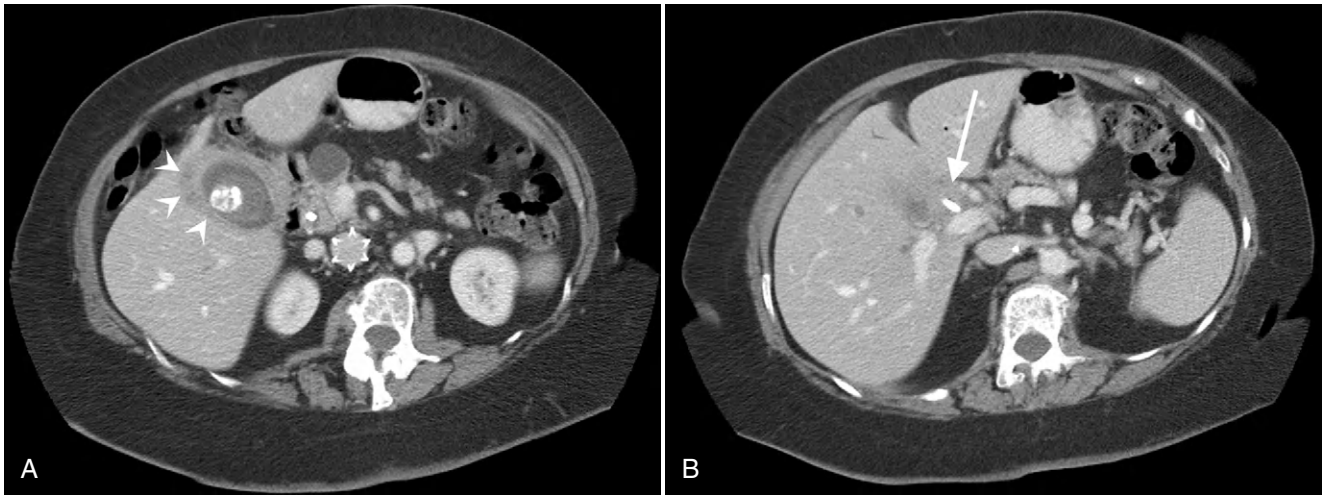

FIGURE 16.47. Mirrizi syndrome. **A,** Contrast-enhanced computed tomography reveals a large calcified gallstone associated with gallbladder wall thickening and extensive pericholecystic inflammatory change (*arrowheads*). **B,** Extensive inflammatory change surrounds the internal biliary stent (*arrow*).

complications such as pericholecystic abscess, emphysematous cholecystitis, or gallbladder perforation are present, and CT can identify patients in need of emergency surgery. CT findings most specific for acute gangrenous cholecystitis are gas in the gallbladder wall or lumen, intraluminal membranes, irregular gallbladder wall enhancement, and pericholecystic abscess (Bennett et al, 2002).

Mirizzi Syndrome

Mirizzi syndrome is an uncommon condition in which the common hepatic duct is obstructed because of stones impacted in or extruded from a Hartmann pouch or cystic duct. Cholecystobiliary and cholecystoenteric fistulae are common complications. It is clinically important to recognize the diagnosis before surgery, because failure to appreciate the extraluminal obstructing process results in unrewarding exploration of the common duct and persistent obstruction. The typical CT features of Mirizzi syndrome are dilation of the biliary system above the level of the neck of the gallbladder with a normal system below. CT reveals a gallstone impacted in a cystic duct or gallbladder neck, and the stone usually appears eccentrically located relative to the bile duct. An irregular cavity with surrounding edema and inflammation may be seen adjacent to the gallbladder neck (Fig. 16.47). Because not all of the findings may be present on CT, direct cholangiography or MRI cholangiopancreatography can be obtained to document the nature of the obstruction and the presence or absence of a biliary fistula.

Choledocholithiasis (See Chapters 35 to 37)

The insensitivity of sonography in detecting choledocholithiasis has been well documented, with a reported detection rate of 18% to 22%, whereas CT has a detection rate of 76% (Baron, 1987). Meticulous attention must be paid to technique, and when a change in duct caliber is detected, thin collimation scans should be performed through the transition area to detect the calculus. The only reliable indicator of choledocholithiasis is the presence of dense intraluminal calcification, or a *target sign*, which is due to a halo of bile surrounding the higher density stone. Calcified stones lying within an obstructed duct present no challenge to the radiologist. Most errors in diagnosis are due to cholesterol stones, which may blend imperceptibly with the surrounding bile. Errors of diagnosis also occur when choledocholithiasis occurs without ductal dilation, which occurs in about one third of patients with choledocholithiasis.

Intrahepatic calculi (see Chapter 39) are rare in Western countries but most frequently occur in association with iatrogenic bile duct strictures (Fig. 16.48). CT is of little value when stones are small and noncalcified and bile duct dilation is minimal or absent. Intrahepatic choledocholithiasis may give a bizarre appearance, owing to segmental or subsegmental biliary radicles filled with calculi. In Asian patients with recurrent pyogenic cholangitis, who subsequently form bile pigment stones,

FIGURE 16.48. Intrahepatic cholelithiasis. Intrahepatic duct dilation is seen after recurrent anastomotic stricture formation at a hepaticojejunostomy. Several laminated, noncalcified calculi can be seen within the dilated ductal system.

the debris filling the biliary system generally has higher attenuation than normal bile. Marked bile duct dilation is present, and often the larger intrahepatic ducts are dilated without side-branch dilation. Eccentric and diffuse extrahepatic bile duct wall thickening is usually seen (Schulte et al, 1990).

Gallbladder Carcinoma

Gallbladder carcinoma (see Chapter 49) is the sixth most common gastrointestinal malignancy in the United States. Risk factors include female gender, age, postmenopausal status, and cigarette smoking (Khan et al, 1999). Gallstones are present in 74% to 92% of patients with gallbladder carcinoma and represent another well-established risk factor (Lowenfels et al, 1985; Nagorney & McPherson, 1988). *Porcelain gallbladder,* a term used to describe calcification within the gallbladder wall, places a patient at increased risk for gallbladder carcinoma. Older studies suggested that 10% to 25% of patients with a porcelain gallbladder develop gallbladder carcinoma (Berk et al, 1973), but more recent reports indicate that the risk may be lower and related to the type of calcification (lower risk with complete calcification of the entire wall compared with selective calcification; Stephen & Berger, 2001; Kim et al, 2009). Most patients with gallbladder carcinoma are diagnosed with advanced disease. Early-stage gallbladder carcinoma typically is detected incidentally because of inflammation related to coexistent cholelithiasis or cholecystitis. In 1% of patients undergoing cholecystectomy for cholelithiasis, gallbladder carcinoma is discovered incidentally (Wanebo & Vezeridis, 1993).

The CT imaging appearances of gallbladder carcinoma include a mass replacing the gallbladder (seen in 40% to 65% of patients), focal or diffuse gallbladder wall thickening (seen in 20% to 30%; Fig. 16.49), and an intraluminal polypoid mass (seen in 15% to 25%; Fig. 16.50) (Franquet et al, 1991; Lane et al, 1989; Yeh, 1979; Yum & Fink, 1980). Additional imaging findings associated with gallbladder carcinoma reflect the pattern of disease spread. The most common mode by which gallbladder carcinoma spreads is direct invasion into the adjacent organs. Direct tumor invasion is enhanced by the thin gallbladder wall, which contains only a single muscle layer. The perimuscular connective tissue of the gallbladder is continuous with the interlobular connective tissue of the liver, facilitating the direct spread of tumor into the hepatic parenchyma (Henson et al, 1992). The liver is the organ most frequently invaded, followed by the colon, duodenum, and pancreas (Sons et al, 1985).

The gallbladder lies in the intersegmental plane between segments IVb and V (see Fig. 16.6), and tumors of the gallbladder fundus may invade directly into these segments at an early stage (Blumgart et al, 2001). Air may be seen within the gallbladder lumen if tumor results in a fistula to the transverse colon or duodenum. Tumors involving the infundibulum or cystic duct may invade directly and obstruct the common bile duct or portal vein, precluding surgical resection (Blumgart et al, 2001). Associated biliary dilation resuting from infiltrative tumor along the cystic duct to the extrahepatic bile duct, lymphadenopathy compressing the bile duct, or intraductal spread of tumor is apparent on CT (Levy et al, 2001). Tumor growth through the gallbladder wall away from the liver results in peritoneal carcinomatosis.

Laparoscopic cholecystectomy has become increasingly accepted as a treatment for symptomatic uncomplicated cholelithiasis (Southern Surgeon's Club, 1991), and approximately 15% to 30% of gallbladder carcinomas are detected incidentally at microscopic review of cholecystectomy specimens (Clair et al, 1993). A serious potential complication of laparoscopic cholecystectomy is the inadvertent dissemination of unsuspected gallbladder carcinoma (Winston et al, 1999a). Wibbenmeyer and colleagues (1995) reported that gallbladder carcinoma recurs more rapidly after laparoscopic cholecystectomy than after open cholecystectomy. Tumor can recur in the laparoscopic port tracks, even if surgical resection of the port sites is performed at subsequent hepatic resection for attempted cure. Recurrent tumor may appear as a mass along the anterior abdominal wall with extension into the subjacent omental fat (Fig. 16.51; Winston et al, 1999a). These observations underscore the need to correctly identify findings suggestive of

gallbladder carcinoma on preoperative imaging when elective laparoscopic cholecystectomy is planned.

Cholangiocarcinoma

Cholangiocarcinoma (see Chapter 50) is an adenocarcinoma that arises from bile duct epithelium. Conditions that place patients at increased risk for developing cholangiocarcinoma include clonorchiasis, hepatolithiasis, choledochal cyst, Caroli disease, hepatitis C viral infection, and primary sclerosing cholangitis (Sherlock & Dooley, 1997). Cholangiocarcinoma usually is classified as either intrahepatic or extrahepatic, and intrahepatic cholangiocarcinoma is classified further as either hilar or peripheral in location; these three types of cholangiocarcinoma—*peripheral*, *hilar*, and *extrahepatic*—are often regarded as distinct clinical and radiologic entities (Han et al, 2002), although this classification scheme is controversial. The Liver Cancer Study Group of Japan (1997) categorized intrahepatic cholangiocarcinoma into three types based on the macroscopic appearance: *mass forming*, *periductal infiltrating*, and *intraductal*.

The hepatic hilus is the most common location of cholangiocarcinoma, occurring in 40% to 60% of patients (Burke et al, 1998; Nagorney et al, 1993; Nakeeb et al, 1996). Tumors involving the distal bile duct account for 20% to 30% of all cholangiocarcinomas, and approximately 10% of cholangiocarcinomas arise peripherally within the intrahepatic biliary tree (Berdah et al, 1996; Chu et al, 1997; Harrison et al, 1998).

HILAR CHOLANGIOCARCINOMA. Cholangiocarcinoma can arise anywhere in the biliary tree, but tumors involving the biliary confluence, termed *hilar cholangiocarcinoma*, are the most common; these are further broken down into *infiltrating*, *exophytic*, and *polypoid* types. Infiltrating hilar cholangiocarcinoma is the most common type, accounting for more than 70% of cases (Fig. 16.52); such tumors usually are seen as focal thickening of the duct wall with obliteration of the lumen (Han et al, 2002). Exophytic cholangiocarcinoma appears as a mass showing peripheral rim enhancement; its appearance is similar to peripheral cholangiocarcinoma. The polypoid type of hilar cholangiocarcinoma appears as an intraductal soft-tissue mass that expands the duct lumen; this type of tumor may be mulifocal within the biliary tree, and it involves the intrahepatic and extrahepatic bile ducts (Han et al, 2002).

Generally, long-term survival is possible only with an en bloc resection of the liver and the extrahepatic biliary ducts (Jarnagin & Winston, 2005). Jarnagin and colleagues (2001) proposed a staging system for hilar cholangiocarcinoma that predicts resectability, likelihood of metastatic disease, and survival. Preoperative imaging should focus on addressing factors that determine resectability. Four crucial components of resectability are 1) level and extent of tumor within the biliary tree, 2) vascular invasion, 3) hepatic lobar atrophy, and 4) distant metastatic disease.

High-resolution MDCT in combination with interactive image viewing in cine mode using PACS has enhanced the radiologist's ability to address these issues (see Fig. 16.52). It is possible to trace the individual dilated bile ducts to determine the point or points of obstruction (Fig. 16.53). Zandrino and colleagues (2002) reported that multislice CT performed without a cholangiographic contrast agent correctly identified the cause of biliary obstruction in 31 (86%) of 36 patients.

One feature of cholangiocarcinoma is subepithelial spread of tumor along the duct wall and periductal tissues, and significant tumor may extend beneath an intact epithelial lining. For this reason, radiologic studies may underestimate the full extent of tumor. This possibility emphasizes the need for frozen section analysis of duct margins (see Fig. 16.52; Jarnagin & Winston, 2005).

Tumor extent along the hepatic arteries can be identified with CT angiography. Lobar atrophy, also apparent on CT, is an important finding in patients with cholangiocarcinoma. Atrophy is a major factor in the proposed clinical T-stage criteria, and it affects resectability. Although long-standing obstruction of the ipsilateral bile duct may cause moderate atrophy, associated portal venous obstruction causes rapid and severe atrophy of the affected lobe (Fig. 16.54; Jarnagin & Winston, 2005). Atrophy also is important to recognize at imaging when biliary decompression is planned. Drainage of an atrophic lobe does not relieve jaundice and is not indicated, unless it is done as treatment for biliary sepsis (Jarnagin & Winston, 2005).

PERIPHERAL CHOLANGIOCARCINOMA. The most common type of intrahepatic cholangiocarcinoma is mass-forming peripheral cholangiocarcinoma. On contrast-enhanced CT, peripheral cholangiocarcinoma appears as a low-attenuation mass with peripheral rim enhancement (Fig. 16.55), and it is associated with focal dilation of the intrahepatic bile ducts around the mass. Contrast enhancement of the mass is often seen on the delayed images (Keogan et al, 1997; Lacomis et al, 1997; Valls et al, 2000). This delayed enhancement is likely due to the increased stromal fibrosis seen within these tumors (Valls et al, 2000).

EXTRAHEPATIC CHOLANGIOCARCINOMA. Infiltrating cholangiocarcinoma is the most common type of cholangiocarcinoma involving the extrahepatic bile duct. It usually appears as a mass or thickening of the bile duct wall at the site of biliary obstruction. The radiologic and pathologic features are identical to those of hilar cholangiocarcinoma, and the assessment and treatment of distal bile duct cancers is similar to that of pancreatic head carcinoma (Blumgart et al, 2001).

FIGURE 16.52. Hilar cholangiocarcinoma. **A,** Axial contrast-enhanced computed tomography (CT) reveals an infiltrative, low-attenuation tumor (*arrow*) surrounding an internal biliary stent (*arrowhead*), resulting in bilobar intrahepatic biliary duct dilation. **B,** Axial contrast-enhanced CT reveals confluent tumor (*large arrows*) encasing a replaced right hepatic artery (*small arrow*), which originates from the superior mesenteric artery. Despite the biliary stent, intrahepatic biliary duct dilation is evident. **C,** Oblique axial maximum intensity projection image reveals narrowing of the right portal vein (*large arrow*) secondary to infiltrative tumor. Bilobar intrahepatic biliary ductal dilation is evident (*smaller arrows*).

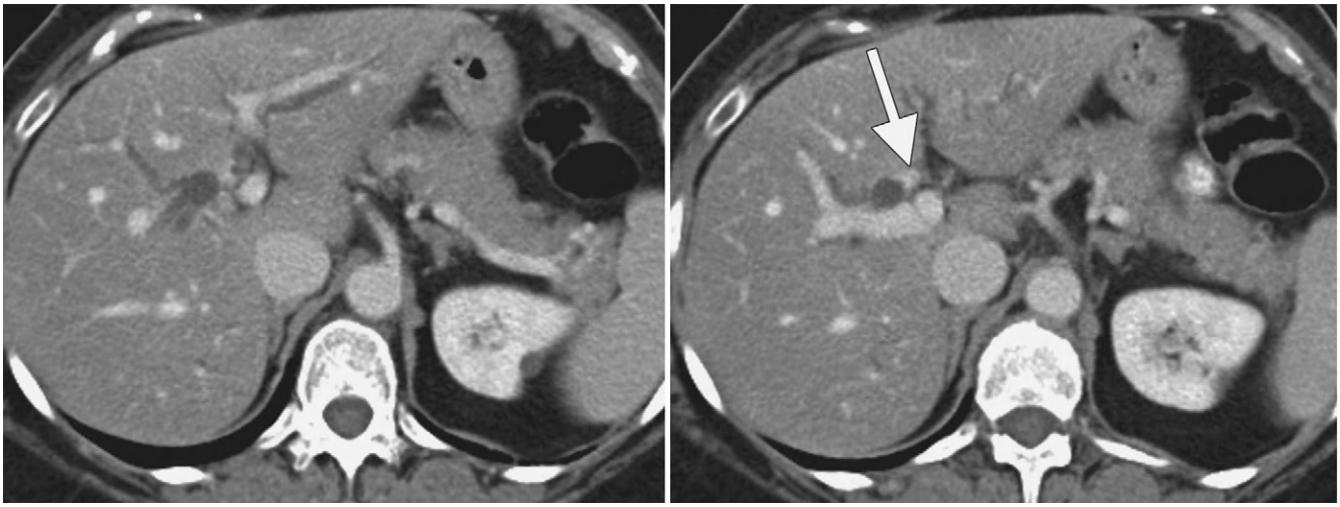

FIGURE 16.53. Cholangiocarcinoma. Contrast-enhanced computed tomography reveals bilobar central intrahepatic biliary duct dilation as a result of an obstructing enhancing mass at the hepatic hilus (*arrow*).

FIGURE 16.54. Infiltrative hilar cholangiocarcinoma. Reformatted oblique axial image with dilated bile ducts appearing bright. The infiltrative mass (*long arrow*) in the left hepatic lobe resulted in left-sided intrahepatic biliary ductal dilation (*short arrows*). Tumor extends along the central portion of the right portal vein with mild atrophy of the left lobe.

The intraductal polypoid or papillary variant of cholangiocarcinoma accounts for approximately 10% of all cholangiocarcinomas. The most common location for this type is the distal bile duct (Baer et al, 1990). As opposed to the infiltrative cholangiocarcinoma that narrows the duct lumen, papillary tumors are intraductal masses that expand the bile duct lumen. Papillary tumors have minute, frondlike projections that may be fixed to or detached from the bile duct wall. On CT, enhancement of the mass depends on whether or not the tumor is fixed or detached to the duct wall, and there may be segmental asymmetric thickening of the bile duct wall with enhancement. Tumors are friable and slough easily, which may result in intermittent or partial biliary obstruction (Lim et al, 2003). Some papillary tumors produce a profuse amount of mucus, resulting in severe biliary dilation (Lim et al, 2004). Recognition of a papillary cholangiocarcinoma is important, because these tumors are more likely resectable and carry a more favorable prognosis than other types (Pitt et al, 1995).

Biliary Cystadenoma and Cystadenocarcinoma

Biliary cystadenomas (see Chapter 48) are uncommon benign cystic lesions that occur predominantly in middle-aged women between 42 and 55 years (Ishak et al, 1977). Although benign, these lesions may recur after excision and have the potential to develop into biliary cystadenocarcinomas. Cystadenomas are most often intrahepatic (83%), but they may also occur within the extrahepatic bile ducts (13%) or gallbladder (0.02%) (Devaney et al, 1994).

CT shows cystadenomas to be multiloculated cystic lesions with internal septations; only rarely are they unilocular (Fig. 16.56). Calcifications may be present within the wall of the cyst or within the septa, and septa may enhance with intravenous contrast media (Fig. 16.57). The attenuation of the cyst fluid depends on the content of the fluid, which may be hemorrhagic, mucinous, proteinaceous, or bilious (Buetow et al, 1995). Tumor nodules and papillary projections extending into the cyst typically enhance with intravenous contrast medium. No specific imaging feature permits reliable differentiation of biliary cystadenoma from biliary cystadenocarcinoma (Buetow et al, 1995a).

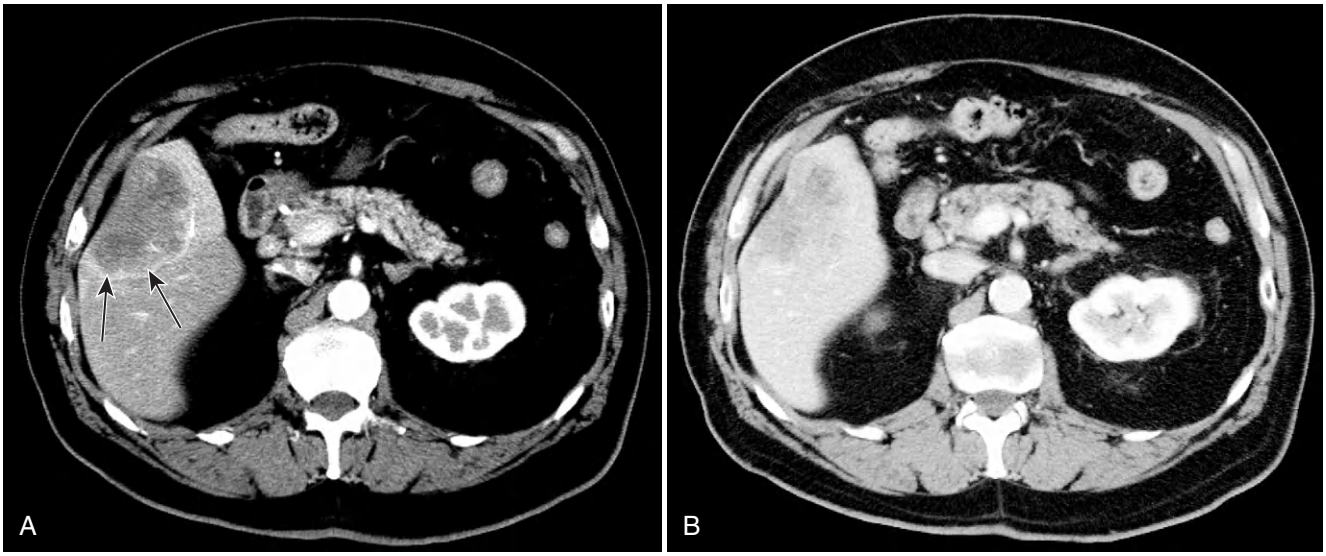

FIGURE 16.55. Late arterial phase and portal venous phase images of a patient with a peripheral cholangiocarcinoma. **A,** Late arterial phase image reveals peripheral enhancement of a heterogeneous mass in the right hepatic lobe (*arrows*). **B,** Portal venous phase image reveals heterogeneous enhancement of the central portion of the mass.

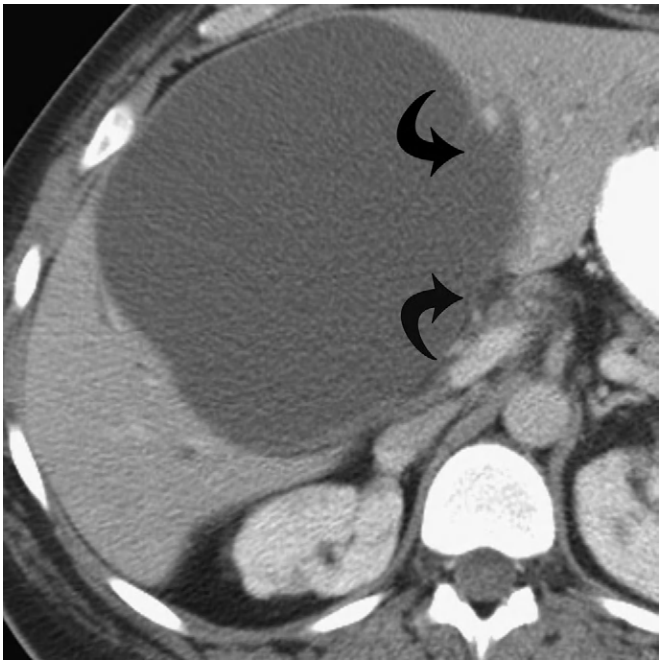

FIGURE 16.56. Biliary cystadenoma. Contrast-enhanced computed tomography reveals a large cystic mass with a very subtle internal septation (*curved arrows*).

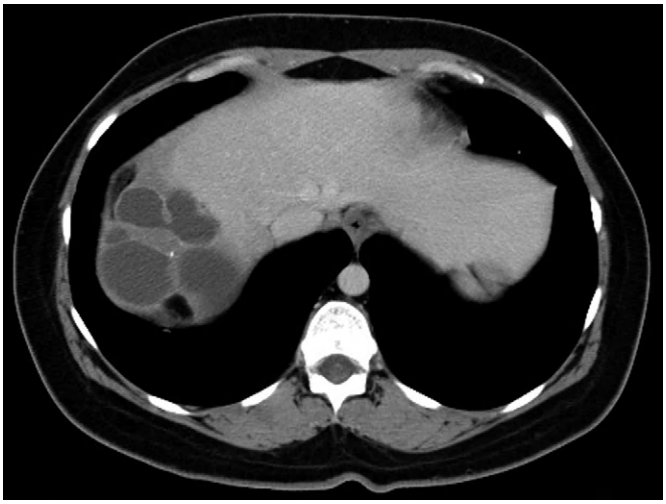

FIGURE 16.57. Recurrent biliary cystadenoma after resection. A multiloculated cystic lesion is seen at the resection margin containing enhancing septa and calcification.

COMPUTED TOMOGRAPHY OF THE PANCREAS

Historical Review

Evaluation of the pancreas was revolutionized by the advent of helical CT scanning, which enabled rapid evaluation of the pancreas during different phases of contrast injection (Ferrucci, 1999; Ishiguchi et al, 2001; Mertz et al, 2000; Van Hoe & Baert, 1997). Newer MDCT scanners have improved pancreatic imaging further by allowing extremely rapid data acquisition, retrospective change in slice thickness and location, and three-dimensional image review in multiple projections (Ferrucci, 1999; Horton & Fishman, 2000; Ishiguchi et al, 2001; Johnson et al, 2003; Mertz et al, 2000; Rubin, 2003; Van Hoe & Baert, 1997).

Technique

The imaging of the pancreas relies on the differential intravenous contrast enhancement between tumor tissue and normal pancreatic parenchyma. The use of intravenous contrast injection is mandatory for accurate diagnosis, and timing of the contrast injection and accurate delivery of the appropriate volume requires use of a dedicated CT power injector. Dedicated pancreatic protocols employ thin-section imaging (slice thicknesses ≤5 mm), but protocol slice thicknesses vary according to the clinical indications. Preoperative planning for surgical pancreatic resection demands a much more detailed evaluation of the pancreas and surrounding vascular structures than does a follow-up scan performed to evaluate response to chemotherapy. Such preoperative protocols often employ scan thicknesses of 2.5 mm or less.

Preoperative imaging to determine resectability of pancreatic carcinoma requires a study directed toward clinically relevant findings and accurate detailed evaluation of peripancreatic arteries and veins. CT angiography has emerged as the technique of choice because of the high-quality imaging, speed of the examination, ease of performance, and ready availability. CT angiography was initially limited by the breath-hold time required for a single-detector helical scanner, but with multidetector scanning, the time for image acquisition has been shortened to less than 15 seconds; with 64-slice scanners, scan time can be shortened to 5 seconds or less, a reasonable breath hold for most patients.

Computed Tomography Scan Protocols for the Pancreas

Initial scan protocols for evaluation of the pancreas recommended four phases for the preoperative evaluation of the pancreas: The *noncontrast phase* permits evaluation of pancreatic calcifications and allows localization of the precise levels for imaging on the postcontrast study. The next two phases are combined early and late arterial phases, obtained within a single breath hold; the *early arterial phase* permits evaluation of pancreatic vasculature without interference from venous opacification. The *late arterial phase* is of greatest benefit to distinguish pancreatic neoplasms from adjacent normal pancreatic tissue by maximizing differences in contrast enhancement. It also is useful to evaluate hypervascular liver metastases as seen in patients with neuroendocrine tumors of the pancreas. The fourth phase is the *routine portal venous phase*, which is best to evaluate for hypovascular liver metastases (Cantisani et al, 2003; Takeshita et al, 2002) in patients with adenocarcinoma. More recent reports (Fletcher et al, 2003) have shown no need for the early angiographic phase of imaging of the pancreas, because the pancreatic and hepatic arterial anatomy and pancreatic parenchyma are well evaluated on the late arterial phase of imaging. This practice further shortens the scan time and reduces the radiation dose to the patient.

An exciting new development in multidetector CT is the promise of dual-energy CT, a technique that scans the patient at

both 80 kvp and 140 kvp simultaneously. Because of the different interactions of soft tissue, bone, and intravenous contrast material, it is possible to eliminate the noncontrast images and obtain a "virtual" noncontrast image. This is done by scanning the patient by injecting contrast and using the differential interactions with the two different scanning energies to digitally subtract the intravenous contrast. It is also possible to eliminate bone with this technique. This technology is still in early development, but it holds great promise for imaging multiple anatomic areas of the body, including hypervascular tumors of the liver and pancreas (Graser et al, 2009; Marin et al, 2009), with the expectation of reducing radiation dose.

For CT angiography of the pancreas, the patient should be fasting to ensure that the stomach and proximal bowel are empty; before the examination, the patient should drink approximately 750 to 1000 mL of water. CT angiography requires the substitution of water for dilute radiopaque oral contrast medium (Lawler & Fishman, 2002; Soriano et al, 2004; Takeshita et al, 2002) to isolate the enhanced vessels from the gastrointestinal tract. Enhanced vessels have CT densities similar to contrast-filled bowel. Water within the lumen of the bowel facilitates identification of vascular anatomy, allows evaluation for possible invasion into adjacent bowel, and facilitates analysis on the three-dimensional workstation.

Noncontrast images are acquired initially to localize the pancreas accurately before intravenous contrast administration and to evaluate for the presence of calcifications. Injection of intravenous contrast medium is done at a high flow rate of 4 to 5 mL/s, with scanning beginning during the late arterial phase; this permits evaluation of the peripancreatic vasculature and maximizes contrast differences between tumor and normal pancreatic tissue. Different methods exist to initiate scanning at the time of maximal arterial enhancement, which may vary from patient to patient. A small timing bolus (Kalra et al, 2004) may be used to determine the appropriate time delay, or CT scanning may be triggered automatically when a vascular structure reaches a predefined density. Other authors use a standard delay for imaging all patients, a potential pitfall in patients with cardiac disease.

Routine scanning for the follow-up of pancreatic cancer in a postoperative patient or for evaluation of response to therapy is done with oral and intravenous contrast material. These patients drink 750 mL of a 2% barium sulfate suspension or equivalent water-soluble iodine solution 45 minutes before scanning, which is performed approximately 70 seconds from the start of intravenous contrast injection using a dedicated power injector for CT, but this will vary with the speed of the scanner. Routine injection is via a 20-gauge catheter placed in an antecubital vein and injected at a rate of 2.5 mL/s with contiguous 5 mm or thinner scans.

Anatomy of the Pancreas

The normal pancreas (see Chapter 1) is well imaged on routine CT of the abdomen. It is a retroperitoneal structure bounded anteriorly by the stomach and posteriorly and inferiorly by the third portion of the duodenum, and it lies medial to the C-loop of the duodenum and medial to the spleen. Crucial to the evaluation of the pancreas and possible tumor resection is its relationship to vessels. The body and tail of the pancreas lie immediately anterior to the splenic vein, and the neck, head, and uncinate process of the pancreas are in close relationship to the superior mesenteric artery (SMA) and vein and lie just caudal to the celiac axis. The normal pancreas has a fat plane completely surrounding the SMA, whereas no fat plane lies between the SMV and the pancreatic head (Fig. 16.58).

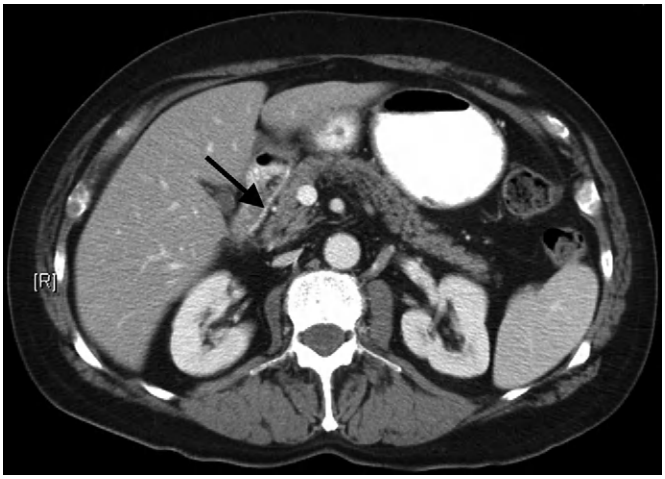

FIGURE 16.58. Normal pancreas. Note the gastroduodenal artery along the anterior margin of the pancreas (*arrow*).

Patients may sometimes be seen with fatty infiltration of a portion of the pancreas or involving the gland diffusely (Fig. 16.59). In such instances, the gland is best identified by identification of surrounding vascular structures and bowel. Severe fatty infiltration permits visualization of fine vascular detail within the pancreas, but a potential pitfall is that a small island of residual normal pancreatic parenchyma may be confused with an intrapancreatic mass.

Vascular anatomy is depicted in exquisite detail on CT angiography (Ibukuro, 2001; Ibukuro et al, 1995; Yamada et al, 2000; Ferrari et al, 2007; Horiguchi et al, 2008). In addition to assessment of the celiac and superior mesenteric arteries and vein and their major branches, smaller vessels are routinely visualized and assessed, including the gastroduodenal artery,

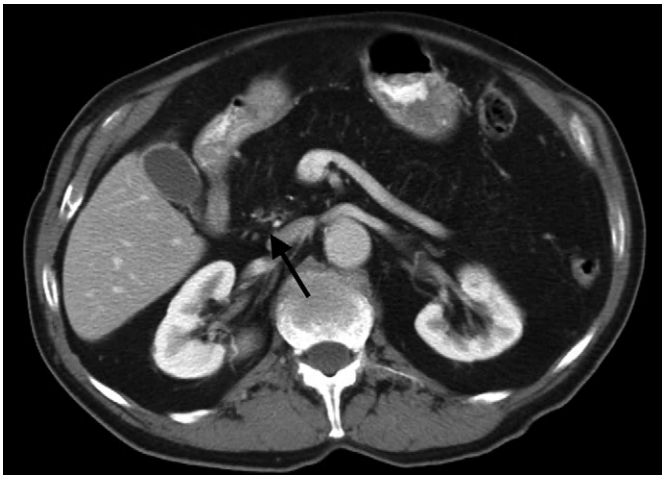

FIGURE 16.59. Extensive fatty replacement of the pancreas. Minimal pancreatic acinar tissue is visible in the posterior aspect of the pancreatic head (*arrow*).

pancreaticoduodenal vessels, and pancreatic branches (Fig. 16.60). MDCT permits even more exquisite evaluation of these small vessels and better three-dimensional evaluation of the data (Fishman & Horton, 2001; Fishman et al, 2000; House et al, 2004; Johnson et al, 2003; Takeshita et al, 2002).

Tumors of the Pancreas

Pancreatic Adenocarcinoma

Pancreatic adenocarcinoma (see Chapter 58A) is the fourth most common cause of death from malignancy (Kim et al, 2004a) and is often discovered at an advanced and inoperable stage. Operative mortality and morbidity rates of 2.8% and 40%, respectively (Wagner et al, 2004), underscore the need for preoperative evaluation to select the subgroup of patients who may be candidates for curative resection.

A recent report describes a new scoring system for tumor invasion that looks at both the length and degree of circumferential encasement of the peripancreatic arteries and veins to determine resectability, using data obtained from 16-slice scanners (Klauss et al, 2008). This score evaluates the length of tumor contact and circumferential extent of tumor involving the SMV, splenic vein, portal vein, aorta, celiac trunk, hepatic artery, splenic artery, and SMA. Veins were also assessed for contour deformations. The authors of this study reported sensitivity and specificity of 89% and 99% for vascular invasion and a sensitivity of 94% and specificity of 89% for the evaluation of resectability.

Pancreatic ducts represent only 4% of the pancreatic tissue but are the source of 90% of pancreatic malignancies (Cubilla & Fitzgerald, 1975; Morohoshi et al, 1983). Adenocarcinoma is the most common form of pancreatic cancer, and it occurs in later life. The clinical presentation depends on the location within the gland; cancers within the pancreatic tail are clinically silent and may not show up until metastasis is widespread, but cancers within the pancreatic head or periampullary region tend to show up earlier, with biliary obstruction a common sign in 50% of patients.

Pancreatic adenocarcinoma appears as a low-attenuation mass, often deforming the contour of the pancreas with secondary signs depending on the tumor location (Figs. 16.61 and 16.62). A mass in the pancreatic head is more commonly associated with biliary or pancreatic ductal dilation. The pancreas proximal to the obstruction is often atrophic, a secondary and often early indication of the tumor site.

Knowledge of vascular involvement or encasement is crucial to preoperative evaluation of the pancreas, because involvement of the superior mesenteric artery or vein, common hepatic artery, or celiac axis generally precludes operative resection for cure. Involvement of the main portal vein is not a contraindication to surgery, because a portion of the main portal vein may be resected and reanastomosed proximal to the jejunal branches (Chae et al, 2003; Lygidakis et al, 2004; Nakao et al, 2004; Yoshimi et al, 2003). Kitagawa and colleagues (2008) reviewed patterns of spread of adenocarcinoma of the pancreatic head

FIGURE 16.62. Dilated pancreatic duct (*arrow*) secondary to carcinoma in the head of the pancreas.

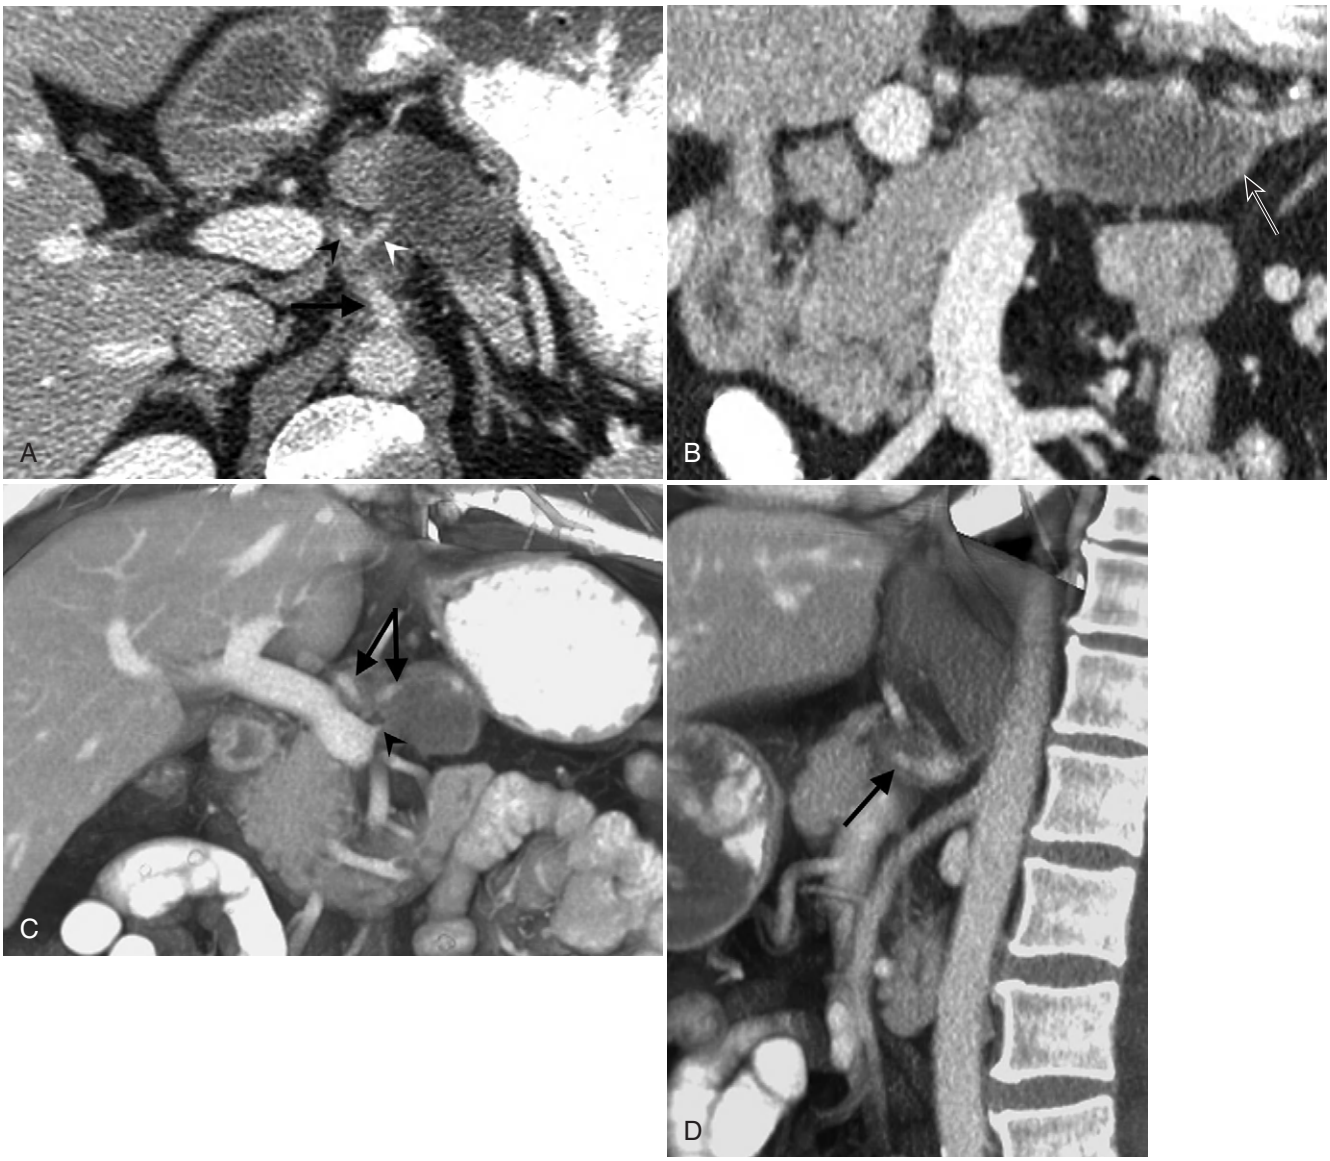

FIGURE 16.63. Pancreatic cancer with vascular encasement. **A,** Cancer in the body of the pancreas tracks posteriorly to encase the celiac axis, proximal hepatic artery (*black arrowhead*), and splenic artery (*white arrowhead*). **B,** Curved multiplanar reconstruction showing the mass (*arrow*) in the body of the pancreas. **C,** Coronal volume-rendered image shows a mass in the body of the pancreas occluding the splenic vein (*arrowhead*) and encasing celiac axis branches (*arrows*). **D,** Sagittal volume-rendered image shows mass encasing the celiac axis (*arrow*).

and found specific patterns, depending upon the origin of the cancer from the dorsal or ventral pancreatic anlagen on an embryologic basis. Tumors confined to the ventral pancreas had metastases along the SMA and peripancreatic nodes, whereas tumors that arose from the dorsal pancreas domain metastasized to the common hepatic artery, hepatoduodenal ligament, and the peripancreatic nodes. Tumors that extended into both domains metastasized widely.

Early findings of pancreatic cancer may be extremely subtle and difficult to detect. In a study at the Mayo Clinic in Rochester, Minnesota, 62 scans obtained before the histologic diagnosis of pancreatic cancer in 28 patients were retrospectively reviewed by two radiologists. Half of the scans obtained before diagnosis showed findings that were interpreted as definite or suspicious for pancreatic carcinoma 2 to 6 months and 6 to 18 months before diagnosis (Gangi et al, 2004). Pancreatic duct dilation and cutoff were early findings. A limitation of this study is that it was a retrospective review of scans obtained between August 1994 and June 2001. Current techniques of thin-section, high-resolution scanning during optimal pancreatic enhancement should improve detection of small lesions. More commonly, pancreatic cancer is detected at an advanced stage, associated with arterial vascular encasement or invasion, venous involvement, peripancreatic adenopathy, hepatic metastases, or ascites (Figs. 16.63 and 16.64). Local arterial encasement or venous occlusion or both preclude resection for attempted cure. Centers with a high volume of pancreatic surgery do a partial resection of the portal vein and primary reanastomosis, but this mandates a cuff of remaining normal portal vein proximal to the first jejunal branch (Chae et al, 2003; Yoshimi et al, 2003). Three-dimensional workstations permit visualization of vascular involvement in coronal and

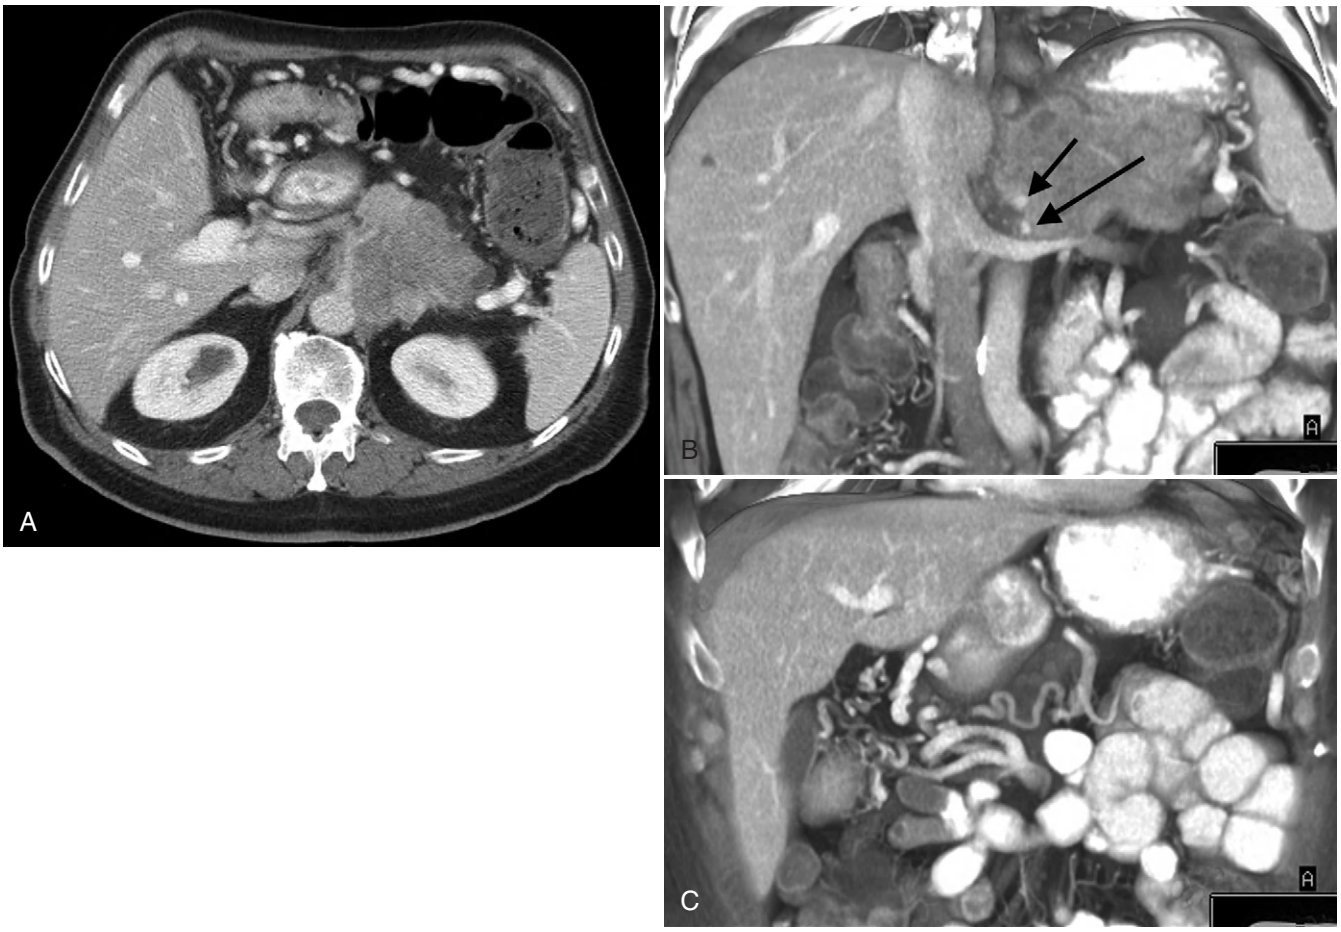

FIGURE 16.64. Large pancreatic mass with vascular encasement and collateral vessels. **A,** Mass in the body and tail of the pancreas encases the celiac artery and its branches. **B,** Coronal volume-rendered image shows the pancreatic mass and encasement of the celiac and superior mesenteric arteries (*arrows*) by tumor. **C,** Coronal volume-rendered image shows extensive collateral vessels in the abdomen from encasement of the splenic vein by pancreatic cancer.

sagittal planes and permit three-dimensional reconstructions using maximum intensity projections or volume rendering (Prokesch, 2003; Tamm & Charnsangavej, 2001; Tamm et al, 2001). Curved multiplanar reformatted images can offer a superb display of pancreatic anatomy and demonstration of adjacent vascular encasement (Vargas et al, 2004, Gong et al, 2004).

Neuroendocrine Cancer of the Pancreas

Neuroendocrine cancer of the pancreas arises predominantly from the islets of Langerhans and may arise in a sporadic fashion or in patients with multiple endocrine neoplasia type I (MEN-I). Pancreatic neuroendocrine tumors generally have a much more favorable prognosis than pancreatic adenocarcinoma. Presentation is diverse and often depends on the presence of hormonal activity and its associated symptoms (Kulke, 2003). Hormonally active tumors may present earlier and are generally smaller than non–hormonally active tumors.

The CT and MR appearances of endocrine tumors of the pancreas according to the World Health Organization (WHO) classification was reviewed recently (Rha et al, 2007). Masses are often hypervascular on imaging and may be associated with liver or nodal metastases or both (Fig. 16.65). Careful attention to detail is required, particularly for imaging of the hormonally

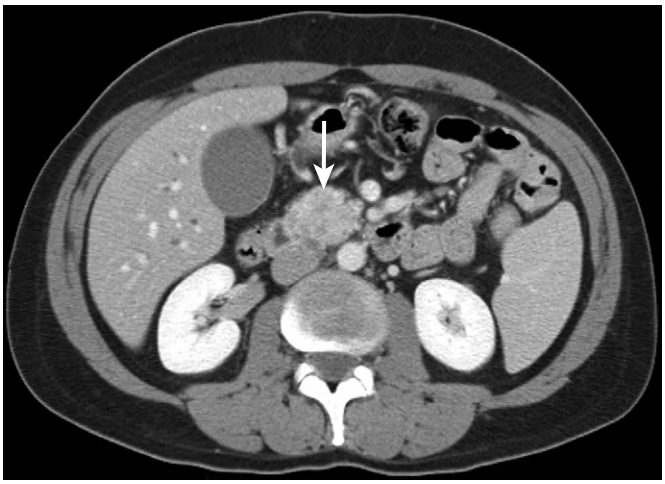

FIGURE 16.65. Pancreatic neuroendocrine cancer/hypervascular mass (*arrow*) on the portal venous phase.

active tumors, which may be small hypervascular masses that often require dedicated thin-section pancreatic protocols for initial detection (Gouya et al, 2003). Arterial phase imaging is necessary to detect masses that otherwise may be isodense on the portal venous phase of imaging (Fig. 16.66). Insulinomas are the most common type of functioning islet cell tumor of the pancreas and are generally extremely hypervascular. Routine follow-up of these patients is best assessed with triphasic scans of the liver to detect masses that may become isodense on portal phase imaging.

In a retrospective review of 50 patients with neuroendocrine cancer (Chu et al, 2002), median survival was 40 months, with overall 1-, 2-, and 5-year survival rates of 84%, 69%, and 36%, respectively. Long-term survival of these patients was related to surgical resection of the primary tumor, absence of liver metastases, metachronous liver metastases, and aggressive treatment of liver metastases using surgery, intrahepatic chemotherapy, or chemoembolization. A German review of 254 patients with neuroendocrine tumors showed 29% to be of pancreatic origin. The 5-year survival from the time of initial diagnosis for this subgroup of patients with pancreatic tumors was 43%. A smaller sized primary tumor (<2 cm) and histologic grading as low-grade malignant were associated with a longer survival (Pape et al, 2004).

Cystic Pancreatic Neoplasms

Cystic pancreatic neoplasms (see Chapter 57) represent a spectrum of disease that includes both benign and malignant entities. Distinguishing benign neoplasms from pancreatic pseudocysts can be difficult, and serial imaging may be necessary to evaluate for stability (Allen et al, 2003; Visser et al, 2004). Included in this group of neoplasms are serous cystadenomas, lymphoepithelial cysts and cystic neuroendocrine tumors, and pseudocysts. Mucinous cystic neoplasms have malignant potential and may present a challenge to distinguish from other benign pancreatic cysts.

INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM. Intraductal papillary mucinous neoplasm (IPMN) of the pancreas is a spectrum of disease, ranging from benign to malignant and characterized overall by improved survival compared with pancreatic adenocarcinoma. There is a greater male/female predominance, with a reported 57% of patients male in the Johns Hopkins experience (Sohn et al, 2004) and a 2.2:1 male/female predominance in a reported Japanese experience (Kimura et al, 1996). The tumor is classified into that of main pancreatic duct, branch duct, or mixed involvement (Bassi et al, 2000; Nagasaka & Nakashima, 2001; Nakamura et al, 2002; Tanaka, 2004; Tan

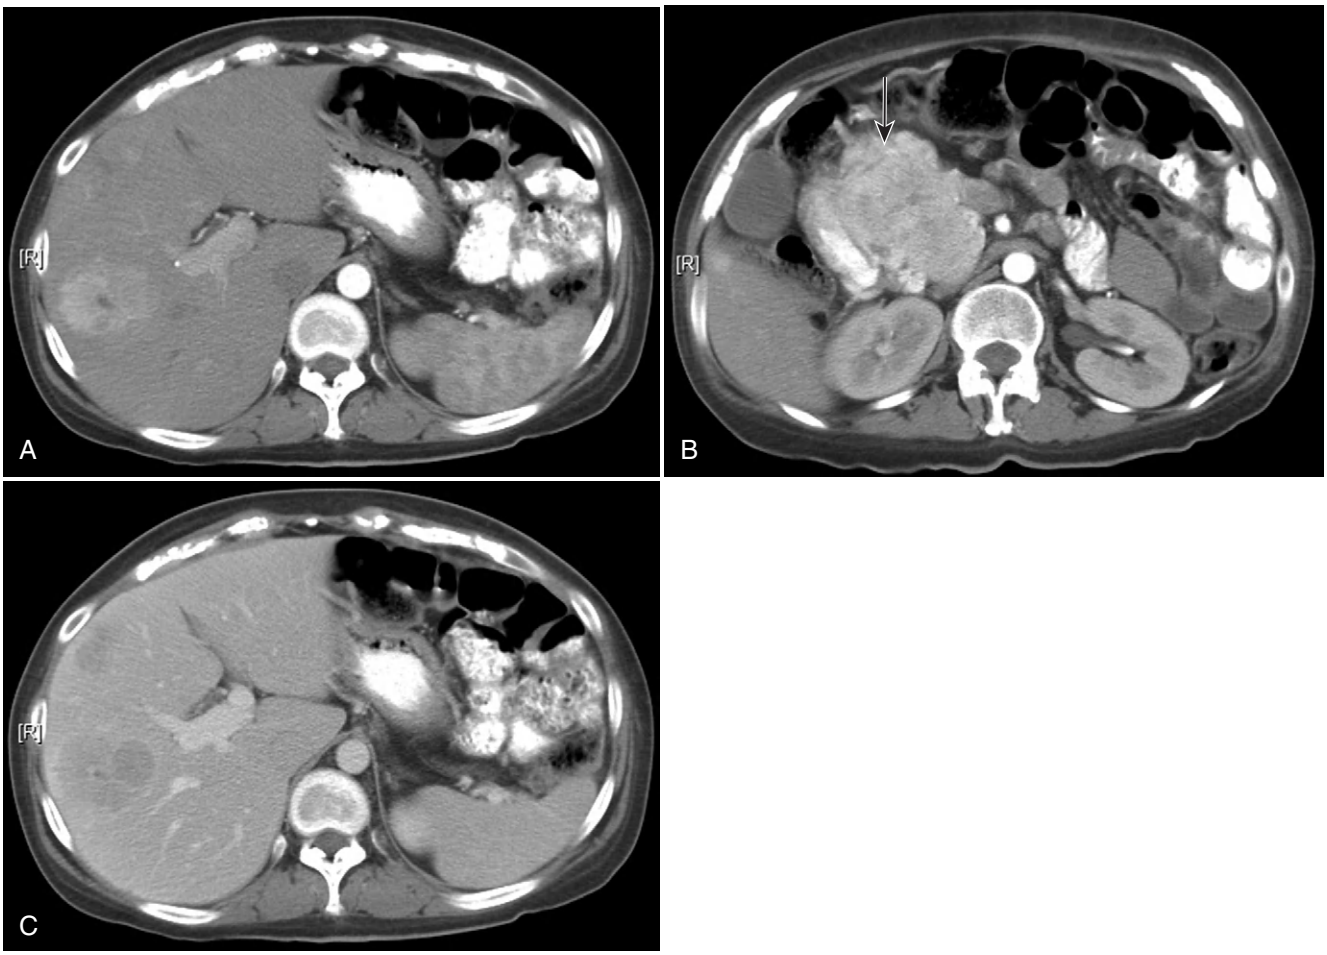

FIGURE 16.66. Islet cell tumor. **A,** Arterial phase scan shows hypervascular liver metastasis from islet cell cancer of the pancreas. **B,** Arterial phase scan shows hypervascular islet cell cancer of the pancreas (*arrow*). **C,** Liver metastasis from islet cell cancer of the pancreas is a lower attenuation than hepatic parenchyma on portal venous phase.

FIGURE 16.67. Intraductal papillary mucinous tumor of the pancreatic head (*arrow*).

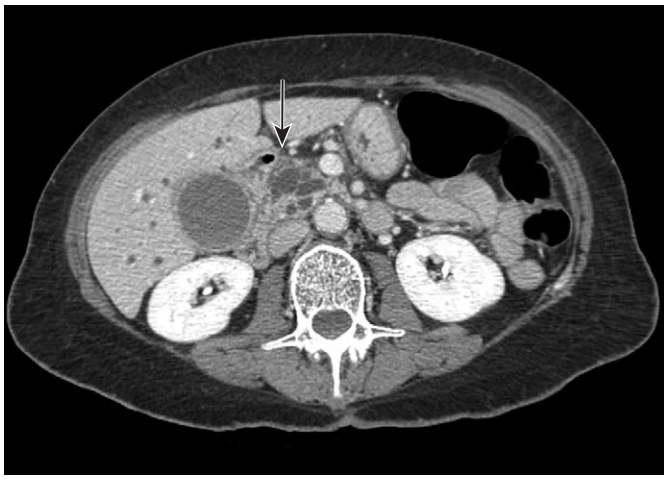

FIGURE 16.68. Intraductal papillary mucinous tumor (*arrow*) of the pancreatic head with invasive adenocarcinoma at pathologic examination; note associated biliary ductal dilation.

et al, 2009; Ogawa et al, 2008; Freeman, 2008). A review of surgical experience of 136 IPMNs from Johns Hopkins (Sohn et al, 2004) found 62% to be benign, and the remaining 38% had IPMNs with associated invasive cancers. The most common presenting symptoms are abdominal pain, weight loss, and nausea and vomiting; patients with invasive IPMNs also may be seen with jaundice.

IPMNs may occur in any portion of the gland. Branch-type neoplasms are most commonly benign, whereas the main duct and mixed types are frequently malignant (Tanaka, 2004; Tan et al, 2009). Multiplanar reformatted images may prove invaluable in the discrimination of branch-type IPMN from main-duct type (Takada et al, 2005). They are cystically dilated ducts that connect to the remainder of the ductal system, lined by flat or papillary mucinous or oncocytic epithelium with or without a component of invasive adenocarcinoma, and they are recognized as identifiable cystic structures of at least 1 cm radiographically or at surgery (Fig. 16.67). Careful attention to radiographic technique, including thin-section imaging with rapid injection of intravenous contrast medium, is crucial to detect these often small masses. Appropriate timing of scanning with the administration of contrast medium is designed to scan the pancreas during the *pancreatogram phase*, when pancreatic parenchyma is maximally enhanced, which maximizes contrast differences between the cystic mass and the enhanced pancreas. Location of the mass within the pancreatic head (Fig. 16.68) may compress the common bile duct with resulting dilation of the intrahepatic bile ducts. Invasive adenocarcinoma may be found at pathologic examination and has been reported to correlate most closely with the presence of mural nodules and pancreatic duct dilation of 7 mm or greater (Sugiyama et al, 2003; Kawamoto et al, 2005; Fig. 16.69). D'Onofrio and colleagues (2009) reported a case of an 8-mm undifferentiated pancreatic adenocarcinoma that had a

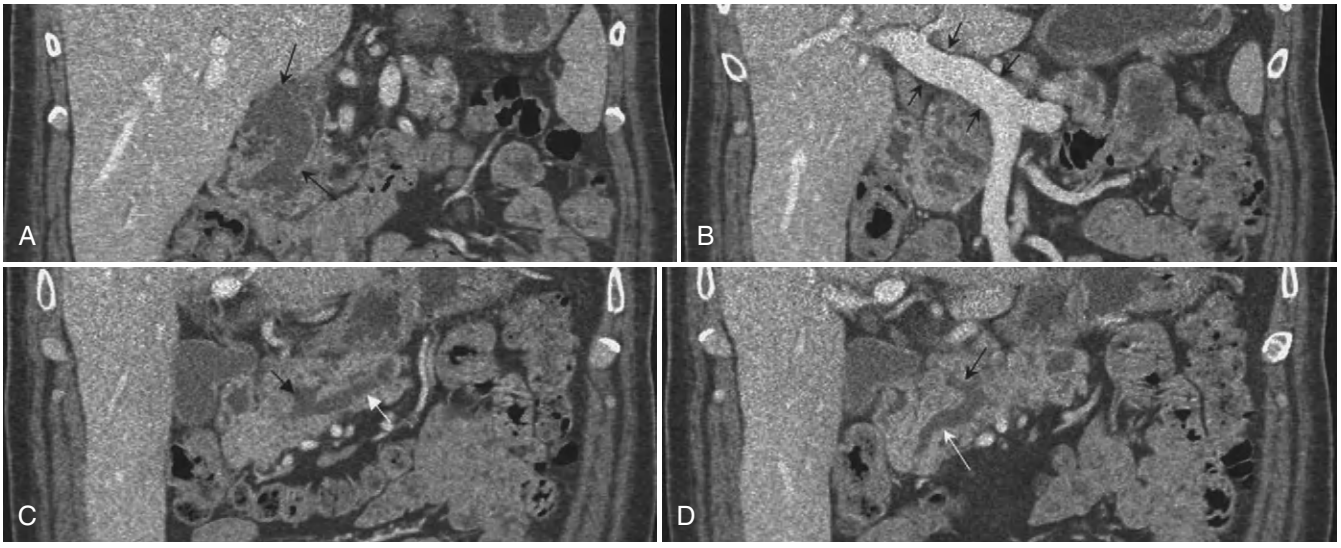

FIGURE 16.69. Intraductal papillary mucinous neoplasm. **A** to **D,** Diffuse involvement of the main (*white arrows*) and branch (*black arrows*) pancreatic ducts with invasive adenocarcinoma. **B,** No evidence of vascular encasement is found, as shown on the normal-appearing portal vein (*arrows*), and none was found at surgery or at pathologic examination.

desmoplastic reaction on an adjacent pancreatic duct, which was dilated and mimicked an IPMN. Intraductal papillary mucinous tumors have a high reported incidence of associated extrapancreatic synchronous and metachronous malignancies of 23.6% to 32%, especially colorectal carcinoma (Sugiyama & Atomi, 1999), and a high incidence of associated pancreatic malignancies (Yamaguchi et al, 2002).

SEROUS CYSTADENOMAS. Often discovered incidentally on abdominal CT scans performed for other indications, pancreatic serous cystadenomas are slow-growing tumors with a 2:1 female/male predominance. These tumors present at a mean age of 63 years versus 54 years for mucinous cystadenomas/carcinomas. Symptoms include vague abdominal pain or back pain. Other symptoms—including nausea, weight loss, and vomiting—are less common. Initially, these tumors were called *microcystic adenomas,* a term that has fallen into disfavor because of reported *macrocystic* tumors (Anderson & Scheiman, 2002).

Serous cystadenomas generally are surrounded by a fibrous capsule and contain numerous tiny cysts, which are sometimes so small that the cystic nature is difficult to appreciate, because it is below the limits of CT resolution. In these instances, ultrasound or MRI may reveal the cystic nature more clearly. Cyst sizes may vary from 1 mm to 2 cm, but occasionally cysts several centimeters in size may be encountered; differentiation from mucinous cystic neoplasms may therefore be difficult (Warshaw et al, 1990; Visser et al, 2008; Chaudhari et al, 2007; Kim et al, 2006). A central stellate scar, when present, is helpful to make the diagnosis. MRI may be useful to visualize the cystic nature when CT findings are equivocal (Allen et al, 2003; Sahani et al, 2002; Visser et al, 2004). Because of their slow-growing nature and vague symptoms in only 50% of patients, these masses may be quite large at the time of discovery (Figs. 16.70 and 16.71).

MUCINOUS CYSTIC NEOPLASMS. Mucinous cystic adenomas of the pancreas often present a mixed picture pathologically, including benign mucin-producing epithelium, dysplasia, carcinoma in situ, and tissue invasion. No imaging criteria permit differentiation of benign from malignant tumors, and all mucinous cystic tumors should be considered malignant or premalignant and should be excised completely (Sarr et al, 2000; Visser et al, 2004; Wilentz et al, 2000).

Mucinous cystic adenomas are found more frequently in women (9:1 predominance) and are frequently within the body and tail of the pancreas. In a series of 52 female patients with pathologically proven mucinous cystic tumors (Procacci et al, 2001), the most highly associated features of malignancy were a thick wall (>2 mm), septations, and calcification in the wall or within septations (Fig. 16.72).

OTHER CYSTIC PANCREATIC MASSES. Cystic masses may also be secondary to degeneration of previously solid masses. Neuroendocrine cancers may become necrotic and present with cystic degeneration (Fig. 16.73). Mucinous tumors may invade adjacent structures and present as cystic masses (Fig. 16.74).

Metastatic Disease to the Pancreas (See Chapter 60)

A pathology review (Adsay et al, 2004) of surgical and autopsy cases showed the most common primary malignancies metastatic to the pancreas were lung carcinomas, gastrointestinal carcinomas, and lymphomas. These are usually found in patients with widely disseminated disease. As at other sites in the body, pancreatic lymphoma tends not to occlude vessels but to encase them. This is a major distinguishing feature useful for diagnosis (Fig. 16.75). Detection of metastatic disease to the pancreas requires a high index of suspicion, because primary pancreatic carcinomas of ductal origin are far more common. When clinical suspicion is present, the study can be tailored to optimize the likelihood of detection. In a patient with renal carcinoma, hypervascular metastases to the pancreas may be detected on routine scanning or triphasic examination (Fig. 16.76).

Solid and Papillary Epithelial Neoplasm of the Pancreas

Solid and papillary epithelial neoplasm (SPEN) of the pancreas is a rare tumor with a low malignant potential (Madan et al, 2004). SPEN has a reported incidence of 0.13% to 2.7% of all pancreatic malignancies and is most commonly encountered in the first three decades of life (Crawford, 1998; Cubilla & Fitzgerald, 1980; Lam et al, 1999), although the reported age range is 8 to 72 years with a mean age of 27 years. Female/male predominance is 9.5:1 (Mao et al, 1995), and these tumors are more common in nonwhites. Patients with malignant SPEN are often older and more often male (Lam et al, 1999). In a review of patients with pathologically proven SPENs, presenting complaints included abdominal pain, palpable mass, dyspepsia with bloating, and early satiety (Buetow et al, 1996; Yoon et al, 2001). Typically, laboratory findings are normal, with no elevation of tumor markers or serum amylase.

On CT, these tumors may have varied findings. They are often large and may have internal hemorrhage or cystic degeneration. Calcification is common (Fig. 16.77), but internal septations are not characteristic for this tumor (Buetow et al, 1996; West & Brady-West, 2000). Although this tumor is of low malignant potential, patients should be followed, because late metastases can occur.

Acinar Cell Carcinoma of the Pancreas

Acinar cell carcinoma is predominantly a tumor of the elderly man, with peak incidence in the 60s and many more men affected than women. Accounting for approximately 1% of all pancreatic tumors, acinar cell carcinoma of the pancreas is defined as a carcinoma of the exocrine pancreas exhibiting pancreatic enzyme production by the neoplastic cells (Cubilla & Fitzgerald, 1975; Morohoshi et al, 1983). They have a characteristic microscopic appearance of a relatively circumscribed periphery and minimal desmoplastic stroma within the tumor, with cells arranged in nests and cords. The tumor is most common in the head, neck, and uncinate process of the pancreas but may arise in any portion of the gland (Holen et al, 2002; Klimstra et al, 1992). Initial symptoms include abdominal pain or fullness, postprandial vomiting, and jaundice. Some patients may be asymptomatic, and the mass may be detected incidentally. Serum tumor markers may be normal, or there may be mild elevation of serum α-fetoprotein, carcinoembryonic antigen (CEA), and CA19-9.

CT features include a well-defined tumor with a thin, enhancing capsule and central necrosis, which may contain areas of internal calcification (Fig. 16.78). Such calcification may be a useful feature in distinguishing this entity, because only 2% of ductal adenocarcinomas and 22% of nonfunctioning islet cell tumors contain calcification (Buetow et al, 1995b; Eelkema et al, 1984). In a more recent series (Chiou et al, 2004), tumor diameters ranged from 3.3 to 18 cm, with an overall mean size of 7.2 cm. Most of these tumors were hypodense with respect to normal pancreatic parenchyma, although some showed hypervascular enhancement on the early arterial phase, some of which persisted into the portal venous phase.

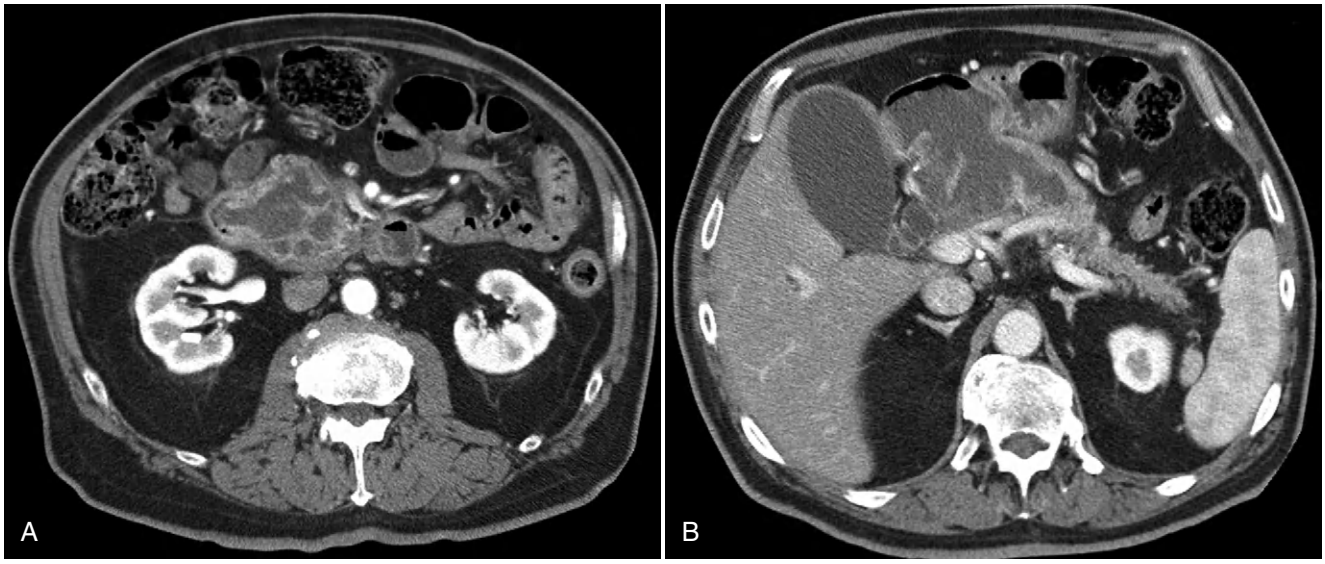

FIGURE 16.74. Intraductal papillary mucinous tumor with invasive mucinous adenocarcinoma. **A,** Large multicystic tumor extends into the papilla. **B,** Computed tomography shows that the mass also invades into the duodenum and stomach.

Inflammatory Diseases of the Pancreas

Pancreatitis (See Chapters 54 and 55)

The most common cystic mass of the pancreas is not a malignancy but rather a complication of acute or chronic pancreatitis. Fluid collections occur in approximately 50% of patients with moderate to severe pancreatitis. Of these, approximately 50% resolve spontaneously within 6 weeks (Baron & Morgan, 1997; Byrne et al, 2002), and 10% to 15% may progress to pseudocyst formation after developing a capsule. Pseudocyst formation is more common in patients with chronic pancreatitis and may occur in 20% to 40% of these patients.

Common causes of pancreatitis include alcohol, gallstones, idiopathic hypertriglyceridemia, drugs, pancreas divisum, trauma, and endoscopic retrograde cholangiopancreatography (Baron & Morgan, 1997). Clinical presentation includes nausea, vomiting, and epigastric pain. Serum amylase, frequently used to monitor pancreatitis, may be normal in acute pancreatitis and elevated in nonpancreatitic conditions. Elevation of the serum lipase may support the diagnosis of acute pancreatitis.

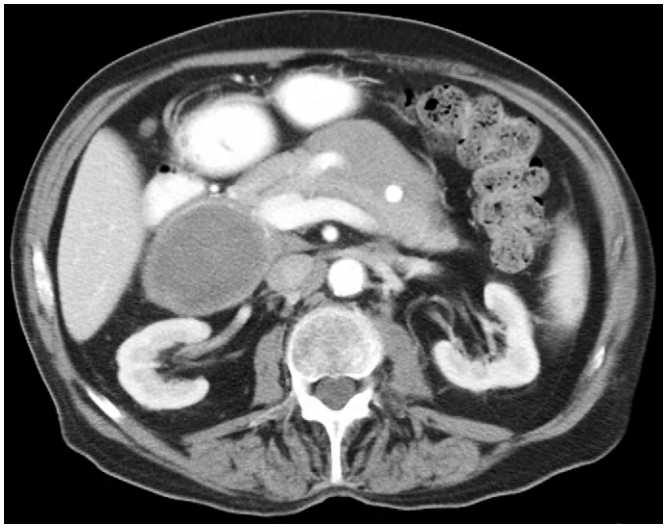

FIGURE 16.75. Lymphoma of the pancreas. Note absence of vascular narrowing.

Mild acute pancreatitis may appear on CT scan as enlargement of the pancreas with loss of definition of the borders of the pancreas. Depending on the part of the pancreas involved, there may be thickening of the right or left anterior pararenal fascia or diffuse thickening of adjacent fascial planes (Figs. 16.79 and 16.80). Acute fluid collections associated with pancreatitis are enzyme-rich collections, which lack a defined wall.

Pancreatic fluid collections may present as an acute fluid collection interspersed with pancreatic parenchyma without a defined wall. The fluid collection may be well circumscribed, or it may infiltrate throughout the pancreas and retroperitoneum; this may dissect retroperitoneal planes and resolve spontaneously 50% of the time. An *acute pseudocyst* is defined as a collection of pancreatic juice confined by a nonepithelialized wall of granulation tissue that occurs as a result of acute pancreatitis (Baron & Morgan, 1997) and requires at least 4 weeks to form (Fig. 16.81). It is characterized by the presence of a well-defined wall and may contain internal septations.

Lymphoplasmacytic Pancreatitis

Lymphoplasmacytic pancreatitis, also known as *autoimmune pancreatitis* (Kawaguchi et al, 1991; Kim KP et al, 2004; Yoshida et al, 1995), was first described as a "primary inflammatory sclerosis of the pancreas" (Sarles et al, 1961). It is characterized by a mixed inflammatory infiltrate centered around pancreatic ducts and ductules, combined with obliterative phlebitis (Hardacre et al, 2003). The clinical presentation can be identical to that of pancreatic adenocarcinoma, with abdominal pain, jaundice, weight loss, and elevated levels of CEA or CA19-9. Elevation of pancreatic enzymes is not a prominent feature of this entity, with mild elevation in serum amylase or lipase levels most commonly reported. Elevated levels of IgG and

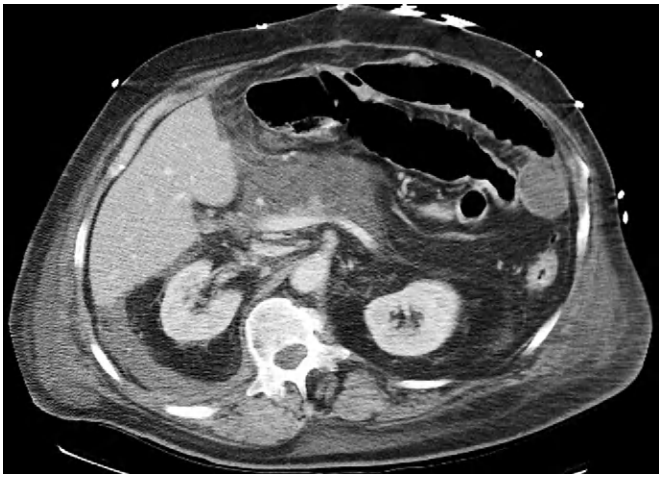

FIGURE 16.80. Severe pancreatitis obliterates tissue planes in a patient after gastrectomy.

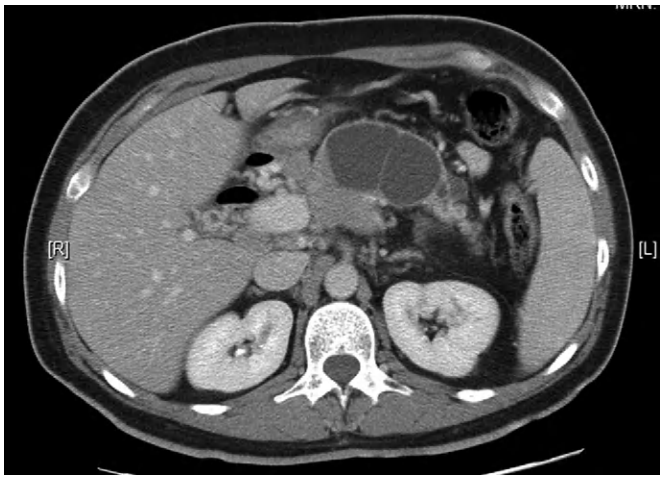

FIGURE 16.81. Pancreatic pseudocyst in portal venous phase. The patient also has adenopathy from an islet cell tumor.

FIGURE 16.82. Lymphoplasmacytic pancreatitis causing diffuse pancreatic enlargement.

hypergammaglobulinemia are reported in 37% to 76% of patients with autoimmune pancreatitis (Kim et al, 2004b). Patients may also present with fluctuating obstructive jaundice without pain (Kamisawa et al, 2007).

Imaging features of this disease include diffuse or focal enlargement of the pancreas without pancreatic calcification or peripancreatic inflammation, often with nonvisualization of the pancreatic duct and associated with a low-attenuation rim around the pancreas (Fig. 16.82). Imaging also may show thickening of the wall of the common bile duct and gallbladder wall (Kawamoto et al, 2004; Takahashi et al, 2008), which pathologically is due to diffuse lymphoplasmacytic infiltration and fibrosis (Kloppel et al, 2003). Distinguishing lymphoplasmacytic pancreatitis from adenocarcinoma is important, because

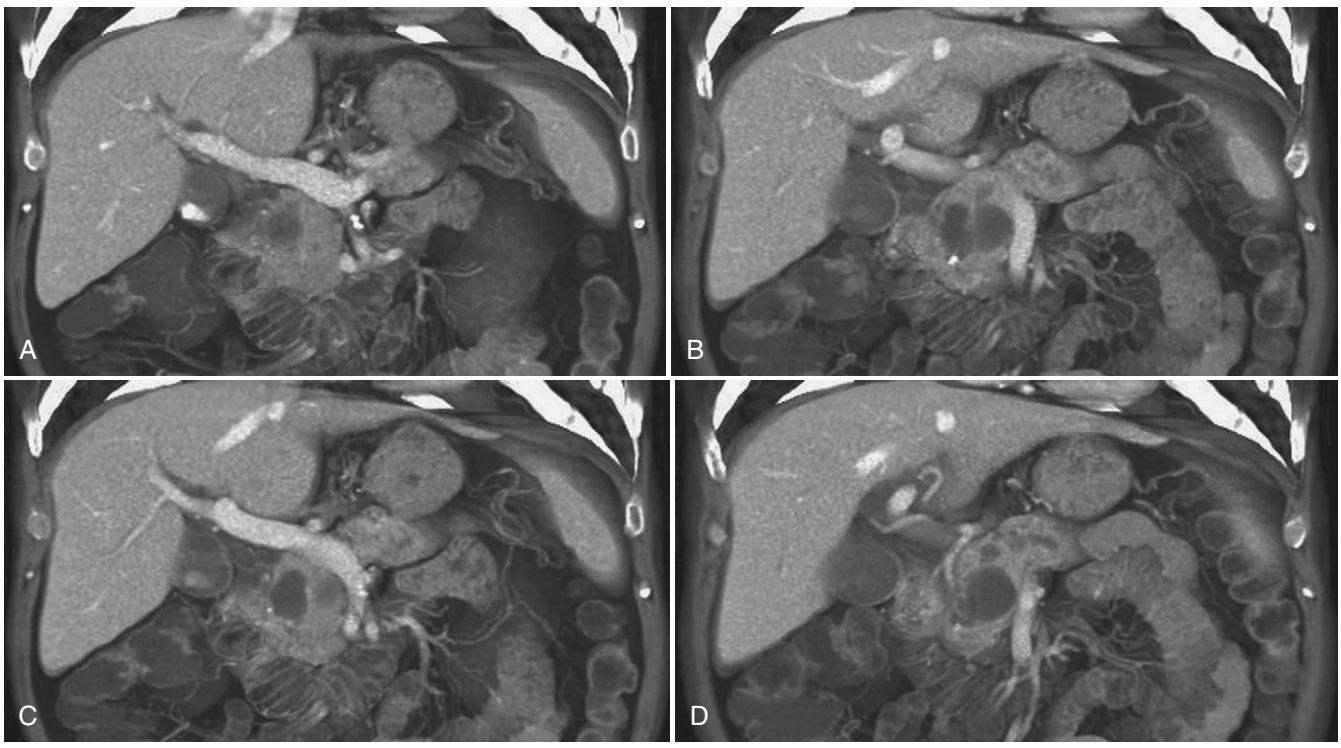

FIGURE 16.83. Groove pancreatitis. Images **A** to **D** show paraampullary duodenal wall cysts with extension to the pancreas along with cystic dilation of the pancreatic duct. At pathologic examination, no malignancy was found. The duodenal wall showed fibrosis and chronic inflammation, and the adjacent pancreas showed focal chronic pancreatitis. The gallbladder showed changes of chronic cholecystitis.

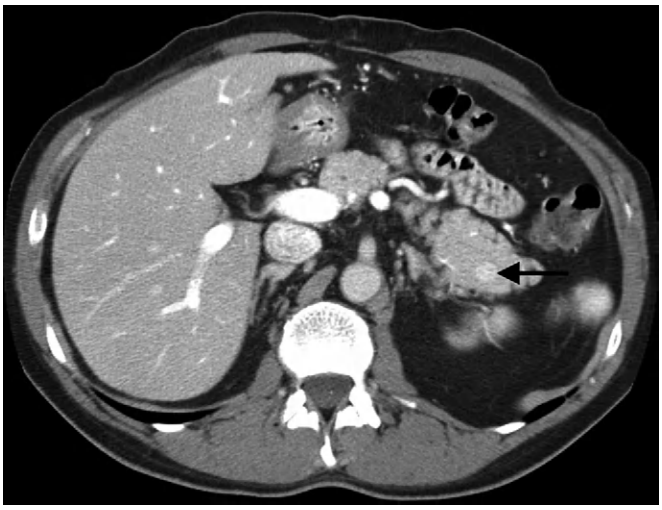

FIGURE 16.84. Hypervascular mass in the pancreatic tail (*arrow*) from ectopic splenic tissue.

lymphoplasmacytic pancreatitis responds to oral steroid administration. Distinguishing focal lymphoplasmacytic pancreatitis with localized stenosis of the main pancreatic duct and associated pancreatic duct dilation from pancreatic carcinoma is often not possible, however, and the diagnosis is made only at laparotomy. A multifocal form of autoimmune pancreatitis has also been reported (Kajiwara et al, 2008).

Groove Pancreatitis

Groove pancreatitis affects the groove between the pancreatic head, duodenum, and the common bile duct and was first described by Becker and named by Stolte and colleagues (Becker, 1973; Stolte et al, 1982). This can be extremely difficult to distinguish from groove pancreatic carcinoma, as patients are seen initially with abdominal pain and vomiting secondary to duodenal stenosis. This represents chronic pancreatitis that occurs with a platelike mass between the head of the pancreas and the duodenum, and it may cause intrahepatic and extrahepatic biliary duct dilation. Duodenal stenosis may be associated with wall thickening and cystlike lesions in the duodenal wall or in the groove area (Gabata et al, 2003; Lauffer et al, 1999; Triantopoulou et al, 2009; Fig. 16.83). Pancreatic duct dilation is much less common than bile duct dilation, and distinguishing groove pancreatitis from groove pancreatic carcinoma is done from a biopsy.

Other Nonneoplastic Pancreatic Masses: Ectopic Splenic Tissue

An unusual masslike entity that may be encountered in the pancreas is ectopic splenic tissue (Fig. 16.84). Autopsy studies have shown that 10% of patients have accessory spleens, and of these, nearly 20% are found in or near the tail of the pancreas (Halpert & Alden, 1964; Halpert & Gyorkey, 1959; Lauffer et al, 1999). This accessory spleen enhances in tandem with the spleen, but prospective diagnosis of this entity is difficult. A Japanese report described identical enhancement of the intrapancreatic splenic tissue and the major spleen, although this was a study using CT angiography and not peripheral venous access (Miyayama et al, 2003). Differentiating ectopic splenic tissue from other hypervascular masses, particularly neuroendocrine cancer, is difficult.

CHAPTER 17

Magnetic resonance imaging of the liver, biliary tract, and pancreas

Lawrence H. Schwartz

Magnetic resonance imaging (MRI) is a cross-sectional scanning technique that allows images to be taken in any plane (Fig. 17.1). MRI uses magnetic fields and radiofrequency pulses to generate images with outstanding tissue contrast and excellent spatial resolution. MR techniques are not new and were first described in the 1940s by Bloch and colleagues (1946) and Purcell and colleagues (1946) as a method for in vitro chemical analysis. Several decades later, Damadian (1972) and Lauterbur (1973) applied some of these basic principles to design an MRI technique capable of in vivo imaging. Today, MRI is used extensively as an imaging tool throughout the body to visualize and distinguish normal and pathologic tissue.

PRINCIPLES OF MAGNETIC RESONANCE IMAGING

MRI is based on the principles of nuclear magnetic resonance. Certain nuclei have a magnetic movement or spin. These nuclei react to placement in a strong magnetic field by aligning themselves in the direction of the field. A proton aligns itself in one of two directions, either up or down. In addition, when placed in a magnetic field, the nuclei rotate or spin parallel to the magnetic field. The precise frequency of the nuclear spin is termed the *Larmor frequency,* which depends on the specific type of nuclei imaged within the magnetic field and the strength of the magnetic field. The most commonly imaged nucleus in clinical practice is hydrogen (^{1}H) because of its great abundance in the human body. Other nuclei that may be imaged by MRI include phosphorus (^{31}P), sodium (^{23}Na), and carbon (^{13}C).

When nuclei are within the stable magnetic field, they are considered to be in equilibrium: an almost an equal number of nuclei are in an "up" or "down" alignment, and an equal number of transitions exist between the two states. Adding a momentary radiofrequency pulse at the precise frequency of the nuclear spin (the Larmor frequency) produces resonance, hence the term magnetic *resonance* imaging. This radiofrequency pulse causes a change in the energy and a change in the transition state. The radiofrequency pulse is then turned off, and the nuclei in the body return to the equilibrium state, emitting a radiofrequency signal. The strength of this emitted signal and the amount of time for the nucleus to return to the equilibrium state determine the signal intensity of a tissue. The precise tissue signal intensity depends on several factors, including longitudinal relaxation (T1), transverse relaxation (T2), proton density (nuclear spin), and flow.

The T1 value, longitudinal or *spin-lattice* relaxation, is the time required for the rotating nuclei to return to the equilibrium state after the radiofrequency pulse. The initial energy absorbed by the nuclei is released and dissipated into the surrounding molecular environment or lattice. The precise T1 value is the time it takes the MRI signal to return to 63% of its maximum value. Most tissue T1 values vary between 200 and 800 ms. Tissue with a short T1 value appears bright (hyperintense) on T1-weighted images by convention.

The T2 relaxation time, transverse or *spin-spin* relaxation, is a measure of the loss of signal in a plane perpendicular to the long axis of the magnetic field. This loss of signal is due to subtle inhomogeneities in the magnetic field because of the presence of spinning protons. The T2 value for a tissue is the time it takes for the signal to decrease to 63% of its equilibrium value. Most tissue T2 values vary between 50 and 200 ms, and the T2 value can never be longer than the T1 value. By convention, tissues with a long T2 value appear bright on T2-weighted images.

The motion of fluid, such as from blood, plays a major role in the appearance of every MRI image. In general, blood flow tends to produce spin dephasing, which results in a loss of signal in an MRI image. Certain pulse sequences are sensitive to flow, and flow produces a higher signal intensity. MRI angiography techniques use this principle to produce images in which flowing blood is bright and background tissue is relatively dark. This technique takes advantage of the fact that blood flow produces moving protons that have a different signal from the static protons within the slice being imaged.

Improvements in MRI equipment and software used to control this machinery have resulted in a decrease in the time needed to create an image. State-of-the-art scanning equipment may create an image in less than 1 second. Also, specialized surface coils, local antennas used to receive the magnetic resonance signal, are now used to obtain images with higher spatial resolution. Fast techniques can produce images with either T1 weighting or T2 weighting. Gradient-recalled echo techniques can be applied to produce high-quality T1-weighted images covering the entire liver in a total scan time of less than 20 seconds. This fast scanning permits breath-hold imaging and allows for the dynamic administration of certain contrast material with hepatic MRI. New techniques using a half-Fourier technique—acquisition of slightly more than 50% of the data and the computer reconstruction of the remaining data set—create subsecond T2-weighted images. Although rapid T2 weighting has been accomplished previously with techniques such as echo-planer imaging, the half-Fourier techniques have significantly fewer artifacts. These new subsecond T2 sequences have several vendor-specific trade names, such as Single Shot Fast Spin Echo (SSFSE) or Half-Fourier Acquisition Turbo Spin Echo (HASTE). Despite different nomenclature, these techniques produce similar, highly effective results.

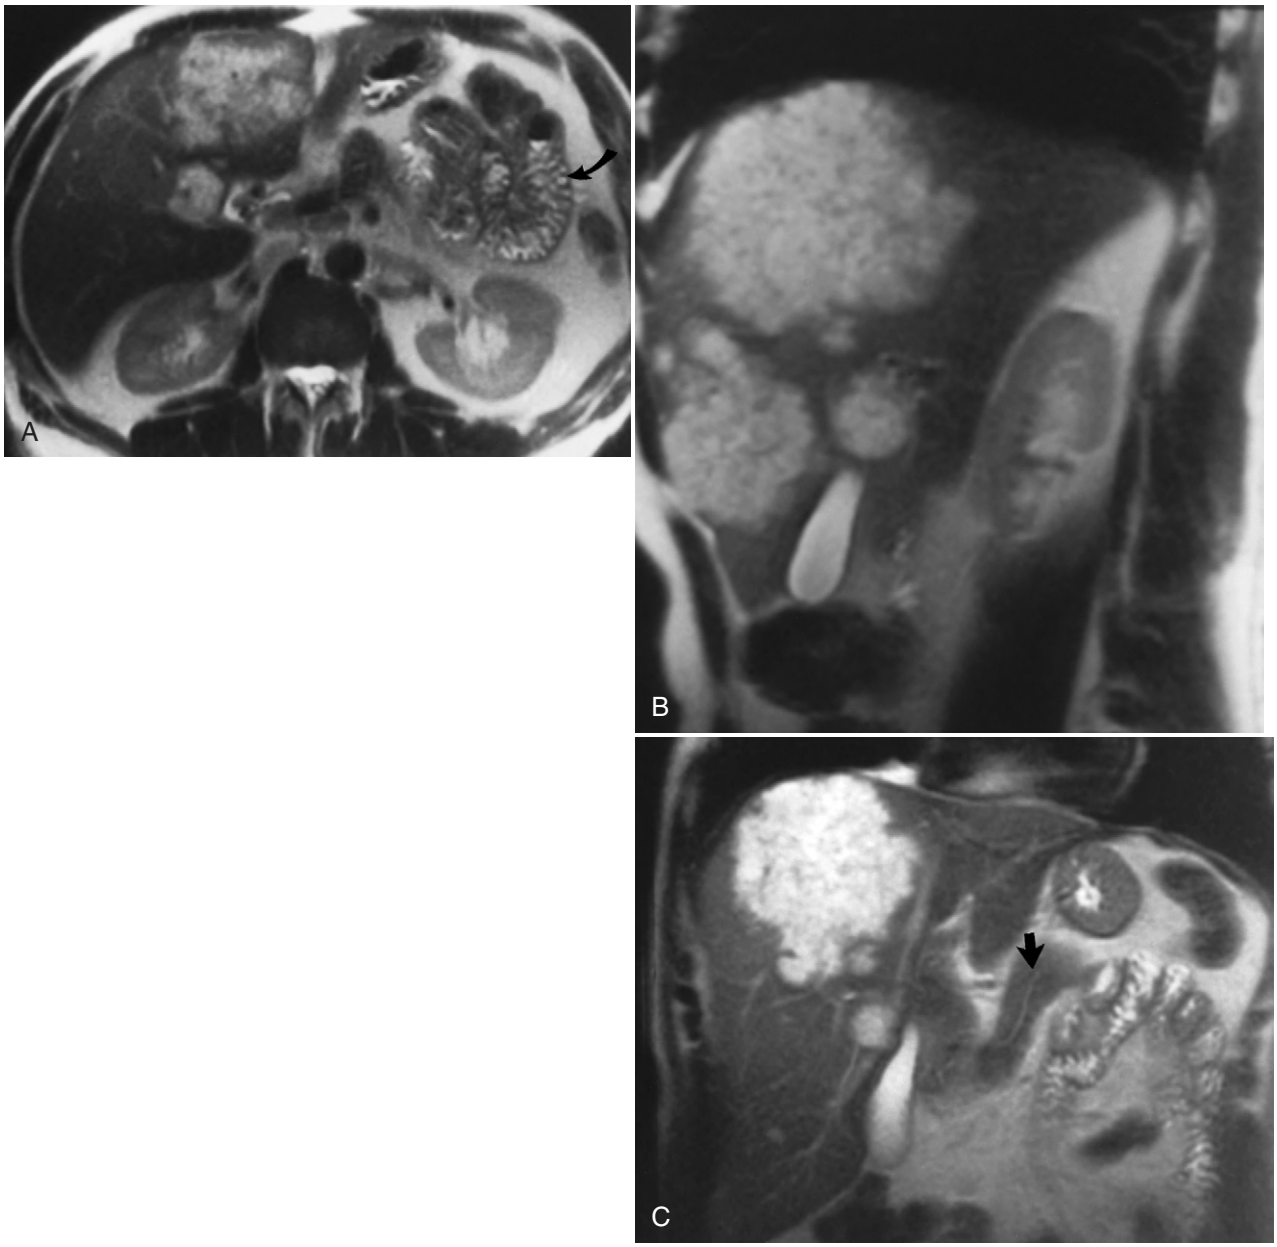

FIGURE 17.1. Multiplanar T2-weighted images through the liver in a patient with multiple hepatic metastases. **A,** Axial image. **B,** Sagittal image. **C,** Coronal image. A variety of techniques can be used to obtain these images. Note that fluid-containing structures, including small bowel (*curved arrow,* **A**), gallbladder, biliary tree, and pancreatic duct (*arrow,* **C**) are bright.

Diffusion MRI is also a new MRI method that produces images of tissues weighted with the local structural properties of water diffusion. Diffusion-weighted imaging (DWI) of the liver may be used to characterize focal hepatic masses and may also be used, for instance, to assess liver fibrosis. In DWI, each image *voxel*, a three-dimensional pixel, has an image intensity that reflects a single best measurement of the rate of water diffusion at that location. This measurement is more sensitive to early changes after a stroke than more traditional MRI measurements such as T1 or T2 relaxation rates. DWI is most applicable when the tissue of interest is dominated by isotropic water movement, for example, gray matter in the cerebral cortex and major brain nuclei, in which the diffusion rate appears to be the same when measured along any axis.

MAGNETIC RESONANCE IMAGING SAFETY

MRI is safe for most patients. However, physicians and patients should be aware of some important considerations, as several contraindications to MRI examination exist. Absolute contraindications include a cardiac pacing device, implanted neurostimulator, intracranial aneurysm clip of unknown composition, and a metallic fragment in the globe of the eye. Relative contraindications for MRI include recent intravascular stent or filter and pregnancy. Depending on the location and composition of a particular stent or filter, a variable time frame exists before an MRI examination is obtainable. Pregnancy is a relative contraindication, because there are no known long-term effects of MRI on the human fetus. It is prudent, however, to

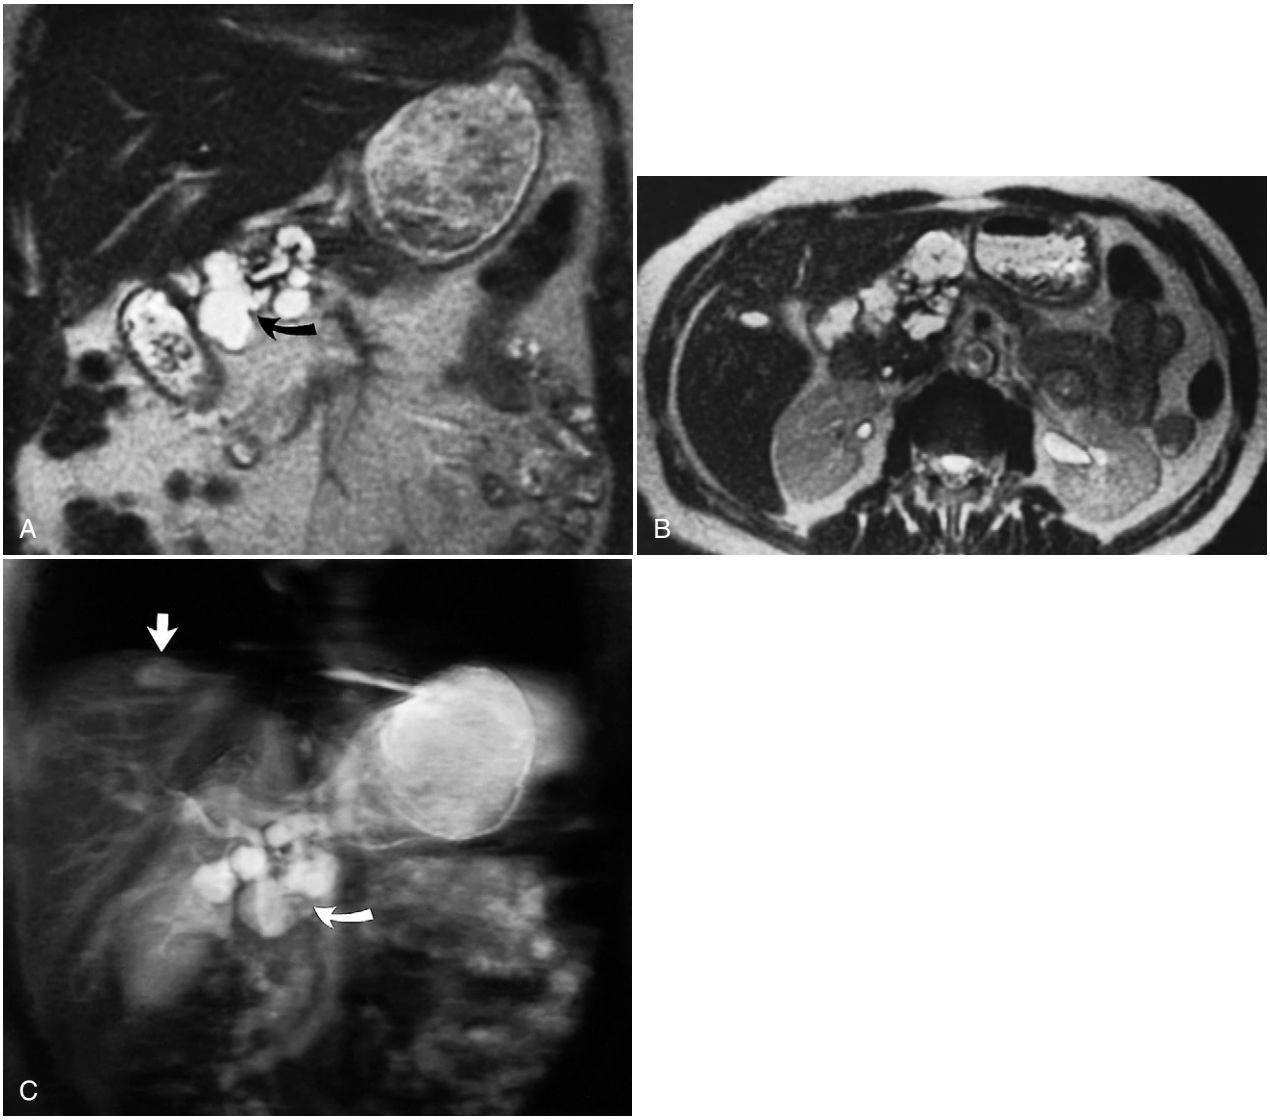

FIGURE 17.2. Cross-sectional images and projection image of the same patient as in Figure 17-1. **A,** Cross-sectional coronal image obtained at a slice thickness of 4 mm. A focal mass (*arrow*) in the pancreas is hyperintense and composed of multiple cysts. **B,** Axial image through the pancreas also shows the mass. **C,** Projection of the abdomen obtained at a slice thickness of 40 mm. The cystic mass within the pancreas (*curved arrow*) is easily identified. Fluid-containing structures and lesions that act like fluid are easily seen with this technique. Note a small hemangioma at the hepatic dome (*straight arrow*).

avoid scanning a pregnant patient before completion of organogenesis. These contraindications are not all-inclusive, and if questions arise about the safety of the patient, it is best to consult with the MRI specialist performing the examination.

MAGNETIC RESONANCE IMAGING CHOLANGIOGRAPHY

MRI cholangiography and MRI cholangiopancreatography (MRCP) are imaging techniques used to evaluate the biliary system. Heavily T2-weighted images are used to provide an overview of the biliary system and pancreatic duct. Excellent diagnostic-quality images are obtainable, with high sensitivity and specificity for evaluation of biliary duct dilation, strictures, and intraductal abnormalities (Sandrasegaran et al, 2010; Palmucci et al, 2010a; Palmucci et al, 2010b; Hekimoglu et al, 2008). Cross-sectional images and projection images (Fig. 17.2) may be produced easily with current MRCP techniques, and the projection images are similar to direct contrast-enhanced cholangiograms obtained with either endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC; see Chapter 18).

The basic principle of MRCP is to use T2-weighted images, in which stationary or slowly moving fluid, including bile, is high in signal intensity; all the surrounding tissues, including retroperitoneal fat and the solid visceral organs, are lower in signal. MR-specific techniques for obtaining cholangiographic images include two-dimensional and three-dimensional sequences, breath-hold or non–breath-hold techniques, and respiratory gated techniques. MRCP plays an important role in imaging benign disorders of the biliary and pancreatic system, and it is part of a comprehensive imaging evaluation of

malignancies of the biliary system (Kim et al, 2002b; Lee et al, 2003; Vaishali et al, 2004). MRCP is noninvasive, eliminating the morbidity associated with ERCP or PTC (Zhong et al, 2004). An additional advantage of MRCP includes visualization of the extrabiliary anatomy, allowing for exclusion or inclusion of alternative diagnoses. Surgical clips may create an artifact known as *susceptibility*, which may obscure the region of interest by producing areas of signal void. This artifact may mimic a stone, so caution must be used in evaluating MRCP images in postoperative patients to avoid a false-positive diagnosis.

MAGNETIC RESONANCE IMAGING CONTRAST AGENTS

MRI contrast agents work by altering the T1 and T2 relaxation times of various tissue types. In the hepatobiliary system, MRI contrast agents can potentially improve the detection of liver lesions and improve the characterization of focal liver abnormalities. MRI contrast agents for hepatobiliary imaging are divided into two basic categories: *intracellular* and *extracellular* agents. The most commonly used contrast agents are the extracellular agents, such as gadopentetate dimeglumine (gadolinium diethylenetriaminepentaacetic acid [Gd-DTPA]), which is distributed within the intravascular compartment initially and rapidly diffuses through the extravascular space, similar to the action of iodinated contrast agents in computed tomography (CT; see Chapter 16). Agents such as gadolinium require fast MRI pulse sequences to preferentially enhance either tumor or normal tissue, so that the difference between the two tissues is great. Metastatic liver lesions enhance irregularly, predominantly in the periphery of the lesion, and slowly; the central portion may or may not accumulate contrast material. Using extracellular contrast agents such as gadolinium and dynamic fast scanning, hepatic hemangiomas can be differentiated from other tumors by their characteristic enhancement patterns. Hepatic hemangiomas fill in slowly (5 to 20 minutes) from the periphery with a nodular appearance (see Chapter 79). An advantage of gadolinium over iodinated CT contrast agents is the lack of renal toxicity even at high doses (Prince et al, 1996). This fact has clinical implications in patients with decreased renal function or in those at risk for potential nephrotoxic effects of iodinated contrast agents.

Several new hepatobiliary-specific contrast agents have been developed to overcome some of the limitations associated with the general extracellular contrast agents. These hepatobiliary-specific contrast agents are taken up to varying degrees by functioning hepatocellular tissue and are excreted at least partially in the bile. They function because of their paramagnetic properties, which cause T1 shortening both of the liver and biliary tree. Hepatobiliary-specific agents include mangafodipir trisodium, gadopentetate dimeglumine, and gadoxetic acid, and both gadobentate dimeglumine (Gd-BOPTA) and gadolinium-ethoxybenzyl-diethylenetriamine pentaacetic acid (Gd-EOB-DPTA) have been approved in the United States. These contrast agents are all administered intravenously, although the dose and duration of the administration are different. These two agents are sometimes referred to as *combination agents* because of their dual capacity for imaging both in the dynamic phase and in the delayed, hepatocyte-specific phase. These agents have the potential to provide extensive and comprehensive information about the lobes of the liver, bile ducts, and liver vasculature. (Giovagnoni & Paci, 1996; Iman & Bluemke, 2000; Stern et al, 2000).

NORMAL HEPATIC APPEARANCE ON MAGNETIC RESONANCE IMAGING

Hepatic MRI is a sensitive technique to evaluate diffuse and focal abnormalities. In normal hepatic parenchyma on T1-weighted images, the liver is brighter (hyperintense) than the spleen. Depending on the specific technique chosen, the vessels may appear dark (flow voids on spin-echo technique), or they may be bright (gradient-echo technique). On T2-weighted images, the spleen is relatively brighter than the liver (Fig. 17.3). Fluid is dark on T1-weighted images and bright on T2-weighted images as a result of long T1 and T2 values. Although many hepatic lesions are low in signal intensity on T1-weighted images, they may be of variable intensity on T2-weighted images, depending on their water content.

DIFFUSE HEPATIC DISEASE

Fatty Infiltration of the Liver

Fat may accumulate within hepatocytes for many reasons, including alcohol abuse, diabetes, drugs, and obesity (see Chapter 65). Fatty change may be diffuse, patchy, or focal. The pattern of fatty infiltration is related to regional differences in perfusion. It is often difficult to distinguish fatty infiltration from focal hepatic lesions on CT, because both appear low in attenuation. Additionally, focal fatty sparing may appear similar to a vascular neoplasm on contrast-enhanced CT. It is easy, however, to distinguish these entities on MRI because of different signal characteristics. On T1-weighted images, areas of fatty infiltration appear bright because of the low T1 value of fat. The appearance on T2-weighted images depends on the specific type of T2-weighted sequence acquired. Conventional spin-echo T2-weighted sequences are relatively insensitive to the presence of fat (Wenker et al, 1984). Areas of focal fatty infiltration may appear hyperintense to normal hepatic parenchyma on fast T2-weighted images because of the high signal intensity of fat in these sequences. Using chemically selective fat suppression techniques, these areas of focal fatty infiltration appear dark.

Chemical shift imaging is another technique that allows differentiation of the signals from fat and water protons. These chemical shift techniques are the most sensitive techniques for distinguishing fatty infiltration (Fig. 17.4; Mitchell et al, 1991; Siegelman, 1997; Springer et al, 2010). Chemical shift imaging techniques rely on the different resonant frequencies present in fat and water protons. Using fast imaging techniques, the signal emanating from fat and water protons may be equal but opposite. Tissues that have relatively equal quantities of fat and water appear dark, because the signals from fat and water cancel each other out. Areas of fatty sparing remain relatively hyperintense to the fatty infiltrated regions. Focal fatty infiltration should not enhance after gadolinium administration. A lesion with characteristic signal intensity findings on T1, T2, and gradient-echo opposed-phase imaging is diagnostic of fatty infiltration (Kreft et al, 1992; Mitchell et al, 1991). Any one of these sequences alone is not characteristic, because other lesions, including hepatocellular carcinoma (HCC) and adenoma, may contain small quantities of fat within them (see Chapters 78, 79, and 80).

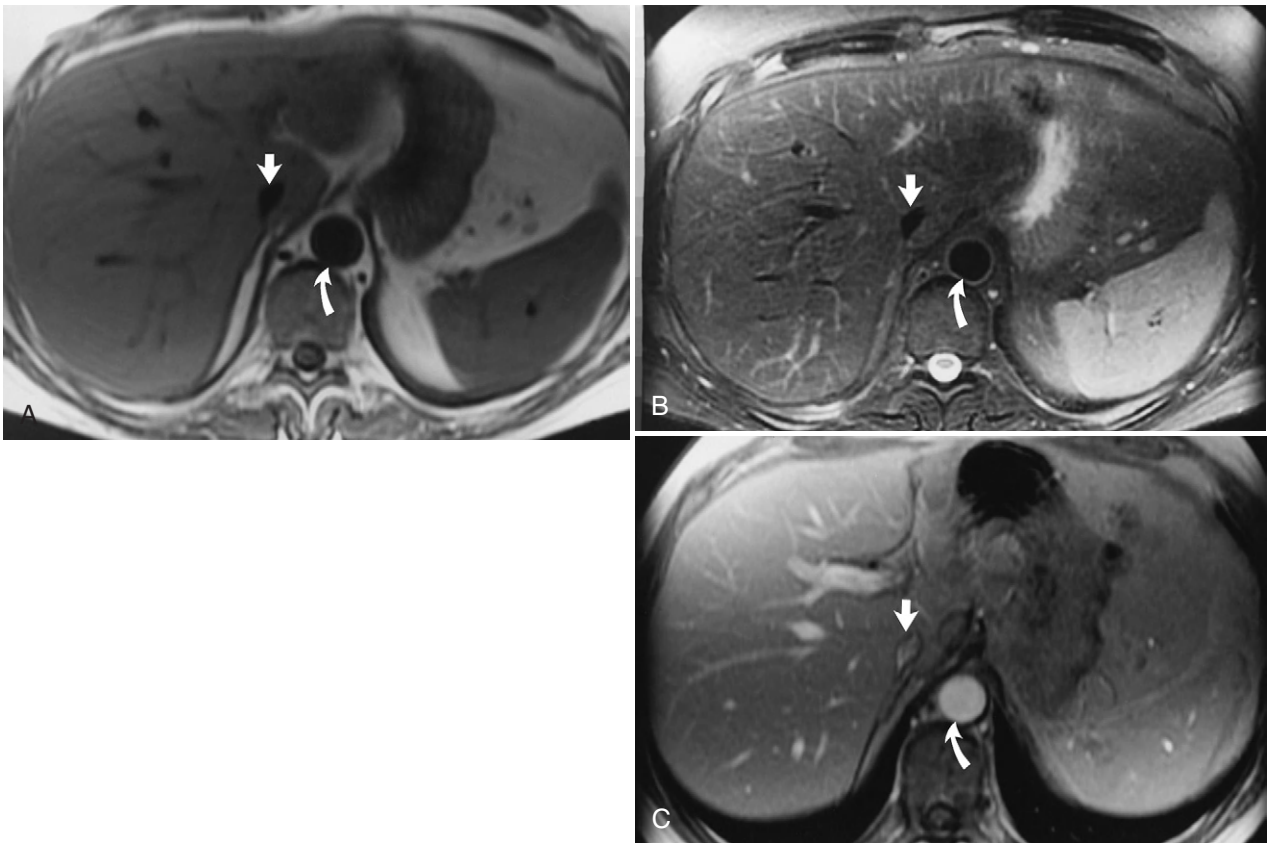

FIGURE 17.3. Normal hepatic magnetic resonance image. **A,** T1-weighted spin-echo image. The liver is brighter (hyperintense) relative to the signal of the spleen. There are normal flow voids that appear as dark areas in the visualized vessels. *Straight arrow,* intrahepatic portion of the inferior vena cava; *curved arrow,* aorta. **B,** T2-weighted fast spin-echo image. Because of reversal of the liver/spleen contrast, the normal spleen is brighter than the liver. Note the flow voids within the vessels. *Straight arrow,* intrahepatic portion of the inferior vena cava; *curved arrow,* aorta. **C,** Postcontrast T1-weighted gradient-echo image. Normal enhancement in the liver and spleen is evident, and the parenchyma of both is about equal in this phase of the injection. All the vessels (*straight arrow,* intrahepatic portion of the inferior vena cava; *curved arrow,* aorta) are bright as a result of the T1 shortening effect of gadolinium.

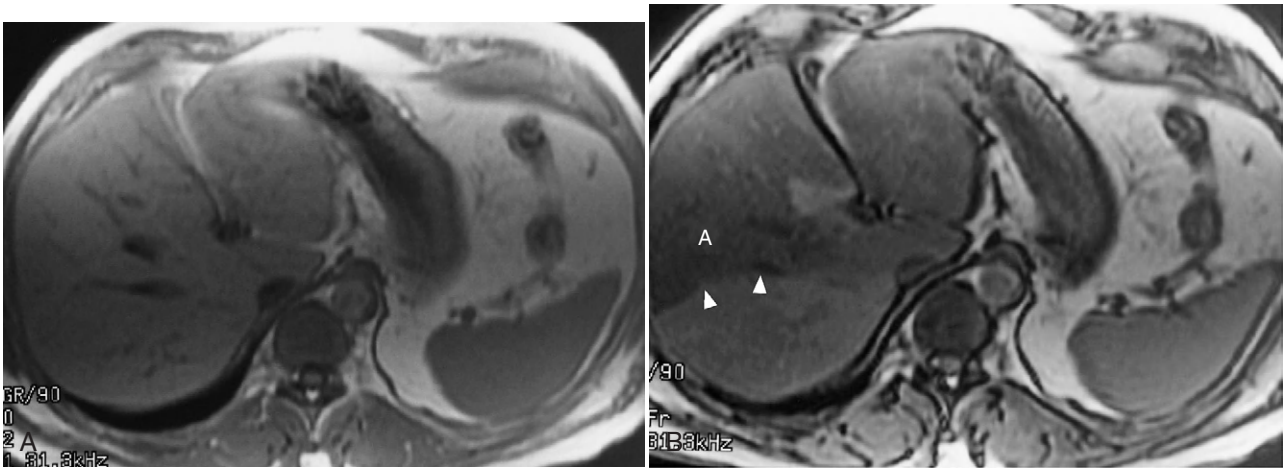

FIGURE 17.4. Fatty infiltration of the liver. **A,** T1-weighted in-phase gradient-echo image (TE 4.2) shows normal liver/spleen contrast. **B,** T1-weighted out-of-phase image (TE 1.8) at the same level shows a geographic area (*A*) that has lost signal (approached signal of the spleen); the transition to normal hepatic parenchyma is shown (*arrowheads*). This area has normal vascularity coursing through it; no mass was present—the typical appearance of fatty infiltration on chemical shift imaging. On the out-of-phase images, a black line "India ink effect" surrounds tissue interfaces.

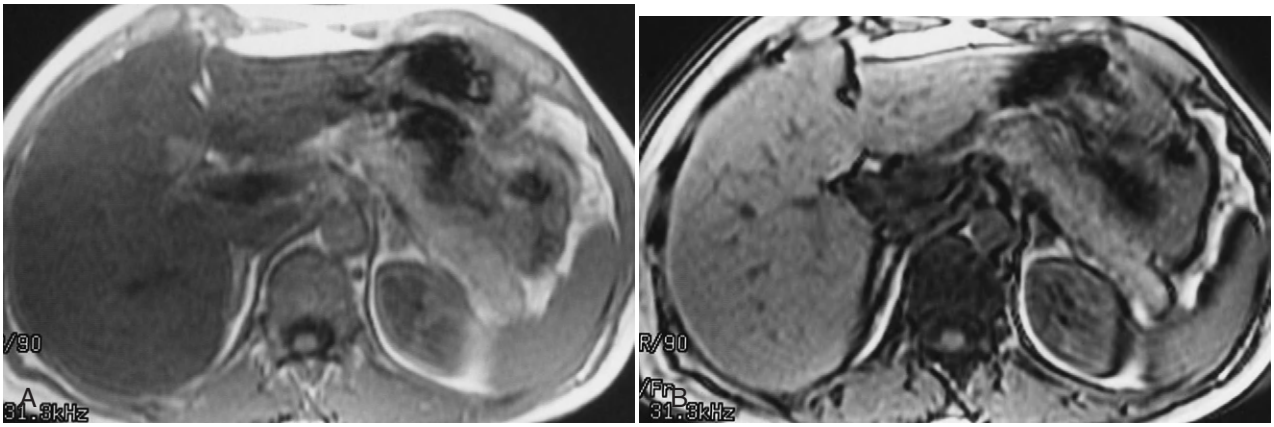

FIGURE 17.5. Hemochromatosis. **A,** T1-weighted in-phase gradient-echo image (TE 4.2) shows abnormal liver/spleen contrast. The liver is homogeneously darker than the spleen from preferential deposition of iron within the hepatic parenchyma. Note the difference from Figure 17.4. **B,** T1-weighted out-of-phase gradient-echo image (TE 1.8) shows the liver/spleen contrast returns to normal, with the liver being brighter than spleen. This is opposite from Figure 17.4 and shows early iron deposition disease within the liver.

Iron Deposition Disease

Iron accumulation within the liver has two main causes: *hemochromatosis* and *hemosiderosis*. Hemochromatosis is characterized by abnormal intestinal absorption of iron, the accumulation of which is predominantly in hepatocytes until late in the disease, when there is "spillover" into the pancreatic parenchyma. The liver shows abnormally low signal intensity compared with spleen on T1-weighted sequences. Gradient-echo sequences are the most sensitive sequence for detecting the presence of iron within the hepatic parenchyma. Primary, or genetic, hemochromatosis is important to diagnosis, because this entity may be unnoticed until late in the disease process, and its long-term sequelae include fibrosis, cirrhosis, and HCC, which also may be imaged with MRI. In addition, screening of family members is important in primary hemochromatosis, because it is an autosomal recessive trait.

Hemochromatosis must be distinguished from hemosiderosis, which is not genetically linked but is associated with multiple blood transfusions; conversely, it has a benign course, with accumulation of hepatic iron in the reticuloendothelial system. MRI is excellent for identifying these entities, because iron changes the expected signal intensities of abdominal organs (Pomerantz & Siegelman, 2002; Queiroz-Andrade et al, 2009). In patients with hemochromatosis, the normal liver–spleen pattern is reversed on T1-weighted images. In more advanced stages, iron also is deposited in the pancreatic parenchyma. Hemosiderosis affects the spleen and bone marrow early on in the disease process, with the liver being affected later. These distinguishing characteristics, and the patient's history, allow for correct differentiation; gradient-echo imaging is sensitive for the detection and characterization of these two processes (Fig. 17.5; Kim et al, 2002a; Rofsky & Fleishaker, 1995).

FOCAL HEPATIC LESIONS

Cysts

Cysts are common hepatic lesions that may be simple (see Chapter 69) or associated with polycystic disease of the kidney (Fig. 17.6). Small cysts (<1 cm) may be difficult to characterize on CT because of volume averaging. The MRI criteria for a simple cyst is a lesion that is homogeneously low in signal intensity on T1-weighted images and homogeneously bright on T2-weighted images. Lengthening the TE value on T2-weighted images allows for "heavier" T2 weighting. Cysts maintain their high signal on these heavy T2 images, and a cyst should not enhance after Gd-DTPA administration. Hepatic cysts may also be associated with infectious causes, such as echinococcal disease. Echinococcal cysts (see Chapter 68) have a different MRI appearance, are usually multiloculated and complex, and may have components that enhance (Mortele et al, 2009).

Hemangioma

Hepatic hemangiomas (see Chapter 79) are benign tumors of the liver found in 7.3% of autopsy specimens (Birnbaum et al, 1990; Ishak & Rabin, 1986). Most hemangiomas are found incidentally on other imaging studies, such as CT or ultrasound. MRI is ideal for characterizing hemangiomas and is the preferred modality for imaging. On T1-weighted images, hemangiomas are hypointense compared with the surrounding hepatic parenchyma; have smooth, well-marginated borders; and are frequently lobulated. Hemangiomas are hyperintense compared with normal liver on T2-weighted images and have a lobulated, well-demarcated border. Hemangiomas tend to retain their high signal on more heavily T2-weighted sequences. The presence of hyperintense peripheral nodular enhancement, especially when large, with either partial or complete filling in after gadolinium administration has been shown to be 100% specific, 84% sensitive, and 95% accurate for the diagnosis of hemangioma (Fig. 17.7; Silva et al, 2009; Mathieu et al, 1997; Semelka & Sofka, 1997).

Dynamic fast MRI after administration of intravenous gadolinium is useful for increasing the specificity of diagnosis of hepatic hemangioma and for differentiating this lesion from others, including metastases and HCCs (Yoon et al, 2003). Larger hemangiomas tend to follow these criteria more

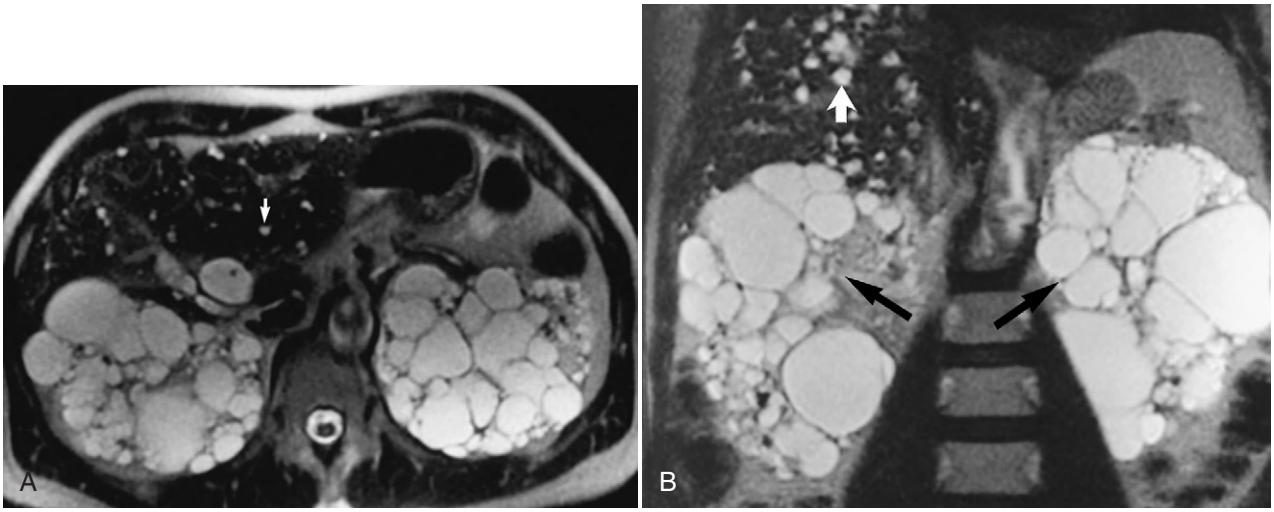

FIGURE 17.6. Hepatic cysts associated with polycystic kidney disease. **A,** Axial T2-weighted image at the level of kidneys shows bilaterally enlarged kidneys with multiple hyperintense cysts. Little normal renal parenchyma is present at this level, and multiple small hepatic cysts (*arrow*) are seen. **B,** Coronal T2-weighted images through the kidneys show similar findings of enlarged kidneys containing multiple cysts (*black arrows*), and small hepatic cysts are identified (*white arrow*).

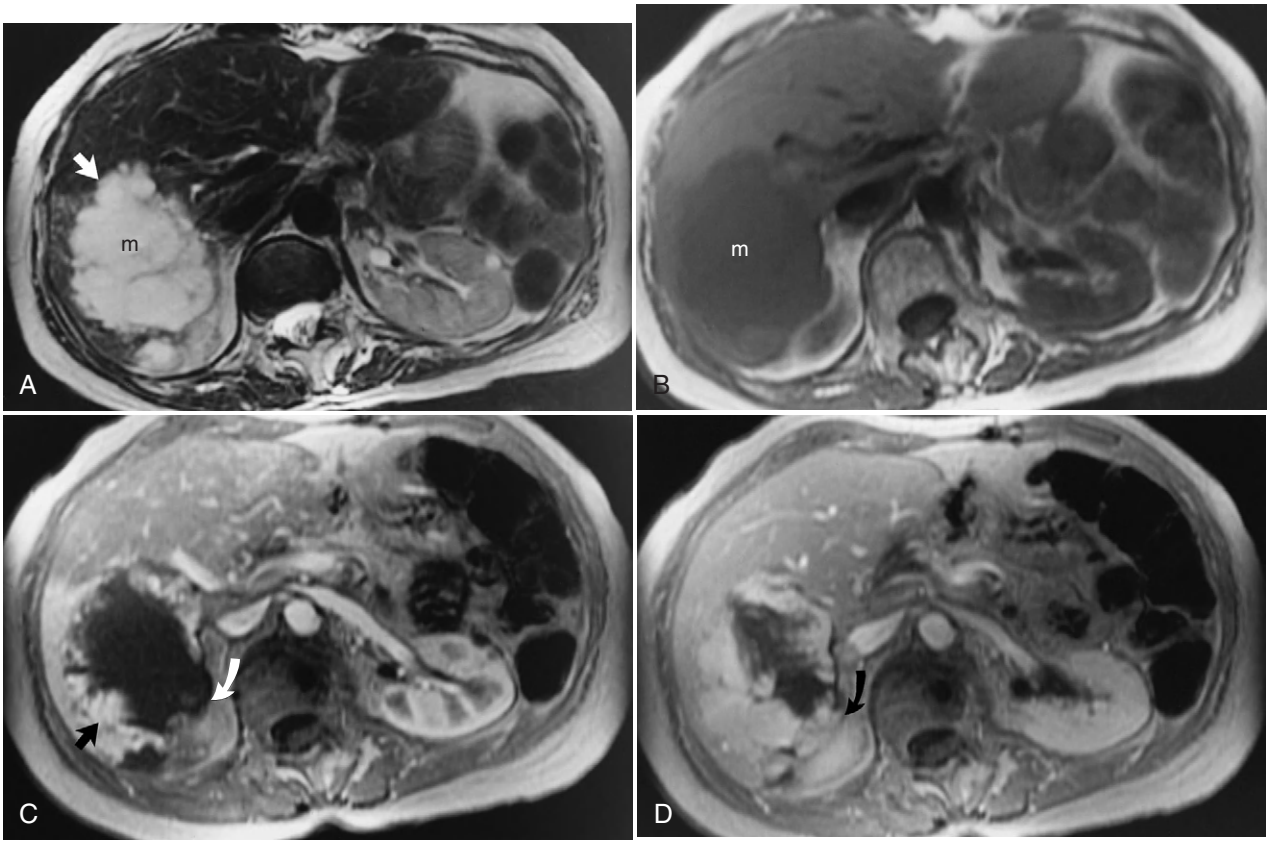

FIGURE 17.7. Hepatic hemangioma. **A,** Heavily T2-weighted image (TE 150) shows a mass (*m*), which is hyperintense to hepatic parenchyma and contains some internal architecture. Note the lobulated, well-defined margins of this lesion (*arrow*). **B,** Precontrast T1-weighted gradient-echo image at the same level shows the mass (*m*) to be dark compared with background parenchyma. **C,** T1-weighted gradient recalled-echo image during contrast administration shows peripheral nodular or broken ring enhancement within this mass (*arrow*). The posterior medial aspect of this lesion fails to show enhancement during this phase of the contrast injection (*curved arrow*). **D,** A delayed T1-weighted gradient-echo sequence postcontrast image shows the lesion has partially filled in toward the central portion. The region identified in *C* has filled in on delayed images (*curved arrow*). This constellation of findings is typical for hepatic hemangioma.

frequently, although giant hemangiomas also may have variable signal intensity (Danet et al, 2003; Yang et al, 2001). Problems arise with smaller hemangiomas, however, which may "flash fill" and appear as hypervascular lesions. These smaller lesions (usually <1 cm) may be distinguished by their T2 characteristics (Outwater et al, 1997). Hemangiomas also may be diagnosed after the administration of iron-based contrast agents (Harisinghani et al, 1997).

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH; see Chapter 79A) is another common benign tumor of the liver, although it occurs less frequently than hemangioma. Pathologically, FNH contains all the elements of normal liver and may have a central fibrous scar surrounded by hepatocytes and small bile ducts. FNH is the second most common benign tumor of the liver, and it has been associated with oral contraceptive use (Christopherson et al, 1977). Most FNH lesions are isointense or slightly hypointense compared with the normal liver parenchyma on T1-weighted images, and they are either isointense or minimally hyperintense on T2-weighted images (Fig. 17.8A and B). Frequently, FNH is visualized by displacement of the normal hepatic vasculature, and classic FNH has an early arterial peak enhancement with dynamic administration of an intravenous contrast agent.

A common feature of FNH is the presence of a central scar. Generally, this scar is hypointense on T1-weighted images and hyperintense on T2-weighted images. The central scar shows contrast enhancement as well, but in a delayed fashion and with prolonged enhancement (Fig. 17.8C; Mortele et al, 2002). Superparamagnetic iron oxide contrast agents are taken up by FNH, because the FNH contains Kupffer cells. Many reports indicate that FNH takes up a significant percentage of superparamagnetic iron oxide particles after administration, showing signal loss (Grazioli et al, 2005). This finding is consistent with the experience of nuclear scanning with technetium 99m–sulfur colloid. Lesions of FNH can be characterized with a high degree of specificity using a variety of MRI techniques (Silva et al, 2009; see Chapter 79A).

Hepatic Adenoma

Hepatic adenomas (see Chapter 79A) also are benign lesions associated with the use of oral contraceptives. They are commonly large, may cause upper abdominal pain, and may rupture and bleed. Hepatocytes are present within adenomas; however, these lesions lack hepatic veins and bile ducts. In addition, there are only a few if any reticuloendothelial cells present, and iron oxide scans show less uptake than with scans of FNH. Hemorrhage, which is one of the most common causes of pain, may be life threatening if it extends into the peritoneum. MRI tissue characterization of hepatic adenomas varies, but they are generally hyperintense on T1-weighted images because of the presence of hemorrhage or fat. Infrequently, the T1-weighted

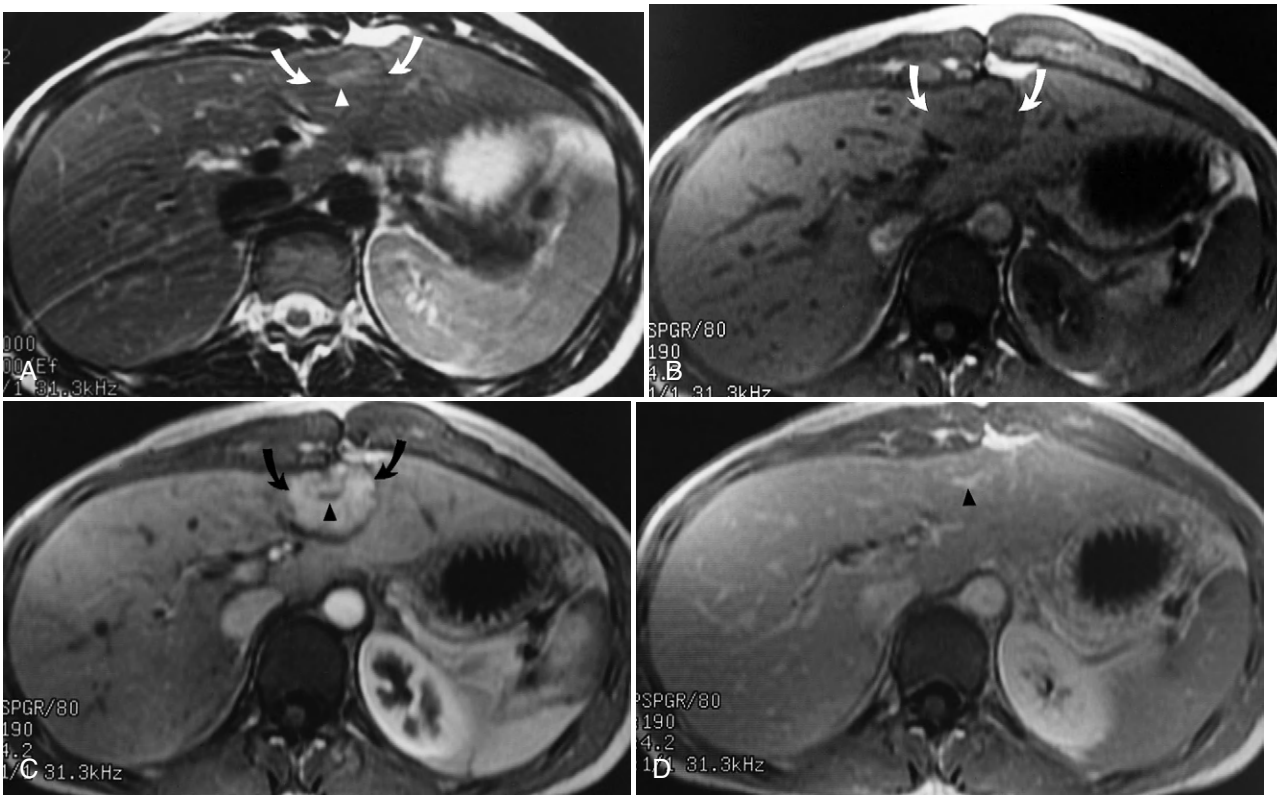

FIGURE 17.8. Focal nodular hyperplasia (FNH). **A,** T2-weighted image shows a mass that is isointense to hepatic parenchyma (*arrows*). Centrally within this mass is a linear, hyperintense focus (*arrowhead*). **B,** A precontrast, T1-weighted gradient-echo image shows the mass (*arrows*) to be mildly hypointense to liver. **C,** Arterial dominant phase T1-weighted gradient-echo sequence shows that the mass enhances intensely with respect to hepatic parenchyma (*arrows*). The central focus, which was bright on the T2-weighted images, does not show enhancement on this phase of the injection (*arrowhead*). **D,** Postcontrast equilibrium phase images show the mass to be isointense to background hepatic parenchyma. The central portion of scar shows delayed enhancement (*arrowhead*) characteristic of FNH.

images may show a low signal intensity pseudocapsule surrounding the adenoma, similar in appearance to HCC (Gabata et al, 1990). A central scar also may be seen within certain adenomas (Rummeny et al, 1989). Adenomas are hypervascular lesions that show enhancement during the arterial dominant phase of the contrast injection. Small adenomas without hemorrhage may be difficult to differentiate from FNH without a central scar and from well-differentiated HCC.

Hepatic Abscesses

CT is generally the modality of choice in recent postoperative patients in whom there is a clinical suspicion of a hepatic abscess (see Chapter 66). Patients with more atypical symptoms may present a diagnostic dilemma. Although some patients show symptoms suggesting abscesses, others do not, but patients suspicious for abscesses may be imaged with MRI. Abscesses are usually hyperintense on T2-weighted images with an irregular rim of intermediate signal intensity surrounding a hyperintense outer rim. Abscesses are generally hypointense on T1-weighted images, unless they have hemorrhage or proteinaceous debris within them. After administration of contrast material, the rim enhances, whereas the central portion does not enhance. The imaging findings may overlap with malignancies, including gallbladder cancer.

Hepatic Metastases

The liver is the most common site for the hematogenous spread of malignant neoplasms (see Chapter 81). Other hepatic lesions, including hemangiomas or fatty infiltration, may appear similar to metastases when imaged with CT or ultrasound. In addition, several types of lesions may coexist in the same patient, which may be challenging for the diagnostic radiologist. These lesions may be distinguished using MRI. In general, metastases are of low signal intensity on T1-weighted images and are hyperintense on T2-weighted images. Metastases tend not to be as bright on T2-weighted images as hemangiomas or cysts. Metastases also tend to have less well-defined borders than other benign lesions and may have peripheral high signal intensity, which has been shown to represent viable tumor (Fig. 17.9). During contrast administration, metastases may show early peripheral rim enhancement. This peripheral rim washes out and appears hypointense on delayed images (Fig. 17.10).

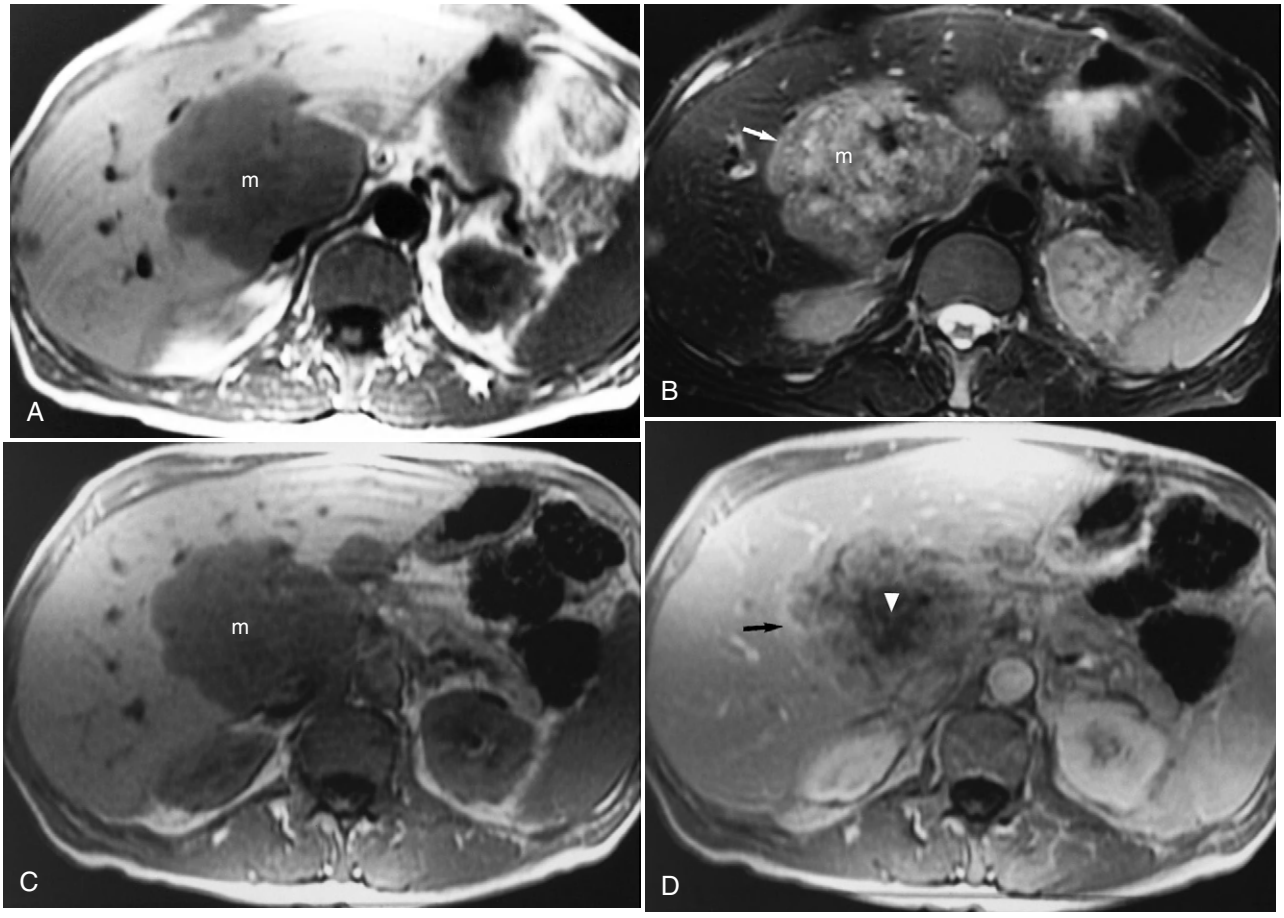

FIGURE 17.9. Hepatic metastasis from colorectal carcinoma. **A,** T1-weighted image shows a large, central, low signal intensity metastasis (*m*) with several smaller lesions within the liver. **B,** T2-weighted image shows the mass (*m*) is brighter than background hepatic parenchyma. The borders are ill defined, and there appear to be internal septations within this lesion. The periphery of the lesion is a rind of tissue (*arrow*) that is mildly hyperintense to liver but darker than the central portion of the mass. **C,** Pre–contrast-enhanced, T1-weighted gradient-echo image shows the large hepatic metastasis (*m*) in contrast to the normal hepatic parenchyma. **D,** Pre–contrast-enhanced, T1-weighted gradient-echo images fail to show the peripheral portion (*arrow*), and internal septations have enhanced, representing viable tumor, whereas the central necrotic portion (*arrowhead*) fails to enhance. Note the distinct difference in appearance from hemangioma (see Fig. 17.7).

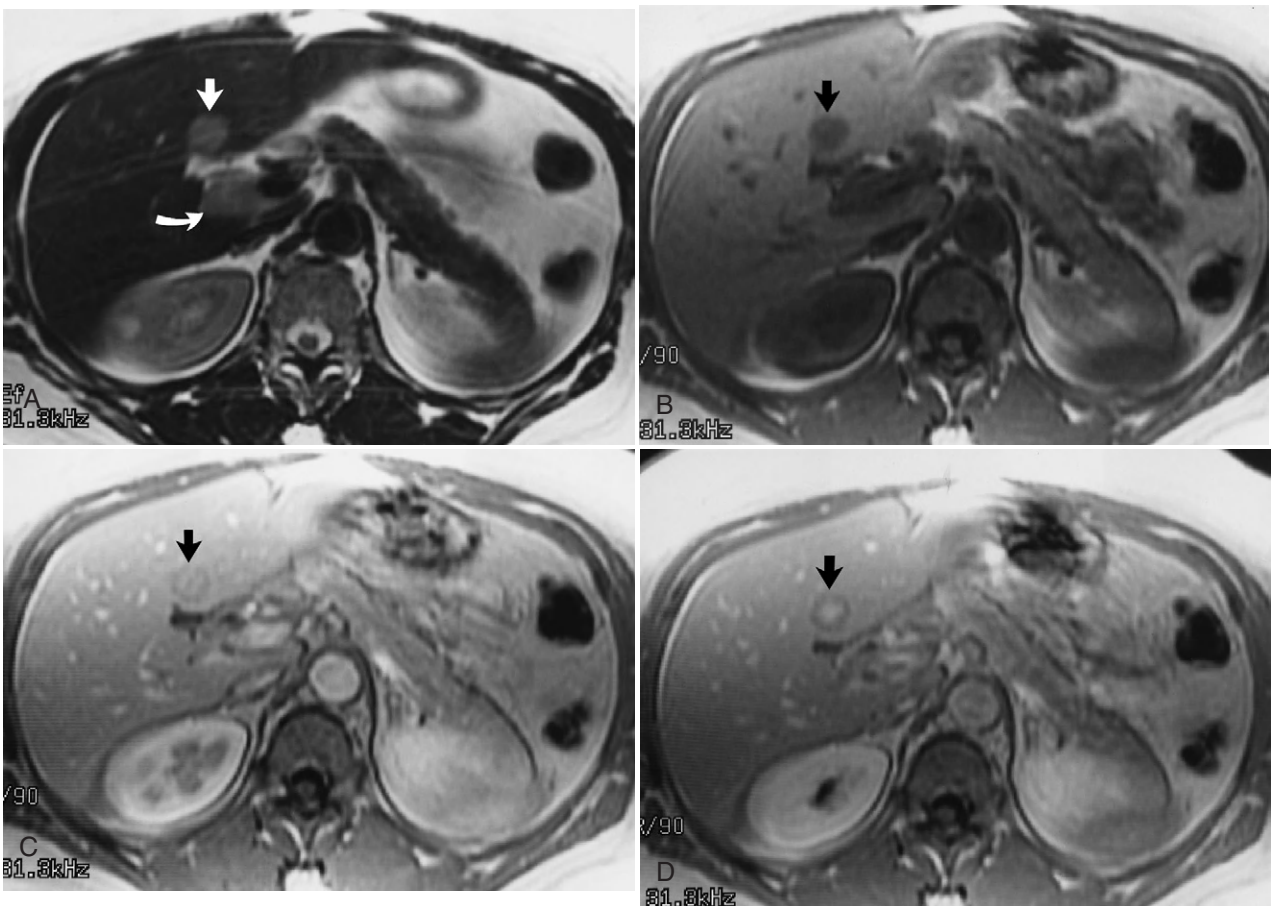

FIGURE 17.10. Hepatic metastasis from breast carcinoma. **A,** T2-weighted image shows a small lesion within the liver (*straight arrow*) that is mildly hyperintense. Portal lymphadenopathy also is present (*curved arrow*). **B,** Pre–contrast-enhanced, T1-weighted gradient-echo image shows a well-defined mass (*arrow*) that is hypointense to liver. **C,** T1-weighted gradient-echo image after the administration of contrast shows the peripheral portion that enhanced irregularly during the arterial dominant phase (not shown) beginning to wash out, suggesting an early target appearance (*arrow*). **D,** Delayed postcontrast gradient-echo image shows continued filling of the central portion of this lesion; the periphery has washed out (*arrow*).

Although this delayed hypointense rim is seen in only a few cases, it is 100% specific for the diagnosis of hepatic malignancy (Mahfouz et al, 1994). Larger metastases tend to have a thick irregular rim of enhancement representing viable tumor with areas of central necrosis. MRI is less invasive and more cost effective than CT arterial portography and is an excellent screening tool for staging hepatic metastases for surgical resection (Iman & Bluemke, 2000). In addition, MRI can easily map out hepatic vasculature and image in multiple planes—coronal, sagittal, and oblique—to allow for complete surgical planning.

Hepatocellular Carcinoma

The diagnosis of HCC (see Chapter 80) on CT and ultrasound is difficult because of its association with chronic liver disease, which appears heterogeneous on CT and MRI (Fig. 17.11), making it difficult to distinguish focal hepatic lesions in these patients. The heterogeneity is created by the presence of a nodular configuration. These nodules may represent regenerative nodules, dysplastic nodules, or HCC. The advantage of MRI in the evaluation of HCC is that areas of carcinoma show signal intensity changes relative to areas of cirrhotic hepatic parenchyma. HCC generally is hypointense on T1-weighted images and hyperintense on T2-weighted images, although the signal intensity can be variable in these sequences (Silva et al, 2009). Well-differentiated HCC is hyperintense on T1-weighted images because of the presence of intracellular lipid (Fig. 17.12; Basaran et al, 2005). On T2-weighted images, large HCCs may have a "mosaic" appearance produced by multiple centers of growth interspersed with areas of necrosis and regenerating liver tissue (Fig. 17.13; Choi et al, 1990; Fujita et al, 1997; Lalonde et al, 1992). The fibrolamellar type of HCC may have a central scar. These fibrous scars tend to be low in signal intensity on T1-weighted and T2-weighted images. The presence of this fibrous scar cannot reliably distinguish between benign and malignant hepatic lesions, however, because FNH also may have a central scar (Kim et al, 2009).

Gradient echo (bright blood technique), MRI, and other flow-sensitive techniques are excellent for evaluating vascular hepatic tumor invasion. MRI is more sensitive than CT, sonography, or angiography for detecting vascular intrahepatic invasion (Itoh et al, 1987). Contrast-enhanced MRI with Gd-DTPA shows irregular and variable patterns of enhancement owing to the vascular nature of the tumor. Most HCCs are hypervascular in nature and show enhancement during the arterial dominant phase of the injection, in contrast to other nodules seen

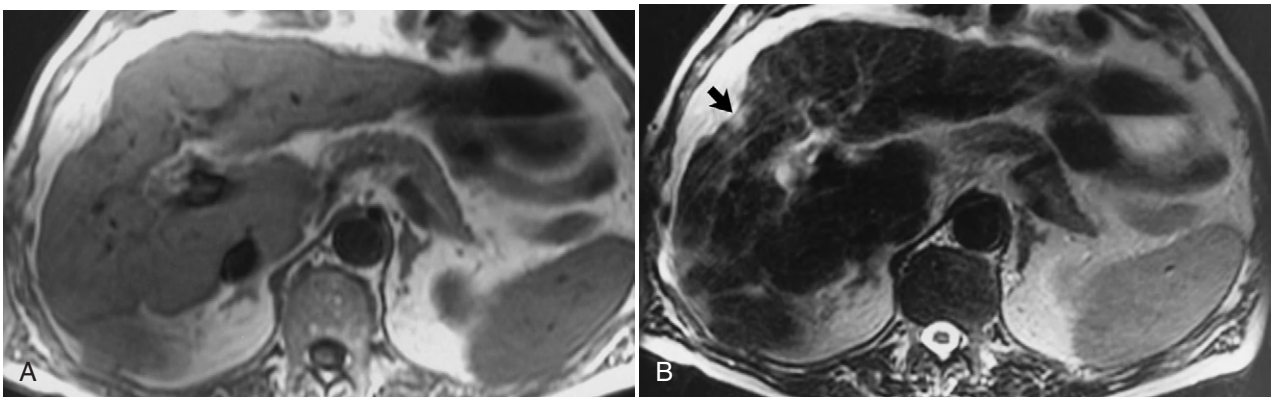

FIGURE 17.11. Liver with cirrhotic configuration. **A,** T1-weighted spin-echo image at the level of the portal vein shows hypertrophy of the left lobe and caudate with atrophy of the right lobe of the liver. **B,** T2-weighted image of the liver at the same level shows mildly heterogeneous signal in the atrophied right lobe, making exclusion of an underlying mass difficult. Note also the focal hepatic scarring (*arrow*).

in cirrhotic livers. Those lesions tend to be isointense to the background liver parenchyma during the equilibrium phase of the examination. Although HCCs are typically hypervascular lesions, multiple dysplastic nodules appearing as hypervascular masses on CT and MRI has been reported (Krinsky et al, 1998; Taouli et al, 2004). MRI also is excellent for identifying additional characteristics that may aid in the diagnosis of HCC, including a capsule surrounding the lesion, which is low in signal intensity on the arterial dominant phase and enhances on delayed images (Fig. 17.14).

LESS COMMON HEPATIC TUMORS

Lymphoma

Non-Hodgkin lymphoma accounts for most hepatic lymphomas. MRI shows masses of varying size, which are generally low in signal intensity on T1-weighted images and hyperintense on T2-weighted images (Rizzi et al, 2001). The degree of hyperintensity is not as great as with other focal benign hepatic lesions, such as hemangiomas or cysts. This difference in signal intensity makes it relatively easy to determine the malignant nature of the lesion but not the specific cause. The imaging characteristics of lymphoma overlap with other malignant hepatic lesions.

FIGURE 17.12. Hepatocellular carcinoma containing intracellular lipids. T1-weighted in-phase gradient-echo image shows a mass (*m*) in the liver that is brighter than normal parenchyma. Siderotic nodules are diffusely present within the liver and present in the spleen (gamma Gandy bodies; *arrow*).

Mesenchymal Tumors

Rarely, tumors of mesenchymal origin—including angiosarcoma, leiomyosarcoma, and fibrous histiocytoma—may be present within the liver (Anderson et al, 2009). The MRI appearance of these tumors is nonspecific; they are generally of low intensity on T1-weighted images and hyperintense on T2-weighted images.

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma (EH) is a rare tumor of adults that should be distinguished from infantile hemangioendothelioma, which occurs in infants and children. The prognosis is better for EH than for other parenchymal tumors, such as sarcoma, although extrahepatic metastases do occur. EH is generally low in signal intensity on T1-weighted images and hyperintense on T2-weighted images, but not as hyperintense as hemangiomas. After Gd-DTPA administration, an irregular nodular and concentric enhancement may be seen. Capsular retraction also may be seen with EH, helping to elucidate the diagnosis (Lin et al, 2010).

Biliary Cystadenoma and Biliary Cystadenocarcinomas

Biliary cystadenomas and biliary cystadenocarcinomas are rare tumors of the liver that present as a predominantly cystic mass containing septations (Fig. 17.15; see Chapter 79B). These lesions may be of low, intermediate, or increased signal on T1-weighted images, depending on the protein content within the mass, and they are usually hyperintense on T2-weighted sequences. The malignant variety may show nodular or irregular internal soft tissue; however, distinction between the two is not always possible.

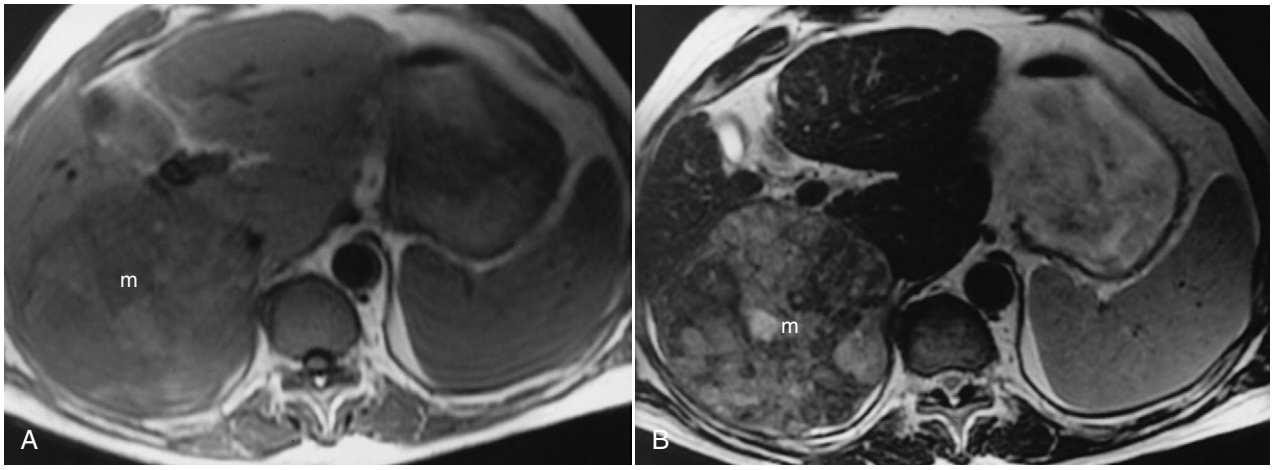

FIGURE 17.13. Large hepatocellular carcinoma showing the mosaic pattern. **A,** T1-weighted image shows a large heterogeneous mass (*m*) in the liver. Note the hypertrophied left hepatic lobe and caudate. **B,** T2-weighted image also shows the mass (*m*) to be heterogeneous, with islands of tissue that are hyperintense with respect to other portions of the same mass. This pattern is known as the *mosaic pattern*, and it can be seen in hepatocellular carcinoma, especially when the lesion is large.

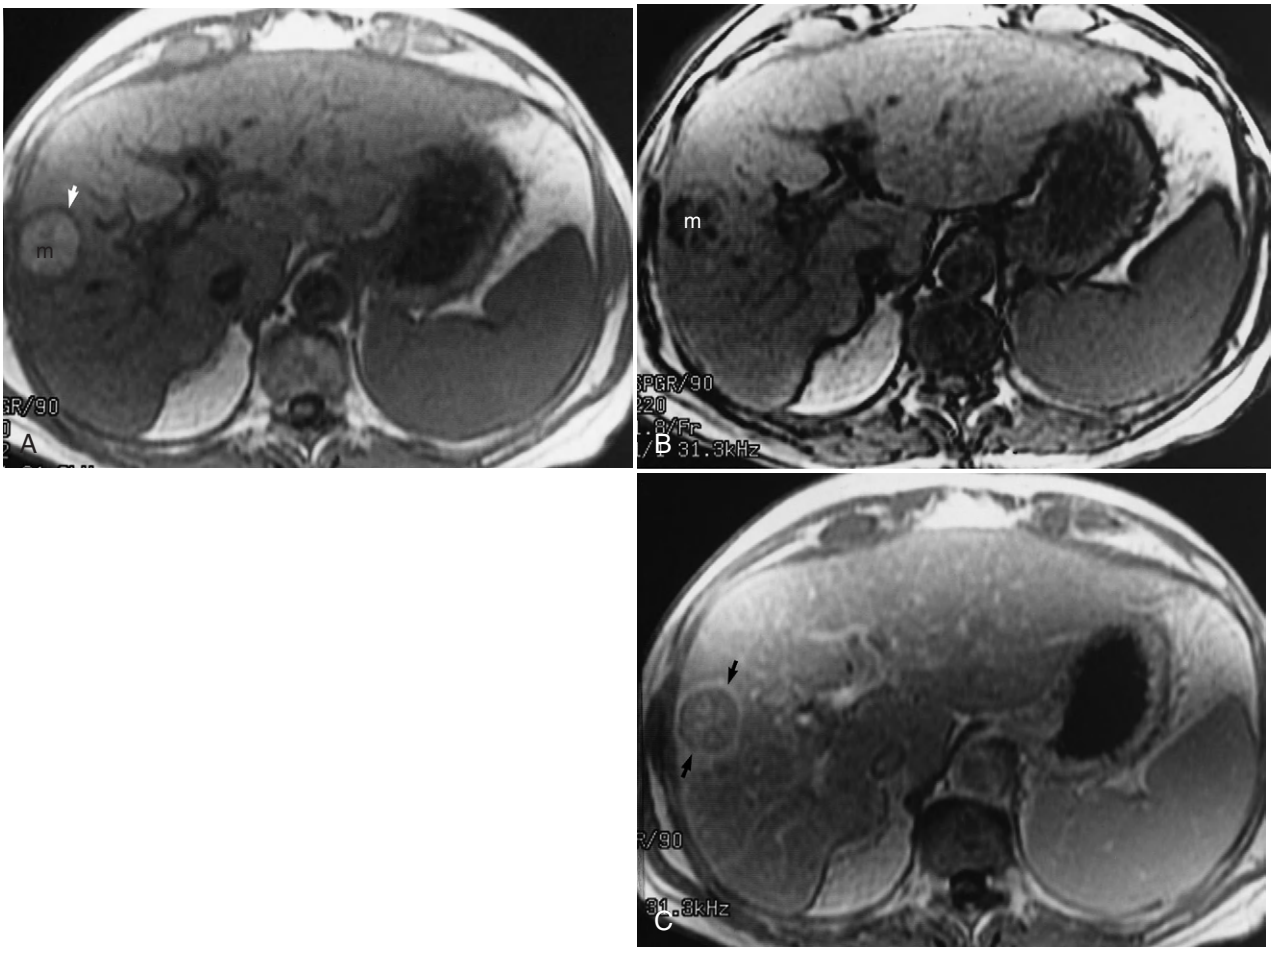

FIGURE 17.14. Hepatocellular carcinoma with intracellular lipid and capsular enhancement. **A,** T1-weighted in-phase gradient-echo image shows a focal hyperintense mass (*m*). A dark rim around this mass makes it appear encapsulated (*arrow*). **B,** A T1-weighted out-of-phase image shows signal loss in this mass (*m*), representing intracellular lipid and water of approximately equal distribution. **C,** Delayed postcontrast image through the lesion shows the "capsule" around the lesion to be enhanced (*arrows*); the capsule did not enhance on the immediate postcontrast images (not shown).

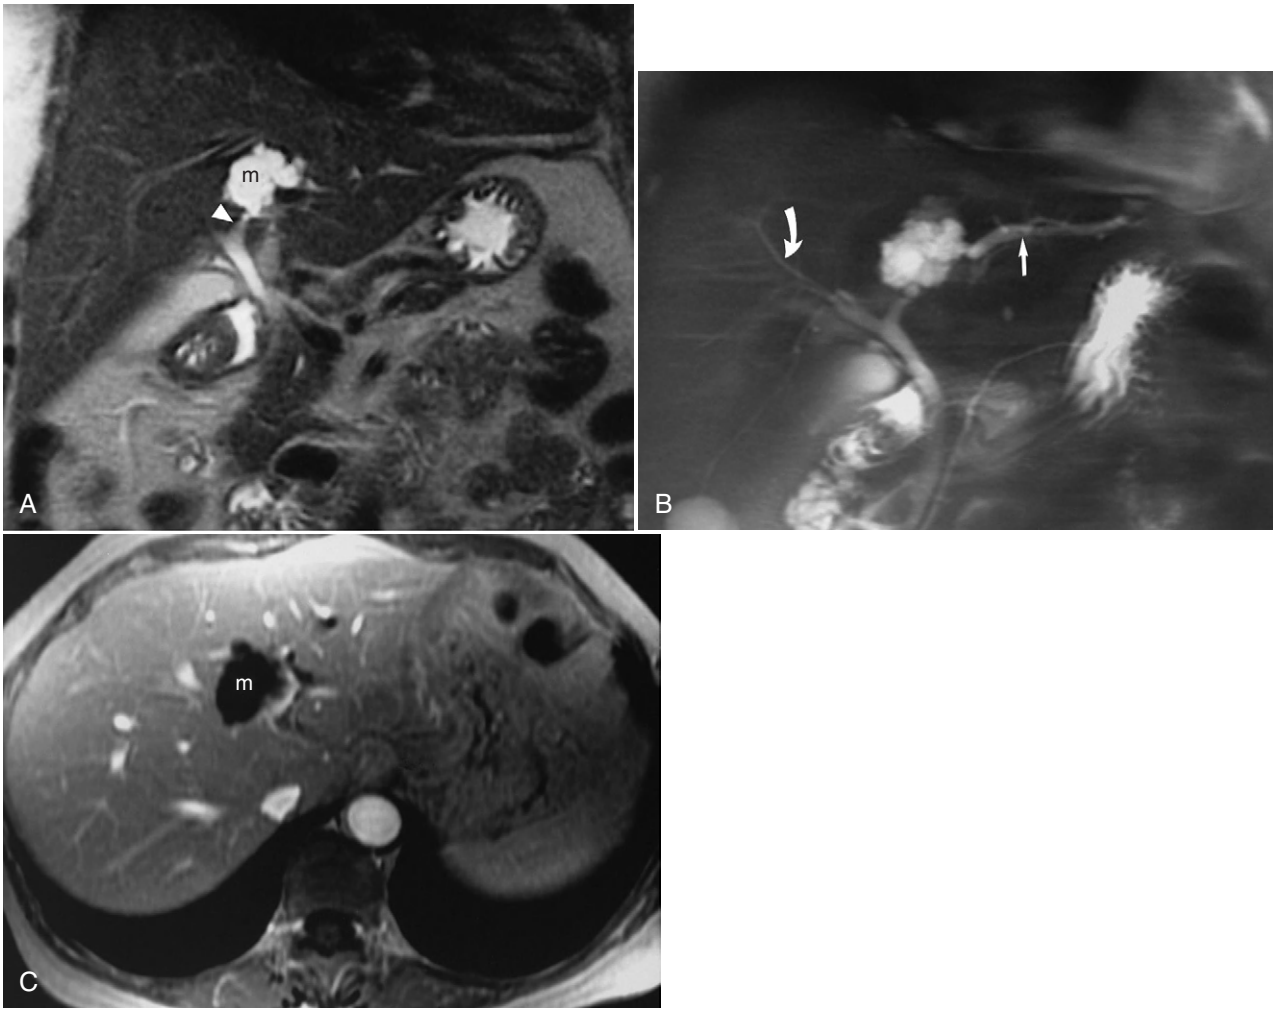

FIGURE 17.15. Biliary cystadenoma. **A,** Coronal T2-weighted image shows a lobulated mass (*m*) in close proximity to the left hepatic duct (*arrowhead*). **B,** Projection image in the coronal oblique plane shows the well-defined hyperintense mass to be in continuity with a mildly dilated left-sided biliary radicle (*straight arrow*). The normal right-sided biliary radicle (*curved arrow*) is easily seen with this technique. **C,** Postcontrast, T1-weighted gradient-echo image shows no enhancement within this mass (*m*).

BILIARY TUMORS

Gallbladder Carcinoma

Gallbladder carcinoma (see Chapter 49) is well evaluated with MRI. This entity is best seen on T2-weighted images as thickening of the gallbladder wall, generally adjacent to multiple gallstones. Cholelithiasis is a predisposing condition. Evidence of liver invasion and spread to regional lymph nodes also may be identified with MRI, which is optimal for evaluation of these lesions because of its outstanding tissue contrast and ability to image directly in multiple planes (Dai et al, 2009; Schwartz et al, 2002; Sikora et al, 2006).

Bile Duct Cancer

Bile duct tumors (see Chapters 50A and 50B) are easily seen on MRI. Central lesions (hilar cholangiocarcinomas) are generally associated with biliary dilation, which is bright on T2-weighted images. The central tumors may be seen as areas of mildly hyperintense signal on T2-weighted images (Fig. 17.16), less so than the surrounding biliary dilation. The level of obstruction and continuity of the tumor with the vasculature are well evaluated with MRI (Lee et al, 2003; Schwartz et al, 2003). Peripheral or intrahepatic cholangiocarcinomas generally present as high signal intensity masses on T2-weighted images. They may appear similar to other malignant neoplasms of the liver, but they generally do not have capsules or areas of high signal intensity on T1-weighted images as may be seen in HCCs. Distinction of peripheral cholangiocarcinoma and confluent hepatic fibrosis is sometimes difficult; however, late enhancement is seen in the malignant lesion.

BENIGN DISEASES OF THE BILIARY TRACT

Cholelithiasis

Gallstones are easily identifiable on T2-weighted images and on MRCP sequences (Fig. 17.17; see Chapter 30). They usually appear as low signal intensity structures in a fluid-filled gallbladder. MRI is usually not the modality of choice in the

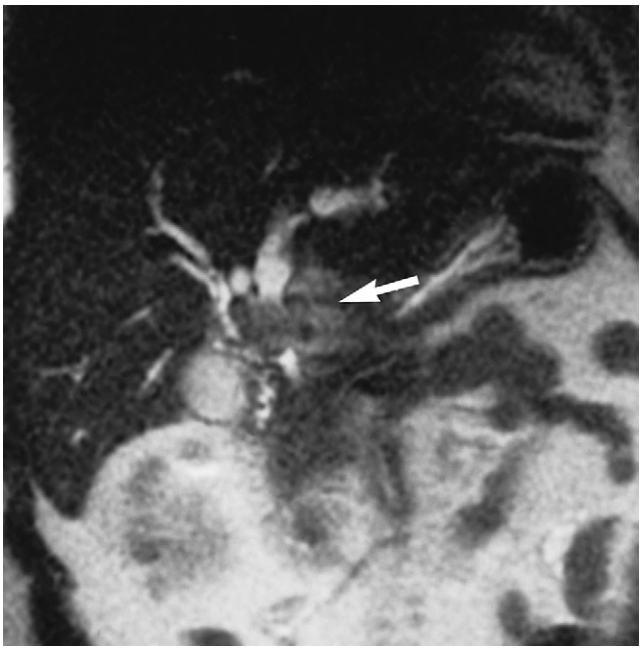

FIGURE 17.16. Hilar cholangiocarcinoma. Oblique coronal T2-weighted image shows dilation of the intrahepatic biliary tree. A soft tissue mass (*arrow*) is present at the bifurcation of the common hepatic duct, causing the duct dilation.

evaluation of cholelithiasis, because ultrasound is highly sensitive and less expensive in uncomplicated cases, but choledocholithiasis can be imaged effectively by MRI (Johnson et al, 2010; Samaraee et al, 2009). Common duct stones are relatively uncommon in children (Rescorla, 1997) but are more common in elderly patients (Catheline et al, 1998; Gonzalez et al, 1997). Direct coronal T2-weighted imaging, readily available with MRI, easily identifies common duct stones. In addition, if multiple stones are present in the common duct, they too should be identifiable by MRI (see Fig. 17.17). MRCP can also be obtained to evaluate whether retained stones are present after cholecystectomy. If no stones are present on MRCP, this may obviate the need for ERCP.

Choledochal Cysts

Choledochal cysts (see Chapter 46) represent dilation of the extrahepatic bile ducts with possible associated intrahepatic biliary duct dilation. This entity is a relatively uncommon congenital anomaly that usually presents before 10 years of age. The classic triad includes a palpable mass, abdominal pain, and jaundice. Five types of cysts have been described (Todani et al, 1977): type I has been subdivided into A, B, and C, in addition to types II, III, IVa and IVb, and V. MRI is well suited not only to diagnose these cysts but also to classify the type of cyst. Not only can MRI cholangiograms be generated to depict the normal and abnormal anatomy, but also direct coronal imaging can be obtained for clearer evaluation.

Postoperative Biliary Complications

Complications from surgical procedures include bile leaks, abscess formation, and biliary strictures (see Chapters 25 and 42). Although using other imaging modalities in the immediate postoperative setting to assess for bile leaks and abscesses may be prudent, MRI is uniquely suited for the assessment of the postoperative biliary tract. Bile duct injuries after surgery can be caused by a number of things, but these may all lead to the same result—a stricture at the anastomotic site. MRI using long-echo train-length imaging (MRCP technique) is uniquely suited for addressing this problem. Surgical clips near the anastomosis may create streak artifacts during CT scanning. MRI has multiplanar capabilities and superior tissue contrast, and MRCP sequences can minimize susceptibility to artifacts, owing to multiple 180-degree refocusing pulses; this can allow for improved visualization of the region of the anastomosis and improved diagnostic confidence (Fig. 17.18; Coakley et al, 1998).

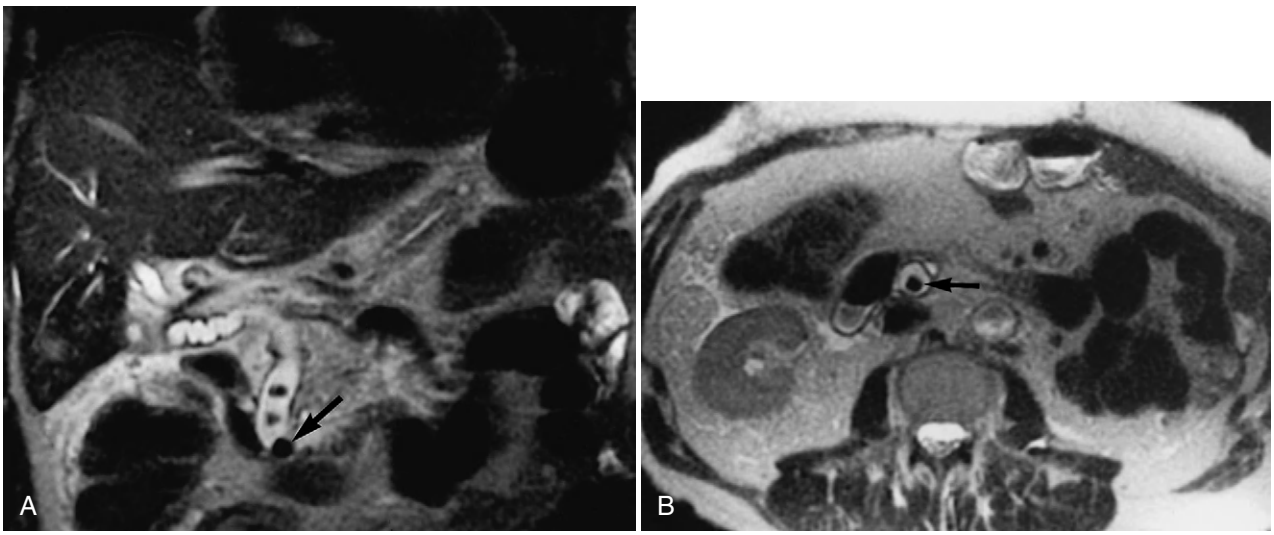

FIGURE 17.17. Choledocholithiasis. **A,** Coronal T2-weighted Single Shot Fast Spin Echo image through the common duct in a patient after cholecystectomy shows multiple stones within the common bile duct. Note the distal stone impacted at the level of the ampulla (*arrow*). **B,** Axial T2-weighted image with the same technique also shows a stone, surrounded by bile, in the distal common bile duct (*arrow*).

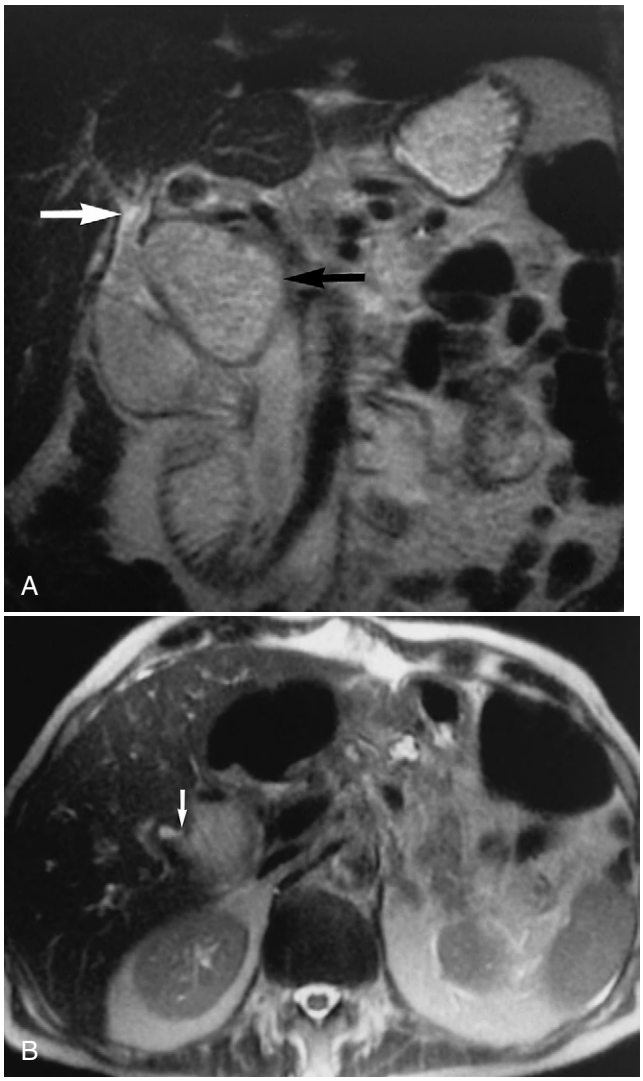

FIGURE 17.18. Afferent loop syndrome. **A,** Coronal T2-weighted sequence in a patient after pancreaticoduodenectomy for pancreatic carcinoma. The patient has a hepatojejunostomy with a patent anastomosis (*white arrow*). The afferent loop is markedly dilated (*black arrow*) compared with other loops of bowel. No mechanical obstruction was noted. **B,** Axial T2-weighted image through the level of the anastomosis (*arrow*) shows the site to be patent without evidence of a stricture. The afferent loop is dilated.

PANCREAS

Pancreatic Cancer

Pancreatic carcinoma (see Chapter 58) is well evaluated on MRI and MRCP. The faster MRI sequences help stage patients with pancreatic cancer and help to characterize lesions of the pancreas. MRI is generally thought to be highly accurate in assessing for vascular invasion, local-regional tumor extension, and liver metastases (Hanninen et al, 2002). Similar to other modalities, accuracy is limited for assessment of lymph node metastases with conventional and fast MRI techniques. Newer lymph node–specific contrast agents may play a role in improving the specificity of MRI for detection of lymph node metastases.

Cystic Lesions of the Pancreas

Pancreatic cystic lesions (see Chapter 57) are relatively common imaging findings and are usually secondary to benign processes, but they may be malignant. Multiple imaging modalities may be used to identify and visualize pancreatic cystic lesions including ultrasound, CT, and MRI. Soft-tissue contrast is optimal with MRI imaging, which permits optimal depiction of the internal features of pancreatic cysts, such as septations, nodularity, and soft-tissue masses. One particularly useful sequence is the single-shot fast spin-echo sequence. Cystic lesions are high in T2 and are bright on these sequences (Zhang et al, 2002; Acar et al, 2010). Evaluation after contrast (Gd-DTPA) administration helps assess cyst wall irregularity or enhancement. Intraductal papillary mucinous tumors may be distinguished from other lesions on MRI by combining ductal visualization with postcontrast images (Lim et al, 2001).

CHAPTER 18

Direct cholangiography: approaches, techniques, and current role

George Getrajdman and Robert C. Kurtz

DIRECT CHOLANGIOGRAPHY OVERVIEW

Direct cholangiography, the introduction of contrast medium into the biliary system, can be achieved radiologically, endoscopically, or intraoperatively via surgically placed tubes. The nonoperative techniques are percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP). Currently, noninvasive magnetic resonance imaging (MRI) and computed tomographic (CT) cholangiography have virtually eliminated the indications and need for direct cholangiography (Stroszczynski & Hünerbein, 2005; Miller et al, 2007; Bakhal et al, 2009; see Chapters 16 and 17). Today ERCP and PTC are almost exclusively performed only as part of a planned interventional procedure, such as drainage, stenting, stone extraction, or stricture dilation (see Chapters 27 and 28).

The most obvious benefits of noninvasive cholangiography are that it is painless, does not require sedation, and has few complications. Thin-section scanning techniques with multiplanar reconstruction allow for a large field of view that enables visualization of the entire biliary tree (Fig. 18.1). Reconstructed three-dimensional data sets can be displayed as a cholangiogram and manipulated in space. By contrast, direct dye injection only allows visualization of the structures in continuity with the opacified, nonisolated segments of the biliary system (Fig. 18.2). In PTC, even with multiple puncture sites and injections, simultaneous cross-sectional imaging may be required to ensure that the entire biliary tree has been opacified. In addition, noninvasive cholangiography has overall superior diagnostic accuracy compared with invasive techniques, allowing for visualization of structures contiguous to the biliary system and the bile duct wall.

PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY (SEE CHAPTER 28)

History

The first report of radiologic visualization of the biliary tree was presented by Burckhardt and Müller in 1921, and cholecystocholangiography was achieved by percutaneous puncture of the gallbladder. The first report of PTC was by Huard and Do-Xuan-Hop in 1937, and cholangiography was performed with the suboptimal contrast agent Lipiodol. The use of transhepatic cholangiography as a diagnostic tool gained popularity 15 years later, after Carter and Saypol's (1952) discussion of PTC with the use of a water-soluble contrast agent. In the ensuing years, many investigators (Flemma & Shingleton, 1966; Glenn et al, 1962; Mujahed & Evans, 1966; Seldinger, 1966; Shaldon et al, 1962; Weicher, 1964) described a variety of different methodologic details, including the use of sheathed or unsheathed needles of various sizes, different sites and directions of puncture, and various numbers of puncture trials to maximize success. The procedure remained associated with a significant risk of bile peritonitis, especially in obstructed systems, and the less frequent complication of hemorrhage. The last essential refinement in transhepatic cholangiography, the use of fine needle technique, was developed at Chiba University and was first presented by Ohto and Tsuchiya (1969) and later by Tsuchiya (1969). The value and decreased complication rate of the fine needle technique was verified by numerous authors (Benjamin et al, 1978; Ferrucci et al, 1976; Fraser et al, 1978; Gold & Price, 1980; Harbin et al, 1980; Hinde et al, 1977; Jain et al, 1977; Pereiras et al, 1977), and the fine needle technique has been generally accepted as the standard.

At present, diagnostic transhepatic cholangiography has been completely supplanted by noninvasive imaging techniques for the evaluation of the biliary tree. In 1985, Kadir reported that less than 5% of patients referred for evaluation of biliary disease required concomitant drainage procedures. With continued advancement of cross-sectional imaging techniques, including the development of MRI cholangiography (Park et al, 2004; Romagnuolo et al, 2003; Simone et al, 2004; Vaishali et al, 2004; Zhong et al, 2003) and CT cholangiography, diagnostic PTC should be performed only as part of a planned radiologic interventional procedure.

The most obvious benefits of noninvasive cholangiography are the elimination of complications and pain, but several other advantages are also important. Puncture and contrast injection techniques in high bile duct obstruction with isolated systems visualize only the portions of the biliary tree that are in continuity with the puncture site, and multiple interventions may be required to visualize the entire biliary tree if there are areas of duct isolation (see Fig. 18.2). Even with multiple punctures and contrast injections, cross-sectional imaging may be necessary sometimes to ensure that the biliary tree has been completely assessed. MRI cholangiography has the advantage of showing the entire biliary system even in the presence of isolation (see Fig. 18.1). Finally, there is the diagnostic advantage gained with cross-sectional imaging. By allowing visualization of many more organs than just the biliary system, diagnostic accuracy of cholangiography is significantly increased.

Preprocedural Preparation

All patients require cross-sectional imaging consisting of CT, ultrasound, or MRCP before the procedure. This imaging is especially important in patients who have undergone hepatic

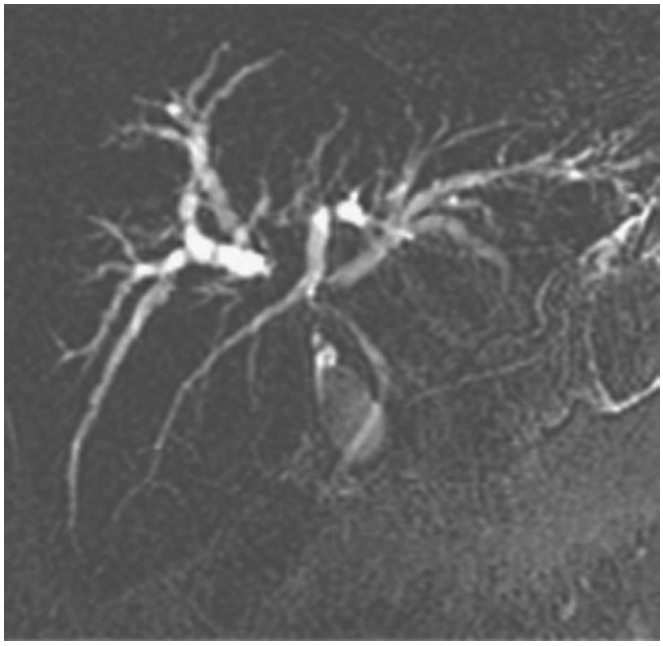

FIGURE 18.1. Magnetic resonance cholangiography showing complete isolation of left-sided and right-sided bile ducts. This clinical scenario would require multiple punctures for percutaneous transhepatic cholangiography delineation of the entire biliary tree.

FIGURE 18.2. Hilar cholangiocarcinoma involving first-order right and left hepatic ducts. Separate needle punctures were required to fill the right and left ducts.

resection. In the authors' institution, intravenous contrast-enhanced CT is the procedure of choice because of its ready availability and its ability to show the level of obstruction, position of the liver, presence of lobar atrophy, status of the portal veins, and relationship of bile ducts to other structures, which could greatly facilitate successful puncture.

Coagulation parameters and platelet count should be corrected when necessary. Patients generally require conscious sedation consisting of midazolam and a pain medication, such as meperidine (Demerol), fentanyl, or morphine, and they should receive only clear liquids after midnight the night before the procedure. All patients must receive broad-spectrum intravenous antibiotic coverage, and antibiotics should be administered 1 hour before the procedure to ensure maximal blood levels at the time of PTC.

Procedure

The procedure is ideally performed on a tilting fluoroscopic table. Because the specific gravity of contrast material is greater than that of bile, when the fluoroscopic table can be tilted, less contrast agent is required to fully delineate the biliary tree.

Right-Sided Puncture

After the patient has been prepared and draped in a sterile fashion, a puncture site is selected in the right midaxillary line one or two interspaces below the costophrenic angle. Puncture sites are generally kept below the ninth intercostal space to avoid inadvertent entry into the pleural space. A 21- or 22-gauge, 15- to 20-cm styletted needle is advanced under fluoroscopic guidance over the rib, rather than under, to avoid laceration of an intercostal vessel. The puncture is performed neither from a particular intercostal space nor aiming at a particular vertebra, rather the site and direction of puncture are chosen based on evaluation of the patient's cross-sectional imaging studies.

Care should be taken to avoid puncture of the gallbladder or extrahepatic biliary tree. A small amount of water-soluble contrast agent is injected while slowly withdrawing the needle until a bile duct is identified. Injection of contrast agent into a bile duct has the appearance of oil being dropped in water. Inadvertent opacification of a vascular structure is recognized by the rapid clearance of the contrast agent. If a bile duct is not entered during withdrawal of the needle, the needle is reintroduced in a slightly different direction. It is generally recommended, however, that the needle not be withdrawn completely from the liver to minimize damage to the liver capsule. When opacification of the biliary tree is difficult, particularly when the ducts are not dilated, the same puncture site may be used up to 12 times before a new intercostal space is selected for needle placement. In patients with biliary obstruction, 10 to 20 mL of contrast agent injected slowly is usually sufficient to opacify the bile ducts. The use of a tilting table is valuable to avoid biliary tree overdistension, which could lead to bacteremia or sepsis. A larger volume of contrast material is often required in nonobstructed systems. When the bile ducts are visualized, radiographs should be obtained in multiple projections to identify specific portions of the biliary tree and to completely delineate abnormal findings.

Left-Sided Puncture

Because the left lateral segment of the liver has variable size and anatomic position, careful review of preprocedural cross-sectional imaging is required to select a proper puncture site. Although left-sided punctures could be performed from the right side, via an anterior axillary line approach into the segment IV bile ducts, the more accepted method is a subxiphoid approach into segment II or III. Ultrasound guidance is more

useful for left-sided subxiphoid punctures than for any transcostal right-sided procedure.

Success Rate and Accuracy

Opacification of the bile ducts is successful in 95% to 100% of patients with biliary obstruction (Mueller et al, 1981; Harbin et al, 1980; Jain et al, 1977). A success rate of 60% to 95% is reported for nondilated biliary systems. The chance of success in the nondilated system is increased by the number of needle passes performed (Jaques et al, 1980). Usually, the level of obstruction is accurately determined by careful attention to detail and liberal use of a tilt table, but the technique is less definitive for determining the cause of obstruction. No radiologic descriptions of obstructed bile ducts are pathognomonic for differentiation of benign and malignant disease (Hadjis et al, 1985; Wetter et al, 1991). Many malignant masquerades are well described, and it is not always possible to differentiate between calculous disease and papillary bile duct cancer. Other radiologic findings and cytology or histology are often required for accurate diagnosis.

Pitfalls in Interpretation

Lack of Opacification

Failure to inject adequate volume of contrast agent can lead to false localization of the level of obstruction. This can occur with complete obstruction and may be recognized by the presence of a hazy margin at the level of the apparent obstruction (Fig. 18.3; Kittredge and Baer, 1975). In high bile duct obstruction, especially when associated with variant anatomy, isolated segments of the biliary tree can be visualized only by direct puncture. If direct cholangiography is incomplete, there also may be difficulty diagnosing duct injuries and bile leaks, both of which can be missed unless the proper duct is punctured and opacified.

Ductal Dilation

Absence of ductal dilation does not exclude obstruction. Disorders such as sclerosing cholangitis, AIDS, and chemotherapy-induced biliary scleroses (CIBS) have associated fibrosis that may impede normal duct dilation. Conversely, dilated bile ducts do not always mean obstruction. An example is the nonobstructive dilation that may be seen in patients with Caroli disease or choledochal cysts.

Complications

Serious complications of PTC are rare and occur in approximately 3% of patients (Harbin et al, 1980). The most common major complications are bile leakage (1% to 2%), sepsis (2% to 3%), and hemorrhage (0.2% to 0.4%); much rarer complications include pneumothorax, biliothorax, colon puncture, and abscess formation. Many of these complications can be decreased and avoided. Ultrasound guidance and puncture below the ninth intercostal space will clearly decrease the incidence of pulmonary complications, and septic complications can be avoided by appropriate antibiotic coverage and by not overdistending the biliary tree. At times, aspiration and decompression of the biliary tree will be valuable in allowing injection of larger volumes of contrast agent without leading to sepsis.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (SEE CHAPTER 27)

History

ERCP was first reported in 1968 by McCune and colleagues and has remained an important diagnostic modality frequently used in the management of patients with hepatobiliary and

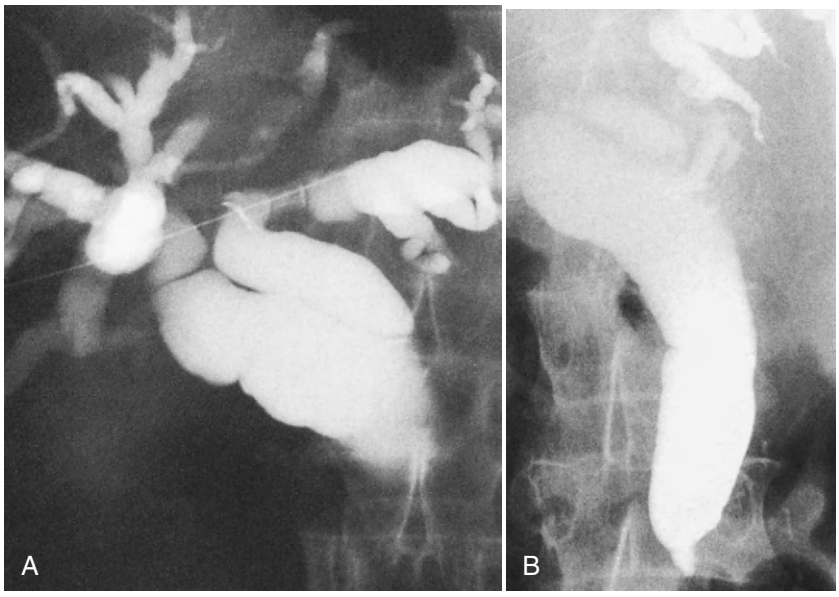

FIGURE 18.3. Ampullary carcinoma. **A,** With the patient supine, contrast pools proximally, giving a false impression of a high bile duct obstruction. The spurious nature of the level is suggested by the hazy inferior margin to the contrast column. **B,** With the patient sitting semierect, the contrast pools at the true point of obstruction, which is sharply defined.

pancreatic diseases (Cotton, 1977; Cotton et al, 1972; Freeney, 1988; Oi et al, 1970). Since the 1970s, there has been continued progress in ERCP instrumentation. One major innovation was the development in the late 1980s of video, or electronic, endoscopy. Video endoscopy enables high-quality photographic and videotape documentation of important endoscopic findings and has made the training of physicians in the technique of ERCP much easier. The endoscopic skills needed to perform ERCP are more difficult to learn than the standard procedures of upper endoscopy and colonoscopy, but now many endoscopists throughout the world can perform diagnostic ERCP easily, rapidly, and safely. Working with a cooperative patient and a well-trained team, this procedure often can be completed in less than 15 minutes. Diagnostic ERCP is rapidly being replaced, however, by noninvasive imaging techniques, such as MRCP.

A 2002 National Institutes of Health consensus conference on ERCP concluded that although MRCP and ERCP had similar sensitivity and specificity in diagnosing common bile duct stones, ERCP, as an invasive procedure, is more operator dependent and has risks associated with it because of the required sedation, and it carries the risk of injection pancreatitis. As a result, stand-alone diagnostic ERCP is being used much less frequently. It is most commonly combined with a therapeutic endoscopic procedure, such as endoscopic sphincterotomy and stone extraction for choledocholithiasis, or the insertion of an endobiliary stent for malignant biliary obstruction.

Technique

Patient selection is important, because ERCP is commonly done in an outpatient setting. Patients should be alert and oriented and must be able to give informed consent. In the rare situation in which this is not possible, such as with an intubated patient on mechanical ventilation, consent is obtained from the next of kin. Patients with uncorrected shock, cardiac arrhythmias, profound neutropenia, or significant coagulopathy should not have an elective diagnostic test such as ERCP performed.

Age is not a contraindication to ERCP, because the procedure is safe even for selected patients in their 90s. Although children less commonly have pancreatic and biliary disease, the standard technique is often all that is necessary for children, and instrumentation is the same except in children younger than 6 months old. General anesthesia is rarely needed for children older than 11 or 12 years (Buckley & Connon, 1990). ERCP has been shown to be a valuable adjunct in the evaluation of infantile cholestasis (Wilkinson et al, 1991). In a case-control study comparing children undergoing ERCP with adults, there were no differences in the success rate or the rate of complications (Varadarajulu et al, 2004). Elderly patients can safely undergo ERCP, and they have the same risks of bleeding and perforation as younger patients do but have a lower risk of pancreatitis.

Patient comfort is maintained by the use of intravenous sedation under monitored control. Drug combinations include narcotics such as meperidine and droperidol and the benzodiazepines midazolam or diazepam. Dosages are titrated for each patient with a total dose of meperidine generally ranging from 50 and 100 mg and midazolam between 2 and 10 mg. More recently, propofol, at 190 μg/kg/min, administered by anesthesia personnel, has been replacing meperidine and a benzodiazepine. Studies have shown that propofol is more effective than sedation with midazolam, it is safe, and it is associated with a faster postprocedure recovery (Wehrman et al, 1999). In some centers, if the endoscopic procedure is expected to be difficult, or if the patient has significant comorbid medical conditions, general anesthesia is used. Excess duodenal motility is controlled by bolus injections of 0.2 to 1 mg of intravenous glucagon. Oxygen is administered by nasal cannula to avoid the hypoxemia that has been described in 40% of patients undergoing ERCP (Woods et al, 1989). The patient's electrocardiogram, blood pressure, oxygen saturation, and overall condition are continually monitored throughout the procedure by a dedicated nurse. Antibiotics are not given routinely for diagnostic procedures except when biliary obstruction is expected. All endoscopic equipment used for this procedure, including the endoscopes, is either chemically disinfected or gas sterilized.

A side-viewing duodenoscope is used to afford excellent visualization of the ampulla of Vater. In patients with a Billroth II type gastrojejunostomy, a standard forward-viewing upper endoscope or pediatric colonoscope may be needed to successfully approach the ampulla. An initial endoscopic evaluation of the stomach and duodenum is performed before cannulation of the ampulla. The pancreatic and biliary ducts are selectively cannulated and identified, and a contrast agent, such as diluted Renografin-60, is injected into the desired duct under fluoroscopic control, with subsequent radiographic images obtained of the duct anatomy. The use of a guidewire to cannulate the ampulla without using contrast is becoming common. In one recent series, 795 (99%) of 801 ERCPs were performed without contrast to initially identify access to the common bile duct (CBD). The pancreatitis rate in this series was 1.3%, as was guidewire perforation of the bile duct, which also occurred infrequently (Adler et al, 2010). An additional way of gaining access to the difficult-to-cannulate CBD is to selectively place a pancreatic duct stent first and then attempt wire-guided cannulation of the bile duct.

Material for pathologic and cytologic evaluation can be obtained from either the biliary or pancreatic duct system with a variety of dedicated endoscopic biopsy forceps and cytology brushes. Pathologic and cytologic material also may be obtained from the ampulla of Vater, duodenum, and stomach.

A skilled endoscopist can be expected to identify the ampulla of Vater in almost all patients with normal anatomy. If the ampulla is inside a duodenal diverticulum, or if the second portion of the duodenum is stenotic, compressed, or invaded by a pancreatic mass, identification of the ampulla may be difficult. When the ampulla is found, success rates for selectively cannulating the CBD and pancreatic duct are greater than 90% (Rosch, 1985). When difficulty occurs in cannulation of the CBD, invasive maneuvers, such as precut papillotomy, can improve the success rate but with an associated increase in the complication rate (Shakoor & Geenen, 1992). In a patient with a Billroth II gastrojejunostomy, success rates for bile duct cannulation are much lower (Katon et al, 1975; Osnes & Myren, 1975).

Endoscopy and Pancreatography during Endoscopic Retrograde Cholangiopancreatography

The ability to perform endoscopy and pancreatography in addition to cholangiography during ERCP affords a major advantage to this procedure. It is common for endoscopic examination

of the stomach and duodenum to provide important diagnostic information that is helpful in management planning. Displacement of the antrum or pylorus or a stricture or narrowing of the second portion of the duodenum may indicate the presence of a pancreatic mass responsible for obstructive jaundice. The diagnosis can be confirmed by biopsy and cytologic specimens taken during the procedure from the infiltrated or ulcerated duodenal wall.

Duodenal diverticula almost always are located near the papilla in the descending duodenum. Large juxtapapillary diverticula are clinically significant, because they are often associated with choledocholithiasis. Although it was thought that periampullary diverticula may make cannulation of the ampulla more difficult, more recent work has shown that this may not be true (Tham & Kelly, 2004). On inspection of the ampulla, anatomic variants should be looked for before attempting cannulation (Phillip et al, 1974). Occasionally, two orifices are found, and this indicates separate biliary and pancreatic duct systems. The minor ampulla is located about 1 to 2 cm above the major papilla. Impacted gallstones give rise to a characteristic distension or bulge of the papilla, and previous spontaneous passage of bile duct stones can be recognized by a fissured splitting of the papillary orifice. Previous surgical dilation of the papilla or spontaneous gallstone perforation above the papilla also produces a characteristic appearance. Occasionally, a fistulous perforation in the roof of the papilla is found as a result of a false passage produced at surgical dilation (Tanaka & Ikeda, 1983). Biliary–enteric anastomoses appear as circular or slitlike openings.

The endoscopic diagnosis of ampullary carcinoma is not difficult, especially if the tumor is exophytic. The diagnosis becomes more challenging, however, when the tumor is predominantly intramural. In such instances, the diagnosis is frequently confirmed by biopsy and cytologic specimens, after endoscopic papillotomy allows the tumor to be exposed. In a series from the Medical College of Wisconsin, the correct diagnosis was made by endoscopic biopsy in 42 of 44 patients with ampullary neoplasia and in 16 of 18 patients with invasive ampullary cancer (Komoroski et al, 1991).

Imaging the pancreatic duct can be an important adjunct to cholangiography during ERCP. Strictures, stones, and other obstructing lesions can be identified. With increasing age comes progressive atrophy and fibrosis of the pancreas. The diameter of the main pancreatic duct also increases with age, although one study found no difference in pancreatic duct length among patients younger than 40 years compared with older patients. Duct diameter throughout the pancreas was significantly greater, however, in patients over 40 (Anand et al, 1989).

Anatomic variations, such as pancreas divisum (Fig. 18.4), also may be identified on a pancreatogram. This abnormality has been described in 7.5% of ERCP procedures and can be confirmed by cannulation of the main pancreatic duct through the orifice in the minor papilla (Bernard et al, 1990).

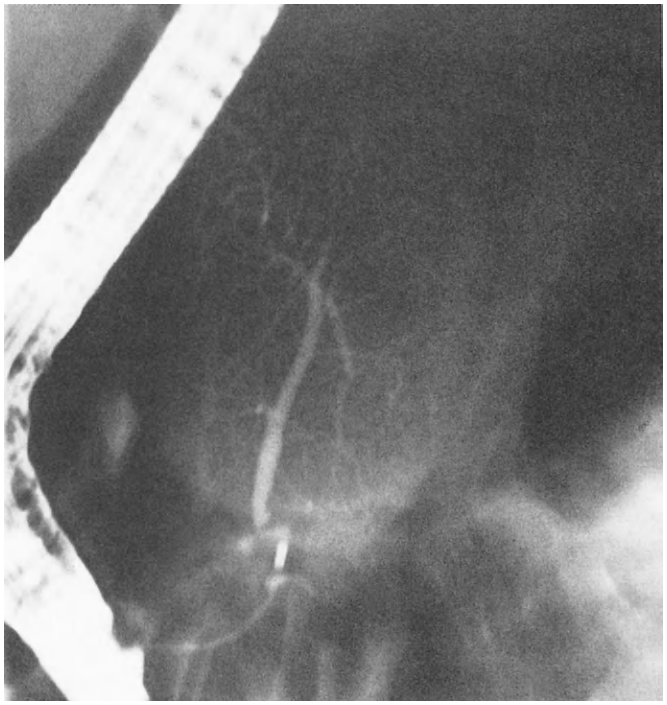

FIGURE 18.4. Pancreas divisum. The cannula is in the major papillary orifice, and contrast injection opacifies the proximal portion of the major pancreatic duct (Wirsung). Injection through the minor papillae allows opacification of the duct of Santorini and the distal duct of Wirsung.

Complications

The experience of the endoscopist is one of the most significant factors related to the development of ERCP complications (Bilbao et al, 1976). Statistics on complication rates vary accordingly. High case volume also has an impact on the complication rate. In a study conducted in Austria, endoscopists performing more that 50 ERCP procedures per year were compared with on those performing fewer than 50 per year. Those in the higher case volume group had a significantly higher success rate (86.9% vs. 80.3%; $P < .001$) and a lower overall complication rate (10.2% vs. 13.6%, $P = .007$; Kapral et al, 2008).

Acute pancreatitis after ERCP occurs in less than 7% of patients (Christensen et al, 2004; Rosch et al, 1981) and should be distinguished from transient asymptomatic hyperamylasemia, which occurs in 40% to 75% of cases (Classen & Demling, 1975). Asymptomatic hyperamylasemia disappears within 1 to 2 days, as do hypertrypsinemia (Phillip & Hagenmuller, 1983) and elevations of serum lipase and elastase 1 levels (Okuno et al, 1985). Radiographic documentation of renal excretion of the contrast agent injected into the pancreatic duct does not predict the development of acute pancreatitis (Hopper et al, 1989), and necrotizing pancreatitis, a serious complication, is observed in about 0.1% of pancreatograms. The prevalence of post-ERCP pancreatitis in children is quite low, about 2.5% in one study (Iqbal et al, 2008).

The use of nonionic contrast medium of low osmolarity has shown no advantage over the less expensive ionic contrast medium in preventing ERCP-related pancreatitis (Hannigan et al, 1985). The risk of pancreatitis is reduced by careful and gentle injection of the contrast medium into the pancreatic duct, by avoiding overdistension or "acinarization" of the pancreatic duct, and by minimizing repeated injection of the pancreatic duct when encountering difficulty in filling the CBD. Prophylactic administration of somatostatin or its analog octreotide has not been shown to prevent pancreatitis during diagnostic or therapeutic ERCP (Borsch et al, 1984; Sternlieb et al, 1992). A large, prospective, randomized,

placebo-controlled study from Italy looked at the efficacy of somatostatin and gabexate in preventing post-ERCP pancreatitis; 966 patients were studied, and no difference in the rate of pancreatitis was observed between the groups (Andriulli et al, 2004). A randomized control study demonstrated that 24 hours of octreotide prophylaxis before ERCP significantly decreased the incidence of post-ERCP pancreatitis compared with a placebo group (2/100 [2%] vs. 9/101 [8.9%]; $P = .03$) (Thomopoulos et al, 2006). Other investigators have suggested that when injection pancreatitis is a possibility, the use of a temporary pancreatic duct stent may serve to prevent its occurrence (Singh et al, 2004). In addition, when pancreatitis has developed, the use of somatostatin does not improve its clinical course (Phillip et al, 1985).

A serious complication of ERCP is the development of postprocedure cholangitis. This condition occurs most commonly when there is a significant and high-grade bile duct obstruction. When an obstructed bile duct is identified on ERCP, it is important to treat the obstruction rapidly by nonsurgical or surgical means (Classen & Phillip, 1982). Although no studies confirm the benefit of prophylactic antibiotics, it is reasonable to administer intravenous antibiotics that are preferentially excreted from the liver into the bile until adequate biliary drainage is achieved.

One study looked at the prophylactic use of antibiotics in routine ERCPs (Sauter et al, 1990). The authors found no difference in cholangitis rates when antibiotics were used, although the frequency of procedure-related bacteremia was significantly reduced. Antibiotics added to the injected radiographic contrast medium are of no benefit (Jendrzejewski et al, 1980). In addition, it was found that endoscopic instruments used in ERCP can be the source of serious infections (Earnshaw et al, 1985). *Salmonella* species are the most common organisms transmitted by contaminated endoscopes (Axon, 1991), and for this reason, it is imperative to ensure that the endoscopic equipment used for ERCP is adequately disinfected or sterilized.

DIRECT CHOLANGIOGRAPHY AND PANCREATOGRAPHY BY PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY OR ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Biliary Anatomy

The anatomy of the bile ducts is discussed in Chapter 1. Knowledge of the common variations of ductal branching is essential for accurate interpretations of cholangiograms, and these are shown in Figures 18.5 and 18.6; segmental nomenclature is summarized in Table 18.1. In the right lobe, the posterior segments lie more laterally than the anterior segments, so that the most lateral ducts on a cholangiogram are usually segments VI inferiorly and VII superiorly. The posterior sectoral duct is often recognizable by an arched course near the confluence (Figs. 18.7 and 18.8B). A right sectoral duct crosses to the left to join the left hepatic duct in 28% of cases according to Healey and Schroy (1953); in 22%, this is the posterior sectoral duct (see Figs. 18.6B and 18.8B), and in 6%, this is the anterior duct (see Figs. 18.6C and 18.8D). Occasionally, a right sectoral or segmental duct, posterior more often than anterior, courses inferiorly and enters the common hepatic duct directly (Fig. 18.9).

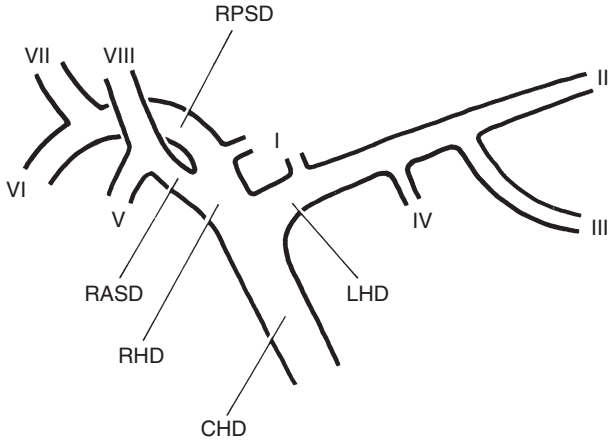

FIGURE 18.5. Standard intrahepatic ductal anatomy. The segments are numbered according to Couinaud's description (see Table 18.1). CHD, common hepatic duct; LHD, left hepatic duct; RASD, right anterior sectoral duct; RHD, right hepatic duct; RPSD, right posterior sectoral duct.

The confluence of the right and left ducts takes the form of a trifurcation rather than a bifurcation in 12% of cases according to Couinaud (1957; see Fig. 18.6A).

In the left lobe, the superior and inferior lateral segment ducts, segments II and III, unite in the line of, or to the right of, the umbilical fissure in 92% of cases. In the latter instance, the

Segmental Nomenclature

I	Caudate lobe
II	Left lateral superior segment
III	Left lateral inferior segment
IV	Left medial segment or quadrate lobe
V	Right anterior inferior segment
VI	Right posterior inferior segment
VII	Right posterior superior segment
VIII	Right anterior superior segment

Table 18.2

Average Duct Diameters Measured Directly from 50 Normal Percutaneous Transhepatic Cholangiography Examinations

Duct Diameter (mm)
Right hepatic = 4.7
Left hepatic = 5.2
Common hepatic = 6.5
Common bile = 7.6

From Okuda K, et al, 1978: Frequency of intrahepatic arteriovenous fistula as a sequela to percutaneous needle puncture of the liver. Gastroenterology 74:1204-1207.

quadrate lobe, segment IV, may drain wholly or partially into the segment II duct. Rarely, segment II and III ducts join at or close to the confluence (see Figs. 18.6E and 18.8C), and segment IV drains directly into the common hepatic duct in 1% of cases (see Fig. 18.6F; Healey & Schroy, 1953).

The caudate ducts are often difficult to identify. Usually two or three ducts drain most commonly into the right posterior sectoral duct, right hepatic duct, or left hepatic duct (Healey & Schroy, 1953). The recognizable caudate ducts are usually a few centimeters long and drain downward or to the right.

The left hepatic duct (average length, 17 mm) is considerably longer than the right hepatic duct (average length, 9 mm) and has a longer extrahepatic course. The normal diameters of the main bile ducts as measured at PTC are shown in Table 18.2. These figures are greater than the true duct dimensions because of some distension produced by direct cholangiography together with considerable magnification occurring on any fluoroscopic "spot film." The magnification is of the order of 40% (Nichols & Burhenne, 1984) and affects all structures in the image, including calculi, tubes, and strictures.

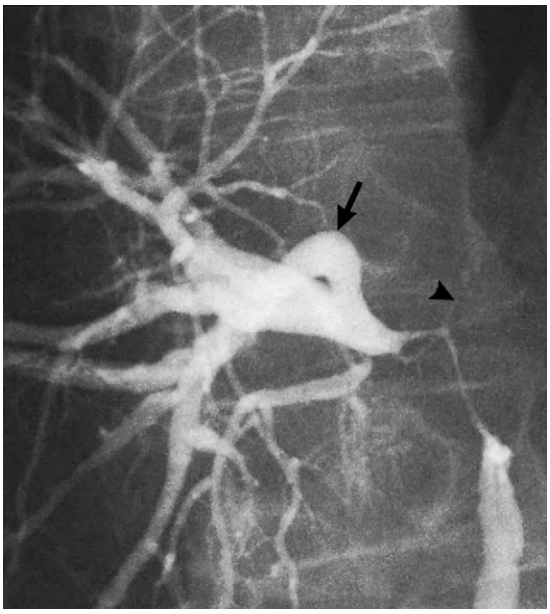

FIGURE 18.7. Hilar cholangiocarcinoma involving first-order right hepatic duct, proximal common hepatic duct, and faintly opacified left hepatic duct (*arrowhead*). Note the characteristic arched course of the right posterior sectoral duct (*arrow*).

The upper limits of normal for the diameter of the extrahepatic bile ducts as measured by ERCP vary between 9 mm and 14 mm (Niederau et al, 1984). Combined radiologic and manometric studies (Poralla et al, 1985) have shown that even in the absence of extrahepatic cholestasis, the diameter of the bile ducts and the pressure difference therein increases with advancing age. The diameter of the bile ducts as measured by ultrasonography is less than those measurements obtained during ERCP (Niederau et al, 1984). Anatomic abnormalities of the hepatobiliary system include cystic dilations (Fig. 18.10) of the bile duct or of the intrahepatic bile ducts (Caroli disease; see Chapter 46). There is a wide variation in where the cystic duct joins the common hepatic duct. A low junction with a correspondingly long cystic duct (Fig. 18.11) may result in difficulties if not recognized,. This is especially true when a cholecystojejunostomy is performed as a palliative biliary bypass for carcinoma of the head of the pancreas, and the jaundice either is not relieved or recurs rapidly in the postoperative period.

Interpretations

Because of its inherent weakness of only allowing visualization of the bile duct lumen, the main problem with the use of direct cholangiography is its lack of specificity. There are few, if any, pathognomonic radiologic findings. Many disease entities, from benign to malignant, overlap greatly in their cholangiographic appearances. The combination of history, blood markers, associated radiologic findings, and clinical scenario can often significantly narrow the differential diagnosis. However, it must be stressed strongly that because the cholangiographic appearance of many biliary diseases may be indistinguishable, biopsy is often required to rule out malignancy or to confirm suspected diagnosis.

Bile Leaks

Bile leaks are seen as sites of free extravasation of contrast agent at a site of bile duct injury. Injury may be secondary to trauma, but most commonly it is iatrogenic in nature. Associated bilomas may be seen at the point of bile leak. Although puncture or opacification of the correct duct is necessary for diagnosis, this is perhaps the remaining diagnostic scenario in which invasive direct cholangiography has a distinct advantage over noninvasive techniques. Because leaking intrahepatic bile ducts are usually not dilated, nonvisualization and inability to localize this finding on MR and CT cholangiography is common. Cystic

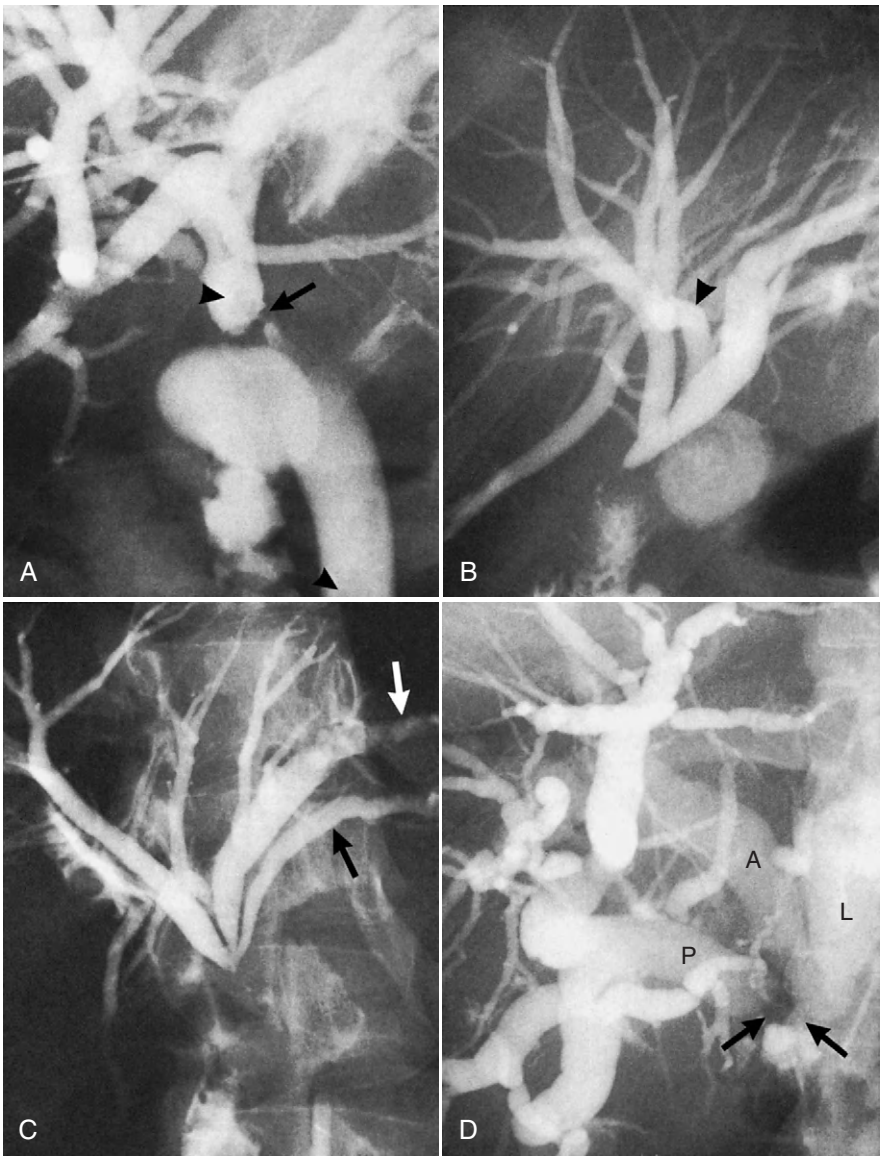

FIGURE 18.8. Postcholecystectomy strictures graded according to Bismuth. **A,** Grade I (>2 cm from the confluence of the right and left hepatic ducts; *arrowheads*): calculi lie above and below the stricture (*arrow*). **B,** Grade II (<2 cm from the confluence): there has been a previous hepatojejunostomy; the right posterior sectoral duct (*arrowhead*) has an exaggerated arched course and enters the left hepatic duct as a normal variant. **C,** Grade III (the confluence is involved by stricture, but the right and left hepatic ducts are not completely separated): ducts of segment II (*white arrow*) and segment III (*black arrow*) join the confluence independently as a normal variant. **D,** Grade IV (the right and left ducts are separated by the stricture): the right anterior sectoral duct (*A*) is draining into the left hepatic duct (*L*), which is separated from the right posterior sectoral duct (*P*) by the stricture (*arrows*).

duct leaks, minor injuries to extrahepatic bile ducts, and leaking anastomoses may also be unidentifiable and nonlocalizable with indirect techniques. Diagnosis and localization of bile duct leaks is therefore perhaps the only remaining indication for direct cholangiography.

Filling Defects

Air Bubbles, Blood Clots, Calculi, Primary and Secondary Bile Duct Cancers, and Parasitic Diseases

Air bubbles, though confusing, most commonly declare themselves by their perfectly circular shape and their distribution to nondependent structures. Blood clots in the bile duct are seen more frequently with PTC than with ERCP. Hemobilia can sometimes take more than 48 hours to resolve, and when it is more severe; it can be castlike and may mask other filling defects.

Calculous disease (see Chapters 36, 37, and 39) remains the most common filling defect in the biliary system. Distinguishing characteristics of gallstones and primary bile duct calculi include a faceted radiologic appearance and disposition to move to gravity-dependent positions. Calculi may be seen as discrete filling defects (Figs. 18.12 and 18.13) or castlike structures filling entire ducts, as occurs in oriental cholangiohepatitis, cystic diseases of the bile ducts, or even proximal to strictures of any etiology. Impacted calculi may be difficult to differentiate from strictures or tumors.

FIGURE 18.9. Pancreatitis producing a typical, incomplete long stricture of the common bile duct. The right posterior sectoral duct has a low entrance into the common hepatic duct, an uncommon but important normal variant.

FIGURE 18.12. Choloedocholithiasis.

FIGURE 18.13. Benign stricture of the right hepatic duct (*arrow*) with multiple ductal calculi proximal to it. The hepatojejunostomy is partially strictured.

Primary bile duct cancer (see Chapter 50), specifically papillary cholangiocarcinomas, can also present as cholangiographic filling defects (Fig. 18.14). T-shaped filling defects may also be detected (Torok & Gores, 2001; Fig. 18.15), and papillary bile duct cancers may cause filling defects as a result of mucin production (Fig. 18.16). Other malignancies, including melanoma and intraductal metastases, such as colon cancer, are also more unusual causes of cholangiographic filling defects (Riopel, 1997).

Parasitic infections (see Chapter 45), such as with hydatid disease or with *Ascaris lumbricoides* or *Clonorchis sinensis,* are

FIGURE 18.14. Papillary hilar cholangiocarcinoma (*arrowheads*). Only the right ducts are opacified.

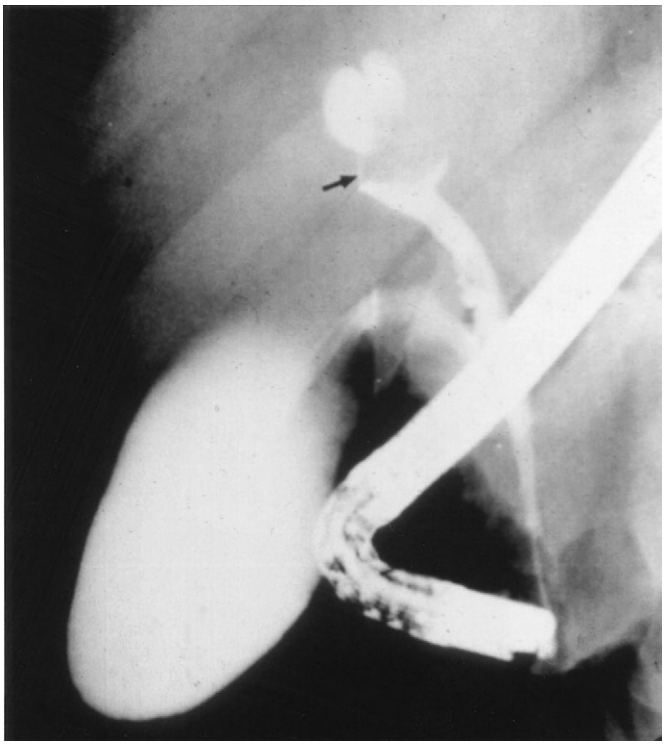

FIGURE 18.15. "Golf tee" appearance of a papillary bile duct cancer (*arrow*) involving the common hepatic duct.

FIGURE 18.16. Nasobiliary cholangiogram opacifying left hepatic ducts. Main left hepatic duct contains a small mucin-secreting papillary cholangiocarcinoma (*arrow*). The mucin results in expansion of the common bile duct below the tumor and appears as strandlike filling defects. *(Courtesy Dr. A. Speer.)*

diseases with worldwide distribution that can also present cholangiographically as intraductal filling defects. A proportion of hepatic hydatid cysts (5% to 10%) rupture into the bile ducts and may simulate choledocholithiasis (see Chapter 68). Calcified cysts are easy to recognize on radiographs, and daughter cysts can cause biliary obstruction. When the calcified cyst is not obvious, biliary strictures with obstruction may be noted on cholangiogram. The biliary ducts can show considerable irregularities in caliber and extensive displacement of the intrahepatic branches secondary to the mass effect of a large hydatid cyst (Cottone et al, 1978; Dyrszka & Sanghavi, 1983; Ibrahim & Kawanishi, 1981).

Ascaris lumbricoides is a commonly seen helminth that has worldwide distribution. Its prevalence is 90% in some parts of Africa and Asia. If the worm passes through the sphincter of Oddi, it may cause acute pancreatitis or a cholestasis syndrome (Winters et al, 1984). In the acute stage, the worm occasionally may be found and extracted from the ampulla, and it can be detected in the biliary tract by cholangiography.

Eating raw meat has been associated with *Clonorchis sinensis* infestation. The prevalence of this disease has been estimated to be 60% of the general population of Hong Kong based on stool ova examinations. This worm can penetrate through the papilla into the bile ducts. In an ERCP study of 31 consecutive patients, the typical filamentous, wavy, or elliptical appearance of the worm in the bile ducts was believed to be pathognomonic. Other common cholangiographic findings include widely dilated extrahepatic bile ducts, which are filled with biliary sludge and stones, and intrahepatic duct strictures, which are predominantly found in the branches of the left hepatic duct (Yellin & Donovan, 1981). The eggs of *C. sinensis* act as a nucleus for the development of the bile duct stones (Lam et al, 1978). Naval and colleagues (1984) reported successful endoscopic biliary lavage to eliminate the eggs.

Invasion of *Fasciola hepatica* into the biliary tract also may cause serious lesions. In the chronic stage, *F. hepatica* infection can resemble sclerosing cholangitis (Hauser & Bynum, 1984). The appearance on ERCP is that of dilated bile ducts with unexplained sludge in the distal bile duct (Figs. 18.17 and 18.18).

FIGURE 18.17. Liver flukes in the distal bile duct presenting as "biliary sludge."

Cystic Diseases

Typing of choledochal cysts (see Chapter 46) is according to the Todani et al (1977) classification. Type 1 cysts, the most common kind (80% to 90%), manifest as a fusiform dilation of the CBD, common hepatic duct (CHD), or both (see Figs. 18.10 and 18.19). A type 2 cyst (2% to 3%) is seen as a diverticular outpouching of the CBD or CHD. A type 3 cyst, also referred to as *choledochocele*, is a dilation of the intraduodenal (mural) portion of the distal CBD. Type 4 cysts (10% to 15%) have intrahepatic and extrahepatic cystic components in any combination, and type 5 cysts, also known as *Caroli disease*, is a rare form in which cysts are only seen in the intrahepatic bile ducts. Although most patients with choledochal cysts are diagnosed in infancy or childhood, 20% to 30% are diagnosed as adults. Associated calculous diseases secondary to bile stasis or stricture are frequently seen with cystic diseases. However, these must be differentiated from other more significant entities, such as bile duct cancers, because of the marked predisposition of biliary malignancies in patients with choledochal cysts (Fig. 18.20).

Bilomas, saccular intrahepatic contrast collections, may be secondary to occlusive disease or trauma, including iatrogenic trauma and trauma from transarterial chemoembolization (TACE) (Sakamito et al, 2003; Kim et al, 2001). Particularly in occlusive disease, bilomas can become infected and may appear as abscesses. Microabscesses seen with suppurative cholangitis typically appear as grapelike clusters in terminal bile ducts (Fig. 18.21).

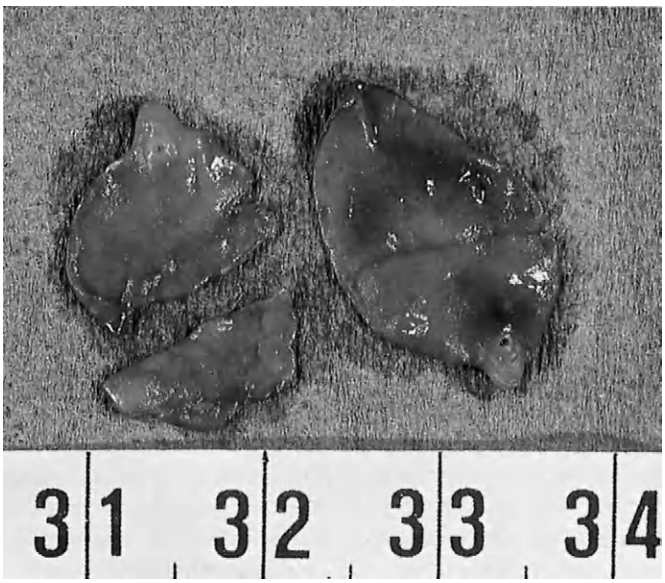

FIGURE 18.18. Extracted liver flukes (same patient as in Figure 18.34).

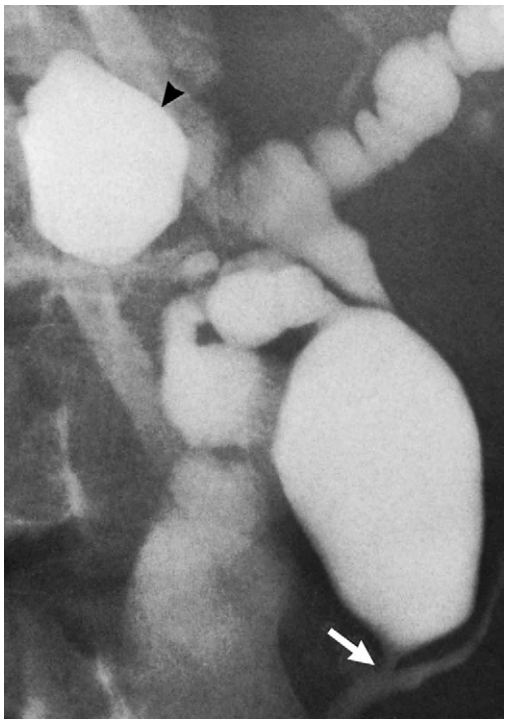

FIGURE 18.19. Choledochal cyst with intrahepatic cyst formation (*arrowhead*). The common bile duct has an abnormally proximal junction with the pancreatic duct (*arrow*).

Strictures

Bile duct strictures may be classified by their morphologic appearance or level of obstruction. Level of obstruction classification, as described by Bismuth and colleagues (1992), has significant surgical implications. When used strictly for etiologic diagnosis, however, neither level of obstruction nor morphologic appearance description is as clinically rewarding. Cholangiographic strictures are present in a diverse group of diseases.

FIGURE 18.20. Cholangiocarcinoma within a choledochal cyst.

FIGURE 18.21. Multiple hepatic abscesses associated with suppurative cholangitis in a patient with hilar duct obstuction.

Many benign and malignant conditions can have strictures that encompass the entire gamut of cholangiographic appearances. Any combination of intrahepatic or extrahepatic distribution, shouldered or smooth, beaded or nonbeaded, long or short, and with or without associated proximal dilation has been described in most of these diseases. Diagnostic limitations of direct cholangiography are due to this great overlap in findings. Visualization of only the bile duct lumen, as achieved with direct cholangiography, offers no advantages over noninvasive imaging techniques when evaluating bile duct strictures. Direct cholangiography is generally reserved for when concomitant biliary intervention is anticipated. In much of the diagnostic spectrum of stricture disease, biopsy is frequently required to rule out malignancy.

Sclerosing cholangitis (see Chapter 41) can produce cholangiographic changes in the intrahepatic and extrahepatic biliary trees, and it is commonly seen in both (La Russo, 1984). The bile ducts in primary sclerosing cholangitis (PSC) are characterized by an annular concentric stenosis, usually multifocal, with areas of normal or mildly dilated ducts between strictures (Fig. 18.22; Rogers et al, 1972). Larger bile ducts can appear beaded (Fig. 18.23), and other radiologic findings include a "prune tree" appearance, from reduction of peripheral bile duct radicles, and diverticular outpouchings of the extrahepatic bile ducts (Gulliver et al, 1991; La Russo et al, 1984; Fig. 18.24). Ulcerative colitis is identified in as many as 70% of patients with PSC, and coexisting cholangiocarcinoma can occur in 15% of these patients (MacCarty et al, 1985; Crippin & Lindor, 1992). Detecting a cholangiocarcinoma in a background of sclerosing cholangitis is difficult. Cholangiographic features suggesting cholangiocarcinoma include progressive focal stricturing, the presence of uniform proximal duct dilation, and nodular filling defects (Li-Yeng & Goldberg, 1984). It has been suggested that evaluating these features together with cross-sectional imaging can detect many tumors (Campbell et al,

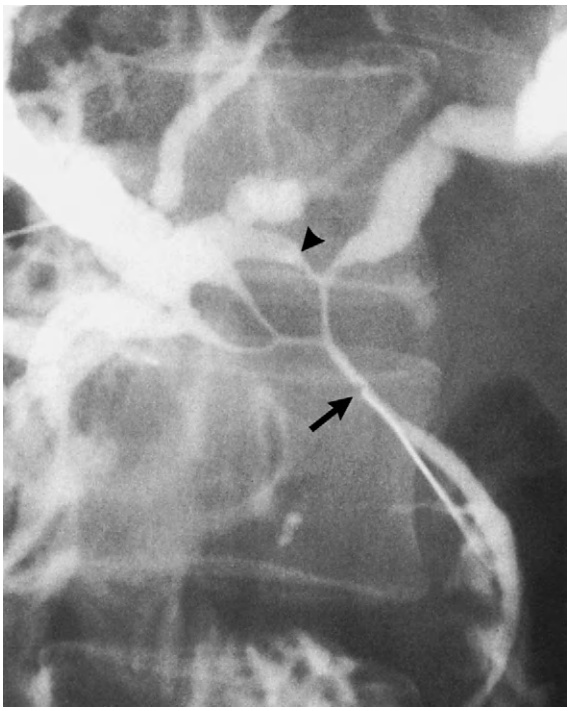

FIGURE 18.22. Sclerosing cholangitis producing a stricture of the common hepatic duct extending into second-order ducts bilaterally. Differentiation from cholangiocarcinoma is aided by fine-needle aspiration cytology (*arrow*). Note the right posterior sectoral duct (*arrowhead*) entering the left hepatic duct.

FIGURE 18.24. Sclerosing cholangitis with multiple intrahepatic and extrahepatic segments of stricturing. A characteristic "diverticulum" (*arrow*) overlies the confluence of the right and left hepatic ducts.

FIGURE 18.23. Primary biliary sclerosis with typical irregularity and beading of large ducts.

1998). Again, biopsy is generally required for definitive diagnosis.

Cholangiocarcinoma (see Chapter 50) is commonly seen as the classic sclerosing Klatskin type with a high-grade Y-shaped obstruction involving the right and left main bile ducts and the proximal common hepatic duct (see Fig. 18.7). Extension of stenoses to subsegmental bile ducts is frequently seen, and biliary dilation proximal to the obstruction is expected, as is a decompressed gallbladder. Klatskin tumors may cause obstruction of adjacent portal veins, resulting in hepatic atrophy that manifests itself cholangiographically as dilated, tortuous, or even beaded, crowded bile ducts (Fig. 18.25).

Like central lesions, the more common (60%) peripheral bile duct cancers are demonstrated in direct cholangiography

FIGURE 18.25. Hilar cholangiocarcinoma with crowded left ducts indicating left lobe atrophy. The right ducts are opacified by a percutaneous transhepatic drainage catheter.

as nonspecific stenoses or obstructions (Longmire et al, 1973; Ohto et al, 1980; Tompkins et al, 1981; Warren et al, 1972). They may also present with bilevel obstruction as a result of central lymphadenopathy. The additional diagnostic benefits of CT and MR cholangiography make these noninvasive techniques preferable for preprocedural planning and in differential diagnosis (Tompkins et al, 1990; Stroszczynski & Hünerbein, 2005).

Direct cholangiography for the diagnosis of gallbladder cancer (see Chapter 49) is rarely required. Gallbladder cancer is best diagnosed with CT, ultrasound, or MRI. Cross-sectional imaging reveals the common radiologic findings of associated calculous disease and direct extension of tumor into the adjacent hepatic parenchyma. Findings in direct cholangiography consist of high-grade stricture or occlusion of the biliary tree at any level (Fig. 18.26), typically with no visualization of the cystic duct or gallbladder.

Approximately two thirds of pancreatic cancers occur in the region of the papilla of Vater and the head of the pancreas, and the bile duct is usually involved (see Chapter 58). Characteristic cholangiographic findings include occlusion of the distal CBD with proximal dilation. The CBD above the occlusion may have a more horizontal course (Freeney, 1988; Fig. 18.27). Cystic duct patency is often preserved, and dilation of the gallbladder may be marked. ERCP, CT, and MRI may show occlusion or stenosis of the main pancreatic duct with proximal pancreatic duct dilation. The more classic double-duct sign of simultaneous obstruction of the pancreatic duct and CBD at proximate levels is also best determined with these techniques (Fig. 18.28).

Periampullary cancer (see Chapter 59) also causes obstruction of the CBD at the level of the papilla of Vater. The site of origin may be the duodenum or distal bile duct, which is indeterminate cholangiographically. A short-segment obstruction with proximal dilation most often identified though more central biliary abnormalities could also be seen (Fig. 18.29). A polypoid filling defect may also occasionally be seen with periampullary cancers. The filling defect, however, is not pathognomonic and must be differentiated from other possible malignancies or filling defects.

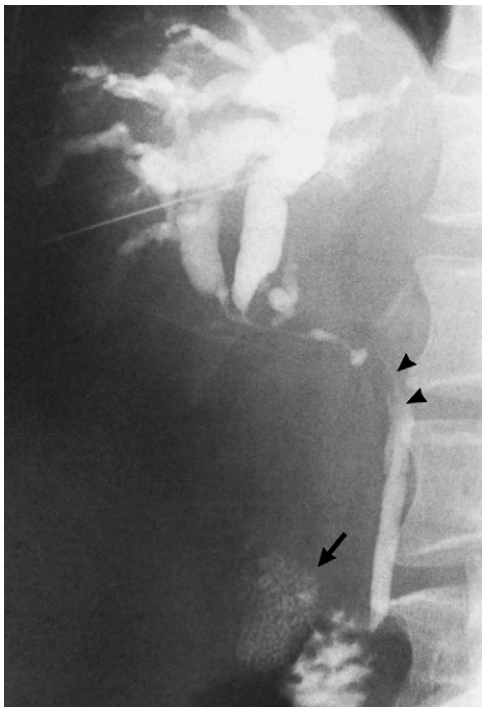

FIGURE 18.26. Gallbladder carcinoma involving right third-order ducts and deviating upper common hepatic duct medially (*arrowheads*). Multiple small calculi appear in the gallbladder fundus (*arrow*), which is separated from the strictured ducts by the tumor.

Malignant bile duct obstruction has also been described with metastatic colon, breast, lung, and gastric cancers (Fig. 18.30). Obstructions can be intrahepatic and/or extrahepatic and may be due to lymph node involvement or direct extension (Lokich et al, 1987). Bile duct obstruction from lymphoma is more commonly extrahepatic, and extrahepatic bile duct strictures can also be seen with benign lymph node enlargements such as in Castleman disease (Przkora et al, 2003).

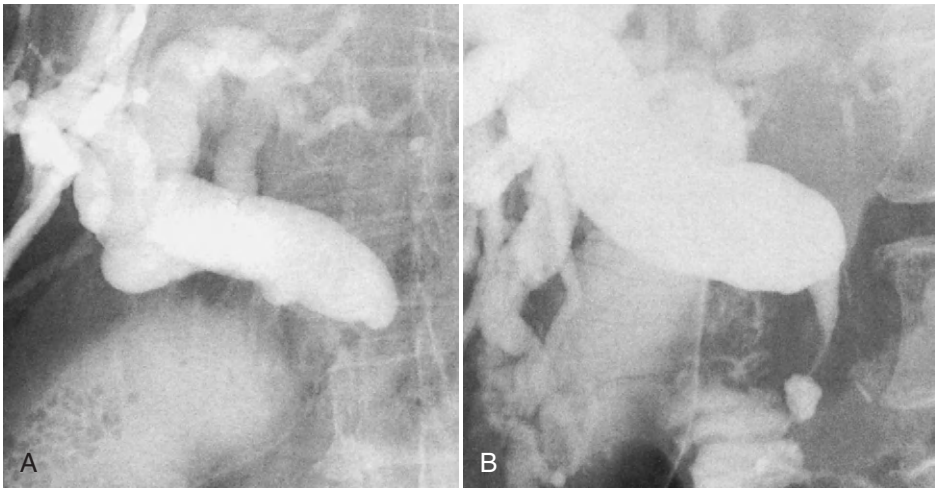

FIGURE 18.27. Two of the common appearances of carcinoma of the pancreas. **A,** Rounded obstruction with characteristic horizontal common bile duct. Note the coincidental stones in the distended gallbladder. **B,** Tapered obstruction with slight shouldering. Compare this with pancreatitis (see Figure 18.9), in which shouldering tends to be absent.

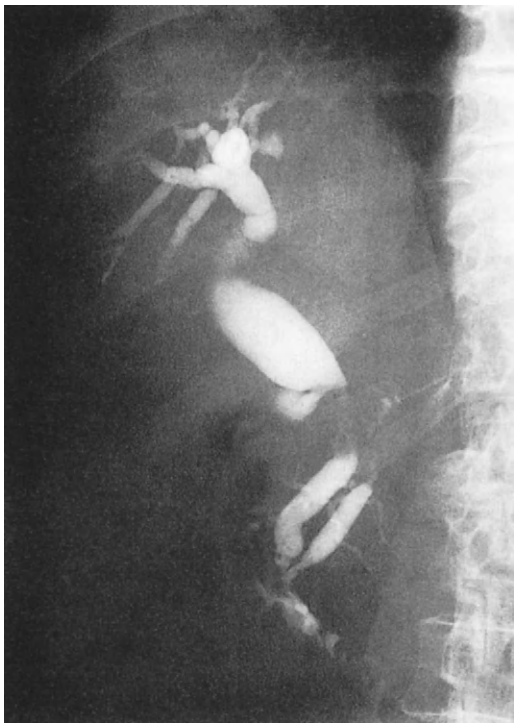

FIGURE 18.28. Double-duct sign, stenosis of the bile duct and pancreatic duct, in a case of pancreatic carcinoma.

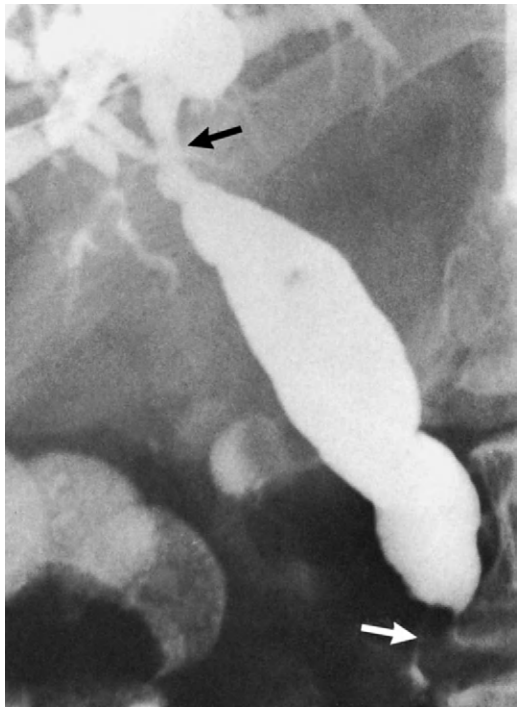

FIGURE 18.29. Periampullary carcinoma producing localized stricture of distal common bile duct (*white arrow*) indistinguishable from pancreatic cancer. Stricturing of the upper common hepatic duct (*black arrow*) is due to porta hepatis lymphadenopathy.

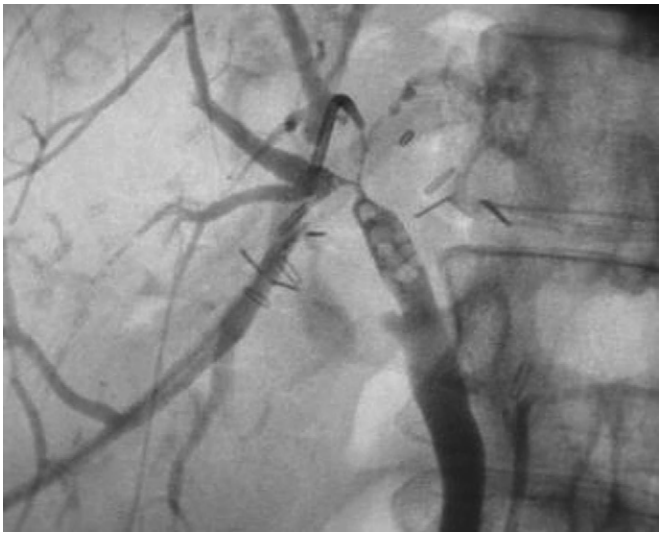

FIGURE 18.30. Hilar obstruction from metastatic breast cancer.

The conundrum of "malignant masquerade" (see Chapter 42) present with direct cholangiography is perhaps most classically demonstrated by Mirizzi syndrome (Hadjis et al, 1985; Clemett & Lowmann, 1965; Becker et al, 1994), which occurs when a gallstone is impacted in the cystic duct or gallbladder neck, causing inflammatory obstruction of the common hepatic duct. The obstruction may be limited and focal or may extend into the intrahepatic bile ducts. On cholangiogram the syndrome is indistinguishable from cholangiocarcinoma, gallbladder cancer, or other malignant strictures (Figs. 18.31 and 18.32).

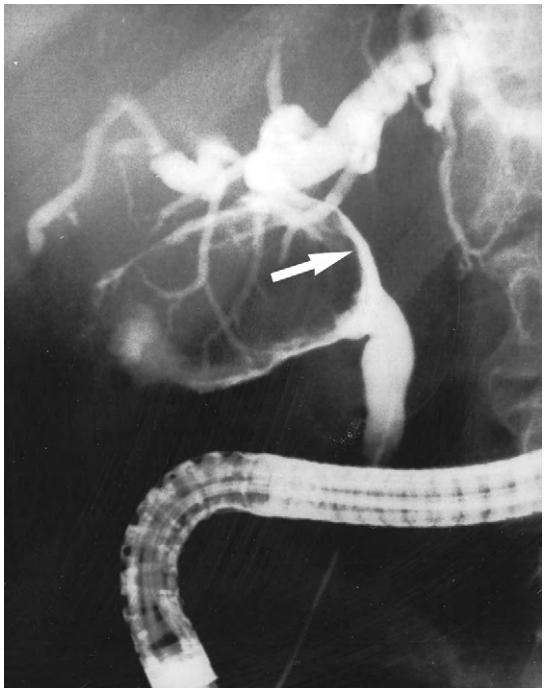

FIGURE 18.31. Mirizzi syndrome. A large gallbladder calculus has eroded into the common hepatic duct (*arrow*), which is narrowed and deviated medially.

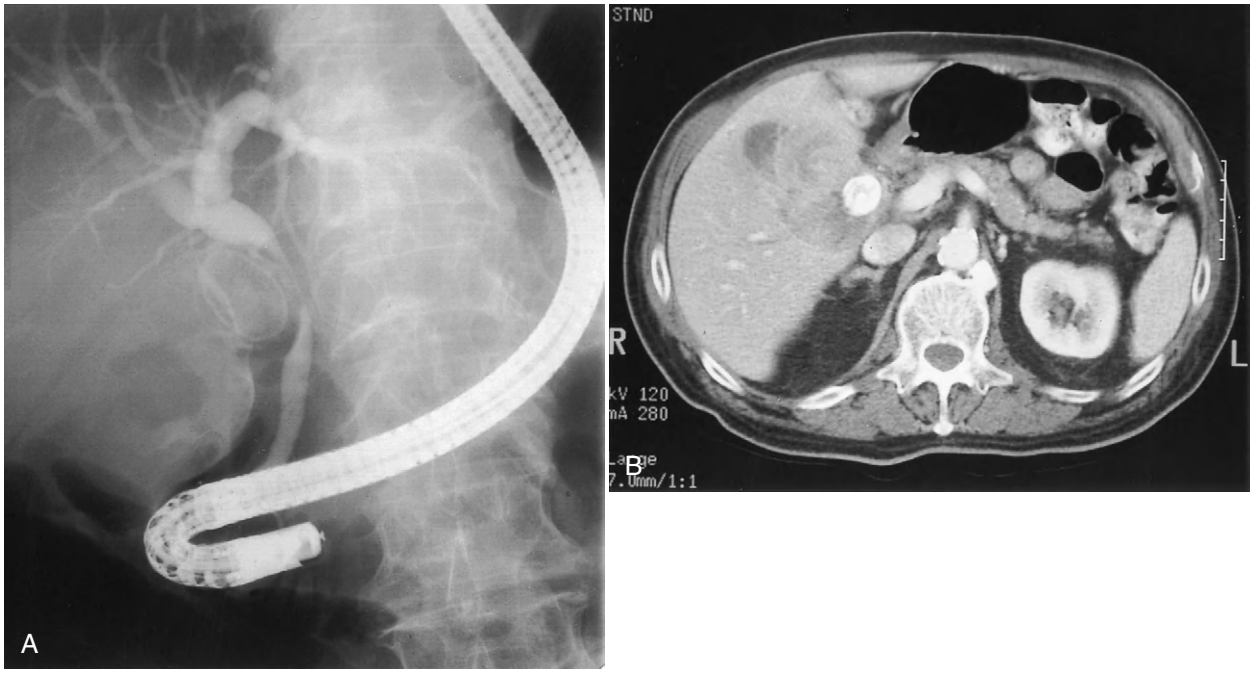

FIGURE 18.32. Mirizzi syndrome. **A,** Endoscopic retrograde cholangiopancreatography shows common hepatic duct stricture resulting from gallstone in a Hartmann pouch of the gallbladder. **B,** CT scan shows the impacted stone. An associated gallbladder cancer is also shown.

Oriental cholangiohepatitis (see Chapter 44) is generally seen in Asian populations. Cholangiography demonstrates strictured intrahepatic or extrahepatic bile ducts with markedly dilated proximal bile ducts. The dilated proximal bile ducts are packed with filling defects, which represent pigmented stones. Although all segments of the biliary tree can be involved, disease in the lateral segment of the left lobe is most common (Lim, 1991). Oriental cholangiohepatitis is characterized by recurrent episodes of cholangitis and is therefore commonly referred to as *recurrent pyogenic cholangitis.*

Acute pancreatitis (see Chapter 54) is usually diagnosed by combination of history, serum chemistry (amylase and lipase elevation), and cross-sectional imaging. Direct cholangiography, especially ERCP, is rarely performed during an acute episode because of the possibility of exacerbation of disease or introduction of infection. Once the episode has subsided, ERCP can be performed and may demonstrate a distal stricture and possible choledocholithiasis (Fig. 18.33). Care must be taken, however, as pancreatic cancer and periampullary cancer can not only have similar cholangiographic appearances but may coexist or even present clinically as acute pancreatitis (Mujica et al, 2000; Murakami et al, 2006; Akatsu et al, 2008).

In chronic pancreatitis as in acute pancreatitis, distal bile duct stricture is the most common cholangiographic abnormality, seen in approximately 25% of patients with chronic pancreatitis (Fig. 18.34; see Chapters 42 and 55). Stricture length and morphology are variable, and the frequently described long, smoothly tapered stenosis occurs in only 27% to 56% of patients (Stolte et al, 1984). MRI and ERCP have greater sensitivity than PTC in chronic pancreatitis because of their ability to demonstrate pancreatic duct abnormalities such as enlargement, ectasia, beading, and the presence of chronic pseudocysts. The development of a pseudocyst can also cause pressure obstruction of more central segments of the bilinear tree.

Hepatic artery infusional chemotherapy via hepatic artery infusion pump (HAIP) and with transarterial chemoembolization have both been implicated as causes of biliary sclerosis (Kim et al, 2001; Brown et al, 1997). Stricture formation is due to either direct action of the chemotherapeutic agent or from ischemia secondary to damage of the arterial vasculature

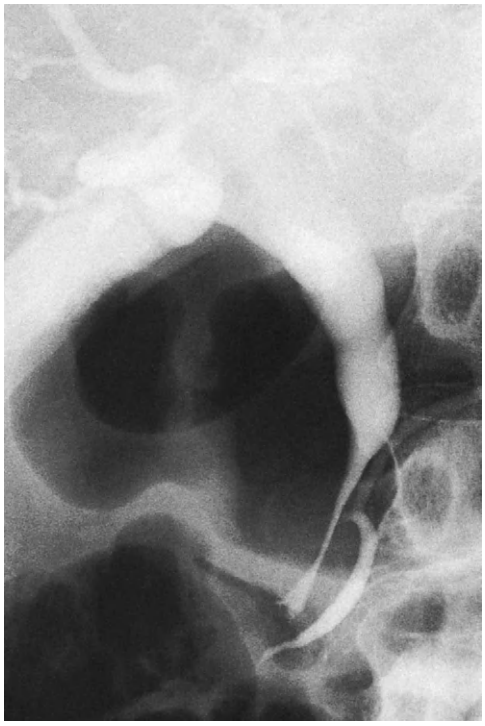

FIGURE 18.33. Acute pancreatitis with pseudocyst in the head of the pancreas (verified on operation), leading to cholestasis.

FIGURE 18.34. Filiform stenosis caused by chronic pancreatitis.

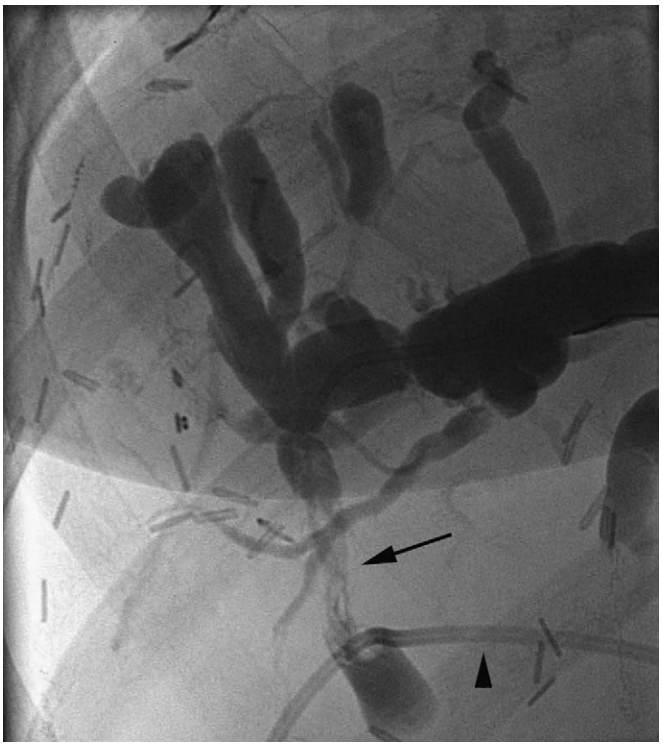

FIGURE 18.35. Chemotherapy-induced biliary sclerosis (CIBS) from hepatic artery infision pump (HAIP) therapy. Note catheter portion of pump (*arrowhead*) and fuzzy, striated appearance of commom hepatic duct stenosis.

supplying the bile ducts. Chemotherapy-induced biliary sclerosis (CIBS) secondary to HAIP most commonly presents cholangiographically as high-grade obstruction of the common hepatic duct (50%) indistinguishable from a Klatskin tumor. Frequently, the area of CHD obstruction takes on a fuzzy, striated, ill-defined appearance (Fig. 18.35); peripheral stenoses may also be seen but are not always present. Biloma formation with or without associated infection (abscess) is not uncommon and may be due to peripheral bile duct necrosis.

Patients with AIDS may have bile duct inflammation from opportunistic infections such as cytomegalovirus and *Cryptosporidium*. The most common radiologic findings are gallbladder and bile duct wall thickening that are not demonstrated with direct cholangiography. Direct cholangiographic findings in AIDS-related cholangitis are very similar to those seen in sclerosing cholangitis: multiple strictures with intervening areas of dilation, beading, and even prune-tree appearances have been described (Farman et al, 1994; Schneiderman et al, 1987; Texidor et al, 1991; Miller et al, 1996).

CONCLUSION

The role of direct cholangiography in the diagnosis of biliary disease has for the most part been supplanted by less invasive CT and MR cholangiography. The ability to visualize the entire biliary tree, the bile duct wall, and other structures besides the bile duct lumen greatly increases the accuracy of the noninvasive techniques and renders them diagnostically superior to direct cholangiography. Coupled with the lack of need for sedation and their minimal complication rate, CT and MR cholangiography have become the gold standard for cholangiography. Other than its use for localization and documentation of bile leaks, direct cholangiography is generally reserved for situations involving concomitant planned therapeutic intervention. The choice of PTC versus ERCP is therefore mostly dependent on the available expertise and likelihood of successful therapeutic intervention of one or the other.

CHAPTER 19

Diagnostic angiography in hepatobiliary and pancreatic disease: indications

Robert K. Kerlan Jr.

IMAGING OVERVIEW

The role of catheter angiography has changed substantially with the development of multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI). These developments have allowed computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) to demonstrate the visceral arterial and venous structures with clarity in many patients. Although catheter angiography remains a critical test in highly selected patients with hepatobiliary and pancreatic disease, the indications for this procedure are quite different than a decade ago.

In the 1980s and 1990s, selective angiography was commonly used as a diagnostic and staging technique. Indications would include ascertaining the organ of origin of an abdominal mass, assessing for vascular invasion by pancreatic or cholangiocarcinoma, and preoperative planning prior to hepatic resection. CT (see Chapter 16) and MRI (see Chapter 17) have completely replaced catheter angiography for these indications. In a prior edition of this book published in 2000, it was suggested that catheter angiography was a dying specialty and that angiographers should accept their fate with grace. However, a new age has dawned, and the volume of selective visceral angiography has increased considerably. The majority of these arteriograms are performed for the purpose of a diagnostic assessment prior to performing catheter-based interventions including radioembolizations (see Chapter 84A), chemoembolizations (see Chapter 83), chemoperfusions (see Chapters 86 and 89), and embolizations of bleeding arteries (see Chapter 25). In addition, endovascular therapies have replaced open surgical arterial interventions in patients with primary vascular pathology using angioplasties, stents, and the placement of stent grafts.

Another technologic advance that involves catheter angiography is the development of hybrid imaging. Hybrid imaging couples two imaging modalities to create unique images that can provide information that would not be available with either technique alone. Catheter angiography can be coupled with a cross-sectional imaging modality, usually MDCT but occasionally MRI. The images can be postprocessed and rendered in a three-dimensional format to provide an anatomic depiction that would not be available by either technique alone. This hybrid imaging is particularly useful in delineating complex splanchnic venous anatomy in patients with portal vein occlusive disease being evaluated for potential portal systemic shunting procedures.

This chapter will be divided into two sections: one will cover arteries, the other will discuss veins. Regarding arteriography relevant to hepatobiliary and pancreatic surgery, we will discuss arteriographic anatomy and technique, arteriography prior to arterial interventions and surgery, localization of occult neuroendocrine tumors of the pancreas, arterial diseases, and hemorrhage. Our discussion on splanchnic veins will include venographic anatomy, venous sampling, techniques of catheter-based venous imaging, and venous imaging prior to surgical or percutaneous venous interventions.

ARTERIES

Arteriographic Technique

Over the past two decades, technologic advances have improved the safety and efficiency of catheter angiography. The historical technique of cut-film angiography is no longer available and has been replaced by highly sensitive flat-panel digital detectors. These detectors are capable of generating a volumetric data set that allows an image to be displayed in multiple formats. Rotational angiography with three-dimensional postprocessing and C-arm computed tomography (CCT) using the angiographic imaging unit are replacing digital subtraction image-intensified designs.

Unless serious comorbidities are present, catheter angiography is routinely performed as an outpatient procedure. The purpose of the examination should be evaluated by the angiographer to confirm that the examination is indicated and can be conducted with a high level of safety. The patient should be interviewed, and consent should be obtained prior to the procedure. A limited physical examination should be completed that includes a detailed pulse examination and assessment of the airway, heart, and lungs to ensure the safety of conscious sedation.

The relevant laboratory parameters include serum creatinine or estimated glomerular filtration rate, hematocrit level, platelet count, and international normalized ratio (INR), and these should be reviewed. The necessity of obtaining laboratory values in otherwise healthy patients without a clinical risk of renal impairment or abnormal bleeding is controversial.

If the patient has impairment of renal function, a number of prophylactic measures have been recommended to diminish the risk of contrast-induced renal failure. These measures include intravenous hydration with a sodium bicarbonate solution as well as the administration of N-acetyl cysteine. The effectiveness of these prophylactic measures is controversial; however, they carry a minimal risk to the patient and have been adopted by the majority of practitioners.

The risk of bleeding from the puncture site is low, and hematomas complicate 1% of femoral punctures and 3% of upper extremity punctures. An abnormal bleeding profile related to

thrombocytopenia or prolongation of the INR increases the risk of hemorrhage. The necessity to correct an underlying coagulopathy is dependent upon the specific procedure to be performed and the preference of the angiographer. Most centers desire a platelet count in excess of $50{,}000 \times 10^6$ per liter and an INR of 1.5 or less. For 6 hours prior to the examination, the patient should be given nothing by mouth, as mild to moderate conscious sedation improves the patient's experience, although the procedure itself is not painful and can be performed solely with local anesthetic agent. Intravenous hydration is recommended before, during, and after the arteriogram to diminish adverse effects of contrast media on renal function. The patient should also be encouraged to drink plenty of fluids following the procedure.

The favored puncture site is the right common femoral artery, although the left common femoral artery, axillary artery, brachial artery, or radial artery may be used as alternatives when clinically appropriate. The desired puncture area is cleansed and the patient is draped in sterile fashion. In most centers, arterial entry is performed under real-time ultrasound guidance using a 21-gauge micropuncture set. The use of ultrasonography allows assessment of the quality of the common femoral artery, depicts the position of the profunda femoris, and detects the presence of aberrant veins extending ventral to the puncture site. Following entry into the vessel, the appropriate catheter is inserted for catheterization of the desired vessel. After diagnostically adequate images are obtained, the catheter is removed, and one of a variety of closure devices is deployed to seal the arteriotomy. Patients are observed in a postprocedural area until they have recovered from sedation, and most can be discharged home 2 to 4 hours later.

Arteriographic Anatomy

Arterial anatomy has been discussed elsewhere (see Chapter 1) and will only be briefly reviewed here. The most frequently encountered anatomy (Fig. 19.1) is the left gastric artery, splenic artery (SA), and common hepatic artery (HA) taking origin from the celiac axis. The common HA divides into the gastroduodenal artery (GDA) and proper HA, with the latter dividing into the right and left hepatic arteries. The right gastric artery most often originates from the base of the left HA, and the cystic artery most often originates from the right HA, but considerable variations in the origins of these arteries exist. Moreover, accessory duodenal arteries, either representing a supraduodenal or a retroduodenal artery, are frequently encountered; this is critical to recognize when planning chemoembolization and radioembolization.

The normal arterial supply to the liver is shown in Figure 19.2 (see the Extrahepatic Vasculature section in Chapter 1B), which shows the commonly recognized variations of the left hepatice artery (LHA), taking origin from the left gastric artery, and the right hepatic artery (RHA), taking origin from the superior mesenteric artery (SMA). It is important to recognize that either a part or the entirety of the right and left hepatic arteries may have these variant origins. When the entire vessel has a variant origin, it is termed *replaced.* If the entire trunk does not take a variant origin, the vessel is termed *accessory.* For example, if the right lobe is supplied by a right HA originating from the common HA, as well as a right HA taking origin from the SMA, the latter would be termed an *accessory right HA*. If the entire right lobe was supplied by an artery taking origin from the SMA, it would be called a *replaced right HA*.

In most patients, the arteries to Couinaud segments I, II, III, and IV are branches of the left HA, and arteries to segments V, VI, VII, and VIII are branches of the right HA. The most variable segmental branch is to segment IV. Although most frequently the artery to segment IV takes origin from the LHA, it may also take origin from the RHA, assuming the misnomer of a "middle hepatic" artery in older works. Separate origins of segment IVa, usually from the LHA, and segment IVb from the RHA are frequently identified. Also, a branch from the segment IV artery is often seen extending outside of the liver, supplying the falciform ligament. Recognition of this vessel is important

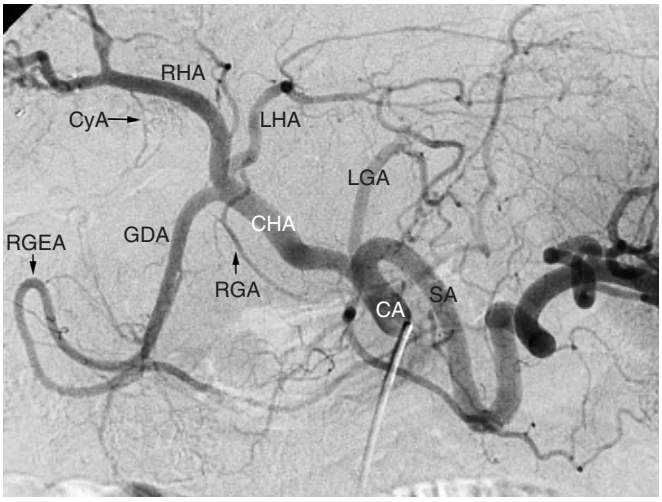

FIGURE 19.1. Conventional celiac artery anatomy. CA, celiac axis; LGA, left gastric artery; SA, splenic artery; CHA, common hepatic artery; GDA, gastroduodenal artery; RGA, right gastric artery; RHA, right hepatic artery; LHA, left hepatic artery; CyA, cystic artery; RGEA, right gastroepiploic artery.

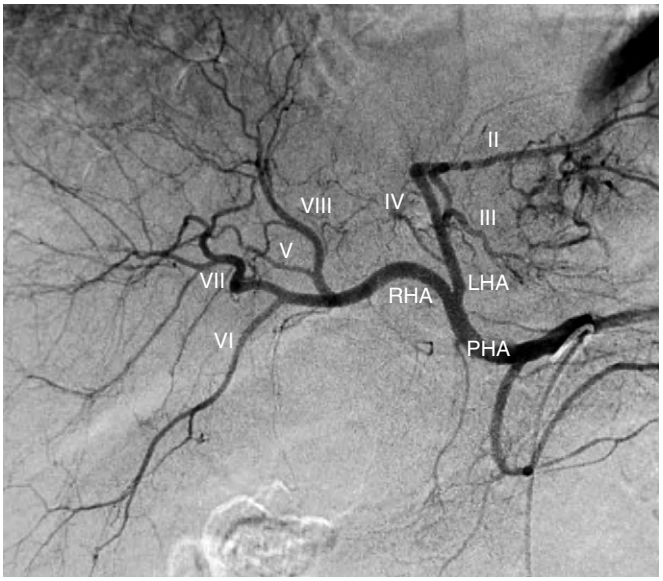

FIGURE 19.2. Arterial anatomy of the liver. PHA, proper hepatic artery; RHA, right hepatic artery; LHA, left hepatic artery. Additional vessels are labeled in accordance to the Couinaud segment they supply.

when conducting chemoembolization or radioembolization to avoid nontarget embolization.

The RHA conventionally divides into an anterior (ventral) and posterior (dorsal) branch. The anterior branch usually is more vertically oriented and supplies segments V and VIII. The posterior branch is usually more horizontally oriented and supplies segments VI and VII. More than one projection is usually required to ascertain with certainty which is the anterior branch and which is the posterior branch. In the right anterior oblique projection, the anterior branch moves medially and the posterior branch moves laterally when compared with the postero-anterior (PA) projection. The entire segmental arterial supply to the liver should be accounted for prior to hepatic arterial therapy, major hepatic resection, partial hepatectomy, or living-donor liver transplantation (LDLT, see Chapter 98B).

The arterial supply to the pancreas is somewhat variable. The most consistent supply is to the pancreatic head, afforded by an arcade formed by the inferior pancreaticoduodenal (IPD) branch of the SMA to the anterior superior and posterior superior pancreaticoduodenal branches of the GDA (Fig. 19.3). The transverse pancreatic artery runs along the middle portion of the long axis of the pancreas and may take origin from the arterial arcade in the head of the pancreas, directly from the GDA, or as a branch of the dorsal pancreatic artery, which variably originates from the common HA or SA (Fig. 19.4). A number of small branches from the SA supply the pancreatic body and tail, but the number and location of these arteries vary and must be identified in each individual patient when clinically relevant.

Preoperative Angiography: Historical Perspective

Prior to the advent of multidetector computed tomography angiography (MDCTA), visceral angiography was performed to assess the resectability of pancreatic and biliary tract tumors by demonstrating the presence or absence of vascular invasion. The sensitivity of catheter angiography for this purpose was low, and MDCTA has replaced catheter angiography for this indication. Using angiography for diagnosis of a hepatic mass, such as differentiating a cavernous hemangioma from a hepatocellular carcinoma, is no longer performed, as no improvement in diagnostic accuracy can be achieved over conventional cross-sectional imaging techniques (see Chapters 16 and 17).

Preoperative arterial mapping of the arterial anatomy of the liver also was routinely performed in some centers prior to major hepatic resections. This procedure has also been replaced by MDCTA and is no longer performed routinely. On rare occasion, there is a specific piece of critical anatomic information that cannot be ascertained with certainty by MDCTA, such as the origin and course of the artery to segment IV prior to a living-donor partial hepatectomy. In this circumstance, catheter angiography can be useful to answer the question.

On extremely rare occasions, large tumors are identified on cross-sectional imaging, but the organ of origin cannot be determined. The majority of these are large sarcomas of the retroperitoneum, but excluding a pancreatic source may be difficult. A similar situation can occur with large right adrenal or renal tumors blending with the hepatic parenchyma. In these highly selected cases, catheter angiography can be useful in delineating the organ of origin by demonstrating the primary arterial supply.

Arteriography in Conjunction with Arterial Interventions

By far the most common use of arteriography is planning an arterial-based intervention such as chemoembolization, radioembolization, or chemoperfusion to treat a primary or metastatic hepatic malignancy. These specific interventions will be discussed elsewhere in this book, and a detailed description will not be repeated here. However, some points deserve emphasis.

Accurate delineation of arterial anatomy has increased in importance remarkably as radioembolization (see Chapter 84A) and chemoembolization (see Chapter 83) have gained widespread application. The inadvertent administration of radiation or chemotherapeutic agents into arteries supplying the stomach or duodenum can lead to significant adverse outcomes. When performing procedures designed to necrose tumor, it is imperative that normal structures be spared. To accomplish

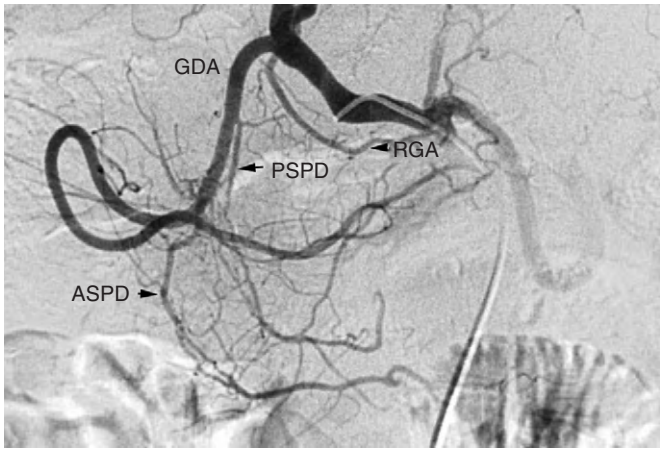

FIGURE 19.3. Arterial anatomy of the pancreas. GDA, gastroduodenal artery; PSPD, posterior-superior pancreaticoduodenal artery; ASPD, anterior-superior pancreaticoduodenal artery; RGA, right gastric artery.

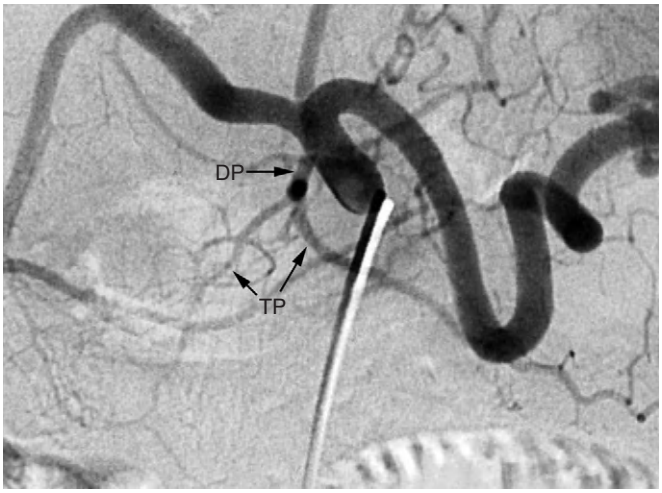

FIGURE 19.4. Arterial anatomy of the pancreas. DP, dorsal pancreatic artery; TP, transverse pancreatic artery.

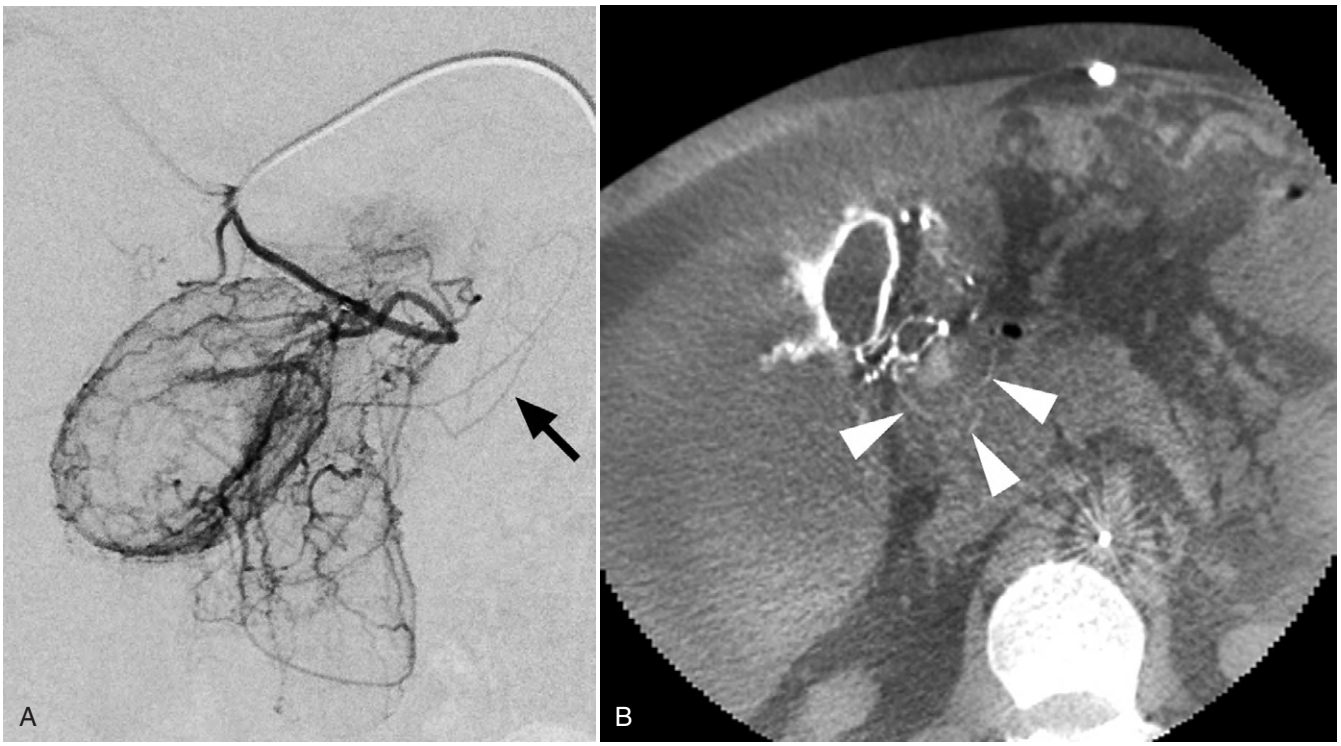

FIGURE 19.5. Extrahepatic perfusion detected with C-arm computed tomography (CCT). **A,** Selective cystic arteriogram shows the gallbladder and several branches extending medially (*arrow*). **B,** CCT performed during contrast injection of the cystic artery confirms aberrant perfusion of the duodenum (*arrowheads*). *(Courtesy Daniel Sze, Stanford University.)*

this, variant anatomy must be recognized. The importance of accessory branches to the duodenum, including the supraduodenal and retroduodenal arteries, is now well known. Communications from intrahepatic branches to the lower esophagus, stomach, and diaphragm are of equal importance (Miyayama et al, 2009; Liu et al, 2005).

With current angiographic technology, it is possible to obtain a volumetric digital image during the arterial injection of contrast media and to display the images in a computerized tomographic format (i.e., C-arm CT) (Wallace et al, 2008). Using this technique it is possible to identify extrahepatic perfusion from aberrant hepatic arterial branches that may be unrecognized on the basis of the angiogram alone (Fig. 19.5).

Hemorrhage

Bleeding from the liver, pancreas, or spleen is most often secondary to iatrogenic or noniatrogenic trauma, but it may occur spontaneously in patients with mycotic aneurysms or pancreatitis. Angiography is usually not used to ascertain whether arterial hemorrhage is present but rather to precisely localize and treat the offending vessel. Embolization of arterial bleeding will be discussed elsewhere in this book, but salient features will be reviewed in this chapter.

Splenic Bleeding

The most common cause of bleeding from the spleen is blunt trauma, and nonoperative management is currently the standard of practice. SA embolization has been established as a method to increase the success rate of nonoperative management of traumatic splenic injuries (Dent et al, 2004). A comparative study between two cohorts consisting of 625 patients over a 15-year period revealed an improved success rate of nonoperative management from 77% to 96% with the advent of splenic embolization (Rajani et al, 2006). The indications for splenic arteriography and splenic arterial embolization are based upon CT findings and include active contrast extravasation, splenic vascular injuries, and significant hemoperitoneum. Moreover, the American Association for the Surgery of Trauma recommends angiography for grade III, IV, and V splenic injuries (Raikhlin et al, 2008).

Two techniques are used to perform splenic embolization: the first is occlusion of the proximal splenic artery with coils or Amplatzer plugs (AGA Medical, Plymouth, MN), and the second is selective small intrasplenic arterial embolization with a gelatin sponge or coils. Collaterals through the short gastric arteries and the gastroepiploic arcade usually maintain splenic viability following occlusion of the proximal splenic artery. Intrasplenic embolization generally results in a variable degree of splenic infarction, depending upon the size of the artery occluded, as intrasplenic arteries have no significant collateral routes. Both techniques are associated with a risk of complications. Minor complications including fever, pleural effusion, and partial splenic infarction have been reported in up to 62% of patients. Major complications including total splenic infarction, splenic atrophy, and postprocedure bleeding have been observed in 28.5% of patients (Wu et al, 2008).

Hepatic Bleeding

Hemorrhage from the liver may be encountered from blunt or penetrating trauma (see Chapter 102) but is most commonly due to an iatrogenic injury related to a biopsy (see Chapter 20)

or percutaneous transhepatic biliary drainage (PTBD; see Chapters 18 and 28). Arteriographic findings indicating a source of hemorrhage include extravasation, pseudoaneurysm formation, and/or arteriovenous fistula (see Chapter 104). Superselective catheterization using coaxial microcatheters to deposit coil-spring emboli both distal and proximal to the area of injury is the preferred technique for embolization when a discrete bleeding site can be identified. In contrast to the spleen, a rich collateral network exists in the hepatic arterial bed, making proximal occlusion of the offending artery ineffective in many cases. For more diffuse injuries with multiple bleeding sites secondary to blunt trauma, using particulate embolization with a gelatin sponge may be a useful adjunct.

As with blunt splenic injuries, nonoperative management has become the preferred method of management in hemodynamically stable patients, with a success rate exceeding 90% (Christmas et al, 2005). In the setting of blunt trauma, hepatic arteriography may also be indicated following surgical exploration and packing of a hepatic parenchymal injury with evidence of continued bleeding or hemodynamic instability. Even patients who present with hemodynamic instability who can be successfully resuscitated can be treated effectively with transcatheter embolization (Misselbeck et al, 2009). The yield of arteriography in identifying an arterial injury amenable to embolization is higher when the CT scan suggests a vascular injury.

Complications following embolization of a hepatic arterial injury secondary to blunt trauma are relatively frequent. These complications include hepatic ischemia, infarction, decompensation of hepatic function, gallbladder ischemia, bile leak, and abscess formation. Obviously, the contribution of the embolization to these complications may be difficult to distinguish from sequelae of the underlying traumatic injury.

Iatrogenic injury to the HA is suspected when a biliary drainage tube puts out blood following placement, or the patient develops melena secondary to hemobilia following an intervention through the hepatic parenchyma. CT in these patients may or may not reveal an abnormality, and patients should undergo hepatic arteriography when a clinical suspicion of a hepatic arterial injury exists. Patients with iatrogenic injuries usually have a single, discrete bleeding source that can be addressed with superselective embolization techniques. Complications related to the embolization procedure tend to be lower when compared with patients who have had blunt trauma, as the traumatic injury to the liver is less extensive.

Pancreas

Bleeding from the pancreas is not common following trauma (see Chapter 103). Bleeding is more commonly encountered in patients with pancreatitis (see Chapter 54) or pancreatic surgery (see Chapter 62). Hemorrhage can occur in the retroperitoneum, or it may extend from the retroperitoneum into the peritoneal cavity or into the gastrointestinal tract via communication with the pancreatic duct (hemosuccus pancreaticus). Hemorrhage complicating acute or chronic pancreatitis is usually arterial in origin. Although this complication is encountered in only 2% to 5% of cases, it may be life threatening. Proteolytic enzymes coupled with intense inflammation can erode small arterial branches and create foci of extravasation or create small pseudoaneurysms. Pseudocysts may erode small arterial branches, leading to hemorrhage within the pseudocyst, or it may erode into larger arterial branches and create a large pseudoaneurysm (Fig. 19.6). These pseudoaneurysms are most frequently identified in the splenic artery or its branches (60% to 65%), followed by the GDA (20% to 25%), pancreaticoduodenal arteries (10% to 15%), HA (5% to 10%), and left gastric artery (2% to 5%) (Kirby et al, 2008).

MDCT has been reported to have 90% sensitivity in detecting pseudoaneurysms in patients with acute pancreatitis, however, tiny aneurysms in the intrapancreatic arteries may not be visible (Hyare et al, 2006). When a patient has clinical evidence of significant hemorrhage, or a CT scan reveals a pseudoaneurysm, arteriography followed by embolization is indicated. When the bleeding site is identified angiographically, it can be controlled with embolotherapy in up to 88% of patients (Mansueto et al, 2007).

In the patient who has bleeding following pancreatic surgery, angiography and embolization may also be useful. Significant hemorrhage was noted in 5.7% of 1669 consecutive patients following partial or total pancreatectomy (Yekebas et al, 2007). Bleeding may manifest clinically as gastrointestinal hemorrhage, retroperitoneal or intraperitoneal bleeding, or bleeding through percutaneous or surgically placed drains. When a pancreaticojejunal anastomosis has been created, disruption of the anastomosis may lead to false localization of the bleeding site. Specifically, an extraluminal bleeding site may drain into the bowel through the dehisced anastomosis, or bleeding from the bowel at the anastomosis may extend outside the lumen to cause an intraperitoneal hematoma or hemorrhage through a drain.

Angiography can be extremely useful in the diagnosis and treatment of these patients. In 25 of 43 patients undergoing angiography to diagnose and treat postpancreatectomy hemorrhage, a bleeding site was located and embolized with an 80% success rate in controlling the hemorrhage (Yekebas et al, 2007). The relatively low rate of positive angiograms may be explained by the high incidence of venous bleeding encountered in the postpancreatectomy patient. Many of these patients develop regional portal hypertension as a result of splenic or superior mesenteric venous compression or occlusion secondary either to the underlying pathology or a surgical complication. Venous extravasation is rarely identified by arteriography but may be suggested by CT. If the underlying etiology is compression of the splenic vein (SV), percutaneous transhepatic stenting of the SV may be potentially useful.

Primary Arterial Disorders

Arterial Occlusive Disease

Many arterial disorders that involve the primary branches of the celiac trunk, as well as the SMA, can be assessed adequately with MDCT or MRA. However, delineation of pathology in smaller branches, such as with vasculitis, or subtle pathologic changes may require the increased morphologic detail afforded by catheter angiography.

Arterial occlusive disease as a result of atherosclerosis and compression of the celiac axis by a median arcuate ligament are common diseases that do not generally influence the conduct of hepatobiliary or pancreatic surgery. The principle exception is in the performance of orthotopic liver transplantation (OLT), when preservation of brisk hepatic arterial flow is essential. In that circumstance, the inflow must be corrected either by surgical or endovascular interventions. Another potential area of concern is pancreaticoduodenectomy, particularly in jaundiced patients. In this situation, sacrifice of the GDA is required, which interrupts the retrograde arterial flow from the SMA to

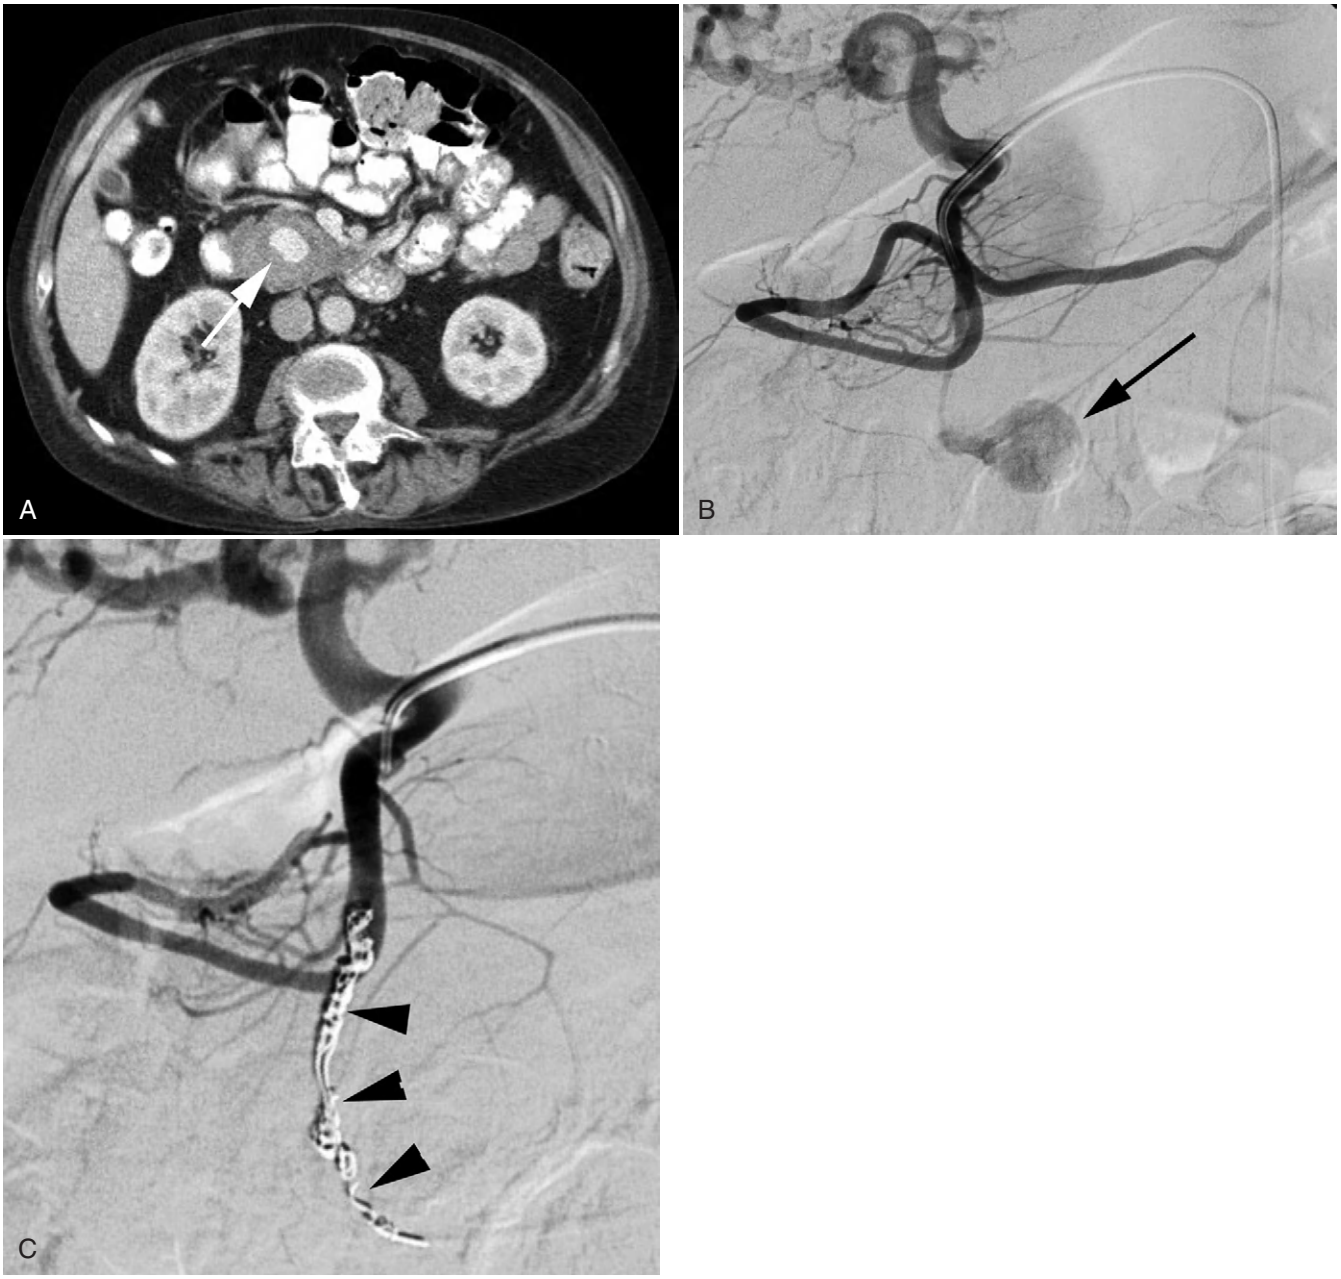

FIGURE 19.6. Pseudoaneurysm secondary to pancreatitis treated with coil embolization. **A,** Contrast-enhanced computed tomography reveals a pseudoaneurysm in the pancreatic head (*arrow*). **B,** Selective gastroduodenal arteriogram reveals the pseudoaneurysm (*arrow*) taking origin from a branch of the anterior superior pancreaticoduodenal artery. **C,** The pseudoaneurysm is occluded with coils (*arrowheads*).

the liver and could result in hepatic ischemia and necrosis. Likewise, fibromuscular dysplasia may rarely involve the SMA, but associated clinical sequelae are extremely uncommon. The SMA may also be compromised in very rare circumstances by a median arcuate ligament.

Visceral Artery Aneurysms

Aneurysms of the celiac, splenic, and hepatic arteries, and less commonly the SMA, have clinical relevance (see Chapter 104). True aneurysms are usually atherosclerotic or developmental in origin and differ from those encountered in pancreatic inflammatory disease, which are typically pseudoaneurysms. Splenic artery aneurysms in women of childbearing age are of particular concern because of their propensity to rupture during childbirth. This clinical circumstance is associated with a 75% mortality rate (Grotemeyer et al, 2009).

Aneurysms of the pancreaticoduodenal arcade are also associated with stenosis of the celiac axis, most commonly secondary to median arcuate ligament compression. In this situation, the increased flow and altered rheologic dynamics through the inferior pancreaticoduodenal arcade likely lead to aneurysm formation (Sugiyama et al, 2007).

Traditionally, visceral artery aneurysms have been managed with a variety of surgical options. More recently, endovascular

therapy using stent grafts has been successful (Rossi et al, 2008). For aneurysms located in nonessential vascular beds—such as the gastroduodenal, pancreaticoduodenal, and proximal splenic arteries—deployment of coil spring emboli in the artery proximal and distal to the aneurysm origin has been successful. Using this technique, a 72% success rate in managing 22 patients with visceral artery aneurysms was recently reported (Ikeda et al, 2008).

Segmental Arterial Mediolysis

A rare vascular disorder, segmental arterial mediolysis (SAM), may also require catheter angiography for definitive diagnosis. This disorder is characterized pathologically by noninflammatory destruction of smooth muscle cytoplasm, leading to arterial dissection and aneurysm formation. Multifocal lesions with skip areas involving the superior mesenteric, hepatic, renal, and middle colic arteries in patients in their fourth to sixth decades are typical (Fig. 19.7). Clinically these lesions are prone to both occlusion by dissection as well as rupture, leading to catastrophic abdominal hemorrhage. Treatment with coil embolization within noncritical arterial beds has been reported (Davran et al, 2009).

Vasculitis

Vasculitides involving the hepatic arterial system may require the spatial resolution provided by catheter angiography for definitive diagnosis, as the characteristic microaneurysms and areas of arterial narrowing may not be apparent by MDCT. The most common vasculitis with hepatic involvement is polyarteritis nodosa, which may not lead to symptoms despite involvement of the visceral arteries, although pancreatitis, cholecystitis, and hepatic dysfunction may be observed.

Arterial abnormalities in the liver have also been identified in patients with systemic lupus erythematosus and Wegener granulomatosus. In most patients, the underlying diagnosis is apparent, and the angiographic findings do not represent a diagnostic dilemma.

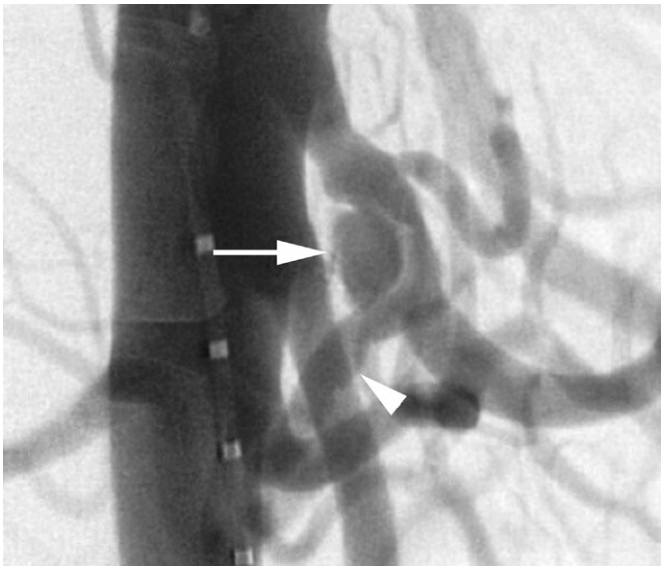

FIGURE 19.7. Segmental arterial mediolysis (SAM). Abdominal aortogram reveals a dissection with a small aneurysm in the celiac artery (*arrow*) as well as undulating irregularity of the common hepatic artery (*arrowhead*) typical of SAM.

Hereditary Hemorrhagic Telangiectasia

An additional condition in which diagnostic arteriography can be a useful adjunct to cross-sectional imaging is hereditary hemorrhagic telangiectasia (HHT). This disorder, also known as *Osler-Weber-Rendu syndrome,* is hereditary; it is transmitted as an autosomal dominant trait, characterized by telangiectasias of the skin and mucous membranes. HHT is also associated with arteriovenous malformations in the pulmonary and hepatic circulation that potentially pose a threat to life. The diagnosis can usually be established on the basis of the family history coupled with abnormalities visible on cross-sectional imaging. However, because of the variability in severity of clinical manifestations, individuals may be unaware that the condition exists in their family. The hepatic arterial malformations that shunt blood into the hepatic venous system may be initially noted on a cross-sectional imaging study, but the findings may be nonspecific. Catheter angiography can be diagnostic by depicting the malformations shunting hepatic arterial blood into the hepatic venous system (Fig. 19.8). Although this disorder has been treated with transcatheter techniques, embolotherapy has currently fallen out of vogue because of the risk of precipitating hepatic failure. OLT is curative if the patient develops high-output cardiac failure.

Peliosis Hepatis

Peliosis is an abnormality of the reticuloendothelia system that is most commonly encountered in the liver (peliosis hepatis). Pathologically it is characterized by blood-filled cystic spaces that range in size from a few millimeters to almost a centimeter. This abnormality has been associated with HIV infection as well as with the use of certain drugs including immunosuppressives, antimetabolites, and oral contraceptives. Although usually benign, it has been associated with spontaneous massive hemorrhage (Choi et al, 2009) and therefore may be encountered angiographically during the investigation of hepatic bleeding. Angiographically (Fig. 19.9) the lesions are easily visible as a disorganized collection of amorphous channels not dissimilar to those observed in HHT or hemangioma; however, the lack of shunting to the hepatic venous system distinguishes it from HHT, and the absence of sharp definition with persistence into the late venous phase distinguishes it from hemangioma.

Arterial Anastomotic Stenoses

Hepatic arterial anastomotic stenoses are observed in up to 12% of patients following OLT (Bechstein et al, 1987; see Chapter 98). Although these stenoses are usually detected by surveillance duplex ultrasound and confirmed with MDCTA, catheter angiography is often performed to improve morphologic delineation and assess the degree of stenosis in preparation for endovascular treatment. Stenosis of the HA anastomosis usually leads to allograft dysfunction, and stenoses of the HA may also be more diffuse (Fig. 19.10). Severe stenosis may lead to hepatic artery thrombosis (HAT). The HA supplies the bile duct, and the bile duct has been rendered devoid of collateral arterial supply during donor hepatectomy. Arterial insufficiency typically leads to biliary strictures and to potentially diffuse biliary ductal infarction. HA thrombosis may lead to irretrievable allograft damage and may necessitate retransplantation. When a hepatic arterial stenosis is identified prior to advanced biliary injury, endovascular therapy with either balloon angioplasty and/or stent placement is warranted.

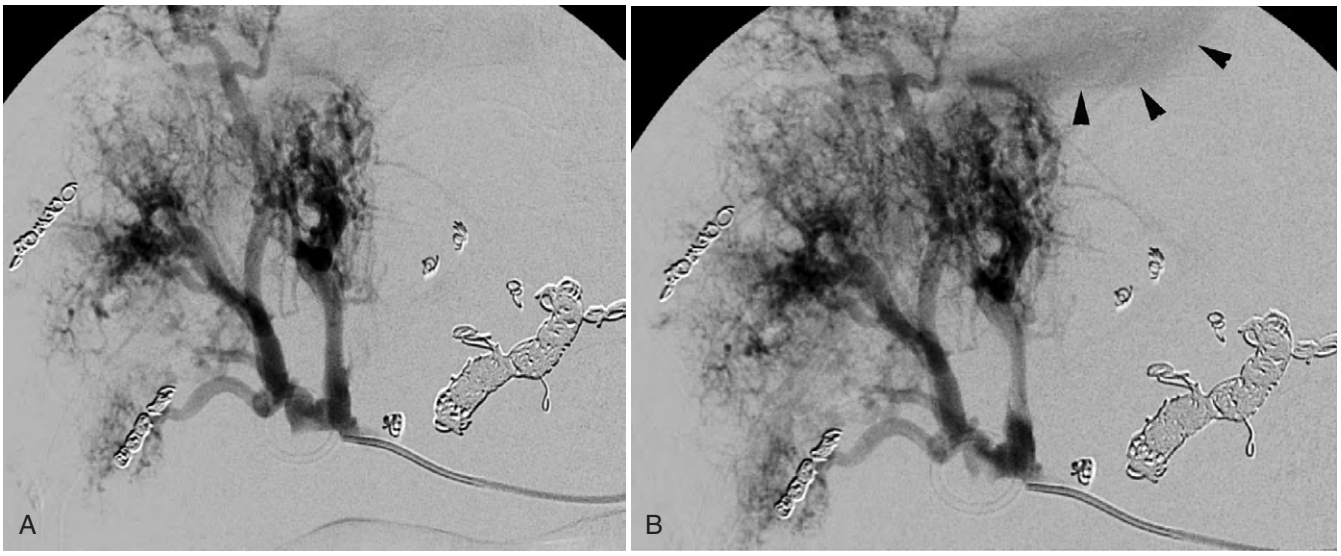

FIGURE 19.8. Hereditary hemorrhagic telangiectasia (HHT). **A,** Selective hepatic arteriogram shows disorganized and dilated intrahepatic vessels typical of HHT. Coils are being placed preoperatively for impending liver transplantation. **B,** Slightly later in the sequence, early opacification of the hepatic vein is visible (*arrowheads*).

Localization of Functioning Pancreatic Neuroendocrine Tumors

Insulinomas

Insulinomas are the most common tumors originating from the islets of Langerhans (see Chapter 61). Because these tumors are usually 2 cm in diameter or smaller, they may not be detected by noninvasive imaging techniques. In a series of 75 surgically proven insulinomas, the sensitivities of CT and MRI were 28% and 35%, respectively (Guettier et al, 2009). This series incorporated cross-sectional imaging dating back to the late 1980s that likely reduced the overall sensitivity. When cross-sectional imaging techniques were examined after 1994, the sensitivity of CT and MRI improved to 80% and 70%, respectively, owing to improved imaging technology (Nikfarjam et al, 2008). Moreover, endoscopic ultrasound (EUS; see Chapter 14) has been used to localize insulinomas with a reported sensitivity ranging from 82% to 94%, making this technique a valuable adjunct

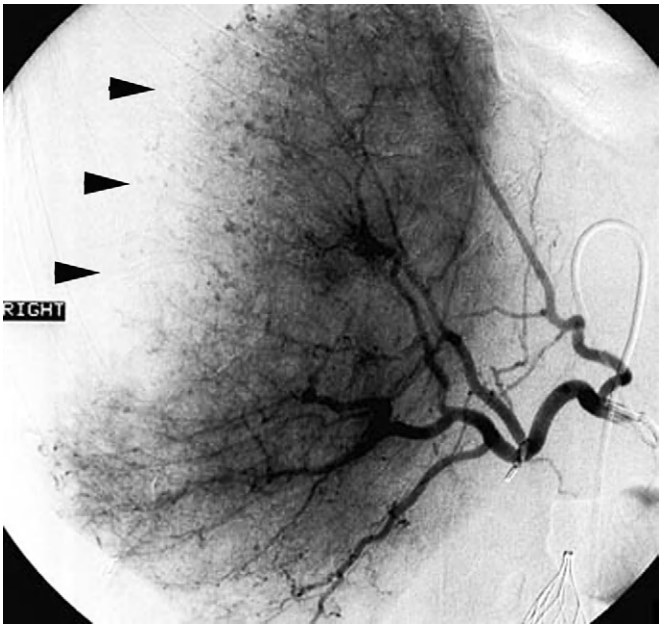

FIGURE 19.9. Peliosis hepatitis. Multiple small contrast collections can be seen within the hepatic parenchyma. This patient had spontaneous hemorrhage that created displacement of the hepatic parenchyma (*arrowheads*).

FIGURE 19.10. Hepatic artery stenosis following orthotopic liver transplantation. Celiac arteriogram shows mild diffuse narrowing of the hepatic artery with two areas of critical stenosis (*arrowheads*).

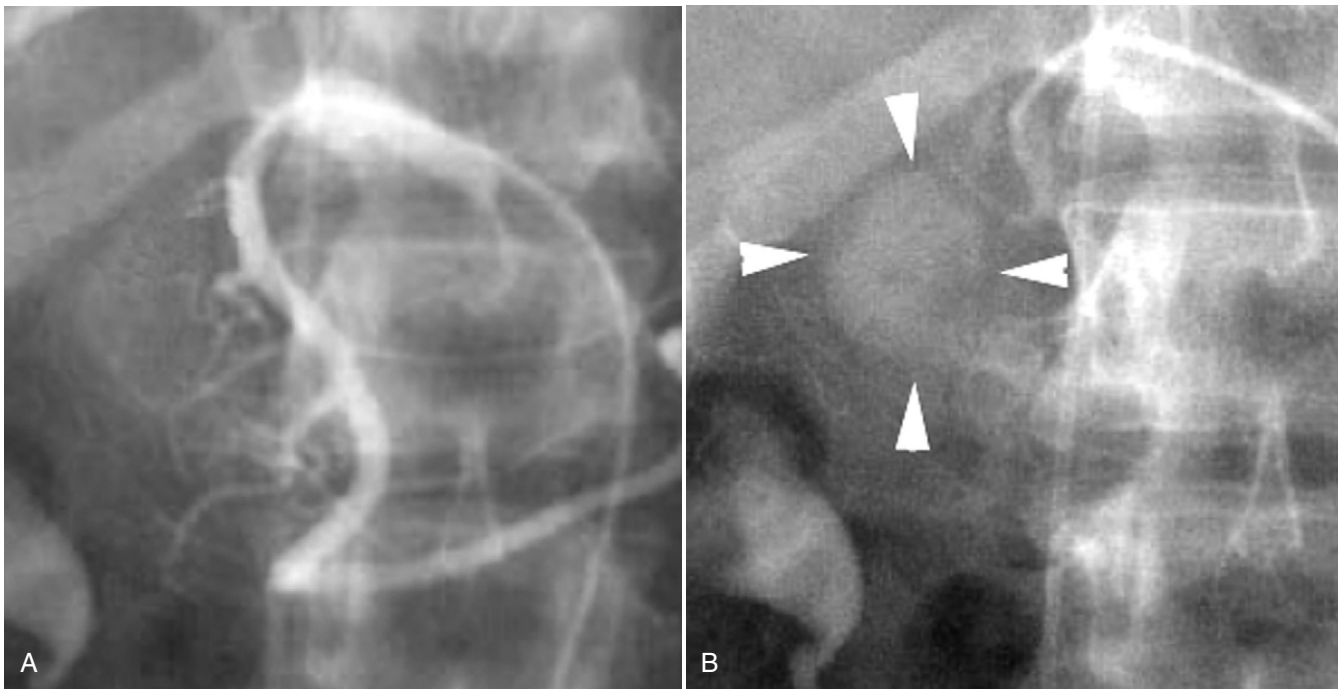

FIGURE 19.11. Insulinoma. **A,** Selective gastroduodenal arteriogram shows no definite abnormality during the arterial phase. **B,** A subtle area of hypervascularity is identified during the capillary phase, possibly representing an insulinoma (*arrowheads*). This was confirmed as the region of tumor by calcium stimulation with venous sampling.

in the management of these patients (McLean, 2004). EUS requires considerable expertise, is not available at all centers, and has reduced sensitivity for lesions in the tail of the pancreas, ranging from 50% to 60% (McLean, 2004).

Calcium stimulation arteriography was developed and described in 1991 (Doppman et al, 1991). Although unnecessary when imaging can confidently detect the offending pancreatic lesion, it is an extremely useful adjunct when the location of the lesion cannot be defined with confidence (Fig. 19.11). When 1 mL of 10% calcium gluconate is injected into an artery supplying the pancreas, tumor cells degranulate and release insulin into the portal venous circulation. Sequential blood samples obtained from the hepatic vein will demonstrate a significant rise in the concentration of insulin when the portion of the pancreas containing the tumor is injected. By sequentially injecting the arterial supplies to different regions of the pancreas, it is possible to ascertain the location of the tumor. The GDA supplies the head of the pancreas, the SMA supplies the head and uncinate process, and the SA supplies the body and tail. The origin of small branches supplying the pancreas from the SA and common HA are important to note in determining the approximate areas of pancreatic arterial supply. In the aforementioned article by Guettier and colleagues (2009), calcium stimulation arteriography was the most sensitive technique for localizing surgically proven insulinomas with an accuracy of 84%, a false-negative rate of 11%, and a false-positive rate of 4%.

Gastrinomas

Gastrin-secreting tumors are associated with Zollinger-Ellison syndrome. These tumors occur in association with multiple endocrine neoplasia (MEN) type 1 in about one third of cases, with the remainder being of the sporadic type. Fifty percent of gastrinomas occur in the pancreas, with the duodenum being the most common extrapancreatic location; about 60% to 90% of gastrinomas are malignant. When a sporadic gastrinoma is identified, surgical resection is indicated. The role of surgery in patients with MEN type 1 is more controversial because of multiplicity of tumors and lack of an established survival benefit.

The diagnosis and location of a gastrinoma can be established with a combination of somatostatin receptor scintigraphy and EUS in approximately 90% of patients. When an occult gastrinoma is encountered, angiography has been used for localization. The principles are identical to the localization of insulinomas; however, secretin has been used in addition to calcium gluconate as the stimulating agent. Sensitivities of arterial stimulation venous sampling (ASVS) in the detection of gastrinomas have ranged from 70% to 100% (Cohen et al, 1997; Turner et al, 2002).

Angiographically, gastrinomas are less hypervascular and more difficult to detect in comparison to insulinomas. Sensitivity of angiography alone without ASVS is less than 50%. Moreover, the 50% extrapancreatic location makes detection more difficult, often requiring superselective catheterization to evaluate the duodenum.

Glucagonoma

Glucagonomas may also occur sporadically, or they may be associated with MEN type 1. These tumors are usually larger than gastrinomas or insulinomas at presentation, therefore localization can generally be achieved with noninvasive imaging or EUS. A single case of successfully using ASVS with calcium gluconate as the stimulating agent to localize an occult glucagonoma has been reported (Okauchi et al, 2009).

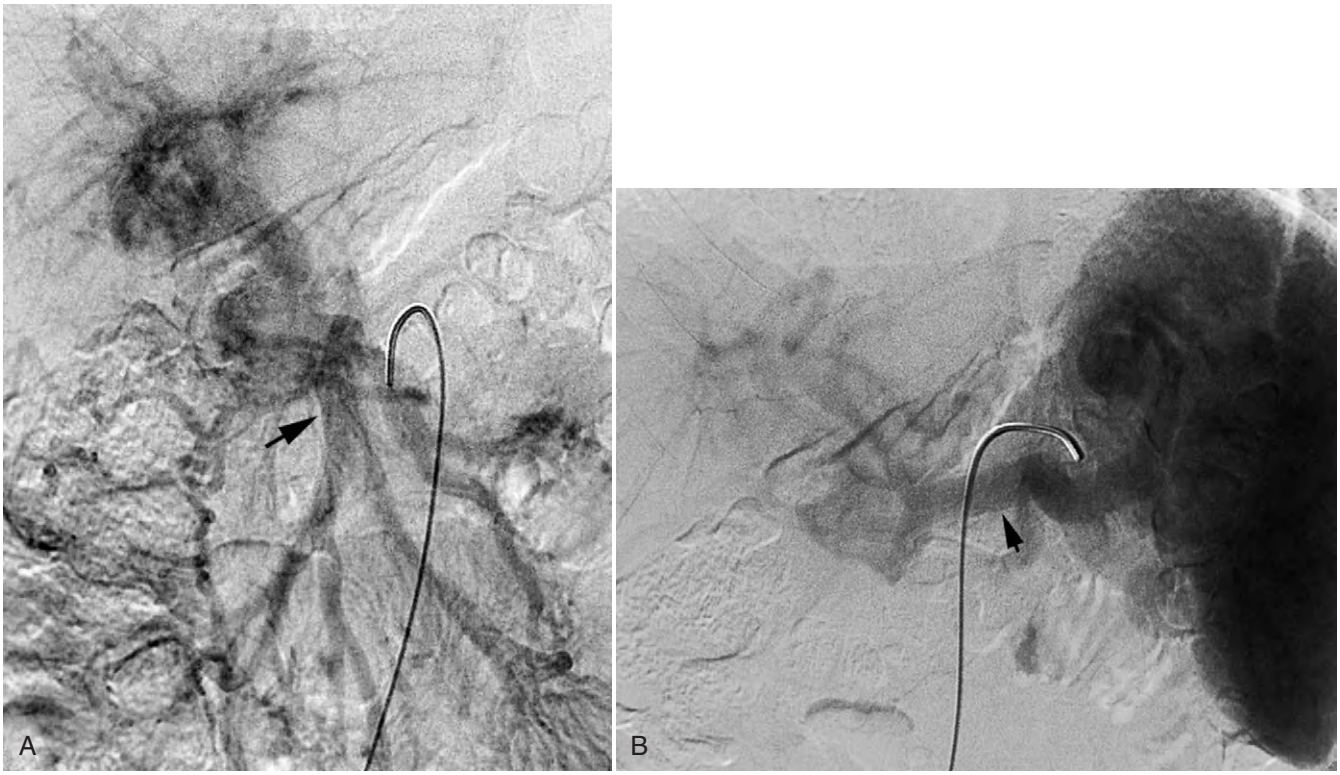

FIGURE 19.12. Arterial portography in a patient with cavernous transformation of the main portal vein. **A,** Venous phase of superior mesenteric arterial injection shows the superior mesenteric vein (*arrow*) and cavernous transformation of the main portal vein. **B,** Venous phase of splenic arterial injection from the same patient shows the splenic vein (*arrow*).

VEINS

Venographic Technique

MDCT, magnetic resonance venography, and ultrasound are usually sufficient for depiction of the major visceral venous trunks and their primary branches in the vast majority of patients. Cross-sectional imaging can accurately depict the relationship of a mass in the pancreas to both the splenic and superior mesenteric veins. It also has the advantage of simultaneous opacification of all of the venous structures. However, in certain clinical situations, it is desirable to visualize the venous structures with a higher level of clarity. These situations include planning of percutaneous venous intervention in situations where occlusions are suspected or occasionally to plan a surgical portosystemic shunt.

The most common technique to visualize the splanchnic vein is transarterial portography, in which selective splenic and superior mesenteric arteriograms are performed with delayed imaging into the venous phase, depicting the splenic and superior mesenteric veins, respectively (Fig. 19.12). When detailed visualization of the venous anatomy is required, a higher dose of contrast media can be used for the arterial injection, increasing the clarity of the venous opacification.

When an extremely detailed evaluation is required, a combination of transarterial portography during MDCT can be performed (Fig. 19.13). The increased contrast sensitivity of the MDCT coupled with multiplanar and three-dimensional reconstruction allows visualization of the veins

FIGURE 19.13. MDCT with three-dimensional reconstruction following superior mesenteric arterial injection. The superior mesenteric vein and cavernous transformation are easily visualized.

that cannot be achieved by any other single technique. This is particularly useful in the presence of portal vein (PV) occlusion, when a complex venous reconstruction or bypass is being considered.

Direct venography of the splanchnic veins can be achieved by three routes: *transjugular, transhepatic,* and *transsplenic*. In the transjugular approach, a catheter is placed into the jugular vein and manipulated into a hepatic vein. Obtaining pressure measurements through this catheter in both the free and wedged position will yield the corrected sinusoidal pressure in patients being assessed for portal hypertension. A biopsy of the hepatic parenchyma (transjugular liver biopsy) may be performed when desirable. Injection of carbon dioxide through a catheter wedged in a hepatic vein or through a balloon catheter will often yield an image of the PV. If direct portography is warranted, one of several specially designed needles can be inserted to puncture the PV through the intervening hepatic parenchyma and through catheters advanced into the portal, splenic, or superior mesenteric venous system. This procedure is performed almost exclusively in patients undergoing a transjugular intrahepatic portosystemic shunt (TIPS), but it is also used to manage selected patients with portal and superior mesenteric vein (SMV) thrombosis (Liu et al, 2009; see Chapter 76E).

The portal venous system may also be accessed by a percutaneous transhepatic approach (Semiz-Oysu et al, 2007). After sterile preparation of the right upper quadrant, an intrahepatic portal venous radicle is punctured under real-time ultrasonographic guidance, permitting a vascular access sheath to be placed using a Seldinger technique. Standard guidewire and catheter manipulations are then used through the sheath for selectively catheterizing the SV and the SMV or its branches. Once the diagnostic images have been taken or venous interventions have been performed, the catheter is removed. The transhepatic tract is then occluded by a variety of techniques including insertion of Gelfoam pledgets, deployment of coils, or injection of fibrin glue. The transhepatic venographic procedure is usually performed as part of a direct pancreatic venous sampling, lobar portal venous embolization to stimulate contralateral hypertrophy prior to major hepatic resection, assessment and management of an anastomotic portal venous stenosis following OLT, pharmacomechanical lysis of a splanchnic vein thrombosis, or rarely to control bleeding from a splanchnic vein.

Percutaneous injection of the splenic parenchyma can also be used to delineate the anatomy of the splenic and portal veins as well as the draining tributaries. This examination is somewhat antiquated and has been generally replaced by MDCT or magnetic resonance venography. In infants, cross-sectional imaging may be inconclusive, and transarterial portography is risky because of the diminutive size of the femoral arteries; however, it remains an alternative in planning a portosystemic shunt procedure.

Percutaneous catheterization of the splanchnic veins is also possible from a transsplenic approach using a technique identical to that described for transhepatic catheterization (Tuite et al, 2007). This procedure is usually done in conjunction with a percutaneous procedure to assess a PV stenosis or occlusion following OLT, but it may also be used in conjunction with the assessment and treatment of a splenorenal venous bypass, when access cannot be achieved from the systemic venous circulation.

Visceral Venographic Anatomy

The SV and SMV join to form the main PV (see Chapter 1B). The inferior mesenteric vein (IMV) usually enters the SV adjacent to the confluence, but it may also enter the SMV either at or just caudal to the confluence. The coronary vein most often drains into the cephalic aspect of the main PV just beyond the confluence of the SMV and SV. The number and location of veins draining the pancreas is variable. Multiple small, unnamed veins drain directly into the SV. Typically the anterior-superior pancreaticoduodenal vein drains directly into the PV, and the posterior-superior pancreaticoduodenal vein drains into the SMV. The inferior pancreaticoduodenal veins drain into the SMV at the caudal margin of the pancreas, and the PV courses obliquely cephalad from near the midline toward the liver, where it divides to supply the right and left lobes. This division, as well as the division into segmental branches, is variable and must be delineated when clinically relevant for each individual patient.

Selective Venous Sampling

Percutaneous transhepatic sampling of the splenic, superior, and portal venous system can be performed to diagnose occult neuroendocrine tumors of the pancreas. This may be done in conjunction with calcium stimulation as previously described, or it may be performed without stimulation because of the higher concentration of the hormone when obtained directly or adjacent to the venous tributary.

Preoperative Planning for Portal Decompression

The majority of portal decompression procedures, whether surgical or percutaneous, can be planned on the basis of venous

FIGURE 19.14. Transhepatic venogram evaluating a Rex shunt. Surgically placed autologous vein conduit (*arrowheads*) extends from superior mesenteric vein (*SMV*) to the left portal vein. A stenosis (*arrow*) is visible within the shunt that has led to portal hypertension with filling of the coronary vein (*CV*).

phase MDCT. The positions of the SMV, SV, PV, left renal vein, and inferior vena cava are well shown by either MDCT or MR. However, particularly in the case of extrahepatic portal venous obstruction, higher definition of the venous anatomy may be required by the surgeon or interventionalist. As previously discussed, transarterial portography coupled with MDCT during arterial injection can be invaluable in delineating the morphology of the splanchnic venous system.

An alternative procedure to portosystemic shunting in selected patients with symptomatic portal hypertension secondary to extrahepatic portal venous obstruction is the Rex shunt (Vanderlan et al, 2009). This procedure involves a venous bypass from the superior mesenteric vein to the umbilical segment of the left PV, the latter being accessed through the fossa of Rex (Fig. 19.14). When successful, this type of bypass avoids the complication of encephalopathy, as all of the splanchnic blood drains through the liver. Careful preoperative imaging is needed prior to this procedure to confirm the patency and demonstrate the size of the umbilical segment of the left PV. Arterial portography coupled with MDCT is ideal for this indication. When insufficient, direct transhepatic portography may be necessary.

CHAPTER 20

Percutaneous biopsy

Anne M. Covey and Lynn A. Brody

BIOPSY OVERVIEW

Image-guided needle biopsy is the mainstay for diagnosis of nonpalpable masses almost anywhere in the body. The indications for biopsy continue to evolve, and although percutaneous biopsy of a given mass is possible, it may not be indicated (Thompson et al, 1985). As with any invasive procedure, percutaneous biopsy has associated risks that should be weighed prior to the procedure. Needle biopsy is warranted when the result of the biopsy would potentially affect patient management. These indications include confirmation of preoperative diagnosis, documentation of primary or metastatic disease in patients who are not surgical candidates, evaluation of organ dysfunction, and sampling for special studies such as receptor or gene mutation status.

Several methods are available to obtain tissue, including biopsy by percutaneous needle or by endoluminal and transvenous techniques. Needles ranging in size from 25- to 14-gauge are typically used, and outside the central nervous system, a biopsy can be obtained from almost any abnormality that can be imaged. Most needles contain an inner stylet, which is removed when the needle is appropriately positioned, immediately before obtaining the specimen; the stylet prevents the needle from coring interposed structures and accumulating nontarget material before optimal placement. Smaller "fine" needles (25 to 20 gauge) are used to obtain cytologic specimens or to obtain samples for culture or flow cytometry. Larger needles (19 to 14 gauge) are used to obtain tissue cores when histologic material is required for pathologic diagnosis or when special studies, such as immunohistochemical staining, are to be performed.

Common malignancies in which core specimens may be necessary for diagnosis include lymphoma, sarcoma, thymoma, and mesothelioma. Core material may also be required to diagnose well-differentiated hepatocellular carcinoma (HCC) or benign hepatic tumors. Tissue cores also may be required for mutational analysis in patients for whom targeted therapies are being considered. In most cases, fine needle aspirates are sufficient, and multiple immunohistochemical stains can be used on a single sample, allowing for accurate cell typing.

To increase the likelihood of a diagnostic biopsy and to minimize complications, a high-quality imaging study should be available for review both when the biopsy is being planned and when it is performed. In some cases, careful review of imaging studies may provide a definitive diagnosis, obviating the need for biopsy. Review of preprocedure imaging also influences selection of the most appropriate modality for guidance and patient positioning during the procedure, so that potential problems such as interposed lung, bowel, or blood vessels may be anticipated and avoided. In addition, knowledge of imaging findings allows for appropriate discussion of relevant risks in the informed consent. With proper preprocedure imaging, the biopsy can be planned to avoid unusual or unsustainable positions, complex needle angulation, and challenging breathing instructions.

Review of imaging studies before biopsy also facilitates targeting of the most viable area of a mass. As large masses outgrow their blood supply, they become necrotic, and diagnostic material cannot be reliably obtained in a background of necrosis. Preprocedure contrast-enhanced computed tomography (CT), magnetic resonance imaging (MRI), and positron-emission tomography (PET) can allow for accurate targeting of areas most likely to yield a diagnostic specimen.

BIOPSY TECHNIQUE

Fine Needle Aspiration

A 25- to 20-gauge needle is advanced into the target lesion, and real-time (ultrasound, fluoroscopy, or CT fluoroscopy) or interrupted imaging (conventional CT or MRI) is performed to guide and assess needle position. Coaxial techniques are sometimes useful but are generally unnecessary, but some operators are partial to this technique. Although coaxial biopsy requires the introduction of a larger needle than is used for biopsy, it has the advantage that multiple samples may be obtained without creating a new tract for each pass, and the tract can be embolized or "plugged" to prevent hemorrhage in high-risk situtations (Billich et al, 2008).

Fine needles come in a variety of tip designs. Many physicians use a Chiba-style needle, in which the needle tip and inner stylet are beveled. Our preference is a Westcott-style needle: in addition to a beveled tip, it has a notch in the sidewall of the needle just proximal to the tip; this facilitates the operator's ability to choose more precisely the location from which the cells will be aspirated.

When needle position has been confirmed, the needle is attached to a disposable syringe. The plunger of the syringe is retracted to apply suction as the needle is moved back and forth within the lesion to obtain a sample. The needle is withdrawn after suction is released, and the specimen is deposited on a glass slide. Smears are made from the biopsy specimen, and these may be used for immediate analysis (e.g., Diff-Quik) or fixed in ethanol for immunohistochemical stains. In some cases, molecular studies may need to be performed on fine needle specimens, and charged slides may be used that electrostatically attract tissue and bind it to the slide. The residual material within the syringe and needle is rinsed in a

cell-preserving solution for preparation of a cell block. For cases in which non-Hodgkin lymphoma is suspected, a specimen for flow cytometry may be obtained by rinsing the needle and syringe in a nutrient-rich culture medium (e.g., Roswell Park Memorial Institute medium). When infection is suspected, material can be set aside for culture.

In the ideal situation, an on-site cytopathologist or cytotechnologist can provide an immediate interpretation of the sample; this has been shown to increase the sensitivity of the biopsy, shorten the procedure time, and minimize the number of passes required to obtain a diagnostic specimen (Nasuti et al, 2002; Silverman et al, 1989).

Core Biopsy

The technique for localizing a lesion is identical for fine needle and core biopsies. To obtain a good core sample, a target lesion should be at least 1 cm in maximum dimension, but preferably 2 cm. Because of the typically larger needle size (14 to 19 gauge) used to perform a core biopsy, care should be taken to minimize the possibility of traversing medium-sized arteries, which lack the muscular wall of larger arteries and have an increased tendency to bleed; traversing the colon can result in peritonitis or abscess. Core biopsy needles come in a variety of sizes and styles, including biopsy "guns" and cutting needles that obtain histologic samples manually as the needle is passed back and forth within the lesion.

To confirm adequacy of the specimen, a touch preparation may be prepared on a glass slide for immediate evaluation by a cytopathologist or cytotechnologist. Before being placed in formalin or saline, the core of tissue is placed on a glass slide and gently moved over the slide to allow some cells to collect on the surface. In addition to the tissue sample, material is often collected at the same time that is suitable for cytology, and this increases the diagnostic yield of the procedure. Core samples are commonly placed in formalin. Occasionally, specimens may be sent "fresh" to pathology in saline or on saline-soaked gauze for special studies. Because cells placed in saline eventually undergo cell lysis related to osmotic shifts of saline into the cell, a specimen in saline needs to be fixed or frozen within a few hours to avoid deterioration of the tissue sample. Tissue also may be snap frozen for future studies. The preferred method for processing tissue may vary from institution to institution, and the preference of the pathologists reviewing the material should be determined before initiating a biopsy.

Despite the fact that more tissue is usually obtained during a core needle biopsy than with a fine needle aspiration (FNA) biopsy, the diagnostic rates for most malignancies are not necessarily higher (Longchampt et al, 2000; Stewart et al, 2002). The incremental benefit of a core biopsy in the liver is most notable in the discrimination of a well-differentiated HCC from nodular regeneration in the setting of cirrhosis and in confirmation of benign diagnoses, including hemangioma, adenoma, and focal nodular hyperplasia (Kulesza et al, 2004; Kuo et al, 2004).

IMAGING GUIDANCE

Ultrasound

Ultrasound (US; see Chapter 13) is commonly used to guide percutaneous biopsies of the liver, because it is widely available, inexpensive, and portable. US may be used at the bedside or in patients in whom CT guidance is impractical. Lesions larger than 1 cm are often visible, and US allows for real-time visualization of the needle as it courses from the skin into the lesion. This is especially helpful in small lesions that move with respiration and are difficult to target with interrupted imaging modalities. Visualization of smaller caliber needles may be difficult, and many manufacturers make needles specially designed to enhance visibility with US.

Another advantage of US guidance is the capability of multiplanar imaging. This is particularly useful in finding a route to lesions at the hepatic dome that avoids aerated lung and eliminates the risk of causing pneumothorax. Because CT provides a two-dimensional image, complex triangulation often is required to accomplish the same result. Doppler imaging is occasionally helpful in performing a biopsy by enhancing the localization of small lesions. US contrast agents may help identify the most viable regions of a tumor, and it does not use ionizing radiation—a benefit to both the patient and the operator.

Limitations of US include interoperator variability and poor transmission through air and bone, which limits the visualization of some lesions. Additionally, patients who are sedated for biopsy may not be able to cooperate with breathing instructions necessary to facilitate visualization of some masses, including small lesions or those high in the hepatic dome.

Computed Tomography

CT (see Chapter 16) is a common modality for guiding percutaneous biopsies, because it provides superb anatomic detail that gives the operator the ability to plan a path from skin to lesion using the safest approach, clearly visualizing interposed structures. CT is the imaging modality of choice for biopsies of the pancreas, adrenal glands, abdominal and retroperitoneal lymph nodes, and bone and liver lesions that are not well visualized with US, or when biopsy is performed by operators who are not skilled with US. CT is also commonly used for lung lesions, although at our institution, fluoroscopy is preferred by some operators to capitalize on the real-time visualization of the target in the moving background of the lung.

Computed Tomographic Fluoroscopy

Many manufacturers now offer CT fluoroscopy as an option on diagnostic scanners. This produces CT images in near real time. It does expose the operator to ionizing radiation and requires that the operator wear lead, as with conventional fluoroscopy; but it is preferred by some physicians, owing to decreased time between needle manipulation and image availability.

Magnetic Resonance Imaging

Biopsies guided by MRI (see Chapter 17) have been made possible by the advent of open-bore MRI systems that provide access to patients during imaging and the availability of nonferrous biopsy needles and monitoring equipment. The superior contrast resolution of MR allows for targeting of lesions that are difficult to visualize with US and noncontrast CT, and the ability of MRI to image in any plane enhances the targeting of lesions that are not safe to approach or easy to access in the axial plane (Stattaus et al, 2008; Fig. 20.1). Owing to high cost and limited availability, MR-guided biopsies are generally reserved for patients whose lesion cannot be seen or targeted with US or

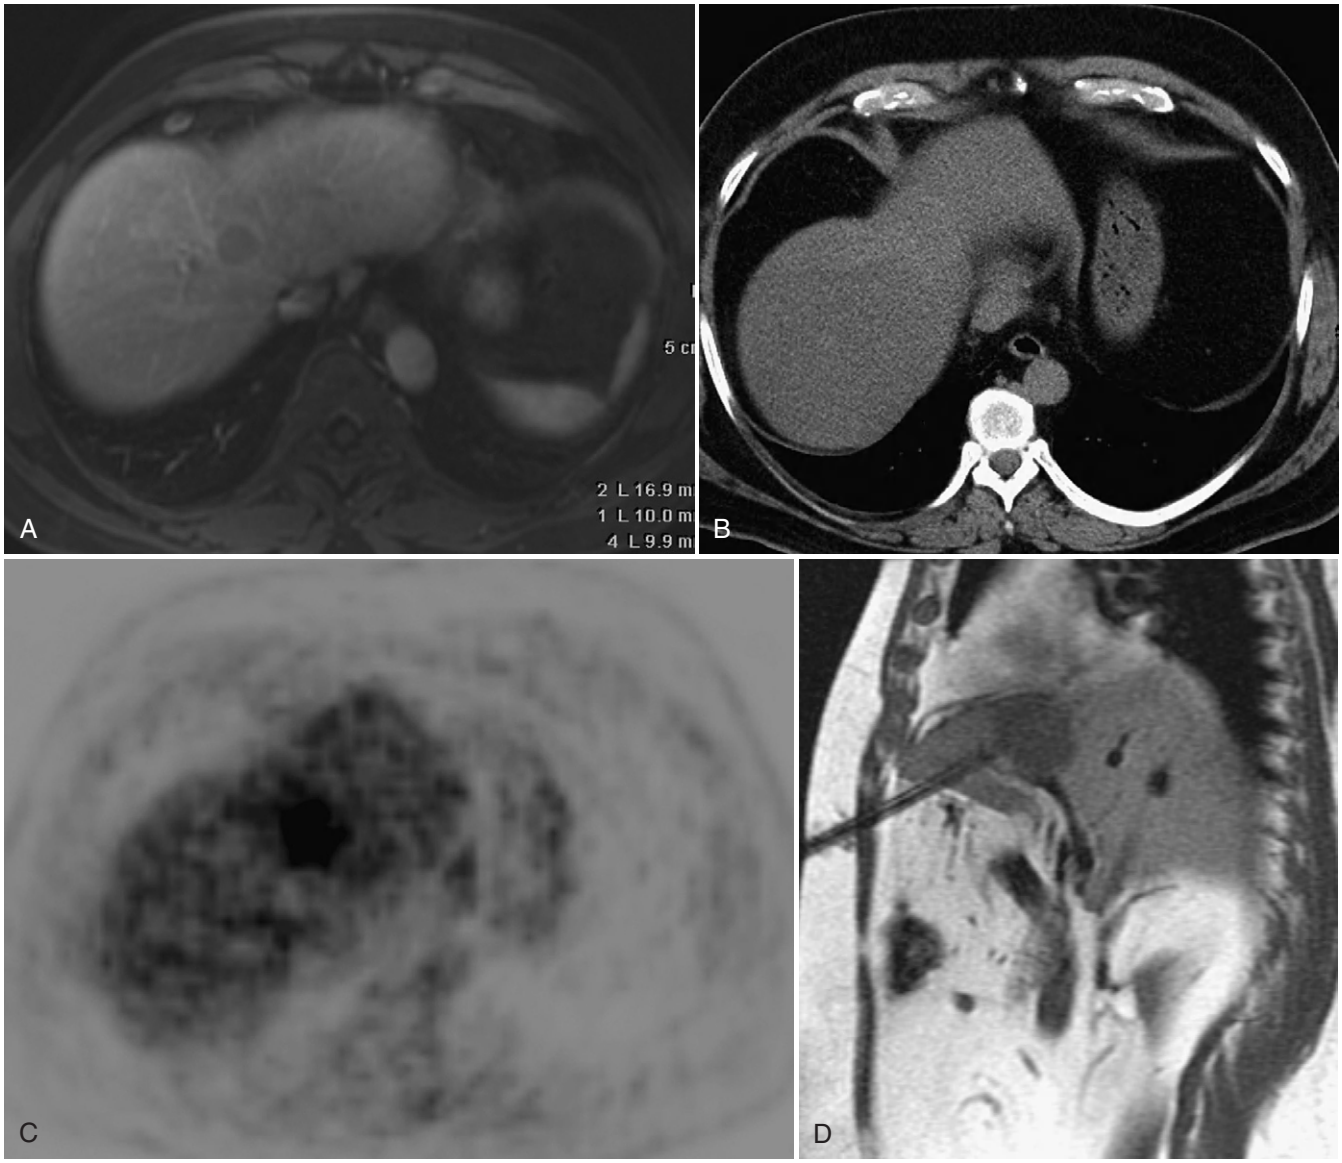

FIGURE 20.1. Magnetic resonance (MR)-guided percutaneous liver biopsy. **A,** Axial T1 MR after contrast administration shows a focal lesion in segment IV in a patient with hepatitis B. **B,** Noncontrast computed tomography in the same patient at the same level failed to show the lesion. **C,** Positron emission tomography scan was positive. **D,** The biopsy was successfully performed using MR guidance in the sagittal plane to avoid the risk of pneumothorax. The biopsy specimen confirmed the diagnosis of hepatocellular carcinoma.

CT. In addition, it is necessary to ensure that nonferromagnetic, MRI-compatible equipment is on hand and that the patient is able to undergo MRI.

Fluoroscopy

Fluoroscopy is useful for guiding bile duct biopsies. Benign and malignant biliary strictures (see Chapters 18, 42, and 50) often have similar cholangiographic appearances and rarely can be distinguished based on imaging alone (Hadjis et al, 1985; Corvera et al, 2005). Lesions originating within the duct may be sampled by either an endoluminal (see Chapter 14) or a direct percutaneous approach (see Chapter 18). Percutaneous transhepatic biliary drainage allows direct access to the biliary tract for endoluminal biopsy, when satisfactory decompression of the biliary tree has been achieved. Biopsy forceps or brush-biopsy catheters can be used through the existing tract to obtain tissue samples of suspicious areas (Fig. 20.2). The sensitivity of forceps biopsy is in the range of 40% to 80%, higher than that of brush biopsy, which is in the range of 30% to 60%. Specificity for each approaches 98% (Stewart et al, 2001; Govil et al, 2002; Weber et al, 2008), and sensitivity is highest for intraductal lesions and when biopsy is done in conjunction with choledochoscopy to provide direct visualization of the lesion (Ponchon et al, 1996).

Alternatively, after the biliary tree is opacified, a direct percutaneous biopsy of a bile duct lesion may be targeted with fluoroscopy using a transhepatic approach (see Chapter 18; Chawla et al, 1989). This technique is most useful for intrinsic bile duct lesions but may also be used to diagnose lesions

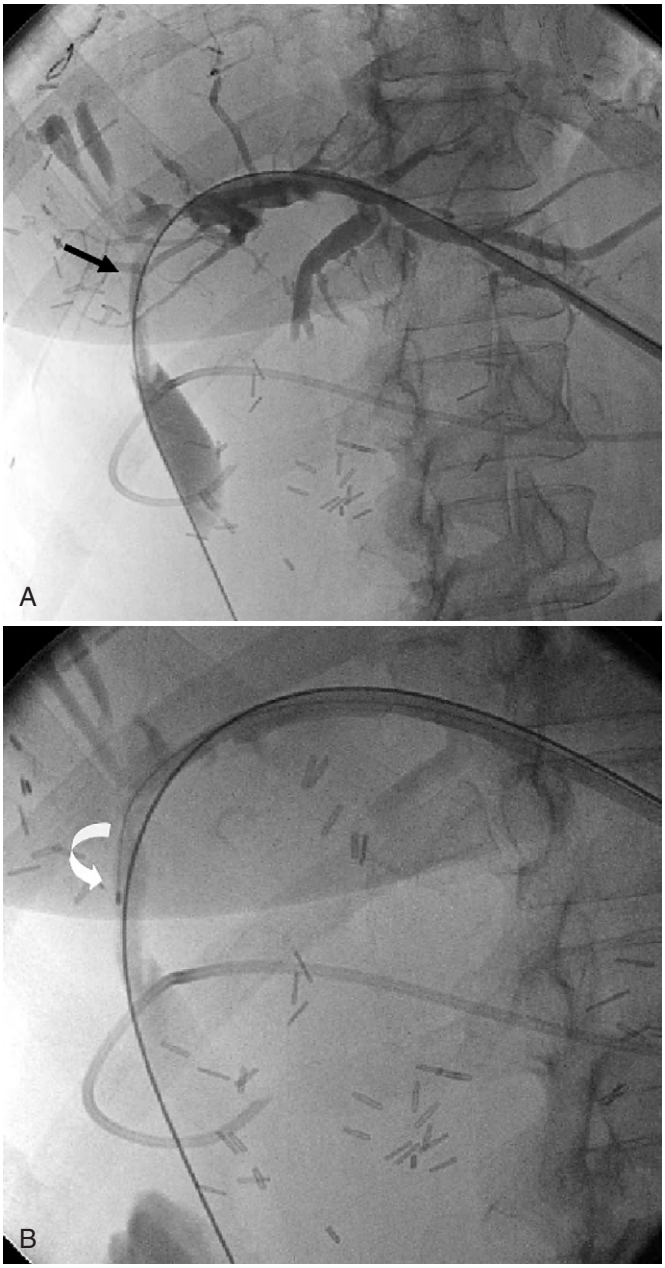

FIGURE 20.2. Biliary brush biopsy. **A,** Transhepatic cholangiogram shows a high bile duct stricture (*arrow*) in a patient with two indwelling endoscopic stents and a percutaneous biliary drainage catheter. Prior brush biopsy was nondiagnostic. **B,** A brush (*curved arrow*) was advanced to the stricture and used to obtain a specimen for cytology. The specimen was diagnostic of cholangiocarcinoma.

adjacent to the bile duct. With this technique, contrast is injected into an indwelling biliary drainage catheter to delineate the targeted bile duct abnormality. A needle is advanced through the anterior abdomen to the lesion, and a specimen is obtained. Confirmation of accurate needle position is made by obtaining oblique fluoroscopic images and by real-time fluoroscopy, when the needle is seen to move the duct or the indwelling catheter or both (Fig. 20.3). Fluoroscopy also is useful to guide percutaneous biopsy of lung nodules and for nontargeted transvenous biopsies of the liver or kidney.

New Guidance Equipment

New technology is being developed that allows fusion of multiple modalities. For example, CT and MRI scans can be overlaid with real-time US images to achieve the clarity of the one imaging modality and the real-time visualization capabilities of the other. PET images (see Chapter 15) also can be fused to demonstrate sites of highest metabolic activity. Additionally, robotic guidance systems have been piloted in an effort to optimize speed and accuracy of needle placement.

BIOPSY OF SPECIFIC SITES

Liver Biopsy

Percutaneous liver biopsy is performed to determine the nature of focal liver masses, the cause and extent of cirrhosis, or the cause of liver dysfunction (see Chapters 64, 65, and 70). Modern cross-sectional imaging techniques—including ultrasound, CT, and MRI—allow percutaneous biopsy of both subcentimeter and deep lesions to be performed on an outpatient basis with minimal morbidity. With current techniques, almost any liver lesion can be targeted percutaneously; most liver lesions larger than 5 mm are suitable for biopsy (Yu et al, 2001). Fine needle biopsy of liver lesions has a sensitivity of 69% to 97% (Ohlsson et al, 2002).

Focal Liver Lesions

Focal liver lesions may be solitary or multiple. For a solitary lesion, several benign conditions—cyst, hemangioma, focal nodular hyperplasia, and adenoma—often can be diagnosed confidently by high-quality cross-sectional imaging, obviating the need for biopsy (see Chapters 16, 17, and 79; Gibbs et al, 2004; Hussain et al, 2004; Kim et al, 2004). These diagnoses should be considered in all solitary liver lesions, unless they are known to be new in the setting of a known cancer or in patients at risk for primary HCC.

HCC may also be diagnosed based on imaging and clinical criteria. In patients with cirrhosis and an arterial enhancing liver mass greater than 2 cm, an α-fetoprotein value of greater than 400, or two concordant imaging studies diagnostic of HCC, biopsy is generally unnecessary (Bruix et al, 1981). When the diagnosis of HCC is considered, and these criteria are not met, the diagnosis often can be established based on cytology alone. Smaller, encapsulated tumors are more likely to be well differentiated, and tissue cores may be required to distinguish a well-differentiated tumor from normal or cirrhotic liver. Because of the risk of tumor seeding in the biopsy tract for a lesion highly suspicious for HCC (Chaudhry et al, 2004; Perkins, 2007; Durand et al, 2007), when a curative treatment is possible, biopsy should be performed only after consultation with a hepatobiliary surgeon and after referencing the most current imaging and clinical criteria.

Multifocal solid liver lesions most commonly represent metastatic disease. In such cases, biopsy may be requested to 1) confirm the presence of metastatic disease in a patient with a known primary; 2) establish tumor type and stage simultaneously at initial presentation; 3) acquire tissue for genetic analysis, such as *c-kit* mutation in a patient with metastatic gastrointestinal stromal tumor; or 4) obtain histologic samples for patients undergoing experimental therapies.

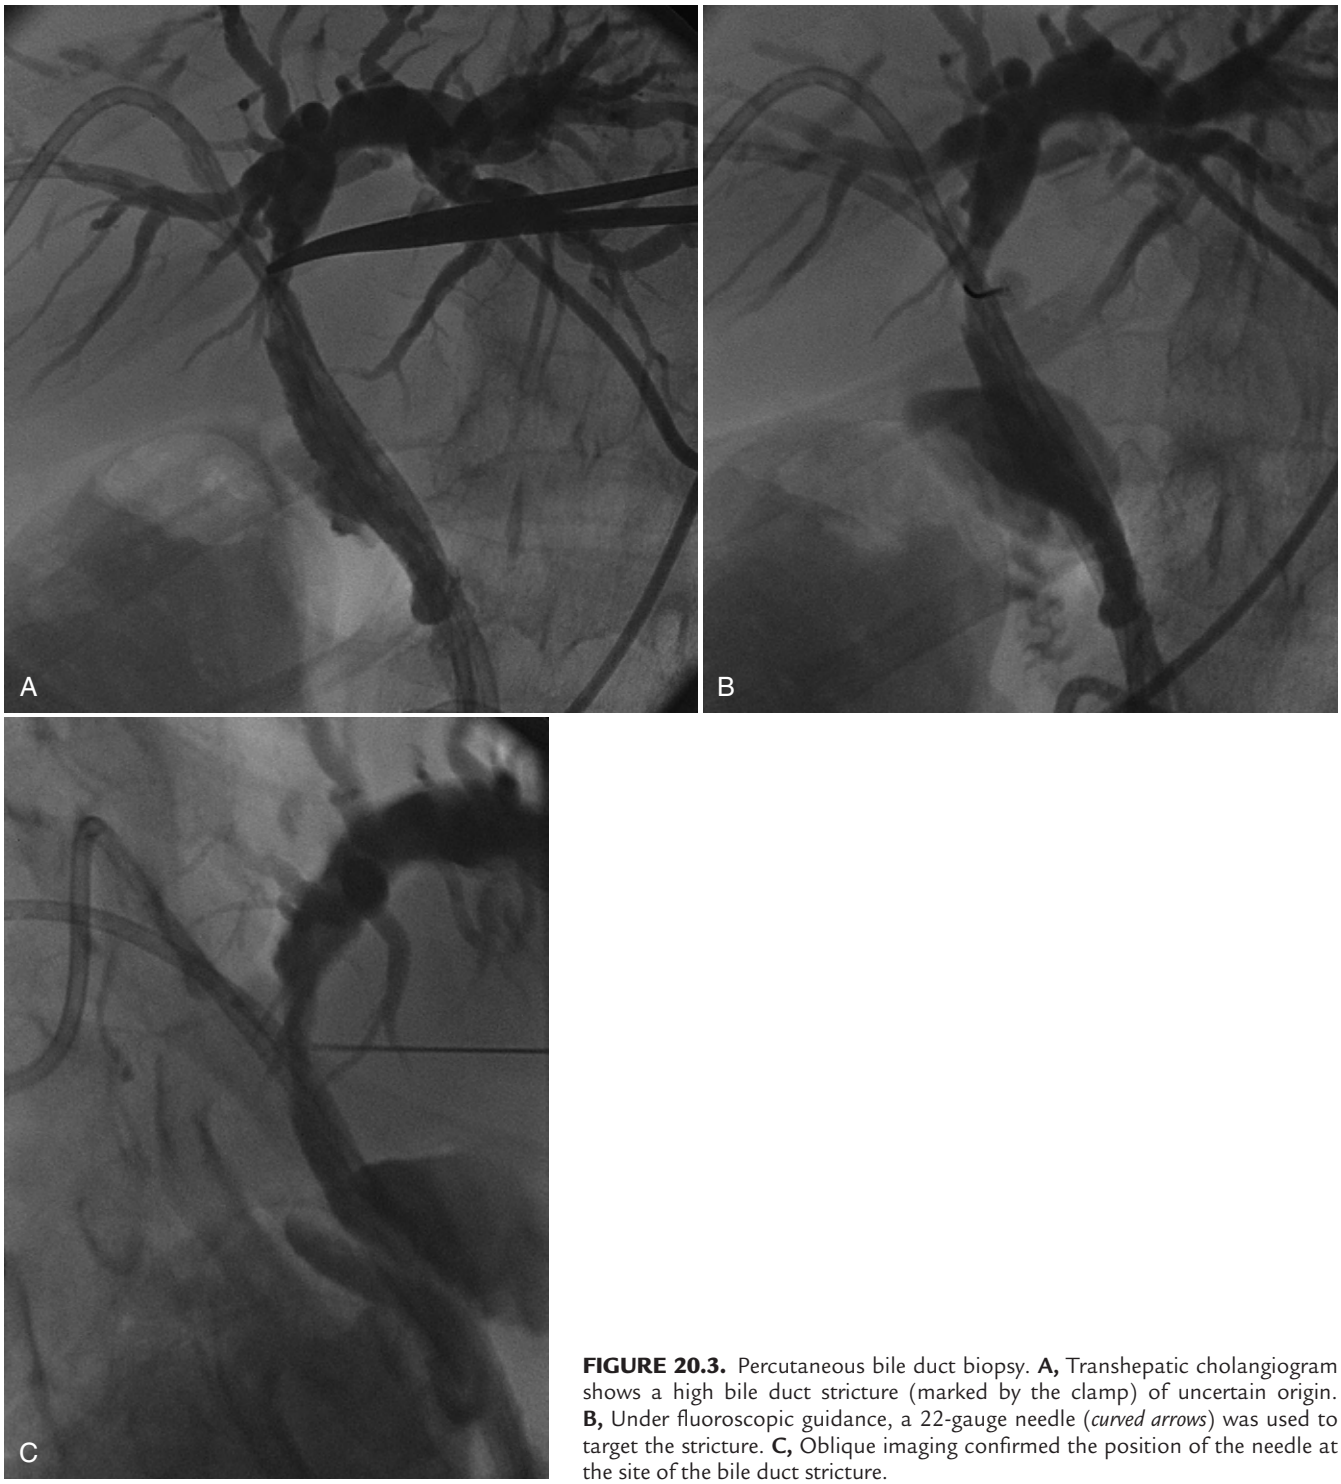

FIGURE 20.3. Percutaneous bile duct biopsy. **A,** Transhepatic cholangiogram shows a high bile duct stricture (marked by the clamp) of uncertain origin. **B,** Under fluoroscopic guidance, a 22-gauge needle (*curved arrows*) was used to target the stricture. **C,** Oblique imaging confirmed the position of the needle at the site of the bile duct stricture.

Liver Parenchyma Biopsy

Core liver biopsy is used to grade and stage liver disease in patients with abnormal liver function studies, chronic hepatitis, and known or suspected cirrhosis (see Chapters 64, 65, and 70). Gastroenterologists have historically performed most liver biopsies without imaging guidance; however, unusual anatomy occasionally makes imaging-guided biopsy advisable. Adequate tissue cores can be obtained with needles 20 gauge and larger, although needles 18 gauge and larger provide a more generous specimen for analysis (Guido & Ruggae, 2004; Maharaj et al, 1986).

Transvenous Biopsy

Transjugular liver biopsy is a useful alternative to percutaneous biopsy in patients with coagulopathy or when hepatic venous pressure measurements are required (Sawyerr et al, 1993;

Garcia-Compean & Cortes, 2004). Although transvenous biopsy is seemingly more invasive than percutaneous biopsy, the risk of significant bleeding in coagulopathic patients is minimized using a transvenous approach, because bleeding from the biopsy site tracks back into the venous circulation and not into the abdominal cavity, as can happen with percutaneous biopsies. Proper technique to avoid puncture of the liver capsule is crucial to optimize safety.

In this technique, a venous sheath is introduced into a hepatic vein, most commonly the right hepatic vein, from a right internal jugular approach. Pressure measurements may be obtained to evaluate the source (presinusoidal, sinusoidal, or postsinusoidal) and degree of portal hypertension. A core biopsy needle or biopsy forceps is introduced through the sheath into the liver parenchyma to obtain histologic samples (Fig. 20.4). Care must be taken to avoid performing the biopsy from a peripheral approach, because this increases the risk that the liver capsule will be punctured and that peritoneal hemorrhage will result.

Transvenous biopsy is only used for nontargeted parenchymal biopsy; it cannot be used for biopsy of a focal lesion. Transvenous biopsy of the kidney also has been reported and may be useful for evaluation of renal dysfunction in coagulopathic patients (Cluzel et al, 2000). This may be particularly convenient in coagulopathic patients who require both parenchymal hepatic and renal biopsies.

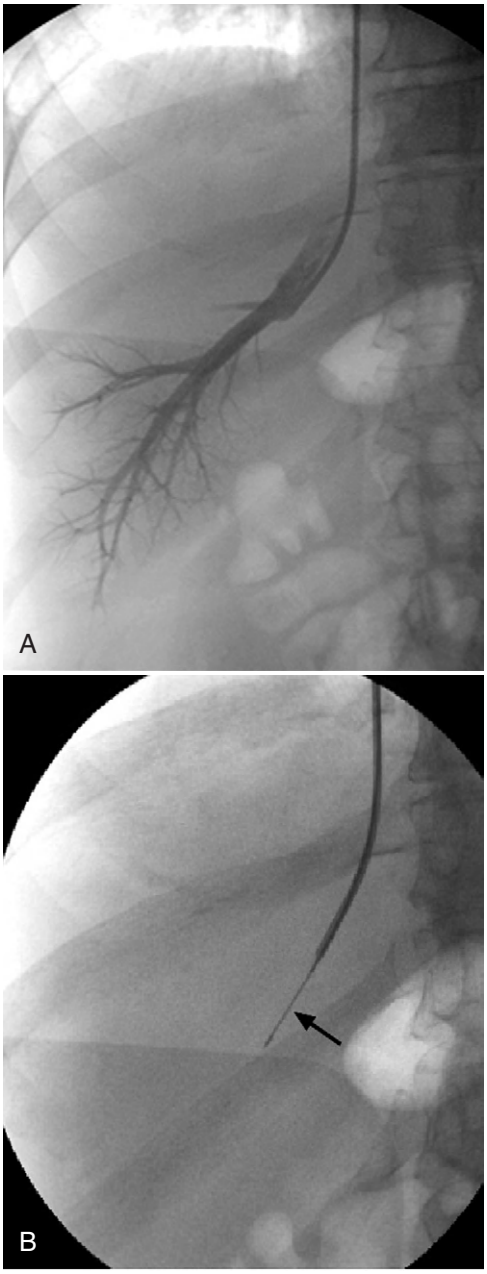

FIGURE 20.4. Transjugular liver biopsy. **A,** Right hepatic venogram through a sheath placed via the right internal jugular vein. **B,** A 19-gauge automated flexible biopsy needle with a 20-mm throw (*arrow*) is advanced through a metal cannula and directed anteriorly as the biopsy specimen is obtained.

Biopsy of Other Organs

Adrenal Biopsy

The adrenal gland is a common site of metastatic disease. This gland also is the site of many benign neoplasms, and adenomas occur in 5% of individuals (Abecassis et al, 1985; Libe et al, 2002). Adrenal biopsy can often be avoided, as MRI can sometimes distinguish between an adenoma and a metastasis (National Institutes of Health, 2002). In some cases, the mass remains indeterminate, and biopsy is indicated. Because of the posterior approach used for all left and some right adrenal biopsies, it is common to traverse the lung, introducing the possibility of a pneumothorax. The right adrenal gland can alternatively be targeted from a lateral, transhepatic approach to eliminate the risk of pneumothorax (Fig. 20.5).

Pancreas Biopsy

Despite the best efforts of clinicians and advances in imaging, most patients with pancreatic cancer still initially present with unresectable disease. Needle biopsy may be requested for tissue diagnosis so that treatment can be initiated, and it is essential to evaluate the preprocedure imaging carefully to determine the safest approach. An anterior approach to the pancreas may be difficult because of interposed colon, spleen, or mesenteric vessels, which we would prefer not to traverse. We often prefer a posterior, transcaval approach (Sofocleous et al, 2004) or a transhepatic approach, particularly for lesions in the head or uncinate process (Fig. 20.6).

Retroperitoneal and Pelvic Biopsy

Most retroperitoneal and pelvic biopsies are performed to determine the cause of lymphadenopathy. When the patient has a known malignancy with the proclivity to spread via retroperitoneal lymphatics, FNA biopsy is indicated, and this is easily and simply performed. When lymphoma is a consideration, biopsy specimens should be obtained either for flow cytometry or surgical pathology (cores), depending on local practice and expertise.

Occasionally, a biopsy is performed to diagnose a soft tissue mass suspected to be a sarcoma. In patients who are candidates for resection, the approach to the lesion should be discussed with the surgeon in case the surgeon plans to include the biopsy path in the resection specimen. For primary diagnosis of sarcoma, histologic material is useful for classifying the sarcoma, and core biopsy should be performed. If recurrence is the issue,

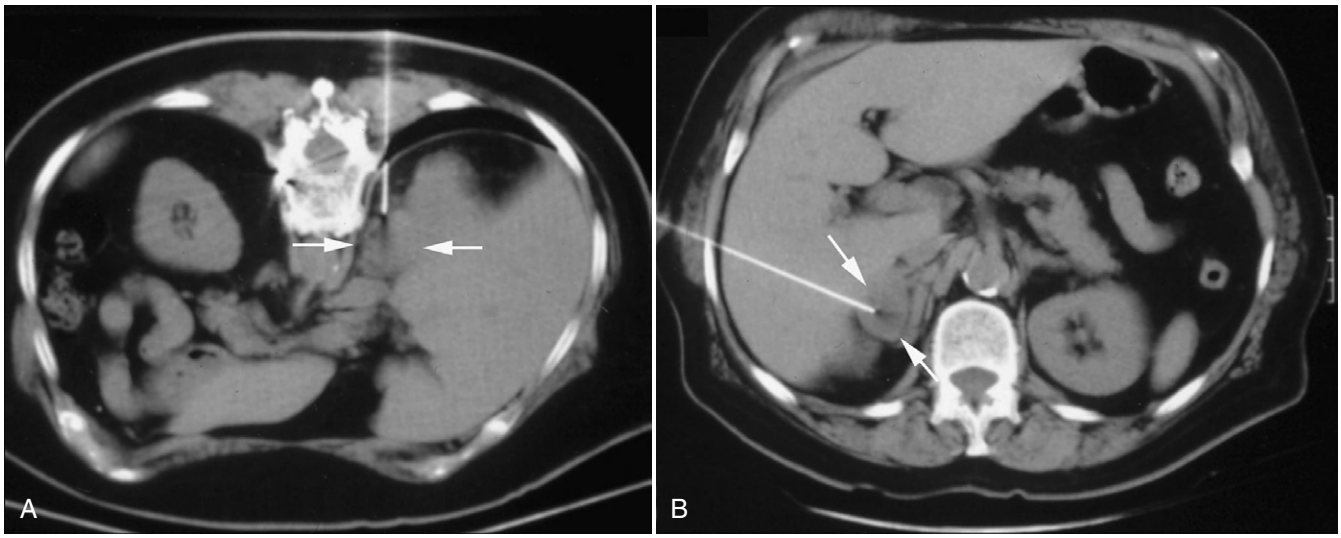

FIGURE 20.5. Adrenal biopsy. **A,** Transpeural biopsy of right adrenal mass (*arrows*). **B,** Transhepatic right adrenal mass (*arrows*) biopsy eliminates the risk of pneumothorax.

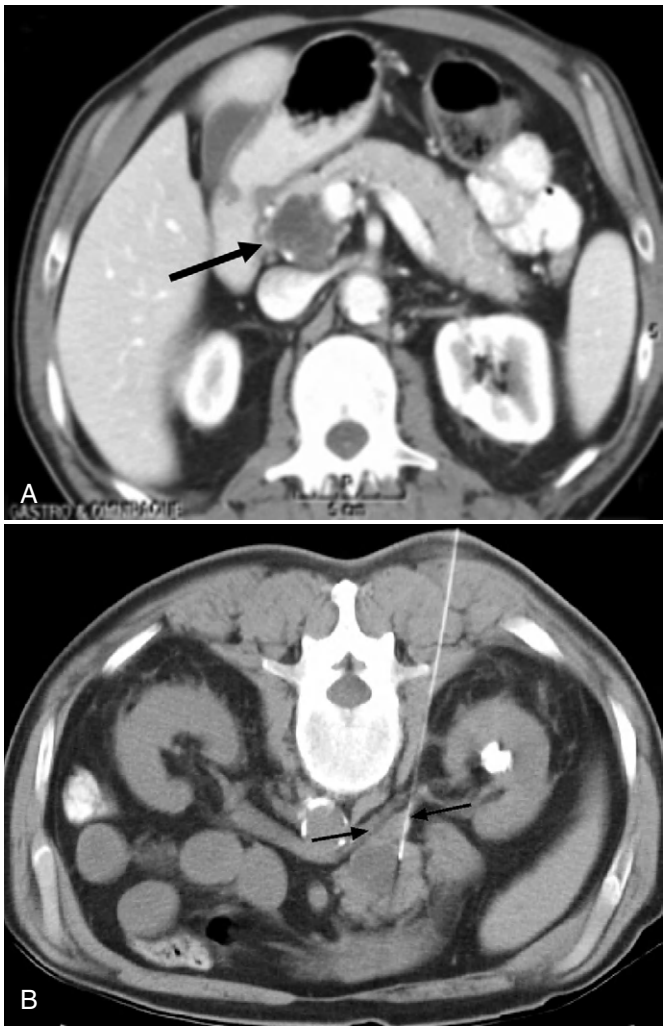

FIGURE 20.6. Transcaval pancreatic biopsy. **A,** Contrast-enhanced computed tomography scan shows a cystic mass (*arrow*) in the head of the pancreas in a patient with a history of non–small cell lung cancer. **B,** Transcaval biopsy performed in the prone position with a 22-gauge needle confirmed the diagnosis of metastasis. The inferior vena cava is indicated by the *arrows*.

the diagnosis usually can be established on the basis of cytology alone. In women with pelvic masses that might be adnexal, needle biopsy should be performed only after the diagnosis of ovarian cancer has been excluded, or after an oncologic gynecologist has been consulted. The biopsy procedure itself may result in peritoneal contamination, relegating the patient to intraperitoneal chemotherapy, when a simpler treatment regimen might have been possible. In addition to previously described guidance modalities, deep pelvic pathology is sometimes best approached using transrectal or transvaginal US guidance.

Lung and Mediastinum Biopsy

Lung biopsies can be performed with CT, CT fluoroscopy, or conventional fluoroscopy, but they are often easiest and fastest with conventional fluoroscopy. The size, location, and nature of the target lesion, as well as operator experience, determine which modality is used. Mediastinal biopsies are usually performed using CT guidance. The size of the needle used and type of specimen acquired vary depending on the clinical indication. Diagnostic rates for needle biopsy of malignant lung lesions have been reported as greater than 90% (Swischuk et al, 1998).

Bone Biopsy

Bone biopsies are typically performed using larger needles (11 to 15 gauge) than those used for organ or soft tissue. Purely lytic lesions are the exception, as small-caliber needles will often suffice to document metastases and are able to penetrate bone in the setting of cortical destruction. For surgical candidates, the biopsy path should be discussed with the surgeon to ensure that a planned procedure is not compromised by violating an uninvolved compartment.

COMPLICATIONS OF PERCUTANEOUS BIOPSY

Any invasive procedure has risks. Risks of biopsy include bleeding, pneumothorax, infection, bile leak, and needle-tract seeding of tumor. The risks vary depending on the organs involved. To

minimize the risk of bleeding, we advocate that all patients should have appropriate laboratory work before biopsy, including a complete blood count and coagulation profile. Although criteria differ from institution to institution and from physician to physician, a platelet count of greater than 50,000 μL and an international normalized ratio (INR) less than 1.5 are acceptable in most cases. Biopsy in thrombocytopenic patients can be performed with platelet coverage, although the decision to proceed with biopsy should be considered carefully. For patients with an elevated INR, transfusion of plasma or supplementation with vitamin K is required. Elevated partial thromboplastin time (PTT) in patients not on heparin usually is due to circulating antiphospholipid cardiolipins and is not typically clinically significant. A test of bleeding time may be performed to evaluate the significance of an elevated PTT in select patients. It is advisable to have patients stop antiplatelet medications, if possible, to minimize the risk of bleeding; however, the risk of stopping antiplatelet therapy must be weighed against the risk of bleeding from the biopsy; occasionally the balance favors performing the biopsy while the patient remains on the regular medication.

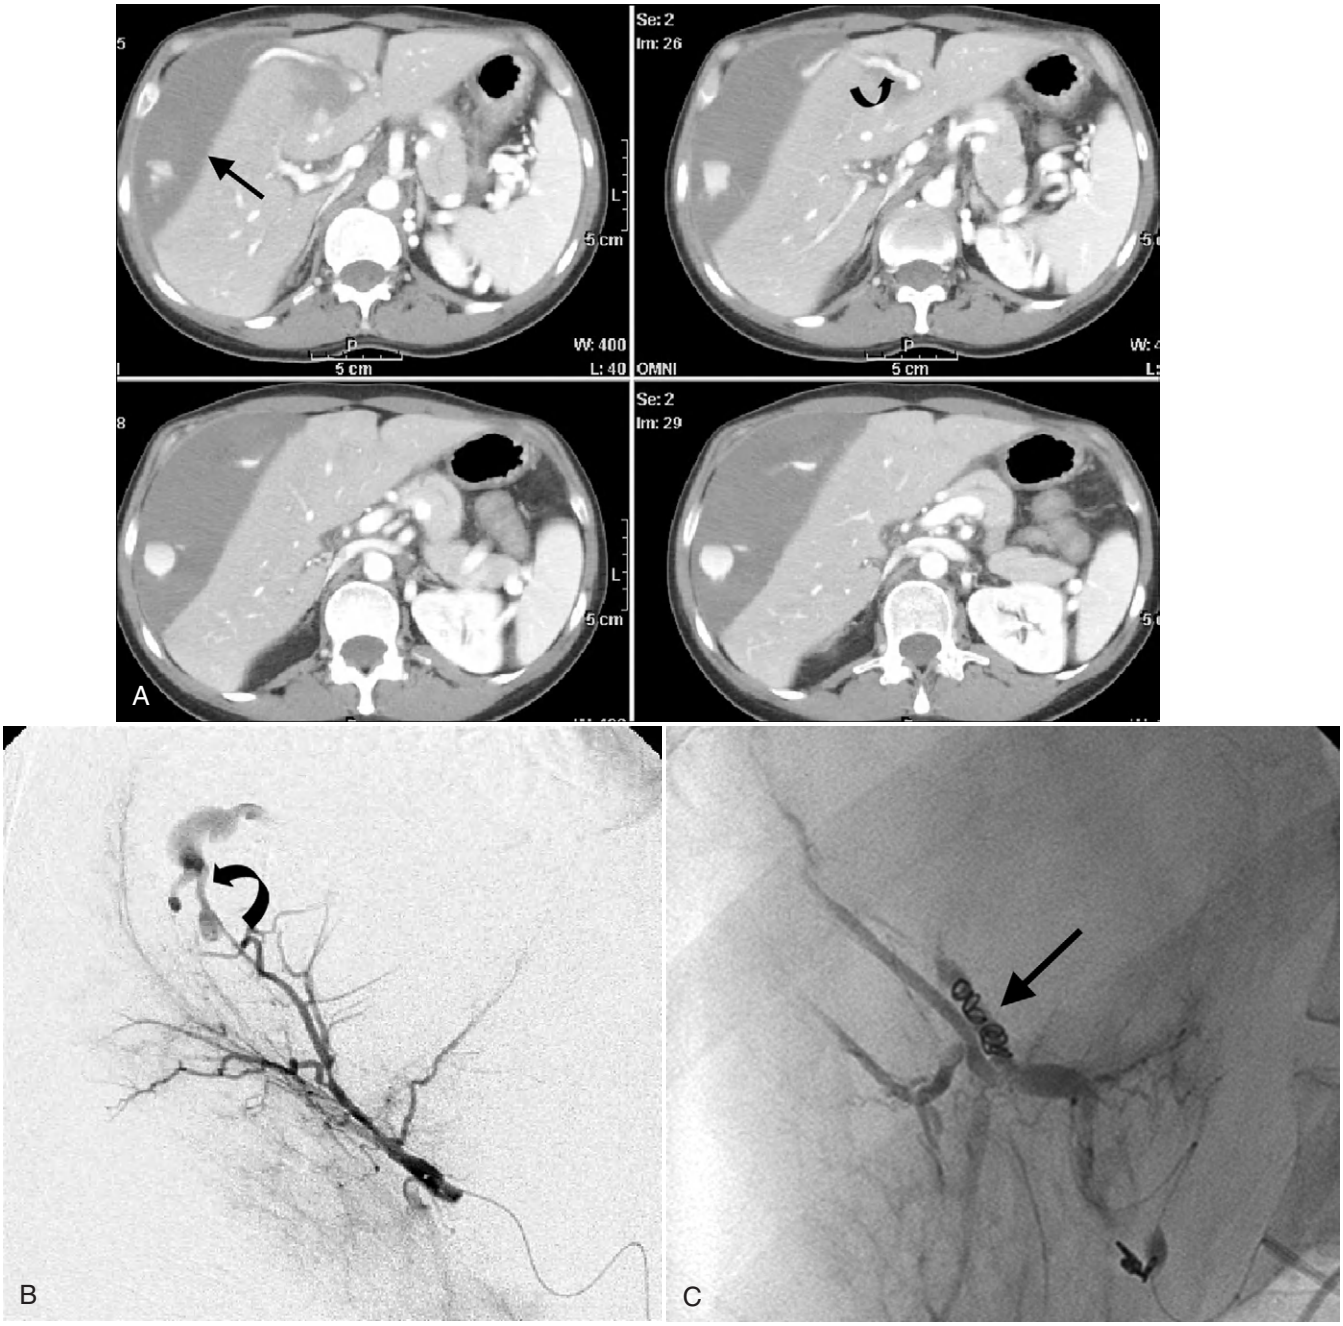

FIGURE 20.7. Hemorrhage complicating liver biopsy. **A,** Contrast-enhanced computed tomographic scan 5 days after liver biopsy shows a large subcapsular hematoma (*arrow*) with active extravasation of contrast from the liver mass (*curved arrow*). **B,** Angiography shows active extravasation (*curved arrow*) from peripheral segment VIII artery that was successfully embolized with stainless steel coils (**C;** *arrow*).

The risk of significant bleeding after liver biopsy is less than 1% (Piccinino et al, 1986; Riemann et al, 2000). In most cases, the bleeding is self-limited, and conservative management comprising observation and hydration is sufficient. In patients with more significant bleeding, hepatic angiography and potential embolization of an injured artery may be required (Fig. 20.7). Some authors advocate placing absorbable gelatin sponge (Gelfoam) pledgets in the biopsy tract through the needle after core biopsy, but this has not been shown definitively to decrease the risk of major bleeding (Hatfield, 2008).

Pain out of proportion to imaging findings after liver biopsy may be due to bile peritonitis (Ruben & Chopra, 1987). Care should be taken to minimize needle passes through the gallbladder, cystic duct, or dilated bile ducts. If the gallbladder is inadvertently punctured, it should be aspirated as completely as possible before removing the needle. Bile leaks resulting in discernible collections are rare after liver biopsy in the absence of downstream biliary obstruction.

Adrenal masses and lesions in the dome of the liver often require an approach for biopsy that crosses the lung base, putting patients at risk for pneumothorax. The two most common complications after lung biopsy include hemoptysis and pneumothorax (Westcott et al, 1997). Hemoptysis occurs in up to 30% of lung biopsies and is usually self-limited, but it can be frightening to the patient. Pneumothorax occurs in 20% to 30% of patients after biopsy and requires placement of a chest tube in approximately 6% of cases. The risk of pneumothorax is typically related more to patient than technical factors, although depth of the target lesion, number of pleural surfaces transgressed, and patient positioning (prone positioning decreases the risk of pneumothorax) have been shown to affect the likelihood. Elderly patients and patients with underlying chronic obstructive pulmonary disease are more prone to developing a pneumothorax requiring treatment (Covey et al, 2004). A symptomatic or enlarging pneumothorax is treated with a small-bore chest tube (generally 8 to 12 Fr) and occasionally necessitates hospital admission.

Hemorrhagic pericardial tamponade is a rare, potentially life-threatening complication after mediastinal biopsy (Kucharczyk et al, 1982). Although hypoxemia may be a feature, this complication can be distinguished from iatrogenic pneumothorax clinically by the development of hypotension with narrowing of the pulse pressure and diminished amplitude of the electrocardiogram complex on the monitor. The diagnosis can be confirmed immediately by scanning the heart and pericardium, and it can be treated by directly placing a drainage catheter into the pericardial space.

Needle-tract seeding after percutaneous biopsy is a worrisome complication. The interval between biopsy and appearance of a tract metastasis is 6 to 24 months (Kosugi et al, 2004; Schotman et al, 1999). The risk overall is likely greater than reported, but current understanding is that the risk in HCC is in the range of 2% to 3% (Perkins, 2007; Stigliano et al, 2007). Although the incidence is relatively small, the possibility of rendering a patient ultimately incurable because of tract or peritoneal seeding should be considered in the risk/benefit analysis for each patient. For this reason, some surgeons do not advocate percutaneous biopsy for patients with potentially resectable lesions highly suspicious for malignancy (Cha et al, 2002; Al-Leswas et al, 2008); this sentiment is particularly strong among transplant surgeons in regard to patients with HCC or other malignant disease undergoing evaluation for a new liver graft (see Chapters 97D and 97E).

CONCLUSION

Percutaneous needle biopsy is a well-established and safe diagnostic tool, and it is an important instrument in the diagnosis of tumors, for determining the cause of organ dysfunction staging, and for documenting recurrent or metastatic disease. Complications occur infrequently, and most are easily treated or self-limiting. Tract seeding has been reported but occurs infrequently. There is no such thing as a "negative" biopsy (Phillips et al, 1998). If a diagnosis of malignancy is not made, a specific benign diagnosis needs to be confirmed. If nonspecific findings are evident on cytology—including inflammatory or reactive changes, fibrous tissue, or normal site tissue—or if atypical cells are present, another biopsy should be performed, or the lesion should be closely followed up, depending on the pretest probability of disease.

The role of biopsy in patient management is evolving in tandem with the development of associated fields, including functional and molecular imaging. Until biopsies are no longer necessary, every effort should be made to keep morbidity low and diagnostic rates high.

CHAPTER 21

Intraoperative diagnostic techniques

M.B. Majella Doyle and Wande B. Pratt

OVERVIEW

The management of hepatobiliary and pancreatic disease has evolved considerably since the 1990s. Today's operative surgeon has a number of valuable adjuncts to aid in accurate preoperative evaluation and planning for benign and malignant disease. Advances in contrast-enhanced computed tomography (CT), endoscopic ultrasound (EUS), magnetic resonance (MR) and endoscopic retrograde cholangiopancreatography (ERCP) have revolutionized the treatment of benign and malignant hepatobiliary and pancreatic disease. Despite these techniques, present-day management of these conditions relies on the appropriate use of intraoperative diagnostic modalities, particularly when confronted with challenging and unanticipated findings during surgical exploration.

Intraoperative ultrasonography (IOUS) continues to be an important component for assessing hepatic and biliary anatomy, for identifying and classifying malignant and cystic neoplasms, and for determining the resectability of malignant disease. Similarly, intraoperative cholangiography (IOC) assists the surgeon in assessing the biliary tree, its anatomy, and the occurrence of injury in both open and laparoscopic procedures. Diagnostic and staging laparoscopy (Table 21.1) have also emerged as important techniques for uncovering small-volume disease not revealed by even the most sophisticated imaging studies; however, controversy still exists regarding the true added value of the procedure (Table 21.2). This chapter will focus on these three intraoperative diagnostic modalities and their use in evaluating and managing hepatobiliary and pancreatic disease.

INTRAOPERATIVE ULTRASONOGRAPHY

IOUS is commonly used during both open and laparoscopic procedures. Particular attention must be given to port placement when IOUS will be performed laparoscopically. Ultrasonography (US) is most useful for evaluating the liver parenchyma or for assessing the extent of mesenteric vasculature involvement of pancreatic tumors (Jakimowicz, 1993). Other common applications include localization of pancreatic endocrine tumors, assessment of biliary calculi, and ablation of hepatic tumors.

Hepatic Disease

Technical Considerations

IOUS is now applied with increasing frequency during hepatic segmental or lobar resection, metastasectomy, and partial liver transplantation. It provides for more precise delineation of the spatial relationships of hepatic tumors to major vascular and biliary structures. Intraoperative transducers appropriate for liver surgery include high-frequency (6 to 10 MHz) T-shaped linear- or curvilinear-array transducers. These probes provide excellent high-resolution images and are capable of identifying lesions approximately 1 to 2 mm in size at depths of penetration of approximately 10 to 12 cm. Transducers with color-flow Doppler enable further discrimination of tumors and normal hepatic vasculature.

Techniques for IOUS continue to evolve. Typically, no coupling gel is required, because the natural surface moisture of the liver provides for adequate acoustic coupling. The transducer is initially held in a transverse position, and the survey of the liver begins by first identifying the confluence of the right and left portal pedicles. Next, all segmental pedicles on the right are visualized, then those on the left are identified. Each hepatic vein is visualized by scanning peripherally and then by traversing toward the vena cava. It is easiest to identify the hepatic veins by placing the transducer cranially, in a midline position and angled toward the heart. Only light pressure should be applied to the liver. The confluence of the left and middle vein has a characteristic appearance and should be observed in all sonographic exams. If the entire liver is to be scanned—for example, to search for metastases—sequential overlapping sagittal strokes are made, beginning at the most lateral margin of segment II and traveling toward the right. More focal scanning can be used to localize impalpable lesions situated deep within the liver parenchyma. Special care must be taken when imaging the high dome of the lateral right lobe, the posterior subdiaphragmatic bare area, and surface lesions, such as hamartomas; these areas are particularly challenging to visualize in the intraoperative setting.

Evaluation of the Liver

IOUS of the liver was first introduced into clinical practice in the early 1980s and rapidly became routine practice for management of malignant liver disease (Makuuchi et al, 1981; Nagasue et al, 1984; Gunven et al, 1985; Bismuth & Castaing, 1985; Belghiti et al, 1986; Gozzetti et al, 1986; Olsen, 1990; Gouillat et al, 1992; Solomon et al, 1992; Bloed et al, 2000). These early reports demonstrated that IOUS frequently altered the course of operative management of malignant hepatic tumors by more precisely delineating the relationship between tumors and major vascular and biliary structures and by detecting hepatic tumors not revealed on preoperative imaging studies (Fig. 21.1). In an analysis of 210 patients with primary and secondary hepatic malignancies, Bismuth and colleagues (1987) reported that IOUS provided additional information in 35% of cases and changed the operative plan in 20%. Parker and associates (1989) reported similar findings, with US influencing

Table 21.1

Benefits of Laparoscopic Staging

Shorter recovery
Shorter hospital stay
Decreased procedure-related morbidity
Improved quality of life
Shorter time to initiation of adjuvant therapy
Reduced hospital cost

Potential Disadvantages of Staging Laparoscopy

Potential for morbidity
Risk of port site recurrence
Increased time of surgery and increased cost

49% of cases. A more recent analysis by Kruskal and Kane (2006) demonstrated that IOUS routinely identifies 25% to 35% more hepatic lesions than preoperative imaging studies.

It must be recognized that the yield of IOUS, particularly for identifying lesions not previously seen, depends critically on the quality of the preoperative imaging studies (see Chapters 13, 16, and 17). The results of these and other studies demonstrate the continued importance of IOUS in liver surgery for identifying and staging malignant disease.

IOUS is particularly useful for determining tumor resectability. Several reports from the 1990s have documented increased resectability rates in patients with hepatobiliary malignancy (Soyer et al, 1993; Lo et al, 1998; Jarnagin et al, 1999). More recent studies estimate that the use of IOUS will lead to changes in 15% to 25% of procedures. Regardless of these estimates, IOUS is a crucial component of the intraoperative assessment and is a useful tool in the armamentarium of liver surgeons (Zacherl et al, 2002).

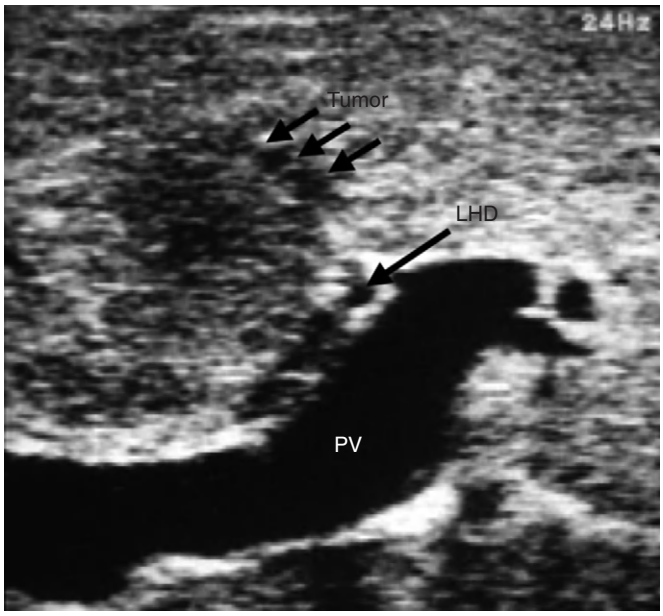

FIGURE 21.1. Intraoperative ultrasound view of a tumor (*arrows*) at the base of segment IV. The confluence of the right and left portal venous branches is shown (*PV*). Dilation of the left hepatic duct (*LHD*) is indicated and suggests possible involvement by tumor.

The sonographer must first evaluate the extent of intrahepatic disease and must then assess for vascular occlusion or invasion. Sonographic features of liver tumors vary and may be foreign to the novice sonographer. In our experience, it is prudent to communicate with radiologists preoperatively so that personnel and equipment are readily available when the surgeon is confronted with a suspicious or challenging lesion.

Recognition of malignant disease can be challenging without the assistance of trained radiologists. Hemangiomas are typically soft and usually lack any visible flow, or they demonstrate only minimal flow compared with adjacent liver parenchyma. Metastases from colon cancer are usually hyperechoic or isoechoic to adjacent liver parenchyma and are frequently surrounded by an ill-defined hypoechoic rim that may have a bull's-eye or target appearance. Mucinous colorectal cancer metastases may contain calcification that produces acoustic shadowing. Hepatocellular carcinoma (HCC) frequently invades major vascular structures and may be associated with porta hepatis lymphadenopathy (Jeffers et al, 1988). Documentation of lesions and their proximity to adjacent vessels will determine resectability. Resection margins of approximately 1 cm are generally sought and appear to be required for an oncologically adequate operation, although the optimal margin size is poorly defined. Keep in mind that an outline of the planned surgical margin with electrocautery of the liver capsule will produce acoustic shadowing and should be reserved until sonography is complete.

Biliary Disease

Technical Considerations

Evaluation of the biliary tree for the presence of common bile duct (CBD) stones is common during elective cholecystectomy. Although this is typically accomplished by cholangiogram, IOUS is a reasonable alternative that may provide comparable results. Laparoscopic US in particular has the added advantage of reducing the risk of biliary and vascular injury. The biliary tree and gallbladder are imaged best from a right subcostal port or from the periumbilical port. Sonographic exam of the gallbladder is approached through the liver using a 5- or 7-MHz transducer. The bile ducts can be visualized through a compressed duodenum or gastric antrum using a 7-MHz transducer, but placing the transducer directly on the ducts should be avoided, because reverberation artifact limits its sensitivity. Color flow images are helpful for distinguishing the CBD from the portal vein, for identifying the insertion of cystic duct into the CBD, and for identifying any aberrant biliary anatomy.

Evaluation of the Biliary Tree

As laparoscopic cholecystectomy has become the standard of care for gallbladder disease, the use of laparoscopic US during this procedure will emerge as an increasing possibility and a viable alternative to cholangiogram. Laparascopic US is now recommended as the primary screening modality for evaluating bile duct calculi because of its safety, efficiency, and overall cost effectiveness (Machi et al, 1999). IOUS is at least as good as cholangiogram, perhaps better, at detecting stones during laparoscopic cholecystectomy (Catheline et al, 1999; Siperstein

et al, 1999; Tranter & Thompson, 2003). Perry and associates recently published their results from a prospective study performed between 1995 and 2005. Laparoscopic US was performed in 236 (60%) of 396 laparoscopic cholecystectomies performed for cholelithiasis. US had a positive predictive value of 100%, a negative predictive value of 99.6%, a sensitivity of 92.3%, and a specificity of 100% for detecting CBD stones (Perry et al, 2008). Proficiency with IOUS requires some time to develop, which may explain why it is not employed more liberally for biliary disease.

Laparoscopic US is a useful adjunct for oncologic staging of gallbladder carcinoma and cholangiocarcinoma. Sonographic findings not only reveal subtle liver metastases but may help to further define the local extent of invasion of these tumors into the adjacent liver bed and also outline the involvement of the ductal system, and Doppler and color flow images may help distinguish biliary sludge from polyps and other intraluminal tumors. Other applications of laparoscopic US include evaluating biliary strictures and malignant biliary obstructions and planning of surgical reconstructions such as biliary bypass procedures. These approaches and others are summarized in a review by Berber and Siperstein (2004).

Pancreatic Disease

Technical Considerations

IOUS is commonly applied in conjunction with oncologic staging of pancreatic and periampullary tumors. When performed laparoscopically, a right upper or left upper quadrant port is used, so as to orient the probe transversely along the long axis of the pancreas. Frequently, a periumbilical port is required to image the head, neck, and uncinate process. A 7-MHz transducer is used that can be placed directly on the surface of the pancreas or through the overlying omentum.

Evaluation of the Pancreas

The principal application of IOUS for pancreatic disease is during staging laparoscopy. Its utility lies in demonstrating vascular invasion, liver metastases, and the degree of resectability. Approximately 20% to 35% of patients deemed resectable based on preoperative radiologic assessment harbor occult metastases or locally invasive disease, which preclude curative resection. These concepts will be discussed further for staging laparoscopy.

Other applications for US in pancreatic surgery include localizing islet cell tumors. These particularly small lesions may be difficult to visualize or palpate in the body or tail, and sonographic images may help delineate these and other malignant or premalignant tumors in the distal portions of the pancreas (Hayashibe et al, 2005). Finally, US can help identify pancreatic ductal abnormalities among patients with pancreatitis and may be useful during drainage procedures, such as cystogastrostomy.

INTRAOPERATIVE CHOLANGIOGRAPHY

Technical Considerations

Intraoperative cholangiography (IOC) is most commonly used during elective cholecystectomy to assess for retained stones and to provide clarification of the biliary anatomy; rarely is it necessary or helpful in assessing extent of biliary tumors or during hepatic resection (Sotiropoulos et al, 2004). Interestingly, Mirizzi first described the procedure in 1937, as a method to help delineate the anatomy of the biliary tree in advanced cases of biliary disease (Mirizzi, 1937).

IOC is typically performed by first identifying the cystic duct at its junction with the gallbladder neck (Yamakawa, 1976). The gallbladder is retracted laterally, and the cystic duct and artery are dissected free and cleared of the fat and overlying peritoneum in the area of the triangle of Calot. A small ductotomy (less than 50% of the duct circumference) is made in the cystic duct adjacent to the gallbladder neck. The cystic duct is best approached from a right subcostal port or from the periumbilical port; we prefer the former. A 60-cm, tapered 5-Fr cholangio catheter is then advanced directly into the cystic duct through the ductotomy. A specialized cholangiogram clamp, often termed an *Olsen cholangiogram clamp,* secures the catheter in place (Decker et al, 2003).

A second method of cholangiography is performed percutaneously. With this method, access to the cystic duct is achieved via a separate puncture in the abdominal wall using at least a 2-inch, 14-gauge needle. In a similar fashion, a 5-Fr cholangio catheter is guided through this needle and directly into the cystic duct. The catheter is first flushed with saline to confirm its patency, and then radiographic contrast is infused, and fluoroscopic images are obtained. A complete study demonstrates flow of contrast into the duodenum and shows opacification of both the right and left hepatic ducts.

Choledocholithiasis

Two factors must be considered when performing intraoperative cholangiography for the evaluation of retained bile duct stones (Hyser et al, 1999; Sigel et al, 1983; Tokumura et al, 2002). First, most stones in the biliary tree are suspected on clinical grounds or after serologic testing for liver enzyme elevation and are often visualized during preoperative US (see Chapter 13), ERCP (see Chapter 18), or MRCP (see Chapter 17). Common presentations include obstructive jaundice, cholangitis, biliary colic with abnormal liver function test results, and acute pancreatitis. The incidence of clinically silent choledocholithiasis is low, occurring in roughly one in 25 cases of biliary colic (Metcalfe et al, 2004; Nugent et al, 2005). Even when missed during cholecystectomy, these residual stones rarely if ever cause symptoms or become clinically relevant (Sarli et al, 2003a; see Chapters 30 and 35). Charfare and Cheslyn-Curtis (2003) investigated the incidence of retained biliary stones after 600 laparoscopic cholecystectomies. With a median follow-up of 3 years among 438 patients (73%), findings from this study indicate that residual bile duct stones occurred in only seven cases (1.2%).

The second factor to consider when performing IOC is that false-positive results are not uncommon, occurring up to 4% of the time (Metcalfe et al, 2004). As a result, routine application of IOC for the evaluation of unsuspected choledocholithiasis may subject patients to unnecessary bile duct explorations or ERCP studies, with considerable costs to both patients and providers (Cuschieri & Berci, 1984; Sarli et al, 2003b).

Biliary Injuries

In the late 1980s, IOC emerged as a method that could potentially help avoid major injury to the biliary system. Today laparoscopic cholecystectomy is the most commonly performed elective abdominal surgical procedure in the United States (see

Chapter 34), with more than 750,000 cases performed annually. Injury to the bile duct is rare but is a major contributor to patient morbidity (see Chapter 38). These injuries are typically due to either technical error or misidentification of the duct: the technical error is that the CBD is inadvertently transected, and a surgical clip is sometimes applied to a misidentified CBD.

Four mechanisms of injury have been described (Way et al, 2003). Class I injuries involve an incision (i.e., an incomplete transection) of the CBD and typically occur when the bile duct is mistaken for a cystic duct. Class II injuries represent lateral damage to the common hepatic duct. Class III injuries are the most common and represent a CBD mistaken for a cystic duct; these are not immediately recognized intraoperatively. Finally, class IV injuries occur when a right hepatic duct is mistaken for a cystic duct.

Flum and colleagues (2003) analyzed nationwide Medicare data from 1992 to 1999. Among 1.6 million cholecystectomies performed, roughly 8000 bile duct injuries occurred overall (0.5%); these occurred in 0.39% of patients undergoing cholecystectomy *with* intraoperative cholangiogram and in 0.58% of patients undergoing cholecystectomy *without* cholangiogram ($P < .001$). The adjusted relative risk of bile duct injury when cholangiogram was not employed was 1.71 (95%, confidence interval [CI], 1.38 to 2.28). Inexperienced surgeons were twice as likely to cause bile duct injuries when cholangiogram was not used, as compared with their more experienced colleagues. These estimates had been observed in an earlier study (Fletcher et al, 1999).

Another benefit of intraoperative cholangiogram, with respect to biliary injuries, is the earlier recognition and correction of biliary injury (see Chapters 42A and 42B). Ideally, IOC should be performed prior to dividing the presumed cystic duct. If cannulation of the CBD, rather than the cystic duct, occurs, the cholangiogram catheter can be removed, and the ductotomy can be addressed by placing a T-tube, without the need for formal biliary reconstruction. The T-tube enables the CBD to heal without stricture formation, and the tube can be removed nonoperatively several weeks after the cholecystectomy. The alternative scenario is complete transection of the CBD, a class III injury. In the absence of cholangiogram, this transection is seldom recognized intraoperatively, typically presents postoperatively, and results in significant patient morbidity. Management undoubtedly requires an open bilioenteric anastomosis for repair, thus intraoperative cholangiogram has the potential to not only prevent bile duct injury but also to mitigate its impact if injury does occur (Giurgiu et al, 1999).

Controversies

The routine application of IOC during elective cholecystectomy has been called into question in recent years and is still a matter of considerable debate (Mills et al, 1985; Soper & Brunt, 1994; Nickkholgh et al, 2006; Metcalfe et al, 2004; Massarweh & Flum, 2007). Critics of routine cholangiogram suggest that such an approach increases the risk of ductal complications (i.e., stricture) and pancreatitis, wastes time and money, and is seldom indicated if the critical view of safety is achieved. Proponents argue that routine cholangiogram is a safe, accurate, quick, and cost-effective method for evaluating the bile duct (Amott et al, 2005; Wenner et al, 2005). Although we favor a selective approach, we also recognize that the success of either approach is highly variable and likely to depend on each surgeon's familiarity with cholecystectomy and cholangiography. Whether a selective or routine cholangiogram policy is adopted, it is critical that surgeons become comfortable with interpreting cholangiogram results. Way and others (2003) reported that although 43 cholangiograms demonstrated a bile duct injury, only nine were correctly interpreted at the time of surgery.

STAGING LAPAROSCOPY

Management of hepatobiliary and pancreatic malignancies is contingent upon accurate oncologic staging to identify patients who might harbor curable disease. Despite refinements in several diagnostic modalities that include but are not limited to EUS, ERCP, high-resolution CT, and MRCP, few patients are appropriate candidates for curative resection. Oncologic staging seeks to determine tumor size and characteristics, the extent of regional spread to adjacent structures, and the magnitude of any distant spread.

The growth in popularity of laparoscopy in the early 1980s added a new modality to the field of hepatobiliary and pancreatic surgery. Specialty surgeons in these disciplines frequently confront occult, unresectable disease at the time of laparotomy (de Rooij et al, 1991; Espat et al, 1999; Lillemoe et al, 1999). Reports vary, but this scenario occurs roughly 20% to 25% of the time. Jarnagin and associates (2000) demonstrated that among a cohort of 186 patients with primary and secondary hepatic malignancies, 25% were noted to harbor unresectable disease at the time of laparoscopic staging, and 65% of this group were spared an unnecessary laparotomy. Callery and colleagues (1997) similarly revealed unresectable pancreatic and periampullary disease among 11 of 50 patients, and comparable outcomes have been described by others (D'Angelica et al, 2003; Vollmer et al, 2002). Overall, these findings demonstrate that staging laparoscopy can further clarify whether curative resection is possible, confirm unresectable disease, and help specialty surgeons tailor curative and palliative operations for patients with hepatobiliary and pancreatic malignancies (see Table 21.1). Controversy still exists, however, regarding the true added value of the procedure, particularly in an era of more effective preoperative imaging (see Table 21.2).

Surgical Technique

Technical Considerations

Staging laparoscopy is typically performed under general anesthesia. The patient is placed supine on the operating table and fully prepared as for laparotomy. The abdomen is marked for the intended open incision; at our institution, we favor a bilateral subcostal incision two to three fingerbreadths below the costal margin. In the case of pancreatic disease, access to the peritoneum is made through a 1-cm subumbilical incision; for hepatobiliary cases, a 1-cm incision is made along the midclavicular line. For both, the fascia and peritoneum are incised under direct vision, a blunt 5- or 10-mm port is placed, and insufflation is begun with the initial flow rate set at 2 L/min and gradually increased to 15 L/min to achieve an intraabdominal pressure of 10 to 14 mm Hg.

We use a 5- or 10-mm, 30-degree angled telescope to inspect the abdomen. Although we prefer a multiport technique to facilitate obtaining biopsy specimens and laparoscopic US, others may use a single-port approach. Two more ports are placed under direct vision, in the left and right upper quadrants. For pancreatic cases, another 5-mm port is inserted along the

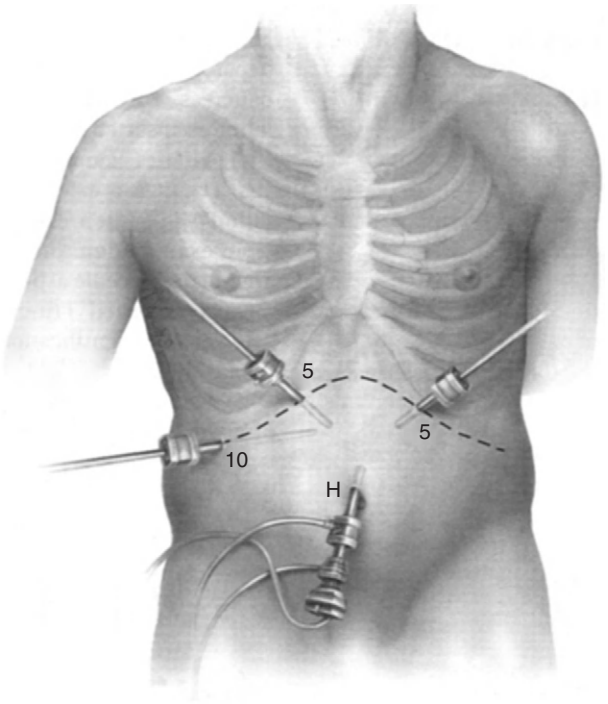

FIGURE 21.2. Port placement for laparoscopic staging. For patients undergoing staging for hepatobiliary diseases, the camera may be placed along the line of a subcostal incision.

incision line to the right of the midline (Fig. 21.2). Entry of these ports is followed by a systematic examination of the peritoneal cavity; adhesions may need to be divided to adequately inspect the abdominal viscera and peritoneum. All four quadrants are examined for evidence of peritoneal deposits; biopsies are taken of any suspicious lesions using standard biopsy forceps, and samples are sent for histologic examination (Fig. 21.3). If clinically indicated, peritoneal cytology can be sampled at this time. After instillation of 200 mL of warm normal saline

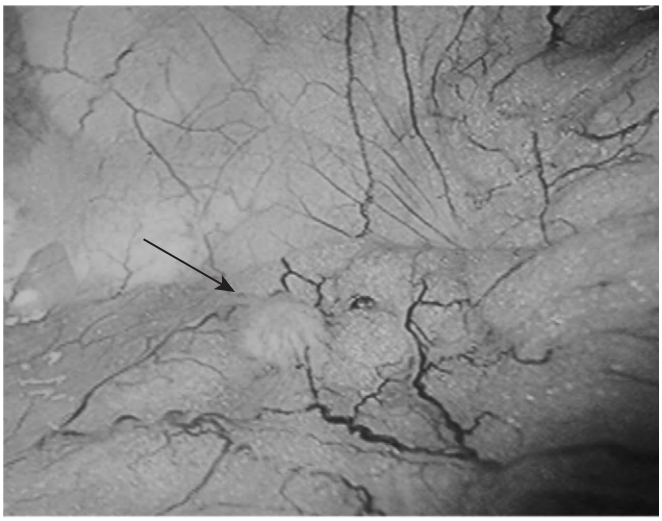

FIGURE 21.3. Peritoneal nodule. *Arrow* indicates a metastatic deposit, which can be sampled easily using a cup forceps to obtain a biopsy.

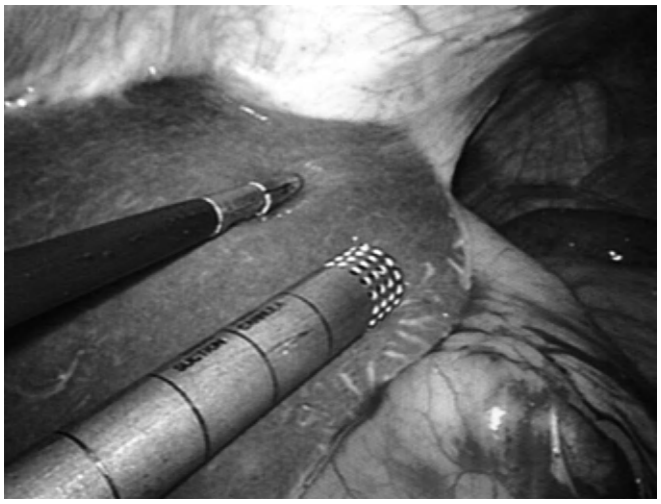

FIGURE 21.4. Examination of the liver. A blunt 10-mm instrument is used in conjunction with a 5-mm grasper.

and gentle agitation, the irrigant is aspirated from the right and left subhepatic spaces and from the pelvis, and a sample is sent for cytologic examination.

Following inspection of the peritoneum, attention is turned to the anterior and posterior surfaces of the left lateral segment of the liver and the anterior and inferior surfaces of the right lobe (Fig. 21.4). Next, the hepatoduodenal ligament, the foramen of Winslow, and hilum of the liver are examined for lymphadenopathy (Fig. 21.5). Any suspicious nodes are excised and sent for pathologic analysis. The patient is then placed in the 10-degree Trendelenburg position, and the omentum is retracted into the left upper quadrant. The ligament of Treitz and the inferior surface of the transverse mesocolon are inspected for metastatic deposits and for lymphadenopathy (Fig. 21.6).

The patient is repositioned in the supine position, and the left lateral segment of the liver is elevated superiorly with a

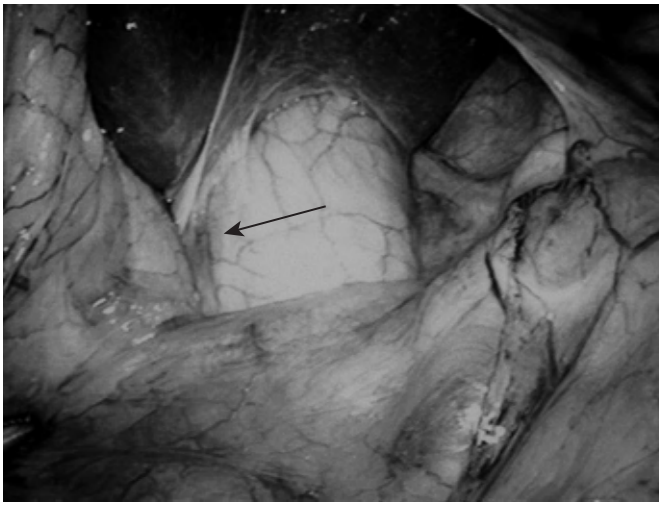

FIGURE 21.5. The hepatoduodenal ligament can be examined from the left (shown) or right side. Periportal adenopathy (*arrow*) is shown.

FIGURE 21.6. Examination of the ligament of Treitz. Proximal jejunum (*solid arrow*) and inferior mesenteric vein (*dashed arrow*) are shown.

retractor via the left upper quadrant port. The lesser omentum is opened to visualize the caudate lobe of the liver and the vena cava. From this vantage point, the anterior aspect of the head of the pancreas, posterior wall of the stomach, and "gastric pillar," which contains the left gastric artery and vein, can be seen (Fig. 21.7). The left gastric artery can be followed to its origin so as to allow inspection of the celiac axis (Table 21.3).

Laparoscopic Ultrasound

US can help the surgeon further assess the relationships of the primary tumor to adjacent structures (see Chapter 13). A systematic examination of the liver, biliary tree, and pancreas takes place as previously described. A 6- to 10-MHz T-shaped linear- or curvilinear-array transducer is placed over the left lateral segment to assess segments I, II, and III. The probe is moved to the right liver and placed on the dome of the liver. The vena cava is visualized posteriorly, and the hepatic and portal veins are seen as the probe is moved anteriorly.

Placement of the probe in the transverse direction over the hepatoduodenal ligament allows the common hepatic duct, CBD, hepatic arteries, and portal vein to be visualized (Fig. 21.8). Similarly, at the confluence of the portal vein, the splenic and superior mesenteric veins can be identified. Finally, the superior mesenteric artery is delineated, and its relationship to any pancreatic tumor is assessed. The probe is placed on the gastrocolic omentum and advanced first caudally and then through the window in the gastrohepatic omentum. Laparoscopic US can help facilitate pathologic biopsies and needle aspirations of any suspicious lesions (Fig. 21.9, Table 21.4).

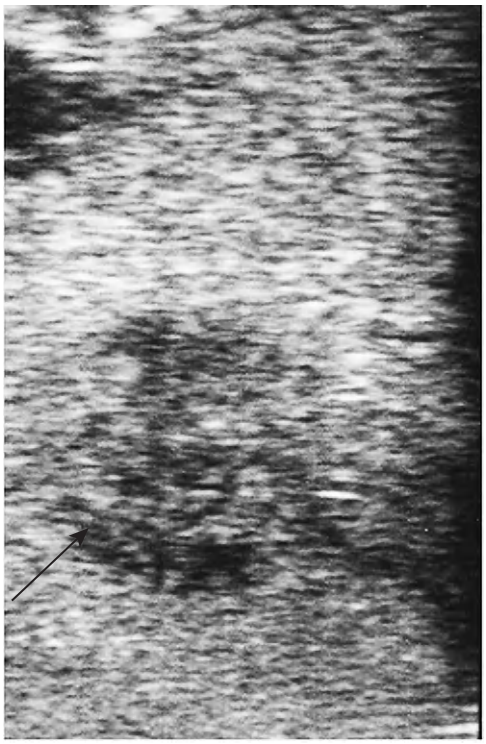

FIGURE 21.9. Hepatic metastasis (*arrow*) in a patient with pancreatic adenocarcinoma.

hemorrhage, visceral perforation, and intraabdominal infection. A common misconception is that suspected malignancy precludes staging laparoscopic examination. An early report raised concern about "port site" tumor implants 2 weeks after laparoscopy in a patient with malignant ascites (Dobronte et al, 1978); this concern was also expressed by later studies in the 1990s, which report rates of port-site recurrence ranging from 0.8% to 2% (Curet, 2004; Nieveen van Dijkum et al, 1999; Pearlstone et al, 1999). Shoup and colleagues (2002) examined this question in a series of 1650 diagnostic laparoscopic procedures, in which 4,299 trocars were inserted. The overall rate of port site recurrence was 0.8% (13 cases); five of those occurred in patients with local disease; the remaining eight occurred in patients with documented metastatic disease. The findings of this study suggest that recurrence is a marker of more advanced disease rather than being an isolated event directly attributable to laparoscopy. Overall, Shoup and associates concluded that staging laparoscopy can be performed safely in the setting of presumed malignancy. This concept has been confirmed by others, most recently by Velanovich (2004), who demonstrated that the incidence of port site recurrence (3%) is equivalent to that of wound recurrence in patients who had an exploratory laparotomy alone (3.9%).

Staging Laparoscopy for Potentially Resectable Disease

Hepatobiliary Malignancy

Determination of resectability of hepatobiliary malignancy begins with CT or MRI; however, laparoscopy plays an essential role in detecting occult disease (Jarnagin et al, 2001a; Jeffers et al, 1988; Lightdale, 1982; Torzilli et al, 2002). Roughly 20% to 25% of patients initially believed to have resectable disease will harbor occult disease detected by laparoscopy that precludes curative resection (Conlon et al, 2003; Weber et al, 2002). As a result, one in five patients is spared a laparotomy. When combined with laparoscopic US, these outcomes are more specific.

In addition to the quality of the preoperative imaging, the yield of laparoscopy will depend critically on the underlying disease. For example, hilar cholangiocarcinoma is frequently unresectable, based on local tumor extent, which is difficult to determine laparoscopically; it infrequently gives rise to peritoneal disease, which relatively easy to identify laparoscopically. The yield of laparoscopy is therefore lower than for other diagnoses, such as gallbladder cancer.

D'Angelica and others (2003) have provided a detailed analysis of staging laparoscopy for suspected hepatobiliary malignancy. Among 401 patients, a complete laparoscopic staging assessment was performed in 291 cases (73%), an incomplete assessment was done in 88 cases (22%), and 22 (6%) were failed examinations. Unresectable disease was discovered at the time of laparoscopy in 84 cases, for an overall incidence of 21%. Of the remaining 317 patients felt to have resectable disease during laparoscopic examinations, 69 had unresectable disease identified during open exploration, for an overall false-negative rate of 22%. This high false-negative rate was attributed primarily to failure to identify lymph node metastases or to detect vascular invasion. However, despite these outcomes, staging laparoscopy increased the resectability rate from 62% to 78%. Concomitant laparoscopic US has the potential to further increase resectability rates and to avoid unnecessary laparotomies, added benefits that have been described by several other studies (John et al, 1994; Callery et al, 1997).

Laparoscopy is most accurate for identifying peritoneal deposits (80% accuracy) and additional hepatic disease (63% accuracy), and it is least accurate for identifying nodal metastases (7% accuracy) and vascular invasion (18% accuracy). Factors that could improve the yield from laparoscopy include the surgeon's preoperative judgment regarding the likelihood of resectability, the completeness of laparoscopic staging examinations, and the primary diagnosis; the yield was highest with biliary malignancies and lowest with colorectal metastases (D'Angelica et al, 2003).

Laparoscopic staging can be used for management of colorectal metastases (Rahusen et al, 1999; see Chapter 81A). Approximately one half of all patients with new diagnoses of colorectal cancer will subsequently develop liver metastases, yet only 20% are suitable candidates for curative hepatic resection. Determination of resectability is less straightforward for these patients, and the controversy relates to the philosophy and expertise of the surgical team. In general, however, most authors agree that hepatic cirrhosis, extrahepatic tumor spread, and significant bilobar disease are relative contraindications for hepatic resection. A recent study explored the role of staging laparoscopy in 51 patients with colorectal liver metastases (de Castro et al, 2004). Occult disease at the time of laparoscopy was discovered in 12% of patients; however, 18% of cases were understaged, and unresectable disease was found at subsequent laparoscopy. The authors suggested that adhesions from prior colon resections contribute to this false-negative rate.

In an effort to improve the yield of staging laparoscopy for hepatic colorectal metastases, a study used a clinical risk score to try to determine which patients are more likely to have nonradiologically detectable disease. The clinical risk score uses five

Table 21.5

Criteria for Clinical Risk Score to Determine Risks for Extrahepatic Disease

Lymph node–positive tumor
Disease-free interval between primary and detection of metastasis: <12 mo
Number of hepatic tumors: >1 (based on preoperative imaging)
Carcinoembryonic antigen: >200 ng/mL within 1 mo of surgery
Size of the largest hepatic tumor: >5 cm

From Jarnagin WR, et al, 2001b: A clinical scoring system predicts the yield of diagnostic laparoscopy in patients with potentially resectable hepatic colorectal metastases. Cancer 91:1121-1128.

Table 21.6

Criteria for Unresectability in Pancreatic Cancer

Histologically confirmed hepatic, serosal, peritoneal, or omental metastases
Tumor extension outside pancreas
Celiac or high portal node involvement confirmed by frozen section
Extensive portal vein involvement by tumor or invasion/encasement of celiac axis, hepatic artery, or superior mesenteric artery

Data from Conlon KC, Brennan MF, 2000: Laparoscopy for Staging Abdominal Malignancies. St Louis, Mosby; and Conlon KC, Minnard EA, 1997: The value of laparoscopic staging in upper gastrointestinal malignancy. Oncologist 2:10-17.

clinical parameters: each is shown as an independent predictor of outcome after resection, and each criterion is assigned one point. Forty-two percent of patients with a clinical risk score greater than 2 had unresectable disease detected at laparoscopy versus 0% of patients with clinical risk score scores of 0 to 1 (Table 21.5; Grobmyer et al, 2004; Jarnagin et al, 2001b). Targeting laparoscopy to high-risk patients should avoid unnecessary laparoscopic staging in low-risk patients, whereas performing it in the high-risk group should prevent needless staging laparotomies and improve the yield overall from laparoscopy.

Pancreatic and Periampullary Malignancy

Our approach for the staging of pancreatic adenocarcinoma is illustrated in Figure 21.10. A minority of patients (20% to 35%) with pancreatic and periampullary malignancies (see Chapters 58 and 59) are suitable for curative resection (Conlon & Minnard, 1997; Conlon & Brennan, 2000; Jimenez et al, 2000). Similar to management of hepatobiliary malignancies, initial diagnostic evaluation begins with high-resolution CT. Today's studies can predict resectability in 57% to 88% of cases (Freeny, 2001; Pisters et al, 2001; Contreras et al, 2009; Mayo et al, 2009). Other useful investigative modalities that may augment CT evaluations include MRI, MRCP, ERCP, EUS, and positron emission tomography (PET).

Cuschieri and colleagues first described staging laparoscopy for pancreatic malignancy in 1978; they revisited it later, in 1988. In the earlier report, laparoscopic examinations demonstrated that 42 (57%) of 73 patients had unresectable disease, mainly peritoneal or omental metastases. Since these landmark papers, technologic advances have allowed laparoscopic staging to develop so as to allow it to be comparable to open exploration in defining resectability (Table 21.6). In 1993, Conlon and associates from Memorial Sloan-Kettering Cancer Center introduced laparoscopic staging for patients with suspected adenocarcinoma of the pancreas (Conlon et al, 1996). Prior to 1993, only about one third of patients considered to harbor resectable disease after preoperative assessment ultimately underwent curative resection procedures. Between 1993 and 1998, this rate increased considerably to roughly 63%.

Other groups have reported similar findings. Warshaw and colleagues (1990) compared CT, MRI, angiography, and laparoscopy in 88 patients and found that CT failed to show peritoneal disease in 22 cases discovered at laparoscopy. MRI conferred no further benefit, and laparoscopy had a sensitivity of 96%, having understaged 1 patient. This same group reported

that 39 patients (44%) were spared a laparotomy because of metastases discovered at laparoscopy not seen on spiral CT. This group performed staging laparoscopy as a day-case procedure, further reducing inpatient hospital time. Reddy and associates (1999) confirmed these findings in a later report; 29% were spared further intervention. A more recent prospective study (Doran et al, 2004) reported outcomes of 239 patients with pancreatic cancer who were submitted to staging laparoscopy; of these, 190 were considered to have resectable disease based on CT findings. After staging laparoscopy, roughly 15% of patients were spared a laparotomy. This estimate likely reflects advancements in high-resolution imaging, but it also demonstrates that despite refinements in imaging techniques, peritoneal disease is not easily revealed on CT.

Beyond these estimates, staging laparoscopy enables the surgeon to more easily detect occult metastases (Shoup et al, 2004). Contreras et al (2009) discovered further that within a 4-year period, occult metastases among 52 patients with potentially resectable pancreatic tumors were more likely to be detected during staging laparoscopy when compared with open explorations (32% vs. 18%). Many other centers have reported similar results (Table 21.7).

Laparoscopic ultrasound is a useful adjunct during staging laparoscopy. John and colleagues (1995) demonstrated that the addition of US improved the sensitivity from 65% to 80%. Callery and associates (1997) similarly reported 96% specificity and 92% sensitivity when laparoscopic US was combined with staging laparoscopy. Vollmer and others (2002) studied 72 patients with pancreatic head cancers and found that 22 had metastatic disease that precluded resection; laparoscopy alone identified 14 of these 22 patients; the remaining 8 patients had major vessel encasement or liver metastases revealed by laparoscopic US. Minnard and colleagues (1998) similarly reported that laparoscopic US altered the planned surgical treatment in 14% of patients, whose staging laparoscopic procedures were equivocal. Sonography was particularly useful in identifying venous (42%) and arterial (38%) involvement, which precludes curative resection.

Controversies

Some critics of routine staging laparoscopy believe that unresectable disease due to vascular involvement or local extension can only be confirmed during open explorations (Friess et al, 1998). Others suggest that the role for laparoscopy is limited only to those patients who do not require some form of palliation, either biliary or gastric bypass (Holzman et al, 1997; Andren-Sandberg et al, 1998). Finally, some argue that staging laparoscopy is costly, time consuming, and of decreasing diagnostic yield because of improvements in radiologic imaging techniques (Spitz et al, 1997).

Two recent studies suggested that the utility of staging laparoscopy depends on the type of malignancy (Vollmer et al, 2002; Brooks et al, 2002). Staging laparoscopy has not been shown to be useful among patients with ampullary or duodenal tumors, because these cancers tend to present earlier and are less likely to have metastatic disease at the time of presentation. In contrast, staging laparoscopy may have a role in patients with nonfunctioning islet cell tumors (Hochwald et al, 2001), which manifest with a large tumor mass and often in the presence of metastatic disease.

CHAPTER 22

Intraoperative and immediate postoperative management

Mary Fischer and Jose A. Melendez

OVERVIEW

Improvements in patient selection criteria and advances in hepatic surgical techniques and perioperative care have expanded the pool of patients who are candidates for hepatobiliary surgical procedures. Patients with known underlying hepatic parenchymal disease are at greater operative risk, particularly for liver-related and biliary tract–related procedures (see Chapters 2, 70B, and 90A). More recent studies have documented the progressive safety of liver resection in noncirrhotic patients (Belghiti et al, 2000; Jarnagin et al, 2002; Mullen et al, 2007). The anesthetic problems in connection with liver transplantation (Chapter 97B) and cirrhosis (Chapter 90A) are discussed elsewhere in this book. This chapter addresses the unique anesthetic considerations of noncirrhotic patients undergoing hepatobiliary operations, with an emphasis on problems related to joint anesthetic and surgical management.

PREOPERATIVE EVALUATION

With the advent of modern techniques, the anesthetic risk attributed to any surgical procedure depends heavily on the preoperative status of the patient. In hepatobiliary patients, the presence of preoperative pulmonary, cardiac, or hepatic disease significantly augments the incidence of postoperative morbidity and mortality. Although in the past, the presence of comorbidities favored elective intensive care unit (ICU) admission, currently they more appropriately designate a select group of patients who may potentially fail fast tracking. These patients need to be recognized at the preoperative visit and clinically optimized before surgery. Postoperative morbidity adversely affects long-term outcome after hepatic resection, therefore efforts aimed at reducing perioperative morbidity will likely further enhance the therapeutic benefit of resection (Ito et al, 2008).

Cardiac Evaluation

Patients undergoing liver surgery are at significant risk of cardiovascular morbidity and mortality. Although the perioperative event rate has declined as a consequence of better anesthetic and surgical techniques, perioperative cardiac complications remain a significant problem. The first step in preoperative care is to identify patients at risk for perioperative cardiac events. The risk of perioperative cardiac complications is the summation of an individual patient's risk and the cardiac stress related to the surgery. Clinical history, physical examination, and review of the electrocardiogram usually provide enough data to estimate cardiac risk. Active cardiac conditions may preclude all but emergent surgery.

For most stable patients, cardiac risk can be derived from the Revised Cardiac Risk Index (Lee et al, 1999b). This simple index identifies six independent risk factors: 1) high-risk type of surgery, 2) history of ischemic heart disease, 3) history of congestive heart failure, 4) history of cerebrovascular disease, 5) diabetes mellitus, and 6) renal insufficiency. The number of clinical risk factors, the risk level of the surgery, and the functional capacity of the patient will determine the need for further testing prior to surgery or pharmacologic intervention perioperatively (Poldermans et al, 2008). For those patients with clinical risk factors, the 2007 American College of Cardiology/American Heart Association guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery are an excellent framework for evaluating cardiac risk in the perioperative period for patients undergoing liver surgery (Fleischer et al, 2007).

Over the years, a shift in perioperative management has been seen, away from treating coronary obstruction with interventions such as surgery and stents and toward medical therapy aimed at stabilizing coronary plaque and preventing myocardial oxygen supply and demand mismatch. Today, preoperative cardiac testing, cardiac stenting, and coronary revascularization are performed for the same indications as those used in the nonoperative setting (Poldermans et al, 2008), but β-blockers, statins, and aspirin are now widely used in the perioperative setting. Compelling evidence supports perioperative β-blocker therapy, unless contraindicated, in patients with coronary artery disease. β-Blocker therapy has been shown to reduce the incidence of perioperative ischemic events and myocardial infarction (Goldman, 2001; Lee et al, 1999a). Recently the risk benefit of this therapy in patients without coronary artery disease has been challenged. The perioperative ischemic evaluation (POISE) study showed an increased incidence of ischemic stroke in combination with intraoperative bradycardia and hypotension (Devereaux et al, 2006). In a retrospective review of patients who underwent noncardiac surgery, perioperative β-blockers showed no benefit—and possible harm—in low-risk patients, but in high-risk patients, a benefit was seen (Lindenauer et al, 2005).

Communication among the patient's cardiologist, surgeon, and anesthesiologist is essential for the management of hepatobiliary surgical patients who have coronary artery stents. Clinical judgment is of the utmost importance to balance the risk–benefit ratio of antiplatelet therapy interruption versus continuation. Aspirin should never be interrupted, unless the risk of bleeding far outweighs the risk of stent thrombosis (Newsome et al, 2008).

In hepatobiliary patients with a history of alcohol abuse, cardiac assessment should include the evaluation of

myocontractile function. Cirrhotic cardiomyopathy classically occurs in men 30 to 55 years old who have been alcohol abusers for more than 10 years (Braunwald, 1997). Putative mechanisms of damage are direct toxic effects of 1) ethanol and its metabolite acetaldehyde; 2) nutritional deficiencies, particularly of thiamine (beriberi); and 3) additives in commercial products, such as cobalt in beer. Alcohol and acetaldehyde have been shown to decrease calcium binding and transport, myocardial lipid metabolism, myocardial synthesis, and myocardial adenosine triphosphatase (ATPase) activity. The two basic patterns of cardiac dysfunction are 1) left ventricular dilation with impaired systolic function and 2) left ventricular hypertrophy with diminished compliance and normal or increased contractile performance. Presenting manifestations range from insidious onset to catastrophic left-sided cardiac failure. Anginal chest pain does not occur, unless the patient has concomitant coronary artery disease or aortic stenosis.

Pulmonary Evaluation

Despite steady advances in care, patients with respiratory disease remain at increased risk for postoperative pulmonary complications (PPCs). Indeed postoperative pulmonary complications may rival cardiovascular complications in frequency and severity (Lawrence et al, 1995). Studies that examine risk factors for PPCs have limitations, but some consistent patterns are seen. The three most important risk factors for PPCs are 1) pulmonary disease, 2) cigarette smoking, and 3) the site of surgery, with abdominal surgery being one of the highest risk sites (Warner, 2000). Of note, pulmonary function testing per se is not useful in predicting risk (McAlister et al, 2003); thus routine pulmonary function testing is not justified unless it is part of an effort to optimize preoperative pulmonary status. The definition of "optimization" depends on the type of respiratory disease and the individual patient. Consultation with the surgeon and pulmonologist will help determine whether a course of systemic corticosteroids or antibiotics is warranted perioperatively. Despite the increased risk of PPCs in patients with preexisting pulmonary disease, no prohibitive level of pulmonary function has been established for which surgery is contraindicated (Nunn et al, 1988; Kroenke et al, 1993). A prospective study did not find an elevated $Paco_2$ level to be a risk factor among surgical candidates, hence clinicians should not use arterial blood gas analyses to identify patients for whom the risk of surgery is prohibitive (Kearney et al, 1994).

Obese patients are at risk of suffering from a number of respiratory derangements, including obstructive sleep apnea (OSA), obesity hypoventilation syndrome, and restrictive impairment. The increase in body mass also results in increased oxygen consumption and carbon dioxide production. With these isssues in mind, it is not surprising that acute PPCs are twice as likely in obese and OSA patients (Rose et al, 1994; Dindo et al, 2003). Many patients with OSA are undiagnosed, but a strong relationship exists between obesity and OSA (Strohl et al, 1996). The American Society of Anesthesiologists addressed this issue with practice guidelines to assess patients for possible OSA before surgery and to provide careful postoperative monitoring for those suspected to be at risk (Gross et al, 2006).

An association was also found between obesity and OSA and several medical conditions, such as increased risk of venous stasis, pulmonary embolism, hypertension, cerebral vascular acccidents, cardiomyopathy, arrythmias, and ischemic heart disease (Dominguez et al, 1993; Strohl et al, 1996; Gupta et al, 2001). With these issues in mind, the anesthesiologist should have an informed discussion with the patient about the increased risk of morbidity and mortality and should also work with other members of the patient care team to determine whether any interventions need to be initiated before surgery in an effort to minimize complication risk.

Polysomnography is the gold standard for diagnosis of OSA, but it is an expensive and limited resource. The most reasonable approach is to check room air pulse oximetry. If the patient has an oxygen saturation level less than 96%, further evaluation is warranted; a 2-week period of continuous positive airway pressure therapy has been shown to be effective in correcting abnormal ventilatory drive and improving cardiac function (Lin, 1994; Loadsman et al, 2001). In addition, deep venous thrombosis prophylaxis should be discussed with the surgeon.

Hepatic Evaluation

Risk factors and symptoms of liver disease are not as well defined as those in other organ systems. The diagnosis of liver disease requires a high degree of suspicion and careful probing of the clinical history to identify specific risk factors for liver disease, such as previous blood transfusions, jaundice, travel, tatoos, high-risk sexual behavior, illicit drug use, excessive alcohol intake, and chemotherapy (Suman & Carey, 2006).

In North America and Europe, most hepatic resections are performed for metastatic disease. The operative outcome for hepatobiliary surgery is linked to severity of hepatic parenchymal disease and the extent of postoperative functional reduction (see Chapter 2). In patients with mild or well-compensated chronic hepatic disease, operative outcome is likely to be indistinguishable from the outcome in the general population. Patients with hepatocellular carcinoma (HCC) have poorer outcome than those with metastatic disease given the propensity of HCC to develop in the cirrhotic liver (Fattowich, 2003).

The goal of preoperative screening is to determine the presence of preexisting liver disease without the need for extensive or invasive monitoring. Liver function tests can measure different aspects of hepatic function, but as a group of tests, they lack specificity and are often affected by nonhepatic function. These biochemical markers cannot quantify the hepatic disease. Another issue is finding abnormal hepatic function test results in asymptomatic patients. In general, for asymptomatic patients with mildly elevated alanine and aspartate aminotransferase levels and a normal bilirubin concentration, cancellation of surgery is rarely indicated. In patients with significant abnormalities, detailed investigation is warranted to evaluate for underlying cirrhosis, given the high perioperative risk observed in patients with cirrhosis. The need for further investigation in these patients is highlighted by studies that report an incidence of undiagnosed cirrhosis of 34% in asymptomatic patients with abnormal liver function results (Hay et al, 1989; Hultcrantz et al, 1986). It is important to identify patients with underlying hepatic impairment, because they may be at increased risk for further injury from alterations in splanchnic blood flow that occur during anesthesia and intraabdominal surgery.

Measurement of metabolic liver function would provide the necessary predictive information to assess this risk. Metabolic liver function tests (see Chapter 2), such as the aminopyrine

breath test and indocyanine green clearance, may have predictive value in this regard but are not routinely performed. To date, risk assessment has been primarily performed in patients with known liver disease (Child-Turcotte-Pugh score), but the quantification of risk in asymptomatic patients should not be extrapolated from these studies. The risk of postoperative hepatic insufficiency is closely related to the volume and function of the remnant liver, and several methods for liver volume determination are available. Most use computerized tomography (CT) combined with three-dimensional CT volumetry (Denys et al, 2002). When the functional liver remnant volume is below a certain threshold, generally 25% to 30% for normal liver and 40% for diseased liver, the risk of postoperative hepatic failure is high, and portal vein embolization may be indicated prior to hepatic resection (Vauthey et al, 2000).

Bloodless Surgery

In the early years of hepatic resection, major intraoperative blood loss was common, transfusion of blood products was routine, and morbidity and mortality were unacceptably high (Foster & Berman, 1977). General improvements in hepatic resection techniques have reduced intraoperative blood loss and transfusion rates; nevertheless, perioperative transfusion remains a potent predictor of increased perioperative morbidity and mortality (Jarnagin et al, 2002). In recent years, liver resection without the need for blood transfusion has become increasingly possible (Belghiti et al, 2000; Cunningham et al, 1994; Fan et al, 1999; Jarnagin et al, 2002). Patient blood management is based on three pillars: 1) detecting and treating preoperative anemia, 2) reducing the loss of red blood cells perioperatively, and 3) optimizing the treatment of anemia (Spahn et al, 2008).

Thorough preoperative planning is essential to avoid perioperative allogeneic transfusion. Any history of bleeding disorders and management of anticoagulation must be evaluated, including discontinuation of drugs that adversely affect clotting (e.g., acetylsalicylic acid, nonsteroidal antiinflammatory drugs, and anticoagulants). In patients with anemia, recombinant human erythropoietin or iron therapy may optimize the starting operative hemoglobin (Monk, 1996). Preoperative autologous donation also has been used to reduce the need for allogeneic red blood products (Brecker & Goodnough, 2001). Preoperative autologous donation may not avoid allogeneic blood, however, because almost half of the patients who donate blood before surgery are anemic on the day of operation, and preoperative strategies to augment the red blood cell mass require more time than is generally reasonable for optimal efficacy. Patients with low hemoglobin levels at the start of surgery are at an increased risk of receiving allogeneic blood (Armas-Loughran et al, 2003). In addition, preoperative autologous donation is costly; it can be associated with clerical errors; and for every 2 units donated, usually only 1 unit gets transfused (Goldman et al, 2002). If the patient is optimized and surgery is bloodless, the autologous units are discarded. Other blood conservation strategies, such as intraoperative blood salvage (cell saver) and acute normovolemic hemodilution (ANH) have been used successfully for hepatobiliary surgery in Jehovah's Witness patients (Jabbour et al, 2005). ANH has been shown in two prospective studies to reduce the amount of red blood cells transfused per patient in major liver resections (Matot et al, 2002a; Jarnagin et al, 2008).

INTRAOPERATIVE MANAGEMENT

Hepatic blood flow in surgical patients can be altered by a variety of factors, including arterial blood pressure, posture changes, carbon dioxide levels, intravascular volume shifts, positive pressure ventilation, positive end-expiratory pressure, regional anesthesia, and volatile anesthetics (Gelman, 1992). Surgical stimulation and manipulation of the liver markedly increases hepatic oxygen extraction ratio and splanchnic vasoconstriction (see Chapter 4) (Kainuma et al, 1991; Whittle & Moncada, 1998). A 16% decrease in hepatic blood flow is associated with anesthesia and mechanical ventilation (Gelman, 1976), and a further 40% decrease is seen with splanchnic surgery. This decrease may be the direct effect of sympathetic control of the hepatic venous bed mediated through the hepatic innervation (Greenway et al, 1986).

Positive end-expiratory pressure decreases hepatic blood flow in a stepwise manner. The response cannot be explained by a decrease in cardiac output alone; investigators postulate a vasoconstrictive response in the preportal vasculature. Intraperitoneal insufflation and head-up tilt result in impairment of hepatic blood flow secondary to decreases in cardiac output (Berendes et al, 1996b; Eleftheriadis et al, 1996). The hepatic blood flow decrease caused by hypotensive spinal anesthesia is attenuated by ephedrine administration (Nakayama et al, 1993). Two human studies using the indocyanine green plasma disappearance rate to evaluate the effects of high lumbar epidural anesthesia (EDA) on hepatic blood flow have found a decrease of 25% to 35% despite a constant cardiac output (Kennedy et al, 1971; Tanaka et al, 1997). Patients treated with norepinephrine to compensate for the EDA-induced decrease in arterial blood pressure had an additional marked decrease in hepatic blood flow (Meierhenrich et al, 2009).

It is controversial whether catecholamines increase hepatic blood flow and oxygen supply, but dobutamine does not cause a significant increase in hepatic arterial blood flow (Kainuma et al, 1992). Total hepatic blood flow and portal venous blood flow are increased, however, resulting in an augmentation of hepatic oxygen delivery. The increase in hepatic oxygen delivery is countered by an increase in hepatic oxygen uptake with no overall improvement in hepatic oxygen supply–uptake ratio. Dopamine and norepinephrine increase hepatic venous oxygen saturation, suggesting that the vasoactive treatment of patients in septic shock may not compromise splanchnic oxygenation (Ruokonen et al, 1991, 1993). Hepatic portal flow does not decrease despite a 20% to 60% reduction in blood pressure as long as cardiac index is maintained during sodium nitroprusside hypotension (Chauvin et al, 1985). A well-planned anesthetic maximizes the relationship between oxygen transport and oxygen use with the premise that reductions in systemic pressure would reduce hepatic blood flow. Anything resulting in significant reductions of systemic pressure and cardiac output–induced hypotension, hypovolemia, and anesthetic overdoses should be avoided.

Volatile Anesthetics

Anesthetic Hepatotoxicity

Fulminant hepatic necrosis and jaundice after halothane, so-called halothane hepatitis, is rare—one in 6000 to 35,000 anesthetics—but often fatal. Halothane hepatitis is an

immunologic phenomenon initiated by halothane metabolism and the binding of its metabolite to liver proteins to form trifluoroacetylated proteins, which stimulate antibodies in susceptible individuals. Upon subsequent halothane reexposure, these antibodies mediate massive hepatic necrosis. Because the extent of metabolism of enflurane, isoflurane, and desflurane is so much less than that of halothane, fulminant hepatitis from these anesthetics is far less common than with halothane (Elliot & Strunin et al, 1993). In 1987, the U.S. Food and Drug Administration determined that there was no conclusive association between isoflurane exposure and postoperative hepatitis (Shingu et al, 1983; Stoelting et al, 1987). Sevoflurane metabolism is different from that of the other volatile anesthetics, however, because it does not result in trifluoroacetyled liver proteins, and immune-based hepatitis after sevoflurane has not been reported. With the disappearance of halothane and enflurane from clinical practice in developed countries, and lack of hepatotoxicity from either isoflurane, desflurane or sevoflurane, anesthetic volatile hepatotoxicity is not a significant concern (Elliot & Strunin, 1993).

Hemodynamics

Volatile anesthetics reduce hepatic blood flow in a dose-dependent fashion by affecting cardiac output and systemic pressure. Surgical manipulation causes an additional decrease in estimated hepatic blood flow. Isoflurane has been considered the agent of choice in cases in which preservation of splanchnic blood flow is required, and liver blood flow and the hepatic artery buffer response are maintained better in the presence of isoflurane than with any other volatile anesthetic agent (Berendes et al, 1996a). In addition, isoflurane is shown to attenuate the increases in hepatic oxygen consumption associated with surgery and liver manipulation.

Desflurane is shown to have no deleterious effects on liver function and hepatocyte integrity, and it is associated with significantly greater gut blood flow than equipotent isoflurane. This difference cannot be explained by systemic hemodynamics alone. There is no difference in total hepatic flow between isoflurane and desflurane groups, however, which suggests that an intact hepatic arterial supply buffers response with desflurane (O'Riordan et al, 1997). Sevoflurane is similar to isoflurane and desflurane with a few exceptions (Ebert et al, 1995). Indocyanine green clearance is better preserved during sevoflurane anesthesia. In Beagles subjected to sevoflurane anesthesia and ligation of the hepatic artery, hepatic oxygen supply–uptake ratio, hemoglobin oxygen saturation, and oxygen partial pressure in hepatic venous blood were significantly lower than with halothane or isoflurane.

Nitrous oxide is used extensively in patients with hepatic disease (Khalil et al, 1994; Lampe et al, 1990). Although it has not been shown to contribute to hepatic disease exacerbation, the sympathomimetic effects of nitrous oxide may increase hepatic metabolic requirements.

Intravenous Anesthetics and Muscle Relaxants

Inhaled anesthetics supply all the aspects needed for anesthesia in one package, but today most anesthesiologists choose multiple drugs to reach their goals: immobility, amnesia, suppression of autonomic reflexes, muscle relaxation, and analgesia. Over the past several decades, dramatic advances have been made in intravenous anesthesia with the result that total intravenous anesthesia is now a workable alternative to the traditional inhalation anesthetic. Anesthesiologists using multiple drugs take advantage of interactions among drugs that have different mechanisms of action but similar therapeutic effects. The therapeutic goal of the anesthetic can often be achieved with less toxicity and faster recovery than when individual drugs are used alone in higher doses. The safety of intravenous anesthetics and muscle relaxants in patients having hepatobiliary surgery is well documented (Gelman, 1992).

The main mechanisms that affect hepatic elimination of a drug are changes in hepatic blood flow and changes in the ability of the liver cells to biotransform and/or excrete a drug. These two mechanisms, hepatic blood flow and hepatocyte function, play an important role in the choice of anesthetics for patients undergoing hepatobiliary surgery. High-extraction drugs (ketamine, flumazenil, morphine, fentanyl, sufentanil, lidocaine) are directly related to liver blood flow and are essentially cleared as they pass through the liver. Protein binding, enzymatic induction, intrahepatic shunting, and the effect of anesthetics on liver blood flow may influence the elimination of drugs with a high extraction rate. Reduced metabolic clearance results in increased peak drug level with minimal change in the elimination half-life. Drugs with a low extraction rate (benzodiazepines) differ from high-extraction drugs in that concentration changes little after passage through the liver, and intrinsic clearance depends on hepatic metabolic function as determined by liver size and total enzyme capacity (Colli et al, 1988). In patients with impaired liver function, such drugs have a prolonged length of activity with no increase in peak levels.

SPECIAL ANESTHETIC CONSIDERATIONS

Anesthesia for Hepatectomy

Fluid loading before resection is commonly practiced in preparation for hepatic resection. This fluid loading often results in a distended and tense vena cava and dilated hepatic veins, both of which contribute to increased blood loss during liver mobilization and parenchymal transection. A relationship exists between extent of intraoperative blood loss and morbidity; blood loss greater than 5 L in an adult is associated with prohibitive mortality (Yanaga et al, 1988). Inadvertently, fluid loading to provide hemodynamic stability during episodes of uncontrolled bleeding may cause technical difficulties and handicap repair of venous injuries.

Another approach, low central venous pressure (CVP) anesthesia, is designed to preclude vena caval distension to facilitate mobilization of the liver and dissection of retrohepatic vena cava and major hepatic veins (Cunningham et al, 1994; Melendez et al, 1998). This surgical anesthetic technique compares favorably with other techniques for major hepatic resection (Delva et al, 1989; Segawa et al, 1993; Yanaga et al, 1988). Low CVP anesthesia is performed in combination with surgical inflow and outflow vascular control before parenchymal transection. Such an approach requires close cooperation between the anesthesiologist and the surgeon. Low CVP anesthesia minimizes hepatic venous bleeding during parenchymal transection and facilitates control of inadvertent venous injury. The blood loss resulting from a vascular injury is directly proportional to the pressure gradient across the vessel wall and the fourth power of the radius of the injury. If the CVP is lowered from 15 mm Hg to

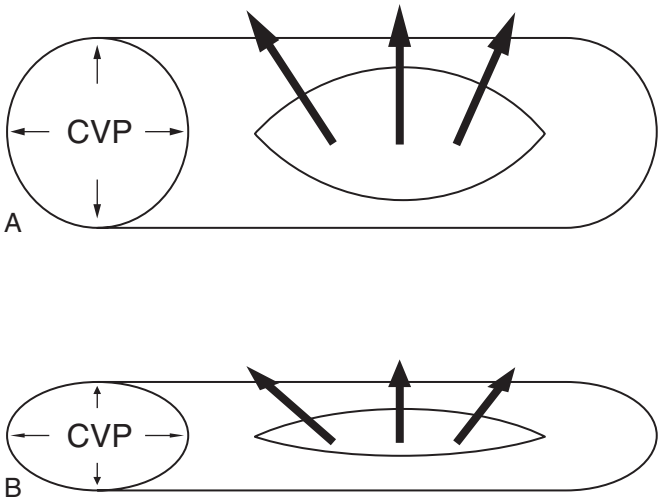

FIGURE 22.1. Vena caval injury profile under various central venous pressure (*CVP*) conditions. **A,** High CVP. **B,** Low CVP. Increased CVP leads to distension of the vena cava with ensuing enlargement in diameter of injury and increase in the bleeding driving pressure.

3 mm Hg, the blood loss through a vena caval injury consequently falls by a factor greater than 5. Lowering CVP lessens the pressure component of the equation and also minimizes the radial component of flow by reducing vessel distension (Fig. 22.1).

Fluid restriction is an important aspect of the low CVP anesthesia technique. Preoperative overnight fluid replacement, a maneuver commonly performed before or immediately after the induction of general anesthesia, is withheld. Strict fluid restriction is practiced until the liver resection is completed. Intermittently, small fluid boluses may be given to maintain hemodynamic stability. To guarantee the safety of patients, appropriate cannulation is carried out, and a high level of vigilance is maintained. Transfusion equipment, such as the Woods pump coupled to a level 1 system, is an important aid to emergency fluid resuscitation, although this is infrequently needed. Intravascular hypovolemia is counteracted with 15-degree head-down tilt. Steep head-down tilt preserves hemodynamic stability and renal function by improving venous return. In animals, head-down tilt increases glomerular filtration rate, sodium excretion, and urine output lasting 8 hours (McCombs et al, 1996). Prolonged head-down tilt improves venous return and yields a 70% increase in plasma atrial natriuretic protein (Hughson et al, 1995; Terai et al, 1995). Although some investigators report intraoperative oliguria during low CVP anesthesia, no increase in the incidence of postoperative renal failure has been observed (Melendez et al, 1998).

Anesthesia is maintained with a combination of isoflurane in oxygen and narcotics, because isoflurane provides vasodilation with minimal myocardial depression (Schwinn et al, 1990). Elimination of nitrogen from the anesthetic gas mixture is necessary to permit expiratory nitrogen monitoring for air emboli. Restriction of nitrous oxide in the gas mixture prevents the diffusion-mediated increase in the volume of circulating air. Consistent with its minimal effect on cardiac output and systemic pressure, fentanyl has no effect on liver blood flow and oxygen delivery. In combination with isoflurane, fentanyl has the least effect on hepatic hemodynamics of any opiate, making it the narcotic of choice for anesthetics. In most patients, fentanyl is the ideal narcotic to aid in the maintenance of anesthesia, providing analgesia with minimal hypotension (Rosow et al, 1982). In a small group of patients, the anesthetic is supplemented with morphine to achieve the desired CVP. Morphine reduces CVP by inducing venous vasodilation caused by histamine release and μ_3 receptor activation (Grossman et al, 1996; Rosow et al, 1982; Stefano et al, 1995). The combination of these anesthetics readily provides the favorable low CVP environment for hepatic resection. With this technique, intravenous nitroglycerin to lower CVP to less than 5 mm Hg is rarely necessary.

The risk of intraoperative air emboli is likely to increase under low CVP anesthesia. Transesophageal echocardiography can be used to monitor air emboli, but this technology is sensitive and overdiagnoses clinically insignificant events. With surgical vigilance and rapid occlusion of open venous channels (see Chapters 90A and 92), low CVP anesthesia results in a low incidence (0.4%) of clinically significant air emboli. More complex low CVP anesthesia management techniques have been described (Rees et al, 1996). They employ epidural blockade and intravenous nitroglycerin. These patients may require intraoperative dopamine for systemic pressure support, a technique this is cumbersome and adds an unnecessary level of complexity to an already challenging situation.

Bloodless Surgery

Red blood cell transfusions are indisputably associated with an increase in mortality, major adverse cardiac and noncardiac outcome, acute lung injury, nosocomial infection, tumor growth, duration of hospitalization, and cost (Murphy et al, 2007; Beattie et al, 2009; Kulier et al, 2007; Marik et al, 2008; Atzil et al, 2008; Shander et al, 2007). Therefore it is important not to confuse the momentary helpful effect of red blood cell transfusion on hypotension and hypovolemia with an outcome benefit. Intraoperative blood cell salvage, hemodilution, and tolerance of normovolemic anemia (Gozzetti et al, 1995) all may contribute to reduced allogeneic red blood cell transfusion in major liver surgery. Autologous blood cell salvage (intraoperative autotransfusion) involves recovery of the patient's shed blood from a surgical wound. The blood is then washed or filtered and reinfused into the patient. Hepatectomies often are performed for cancer but previously, cell salvage had been excluded in oncologic surgery because of the concern for potential dissemination of cancer cells. This concern has been challenged because of the availability of leukocyte-depleting filters and irradiation of blood removed during cancer surgery (Hansen et al, 1999).

Another transfusion-sparing technique is acute normovolemic hemodilution (ANH), a recycling technique that can be performed intraoperatively by the anesthesiologist. Blood is removed from the patient after induction and is replaced with crystalloid or colloid fluid. By removing the patient's blood and replacing it with acellular fluid, the blood loss is diluted. The previously removed blood is stored at room temperature in the operating room and is returned to the patient at the conclusion of the operation. Two randomized studies of ANH in major hepatic resection showed a significant reduction in the percentage of patients requiring allogeneic red blood cell transfusion (Matot et al, 2002a; Jarnagin et al, 2008).

Epidural Anesthesia and Analgesia

Epidural block is widely used to manage major abdominal surgery and postoperative analgesia, but its risks and benefits are uncertain. Studies do not support the routine use of epidural anesthesia (EDA), rather than parenteral analgesia, to prevent postoperative mortality (Fanzca et al, 2002; Park et al, 2001; Wijeysundera et al, 2008). There are, however, other reasons to prefer EDA, including better postoperative pain relief and reduced pulmonary complications (Fanzca et al, 2002). In contrast to EDA for other abdominal surgery, the use of an indwelling epidural catheter and the timing of its removal in patients undergoing liver resection remain controversial (Matot, et al, 2002b).

The hemostatic abnormalities associated with liver resection are not always predictable and/or reversible. Significant disturbances of prothrombin time (PT) can be seen in patients undergoing uncomplicated liver resection. In patients who undergo minor liver resections, the PT usually returns to control levels within 1 day. In patients having major liver resections, the disturbances in PT can be prolonged and, as a result, the epidural catheter cannot be removed without administering fresh frozen plasma to normalize the coagulation profile because of a theoretically increased risk of spinal hematoma (Siniscalchi et al, 2004). In addition, thoracic EDA is associated with a decrease in hepatic blood flow and, if combined with continuous infusion of norepinephrine to counteract the EDA-related decrease in systemic arterial blood pressure, hepatic blood flow is decreased further (Meierhenrich et al, 2009; Tanaka et al, 1997). Hepatic hypoperfusion is regarded as an important factor in the alteration of hepatic oxygen balance and metabolic activity and the pathophysiology of perioperative liver injury. Furthermore, it has been hypothesized that hypoperfusion of the liver may initiate or contribute to the development of a systemic inflammatory response syndrome that may lead to multiple organ failure (Maynard et al, 1997). The decision to insert an epidural catheter for either intraoperative anesthesia or postoperative analgesia in patients undergoing hepatic resection should be made with care.

Obstructive Jaundice

Bile duct obstruction affects hepatic hemodynamics. Acute biliary obstruction is associated with an increase in liver blood flow (see Chapter 4), but flow is decreased with chronic obstruction. Relief of long-term obstruction is not associated with a return to normal pressures and may be associated with hemodynamic embarrassment and shock. The exact cause of hemodynamic derangement in the face of biliary obstruction is unknown, but increased portal resistance is believed to play a role. Biliary sepsis may contribute to the exacerbation of the hemodynamic embarrassment. In these cases, aggressive hemodynamic monitoring may be lifesaving. Either by percutaneous or endoscopic approaches, preoperative biliary drainage does not necessarily improve the perioperative morbidity of patients who show no evidence of infection, and it is therefore not recommended as a routine (Lai et al, 1994; see Chapter 50). When there is clinical concern for the development of acute cholangitis, rapid biliary decompression and intravenous antibiotics should be administered preoperatively, and surgery should be delayed until the infection resolves (Lai et al, 1992).

ANESTHESIA FOR VASCULAR ISOLATION (SEE CHAPTER 91)

Prolonged inflow occlusion with or without hepatic vascular isolation is an alternative surgical approach for liver resection. Hepatic vascular isolation induces significant hemodynamic changes. The anesthetic management is more complex, and many patients require pulmonary artery catheters during the procedure. Hepatic vascular isolation typically causes a decrease in venous return with a resultant decrease in cardiac index and an increase in systemic vascular resistance. Mean arterial pressure is maintained by infusing large volumes of fluid to keep the CVP high. Some patients require vasopressor support to maintain adequate perfusion during the cross-clamping period. Most patients tolerate these hemodynamic changes reasonably well, although in some cases, persistent hypotension or low cardiac index or both demand that the procedure be abandoned. Several studies of hepatic vascular isolation are summarized in Table 22.1 (Belghiti et al, 1996; Delva et al, 1989; Emond et al, 1995; Emre et al, 1993; Habib et al, 1994; Hannoun et al, 1993; Melendez et al, 1998). In these studies, blood loss and transfusion requirements were greater than those reported by the authors using portal triad clamping with extrahepatic control of the hepatic veins. Hepatic vascular isolation is more complex and has not yielded better results than portal triad clamping and extrahepatic control of the hepatic veins (Belghiti et al, 1996; Cunningham et al, 1994).

POSTOPERATIVE CARE

Mortality and morbidity after hepatobiliary surgery have decreased as a result of surgical and anesthetic advances and a better understanding of hepatic physiology (Belghiti et al, 2000; Jarnagin et al, 2002; Melendez et al, 1998; Ryan et al, 1982). Hepatobiliary surgery is increasingly common at major medical centers, and postoperative recovery is becoming indistinguishable from that after other major abdominal surgery. At Memorial Sloan-Kettering Cancer Center, most patients recover after major surgery in the postanesthesia care unit (day 1) and then are transferred to the general ward without any need for intensive care.

Immediate Postoperative Concerns

Some of the problems that cause metabolic and functional changes after hepatobiliary surgery are common to all major intraabdominal procedures (Aronsen et al, 1969). Others are unique and require an in-depth understanding of liver physiology. Immediate postoperative concerns are bleeding, intravascular volume, renal function, and oxygenation. Important laboratory tests are hematocrit, electrolytes, serum creatinine, blood urea nitrogen, PT/partial thromboplastin time, liver enzymes, and chest radiograph.

At least three mechanisms contribute to impaired pulmonary function in the postoperative period: 1) respiratory muscles disrupted by surgical transection of the abdominal muscles will not function normally; 2) patients may limit motion of respiratory muscles to minimize postoperative pain; and 3) stimulation of the visceral afferent nerves markedly changes the activation of respiratory muscles. For example, removal of the gallbladder activates vagal efferents that produce a reflex inhibition of

Table 22.1

Comparison of Operative Parameters Between HVI and LCVP Anesthesia-Aided Hepatectomy

*Major resections include all lobectomies and extended lobectomies.
†Values are reported in mean ± SD.
‡Denotes inclusion of cirrhotic patients in series.
HVI, hepatic vascular isolation; LCVP, low central venous pressure

diaphragmatic activity. Of note, laparascopic surgery may ameliorate the first two mechanisms but not the third, and significant decrements in pulmonary function may still be observed after laparascopic surgery.

The nature and magnitude of the patient's preexisting respiratory condition determine the effect of a standard anesthetic on respiratory function. Anesthesia results in a decrease in mucus transfer and reductions of the functional residual capacity/closing capacity ratio. Airway closure can occur with mild, active expiration in patients with emphysema, bronchitis, and asthma. In addition, inflammation and scarring can compromise bronchial structural integrity and increase further the risk of alveolar collapse. In patients with asthma or obstructive lung disease, high airway resistance favors deep, slow respiration; this may not be possible in patients with large abdominal incisions. Anticipated respiratory compromise after upper abdominal surgery may preclude early extubation, especially in combination with any baseline abnormality in gas exchange.

Unique postoperative concerns in patients after hepatobiliary surgery include phosphorus replacement, anesthetic elimination, drug metabolism, coagulation, and postoperative pain control. Data suggest that hepatocellular regeneration may be critically dependent on cellular ATPase stores (Campbell et al, 1990; Greene, 1981). Liver regeneration after partial hepatectomy involves rapid cell division 24 to 72 hours after liver resection. Standard therapy for posthepatic resection should include the supplementation of intravenous fluids with sodium or potassium phosphate. Particular attention must be paid to anesthetic elimination and residual drug effect—especially sedative, analgesic, and neuromuscular blockers—in patients who have altered drug pharmacodynamics and pharmacokinetics. Postoperative pain management must be adapted to this population. Patient-controlled analgesia, commonly employed for postoperative pain management, should be employed initially without a basal narcotic infusion rate. After hepatic resection, patients experience an unpredictable reduction in the metabolism of narcotics.

The half-life of coagulation factors is 6 hours, so coagulation factor deficiency is likely to evolve rapidly. Routine parenteral administration of vitamin K commonly corrects the coagulation abnormalities within 48 hours. More rapid correction may be accomplished by fresh frozen plasma but is rarely needed, unless the PT or international normalized ratio (INR) exceeds 2, or if there are concerns of ongoing postoperative blood loss (Martin et al, 2003).

Delayed Perioperative Complications

Identifying patients at high risk for complications is an important but difficult component of the overall management strategy. A study from Memorial Sloan-Kettering Cancer Center showed that when postoperative hepatobiliary patients required admission to the intensive care unit, mortality ranged from 37% to 79% regardless of admission diagnosis (Melendez et al, 1998). A systematic proactive approach that identifies early deviations from the norm would be preferable to having to treat organ failure (Sesto et al, 1987).

Jaundice

The differential diagnosis of postoperative jaundice is listed in Table 22.2. Mild jaundice in the early postoperative period after partial hepatectomy is relatively common, particularly in patients who undergo a major resection and have a transient, self-limited hyperbilirubinemia in the first few days after operation, which may be exacerbated by hematoma reabsorption and hemolysis of transfused blood. Progressive jaundice that does not resolve portends a more significant problem.

One suggested definition of postoperative hepatic insufficiency is a peak bilirubin greater than 7 mg/dL. In a cohort of 1059 noncirrhotic patients undergoing hepatic resection, a postoperative bilirubin greater than 7 mg/dL was associated with 30% chance of dying of hepatic insufficiency (Mullen et al, 2007). On the other hand, in the same cohort, 70% survived; this highlights the importance of identifying any correctable problem that may be contributing to the hyperbilirubinemia.

It is prudent to be suspicious of a bile duct injury at the time of surgery when faced with postoperative extrahepatic obstructive jaundice. Hemobilia may occur with temporary obstruction

Table 22.2

Differential Diagnosis of Postoperative Jaundice

Increased Bilirubin Load	Biliary Obstruction	Hepatocellular Injury
Blood transfusion	Intrahepatic cholestasis	Hepatic hypoxemia
Hematoma	Drug induced	Exacerbated chronic hepatitis
Hemolytic anemia	Infection induced	Acute hepatitis
Extracorporeal circulation hemolysis	Extrahepatic cholestasis	Viral
	Bile duct injury	Alcoholic
	Pancreatitis	Gilbert disease
	Retained gallstones	Sepsis
		Trauma
		Toxins, drugs

Modified from Brown BR, 1988: Postoperative jaundice. In Brown BR (ed): Anesthesia in Hepatic and Biliary Disease. Philadelphia, FA Davis, pp 265-273; and Gelman S, 1992: Anesthesia and the liver. In Barash PG, et al, (eds): Clinical Anesthesia, 2nd ed. Philadelphia, Lippincott, pp 1185-1214.

of the bile ducts by blood clots, and the possibility of a bile leak also must be considered. Hepatocellular injury is another possibility in the differential diagnosis of postoperative jaundice. Sepsis is a common condition causing a low-flow state to the liver, and infectious hepatitis may manifest as postoperative jaundice, often related to intraoperative blood transfusions; in some cases, the responsible virus has no serologic marker. Postoperative hepatic failure from excessive sacrifice of functional parenchyma or vascular embarrassment also must be included in this differential diagnosis. In developed countries, halothane is not used, so anesthetic-induced liver failure rarely should be included in the differential diagnosis.

Ascites

Ascites (see Chapter 74) occurs as a result of several factors: 1) impaired albumin and protein synthesis; 2) increased hydrostatic pressure in hepatic sinusoids and splanchnic capillaries; 3) overproduction of hepatic and splanchnic lymph, leading to a transudation of lymph into the peritoneal space; 4) limited or reduced reabsorption of water and protein by peritoneal lymphatics; 5) sodium retention by the kidney secondary to hyperaldosteronism, increased sympathetic stimulation, and alterations in metabolism of prostaglandins and kinins; and 6) impaired renal water excretion, partially owing to increased concentrations of antidiuretic hormone. The decreased serum albumin 1 to 2 weeks after hepatobiliary surgery, by itself, is generally unimportant clinically (Grundmann & Heistermann, 1985), and even in the presence of severe hypoalbuminemia, albumin infusion has no beneficial effect.

The medical management of ascites emphasizes bed rest and sodium restriction. If a spontaneous diuresis does not occur, therapy is begun with the aldosterone antagonist spironolactone. In patients with ascites, contraction alkalosis and electrolyte abnormalities, such as hyponatremia, hyperkalemia, hypochloremia, and hypokalemia, are commonly encountered. If ascites is refractory to medical management, paracentesis may offer temporary palliation. If life-threatening complications such as cardiac or respiratory compromise occur, patients should be transferred to the ICU.

Renal Failure

After hepatobiliary surgery, rapidly progressive renal failure may occur (see Chapter 23), although this is uncommon after routine resections (Belghiti et al, 2000; Jarnagin et al, 2002; Melendez et al, 1998). Hepatic resection using low CVP anesthesia is associated with a very low incidence of postresection renal dysfunction, as shown by Melendez and colleagues (1998). The principal differential diagnoses include acute tubular necrosis, prerenal azotemia, and hepatorenal syndrome, which is the development of otherwise unexplained renal failure in patients with advanced liver disease.

In hepatorenal syndrome, urine sodium is typically less than 10 mEq/L with hyperosmolar urine, oliguria (<400 mL/24 h), fractional excretion of sodium less than 1, and urine creatinine/plasma creatinine ratio greater than 30:1. The pathophysiology of hepatorenal syndrome is based on the pooling of blood in the splanchnic bed and decreasing plasma volume (Hartleb et al, 1997). The kidney perceives a decreased glomerular filtration rate, and the resulting vasoconstriction shunts blood away from the renal cortex. In some cases, the precipitating event can be attributed to hemodynamic instability, nephrotoxic drugs, infection, or overzealous diuresis and paracentesis. Although no specific treatment for hepatorenal syndrome is available, it should always be assumed that the primary pathophysiologic event is circulatory, which requires transfer of the patient to the ICU.

Pulmonary Care

Minor pulmonary complications, such as atelectasis or pleural effusion, are common after liver resection. With aggressive postoperative pulmonary toilet and early mobilization, such problems resolve without the need for further intervention. Perioperative pulmonary complications include pneumonia, bronchospasm, atelectasis, hypoxemia, exacerbation of underlying chronic lung disease, and respiratory failure, usually defined as the need for mechanical ventilatory support. Patients with significant hepatic parenchymal disease are at potential risk for hepatopulmonary syndrome, which is defined as a triad of signs that comprise 1) liver disease, 2) increased alveolar-arterial gradients, and 3) evidence of intrapulmonary vascular resistance (Krowka & Cortese, 1994). Autopsy specimens of human and animal lung have shown precapillary pulmonary dilations and direct arteriovenous communications. Hepatopulmonary syndrome is rare after hepatic resection, and these patients generally require management in the ICU.

Glucose Metabolism

Glucose deprivation leads to hepatic glycogenolysis to provide glucose. After glycogen stores in the liver are exhausted (12 to 24 hours), the liver must synthesize glucose from other substrates (gluconeogenesis). The hormones insulin, glucagon, and epinephrine are important modulators of these processes. On balance, the postoperative patient would seem to be prone to hypoglycemia secondary to diminished glycogen reserves, increased insulin levels, and impaired gluconeogenesis; but dangerous hypoglycemia is rare, and its presence must raise the suspicion of acute hepatic failure. In most resections, isotonic saline solutions without dextrose can be used during the first 12 to 24 hours after resection, following which routine dextrose solutions should be ordered and glucose levels monitored.

Coagulation

After routine liver resections, transient and self-limited prolongation of PT that commonly occurs usually resolves without the need for transfusion of fresh frozen plasma or

administration of other agents. The liver synthesizes vitamin K–dependent factors II (prothrombin), VII, IX, and X; protein S; and protein C. Improvements in coagulation may be achieved with vitamin K (10 mg/day). If this treatment fails to correct a prolonged INR or PT after 2 to 3 days, vitamin K administration should be stopped and additional causes should be sought.

In addition to the vitamin K–dependent factors, the liver also synthesizes antithrombin III and factor I (fibrinogen). In this setting, fresh frozen plasma may be administered at a dose of 12 to 20 mL/kg (2 to 6 U) with the goal of decreasing the PT to within 3 seconds of control. If coagulopathy persists, dysfibrinogenemia should be considered. Patients with liver disease who do not respond to standard corrective measures may respond to vasopressin. Vasopressin is a synthetic peptide that increases factor VIII concentrations and shortens PT, and it may be used in concert with fresh frozen plasma. After hepatectomy, persistent INR greater than 2 and thrombocytopenia less than 100,000 have been identified as warning signs for hepatic insufficiency.

Sepsis

Mortality after hepatic resection is often caused by abdominal sepsis (Bozzetti et al, 1992). In one series, 6 of 14 deaths were the result of intraabdominal sepsis (Melendez et al, 1998). Biliary manipulation and placement of biliary stents, culture-positive bile, retained gallstones, ascites, and blood loss all may predispose to abdominal sepsis. Patients undergoing hepatic resection for hilar cholangiocarcinoma are at particular risk for postoperative infective complications. Other sources of sepsis include the respiratory and urinary systems. Upper abdominal incision, pleural effusion, chronic obstructive pulmonary disease, and poor pulmonary toilet may promote the development of pneumonia, so wound inspections and central line catheter changes should be performed routinely.

Gastrointestinal Bleeding

Although the incidence of stress-related gastric mucosal lesions is high, the actual incidence of bleeding ulcers is 5% with a mortality of 50% reported. In practice, clinically significant gastrointestinal bleeding after hepatic resection is rare (Jarnagin et al, 2002). Endoscopy allows identification of the bleeding site, and treatment is largely supportive with transfusions, antacids, and H_2 blockers. Prophylactic therapy for prevention of stress ulceration should be considered in all patients after major hepatobiliary procedures.

Encephalopathy

A sudden change in a patient's mental status and the onset of asterixis, a flapping tremor related to loss of extensor tone, are signs of hepatic insufficiency that should precipitate a search for the cause and the start of therapy for hepatic encephalopathy (Gitlin, 1998). Precipitating factors include gastrointestinal bleeding, infection, drugs, diet, and dehydration. The exact pathogenesis of hepatic encephalopathy is unknown, but accumulation of endogenous ammonia is associated with the onset of encephalopathy and has been suggested as causative. Other possible contributory factors include 1) changes in the blood–brain barrier permeability, 2) abnormal neurotransmitter balance, 3) altered cerebral metabolism, 4) impairment of neuronal Na^+-K^+-ATPase activity, and 5) increased endogenous benzodiazepines. Standard therapy is designed to reduce levels of ammonia and other potentially toxic metabolites, and short-term benefit from flumazenil administration has been reported (Ferenci et al, 1989). Dietary protein restriction and lactulose, however, remain the gold standard of care.

CHAPTER 23

Perioperative critical care in hepatopancreatobiliary patients

Louis Voigt, Stephen M. Pastores, and Neil A. Halpern

OVERVIEW

Patients with cirrhosis or decompensated liver disease (see Chapters 2, 70B, 72, 73, 74, 75A, 75B, and 75C) are at particularly high risk for perioperative morbidity and mortality after major surgery, often necessitating admission to the intensive care unit (ICU). Compared with noncirrhotic patients, patients with cirrhosis who are admitted to the ICU have higher rates of complications and hospital mortality, extended lengths of stay, and greater resource use (Aggarwal et al, 2001; Cholongitas et al, 2006). Combined respiratory and renal failure requiring the use of mechanical ventilation and renal replacement therapy carries a mortality rate ranging from 61% to 89% (Arabi et al, 2004; Cholongitas et al, 2009). Meticulous perioperative assessment, planning, and care are essential to minimize complications and decrease mortality rates in these patients. Although this chapter addresses the special perioperative concerns of cirrhotic patients, unless otherwise specified, the data are applicable to all types of chronic liver disease, including chronic infections with hepatitis B or C virus, chronic autoimmune hepatitis, biliary cirrhosis, sclerosing cholangitis, and hemochromatosis.

PREOPERATIVE ASSESSMENT AND CARE

Global Assessment

The loss of hepatic reserve capacity and the associated systemic derangements that result from liver dysfunction cause patients with chronic liver disease to have an inappropriate response to surgical stress. Increased surgical risk has been reported for various types of surgery in cirrhotic patients, including cardiac operations, open cholecystectomy, hysterectomy, nephrectomy, and transurethral resection of the prostate (Shaheen et al, 2009; Hayashida et al, 2004; Thulstrup & Sorensen, 2001; Lund et al, 2003; Nielsen et al, 2001, 2002). Emergency surgery and unscheduled laparotomy for trauma carry a high mortality rate (Pronovost et al, 1999; Carbonell et al, 2005; Wahlstrom et al, 2000; Demetriades et al, 2004). In contrast, patients with cirrhosis who undergo laparoscopic cholecystectomy have generally favorable outcomes (Morino et al, 2000; Pavlidis et al, 2009).

Two risk-stratification scoring systems have been developed to evaluate the preoperative severity of liver dysfunction and to predict postoperative outcome in cirrhotic patients. The Child score and its modification, the Child-Turcotte-Pugh (CTP) score, has been most commonly used. In the CTP score, a composite score of the degree of hepatic synthetic dysfunction (based on prothrombin time and serum levels of albumin and bilirubin), degree of ascites, and presence of hepatic encephalopathy yields a total score that ranges from well-compensated cirrhosis (class A, 5 to 6 points) to mild (class B, 7 to 9 points) and severe (class C, 10 to 15 points) decompensation. Cirrhotic patients undergoing elective or emergency extrahepatic surgery have a mortality rate ranging from 0% to 7.1% for class A to 84% to 100% for class C (Franzetta et al, 2003). Other risk factors for perioperative complications and mortality among cirrhotic patients undergoing surgery include male gender, preoperative infection or upper gastrointestinal bleeding, elevated creatinine concentration, and thrombocytopenia (Ziser et al, 1999).

In 2000, the Model for End-Stage Liver Disease (MELD) score was developed and proved to be superior to the CTP score in predicting the 3-month survival of patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) (Malinchoc et al, 2000; Salerno et al, 2002). The MELD score is based on the prothrombin time–international normalized ratio (PT-INR) and serum bilirubin and creatinine levels, and it is calculated as follows:

$$\text{MELD Score} = 3.8[\text{Ln Serum bilirubin (mg/dL)}] + 11.2[\text{Ln INR}] + 9.6[\text{Ln Serum creatinine (mg/dL)}] + 6.4$$

The MELD score has been shown to correlate well with the CTP score in predicting postoperative mortality in cirrhotic patients undergoing elective and emergent surgery (Farnsworth et al, 2004). Other studies have shown that high MELD scores predict a poor outcome after hepatic resection for hepatocellular carcinoma (HCC) and following abdominal nonhepatic surgery in cirrhotic patients (Befeler et al, 2005; Teh et al, 2005). Finally, functional assays, such as the monoethylglycinexylidide (MEGX) test and indocyanine green clearance, may be used to assess hepatic functional reserve to predict postoperative morbidity and mortality prior to liver resection (Ercolani et al, 2000; Oellerich & Armstrong, 2001; Ravaioli et al, 2003; Lorf et al, 2008).

Risk Assessment (See Chapter 2)

Although surgical and anesthetic risks are largely related to the severity and not the cause of cirrhosis, determination of the etiology of the liver disease may be helpful in guiding the perioperative management and the timing of surgery (Table 23.1). A

Table 23.1

Risk Factors for Surgery and Preventive and Therapeutic Interventions

Risk Factors	Detrimental Effects	Interventions
Active alcohol use	Acute alcohol hepatitis	Cancel elective surgery
	Increased tolerance to sedatives and anesthetics	Prolonged alcohol abstinence
	Alcohol withdrawal and delirium	Use sedative and defer elective surgery
Iron overload	Cardiomyopathy and arrhythmias	Therapeutic phlebotomies
Hepatitis B infection	Flare of hepatitis	Antiviral agents
Autoimmune hepatitis	Flare of hepatitis	Stress-dose steroids

Table 23.2

Preoperative Risk Factors and Recommendations

Risk Factors	Evaluation and Management
Esophageal varices	Esophagogastroduodenoscopy Nonselective β-blockers Band ligation
Ascites	Abdominal ultrasound Paracentesis to rule out spontaneous bacteral peritonitis Sodium restriction Diuretics
Refractory ascites with low MELD score	TIPS
Hepatopulmonary syndrome	Arterial blood gas and bubble electrocardiogram Quantitative tagged microaggregated lung perfusion scan Echocardiogram Right heart catheterization for confirmation

MELD, Model for End-Stage Liver Disease; TIPS, transjugular intrahepatic portosystemic shunt

history of alcohol use should be obtained for all cirrhotic patients. Surgery should be deferred, if possible, in patients who are actively drinking alcohol because alcohol increases tolerance to narcotic and anesthetic agents, increases the risk of general anesthesia, and predisposes patients to alcohol withdrawal in the postoperative period (May et al, 2001; Spies et al, 2001). Prolonged alcohol abstinence (≥6 months) may lead to a significant reduction in the severity of portal hypertension and improvement in synthetic function in patients with alcoholic hepatitis. However, postponing surgery to allow alcohol abstinence is generally not practical in case of surgery for trauma or liver cancer.

Similar to active alcohol use, chronic viral and autoimmune hepatitis increase the risk of perioperative complications. Among patients undergoing hepatectomy for hepatocellular carcinoma, the presence of high-grade inflammation of the remaining healthy liver is associated with postoperative hepatic dysfunction (Nanashima et al, 2003). Patients with cirrhosis as a result of chronic hepatitis B may benefit from antiviral and immunologic agents such as lamivudine, adefovir, entecavir, telbivudine, tenofovir, interferon alfa-2b, and peginterferon alfa-2a before surgery (Keeffe et al, 2008; Lau et al, 2005; Hadziyannis et al, 2005, 2006; Schalm et al, 2000; Chan et al, 2005). Patients with chronic autoimmune hepatitis who have been on long-term steroid therapy should receive stress-dose steroids in the perioperative period, and adjunctive immunomodulatory agents should be resumed as soon as possible (Czaja, 2009).

Portal Hypertension, Varices, and Ascites (See Chapters 70A, 70B, 74, 75A, 75B, and 75C)

The severity of portal hypertension, as manifested by ascites and varices, is a major concern in the preoperative evaluation of cirrhotic patients. Preoperative endoscopy and measurement of hepatic venous pressures identify patients with severe portal hypertension who are at risk for variceal bleeding (Dittrich et al, 2003). Elevated hepatic venous pressures may portend the development of postoperative complications and higher hospital mortality in cirrhotic patients undergoing various surgical procedures including cholecystectomy, coronary artery bypass grafting, abdominal aortic aneurysm repair, and colorectal surgery (Csikesz et al, 2009; Nguyen et al, 2009). A platelet count of less than 100,000/μL is another useful surrogate marker of severe portal hypertension and of eventual hepatic decompensation (Zaman et al, 2001).

In patients with significant risk factors for variceal hemorrhage, nonselective β-blockers, such as propranolol or nadolol, are recommended to decrease the resting heart rate by 25% of pretreatment level or to approximately 50 to 60 beats/min. These agents, used either alone or in combination with nitrates, may reduce the variceal bleeding rate by half (Bureau et al, 2002; Patch et al, 2002). Alternatively, esophageal variceal band ligation or TIPS placement (see Chapter 76E) could be considered (Escorsell et al, 2002; Lo et al, 2002).

Ascites predisposes to bacterial peritonitis, respiratory compromise as a result of reduced lung expansion, and delayed wound healing. Adequate control and evaluation of ascites is important in cirrhotic patients scheduled to undergo abdominal surgery. In general, control of ascites may require several months and can be achieved with a low-sodium diet, diuretics, and/or large volume paracentesis (Table 23.2). In approximately two thirds of patients with ascites that is refractory or intolerant to diuretics, TIPS may be beneficial. Doppler ultrasound is advocated prior to TIPS procedure, as findings of abnormal blood flow in the portal venous system correlate well with increased mortality (Harrod-Kim & Waldman, 2005). Patients who undergo TIPS are also at increased risk for hepatic encephalopathy and should be monitored closely (Sahagun et al, 1997; Maleux et al, 2004). Patients with high MELD scores (>15) are at high risk for 30-day mortality and should not undergo TIPS for refractory ascites (Ferral et al, 2004; Schepke et al, 2003). In general, cirrhotic patients whose ascites is refractory to diuretics or TIPS should avoid abdominal surgery because of the high rates of postoperative morbidity and death. Finally, a high MELD score and use of a proton pump inhibitor are also associated with increased risks of spontaneous bacterial peritonitis (Bajaj et al, 2009; Obstein et al, 2007).

Avoiding preoperative intravascular volume depletion is important, as hypovolemia can lead to intraoperative and postoperative hypotension and shock, particularly in cases of surgery for emergent or life-threatening indications. Paracentesis and diuretics should be used judiciously, because they can trigger hypovolemic shock. Paracentesis may be performed with concomitant intravenous administration of selective colloid solutions. Albumin solutions are the preferred colloids used for resuscitation, as isotonic saline or dextran solutions may lead to ongoing accumulation of ascites (Garcia-Compean et al, 2002; Planas et al, 1990).

Nutrition (See Chapter 24)

Severe malnutrition affects up to 40% of cirrhotic patients and is associated with a high incidence of morbidity and mortality in patients with cirrhosis who are undergoing surgery (Kalaitzakis et al, 2007; Merli et al, 2002; Sam & Nguyen, 2009). In patients with advanced cirrhosis, several of the common parameters of nutritional status—such as body weight, body mass index, and albumin level—are not valid and reliable tools for assessment.

Perioperative interventions to enhance the nutritional status of cirrhotic patients may be associated with improved outcomes. Although special supplements with branched-chain amino acids are available and may reduce the risk of hepatic encephalopathy (Marchesini et al, 2003), in practice, their benefit is at most marginal. Nutrition via the enteral route is advocated, and nasogastric tubes can be employed safely in patients with esophageal varices. Total parenteral nutrition may be difficult to administer in cirrhotic patients because of concerns with fluid overload and infection.

Anemia

Bleeding, hemolysis, splenic sequestration, malnutrition, and underlying liver disease are among the multifactorial causes of anemia in cirrhotic patients. Longitudinal studies of patients with compensated cirrhosis without esophageal varices demonstrate that anemia may develop an average of 39 months after the onset of cirrhosis (Qamar et al, 2009). In 20% to 40% of patients with advanced cirrhosis of nonbiliary origin, a spur-cell hemolytic anemia associated with iron overload may become evident. Iron should be administered only in the presence of documented deficiency. In patients scheduled for partial hepatectomy for HCC, autologous blood transfusion and erythropoietin therapy have been used successfully to prevent the need for red blood cell transfusions (MacLaren et al, 2004; Shinozuka et al, 2000; Kajikawa et al, 1994).

Coagulopathy

Coagulation abnormalities are frequently found in cirrhotic patients undergoing surgery. Etiologies include decreased hepatic synthetic function, abnormal synthesis of coagulation factors, malnutrition, vitamin K deficiency, thrombocytopenia, and dysfibrinogenemia (Amitrano et al, 2002; Qamar et al, 2009; Richard et al, 2007). The degree of coagulopathy is proportional to the severity of cirrhosis. For patients with prolonged PT-INR and suspected vitamin K deficiency, a 3-day trial of vitamin K is recommended to determine whether the coagulopathy is correctable. Intravenous administration of vitamin K is the favored method in the ICU: subcutaneous administration has an inconsistent rate of absorption, and intramuscular injection carries the risk of hematoma formation. Oral menadiol, the water-soluble formulation of vitamin K, is effective for patients with cholestasis. If the PT-INR fails to correct with vitamin K, mixing studies may help identify possible inhibitors and guide therapy with fresh frozen plasma (FFP) or recombinant factors. Of note, the number of units of FFP commonly used in clinical practice infrequently corrects the coagulopathy (Youssef et al, 2003). In general, administration of cryoprecipitate is recommended when serum fibrinogen levels are less than 100 mg/dL, particularly in the presence of bleeding.

Excessive plasma transfusions can lead to volume overload and may exacerbate ascites. Human recombinant activated factor VIIa (rFVIIa) has been shown to be beneficial as an alternative to plasma. Rapid correction of the PT-INR has been documented within 15 minutes of a small, single intravenous dose of rFVIIa (Surudo et al, 2003), and rFVIIa has been used successfully in cirrhotic patients with coagulopathy to achieve hemostasis for colonic polypectomy, liver biopsy, dental extraction, and bleeding esophageal varices refractory to standard endoscopic therapy (Anantharaju et al, 2003; Berthier et al, 2002; Carvalho et al, 2002; Ejlersen et al, 2001; Romero-Castro et al, 2004). Transfusion of platelets is recommended before invasive procedures. A platelet count of less than 50,000/μL is the usual trigger for transfusion (Rebulla, 2001). Finally, desmopressin may be considered for refractory hemorrhage, particularly when azotemia is present.

Cardiorespiratory Evaluation

Patients with advanced cirrhosis typically have a hyperdynamic hemodynamic profile similar to the systemic inflammatory response syndrome: high cardiac output and vasodilatation of the pulmonary, splanchnic, and peripheral beds (Cazzaniga et al, 2009). Patients with alcoholic liver disease and iron overload are predisposed to cardiomyopathy and cardiac arrhythmias (Moller & Henriksen, 2008). Patients with cirrhosis also are at risk for coronary artery disease because of a high prevalence of cigarette smoking and diabetes mellitus (Hickman & Macdonald, 2007).

Hypocapnia is the most frequent gas-exchange abnormality in patients with cirrhosis (Aller et al, 1999), and pulmonary function can be compromised by tense ascites. Large-volume paracentesis may lead to improvement in the forced expiratory volume in 1 second (FEV_1), functional residual capacity (FRC), and arterial oxygenation (Gupta et al, 2000).

Patients with cirrhosis are also at risk for the development of hepatopulmonary syndrome (HPS) (Gupta et al, 2001). Subclinical or overt HPS is often associated with portopulmonary hypertension and causes significant pulmonary abnormalities as a result of alterations in the pulmonary vasculature by various toxins that accumulate and bypass the cirrhotic liver. Patients with HPS are seen with hypoxemia, platypnea, orthodeoxia, clubbing, and spider angiomata. The predictive value of the alveolar-arterial oxygen gradient in identifying patients with HPS remains a matter of controversy (Schenk et al, 2002; Lima et al, 2004); however, transthoracic echocardiography can be performed to screen for HPS and portopulmonary hypertension; bubble contrast echocardiography identifies the presence of intrapulmonary shunts indicative of HPS (see Table 23.2).

The presence of HPS worsens the overall prognosis of patients with liver cirrhosis (Schenk et al, 2003). The severity of HPS can be quantified with a tagged, macroaggregated albumin lung perfusion scan and arterial blood gas analysis. Postoperative mortality from cardiorespiratory complications

can be estimated by a preoperative Pao_2 of 50 mm Hg or a macroaggregated albumin scan quantification shunt fraction of 20% or higher (Arguedas et al, 2003). General anesthesia for hepatic and extrahepatic procedures in patients with HPS is associated with increased perioperative risk (Mazzeo et al, 2004).

Portopulmonary hypertension, an integral component of HPS, is often asymptomatic and difficult to diagnose; however, this syndrome predisposes to intraoperative cardiac arrhythmias and cardiac arrest. Mortality of portopulmonary hypertension is high, with 1- and 5-year survival rates of 54% and 14%, respectively (Swanson et al, 2008). Although transthoracic echocardiogram may be the initial study performed, right heart catheterization is the best diagnostic tool for portopulmonary hypertension, and it helps discriminate this process from other causes of pulmonary hypertension (Krowka et al, 2006). Elective surgery under general anesthesia in patients with severe HPS-associated pulmonary hypertension should be deferred until the pulmonary hypertension is controlled with vasodilator agents.

Electrolytes

Hyponatremia is quite common in patients with cirrhosis because of their impaired ability to excrete free water, and it is associated with increased mortality (Borroni et al, 2000). Hyponatremia often occurs in the setting of severe ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, and hepatorenal syndrome (Angeli et al, 2006). Hyponatremia and other electrolyte abnormalities, such as hypokalemia and hypomagnesemia, can result from the use of loop diuretics and as a consequence of the chronic respiratory alkalosis associated with cirrhosis. Patients with active alcohol use are also at increased risk of hypophosphatemia. Electrolyte imbalances should be evaluated and corrected before surgery to limit cardiac arrhythmias, peritonitis, and hepatic encephalopathy.

Infection

Spontaneous bacterial peritonitis (SBP) develops in 20% of hospitalized patients with cirrhosis. Risk factors for SBP include gastrointestinal hemorrhage, metabolic alkalosis, dehydration, hyponatremia, and a high MELD score (Obstein et al, 2007). SBP carries an increased mortality rate, which can be worsened by age, renal dysfunction, bacteremia, and elevated MELD score (Perdomo Coral & Alves de Mattos, 2003; Nobre et al, 2008; Cho et al, 2007). It is prudent to have a low threshold to perform a diagnostic paracentesis if SBP is suspected, especially in the setting of large-volume ascites (Kuiper et al, 2007). If SBP is present, elective surgery should be deferred until the infection has been adequately controlled. Prophylactic antimicrobial intestinal decontamination can prevent SBP in hospitalized patients with cirrhosis who have gastrointestinal hemorrhage or a low protein level in the ascitic fluid (Loomba et al, 2009; Terg et al, 2008).

INTRAOPERATIVE MANAGEMENT

Intraoperative management of cirrhotic patients involves careful selection of anesthetic, narcotic, and sedative agents; maintenance of intravascular volume in the setting of fluid losses and shifts; and adjustment to blood losses in the setting of relative anemia and coagulopathy.

Anesthesia

The degree of impairment in hepatic synthetic function and other hepatic functions has to be strongly considered when selecting anesthetics, muscle relaxants, analgesics, and sedatives in the perioperative period. General anesthesia, which is required during hepatic surgery, decreases total hepatic blood flow. Inhalational agents such as isoflurane and sevoflurane, which undergo less hepatic metabolism, continue to be the preferred anesthetic agents in patients with liver disease Although significant increases in liver transaminases and alkaline phosphatase were observed when isoflurane was used compared with sevoflurane (Nishiyama et al, 2004), isoflurane continues to be favored because of its minimal effects on hepatic blood flow. Halothane is not used because of the high risk of hepatotoxicity (Golembiewski, 2004). Endotracheal intubation and induction are achieved in patients with liver disease similar to that in the general population. Atracurium and cisatracurium are the preferred neuromuscular blocking agents to facilitate intubation, because they are not metabolized through the hepatic or renal system.

Low doses of intravenous agents, such as fentanyl and midazolam, are generally used for induction and sedation. Midazolam may exacerbate hepatic encephalopathy, an adverse effect that is still evident several hours after surgery or an endoscopic procedure (Assy et al, 1999). Decreased protein binding and increased volume of distribution hinder the clearance of midazolam in cirrhotic patients, and significant delays in the elimination of midazolam and decreased psychomotor function have been shown in patients with severe alcohol-induced cirrhosis. Midazolam and meperidine are extensively metabolized by hepatocytes, and their half-life is altered in liver disease (Delco et al, 2005), therefore it is recommended that the doses of midazolam and meperidine be reduced by 50% in cirrhotic patients. Cirrhosis delays the elimination of alfentanil, whereas the metabolism of fentanyl, sufentanil, and remifentanil does not seem to be affected (Lentschener & Ozier, 2002). Nonetheless, opioids are avoided intraoperatively.

Ventilation

Patients with chronic liver disease are at increased risk of hypoxemia because of diffusion abnormalities, ventilation/perfusion mismatch, and decreased functional reserve capacity. Muscle relaxants and inhaled anesthetic agents may reduce the oxygen debt. From a ventilatory perspective, large–tidal volume ventilation may increase intraabdominal pressure, exacerbate respiratory alkalosis, lead to barotrauma, reduce ventricular preload, and result in systemic hypotension and organ injury. Cirrhosis is a relative contraindication to the use of carbon dioxide during exploratory laparoscopy.

Hemodynamic Parameters

Alterations in volume status may be a significant intraoperative problem. Decreased effective circulatory volume is frequently present despite the presence of total body fluid overload. The initial periods of surgery may be associated with significant fluid shifts resulting from the removal of ascites when the peritoneal cavity is accessed. The administration of fluid in the immediate preoperative period may reduce the hemodynamic perturbations and prevent other complications related to

hypovolemia, such as hepatic encephalopathy and postoperative renal failure.

During surgery, the mean arterial blood pressure should be maintained above 70 mm Hg to avoid organ injury. Surgery may be complicated by excessive intraoperative hemorrhage resulting from the presence of portal hypertension and coagulopathy. As a result, it is often necessary to infuse large volumes of blood products or intravenous fluids during a limited time to maintain hemodynamic stability; this may result in exacerbation of portal hypertension and volume overload. To avoid excessive fluid overload, colloid solutions such as albumin should be administered. Permissive hypotension and ischemic conditioning are relatively contraindicated in cirrhotic patients (Clavien et al, 2003), and intraoperative blood transfusion is a significant factor related to morbidity and mortality in patients undergoing hepatic resections. Despite the lack of randomized trials, rFVIIa may limit bleeding and the need for red blood cells, plasma, and platelets transfusions (Franchini et al, 2008; Tsochatzis et al, 2007).

Electrolytes

Correction of electrolyte abnormalities is important to prevent arrhythmias and hemodynamic compromise. Administration of calcium should be considered, because hypocalcemia develops after transfusion of large volumes of blood as a result of high citrate load. Intraoperative and postoperative serum levels of potassium, calcium, magnesium, and phosphorus should be obtained, and abnormalities should be corrected.

POSTOPERATIVE MANAGEMENT

Admission to the ICU may become necessary for postoperative patients with underlying cirrhosis given the high risk of complications and mortality in these patients. Among the important critical care issues requiring careful postoperative assessment are fluid derangements, abdominal compartment syndrome, renal failure and hepatorenal syndrome, hepatic encephalopathy, venous thromboembolism, and bleeding as a result of coagulopathy and thrombocytopenia. Once a patient is admitted to the ICU, postoperative mortality rises with increasing length of stay (Povoski et al, 1999).

Fluid Management and Abdominal Compartment Syndrome

Postoperatively, cirrhotic patients are prone to transient hypotension, vasodilation, and fluid shifts. Oliguria also may occur because of reaccumulation of ascites at the expense of the intravascular space. Ascites may occur even in stable cirrhotic patients without documented preoperative ascites. Maintenance of normal renal function is paramount (Cholongitas et al, 2006). Colloid rather than crystalloid fluids should be administered (Garcia-Compean et al, 2002; Planas et al, 1990), and fluid replacement may be guided by the volume of peritoneal fluid drained intraoperatively. If hypotension develops that is refractory to the administration of colloids, vasopressor agents such as norepinephrine may be necessary (Saner et al, 2003). The goal is to limit ascites formation as much as possible. In general, oliguria should not be an indication for diuretic therapy in the setting of significant peritoneal fluid drainage, but rather an indication for fluid (colloids) and vasopressor support, especially if the patient is hemodynamically unstable (Moreau et al, 2002; Appenrodt et al, 2008).

The development of tense ascites may predispose to surgical wound dehiscence, renal failure, peritonitis, and abdominal compartment syndrome (ACS). ACS is characterized by an acute and progressive elevation of the intraabdominal pressure to more than 20 mm Hg in association with failure of one or more organs (Malbrain et al, 2007). The 24-hour fluid balance and peak airway pressure are two independent variables predictive of the development of ACS in nontrauma surgical patients (McNelis et al, 2002). Patients with ACS may have hypotension resulting from decreased venous return, hypoxemia from decreased FRC and ventilator dyssynchrony, and laboratory and radiologic abnormalities from renal failure and bowel ischemia. Measurement of intraabdominal pressure using the bladder is the current mainstay of diagnosis. Excessive fluid administration should be avoided by establishing appropriate endpoints of resuscitation (An & West, 2008). Paracentesis and, in extreme situations, surgical decompression may be necessary to prevent organ injury and wound dehiscence.

Acute Renal Failure and Hepatorenal Syndrome

Acute renal failure (ARF) after liver resection occurs in more than 15% of cases with an attributed mortality rate of 4.2% (Slankamenac et al, 2009). In contrast, ARF is uncommon after cardiac and noncardiac surgery with an overall incidence of 0.85 to 1.7% (Thakar et al, 2005; Kheterpal et al, 2007). A recent scoring system using four criteria—1) cardiovascular disease, 2) elevated alanine aminotransferase (ALT), 3) underlying renal disease, and 4) diabetes mellitus—demonstrated an increased risk of ARF after hepatic resection (Slankamenac et al, 2009). Postoperative ARF in patients with cirrhosis may be caused by parenchymal renal disease, administration of nephrotoxic drugs in the perioperative period, hypovolemia, and hepatorenal syndrome (HRS) (Gines & Schrier, 2009). Management of ARF varies with the etiology and ranges from providing fluid resuscitation in cases of hypovolemia-induced renal failure to renal replacement therapy (Table 23.3).

HRS represents the most dreadful postoperative renal complication in patients with underlying liver disease, and it develops in the setting of advanced cirrhosis, when splanchnic and peripheral vasodilation lead to decreased effective intravascular volume, impaired renal perfusion, and increased reabsorption of sodium (Kramer & Horl, 2002). HRS can be precipitated by infection or intravascular volume depletion as a result of perioperative peritoneal fluid drainage or diuretic administration. Subsequent renal ischemia and tubular injury can progress to renal failure. HRS is characterized by oliguria and a low urine sodium concentration.

Acute tubular necrosis (ATN) may be indistinguishable from HRS, as both conditions share similar clinical presentations and findings on urinalysis. The diagnosis of HRS can be established using the criteria of the International Ascites Club (Arroyo et al, 1996). When HRS is documented, the presence of infection, especially peritonitis, should be considered; empiric antibiotic therapy should also be considered, and peritoneal fluid cultures should be monitored (Fernandez et al, 2007). Administration of vasoconstrictors, such as vasopressin or terlipressin, has been shown to improve renal function and reverse HRS (Sanyal et al, 2008; Sharma et al, 2008; Alessandria et al, 2007; Gines et al, 2004). Randomized controlled

Table 23-3

Postoperative Issues and Management in Hepatobiliary Surgery

Issues	Evaluation and Management
Fluid derangements	Maintenance of normal renal function Use colloid rather than crystalloid fluids Use vasopressor agents for refractory hypotension
Abdominal compartment syndrome	Measure intraabdominal pressure Avoid excessive fluid administration Paracentesis, surgical decompression
Renal failure and hepatorenal syndrome	Avoid intravascular depletion, excessive diuresis Renal replacement therapy Vasopressin or terlipressin for HRS Consider antibiotics for peritonitis-induced HRS
Bleeding due to coagulopathy and thrombocytopenia	RBCs, platelets, plasma transfusion Erythropoietin rFVIIa Octreotide and vasopressin or terlipressin for variceal hemmorhage
Hepatic encephalopathy	Use sedatives and analgesics judiciously Avoid NSAIDs Remifentanil is preferred narcotic Propofol preferred for sedation in mechanically ventilated patients Lactulose or lactitol enemas Oral antibiotics (neomycin, metronidazole, rifaximin)
Venous thromboembolism	Early mobilization Pneumatic compression devices and/or GPS UFH or LMWH

HRS, hepatorenal syndrome; RBCs, red blood cells; rFVIIa, recombinant factor VIIa; NSAIDs, nonsteroidal antiinflammatory drugs; GPS, graduated pressure stockings; UFH, unfractionated heparin; LMWH, low-molecular-weight heparin

studies are notably absent, but most reports indicate slow improvement of renal function in approximately two thirds of cases after several days of therapy with terlipressin (Halimi et al, 2002).

Anemia and Hemorrhage

Postoperative bleeding, variceal hemorrhage, and anemia are usually caused by cirrhosis-induced coagulopathy and thrombocytopenia. The risk of postoperative variceal rupture and bleeding is increased by large-volume ascites, excessive blood transfusion, increased portal pressure, and infection. Paracentesis may reduce the hepatic venous pressure gradient, the variceal pressure, and the wall tension in patients with ascites. Infection increases portal pressure, especially peritonitis, through endotoxin and cytokine-mediated responses (Bambha et al, 2008; Hou et al, 2004); this adversely affects coagulation in cirrhotic patients as a result of a heparin effect (Montalto et al, 2002; Zambruni et al, 2004). Octreotide alone or in combination with diuretics may prevent rebleeding by limiting portal hypertension (Morales et al, 2007; Kalambokis et al, 2006).

Anemia and the need for blood products may be prevented by the administration of recombinant erythropoietin if initiated on arrival in the ICU. Administration of FFP is commonly used to treat the coagulopathy; however, volume overload is a major limitation of FFP. Also, rFVIIa may be used to rapidly correct the coagulopathy of postoperative cirrhotic patients, who would need a large volume of FFP otherwise (Ejlersen et al, 2001; Romero-Castro et al, 2004; Bosch et al, 2004). In addition to blood transfusion, acute management of variceal hemorrhage and anemia includes administration of octreotide, vasopressin, and terlipressin (Morales et al, 2007; Abid et al, 2009; Escorsell et al, 2000; Feu et al, 1996; Ioannou et al, 2003).

Sedative and Pain Management and Hepatic Encephalopathy

Sedatives and pain medications should be used judiciously in postoperative patients with cirrhosis to prevent an exacerbation of hepatic encephalopathy. In cirrhotic patients, the pharmacokinetics and pharmacodynamics of sedative and narcotic agents are altered with prolongation of their elimination half-lives as a result of decreased clearance and increased volume of distribution (Delco et al, 2005; MacGilchrist et al, 1986). By impairing respiratory drive and delaying extubation, narcotics and sedatives may predispose to atelectasis, aspiration, and postoperative pneumonia. Among the narcotic agents available, remifentanil is preferred because of its limited hepatic metabolism. Propofol is a better choice than benzodiazepines for sedation because of its shorter recovery time, which may allow for more reliable serial neurologic assessment (Weston et al, 2003; Schilsky et al, 2009). Nonsteroidal agents should be avoided because of the potential for peptic ulceration, fluid retention from inhibition of renal prostaglandin synthesis, and precipitation of hepatorenal syndrome. Hepatic encephalopathy is commonly treated with lactulose orally or with lactitol enemas (Wright & Jahan, 2007). Side effects of lactulose include gaseous distension, abdominal cramps, and anorexia, which may result in higher narcotic requirements and a self-perpetuating cycle. To prevent these complications, simethicone and a polyethylene glycol laxative may be employed. Second-line agents for the treatment of hepatic encephalopathy include oral antibiotics such as neomycin, metronidazole, and rifaximin (Al Sibae & McGuire, 2009).

Prophylaxis against Venous Thromboembolism

The general guidelines for prophylaxis against venous thromboembolism (VTE) include early mobilization, use of intermittent pneumatic compression devices and/or graduated compression stockings, and pharmacologic thromboprophylaxis. Mechanical thromboprophylaxis should be used primarily in patients at high risk of bleeding. In postoperative cirrhotic patients, pharmacologic thromboprophylaxis with unfractionated heparin or low-molecular-weight heparins (LMWHs) must be applied judiciously, because these patients already are predisposed to bleeding (Geerts et al, 2008). The clinical advantages of LMWHs over unfractionated heparin include its once-daily administration and the lower risk of heparin-induced thrombocytopenia (Martel et al, 2005). When the high bleeding risk decreases postoperatively, pharmacologic thromboprophylaxis should be substituted for or added to the mechanical prophylaxis. Renal function must be considered when making decisions regarding the use of LMWHs, as these agents are cleared by the kidney.

CHAPTER 24

Preoperative and postoperative nutrition in hepatobiliary surgery

Christine Van Cott, Randall Zuckerman, and William S. Helton

GOALS OF NUTRITIONAL SUPPORT IN HEPATOBILIARY SURGERY

The general objective of nutritional support in patients undergoing hepatobiliary surgery are the same as for any other patient undergoing surgery: to decrease postoperative morbidity and mortality. Nutritional intervention should attempt to maintain or restore immunity, support anabolism, and attenuate the catabolic response to injury. In addition, nutritional intervention should strive to restore specific hepatocellular functions, attenuate hepatocellular injury in response to ischemia and reperfusion (I/R), and optimally support hepatocellular function and regeneration after transplantation or resection.

In addition to providing the basic components to correct protein-calorie malnutrition, nutritional strategies have tried to identify and provide disease-specific nutrient requirements for individual organs, cells, and tissues. This new direction or application of nutritional science has been termed *nutritional pharmacology*, and it is based on the observation that individual components of the immunoinflammatory response to injury and infection can be influenced and manipulated by the timely administration of specific nutrients, in specific concentrations, and by specific routes of feeding. Using the principles of nutritional pharmacology, clinicians and scientists have observed that liver structure and function in health and disease can be influenced significantly by nutritional means. This chapter discusses preoperative and postoperative applications of nutrition in hepatobiliary surgery, integrating more recent developments with established practices.

ALTERATIONS IN LIVER METABOLISM THAT AFFECT NUTRITIONAL STATUS

The liver plays a crucial role in the metabolism and assimilation of nutrients, and it is central in the orchestration of protein and carbohydrate metabolism. Any defect or disease of the liver results in significant metabolic derangements. Progression of liver dysfunction results not only in metabolic derangement from a decrease in the number of functioning hepatic cells but also in shunting of portal blood, which decreases the delivery of nutrients, growth factors, and hormones to the remaining cells. Patients with advanced liver disease and cirrhosis also have increased circulating serum levels of growth hormone, glucagon, epinephrine, and cortisol. The cause of this altered hormonal pattern is not completely understood but is typical of a catabolic state and results in carbohydrate intolerance and muscle proteolysis (Eigler et al, 1979; Sherwin et al, 1974). It is speculated further that the catabolic profile of patients with cirrhosis and ascites may be due in part to a defective gastrointestinal (GI) mucosal barrier, which leads to the escape of endotoxin from the lumen of the bowel into the peritoneal cavity (Helton, 1994). The transmigrated endotoxin stimulates peritoneal mononuclear phagocytic cells and Kupffer cells in the liver to release proinflammatory cytokines and mediators (interleukin [IL]-1, tumor necrosis factor [TNF], IL-6, eicosanoids, and nitric oxide). These mediators and cytokines modulate numerous metabolic functions of the liver, including amino acid, protein, lipid, carbohydrate, and trace mineral metabolism (Andus et al, 1991). The proinflammatory cytokines are produced by cells in the intestine and liver to mediate anabolic and catabolic functions and regulate hepatic blood flow, bile flow, liver regeneration, and the response to I/R injury.

TNF is the proximal cytokine signal produced by hepatic Kupffer cells in response to endotoxin or I/R injury. TNF initiates a cascade of inflammatory events that are important in the pathogenesis of many types of surgically induced liver injury, such as I/R injury that occurs with liver resection and transplantation. Endotoxemia occurring in response to manipulation of the biliary tree in patients with biliary obstruction also stimulates the release of TNF, which is believed to mediate in part the systemic sepsis response and subsequent increased organ failure rate associated with operating in the setting of biliary obstruction and infection (Nolan, 1981; Wilkinson et al, 1976). TNF and IL-6 cause a reprioritization of hepatic protein synthesis, a process involving accelerated production of acute-phase proteins at the expense of constitutive proteins. Some indirect evidence suggests that parenteral nutrition also weakens the intestinal barrier, allowing endotoxin to escape from the gut, where it then primes Kupffer cells for cytokine release in response to later infection (Fong et al, 1989).

Increased skeletal muscle proteolysis and muscle wasting in advanced cirrhosis may be related in part to the fact that the cirrhotic liver does not respond appropriately to growth hormone because of low levels of growth hormone–binding protein (Hattori et al, 1992). Growth hormone normally binds to growth hormone–binding protein on hepatocytes and stimulates the production of insulin-like growth factor-1 (IGF-1), the principal mediator of growth hormone–induced protein synthesis and IGF-1 binding proteins. Patients with advanced cirrhosis have low circulating plasma levels of IGF-1 and IGF-1 binding proteins (Hattori et al, 1992; Poggi et al, 1979). The net effect of this metabolic derangement is impaired glucose disposal by skeletal muscle and impaired skeletal muscle protein synthesis. Simultaneously, there is decreased protein synthesis by the diseased liver for the major secretory proteins, such as albumin, and proteins in the coagulation cascade (Nachbauer &

Fischer, 1983). As a result of the aforementioned alterations, the administration of recombinant IGF-1, but not growth hormone, may enhance protein synthesis (Inaba et al, 1994) and may be an important adjunct to improving the nutritional state of patients with liver disease who are undergoing operation (Sato et al, 1994).

Subclinical steatorrhea is common in patients with cirrhosis or obstructive jaundice and leads to fat-soluble vitamin and trace element deficiencies (Gitlin & Heyman, 1984). These deficits are underappreciated in the nutritional assessment of patients with hepatobiliary disease who are undergoing surgery, and such deficits should be corrected.

IDENTIFICATION OF PATIENTS AT RISK FOR POSTOPERATIVE COMPLICATIONS

To use nutritional support appropriately in a cost-effective and clinically efficacious manner, it is necessary to identify which patients are at risk for nutritionally related complications and which would benefit from nutritional intervention. Malnutrition is recognized as an important predisposing factor in the morbidity and mortality of patients undergoing major abdominal surgery (Table 24.1; Mullen et al, 1979). Approximately 48% to 70% of patients with obstructive jaundice (Foschi et al, 1986; Pitt et al, 1981; Padillo et al, 2001) and nearly all patients with advanced cirrhosis undergoing operation have significant malnutrition and are at risk for postoperative complications. Infection is the most common complication in patients undergoing liver and biliary surgery and occurs in 22% to 40% of all patients (Dixon et al, 1983; Foschi et al, 1986; McPherson et al, 1984; Pitt et al, 1981; Smith et al, 1985; Stimpson et al, 1987). Sepsis and sepsis-induced multiple organ failure are the most common causes of death in liver transplant recipients (Colonna et al, 1988; Yokoyama et al, 1989; Torbenson et al, 1998) and in patients with jaundice and cirrhosis undergoing abdominal operations (Armstrong et al, 1984; McPherson et al, 1984; Pitt et al, 1981, 1985). Because most patients with severe liver disease or jaundice are malnourished, and because malnutrition leads to infection, nutritional intervention and repletion may decrease postoperative morbidity and mortality rates in patients undergoing hepatobiliary surgery.

Several prognostic scoring systems have been developed to identify malnourished patients at risk for developing postoperative complications (Buzby et al, 1980). Although no consensus has been reached on the best method for assessing the nutritional status of hospitalized patients, the Nutritional Risk Index (NRI), Maastricht Index (MI), Subjective Global Assessment (SGA), and Mini Nutritional Assessment (MNA) can all be safely applied in the clinical setting with no significant difference in predictive value (Kuzu et al, 2006; Clugston et al, 2006). Although the use of such scoring systems allows prediction of postoperative complications in specific patient groups, their applicability in patients with significant liver disease or cirrhosis is not well established (Shronts, 1988). The most recent (2009) guidelines from the European Society for Clinical Nutrition and Metabolism (ESPEN) recommend the use of simple bedside methods, such as the SGA, for patients with either liver or pancreas disease. Because conventional markers, such as weight status and serum protein levels, are altered and depend on nonnutritional factors, other subjective measures must be relied upon. A dietary and medical history combined with physical examination continues to be the most sensitive means of assessing nutritional risk in patients undergoing hepatobiliary surgery.

The evaluation of a patient's nutritional status should begin with an initial baseline evaluation and continue throughout the patient's course of treatment. A complete nutritional assessment includes 1) physical examination and clinical evaluation, 2) assessment of muscle mass and strength, 3) evaluation of serum albumin and C-reactive protein, 4) assessment of vitamin and mineral deficits, and 5) determination of nutrient requirements (Table 24.2; Shronts, 1988). Historical questions should focus on the patient's nutritional intake, the degree and rate of weight loss over the previous 6 months (Windsor, 1993), use of alcohol, length of time with jaundice, and problems with diarrhea, which may indicate fat malabsorption and steatorrhea. This assessment, although not clinically tested in prospective trials in patients undergoing liver surgery, is similar to the global

Table 24.1

Causes of Malnutrition in Cirrhosis

Poor Dietary Intake
Anorexia, nausea, alcohol abuse, dietary restrictions (protein, fat, sodium, fluid)
Malabsorption/Maldigestion
Cholestasis, intraluminal bile deficiency, coexisting pancreatic exocrine insufficiency, fat malabsorption
Increased Catabolism
Muscle proteolysis
Decreased Protein Synthesis
Decreased hepatocyte growth hormone receptor, IGF-1 and IGF-BP, hepatic transport proteins, fibrinogen, coagulation factors, lipoproteins
Drug Therapy Effects
Neomycin: villous atrophy, diarrhea, zinc deficiency Lactulose: diarrhea, zinc deficiency Diuretics: potassium, magnesium, zinc deficiency Cholestyramine: diarrhea, fat-soluble vitamin deficiency

IGF, insulin-like growth factor; BP, binding protein

Table 24.2

Nutritional Assessment

Clinical Evaluation
Dietary and medical history Physical activity Weight loss over past 6 months
Physical Examination
Body weight Skin changes Ascites Muscle mass and strength
Protein Synthetic Function
Albumin, transferrin Prealbumin, prothrombin time C-reactive protein
Vitamin, Mineral, Trace Element Deficits
Vitamins A, D, E, K, B_6, niacin, folate, B_{12} Thiamine, magnesium, potassium, zinc, iron, phosphorus

Table 24.3

Nutritional Risk Factors for Postoperative Complications in Hepatobiliary Surgery

Weight loss >4% of lean body mass weight over previous 6 months
Serum albumin <3 g/dL
Hematocrit <30%
Skin test allergy
<25th percentile for mid-arm circumference and triceps skin fold
Total body potassium <85% normal

Data from Halliday A, et al, 1988: Nutritional risk factors in major hepatobiliary surgery. J Parenter Enteral Nutr 12:43-48; Harrison J, et al, 1997: A prospective study on the effect of recipient nutritional status on outcome in liver transplantation. Transplant Int 10:369-374; and Pitt H, et al, 1981: Factors affecting mortality in biliary tract surgery. Am J Surg 141:66-71.

nutritional assessment scale of Baker and Detsky (Baker et al, 1982; Detsky et al, 1987) and should provide a sensitive means of detecting patients at risk for nutrition-related problems after surgery. Dixon et al (1983), Pitt (1981), and Halliday et al (1988) and their colleagues identified several nutritional risk factors in patients undergoing biliary tract surgery that were predictive of postoperative morbidity and mortality (Table 24.3). If these factors are identified in a patient being considered for an elective operation, preoperative nutritional repletion is probably indicated.

ANTIOXIDANT NUTRIENT DEPLETION IN THE PATHOGENESIS OF LIVER INJURY

Patients with liver disease, biliary obstruction, bacterial or viral infection, or malnutrition have impaired antioxidant defenses coupled with increased oxidant stresses (Bell et al, 1992; Burra et al, 1992). Additional factors that deplete hepatic antioxidants include smoking, alcohol ingestion, general anesthesia, and surgery (Bulger & Helton, 1998; Goode et al, 1994). This antioxidant depletion likely contributes to increased risk for postoperative infection and multiple organ dysfunction in this patient population. Data from animal studies suggest that a major pathophysiologic event in hepatocellular injury is depletion of endogenous antioxidants (Bell et al, 1992; Burra et al, 1992) at the time of increased oxidative stress from infection (Sugino et al, 1987, 1989), liver resection (Ouchi et al, 1991), or transplantation (Serino et al, 1990).

Patients with chronic liver disease are at particularly high risk for having depleted stores of fat-soluble vitamins. Patients with chronic liver disease (see Chapter 2) have altered bile salt pools and enterohepatic circulation of bile salts, leading to impaired micelle formation, which leads to malabsorption of fat and fat-soluble vitamins A, D, E, and K. Patients with advanced cirrhosis were found to have markedly depleted preoperative plasma levels of vitamin E, vitamin A, and carotene, and these decreased even further after transplantation (Goode et al, 1994).

Patients with cirrhosis have lower antioxidant defenses, which compounds the insult of reperfusion injury by oxygen free radicals. Also, plasma levels of vitamin E decrease significantly in the first hours after surgery or acute injury; a significant reduction in the levels of liver α-tocopherol, an active form of vitamin E, was observed during the first hour of reperfusion in a rat model of liver ischemia (Marubayashi et al, 1984; Maderazo et al, 1990, 1991). Low levels of vitamin E also have been reported in patients with varying levels of chronic liver damage (Goode et al, 1994). Obstructive jaundice often is associated with endotoxemia (Bailey, 1976; Ding et al, 1992), which leads to Kupffer cell production of oxygen free radicals and nitric oxide, which inhibit protein synthesis (Curran et al, 1990). Endotoxemia also reduces endogenous levels of the antioxidants glutathione, vitamin E, and coenzyme Q (Marubayashi et al, 1986).

Two of the most important components of the human antioxidant system are ascorbic acid (vitamin C) and α-tocopherol. Ascorbate is required as a cofactor for many enzymes involved in the scavenging of many free radicals; α-tocopherol has the ability to scavenge intermediate peroxyl radicals and therefore interrupt the chain reactions of lipid peroxidation (Birlouez-Aragon et al, 2003; Halliwell et al, 1990; Traber, 1994), and it is the most important inhibitor of the free-radical chain reaction of lipid peroxidation. Studies in rodents show that supplemental vitamin E significantly attenuates liver I/R injury and hepatic lipid peroxidation (Sugino et al, 1989). In vitro, physiologic concentrations of vitamin E inhibit lipopolysaccharide-stimulated TNF secretion by Kupffer cells, suggesting that subnormal tissue or plasma levels of vitamin E may potentiate macrophage cytokine release (McClain et al, 1994; see Chapters 9 and 10).

Vitamin E has a variety of protective effects on the hepatobiliary system (Leo et al, 1995). It attenuates endotoxemia (Powell et al, 1991; Sugino et al, 1989) and hepatocellular membrane lipid peroxidation and cellular damage after I/R injury (Lee & Clemens, 1992; Marubayashi et al, 1986). In rodents with bile duct obstruction, the concentrations of vitamin E and other antioxidants are reduced in liver tissue (Singh et al, 1992; Sokol et al, 1991). Large doses of enterally administered vitamin E inhibit the release of TNF in models of infection (Bulger et al, 1997; Marubayashi et al, 1989). Under these conditions, vitamin E supplementation improves survival after a septic challenge (Yoshikawa et al, 1984). Pretreatment with α-tocopherol improved adenosine triphosphate (ATP) levels, prevented the increase in lipid peroxidation products, and decreased the loss of hepatic glutathione during the early phase of reperfusion after warm ischemia in rats (Giakoustidis et al, 2002); α-tocopherol also increased the survival of rats with steatotic liver that underwent warm liver ischemia, and it has shown beneficial effects in cold I/R injury (Gondolesi et al, 2002; Eum et al, 2002). These animal studies show a protective effect of vitamin E on liver function and survival during conditions commonly encountered in patients undergoing hepatobiliary surgery.

Vitamin C deficiency is evident in 50% of patients with alcoholic liver disease (Muller, 1995) and is probably even lower in alcoholics who smoke. Vitamin C recycles reduced α-tocopherol and is intimately linked to vitamin E's ability to quench free radical–mediated cellular damage (Sardesai, 1995). The simultaneous administration of ascorbate and α-tocopherol is more effective in inhibiting oxidation than either alone (Niki et al, 1995). Ascorbate and vitamin E are located in different domains; vitamin C acts as a first defense, when the radicals are generated in the plasma, with vitamin E breaking the chain propagation at the cellular membrane level. The synergistic protective effects of vitamin C and vitamin E in preventing lipid peroxidation and cellular damage suggest that these vitamins should be administered together for maximal potential benefit (Bulger & Helton, 1998). A prospective randomized study in patients undergoing

liver resection using an infusion containing 10 mg α-tocopherol acetate and 1 g ascorbate administered prior to reperfusion demonstrated that in the treated group, less plasma lipid peroxidation and acute liver damage occurred as assessed by measurement of the prothrombin time (PT) and aminotransferase levels. The treated group also had fewer postoperative complications (Cerwenka et al, 1999).

The administration of fish oils or omega-3 fatty acids also can influence cytokine and prostanoid release by the intestine (Ogle et al, 1995) and Kupffer cells of the liver (Bankey et al, 1989; Billiar et al, 1988). These observations show that hepatocellular function before and after hepatobiliary operations can be modulated by the administration of specific nutrients and vitamins (Helton, 1994; Marubayashi et al, 1989) and provide a potential opportunity whereby the hepatobiliary surgeon can influence patient outcome by nutritional means. In mice models, administration of omega-3 fatty acids demonstrates trends toward biochemical protection and a marked reduction of necrosis and inflammation after bile duct ligation (Lee et al, 2008). No clinical trials to date have shown that diets supplemented with fish oil, omega-3 fatty acids, or vitamin E improve the outcome of patients undergoing hepatobiliary operations, but this is an area of nutritional support that should be studied in patients undergoing hepatobiliary operations.

SPECIFIC NUTRITIONAL PROBLEMS IN PATIENTS WITH HEPATOBILIARY DISEASES

Obstructive Jaundice

Patients with significant jaundice (see Chapters 2 and 7) often have anorexia and lose weight because of decreased oral intake. Approximately 45% to 70% of patients with obstructive jaundice present with malnutrition as evidenced by greater than 10% weight loss, albumin less than 3 g/dL, decreased triceps skin fold, and impaired delayed hypersensitivity reactivity (Foschi et al, 1986). The NRI is simple to use and can define a high-risk subgroup of patients with obstructive jaundice; an NRI less than 83.5 has been found to be significantly associated with an increased mortality risk and longer duration of hospital admission but not an increased complication rate in this population subgroup (Clugston et al, 2006). The primary nutritional deficit resulting from obstructive jaundice is malabsorption of fat and fat-soluble vitamins. In addition, there is loss of trace minerals, such as phosphate, calcium, magnesium, and zinc, owing to salt formation from unabsorbed dietary fat (Shronts, 1988).

Patients with obstructive jaundice may have ascites secondary to decreased serum albumin levels, but the metabolism of carbohydrates and proteins is rarely altered (Flannigan et al, 1985). Biliary sepsis in a patient with obstructive jaundice contributes to malnutrition by shifting protein synthesis from anabolic protein synthesis to acute-phase protein synthesis (O'Neill et al, 1997). This reprioritization of protein synthesis occurs as a result of endotoxin-stimulated Kupffer cell production of TNF, IL-6, eicosanoids, nitric oxide, and other inflammatory mediators that directly inhibit protein synthesis (Curran et al, 1990; Heinrich, 1990; see Chapters 9 and 10). Because of these derangements, some authors have advocated preoperative biliary drainage (PBD) in both liver and pancreas surgery. A Cochrane 2008 analysis demonstrated that PBD is not recommended in patients who need surgery for obstructive jaundice. However, another recent Cochrane review showed no evidence to support or refute routine endoscopic retrograde cholangiopancreaticography (ERCP) with stenting in patients with malignant pancreaticobiliary diseases awaiting surgery (Wang et al, 2008; Mumtaz et al, 2007). PBD in pancreatic adenocarcinoma should not be routine practice, as it is associated with a stent-related complication rate of 23% and has resulted in a twofold increase in postpancreatectomy infectious complications (Mezhir et al, 2009); however, trials have supported PBD in extended hepatectomy for hilar colangiocarcinoma, if the future liver remnant volume is anticipated to be less than or equal to 30%. To reverse the catabolic effects of chronic endotoxemia and restore hepatic protein synthesis, patients with biliary infection should be treated with biliary decompression for at least 4 weeks before major hepatobiliary surgery to allow hepatocytes to recover their protein synthetic capacity.

Cirrhosis and Liver Failure

Patients with cirrhosis (see Chapters 70, 73, and 74) provide the clinician with a major challenge, as they have multiple hormonal and metabolic alterations (see Chapter 2). Characteristics of cirrhotic patients include wasting symptoms, especially loss of fat and muscle mass; growth failure; glucose intolerance; hyperinsulinemia; insulin resistance; increased plasma glucagon and catecholamines; elevated serum free fatty acids; elevated glycerol; hypoproteinemia; hyperammonemia; hypophosphatemia; and alterations in plasma and cerebrospinal fluid amino acid profiles (Achord, 1987; Henriksen et al, 1985; Petrides & De Fronzo, 1989; Riggio et al, 1984). These hormonal and metabolic aberrations lead to altered metabolism of all three macronutrients: fat, protein, and carbohydrate. The hormonal and metabolic changes seen in cirrhosis also lead to an increased skeletal muscle proteolysis for energy provision, which leads to eventual muscle wasting. In addition, there is increased peripheral lipolysis with a decreased ability to use fat and carbohydrate, which leads to hyperglycemia and hyperlipidemia (Katz, 1986).

Compounding these metabolic alterations are issues that predispose patients with cirrhosis to malnutrition, including decreased dietary intake owing to nausea and vomiting, and the common practice of imposing protein restriction in an effort to prevent encephalopathy. This practice of protein restriction is questionable in an already malnourished patient. Protein restriction exacerbates the problems inherently associated with malnutrition and prohibits the goal of liver regeneration. An alteration of plasma and cerebrospinal fluid amino acid profiles caused by catabolism, impaired hepatocellular function, and portal shunting leads to decreased levels of branched-chain amino acids (BCAAs) valine, leucine, and isoleucine and preferred uptake into the brain of aromatic amino acids phenylalanine, tyrosine, and tryptophan. The increased uptake of aromatic amino acids is thought to alter the production of neurotransmitters, resulting in encephalopathy. This theory led to the use of BCAA as dietary treatment for patients with liver disease (Marchesini et al, 2005). Correcting the serum amino acid profile by BCAA administration aims to reverse mental status changes and promote anabolism (Fischer et al, 1976). Oral supplementation with a BCAA preparation that can be administered for a long period improves event-free survival, serum albumin concentration, and quality of life in patients with decompensated cirrhosis (Bianchi et al, 2005; Marchesini et al, 2003; Muto et al, 2005). Changes in Model for End-Stage Liver Disease (MELD) and Child-Turcotte-Pugh (CTP) scores were

smaller in a BCAA-administered group than in a control group, and serum total bilirubin and serum albumin were better preserved. The incidence of major cirrhotic complications was also lower in the BCAA group than in the control group (Kawamura et al, 2009). ESPEN upgraded the recommendation of BCAA supplementation in decompensated liver cirrhosis in the latest revision of its guidelines in 2006. Recent work has demonstrated that BCAA may affect microinflammation in hepatitis C–positive patients with cirrhosis, reducing the production of oxidative stress and possibly leading to a decrease in the occurrence of hepatocellular carcinoma (HCC) (Ohno et al, 2008). More studies are needed to identify those who might benefit and what the benefit may be from BCAA supplementation.

Liver Resection

Metabolic alterations occur in the regenerating liver after liver resection (Diehl, 1991; see Chapters 5 and 64). Krebs cycle activity is depressed, as is the reduction–oxidation state of the hepatic mitochondria, with a switch from the use of glucose to fat as the preferred source of energy by way of β-oxidation (Nakatoni et al, 1981). Because hyperglycemia and hyperinsulinemia suppress the release of fatty acids from adipose tissue and decrease ketone body production by the liver (Riou et al, 1986), hypertonic glucose infusions and insulin administration should be avoided in the immediate (<6 hours) postoperative period (Ozawa, 1992).

These observations indicate that selective administration of fat or ketone bodies shortly after liver resection or transplantation may be beneficial. In rodents, the provision of intravenous fat (30% of total nonprotein calories) (Hamada, 1993; Nishiguchi et al, 1991) or the ketone body monoacetoacetate (Birkhahn et al, 1989) immediately after liver resection accelerates liver regeneration. The administration of medium-chain triglycerides after liver resection results in better hepatic energy charge and decreased lipid peroxidation compared with the effects of intravenous glucose or long-chain triglyceride infusions (Hamada, 1993).

Sarac and colleagues (1994) hypothesized that increasing fat oxidation preoperatively via fasting would improve liver function after extensive liver resection in rats. Rats subjected to 90% hepatectomy had improved survival to almost 100% when fasted 24 hours before operation and fed oral glucose immediately after operation. Greater use of ketone bodies was observed in the liver of fasted rats, suggesting that the enzyme machinery for using free fatty acids was induced by the previous fast. This and many animal models have demonstrated that glycogen is essential to maintaining hepatocellular integrity and function by supplying glucose for ATP generation. A recent trial that administered high concentrations of glucose to patients intravenously 24 hours before hepatic lesion resection with portal clamping found significantly improved liver function on the first and fifth days postoperatively by reducing liver I/R injury (Tang et al, 2007).

The regenerating liver has an increased demand for specific amino acids, and provision of these in the diet accelerates regeneration. Immediately after liver resection, an abrupt increase is seen in the synthesis of the system A amino acid transporter—which transports alanine, serine, and methionine—but not those of system N (glutamine, histidine, asparagine) or system ASC (e.g., cysteine) (Fowler et al, 1992). Increased system A activity depends on portal glucagon and insulin secretion and substrate amino acid supply (Dolais-Kitabgi et al, 1981); system N and system ASC are not similarly regulated (Fowler et al, 1992). This fact supports the argument by many liver surgeons that enteral administration of glucose is the preferred route of feeding because of the effect on insulin release, which is vital to the function of the regenerating liver (Ozawa, 1992; Ozawa et al, 1974).

Provision of adequate protein and calories is important to ensure adequate liver regeneration. Rats subjected to 50% of normal daily caloric intake for 1 week before and after liver resection had significantly impaired liver regeneration, even when administered exogenous IGF-I, compared with normally fed rats (Sato et al, 1994). Specific types of protein-supplemented diets, such as a nucleoside-nucleotide supplemented total parenteral nutrition (TPN) solution, may improve protein synthesis after hepatectomy (Ogoshi et al, 1989).

John and colleagues (1992) reported that postoperative TPN consisting of 45% fat calories significantly impaired hepatic regeneration and albumin synthesis, caused cholestasis, and increased mortality compared with the same diet administered by the enteral route after 70% hepatectomy in rats. Mortality was 68% in rats fed TPN, 9% in rats fed enterally, and 8% in rats fed chow. This increased mortality rate in TPN-fed rats could be due to increased bacterial translocation and lipopolysaccharide migration across the gut, which overwhelms the limited phagocyte capacity of the remnant Kupffer cell mass (van Leeuwen et al, 1991). The increased mortality rate may also be due to excessive administration of intravenous glucose calories, which adversely affects liver substrate metabolism (Ozawa, 1992; Ozawa et al, 1976). Investigators subsequently showed that the lethal consequences of parenteral nutrition after liver resection in rats could be ameliorated by decreasing the caloric and amino acid load (Delany et al, 1994). A more recent study has demonstrated that increased parenteral caloric intake, and not hyperglycemia, is an independent risk factor for bacteremia in patients receiving TPN (Dissanaike et al, 2007).

Transplantation

In the first 6 hours after liver transplantation (see Chapters 97 and 100), glucose use by the transplanted liver is impaired until the redox state of the mitochondria improves (Ozaki et al, 1991). During this time, the liver preferentially uses fatty acid oxidation for ATP generation (Ozaki et al, 1991; Takada et al, 1993). After 6 hours, normally functioning liver allografts shift substrate use from fat to glucose, whereas failing livers continue to use fat. This shift in metabolism can be followed by measuring the plasma concentration of total ketone bodies and arterial ketone body ratio (Takada et al, 1993). Based on these observations, Takada and colleagues suggested that glucose should be administered in small quantities in the immediate postoperative period without insulin to avoid suppressing peripheral fat mobilization. Glucose infusion should be increased steadily, as mitochondria respiration recovers and the Krebs cycle becomes active. When the redox state of mitochondria is sufficiently improved (e.g., arterial ketone body ratio approximately 0.7), amino acids and increased amounts of glucose can be administered. It has been demonstrated that intraportal insulin administration augments liver regeneration during the first postoperative transplant week by improving hepatic function in live-donor liver transplant recipients (Xu et al, 2009).

The nutritional status of the donor liver may be an important factor affecting posttransplant allograft function. Initially, it

was believed that liver allografts obtained from fasted subjects were more susceptible to anoxic liver injury than allografts obtained from subjects being administered glucose up to the time of liver donation because of an absence of glycogen as a source of glucose from glycolysis in the fasted group (Bradford et al, 1986). In addition, it was shown that livers from fasted animals had enhanced generation of oxygen radicals by Kupffer cells (Gasbarrini et al, 1993). Subsequent work in animal liver transplant models (Astarcioglu et al, 1991; Palombo et al, 1988) and human liver donors (Cywes et al, 1992) showed that glucose administration to the donor increases liver glycogen and ATP content before cold preservation and attenuates liver injury after transplantation.

Work by Sumimoto and colleagues (1993) shows, however, that the effects of fasting and feeding on liver allograft function after cold preservation and reperfusion are more complex. They reported no relationship between hepatic glycogen content and posttransplant function after cold preservation. The same investigators also showed that livers from fasted rats undergo two changes, one that sensitizes it to preservation and reperfusion injury (short-term fast [1-3 days]) and one that increases its tolerance to preservation injury (long-term fast [4 days]). Long-term fasting improves subsequent liver allograft function in rats (Sumimoto et al, 1993). The mechanisms for this protection are unclear, but it may be related to the accumulation of metabolites within the liver that are readily used as a source of energy or to the decreased apoptosis of sinusoidal endothelial cells. A study comparing rats that were orthotopically transplanted with donor rat livers, either fasted or fed, found that the number of apoptotic sinusoidal edothelial cells was significantly higher in the fed group than in the fasted group, suggesting that donor fasting decreases sinusoidal endothelial cell apoptosis after reperfusion, leading to the protection of the liver graft from reperfusion injury (Sun et al, 2001). The latter change may explain why livers from rats subjected to prolonged periods of fasting generate fewer oxygen radicals after reperfusion.

Hepatic Cancer

Hepatic cancer (see Chapters 80 and 81) is commonly accompanied by progressive weight loss, anorexia, and malnutrition. Patients with hepatocellular carcinoma (HCC) usually have advanced cirrhosis, and for that reason, their malnutrition is often more pronounced (see Chapters 2, 70, 72, and 73). Inefficient energy use resulting from increased Cori cycle activity (Holroyde & Reichard, 1981) and other common occurrences with liver damage may be seen, such as increased protein turnover rates with altered amino acid profiles, increased gluconeogenesis, and increased lipid oxidation (Holroyde & Reichard, 1981; Waterhouse et al, 1979; Young, 1977). If jaundice is present, fat malabsorption often occurs in these patients. Profoundly malnourished patients with cirrhosis or chronic active hepatitis and HCC usually are seen initially in an advanced clinical stage, such as Okuda class III. These patients generally should not undergo operation because of a prohibitive operative mortality (Okuda et al, 1985).

Pancreatic Cancer

Pancreatic cancer (see Chapter 58) is associated with a severe metabolic derangement referred to as the *cancer anorexia-cachexia syndrome* (Ryan et al, 1998; Inui, 2002). This syndrome is associated with anorexia tissue wasting, malnutrition, weight loss, and a loss of compensatory increase in feeding. The pathogenesis is dependent on disorders of carbohydrate, protein, lipid, and energy metabolism mediated by cytokine elaboration (IL-1, IL-6, TNF, interferon [IFN] γ, leukocyte-inhibiting factor [LIF], TGF-β) and an overall increase in leptin levels (Bruera et al, 2000; Walker, 2001). Pancreatic cancer has the highest incidence of cachexia among patients with cancer, and up to 80% of such patients have cachexia at the time of their initial diagnosis. For this reason, patients with pancreatic cancer are perhaps the most likely of all patients undergoing hepatopancreatobiliary surgery to benefit from nutritional support strategies.

NUTRITIONAL MANAGEMENT IN PATIENTS UNDERGOING HEPATOBILIARY SURGERY, INCLUDING LIVER TRANSPLANTATION

The primary indication for nutritional support in any patient before and after hepatobiliary surgery is to decrease the incidence of postoperative complications by repleting nutrient deficits that occurred as a result of anorexia, malabsorption, and catabolic states. In addition, nutritional support strives to preserve protein synthesis, prevent hepatocellular dysfunction and injury, and provide a favorable environment for liver cell repair and regeneration. No data support the routine use of nutritional support in well-nourished patients undergoing hepatobiliary surgery. The administration of parenteral nutrition to well-nourished patients undergoing surgery is associated with a higher incidence of postoperative complications (Brennan et al, 1994; Buzby, 1991). Conversely, patients who are profoundly malnourished or deficient in specific vitamins probably benefit from preoperative and postoperative nutritional support (Buzby, 1991; Halliday et al, 1988; Helton, 1994).

Several methods are available to provide patients nutritional support. Most common and most physiologic is an oral diet tailored to the patient's specific needs. If the patient is unable to consume an oral diet or meet the estimated caloric needs orally, a soft silicon nasogastric or nasoduodenal feeding tube should be placed, even in the presence of known esophageal varices. If the patient is unable or unwilling to accept a nasoenteric feeding tube, placing a feeding jejunostomy or gastrostomy tube using the laparoscopic approach should be considered (Duh & Way, 1993); placement of a percutaneous endoscopic gastrostomy tube is associated with a higher risk of complications and is not recommended (ESPEN guidelines, 2006). Lastly, in the rare event that a patient can tolerate oral and enteral nutrients but cannot meet his or her total nutritional needs by oral intake alone, combination diets using partial enteral feeding or partial parenteral feeding are appropriate. Standard parenteral solutions usually are acceptable in these patients. The increased infectious complications and costs associated with parenteral nutrition mandate that this route of feeding be used only when the enteral route is unavailable. Profoundly malnourished patients with malabsorption who develop diarrhea in response to enteral feeding can receive partial enteral nutrition with the balance of calories, protein, fat, trace elements, and vitamins administered by the peripheral intravenous route (Benya et al, 1990).

An enteral formula should be chosen based on the patient's ability to digest and absorb nutrients. For most patients, a

Table 24.4

General Guidelines for Nutritional Support

Oral route > enteral > PICC > TPN
kcal: 30 kcal/kg/day
Nitrogen: 1-1.5 g/kg/day
Glucose: ≤5 mg/kg/min
Fat calories: ≤30% of total calories

PICC, percutaneous indwelling central catheter; TPN, total parenteral nutrition.

standard enteral diet is sufficient. General guidelines for feeding are listed in Table 24.4, and these guidelines are sufficient for most patients. In a few situations, modified specially formulated diets may be beneficial for a patient with hepatobiliary disease or pancreatic insufficiency. In theory, modulating the inflammatory and cytokine systems before operation by the administration of fish oils alone or in combination with antioxidants has the potential to improve patient outcomes (Ok et al, 2003; Persson et al, 2005) but has not been studied to date.

Obstructive Jaundice (See Chapter 7)

If patients are profoundly malnourished, and preoperative nutritional repletion is indicated, an argument can be made for reestablishing bile flow by placing a biliary stent for decompression of the biliary tree before proceeding with a major operation. Before undertaking this step, however, patients should be assessed for their ability to tolerate fat, and dietary recommendations should be made based on this assessment. Generally, restoration of bile flow improves absorption of fat and fat-soluble vitamins. Foschi and colleagues (1986) reported a prospective randomized trial in which patients with obstructive jaundice were randomized to biliary decompression followed by operation or biliary decompression combined with 2 weeks of alimentation followed by operation. Malnutrition was present in 70% of the patients. Of the patients receiving alimentation, 85% received at least partial enteral feeding. Patients receiving alimentation for 2 weeks had lower morbidity (17% vs. 46%), mortality (3.5% vs. 12.5%), and postoperative infection (14% vs. 28%) rates compared with patients receiving only biliary decompression.

When bile flow is not reestablished in patients with biliary obstruction who require nutritional support, ability to tolerate fat in the diet is impaired. These patients should ingest a low-fat diet supplemented with water-soluble forms (e.g., Aquasol E, vitamins A, D, E, and K) of the fat-soluble vitamins. They also should receive supplements of calcium, phosphorus, and magnesium (Shronts, 1988). Rather than struggle with the problems of inadequate oral intake in these anorectic patients, they are more easily and effectively repleted nutritionally by tube feedings because of the ability to administer more physiologically appropriate diets, containing predigested protein (dipeptides and tripeptides) and a blend of medium-chain triglycerides and long-chain triglycerides. These specialized diets help avoid diarrhea from fat maldigestion and malabsorption, because the absorption of medium-chain triglycerides depends on neither bile salts nor pancreatic lipase, as does absorption of long-chain triglycerides (McCullough et al, 1989; Snopko et al, 1991).

Patients with obstructive jaundice require approximately 25 to 35 kcal/kg dry weight to maintain nitrogen balance, and it is recommended that 25% to 40% of total calories be provided by fat as tolerated, but this is unlikely without biliary decompression (McCullough et al, 1989). Patients with externally draining biliary catheters represent a particularly difficult problem, because they not only have problems related to biliary obstruction but also suffer under the added insult of continuous fluid, electrolyte, and protein loss. This situation has become increasingly less common as interventional radiologists and gastroenterologists have gained greater proficiency with biliary drainage procedures.

Cirrhosis and Hepatic Failure (See Chapters 70, 72, and 73)

The following discussion summarizes the essentials of nutritional management of cirrhotic patients. For more detailed discussions, the interested reader is referred to other authors on this topic (Cabre & Gassull, 2001; McCullough & Tavill, 1991; Nompleggi & Bonkovsky, 1994; Shronts, 1988). Hospitalized patients with cirrhosis requiring operation have substantial morbidity and mortality (Rice et al, 1997; Alberino et al, 2001). Because malnutrition is a major problem in these patients, aggressive nutritional support should be undertaken when surgery is being contemplated or carried out. Prospective, randomized clinical trials have shown that hospitalized patients with cirrhosis do not meet their nutritional needs with aggressive daily dietary counseling and have reduced hospital mortality and morbidity when fed via nasogastric or duodenal tubes (Cabre et al, 1990). It is recommended that all hospitalized cirrhotic patients undergoing emergency operation be fed via the enteral route unless otherwise contraindicated; use of parenteral nutrition in these patients is not indicated if the GI tract is functional.

Because the metabolic derangement of advanced liver disease affects all three macronutrients, any dietary intervention needs to supplement all three. The caloric needs of patients with liver disease are increased (35 to 40 kcal/kg body weight/day), particularly if they have ascites (McCullough & Tavill, 1991; ESPEN guidelines, 2006). Protein needs depend on the patient's current nutritional status, ability to tolerate protein, and history or presence of encephalopathy. In a nonencephalopathic patient, 1 to 1.5 g protein/kg dry weight is recommended. If encephalopathy is present, a thorough diet history should be taken to determine the tolerable amount of protein with recommendations to supply at least a minimum 0.5 to 0.7 g/kg dry weight per day.

Fluid and sodium restriction is often necessary, depending on the severity of ascites and edema. A level of at least 2 g of sodium per day is recommended, because lower levels are unpalatable and usually decrease dietary intake further, exacerbating the patient's malnutrition. In cases of intractable ascites, some nutritional support experts (Shronts & Fish, 1993) have recommended a 500 to 1000 mg sodium diet and 1 to 1.5 L of fluid. The authors believe, however, that treatment of massive ascites should rely more on aggressive diuretics rather than drastic limits on fluid intake. Patients with cirrhosis and those with hepatic failure commonly have micronutrient deficiencies of phosphate, magnesium, and zinc; these should be measured, monitored, and aggressively repleted as necessary by the intravenous route (Shronts, 1988). As stated earlier, the use of BCAA-enriched formula should be used in patients with encephalopathy and decompensated cirrhosis, leading to

improved long-term event-free survival and decreased major complications.

Preliminary data suggest that use of recombinant growth hormone may improve nutritional recovery and liver regeneration in cirrhotic patients (Luo et al, 2004). A smaller study demonstrated increased albumin levels and energy metabolism in patients with cirrhosis after a 4-month administration of IGF-I (Conchillo et al, 2005). More recently, patients treated with parenteral nutrition and recombinant growth hormone versus parenteral nutrition alone were found to have increased levels of serum prealbumin, growth hormone, IGF-1, IGF binding protein (IGF-BP)-3, hepatic IGF-1 mRNA, IGF-BP-3 mRNA, and liver Ki67 labeling index (Cao et al, 2007). Although these studies resulted in no actual clinical improvements, this data would encourage further testing of growth hormone in this subgroup of patients.

Liver Resection

Most patients in Western countries undergoing liver resection (see Chapters 90, 91, and 92) have no associated cirrhosis and no need for specialized nutritional support preoperatively or postoperatively. Most can begin an oral diet safely on the first or second postoperative day, and most are able to tolerate a full regular diet within 5 days. Malnourished patients being considered for elective liver resection should receive nutritional repletion preoperatively and postoperatively by the oral or enteral route. In addition, patients undergoing extensive liver resection, particularly patients with compromised preoperative hepatocellular function (e.g., steatosis, chronic viral hepatitis, or cirrhosis), may benefit from specialized nutritional support.

Based on the physiology discussed previously, it is strongly recommended that patients not receive hypertonic glucose infusions in the immediate (<6 hours) postoperative period, because this can interfere with the liver's preferential use of fatty acids for energy and hepatic regeneration. If nutritional support is initiated within 24 or 48 hours after liver resection, it should be administered via the enteral route through a nasoduodenal or jejunal tube. If the patient is profoundly malnourished preoperatively, and the surgeon intends to administer postoperative nutrition, placement of a feeding jejunostomy tube at the time of surgery should be considered.

Nutritional therapy has the potential to attenuate damage to the residual liver in patients scheduled to undergo elective liver resection by preventing further reductions in endogenous antioxidants and by repleting deficient antioxidant defenses. Patients at risk for depleted hepatic antioxidant defenses are alcoholics, smokers, and patients with a long history of obstructive jaundice, chronic biliary infection, or chronic active viral hepatitis (Bulger & Helton, 1998; Helton, 1994). It is imperative that all patients stop smoking and cease ethanol ingestion approximately 2 weeks preoperatively to replete their intrinsic antioxidant defenses and avoid further oxidation stress and lipid peroxidation after operation. It can take 2 weeks of oral vitamin E supplementation to increase vitamin E content significantly in some tissues (Yau et al, 1994). Patients at risk for vitamin E deficits should receive supplements for 2 weeks preoperatively when possible.

A prospective randomized trial evaluated the effect of an antioxidant vitamin infusion (Omnibionta) that included 10 mg of α-tocopherol acetate, 2 mg of dl-α-tocopherol, and 1 g of ascorbate in patients undergoing liver surgery (Cerwenka et al, 1998). An antioxidant protective effect was shown by significantly less postischemic increases in transaminases and prothrombin time (PT) compared with patients who did not receive the vitamin infusion. A 2005 placebo-controlled double-blind study of 47 patients who underwent partial liver resection again demonstrated that the group receiving infusions containing vitamin E had a significantly shorter length of stay in the intensive care unit (ICU) and showed improvement in aspartate aminotransferase, alanine aminotransferase, and glutamic dehydrogenase (Bartels et al, 2004). When considering the fact that vitamins are cheap, safe, and readily available and that patients undergoing hepatobiliary operations are at risk for oxygen radical–mediated injury, it is reasonable to consider administration of vitamin E and vitamin C for several days preoperatively in patients at risk for postoperative complications.

To explore the hypothesis that the remnant liver after liver resection has limited capacity to metabolize glucose, Nishizaki and colleagues (1996) randomized patients after liver resection to receive peripheral glucose infusion (10 kcal/kg body weight/day) or hypertonic glucose via a central catheter for 7 days; both groups were allowed ad libitum food intake when tolerated. The average caloric intake of the two groups was 20 kcal/kg body weight/day (peripheral dextrose) and 30 kcal/kg body weight/day (hypertonic glucose) with no untoward effects from the hypertonic glucose infusion (Nishizaki et al, 1996); patients in that group had improved prealbumin, decreased urinary 3-methylhistidine excretion, and improved nitrogen balance compared with those who received peripheral glucose. The results of this study showed that the remnant liver is not harmed by increased loads of glucose.

A 2006 systematic review of nutritional support after open liver resection concluded that early enteral nutrition is safe, resulting in a significantly lower rate of wound infection and catheter-related complications when compared to parenteral nutrition; however, no differences in mortality were found with either enteral or parenteral nutrition, but patients who received enteral nutrition did show an improved postoperative immune competence (Richter et al, 2006).

Liver Transplantation (See Chapters 97 and 100)

Clinical and experimental observations show that nutrition plays an extremely important role in just about all aspects of liver transplantation. The status of the donor, the function of the transplanted liver, the overall health of the recipient, the rejection process, the absorption and metabolism of immunosuppressive drugs, and a variety of metabolic pathways are influenced by nutrients and how they are administered. Clinical observations show that malnourished patients undergoing liver transplantation have a significantly poorer outcome than well-nourished patients (Porayko et al, 1991; Shaw et al, 1985). Pretransplant nutritional status, hemoglobin levels, and disease severity were independently associated with the number of infectious episodes during hospitalization (Meril et al, 2009). Degree of malnutrition correlates significantly with days spent in the ICU, days spent mechanically ventilated, and length of hospital stay, and it also correlates significantly with mortality after transplantation (Pikul et al, 1994; Meril et al, 2009). Patients who were seen initially at less than 90% of ideal body weight had a longer hospital stay, needed longer ventilatory

support, and had a higher rate of infectious complications; and conversely, patients who were obese also required a longer period of support (Hade et al, 2003).

Liver transplant recipients are predisposed to postoperative infectious complications not only because of severe preoperative protein calorie malnutrition but also because of immunosuppressive drug therapy (O'Keefe et al, 1980, 1981). Profoundly malnourished recipients have an incidence of infectious morbidity and 3-month mortality rates twice that of well-nourished patients undergoing liver transplant (Harrison et al, 1997).

Several studies have investigated the effects of nutritional support in liver transplant patients (Charlton et al, 1992; Chin et al, 1990; Harrison et al, 1997; Hasse et al, 1995; Martin et al, 1993; Mehta et al, 1995; Reilly et al, 1990; Wicks et al, 1994). Based on these studies, patients awaiting transplantation who are malnourished should receive aggressive nutritional counseling and support (Cabre & Gassull, 2001; Harrison et al, 1993, 1997; Plauth et al, 1997). Nutritional supplements, including vitamins, should be taken in an effort to attenuate further nutritional deficits and to replenish losses. Patients who ingest inadequate amounts of calories should be fed via a soft nasogastric feeding tube. In contrast to what most people and physicians believe, these tubes are well tolerated and can be used for months without much difficulty or patient discomfort.

Reilly and colleagues (1990) prospectively studied the effects of three intravenous diets in hypoalbuminemic patients after liver transplantation. The three diets were a BCAA-based TPN solution, a standard TPN diet, and intravenous glucose (Reilly et al, 1990). Both TPN diets provided 1.5 g protein/kg body weight/day and 35 kcal/kg body weight/day. Glucose was limited to 5 mg/kg body weight/min, and the balance of energy was provided as Intralipid 10%. Patients in both TPN groups were extubated and discharged from the ICU a mean of 2.3 days earlier compared with patients receiving only glucose. In addition, overall hospital charges were estimated to be $21,000 less in the patients who received either standard TPN or BCAA-based TPN. The investigators concluded that malnourished patients undergoing transplantation can and should receive postoperative TPN.

Numerous transplant centers subsequently showed that liver transplant patients can be fed successfully and safely by a nasoduodenal or nasojejunal tube within hours after transplantation (Hasse et al, 1995; Martin et al, 1993; Mehta et al, 1995; Sekido et al, 2003; Wicks et al, 1994). Enteral nutrition as early as 12 hours after surgery seemed to improve nutritional parameters and measures of immune function such as total lymphocyte count (Bengmark, 2002; Sekido et al, 2003). In three studies, early initiation of feeding after operation (<24 hours) was associated with a postoperative infection rate that was lower than expected (Hasse et al, 1995; Martin et al, 1993; Mehta et al, 1995; Wicks et al, 1994). In the prospective, randomized study reported by Hasse and colleagues (1995), the enterally fed patients had no viral infections in the first 2 postoperative weeks compared with 17% of patients fed intravenously ($P < .05$). Bacterial and overall infection rates also were decreased in the enterally fed group (14% vs. 29% and 21% vs. 41%, respectively), although the differences did not reach statistical significance. Mehta and colleagues (1995) reported that postoperative liver transplant patients fed immediately via the enteral route had decreased incidence of postoperative ileus (5% vs. 28%; $P < .01$) and started on oral feedings much sooner (8 days vs. 12 days; $P = .07$) than patients fed intravenously. Based on these studies, postoperative nutritional support should be administered via a nasoduodenal or jejunal tube if indicated for nutritional repletion or maintenance.

Based on the hypothesized benefits of increasing glycogen levels of the liver before cold preservation, the University of Toronto Liver Transplant Group carried out a prospective, randomized trial investigating treatment of the donor liver before procurement with a short-term intraportal glucose and insulin infusion (Cywes et al, 1992). This study showed that increasing liver glycogen content decreased preservation and reperfusion injury compared with untreated livers. The protective effect of glycogenation was not clinically apparent and manifested only as differences in serum transaminase levels. The protective effects were predominantly evident in patients with prolonged warm ischemia times, suggesting that the extra glycogen provided substrate for anaerobic glycolysis as the liver rewarmed before reperfusion. Another area under investigation is the use of both prebiotics and probiotics to enhance the GI immune response. A prospective, randomized, double-blind trial treated all postoperative liver transplant recipients with enteral nutrition and a combination of lactic acid bacteria and fibers, thereby reducing bacterial infection rates from 48% to 3% following liver transplantation (Rayes et al, 2005).

Hepatic Cancer

Many liver cancer patients experience major metabolic alterations coupled with some degree of wasting. Each individual patient should be evaluated for current nutritional status, and an individual nutritional plan should be devised to maintain or replete the patient's nutritional status. This includes increased calorie and protein provision when necessary (35 kcal/kg dry weight/day, 2 g protein/kg dry weight/day, and micronutrient supplementation as needed; Fan et al, 1994). Dietary restrictions of any kind should be avoided if at all possible in these patients, including sodium and fluid restrictions.

Fan and colleagues (1994) showed the utility of preoperative and postoperative TPN in patients undergoing elective liver resection for HCC. In this study, the authors randomized 120 patients to one of two groups: standard oral diet preoperatively and intravenous dextrose postoperatively or TPN in addition to oral diet preoperatively and postoperatively. Perioperative nutritional therapy consisted of a solution enriched with 35% BCAA, dextrose, and lipid emulsion (50% medium-chain triglycerides), given intravenously for 14 days (7 days preoperatively for 12 h/day and 7 days postoperatively continuously). The TPN diet provided 30 kcal/kg body weight/day and 1.5 g amino acid/kg body weight/day. The TPN-supplemented group of patients had a reduction in overall postoperative morbidity compared with the control group (34% vs. 55%), predominantly because of fewer septic complications (17% vs. 37%). In addition, less deterioration of liver function was seen, as measured by the change in the rate of clearance of indocyanine green, and less ascites. Postoperative mortality in the perioperative TPN group also was 45% less than in the control group.

Two important aspects of this study are that 90% of the patients had either cirrhosis or chronic active hepatitis, and the average nutritional status of patients in both groups was adequate. The complication rates and deaths were not stratified according to the preoperative severity of malnutrition, and it is

unknown whether the beneficial treatment effect of perioperative TPN was beneficial to all patients or only for patients with malnutrition. Nevertheless, the general conclusion of this well-conducted study was that patients with cirrhosis or chronic active hepatitis with HCC who undergo liver resection seem to benefit from perioperative parenteral nutrition. Postoperative parenteral nutrition with solutions enriched with BCAAs in major liver resections for colorectal metatasis has a positive impact on liver function tests during the postoperative period (Vyhnánek et al, 2008).

Pancreatic Cancer

Although the pathogenesis of the cancer anorexia–cachexia syndrome is better understood, few clinical studies have addressed prevention or treatment of this syndrome in patients with pancreatic cancer. A 2005 Cochrane Database meta-analysis demonstrated a benefit of megastrol as compared with placebo for increased weight gain and appetite in anorexia-cachexia related to cancer, AIDS, and other pathologies (Berenstein et al, 2005). Omega-3 fatty acids have been shown to modulate both proinflammatory cytokines and acute-phase reactants. In pancreatic cancer patients, n-3 fatty acids have decreased the acute-phase protein response and increased serum albumin and fibrinogen (Barber et al, 2004). Eighteen patients with advanced pancreatic cancer received oral supplementation with fish oil and after 3 months had an increase in weight, a significant reduction of acute-phase proteins, and stabilization of resting energy expenditure (Wigmore et al, 1996). Similarly, a report of 20 patients receiving eicosapentaenoic acid, an n-3 fatty acid, also showed a benefit in terms of weight gain and an improvement in performance status and appetite (Barber et al, 1999). Barber and colleagues also found a decrease in IL-6, a rise in insulin, and a fall in the cortisol–insulin ratio in patients with pancreatic cancer who received a nutritional supplement (600 kcal/day and 2 g/day of EPA; Barber et al, 2001).

A prospective, randomized, double-blinded clinical trial showed, in the post ad hoc analysis, that although a diet enriched with n-3 fatty acids did not provide a clear-cut therapeutic advantage, a correlation was found between supplement intake and weight gain, lean body mass gain, and quality of life as compared with intake of an isocaloric control diet not rich in omega-3 fatty acids (Fearon et al, 2003). Further investigations need to be made into the above supplements in pancreatic cancer patients to clarify a possible role in improving survival benefit and quality of life.

SUMMARY

Careful attention must be paid to the hepatobiliary patient's overall clinical condition, inadequacy of diet, and degree of malnutrition to determine the appropriate level, if any, of nutritional support. Inappropriate therapy can result in further metabolic abnormalities and harm to the patient. Increasing evidence shows that specific nutrients administered under specific conditions to selected patients can modulate metabolic events in patients with hepatobiliary disease. Before prescribing nutritional therapy to a patient, a clinician or dietitian with experience and expertise in liver metabolism should be consulted to evaluate the patient, provide recommendations for a diet, and monitor the patient's course.
